Message from the General Chair

Welcome to EACL 2021, the 16th conference of the European Chapter of the Association for Computational Linguistics! This year's conference is held from the 21st to the 23rd of April, 2021. While we were planning to hold the conference in Kyiv, due to the current COVID situation the conference is held entirely online. EACL 2021 is also an anchor conference to several workshops and tutorials, that are held on April 19th and 20th, also online.

This year's conference continues the successful growing trend of the community, and further requires a large organisational effort due to the COVID restrictions. We are learning how to organise and run conferences online, how to attend them and interact, and how to weave them into this strange suspension of our ordinary physical lives, that is our common current experience.

I would like to take the opportunity here to thank all the people involved, who have managed to pull through despite lockdowns, lack of child care, and the many other daily disruptions.

- Scientific programme chairs Jorg Tiedemann, from University of Helsinki and Reut Tsarfaty, from Bar Ilan University chaired a large scientific programme committee and introduced several innovative topics in the submissions.
- Workshop chairs Jonathan Berant, from Tel-Aviv University and Angeliki Lazaridou, from DeepMind selected the workshops, fourteen of which are affiliated to EACL 2021. Tutorial chairs Isabelle Augenstein, from University of Copenhagen and Ivan Habernal, from Technische Universitaet Darmstadt selected the tutorials. Demonstration chairs Dimitra Gkatzia, from Edinburgh Napier University and Djamé Seddah, University Paris la Sorbonne selected the system demonstrations. They have generated very interesting programmes, which add variety of topics and serve focussed subcommunities.
- The work of the younger members of our community have been the object of attention of our Student Research Workshop chairs Ionut-Teodor Sorodoc, from Pompeu Fabra University, Madhumita Sushil, from University of Antwerp and Ece Takmaz, from University of Amsterdam, and of their faculty advisor, Eneko Agirre, from the University of the Basque Country.
- Special thanks go to the publication chairs Valerio Basile, from the University of Turin and Tommaso Caselli, from the University of Groningen, who had to deal with our self-produced proceedings.
- Thank you also to our publicity chair Julie Weeds, from University of Sussex for making our conference known online, before and during the meeting.
- We belong, we know, to a scientific community of extreme demographic uniformity and we are striving to become more aware of issues of inclusivity and diversity. Thanks to our diversity and inclusion chair, Aline Villavicencio, University of Sheffield and Federal University of Rio Grande do Sul.
- When we decided to move to a virtual conference, we contacted a knowledgeable crowd of colleagues to form a Virtual Infrastructure Committee: Amirhossein Kazemnejad, Bruno Guillaume, Cyril Weerasooriya, Gisela Vallejo, Jan-Christoph Klie, Oles Dobosevych, Viktoria Kolomiets. The virtual organisation all happens thanks to them. Thanks especially to Jan-Christoph for sharing all the accumulated knowledge from past conferences and his senior advisor role for this one, and to Bonnie Webber, for sharing past experiences.

- We are very grateful to the local chairs from Grammarly and Ukrainian Catholic University, Viktoria Kolomiets, Dmytro Lider, Iryna Kotkalova, Oleksii Molchanovskyi, Oles Dobosevych. Thank you for offering to host the conference, manage the web site and be remarkably supportive and cooperative even when we had to decide to put off the opportunity to visit beautiful Kyiv.
- A large number of volunteers is being recruited as I write: thank you for your availability and enthusiasm. And thanks to the volunteer chair, Carolina Scarton, from the University of Sheffield, for hitting the ground running.
- We thank EACL 2021's sponsors for their very welcome contributions, which were obtained by the efforts of Raffaella Bernardi, our ACL sponsorship committee members for Europe. Their names and logos can be seen in the proceedings and on the conference web site.
- Thanks also to David Yarowsky and Priscilla Rasmussen from ACL for their help and advice.

Finally, and foremost, thank to all the authors and conference attendees that have made and will make this conference a success and source of inspiration.

EACL 2021 General Chair

Paola Merlo, University of Geneva, Switzerland

Message from the Program Chairs

Welcome to EACL 2021 — the 16th meeting of the European Chapter of the Association for Computational Linguistics. It has now been almost 4 years since EACL was last held, in Valencia, Spain, 2017, and it is the first time that the EACL conference will be held entirely virtually. This edition of the EACL conference comes at a challenging time for many in our community, due to consequences of the covid19 pandemic, but also at an exciting time for NLP researchers, seeing unprecedented growth and interest in the progress in our field, from both within and outside of our community. We are grateful for all the contributions and support that we have received, which allowed us to hold a successful and memorable event, despite having to cope with the challenges of covid and despite EACL being held and attended from remote.

EACL 2021 had received a record number of submissions compared to all past EACL events — exactly 1,400 submissions, an increase of 35

Organising a conference at this scale is a huge undertaking and the process is demanding, but exciting at the same time. We have been able to recruit a large number of reviewers with expertise that is necessary for making appropriate decisions in the many research areas that this conference covers, and we are beyond thankful for the tremendous support we got from the dedicated senior area chairs, area chairs and all reviewers involved in the selection process. Altogether, we have been fortunate to have been able to recruit 1691 reviewers, 149 area chairs and 34 senior area chairs, all professional experts in their fields.

We adopted the recent strategy of automatic COI detection and paper assignments to reviewers, according to their scholarly profiles and affiliations. This process is fairly new and has its own learning curve, but it comes with great advantages, in particular the ability to scale for the increasing number of submissions and reviewers in the *ACL conferences. At the same time, this process also demonstrated the importance of humans in the loop to make proper adjustments and (re)assignments of papers where the automatic decisions may be suboptimal. With the enormous help of the senior area chairs we could successfully run a detailed review process with at least three reviewers per paper, an author rebuttal period, and reviewer discussions. Thank you all for your efforts to ensure the scientific quality of the reviewing process and the resulting conference programme!

After the reviewing process, we could include a total of 326 excellent papers, referring to an acceptance rate of 24.7

The event will be organised in a similar fashion to other recent on-line conferences, emphasising pre-recorded talks with dedicated live question/answering sessions and interactive poster sessions in a virtual environment. Setting up the virtual event is yet another challenge, especially considering the various time zones around the world our keynotes, authors and participants come from. We opted for a morning session and a late-afternoon session according to the Central European calendar, to emphasise the European focus of the event . At the same time, in this EACL we introduce a certain novelty: all papers get assigned a slot at an interactive poster session that takes place at a time-slot that can reasonably be attended across all different time zones. We hope that this setup will provide the opportunity to truly immerse in the event, scientifically and socially, to increase both the impact of the different works and the opportunity of participants to network.

One of the important highlights in the conference is the lineup of renowned keynote speakers who we could attract to join EACL 2021. We are excited to have the following three speakers who have graciously accepted to provide lectures at the conference: Melanie Mitchell from the Santa Fe Institute, Fernanda Ferreira from the University of California, Davis and Marco Baroni from Facebook AI Research and the University of Trento. We are also delighted to announce a panel discussion on information accessibility and language technology in situations of emergency and ongoing crises, with international experts and representatives from the non-profit organization of Translators without Borders (Alp Öktem), the Masakhane NLP community, the University of Oxford (Scott Hale), the Bay Area NLP community (Robert Monarch) moderated by the language enthusiast and internet linguist Gretchen McCulloch.

Needless to say, an event like EACL would have not been possible without the efforts and contributions of a large number of people, to whom we are indebted:

- Our great 34 Senior area chairs, who meticulously managed the reviewing process in individual tracks, and led the discussion and selection process.
- and 149 area chairs, who carefully checked the papers, led reviewers' discussions, wrote meta-reviews and provided indispensable inputs for the selection process.
- Our 1691 reviewers, who wrote dedicated reviews and provided valuable feedback to the authors. Special thanks to reviewers who stepped in at the last minute to serve as emergency reviewers.
- Our Excellent Best Paper Committee for selecting the best EACL papers under a very tight schedule.
- The ACL Executive Review Committee. In particular, Amanda Stent, Arya McCarthy and Graham Neubig for making the COI detection and reviewer-paper assignment software available to us — these tools were instrumental in streamlining the paper assignment process. Special thanks for Graham Neubig and Trevor Cohn for technical advice in using these tools throughout the process.
- The 3343 authors who submitted their work to EACL 2021. While not being able to accept all submissions, it is their work that eventually makes up the exciting contributions and advances in our community.
- TACL editors-in-chief Ani Nenkova and Brian Roark, TACL Editorial Assistant Cindy Robinson, and CL Editor-in-Chief Hwee Tou Ng for coordinating the TACL and CL paper presentations with us.
- The Program co-Chairs of ACL 2020: Joel Tetreault, Natalie Schluter and Joyce Chai; and the Program co-Chairs of of EMNLP 2020: Trevor Cohn, Yulan He and Yang Liu, for sharing their experience and providing invaluable advice for the conference organization and the PC-chairing activities.
- Our Publication Chairs, Valerio Basile and Tommaso Caselli, for the efficient and streamlined production of the EACL conference proceedings.
- Our Publicity Chair, Julie Weeds and our Web Infrastructure Chair, Viktoria Kolomiets, for effectively and efficiently taking care of all event communication and PR aspects of the conference.
- Jarda Fikr from SlidesLive, for coordinating the presentations and recordings by the authors with the SlideLive team.
- Rich Gerber at SoftConf, for extremely quick responses on any email inquiry or emerging difficulties encountered with the START system.
- Our students, interns, postdocs, colleagues, and families. Sorry for not being available to you as much as we hoped to, especially in these crazy times of global pandemic. We promise to make up for it!
- Last but not least, we wish to express our deepest thanks to our General Chair Paola Merlo. She has been extremely professional and supportive from the start, providing us with solid advice while completely trusting us and providing flexibility and room to innovate. From the initial plan to have

EACL as a physical conference all the way to its realization as a virtual event, Paola has led and coordinated all efforts through the thick and thin of covid-related uncertainties, confidently leading to this successful event.

Our deepest gratitude to all of you. We hope you will enjoy this conference experience.

EACL 2021 Program Committee Co-Chairs

Reut Tsarfaty, Bar-Ilan University

Jörg Tiedemann, University of Helsinki

Organizing Committee

General Chair:

Paola Merlo, University of Geneva

Program Chairs:

Jorg Tiedemann, University of Helsinki
Reut Tsarfaty, Bar Ilan University

Tutorial Chairs:

Isabelle Augenstein, University of Copenhagen
Ivan Habernal, Technische Universitaet Darmstadt

Workshop Chairs:

Jonathan Berant, Tel-Aviv University
Angeliki Lazaridou, DeepMind

Publication Chairs:

Valerio Basile, University of Turin
Tommaso Caselli, University of Groningen

Student Research Workshop Chairs:

Ionut-Teodor Sorodoc, Pompeu Fabra University
Madhumita Sushil, University of Antwerp
Ece Takmaz, University of Amsterdam

Faculty Advisor to the Student Research Workshop:

Eneko Agirre, University of the Basque Country

Demonstration Chairs:

Dimitra Gkatzia, Edinburgh Napier University
Djamé Seddah, University Paris la Sorbonne

Diversity & Inclusion (D&I) Chair:

Aline Villavicencio, University of Sheffield and Federal University of Rio Grande do Sul

Publicity Chair:

Julie Weeds, University of Sussex

Virtual Infrastructure Committee:

Amirhossein Kazemnejad, Mila
Bruno Guillaume, LORIA, Inria NGE
Carolina Scarton, University of Sheffield
Cyril Weerasooriya, Rochester Institute of Technology
Gisela Vallejo, Independent researcher
Jan-Christoph Klie, UKP Lab, Technical University of Darmstadt
Oles Dobosevych, Ukrainian Catholic University

Viktoria Kolomiets, Grammarly

Local Chairs:

Viktoria Kolomiets, Grammarly
Dmytro Lider, Grammarly
Iryna Kotkalova, Grammarly
Oleksii Molchanovskyi, Ukrainian Catholic University
Oles Dobosevych, Ukrainian Catholic University

Program Committee

Program Chairs:

Jorg Tiedemann, University of Helsinki
Reut Tsarfaty, Bar Ilan University

Senior Area Chairs and Area Chairs:

Senior area chairs are in bold.

Computational Social Science and Social Media

Oren Tsur, Dirk Hovy, Sara Rosenthal, Dan Goldwasser, Brendan O'Connor, Svitlana Volkova, Djame Seddah

Discourse and Pragmatics

Bonnie Webber, Shafiq Joty, Yufang Hou, Sharid Loaiciga, Mohsen Mesgar

Dialogue and Interactive Systems

Matthew Purver, **Verena Rieser**, Layla El Asri, Casey Kennington, Pierre Lison, Luciana Benotti, Stefan Ultes, Ravi Shekhar, Malihe Alikhani, Svetlana Stoyanchev, Julian Hough, Arash Eshghi, Paweł Budzianowski, Christine Howes, Jason Williams, Nikola Mrkšić

Document analysis, Text Categorization and Topic Models

Udo Kruschwitz, Jochen Leidner, Andrew Yates, Anders Søgaard, Mark Stevenson, Iris Hendrickx, Jeff Dalton, Tony Russell-Rose

Generation and Summarization

Anya Belz, **Annie Louis**, Claire Gardent, Sebastian Gehrmann, Xiaojun Wan, Shashi Narayan, Manabu Okumura, Laura Perez-Beltrachini, Katja Markert, Angela Fan, Jackie Chi Kit Cheung, Fei Liu

Green and Sustainable NLP

Roy Schwartz, **Emma Strubell**, Jesse Dodge, Dallas Card, Angela Fan, Anna Rogers, Aleksandr Drozd

Information Retrieval, Search, Question Answering

Maarten de Rijke, **Mounia Lalmas**, Suzan Verberne, Aleksandr Chuklin, Gabriella Pasi, Julia Kiseleva, Julio Gonzalo, Azadeh Shakery, Theodora Tsikrika

Information Extraction and Text Mining

Antoine Doucet, Jing Jiang, Adam Jatowt, Jaap Kamps, Paolo Rosso, Efstathios Stamatatos, Kang Liu, Cornelia Caragea

Interpretability and Model Analysis in NLP

Arianna Bisazza, **Aurelie Herbelot**, Raffaella Bernardi, German Kruszewski, Dieuwke Hupkes, Alessandro Raganato, Lisa Beinborn

Language Resources and Evaluation

Barbara Plank, **Vera Demberg**, Asif Ekbal, Yvette Graham, Henning Wachsmuth, Ines Rehbein, Alexis Palmer, Ondřej Dušek, Manfred Stede, Taylor Berg-Kirkpatrick

Language Grounding to Vision, Robots, and other

Marie Sien Moens, Iacer Calixto, Douwe Kiela, Jean Oh

Linguistic Theories, Cognitive modeling and Psycholinguistics

Afra Alishahi, Roger Levy, Emily Prud'hommeaux, Antske Fokkens, Cassandra Jacobs

Machine Learning in NLP

Shay Cohen, **Andre F. Martins**, Matthias Galle, Andreas Vlachos, Karl Stratos, Xavier Carreras, Lei Yu, Julia Kreutzer, Philip John Gorinski, Reza Haffari, Carolin Lawrence, Edwin Simpson, Zita Marinho, Jasmijn Bastings

Machine translation

Martin Volk, **Mark Fishel**, Inguna Skadina, Marco Turchi, Dagmar Gromann, Andrei Popescu-Belis, Alex Fraser, Marcello Federico, Maja Popovic, Antonio Toral, Thierry Etchegoyhen

Multidisciplinary and COI

Marco Kuhlmann, Marco Guerini, Aurélie Névéol, Enrico Santus

Multilinguality

Roi Reichart, Omri Abend, Ivan Vulić , Sebastian Ruder, Goran Glavaš, Lea Frermann

NLP Applications for Crisis Managment and Emergency Situations

Robert Munro, Rada Mihalcea, Graham Neubig, Antonios Anastasopoulos, Ishan Jindal

Semantics: lexical

Sebastian Pado, **Marianna Apidianaki**, Gemma Boleda, Jose Camacho Collados, Emmanuele Chersoni, Anne Cocos, Tim Van de Cruys, Katrin Erk, Manaal Faruqui, Alexander Panchenko, Lonneke van der Plas, Vered Shwartz

Semantics: sentence level and other areas

James Henderson, Mike Lewis, Wai Lam, Nafise Sadat Moosavi, Daniel Khashabi, Michael

Roth, Adam Poliak, Swabha Swayamdipta

Sentiment Analysis and Argument Mining

Roman Klinger, **Viviana Patti**, Jeremy Barnes, Steffen Eger, Orphée De Clercq, Els Lefever, Farah Benamara, Tamar Solorio Solorio, Serena Villata, Svetlana Kiritchenko, Torsten Zesch

Phonology, Morphology, and Word Segmentation

Ryan Cotterell, Adina Williams, Johannes Bjerva, Ekaterina Vylomova, Edoardo Ponti, Christo Kirov

Speech

Mikko Kurrimo, Tanel Alumäe, Ebru Arisoy, Dhananjaya Gowda

Tagging, Chunking, Syntax, and Parsing

Joakim Nivre, **Carlos Gómez**, Miguel Ballesteros, Jonas Kuhn, Zeljko Agic, Jennifer Foster, Yue Zhang, Kenji Sagae

Outstanding Members of the PC:

Outstanding Area Chairs

Jennifer Foster, Ebru Arisoy, Tanel Alumäe, Dhananjaya Gowda, Jeremy Barnes, Svetlana Kiritchenko, Vered Shwartz, Katrin Erk, Omri Abend, Lea Frermann, Goran Glavaš, Ivan Vulić, Sebastian Ruder, Aurélie Névéol, Alex Fraser, Marcello Federico, Antonio Toral, Maja Popovic, Andrei Popescu-Belis, Dagmar Gromann, Marco Turchi, Carolin Lawrence, Julia Kreutzer, Jazmijn Bastings, Andreas Vlachos, Edwin Simpson, Ondrej Dusek, "Cassandra L. " Jacobs, Jing Jiang, Jaap Kamps, Adam Jatowt, Paolo Rosso, Kang Liu, Efstathios Stamatatos, Aleksandr Chuklin, Gabriella Pasi, Suzan Verberne, Laure Soulier, Olivier Sprangers, Iacer Calixto, Douwe Kiela, Jean Oh, Claire Gardent, Fei Liu, Sebastian Gehrmann, Angela Fan, Katja Merkert, Anders Søgaard, Andrew Yates, Yufang Hou, Shafiq Joty, Sharid Loáiciga, Mohsen Mesgar, Jason Williams, Luciana Benotti, Casey Kennington, Svetlana Stoyanchev, Djame Seddah.

Outstanding Reviewers

James Barry, Aditya Bhargava, Mathieu Dehouck, Miryam de Lhoneux, Timothy Dozat, Agnieszka Falenska, Nikita Kitaev, Giorgio Satta, David Vilares, Joachim Wagner, Johannes Daxenberger, Christopher Hidey, Udo Hahn, Caroline Brun, Andrew Moore, Esther van den Berg, Wenbo Wang, Mario Sänger, Lilja Øvrelid, Erik Velldal, Aditya Joshi, Chloé Clavel, Cynthia Van Hee, Daniel Dahlmeier, Shachar Mirkin, Forrest Sheng Bao, Patrick Paroubek, Gilles Jacobs, Thomas Haider, Anette Frank, Florian Mai, Yinfei Yang, Mathias Creutz, Hiroki Ouchi, Esther Seyffarth, Francis Ferraro, Pengxiang Cheng, James H. Martin, Ji-Ung Lee, Panupong Pasupat, Julian Michael, Aina Garí Soler, Delphine Bernhard, Eduard Hovy, Shoaib Jameel, Ingrid Falk, Guy Emerson, Leonardo Zilio, Diarmuid Ó Séaghdha, Enrico Santus, Olivier Ferret, Shiva Taslimipoor, Aditya Gupta, Daniil Sorokin, Pavankumar Reddy Muddireddy, Ellie Pavlick, Carlos Ramisch, Thomas Kober, Tristan Miller, Timothy Baldwin, Mikel Artetxe, Xilun Chen, Benjamin Heinzerling, Yova Kementchedjhieva, Shruti

Rijhwani, Mareike Hartmann, Edoardo Maria Ponti, Shuyan Zhou, Shuly Wintner, Haim Dubossarsky, Yulia Tsvetkov, Takashi Wada, Richart Sproat, Diana McCarthy, Telmo Pires, David Reitter, Saranya Venkatraman, Mathias Müller, Rico Sennrich, Mirjam Sepesy Maucec, Alberto Poncelas, Mattia A. Di Gangi, Raivis Skadiņš, Dusan Varis, Nikolay Bogoychev, Maarit Koponen, Jean-Yves Antoine, Marcel Bollmann, Bruno Martins, Naoki Otani, Agata Savary, Yves Scherrer, Miguel A. Alonso, Cristina Bosco, Tommaso Caselli, Joachim Wagner, Johnny Wei, Dian Yu, Marcos Zampieri, Heike Zinkmeister, Joel Tetreault, Emma Manning, Jakob Prange, Stefanie Dipper, Leila Arras, Matthijs Westera, John Hewitt, Sandro Pezzelle, Allyson Ettinger, Guy Emerson, Ludovic Tanguy, Pia Sommerauer, Thomas McCoy, Yonatan Belinkov, Noah Smith, Denis Emelin, Jindřich Libovický, Xiaochuang Han, Georgeta Bordea, Emanuela Boros, Yung-Chun Chang, John Chen, Hsin-Hsi Chen, Jennifer D'Souza, Xiang Dai, Herve Dejean, Luciano Del Corro, Gal Dias, Ismail El Maarouf, Ahmed El-Kishky, Rob Koeling, Bhushan Kotnis, Gal Lejeune, Fei Li, Xiang Li, Xiao Liu, Yuanliang Meng, Lidia Pivovarova, Julien Tourille, Guorui Zhou, Ozam Caglayan, Steven Bedrick, Sofia Serrano, Tim Dettmers, Louis Martin, Chris Quirk, Zhihan Zhang, Zhihan Zhang, Nadjet Bouayad-Agha, Deng Cai, Xutan Peng, Gerasimos Lampouras, Aman Madaan, Michael Elhadad, Ji Ma, Yao Fu, Mark Cieliebak, Jiawei Zhou, Jack Hessel, Timothy Miller, Laure Thompson, Mijail Kabadjov, Cyril Goutte, Luca Soldaini, Berfin Aktaş, Chloé Braud, Debopam Das, Junyi Jessy Li, Ana Marasović, Tatjana Scheffler, Noriki Nishida, Thomas Brox Røst, David DeVault, Kai Yu, Nurul Lubis, Sakriani Sakti, Shikib Mehri, Raghav Gupta, Andrea Kahn, Takenobu Tokunaga, David Traum, Zdeněk Kasner, Alborz Geramifard, Jan Alexandersson.

Table of Contents

Conference Program

Unsupervised Sentence-embeddings by Manifold Approximation and Projection
Subhradeep Kayal

Contrastive Multi-document Question Generation
Woon Sang Cho, Yizhe Zhang, Sudha Rao, Asli Celikyilmaz, Chenyan Xiong, Jianfeng Gao, Mengdi Wang and Bill Dolan

Disambiguatory Signals are Stronger in Word-initial Positions
Tiago Pimentel, Ryan Cotterell and Brian Roark

On the (In)Effectiveness of Images for Text Classification
Chunpeng Ma, Aili Shen, Hiyori Yoshikawa, Tomoya Iwakura, Daniel Beck and Timothy Baldwin

If you've got it, flaunt it: Making the most of fine-grained sentiment annotations
Jeremy Barnes, Lilja Øvrelid and Erik Velldal

Keep Learning: Self-supervised Meta-learning for Learning from Inference
Akhil Kedia and SAI CHETAN CHINTHAKINDI

ResPer: Computationally Modelling Resisting Strategies in Persuasive Conversations
Ritam Dutt, Sayan Sinha, Rishabh Joshi, Surya Shekhar Chakraborty, Meredith Riggs, Xinru Yan, Haogang Bao and Carolyn Rose

BERxiT: Early Exiting for BERT with Better Fine-Tuning and Extension to Regression
Ji Xin, Raphael Tang, Yaoliang Yu and Jimmy Lin

Telling BERT's Full Story: from Local Attention to Global Aggregation
Damian Pascual, Gino Brunner and Roger Wattenhofer

Effects of Pre- and Post-Processing on type-based Embeddings in Lexical Semantic Change Detection
Jens Kaiser, Sinan Kurtyigit, Serge Kotchourko and Dominik Schlechtweg

The Gutenberg Dialogue Dataset
Richard Csaky and Gábor Recski

On the Calibration and Uncertainty of Neural Learning to Rank Models for Conversational Search
Gustavo Penha and Claudia Hauff

No Day Set (continued)

No Day Set (continued)

No Day Set (continued)

MONAH: Multi-Modal Narratives for Humans to analyze conversations
Joshua Y. Kim, Kalina Yacef, Greyson Kim, Chunfeng Liu, Rafael Calvo and Silas Taylor

Does Typological Blinding Impede Cross-Lingual Sharing?
Johannes Bjerva and Isabelle Augenstein

AdapterFusion: Non-Destructive Task Composition for Transfer Learning
Jonas Pfeiffer, Aishwarya Kamath, Andreas Rücklé, Kyunghyun Cho and Iryna Gurevych

CHOLAN: A Modular Approach for Neural Entity Linking on Wikipedia and Wikidata
Manoj Prabhakar Kannan Ravi, Kuldeep Singh, Isaiah Onando Mulang', Saeedeh Shekarpour, Johannes Hoffart and Jens Lehmann

Grounding as a Collaborative Process
Luciana Benotti and Patrick Blackburn

Does She Wink or Does She Nod? A Challenging Benchmark for Evaluating Word Understanding of Language Models
Lutfi Kerem Senel and Hinrich Schütze

Joint Coreference Resolution and Character Linking for Multiparty Conversation
Jiaxin Bai, Hongming Zhang, Yangqiu Song and Kun Xu

Improving Factual Consistency Between a Response and Persona Facts
Mohsen Mesgar, Edwin Simpson and Iryna Gurevych

PolyLM: Learning about Polysemy through Language Modeling
Alan Ansell, Felipe Bravo-Marquez and Bernhard Pfahringer

Predicting Treatment Outcome from Patient Texts:The Case of Internet-Based Cognitive Behavioural Therapy
Evangelia Gogoulou, Magnus Boman, Fehmi Ben Abdesslem, Nils Hentati Isacsson, Viktor Kaldo and Magnus Sahlgren

Scalable Evaluation and Improvement of Document Set Expansion via Neural Positive-Unlabeled Learning
Alon Jacovi, Gang Niu, Yoav Goldberg and Masashi Sugiyama

The Role of Syntactic Planning in Compositional Image Captioning
Emanuele Bugliarello and Desmond Elliott

No Day Set (continued)

Is “hot pizza" Positive or Negative? Mining Target-aware Sentiment Lexicons
Jie Zhou, Yuanbin Wu, Changzhi Sun and Liang He

Quality Estimation without Human-labeled Data
Yi-Lin Tuan, Ahmed El-Kishky, Adithya Renduchintala, Vishrav Chaudhary, Francisco Guzmán and Lucia Specia

How Fast can BERT Learn Simple Natural Language Inference?
Yi-Chung Lin and Keh-Yih Su

GRIT: Generative Role-filler Transformers for Document-level Event Entity Extraction
Xinya Du, Alexander Rush and Claire Cardie

Cross-lingual Entity Alignment with Incidental Supervision
Muhao Chen, Weijia Shi, Ben Zhou and Dan Roth

Query Generation for Multimodal Documents
kyungho kim, Kyungjae Lee, Seung-won Hwang, Young-In Song and seungwook lee

End-to-End Argument Mining as Biaffine Dependency Parsing
Yuxiao Ye and Simone Teufel

FakeFlow: Fake News Detection by Modeling the Flow of Affective Information
Bilal Ghanem, Simone Paolo Ponzetto, Paolo Rosso and Francisco Rangel

CTC-based Compression for Direct Speech Translation
Marco Gaido, Mauro Cettolo, Matteo Negri and Marco Turchi

A Crowdsourced Open-Source Kazakh Speech Corpus and Initial Speech Recognition Baseline
Yerbolat Khassanov, Saida Mussakhojayeva, Almas Mirzakhmetov, Alen Adiyev, Mukhamet Nurpeiissov and Huseyin Atakan Varol

TDMSci: A Specialized Corpus for Scientific Literature Entity Tagging of Tasks Datasets and Metrics
Yufang Hou, Charles Jochim, Martin Gleize, Francesca Bonin and Debasis Ganguly

Top-down Discourse Parsing via Sequence Labelling
Fajri Koto, Jey Han Lau and Timothy Baldwin

No Day Set (continued)

Does the Order of Training Samples Matter? Improving Neural Data-to-Text Generation with Curriculum Learning
Ernie Chang, Hui-Syuan Yeh and Vera Demberg

TrNews: Heterogeneous User-Interest Transfer Learning for News Recommendation
Guangneng Hu and Qiang Yang

Dialogue Act-based Breakdown Detection in Negotiation Dialogues
Atsuki Yamaguchi, Kosui Iwasa and Katsuhide Fujita

Neural Data-to-Text Generation with LM-based Text Augmentation
Ernie Chang, Xiaoyu Shen, Dawei Zhu, Vera Demberg and Hui Su

Self-Training Pre-Trained Language Models for Zero- and Few-Shot Multi-Dialectal Arabic Sequence Labeling
Muhammad Khalifa, Muhammad Abdul-Mageed and Khaled Shaalan

Multiple Tasks Integration: Tagging, Syntactic and Semantic Parsing as a Single Task
Timothée Bernard

Coordinate Constructions in English Enhanced Universal Dependencies: Analysis and Computational Modeling
Stefan Grünewald, Prisca Piccirilli and Annemarie Friedrich

Ellipsis Resolution as Question Answering: An Evaluation
Rahul Aralikatte, Matthew Lamm, Daniel Hardt and Anders Søgaard

Jointly Improving Language Understanding and Generation with Quality-Weighted Weak Supervision of Automatic Labeling
Ernie Chang, Vera Demberg and Alex Marin

Continuous Learning in Neural Machine Translation using Bilingual Dictionaries
Jan Niehues

Adv-OLM: Generating Textual Adversaries via OLM
Vijit Malik, Ashwani Bhat and Ashutosh Modi

Conversational Question Answering over Knowledge Graphs with Transformer and Graph Attention Networks
Endri Kacupaj, Joan Plepi, Kuldeep Singh, Harsh Thakkar, Jens Lehmann and Maria Maleshkova

No Day Set (continued)

DRAG: Director-Generator Language Modelling Framework for Non-Parallel Author Stylized Rewriting
Hrituraj Singh, Gaurav Verma, Aparna Garimella and Balaji Vasan Srinivasan

Leveraging Passage Retrieval with Generative Models for Open Domain Question Answering
Gautier Izacard and Edouard Grave

Clinical Outcome Prediction from Admission Notes using Self-Supervised Knowledge Integration
Betty van Aken, Jens-Michalis Papaioannou, Manuel Mayrdorfer, Klemens Budde, Felix Gers and Alexander Loeser

Combining Deep Generative Models and Multi-lingual Pretraining for Semi-supervised Document Classification
Yi Zhu, Ehsan Shareghi, Yingzhen Li, Roi Reichart and Anna Korhonen

Multi-facet Universal Schema
Rohan Paul, Haw-Shiuan Chang and Andrew McCallum

Exploring Transitivity in Neural NLI Models through Veridicality
Hitomi Yanaka, Koji Mineshima and Kentaro Inui

A Neural Few-Shot Text Classification Reality Check
Thomas Dopierre, Christophe Gravier and Wilfried Logerais

Multilingual Machine Translation: Closing the Gap between Shared and Language-specific Encoder-Decoders
Carlos Escolano, Marta R. Costa-jussà, José A. R. Fonollosa and Mikel Artetxe

Clustering Word Embeddings with Self-Organizing Maps. Application on LaRoSeDa - A Large Romanian Sentiment Data Set
Anca Tache, Gaman Mihaela and Radu Tudor Ionescu

Elastic weight consolidation for better bias inoculation
James Thorne and Andreas Vlachos

Hierarchical Multi-head Attentive Network for Evidence-aware Fake News Detection
Nguyen Vo and Kyumin Lee

Identifying Named Entities as they are Typed
Ravneet Arora, Chen-Tse Tsai and Daniel Preotiuc-Pietro

No Day Set (continued)

SANDI: Story-and-Images Alignment
Sreyasi Nag Chowdhury, Simon Razniewski and Gerhard Weikum

Question and Answer Test-Train Overlap in Open-Domain Question Answering Datasets
Patrick Lewis, Pontus Stenetorp and Sebastian Riedel

El Volumen Louder Por Favor: Code-switching in Task-oriented Semantic Parsing
Arash Einolghozati, Abhinav Arora, Lorena Sainz-Maza Lecanda, Anuj Kumar and Sonal Gupta

Generating Syntactically Controlled Paraphrases without Using Annotated Parallel Pairs
Kuan-Hao Huang and Kai-Wei Chang

Data Augmentation for Hypernymy Detection
Thomas Kober, Julie Weeds, Lorenzo Bertolini and David Weir

Few-shot learning through contextual data augmentation
Farid Arthaud, Rachel Bawden and Alexandra Birch

Zero-shot Generalization in Dialog State Tracking through Generative Question Answering
Shuyang Li, Jin Cao, Mukund Sridhar, Henghui Zhu, Shang-Wen Li, Wael Hamza and Julian McAuley

Zero-shot Neural Passage Retrieval via Domain-targeted Synthetic Question Generation
Ji Ma, Ivan Korotkov, Yinfei Yang, Keith Hall and Ryan McDonald

Discourse-Aware Unsupervised Summarization for Long Scientific Documents
Yue Dong, Andrei Mircea Romascanu and Jackie Chi Kit Cheung

MIDAS: A Dialog Act Annotation Scheme for Open Domain HumanMachine Spoken Conversations
Dian Yu and Zhou Yu

Analyzing the Forgetting Problem in Pretrain-Finetuning of Open-domain Dialogue Response Models
Tianxing He, Jun Liu, Kyunghyun Cho, Myle Ott, Bing Liu, James Glass and Fuchun Peng

Leveraging End-to-End ASR for Endangered Language Documentation: An Empirical Study on Yolóxochitl Mixtec
Jiatong Shi, Jonathan D. Amith, Rey Castillo García, Esteban Guadalupe Sierra, Kevin Duh and Shinji Watanabe

No Day Set (continued)

Mode Effects' Challenge to Authorship Attribution
Haining Wang, Allen Riddell and Patrick Juola

Generative Text Modeling through Short Run Inference
Bo Pang, Erik Nijkamp, Tian Han and Ying Nian Wu

Detecting Extraneous Content in Podcasts
Sravana Reddy, Yongze Yu, Aasish Pappu, Aswin Sivaraman, Rezvaneh Rezapour and Rosie Jones

Randomized Deep Structured Prediction for Discourse-Level Processing
Manuel Widmoser, Maria Pacheco, Jean Honorio and Dan Goldwasser

Automatic Data Acquisition for Event Coreference Resolution
Prafulla Kumar Choubey and Ruihong Huang

Joint Learning of Representations for Web-tables, Entities and Types using Graph Convolutional Network
Aniket Pramanick and Indrajit Bhattacharya

Multimodal Text Style Transfer for Outdoor Vision-and-Language Navigation
Wanrong Zhu, Xin Wang, Tsu-Jui Fu, An Yan, Pradyumna Narayana, Kazoo Sone, Sugato Basu and William Yang Wang

Unsupervised Sentence-embeddings by Manifold Approximation and Projection

Subhradeep Kayal

deep.kayal@pm.me

Abstract

The concept of unsupervised *universal sentence encoders* has gained traction recently, wherein pre-trained models generate effective task-agnostic fixed-dimensional representations for phrases, sentences and paragraphs. Such methods are of varying complexity, from simple weighted-averages of word vectors to complex language-models based on bidirectional transformers. In this work we propose a novel technique to generate sentence-embeddings in an unsupervised fashion by projecting the sentences onto a fixed-dimensional manifold with the objective of preserving local neighbourhoods in the original space. To delineate such neighbourhoods we experiment with several set-distance metrics, including the recently proposed *Word Mover's distance*, while the fixed-dimensional projection is achieved by employing a scalable and efficient manifold approximation method rooted in topological data analysis. We test our approach, which we term *EMAP* or *Embeddings by Manifold Approximation and Projection*, on six publicly available text-classification datasets of varying size and complexity. Empirical results show that our method consistently performs similar to or better than several alternative state-of-the-art approaches.

1 Introduction

1.1 On sentence-embeddings

Dense vector representation of words, or *word-embeddings*, form the backbone of most modern NLP applications and can be constructed using context-free (Bengio et al., 2003; Mikolov et al., 2013; Pennington et al., 2014) or contextualized methods (Peters et al., 2018; Devlin et al., 2019).

Given that practical systems often benefit from having representations for sentences and documents, in addition to word-embeddings (Palangi et al., 2016; Yan et al., 2016), a simple trick is to use the weighted average over some or all of the embeddings of words in a sentence or document. Although *sentence-embeddings* constructed this way often lose information because of the disregard for word-order during averaging, they have been found to be surprisingly performant (Aldarmaki and Diab, 2018).

More sophisticated methods focus on jointly learning the embeddings of sentences and words using models similar to *Word2Vec* (Le and Mikolov, 2014; Chen, 2017), using encoder-decoder approaches that reconstruct the surrounding sentences of an encoded passage (Kiros et al., 2015), or training bi-directional LSTM models on large external datasets (Conneau et al., 2017). Meaningful sentence-embeddings have also been constructed by fine-tuning pre-trained bidirectional transformers (Devlin et al., 2019) using a Siamese architecture (Reimers and Gurevych, 2019).

In parallel to the approaches mentioned above, a stream of methods have emerged recently which exploit the inherent geometric properties of the structure of sentences, by treating them as sets or sequences of word-embeddings. For example, Arora et al. (2017) propose the construction of sentence-embeddings based on weighted word-embedding averages with the removal of the dominant singular vector, while Rücklé et al. (2018) produce sentence-embeddings by concatenating several power-means of word-embeddings corresponding to a sentence. Very recently, spectral decomposition techniques were used to create sentence-embeddings, which produced state-of-the-art results when used in concatenation with averaging (Kayal and Tsatsaronis, 2019; Almarwani et al., 2019).

Our work is most related to that of Wu et al. (2018) who use Random Features (Rahimi and Recht, 2008) to learn document embeddings which preserve the properties of an explicitly-defined kernel based on the Word Mover's Distance (Kusner

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1–11
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

et al., 2015). Where Wu et al. predefine the nature of the kernel, our proposed approach can learn the similarity-preserving manifold for a given set-distance metric, offering increased flexibility.

1.2 Motivation and contributions

A simple way to form sentence-embeddings is to compute the dimension-wise arithmetic mean of the embeddings of the words in a particular sentence. Even though this approach incurs information loss by disregarding the fact that sentences are sequences (or, at the very least, sets) of word vectors, it works well in practice. This already provides an indication that there is more information in the sentences to be exploited.

Kusner et al. (2015) aim to use more of the information available in a sentence by representing sentences as a weighted point cloud of embedded words. Rooted in transportation theory, their *Word Mover's distance (WMD)* is the minimum amount of distance that the embedded words of a sentence need to travel to reach the embedded words of another sentence. The approach achieves state-of-the-art results for sentence classification when combined with a k-NN classifier (Cover and Hart, 1967). Since their work, other distance metrics have been suggested (Singh et al., 2019; Wang et al., 2019), also motivated by how transportation problems are solved.

Considering that sentences are sets of word vectors, a large variety of methods exist in literature that can be used to calculate the distance between two sets, in addition to the ones based on transport theory. Thus, as a *first contribution*, we compare alternative metrics to measure distances between sentences. The metrics we suggest, namely the *Hausdorff distance* and the *Energy distance*, are intuitive to explain and reasonably fast to calculate. The choice of these particular distances are motivated by their differing origins and their general usefulness in the respective application domains.

Once calculated, these distances can be used in conjunction with k-nearest neighbours for classification tasks, and k-means for clustering tasks. However, these learning algorithms are rather simplistic and the state-of-the-art machine learning algorithms require a fixed-length feature representation as input to them. Moreover, having fixed-length representations for sentences (*sentence-embeddings*) also provides a large degree of flexibility for downstream tasks, as compared to having only relative distances between them. With this as motivation, the *second contribution* of this work is to produce sentence-embeddings that approximately preserve the topological properties of the original sentence space. We propose to do so using an efficient scalable manifold-learning algorithm termed *UMAP* (McInnes et al., 2018) from topological data analysis. Empirical results show that this process yields sentence-embeddings that deliver near state-of-the-art classification performance with a simple classifier.

2 Methodology

2.1 Calculating distances

In this work, we experiment with three different distance measures to determine the distance between sentences. The first measure (Energy distance) is motivated by a useful linkage criterion from hierarchical clustering (Rokach and Maimon, 2005), while the second one (Hausdorff distance) is an important metric from algebraic topology that has been successfully used in document indexing (Tsatsaronis et al., 2012). The final metric (Word Mover's distance) is a recent extension of an existing distance measure between distributions, that is particularly suited for use with word-embeddings (Kusner et al., 2015).

Prior to defining the distances that have been used in this work, we first proceed to outline the notations that we will be using to describe them.

2.1.1 Notations

Let $\mathscr{W} \in \mathbb{R}^{N \times d}$ denote a word-embedding matrix, such that the vocabulary corresponding to it consists of N words, and each word in it, $w_i \in \mathbb{R}^d$, is d-dimensional. This word-embedding matrix and its constituent words may come from pre-trained representations such as Word2Vec (Mikolov et al., 2013) or GloVe (Pennington et al., 2014), in which case $d = 300$.

Let $\mathscr{S}$ be a set of sentences and s, s' be two sentences from this set. Each such sentence can be viewed as a set of word-embeddings, $\{w\} \in s$. Additionally, let the length of a sentence, s, be denoted as $|s|$, and the cardinality of the set, $\mathscr{S}$, be denoted by $|\mathscr{S}|$.

Let $e(w_i, w_j)$ denote the distance between two word-embeddings, w_i, w_j. In the context of this paper, this distance is Euclidean:

$$e(w_i, w_j) = \|w_i - w_j\|_2 \qquad (1)$$

Finally, $D(s, s')$ denotes the distance between two sentences.

2.1.2 Energy distance

Energy distance is a statistical distance between probability distributions, based on the inter and intra-distribution variance, that satisfies all the criteria of being a metric (Székely and Rizzo, 2013).

Using the notations defined earlier, we write it as:

$$\begin{aligned} D(s, s') = &\frac{2}{|s||s'|} \sum_{w_i \in s} \sum_{w_j \in s'} e(w_i, w_j) \\ &- \frac{1}{|s|^2} \sum_{w_i \in s} \sum_{w_j \in s} e(w_i, w_j) \\ &- \frac{1}{|s'|^2} \sum_{w_i \in s'} \sum_{w_j \in s'} e(w_i, w_j) \end{aligned} \tag{2}$$

The original conception of the energy distance was inspired by gravitational potential energy of celestial objects. Looking closely at Equation 2, it can be quickly observed that it has two parts: the first term resembles the attraction or repulsion between two objects (or in our case, sentences), while the second and the third term indicate the self-coherence of the respective objects. As shown by Székely and Rizzo (2013), energy distance is scale equivariant, which would make it sensitive to contextual changes in sentences, and therefore make it useful in NLP applications.

2.1.3 Hausdorff distance

Given two subsets of a metric space, the *Hausdorff distance* is the maximum distance of the points in one subset to the nearest point in the other. A significant work has gone into making it fast to calculate (Atallah, 1983) so that it can be applied to real-world problems, such as shape-matching in computer vision (Dubuisson and Jain, 1994).

To calculate it, the distance between each point from one set and the closest point from the other set is determined first. Then, the Hausdorff distance is calculated as the maximal point-wise distance. Considering sentences $\{s, s'\}$ as subsets of word-embedding space, $\mathbb{R}^{d \times N}$, the *directed* Hausdorff distance can be given as:

$$h(s, s') = \max_{w_i \in s} \min_{w_j \in s'} e(w_i, w_j) \tag{3}$$

such that the symmetric Hausdorff distance is:

$$D(s, s') = \max\{h(s, s'), h(s', s)\} \tag{4}$$

2.1.4 Word Mover's distance

In addition to the representation of a sentence as a set of word-embeddings, a sentence s can also be represented as a N-dimensional normalized term-frequency vector, where n_i^s is the number of times word w_i occurs in sentence s normalized by the total number of words in s:

$$n_i^s = \frac{c_i^s}{\sum_{k=1}^{k=N} c_k^s} \tag{5}$$

where, c_i^s is the number of times word w_i appears in sentence s.

The goal of the *Word Mover's distance (WMD)* (Kusner et al., 2015) is to construct a sentence similarity metric based on the distances between the individual words within each sentence, given by Equation 1. In order to calculate the distance between two sentences, WMD introduces a transport matrix, $T \in \mathbb{R}^{N \times N}$, such that each element in it, T_{ij}, denotes how much of n_i^s should be transported to $n_j^{s'}$. Then, the WMD between two sentences is given as the solution of the following minimization problem:

$$\begin{gathered} D(s, s') = \min_{T \geq 0} \sum_{i,j=1}^{N} T_{ij} e(i, j) \\ \text{subject to, } \sum_{j=1}^{N} T_{ij} = n_i^s \text{ and } \sum_{i=1}^{N} T_{ij} = n_j^{s'} \end{gathered} \tag{6}$$

Thus, WMD between two sentences is defined as the minimum distance required to transport the words from one sentence to another.

2.2 Generating neighbourhood-preserving embeddings via non-linear manifold-learning

In this work, we propose to construct sentence-embeddings which preserve the neighbourhood around sentences delineated by the relative distances between them. We posit that preserving the local neighbourhoods will serve as a proxy for preserving the original topological properties.

In order to learn a topology-preserving fixed-dimensional manifold, we seek inspiration from methods in non-linear dimensionality-reduction (Lee and Verleysen, 2007) and topological data analysis literature (Carlsson, 2009). When broadly categorized, these techniques consist of methods, such as *Locally Linear Embedding* (Roweis and Saul, 2000), that preserve local distances between points, or those like *Stochastic Neighbour Embedding* (Hinton and Roweis, 2003; van der Maaten and Hinton, 2008) that preserve the conditional probabilities of points being neighbours. However, existing manifold-learning algorithms suffer from two shortcomings: they are computationally expensive and are often restricted in the number of output dimensions. In our work we use a method termed *Uniform Manifold Approximation and Projection (UMAP)* (McInnes et al., 2018), which is scalable and has no computational restrictions on the output embedding dimension.

The building block of UMAP is a particular type of a simplicial complex, known as the Vietoris-Rips complex. Recalling that a *k-simplex* is a k-dimensional polytope which is the convex hull of its $k + 1$ vertices, and a simplicial complex is a set of simplices of various orders, the Vietoris-Rips simplicial complex is a collection of 0 and 1-simplices. In essence, this is a means to building a simple neighbourhood graph by connecting the original data points.

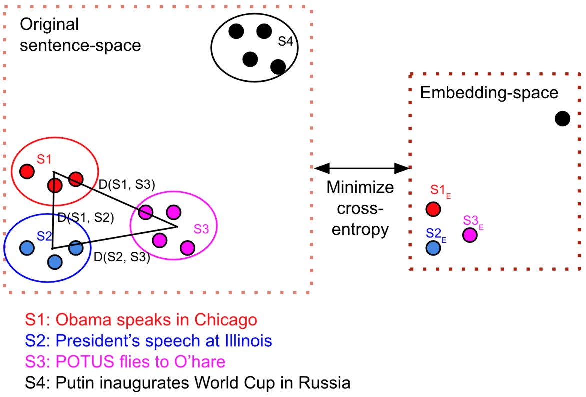

Figure 1: Figure showing a simple example of the embedding algorithm. On the left is the original sentence-space, approximated by the nearest neighbours graph formed by the Vietoris-Rips complex. Instead of points and edges, our simplicial complex has sets of points and edges between them, formed by one of the distance metrics mentioned in Section 2.1. In this example, four sentences, denoted by $S1$ through $S4$, form two simplices, with $S4$ being a *0*-simplex. The sentences are denoted by colored ellipses, while the high-dimensional embedding of each word in a sentence is depicted by a point having the same color as the parent sentence ellipse. The UMAP algorithm is then employed to find a similarity-preserving Euclidean embedding-space, shown on the right, by minimizing the cross-entropy between the two representations.

A key difference, in this work, to the original formulation is that an individual data sample (i.e., the vertex of a simplex) is not a d-dimensional point but a set of d-dimensional words that make up a sentence. By using any of the distance metrics defined in Section 2.1, it is possible to construct the simplicial complex that UMAP needs in order to build the topological representation of the original sentence space. An illustration can be found in Figure 1.

As per the formulation laid out for UMAP, the similarity between sentences s' and s is defined as:

$$v_{s'|s} = \exp \frac{-(D(s,s') - \rho_s)}{\sigma_s} \tag{7}$$

where σ_s is a normalisation factor selected based on an empirical heuristic (See Algorithm 3 in the work of McInnes et al. 2018), $D(s,s')$ is the distance between two sentences as outlined by Equation 2, 4 or 6, and ρ_s is the distance of s from its nearest neighbour. It is worth mentioning that for scalability, $v_{s'|s}$ is calculated only for predefined set of approximate nearest neighbours, which is a user-defined input parameter to the UMAP algorithm, using the efficient *nearest-neighbour descent* algorithm (Dong et al., 2011).

The similarity depicted in Equation 7 is asymmetric, and symmetrization is carried out by a fuzzy set union using the probabilistic t-conorm:

$$v_{ss'} = (v_{s'|s} + v_{s|s'}) - v_{s'|s} v_{s|s'} \tag{8}$$

As UMAP builds a Vietoris-Rips complex governed by Equation 7, it can take advantage of the nerve theorem (Borsuk, 1948), which makes this construction a homotope of the original topological space. In our case, this implies that we can build a simple nearest neighbours graph from a given corpus of sentences, which has certain guarantees of approximating the original topological space, as defined by the aforementioned distance metrics.

The next step is to define a similar nearest neighbours graph in a fixed low-dimensional Euclidean space. Let $s_E, s'_E \in \mathbb{R}^{d_E}$ be the corresponding d_E-dimensional sentence-embeddings. Then the low dimensional similarities are given by:

$$w_{ss'} = (1 + a||s_E - s'_E||_2{}^{b}))^{-1} \tag{9}$$

where, $||s_E - s'_E||$ is the Euclidean distance between the d_E-dimensional embeddings, and setting a, b are input-parameters, set to 1.929 and 0.791, respectively, as per the original implementation.

Algorithm 1: Constructing sentence-*E*mbeddings by *M*anifold *A*pproximation and *P*rojection: *EMAP*

```
Data: A pre-trained word-embeddings matrix, $\mathscr{W}$; a set of sentences, $\mathscr{S}$;
      desired dimension of the generated sentence-embeddings, $d_E$
Result: A set of sentence-embeddings, $\{s_E\} \in \mathscr{S}_E$
Calculate the distance matrix for the entire set of sentences, such that the distance
    between any two sentences is given by Equation 2, 4 or 6;
Using this distance matrix, calculate the nearest neighbour graph between all input
    sentences, given by Equations 7 and 8;
Calculate the initial guess for the low dimensional embeddings, $\mathscr{S}_E \in \mathbb{R}^{|\mathscr{S}| \times D_E}$,
    using the graph laplacian of the original nearest neighbour graph;
Until convergence, minimize the cross-entropy between the two representations
    (Equation 10) using stochastic gradient descent;
Return the set of $d_E$-dimensional sentence-embeddings, $\mathscr{S}_E$;
```

The final step of the process is to optimize the low dimensional representation to have as close a fuzzy topological representation as possible to the original space. UMAP proceeds to do so by minimizing the cross-entropy between the two representations:

$$C = \sum_{s \neq s'} v_{ss'} \log \frac{v_{ss'}}{w_{ss'}} + (1 - v_{ss'}) \log \frac{1 - v_{ss'}}{1 - w_{ss'}} \tag{10}$$

usually done via stochastic gradient descent.

A summary of the proposed process used to produce sentence-embeddings is provided in Algorithm 1, and pictorially presented in Figure 1.

3 Datasets and resources

3.1 Datasets

Six public datasets[1] have been used to empirically validate the method proposed in this paper. These datasets are of varying sizes, tasks and complexities, and have been used widely in existing literature, thereby making comparisons and reporting possible. Information about the datasets can be found in Table 1.

3.2 Resources

Pre-trained word-embedding corpus: We use the pre-trained set of word-embeddings provided by Mikolov et al (2013)[2].

Software implementations: We use a variety of software packages and custom-written programs perform our experiments, the starting point being the calculation of sentence-wise distances. We calculate the Hausdorff distance using a directed implementation provided in the *Scipy* python library[3], whereas the energy distance is calculated using *dcor*[4]. Lastly, the word mover's distance is calculated using implementation provided by Kusner et al. (2015)[5]. In order to produce the symmetric distance matrix for a dataset, we employ custom parallel implementation which distributes the calculations over all available logical cores in a machine.

To calculate the sentence-embeddings, the implementation of UMAP provided by McInnes et al (2018) is used[6]. Finally, the classification is done via linear kernel support vector machines from the *scikit-learn* library (Pedregosa et al., 2011)[7].

All of the code and datasets have been packaged and released[8] to rerun all of the experiments.

Compute infrastructure: All experiments were run on a *m4.2xlarge* machine on AWS-EC2[9], which has 8 virtual CPUs and 32GB of RAM.

4 Experiments

4.1 Competing methods

In order to check the usefulness of our proposed approach, we benchmark its performance in two different ways. The first, and most obvious, approach is to consider the performance of the k-NN

Table 1: **Dataset information**: Metadata describing the datasets used in our experiments.

classifier as a baseline. This is motivated by the state-of-the-art k-NN based classification accuracy reported by Kusner et al. for the word mover's distance. Thus, our embeddings need to match or surpass the performance of a k-NN based approach, in order to be considered for practical use.

The second approach is to compare the classification accuracies of several state-of-the-art embedding-generation algorithms on our chosen datasets. These are:

dct (Almarwani et al., 2019): embeddings are generated by employing discrete cosine transform on a set of word vectors.

eigensent (Kayal and Tsatsaronis, 2019): sentence representations produced via higher-order dynamic mode decomposition (Le Clainche and Vega, 2017) on a sequence of word vectors.

wmovers (Wu et al., 2018): a competing method which can learn sentence representations from the word mover's distance based on kernel learning, termed in the original work as *word mover's embeddings*.

p-means (Rücklé et al., 2018): produces sentence-embeddings by concatenating several power-means of word-embeddings corresponding to a sentence.

doc2vec (Le and Mikolov, 2014): embeddings produced by jointly learning the representations of sentences, together with words, as a part of the word2vec procedure.

s-bert (Reimers and Gurevych, 2019): embeddings produced by fine-tuning a pre-trained BERT model using a Siamese architecture to classify two sentences as being similar or different.

Note that the results for *wmovers* and *doc2vec* are taken from Table 3 of Wu et al.'s work (2018), while all the other algorithms are explicitly tested.

4.2 Setup

Extensive experiments are performed to provide a holistic overview of our neighbourhood-preserving embedding algorithm, for various sets of input parameters. The steps involved are as follows:

Choose a dataset (one of the six mentioned in Section 3.1). For every word in every sentence in the train and test splits of the dataset, retrieve the corresponding word-embedding from the pre-trained embedding corpus (as stated in Section 3.2).

Calculate symmetric distance matrices corresponding to each of the chosen distance metrics, for all of the sets of word-embeddings from the train and test splits.

Apply the UMAP algorithm on the distance matrices to generate embeddings for all sentences in the train and the test splits.

Calculate embeddings for competing methods for the methods outlined in Section 4.1.

Embeddings are generated for various hyperparameter combinations for *EMAP* as well as all the compared approaches, as listed in Table 2.

Train a classifier on the produced embeddings to perform the dataset-specific task. In this work, we train a simple linear-kernel support vector machine (Cortes and Vapnik, 1995) for every competing method and every dataset tested. The classifier is trained on the train-split of a dataset and evaluated on the test-split. The only parameter tuned for the SVM is the L2 regularization strength, varied between 0.001 and 100. The overall test *accuracy* has been been reported as a measure of performance.

5 Results and Discussion

The results of all our experiments are in compiled in Tables 3 and 4. All statistical tests reported are z-tests, where we compute the right-tailed p-value and call a result significantly different if $p < 0.1$.

Performance of the distance metrics: From Table 3 it can be observed that the word mover's distance consistently performs better than the others experimented with in this paper. WMD calculates the total effort of aligning two sentences, which seems to capture more useful information compared to the hausdorff metric's worst-case effort of alignment. As for the energy distance, it calculates pairwise potentials amongst words within and between sentences, and may suffer if there are

Method	Parameter	Value(s) Tested
EMAP	*n_neighbors*	40
	embedding_dim	50, 100, 300, 1000
	min_dist	1.0, 1.5, 2.0
	spread	1.0, 2.5
	n_iters	1000
	distance	wmd, hausdorff, energy
kNN	*k*	1
	distance	wmd, hausdorff, energy
dct	*components*	1 through 6
eigensent	*components*	1 through 3
	time_lag	1, 2, 3, [1,2], [1,2,3], [1,2,3,4]
pmeans	*powers*	1, [1,2], [1,2,3], [1,2,3,4,5,6]
s-bert	*model*	bert-base-nli-mean-tokens

Table 2: **Hyperparameter values tested**. For *EMAP*, *n_neighbours* refers to the size of local neighborhood used for manifold approximation, *embedding_dim* is the fixed dimensionality of the generated sentence-embeddings, *min_dist* is the minimum distance apart that points are allowed to be in the low dimensional representation, *spread* determines the scale at which embedded points will be spread out, *n_iters* is the number of iterations that the UMAP algorithm is allowed to run, and finally, *distance* is one of the metrics proposed in Section 2.1. For the spectral decomposition based algorithms, *dct* and *eigensent*, *components* represents the number of components to keep in the resulting decomposition, while *time_lag* corresponds to the window-length in the dynamic mode decomposition process. For *pmeans*, *powers* represents the different powers which are used to generate the concatenated embeddings.

Table 4: **Comparison versus competing methods**. We compare *EMAP* based on word mover's distance to various state-of-the-art approaches. The best and second-best classification accuracies are highlighted in **bold** and *italics*. We perform statistical significance tests of our method (*wmd-EMAP*) against all other methods, for a given dataset, and denote the outcomes by $\vee$ when the compared method is worse and $\wedge$ when our method is worse, while the absence of a symbol indicates insignificant differences. In terms of absolute accuracy, we observe that our method achieves state-of-the-art results in 2 out of 6 datasets.

shared commonly-occurring words in both the sentences. However, given that energy and hausdorff distances are reasonably fast to calculate and perform respectably well, they might be worth using in applications with a large number of long sentences.

Comparison versus kNN: *EMAP* almost always outperforms k-nearest neighbours based classification, for all the tested distance metrics. The performance boost for WMD is between a relative percentage accuracy of 0.5% to 14%. This illustrates the efficiency of the proposed manifold-learning method.

I have spent thousands of dollar's On Meyers cookware everthing from KitchenAid Anolon Prestige Faberware & Circulan just to name a few Though Meyers does manufacture very high quality pots & pans and I would recommend them to anyone it's just sad that if you have any problem with them under warranty you have to go throught the chain of command that never gets you anywhere even if you want to speak with upper management about the rudeness of the customer service department Their customer service department employees are always very rude and snotty and they act like they are doing you a favor to even talk to you about their products	When I opened the box I noticed corrosion on the lid When I contacted Rival customer service via email they told me I had to purchase a new lid I called and spoke with a customer service representative and they told me that a lid was not covered under warranty When I explained that I just opened it and it was defective they told me to just return the product that there was nothing that they were going to do After being treated this way I will NOT be purchasing any more Rival products if they don't stand behind their product VERY VERY poor customer service	0.997
This movie will bring up your racial prejudices in ways that most movies just elude to It demonstrates how connected we all are as people and how seperated we are by only one thing our viewpoints The acting is superb and you get one cameo appearance after another which is a treat Of course the soundtrack is terrific The ending is intense to witness one situation after another coming to an unfortunate finish	I waited years for this movie to be released in the United States As far as I was concerned it wasn't about the acting as much as it was about the feeling the actors wanted to portray in which they profoundly accomplished I would recommend this movie to anyone who can reach that one step deeper into the minds of creativity and passion and appreciate the struggles of rising above and beyond the pain of broken dreams	0.998
We see a phrase a lot when we visit how to sites for writers World building By this we mean the setting the characters and everything else where our story will occur For me this often means maps memories and visits since I write about where I live But if you'd like to see exactly what world building means head down to your local library and grab SALEM'S LOT by Stephen King When Stephen King mania first gripped the English speaking world I missed it I saw the film of CARRIE and hated it Years later at a guard desk on a long shift scheduled so suddenly that I hadn't had a chance to visit the library I read what was in the desk instead THINNER If I were Stephen King I'd have put a pen name on that crap as well One of King's fans brought me around She recommended THE SHINING Of course I thought of that Kubrick/Nicholson travesty No no she said read the book It's much different Yes it is It's fantastic for its perceptiveness Next up PET SEMATARY which scared the crap out of me And that my friends is not easy ON WRITING I've gushed about that enough times The films STAND BY ME and THE APT PUPIL So in the end I appreciate King and forgive him for CARRIE and I think he's forgiven himself	in the possibility that Steve Berry could ever transcend his not so great debut The Amber Room Romanov Prophecy started in the right direction Third Secret was OK but I think he hit his *peak* right there	0.955

Table 5: **Examples of best-matching sentences**. From the *amazon* reviews dataset using *wmd-EMAP*.

Comparison versus state-of-the-art methods: Consulting Table 4, it seems that *wmovers*, *pmeans* and *s-bert* form the strongest baselines as compared to our method, *wmd-EMAP* (*EMAP* with word mover's distance). Considering the statistical significance of the differences in performance between *wmd-EMAP* and the others, it can be seen that it is almost always equivalent to or better than the other state-of-the-art approaches. In terms of absolute accuracy, it *wins* in 3 out of 6 evaluations, where it has the highest classification accuracy, and comes out second-best for the others. Compared to it's closest competitor, the *word mover's embedding* algorithm, the performance of *wmd-EMAP* is found to be on-par (or slightly better, by 0.8% in the case of the *classic* dataset) to slightly worse (3% relative p.p., in case of the *twitter* dataset). Interestingly, both of the distance-based embedding approaches, *wmd-EMAP* and *wmovers*, are found to perform better than the siamese-BERT based approach, *s-bert*.

Thus, the overall conclusion from our empirical studies is that *EMAP* performs favourably as compared to various state-of-the-art approaches.

Examples of similar sentences with EMAP: We provide motivating examples of similar sentences from the *amazon* dataset, as deemed by our approach, in Table 5. As can be seen, our method performs quite well in matching complex sentences with varying topics and sentiments to their closest pairs. The first example pair has the theme of a customer who is unhappy about poor customer service in the context of cookware warranty, while the second one is about positive reviews of deeply-moving movies. The third example, about book reviews, is particularly interesting: in the first example, a reviewer is talking about how she disliked the first Stephen King work which she was exposed to, but subsequently liked all the next ones, while in the matched sentence the reviewer talks about a similar sentiment change towards the works of another author, Steve Berry. Thus in the last example, the similarity between sentences is the change of sentiment, from negative to positive, towards the works of books of particular authors.

6 Conclusions

In this work, we propose a novel mechanism to construct unsupervised sentence-embeddings by preserving properties of local neighbourhoods in the original space, as delineated by set-distance metrics. This method, which we term, *EMAP* or *Embeddings by Manifold Approximation and Projection* leverages a method from topological data analysis can be used as a framework with any distance metric that can discriminate between sets, three of which we test in this paper. Using both quantitative empirical studies, where we compare with state-of-the-art approaches, and qualitative probing, where we retrieve similar sentences based on our generated embeddings, we illustrate the efficiency of our proposed approach to be on-par or exceeding in-use methods. This work demonstrates the successful application of topological data analysis in sentence embedding creation, and we leave the design of better distance metrics and manifold approximation algorithms, particularly targeted towards NLP, for future research.

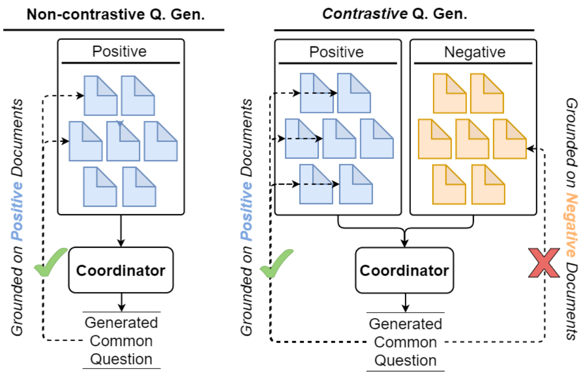
Abstract

Multi-document question generation focuses on generating a question that covers the common aspect of multiple documents. Such a model is useful in generating clarifying options. However, a naive model trained only using the targeted ("positive") document set may generate too generic questions that cover a larger scope than delineated by the document set. To address this challenge, we introduce the contrastive learning strategy where given "positive" and "negative" sets of documents, we generate a question that is closely related to the "positive" set but is far away from the "negative" set. This setting allows generated questions to be more specific and related to the target document set. To generate such specific questions, we propose Multi-Source Coordinated Question Generator (MSCQG), a novel framework that includes a supervised learning (SL) stage and a reinforcement learning (RL) stage. In the SL stage, a single-document question generator is trained. In the RL stage, a coordinator model is trained to find optimal attention weights to align multiple single-document generators, by optimizing a reward designed to promote specificity of generated questions. We also develop an effective auxiliary objective, named Set-induced Contrastive Regularization (SCR) that improves the coordinator's contrastive learning during the RL stage. We show that our model significantly outperforms several strong baselines, as measured by automatic metrics and human evaluation. The source repository is publicly available at `www.github.com/woonsangcho/contrast_qgen`.

1 Introduction

User queries on web search engines can sometimes be vague. Search engines may resolve this ambiguity by suggesting clarification options back to the user in the form of questions (Braslavski et al., 2017; Aliannejadi et al., 2019; Zamani et al., 2020). However, asking the right clarification questions is a challenging information-seeking task, given a plethora of possible questions (Rao and Daumé III, 2018, 2019; Qi et al., 2020). One workaround is to take informational cues from the search engine results given the initial query. The clarification options are then generated from non-ranked and non-overlapping thematic partitions of the search engine results. The whole pipeline is akin to the pseudo-relevance feedback (Rocchio, 1971; Cao et al., 2008). This can significantly reduce the search space, and has the potential to generate correct clarification questions within the context (Cho



Positive set about:	*number of saturn's moons*
Negative set about:	*uranus how many moons*
Non-contrastive Q. Gen	*what is the largest moon*
Contrastive Q. Gen	*how many moons are there in saturn*

Figure 1: Non-contrastive and contrastive method for multidocument question generation. Left: non-contrastive modeling that takes input as a set of positive documents. However, model-generated questions from this method are rather generic and not specific to the input documents. Right: *contrastive* modeling, which considers both positive and negative document sets, and learns to generate questions that are more grounded on the positive document set.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 12–30
April 19 - 23, 2021.

et al., 2019b).

This particular approach may involve three non-trivial phases: i) *retrieval*: gather the initial return documents by the search engine; ii) *partition*: partition the documents into semantically similar clusters in an unsupervised manner; iii) *multi-document question generation*: generate a clarification question by finding an "overlap" among documents in each cluster. In principle, the clarification questions should be **specific** to each cluster rather than generic and bland, otherwise it is counter to the objective of clarification (Radlinski and Craswell, 2017). In this work, we focus on developing a multi-document question generator to generate cluster-specific questions in the iii) step. Nevertheless, we believe our approach can be readily applied to multi-document text generation such as summarization (Liu and Lapata, 2019) and response generation (Zhang et al., 2020).

We address this challenge by leveraging contrastive learning. Given a set of positive documents $\mathfrak{D}^+$ and a set of negative documents $\mathfrak{D}^-$ (where $\mathfrak{D}^-$ is yet semantically close to $\mathfrak{D}^+$), we propose a new strategy to generate a question that is semantically relevant to $\mathfrak{D}^+$ and far away from $\mathfrak{D}^-$. Ideally, the model would use both $\mathfrak{D}^+$ and $\mathfrak{D}^-$ to identify distinguishing features between the two sets and constrain the generation to be *specific* to $\mathfrak{D}^+$. The similarity between the $\mathfrak{D}^+$ and $\mathfrak{D}^-$ makes the generation more challenging and forces the model to be as specific as possible in order to distinguish between the two sets. The comparison between the contrastive and non-contrastive multi-document question generation is illustrated in Figure 1.

This task is particularly challenging because i) there does not exist direct supervised *ground-truth* multi-document question given positive and negative sets of documents. ii) The whole procedure involves multiple aspects including language understanding, inter-document information aggregation, coordinative planning and language generation. In theory, the generator can be trained to maximize the chance that the generated question specifically retrieves the given document cluster, using RL. However, the space of possible sequence is prohibitively large which results in large variance in RL (Lewis et al., 2017). To effectively reduce the search space of RL, we employ a hybrid supervised learning (SL) and RL strategy. We also propose a novel reward-shaping auxiliary objective, Set-induced Contrastive Regularization (SCR) (Section 2), which heuristically drives the generation closer towards $\mathfrak{D}^+$, by *minimizing/maximizing* the KL divergence between the hypothesis distribution and distributions induced by $\mathfrak{D}^+/\mathfrak{D}^-$.

Our contributions are summarized below: i) We develop a novel Multi-Source Coordinated Question Generator (MSCQG) model that is trained using a hybrid hierarchical generation scheme. The document-specific generator is fine-tuned from GPT-2 and the inter-document coordinator is trained using reinforcement learning. ii) We introduce Set-induced Contrastive Regularization (SCR), an auxiliary regularizer that pushes MSCQG toward $\mathfrak{D}^+$ relative to $\mathfrak{D}^-$ while limiting the effect of $\mathfrak{D}^-$ in a principled manner. iii) Empirical results show that our model is able to generate more grounded and specific questions, significantly outperforming existing baseline models in automatic measures and human evaluation.

2 Method

Overview: The overview of our model is illustrated in Figure 2. The model consists of two major components: i) The *document-specific generator* generates a question from a single document, and is fine-tuned from OpenAI GPT-2. ii) The *inter-document coordinator* integrates multiple-document information from the *document-specific generator* instances. The coordinator is trained using reinforcement learning after fixing the document-specific generator.

During the RL training, at each generation time step, each (positive and negative) document will independently use the same generator trained from i) to predict the next token. The coordinator will learn to aggregate the probabilities to a *consensus probability* by maximizing a reward function. The reward function is designed to encourage the generated question to tie to the positive set and to be away from the negative set. The word newly generated from the *consensus probability* are concatenated to all documents as inputs for next time step.

Document-specific Generator: At the first pre-training stage, we load the publicly available GPT-2 (Radford et al., 2019) model as our underlying document-specific generator. The GPT-2 model leverages massive out-domain data and serves as a good initialization to generate grammatical and

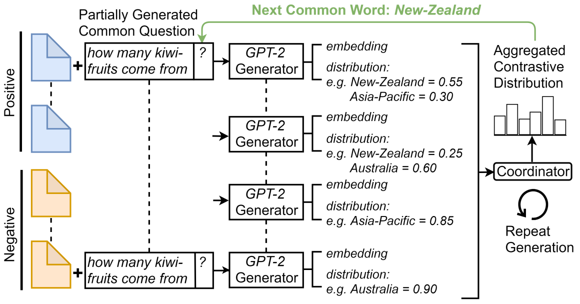

Figure 2: System overview. The example is an illustration using fictitious tokens for ease of understanding. Our MSCQG model learns to attend different weights and form a final aggregated distribution at each decoding time. The decision to enforce or penalize the negative set distributions to the aggregated distribution is controlled in a principled manner.

informative question. Then, we further fine-tune the language model on MS-MARCO (Nguyen et al., 2016) *selected* document as an input and the corresponding question as an output.

Ranking-based Rewards: Before moving to the RL training, we first describe calculating the reward signal based on retrieval statistics from a BERT-based ranker (Nogueira and Cho, 2019) ($Ranker$), a state-of-the-art model [*] in the MS-MARCO document retrieval task (Nguyen et al., 2016) , is trained to rank (document, question) pairs. This ranker assigns high scores for *true positive* document and question pairs. We assume the ranker delivers an accurate reward signal since it achieves good performance on the challenging MARCO retrieval task, which covers a vast range of general topics. Let $\tilde{q}$ be the generated question from the underlying generator block and coordinator with the positive and negative document sets ($\mathfrak{D}^+$ and $\mathfrak{D}^-$) as the input.

$$Ranker(d, \tilde{q}) = \text{score} \in (0, 1) \qquad (1)$$
$$\forall d \in \mathfrak{D}^+, \mathfrak{D}^-$$

We pair $\tilde{q}$ with each of the documents in the positive and negative set, and evaluate the question-document pairs through the ranker for answer-relevancy. Using the scores and their memberships in $\mathfrak{D}^+$ or $\mathfrak{D}^-$, we compute retrieval statistics, such as *Precision@10* and *mean-Average-Precision (mAP)* (Zhu, 2004) which are candidate non-differentiable rewards R.

Training an Inter-generator Coordinator via RL: Next, we train a coordinator system using policy gradient to optimize the reward described above. The separation between the generator and the coordinator aims to ease the RL training by significantly reducing the action space.

Note that the generator model is fixed during this stage. We find that using RL to train the entire generating pipeline yields large variance since the action space is large and the auto-regressive nature of the generation process further amplifies such variance. Therefore, we fix the underlying generator component and then on top of multiple instances of the underlying generator, we stack our coordinator model, which is trained using RL in isolation. Instead of training *both* token-level GPT-2 and document-level coordinator over multiple GPT-2 instances using RL, only the coordinator is trained using RL, which structure dramatically reduces variance.

The coordinator is a transformer-based (Vaswani et al., 2017) model to utilize its superior attention capabilities across input documents.Unlike Transformer Decoder (Liu et al., 2018), there is no causal mask. Instead, the coordinator model uses the hidden states updated every decoding time from the underlying fine-tuned GPT-2 (Radford et al., 2019) language model generators.

We add learned *cluster embedding* c_i to the input document hidden states h_i, similar to learned positional embedding (Devlin et al., 2019), to indicate whether the source document i is in $\mathfrak{D}^+$ or $\mathfrak{D}^-$.

$$x_i^0 = h_i + c_i \qquad (2)$$

The coordinator model consists of n recurrent transformers blocks (Vaswani et al., 2017), followed by three different feed-forward layers (FF_w, FF_v, and FF_z) to output w, v, and z.

$$\begin{aligned} x^k &= \text{Add-Norm}(u, \text{FF}_x(u)) && (3) \\ u &= \text{Add-Norm}(x^{k-1}, \text{MultiHead}(x^{k-1})) && (4) \\ &\quad \text{for } k = 1, \ldots, n \\ w &= \text{FF}_w(x^n) && (5) \\ v &= \text{FF}_v(x^n) && (6) \\ z &= \text{FF}_z(x^n) && (7) \end{aligned}$$

w and v are the 10-dimensional attention weights that sum to 1.0 among the positive documents $\mathfrak{D}^+$, and negative documents $\mathfrak{D}^-$.

z parametrizes η in how much the coordinator model penalizes, or sometimes reinforces,

---

[*] http://www.msmarco.org/leaders.aspx

weighted average of decoding distributions from the negative set $\mathfrak{D}^-$. η is a simple heuristic variation of $\tanh$ such that the image lies in $(-1, 0.5)$ for all real numbers $\mathbb{R}$. Thus, η is a damped penalization coefficient.

$$\eta(z) = -\frac{e^{2z} - 0.5}{e^{2z} + 1} \in (-1, 0.5) \quad \forall z \in \mathbb{R} \tag{8}$$

Given w, v, and z, we obtain the final question decoding distribution at test time t.

$$\pi_\theta^t = \frac{1}{C}\Big[\sum_{i \in \mathfrak{D}^+} w_{i,\theta}^t \pi_i^t - \eta(z_\theta^t) \cdot \sum_{i \in \mathfrak{D}^-} v_{i,\theta}^t \pi_i^t\Big]_+ \tag{9}$$

where θ is the coordinator's parameters, the subscript $+$ is a ReLU (Nair and Hinton, 2010) operator that selects non-negative weighted tokens, and C is the normalizing factor that converts it into a distribution. The concatenations of each input document in $\mathfrak{D}^+$ and $\mathfrak{D}^-$, EOS token, and partially decoded question word sequence are used to obtain new hidden states and next decoding distributions. The decoding process is repeated until the generation is complete.

Policy Gradient Loss: The policy gradient loss is defined as follows:

$$\begin{aligned}\mathcal{L}_{\text{PG}}(\theta) = -\mathbb{E}\Big[&(R(\tilde{q}|\mathfrak{D}^+, \mathfrak{D}^-) - R_{\text{baseline}}) \\ &\cdot \sum_t \log \pi_\theta^t(o_t|\tilde{q}_{<t}, G, \mathfrak{D}^+, \mathfrak{D}^-)\Big]\end{aligned} \tag{10}$$

With a complete generation $\tilde{q}$, a terminal retrieval statistics reward is computed from the *Ranker* scores and score memberships, noted as $R(\tilde{q}|\mathfrak{D}^+, \mathfrak{D}^-)$. This reward weights the sum of log-likelihoods of generating the observed words o_t given the generation so far $\tilde{q}_{<t}$, from the underlying generator G, and the two document sets. We use *oracle* questions as the policy gradient baseline for variance reduction in R_{baseline}. Results using a different policy gradient baseline are in Appendix.

Set-induced Contrastive Regularization: We further propose an auxiliary to provide richer signals when optimizing the coordinator model. The intuition is that we would like to encourage the coordinator model to generate questions *toward* the positive set $\mathfrak{D}^+$ relative to the negative set $\mathfrak{D}^-$. We name the regularizer as *Set-induced* Contrastive Regularization (SCR) because the decoding distributions from $\mathfrak{D}^+$ and $\mathfrak{D}^-$ guide the coordinator to learn to make contrasts between the two sets. Although the decoding distributions from $\mathfrak{D}^+$ and $\mathfrak{D}^-$ are not gold supervision signals, modifying distributional distance toward or away from them helps regulate specificity to $\mathfrak{D}^+$. The former idea can be formulated as *minimizing* the KL-divergence, evaluated at timestep t:

$$\begin{aligned}\min_\theta \mathcal{L}_{\text{KL},t}^{\text{pos}}(\theta) = \min_\theta \sum_{i \in \mathfrak{D}^+} \Big[&D_{\text{KL}}(\pi_\theta^t || \pi_i^t) \\ &+ D_{\text{KL}}(\pi_i^t || \pi_\theta^t)\Big]\end{aligned} \tag{11}$$

We minimize both the forward and the reverse KL divergence since the forward KL does not penalize high mass of π_θ where π_i does not. Likewise for the reverse KL. On the other hand, the latter idea can be formulated as *maximizing* the KL-divergence against the negative set, evaluated at time step t:

$$\begin{aligned}\max_\theta \mathcal{L}_{\text{KL},t}^{\text{neg}}(\theta) = \max_\theta \sum_{i \in \mathfrak{D}^-} \Big[&D_{\text{KL}}(\pi_\theta^t || \pi_i^t) \\ &+ D_{\text{KL}}(\pi_i^t || \pi_\theta^t)\Big]\end{aligned} \tag{12}$$

However, we need to *cap* the negative set penalty rather than naïvely maximizing it, more restrictively if the positive set and the negative sets are semantically close. Intuition is that if the KL divergence against the negative set is too large, then we do not penalize further. Therefore, we define our contrastive regularization function as follows:

$$\begin{aligned}\mathcal{L}_{\text{SCR}}(\theta) = \frac{1}{T}\sum_{t=1}^{T} \Big[&\mathcal{L}_{\text{KL},t}^{\text{pos}}(\theta) - \mathcal{L}_{\text{KL},t}^{\text{neg}}(\theta) \\ &\cdot \mathbb{1}_{\nu_t \cdot \mathcal{L}_{\text{KL},t}^{\text{neg}}(\theta) < \mathcal{L}_{\text{KL},t}^{\text{pos}}(\theta)}\Big]\end{aligned} \tag{13}$$

where T is the length of the completed generation, and ν_t is the similarity measure between positive and negative sets at decoding time t. Specifically,

$$\nu_t = \cos\text{sim}\left(\frac{1}{|\mathfrak{D}^+|}\sum_{i \in \mathfrak{D}^+} \pi_i^t, \frac{1}{|\mathfrak{D}^-|}\sum_{i \in \mathfrak{D}^-} \pi_i^t\right) \tag{14}$$

Negative Entropy Loss: We add negative entropy loss $\mathcal{L}_{\text{H}}$ across the attention weights w and v, averaged over T to encourage the model attend to all the documents rather than attend to a small subset of the documents and risk losing positive and

Table 2: Comparison against the *oracle* MARCO questions for $\mathfrak{D}^+$. Since retrieval scores cannot give a complete picture of the generation, we aim to understand how close the generations are in terms of various metrics. The numbers show that our proposed model generates questions similar to the *oracle* MARCO questions. **Notations:** BL for BLEU; ST for Skip-Thought similarity; EM for Embedding Mean similarity; VE for Vector Extrema similarity; and GM for Greedy Matching.

negative set representational information.

$$\mathcal{L}_{\mathrm{H}}(\theta) = \frac{1}{T}\sum_{t=1}^{T}\Big[\sum_{i\in\mathfrak{D}^+} w^t_{i,\theta}\log w^t_{i,\theta} + \sum_{i\in\mathfrak{D}^-} v^t_{i,\theta}\log v^t_{i,\theta}\Big] \tag{15}$$

We finally optimize for the following loss:

$$\mathcal{L}(\theta) = \lambda_1\mathcal{L}_{\mathrm{PG}}(\theta) + \lambda_2\mathcal{L}_{\mathrm{SCR}}(\theta) + \lambda_3\mathcal{L}_{\mathrm{H}}(\theta) \tag{16}$$

where $\lambda_{1,2,3}$ are the scaling hyper-parameters.

3 Experiments

Dataset: We use the MS-MARCO Q&A dataset (Nguyen et al., 2016) where for the Bing query q, we consider the top-10 retrieved documents as our positive set $\mathfrak{D}^+$. To get our negative set $\mathfrak{D}^-$, we use the Conversational Search[†] dataset, which contains additional annotations for the same MS-MARCO Bing queries, to find a query q' that is similar to q yet not a paraphrase and consider the top-10 documents retrieved for q' as our negative set $\mathfrak{D}^-$. In total, we gather 100K train/10K dev/10K eval data points. Details of the pre-processing, usage of additional annotations from the secondary dataset, and experimental configuration are in Appendix.

Automatic evaluation: The generated questions are evaluated through standard retrieval-based metrics: MRR and MRR10 (Voorhees, 1999; Radev et al., 2002), nDCG (Järvelin and Kekäläinen, 2002), precision, mAP. These metrics are computed from the 10 positive and 10 negative document sets (=: *Out-Sample IR*). In addition, as a standardized evaluation routine in the MS-MARCO Retrieval task, for each generated question, we use Lucene[‡] to retrieve the most relevant 100 MARCO documents via BM25 (Robertson and Zaragoza, 2009), and use the retrieved document set and a trained model to rank (document, generated question) pairs, thus compute the retrieval statistics (=: *Search-Engine Augmented IR*).

The generated questions are also evaluated in

[‡] https://lucene.apache.org/

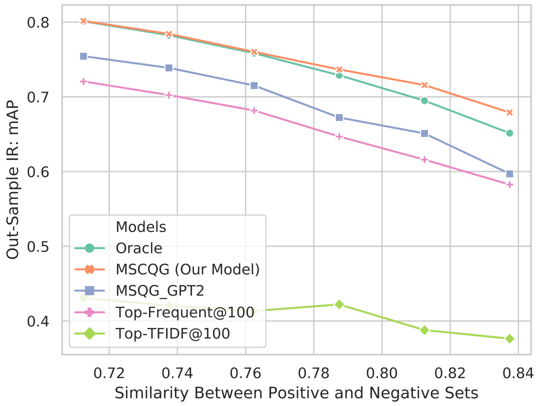

Figure 3: Out-Sample IR: mAP among $\mathfrak{D}^+$ and $\mathfrak{D}^-$

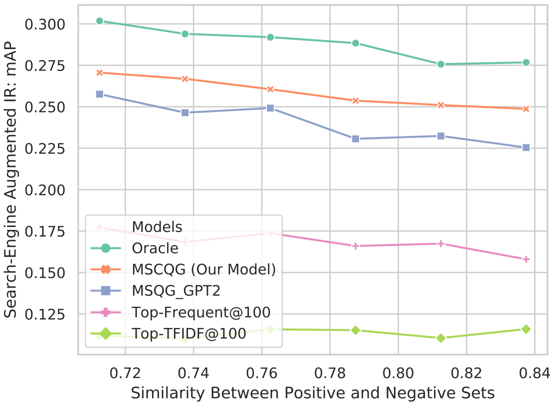

Figure 4: Search-Engine Augmented IR: mAP

Figure 3 shows that our model $\text{MSCQG}_{PG+SCR+H}$ outperforms the *oracle* questions by a small margin on the Out-Sample IR. In the larger retrieval evaluation using Lucene, it performs subpar against the *oracle* questions, but performs significantly better than all the considered baseline models, shown in Figure 4.

terms of BLEU (Papineni et al., 2002), ROUGE (Lin and Hovy, 2003), METEOR (Banerjee and Lavie, 2005), CIDEr (Vedantam et al., 2015), Greedy Matching (Rus and Lintean, 2012), Skip-Thought (Kiros et al., 2015), Embedding Average (Kenter et al., 2016) and Vector Extrema (Forgues et al., 2014) cosine similarities.

Human evaluation: We conduct human evaluation through Amazon Mechanical Turk where we evaluate questions generated by MSCQG, MSQG_{GPT2}, and the *oracle* question in four criteria: *fluency*, *relevancy*, *answerability*, and *overall*. First, we randomly select 600 (d, q_A, q_B) tuples where the d is any from $\mathfrak{D}^+$ and q_A, q_B from the three questions, and collect responses on which question is preferred over the other. Secondly, we evaluate 600 (d^+, d^-, q) tuples where given a question, d^+, d^- are randomly chosen from $\mathfrak{D}^+$ and $\mathfrak{D}^-$. This can determine questions' specificity to $\mathfrak{D}^+$ relative to $\mathfrak{D}^-$. Each sample is judged by 3 crowd-sourced workers who passed a rigorous spam-detection screening, totalling 3,600 samples to obtain reliable results. For details, see Appendix.

3.1 Baseline models

Multi-Source Question Generator: This model MSQG_{GPT2} is similar to MSQG in Cho et al. (2019b). It processes individual documents in parallel through the fine-tuned GPT-2 generator, rather than RNN-based Seq2Seq model in MSQG, and averages the decoding distributions at test time t.

$$\pi^t_{\text{MSQG}_{GPT2}} = \frac{1}{|pos|} \sum_i^{pos} \pi^t_i \tag{17}$$

Unlike MSQG in Cho et al. (2019b), no further heuristic modifications are made to the model.

Top-TFIDF@K: *Why do we not simply retrieve the top question implied by the 10 positive documents?* To this end, we design a retrieval baseline using the learned TF-IDF (Luhn, 1957; Jones, 1972; Salton and McGill, 1983) weights. This baseline re-evaluates the collection of retrieved questions from the corpus, gathered against each document in $\mathfrak{D}^+$ using TF-IDF, and retrieves the most relevant question. For design details, see Appendix.

Top-Frequent@K: Another retrieval model is to find an intersecting subset among all the 10 top-k question sets. For pseudo-code details, see Appendix.

3.2 Results and Analysis

Model comparison and ablation study: For simplicity, we abuse the term *oracle* by calling the ground-truth question that retrieves $\mathfrak{D}^+$ when constructing the dataset as the *oracle* question. However, these questions are not gold questions as they might not be the most relevant and specific questions to the given positive and negative sets.

Table 1 shows that our proposed model is effective at generating questions given multiple documents. In particular, it shows that policy gradient or set-induced contrastive regularization alone is effective in improving performance. The coordinator performs better when optimized for both policy gradient and regularization objectives.

The retrieval results for the questions that initially clustered $\mathfrak{D}^+$ sets are presented. Note that these are not *gold* questions because in most cases not all the retrieved documents in $\mathfrak{D}^+$ answer the questions. For clarity of our presentation, we abuse the term and name them as *oracle* questions. Search-engine augmented IR evaluation shows that our methods are upper-bounded by the *oracle* MARCO questions.

Entropy regularization improves the search-engine augmented IR scores, in particular, MRR. However, it is not crucial as supplemented by Table 2. For additional results, see Table 4 in Appendix.

Model performance v.s. similarities between $\mathfrak{D}^+$ and $\mathfrak{D}^-$: $\cos\mathrm{sim}(\mathfrak{D}^+, \mathfrak{D}^-)$ is approximated using the *oracle* questions that are available in the dataset. The similarity is computed by the cosine similarity of the two GEN-Encoder (Zhang et al., 2019) representations. Figures 3 and 4 show that our model generated questions are more grounded on $\mathfrak{D}^+$ than the baseline model generations. The more similar the two sets $\mathfrak{D}^+$ and $\mathfrak{D}^-$, the more difficult for the models, even humans, to distinguish which document is more relevant, if not answerable, given the generated question. The model outperforms the baseline model uniformly across different similarities between $\mathfrak{D}^+$ and $\mathfrak{D}^-$.

Role of $\mathfrak{D}^-$ by visualizing w, v, and z: Figures 5 and 6 show that our model MSCQG learns to gradually penalize $\mathfrak{D}^-$ as it sequentially generates words that are more grounded on $\mathfrak{D}^+$. Notice the roughly uniform weights across $\mathfrak{D}^+$ but increasing penalization weights across $\mathfrak{D}^-$, in decoding time.

η, which is controlled by the z, is learned to encourage, rather than discourage, certain words during decoding. The displayed $\mathfrak{D}^-$ weights v are multiplied by the dampening factor $-\eta(z)$ for interpretation purposes, thus it does not necessarily sum to 1, see equation 9. We observe that words that are not semantically distinguishing between $\mathfrak{D}^+$ and $\mathfrak{D}^-$, are encouraged by the coordinator to maintain readability. For example, the weights of the word *of* is mostly non-negative, whereas weights for other words are mostly negative. This indicates that the coordinator learns to selectively activate/suppress decoding of certain words by coordinating information from $\mathfrak{D}^+$ and $\mathfrak{D}^-$.

Human judgments: Table 3 shows that our model significantly outperforms the strong baseline in every aspect. Furthermore, we draw a more favorable conclusion toward our model-generated questions when compared against the *oracle* questions than from the automatic metrics, which are approximate yet reasonable metrics. The pairwise agreement between judges is 54% ± 1%. The Cohen's Kappa score is 0.19 ± 0.01. Note that this is a reasonable number given the *"same"* or ambiguous option in pairwise comparisons. $Ranker$ achieves a relatively high Pearson correlation of 0.6 with respect to human evaluation. For details, see Appendix.

4 Related Work

Multi-Source Encoder-Decoder: Ensemble set induction mechanism (Rokach, 2010) has been widely applied to neural machine translation (NMT) tasks (Bojar et al., 2014). Firat et al. (2016) introduced a new type of ensemble of NMT systems which take inputs as multiple sentences in different languages and output a translation into a single language. Each NMT system is trained on a mono-lingual source to target language translation dataset. Garmash and Monz (2016) further developed the multi-source encoder-decoder framework for multi-lingual NMT systems, by learning to assign uneven attention weights, called *expert combination weights*. To handle multi-source input, we take a similar multi-source encoder-decoder approach

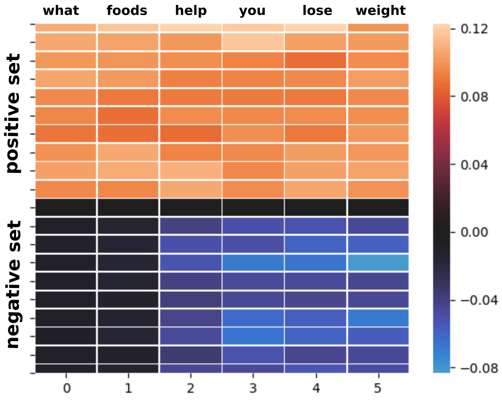

Figure 5: Example attention weights #1

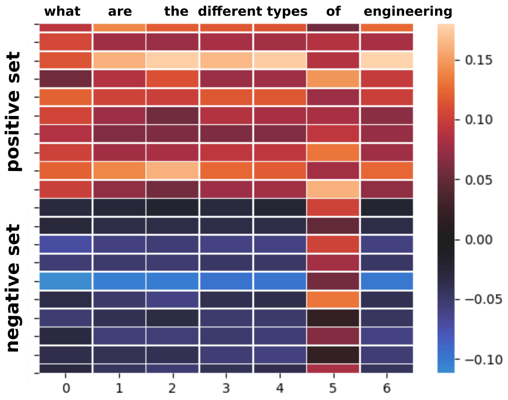

Figure 6: Example attention weights #2

Visualization of sequential attention weights. In the vertical axis, 0-9 indices indicate documents in $\mathfrak{D}^+$, and 10-19 in $\mathfrak{D}^-$. For explanation on $\mathfrak{D}^-$ weights v, see analysis below. Figure 5 shows that the model learns to push the sequential generation semantics more toward $\mathfrak{D}^+$ by gradually penalizing $\mathfrak{D}^-$. Figure 6 shows that frequent and semantically less distinguishing words such as *'of'* are encouraged even by $\mathfrak{D}^-$, which empirically aligns with our intuition for TF-IDF.

for our coordinator model. For such multi-lingual translation tasks, the target translation is available. However, in our task of generating multi-document questions, the target *does not exist* which makes it more challenging, thus we train via RL, rather than supervised learning.

Question Generation: Most prior work on question generation has been on single document i.e. given a document and an answer phrase in the document, generate a question that is answered by the answer phrase (Heilman, 2011; Rus et al., 2010). For a survey, see Pan et al. (2019). However, in our work, we aim to generate a multi-document question that is answerable by multiple input documents. Fan et al. (2018) propose a visual question generation model to generate natural questions about images using reinforcement learning where they use naturalness and human-like as reward signals. In our work, we use retrieval statistics, similar to Nogueira and Cho (2017), derived from a document-question ranker as the reward for training our coordinator model in isolation, rather than the entire generating pipeline.

Contrastive learning in NLP: Contrastive learning has been widely used in NLP (Smith and Eisner, 2005; Collobert et al., 2011; Bordes et al., 2013; Hjelm et al., 2019; Deng et al., 2020). Broadly, contrastive learning methods differentiate observed data from artificial negative examples. Gutmann and Hyvärinen (2010) leverages the Noise Contrastive Estimation (NCE) metric to differentiate the target sample from noise samples. Negative Sampling proposed by Mikolov et al. (2013) is a simplified variation of NCE loss. Recently, contrastive learning has also been employed in learning sentence representations (Clark et al., 2020). To our best knowledge, we are the first to leverage contrastive learning and establish set-induced penalization in the context of question generation.

5 Conclusion

We proposed a novel coordinator model that can generate questions that are more grounded on documents of interest. This coordinator model consists of transformer blocks, and is trained through reinforcement learning and an effective auxiliary: Set-induced Contrastive Regularization.

The rewards are derived from a publicly available state-of-the-art pre-trained ranker (Section 2) to compute retrieval statistics among $\mathfrak{D}^+$ and $\mathfrak{D}^-$. Our novel contrastive regularization induces generations to be more specific to $\mathfrak{D}^+$ than to $\mathfrak{D}^-$ while limiting the effect of $\mathfrak{D}^-$ in a principled manner by accounting for their semantic similarity.

We evaluate a generated question from each model by assessing how many of the input $\mathfrak{D}^+$ documents among a pool of relevant documents it can retrieve, based on the (document, question) ranker that is trained on the same wide-ranging domain. For a comprehensive automatic evaluation of the models, retrieval statistics are computed from a larger pool of relevant documents gathered via BM25. Experiment results show that our model significantly outperforms previous neural generation as well as strong retrieval baselines in both automatic and human metrics.

Given the promising comprehensive results of the proposed models and training approach, we can extend the framework with appropriate modifications and train via imitation learning algorithms, and this is left for future work.

Appendix

Appendix A. Data Pre-processing Details

Data Pre-processing: MS-MARCO Q&A data-set (Nguyen et al., 2016) contains 1,010,916 questions, in which each question is associated with top-10 documents. Each data point contains a question and its top-10 returned documents from the Bing search engine[§]. This question is not a target itself since not all the top-10 retrieved documents answer the question. However, it can give relative evaluation against a model-generated question based on the top-10 retrieved documents. We target a broader class of problems where only document groups are available but no such group-inducing or *oracle* questions.

In fact, among the top-10 retrieved documents, often one document is labeled '*selected*' by human annotators to indicate that the document answers the question (*true positive*), and left unknown or unlabeled for the rest of the documents, implying they may or may not answer the question (*true*

[§] `https://www.bing.com`

negative or *false negative*). This label information is used to train the underlying generator block of their MSQG model (Cho et al., 2019b). A single *selected* MS-MARCO (Nguyen et al., 2016) document is fed into a long short-term memory-based sequence-to-sequence model to output the corresponding question. An example of the input *selected* document is: *The House of Representatives shall be composed of Members chosen every second Year by the People of the several States.... Article I, Section 2, Clause 1*, and the corresponding question is: *how long is a term for a member of the house of representatives*. We chose this dataset since the question that retrieve the top-10 documents can shed light to relative performance of our model.

To find two 10-document sets $\mathfrak{D}^+$ and $\mathfrak{D}^-$ that are similar, we find a pair of questions that are semantically similar. However, computing pair-wise similarities among roughly 1 million questions is computationally intractable. Therefore, we leverage another dataset: MS-MARCO-Conversational Search[¶]: an artificially constructed public dataset that simulate user search sequences.

Each data point or session is an artificial sequence of similar questions grounded on true user behavior. Since many similar questions are grouped together, we can reduce the search space for finding pairs of similar questions. Then we take pairs of high semantic similarity (≥ 0.7) yet not a paraphrase (≤ 0.85 following their classification criteria) using GEN-Encoder (Zhang et al., 2019) which two associated 10-document sets do not have overlaps, primarily for prototype evaluation convenience. For deployment models, one may choose to allow overlaps between two sets for more challenging learning. From the two similar 10-document sets, either one is set to positive $\mathfrak{D}^+$ or negative $\mathfrak{D}^-$, yielding two data points for the our derived dataset.

These pre-processing steps yield 346,215 data points, each of which contains a pair of positive and negative questions, and positive and negative 10-document sets. Training MSCQG on the entire dataset requires processing about 7 million MARCO documents. This is computationally intensive and takes about two days on 8 Nvidia Tesla V100 GPU cards for a single epoch. Therefore, for building small research prototypes and benchmarks, we will also release a subset of the data, that consists of 100K/10K/10K training, development, and evaluation data points.

Appendix B. Data Example

***Oracle* question for $\mathfrak{D}^+$:**
number of saturn's moons

***Oracle* question for $\mathfrak{D}^-$:**
uranus how many moons

Positive Set $\mathfrak{D}^+$:

1. moons of saturn. there are 62 moons orbiting saturn. the moons of saturn vary not only in size but also in composition and shape. the largest of the moons of saturn is the aptly named titan, more than 5,000 km across and is bigger than mercury. there are 7 major moons of saturn and the rest are grouped based on the mythology from which it is taken.

2. iapetus with a diameter of 1,470 km, it is the 3rd largest moon of saturn. it was discovered by giovanni cassini in 1671. it has a distinct feature of having a bright and dark hemisphere. dione the 4th largest moon of saturn named after a vague character in greek mythology.

3. titan is the largest of saturn's moons and the first to be discovered. titan is the only moon in the solar system known to have a significant atmosphere. nitrogen and methane extend around the moon 10 times as far into space as earth's atmosphere, sometimes falling to the surface in the form of methane rain.

4. saturn has at least 150 moons and moonlets, 53 of which have formal names. titan, the largest, comprises more than 90% of the mass in orbit around saturn, including the rings. saturn's second-largest moon, rhea, may have a tenuous ring system of its own, along with a tenuous atmosphere.

5. their journeys around the ringed planet average from half an earth day to just over four earth years. saturn's moons formed early in the history of the solar system. one of the moons, titan, makes up 96 percent of the mass orbiting the planet. scientists think that the system may have originally housed

---

[¶] https://github.com/microsoft/MSMARCO-Conversational-Search *two such moons, but the second broke up, creating the debris that formed the rings and smaller, inner moons.*

6. saturn has a prominent ring system that consists of nine continuous main rings and three discontinuous arcs and that is composed mostly of ice particles with a smaller amount of rocky debris and dust. sixty-two moons are known to orbit saturn, of which fifty-three are officially named.

7. sixteen of the moons are tidally locked, with one face permanently turned toward saturn. the first moon was discovered in 1655. over the next 200 years, the other seven major satellites were spotted. by 1997, astronomers on earth had found 18 moons in orbit around the planet.

8. saturn is the sixth planet from the sun and the second-largest in the solar system, after jupiter. it is a gas giant with an average radius about nine times that of earth. although only one-eighth the average density of earth, with its larger volume saturn is just over 95 times more massive.

9. this temporary name usually consists of the year of discovery and a number indicating the order of discovery in that year. in the case of saturn's moons, these provisory names follow the format s/2005-s1, s/2005-s2 etc. the first s (before the slash) is for saturn. the second s (after the dash) is for satellite.

10. this does not include the hundreds of moonlets comprising the rings. titan, saturn's largest moon, and the second-largest in the solar system, is larger than the planet mercury, although less massive, and is the only moon in the solar system to have a substantial atmosphere.

Negative Set $\mathfrak{D}^-$:

11. uranus has 27 moons that we know of. five of the moons are large and the rest are much smaller. the five large moons are called miranda, ariel, umbriel, titania, and oberon. titania is the largest moon of uranus and it is covered with small craters, a few large craters, and very rough rocks. ariel is the brightest moon of uranus and has canyons and valleys as well as a lot of craters. umbriel is very dark.

12. uranus can't seem to catch a break these days. besides spinning on its side like the drunkard of the solar system and being the butt of everyone's jokes, new research suggests several of its tiny moons will collide in a million years. uranus can't seem to catch a break these days.

13. the gas giant uranus is the third largest planet in our solar system, has many moons, a ring system, and composed of gases and ices. universe today space and astronomy news login

14. the researchers used cressida's mass and orbit to determine its possible doom. since uranus' 27 moons are tightly packed together, the team posits that in a million years, cressida will likely have a deadly encounter with one of its neighboring moons, called desdemona. previous research and simulations suggest cupid and belinda will also probably smack into each other some time between 1,000 and 10 million years from now.

15. puck, at 162 km, is the largest of the inner moons of uranus and the only one imaged by voyager 2 in any detail while puck and mab are the two outermost inner satellites of uranus. all inner moons are dark objects.

16. uranus, which takes its name from the greek god of the sky, is a gas giant and the seventh planet from our sun. it is also the third largest planet in our solar system, ranking behind jupiter and saturn. like its fellow gas giants, it has many moons, a ring system, and is primarily composed of gases that are believed to surround a solid core.

17. in 1986, the voyager 2 spacecraft hit the jackpot while studying uranus and discovered 10 other moons, including desdemona and cressida. since then, hubble observations have helped bring that number up to 27 for now.

18. at an average distance of 3 billion km from the sun, it takes uranus roughly 84 years (or 30,687 days) to complete a single orbit of the sun. 1 the rotational period of the interior of uranus is 17 hours, 14 minutes. as with all giant planets, its upper atmosphere experiences strong winds in the direction of rotation.

19. uranus' size, mass and orbit: with a mean *radius of approximately 25,360 km, a volume of 6.833—10^13 km3, and a mass of 8.68 — 10^25 kg, uranus is approximately 4 times the sizes of earth and 63 times its volume.*

20. uranus has 27 known satellites, which are divided into the categories of larger moons, inner moons, and irregular moons (similar to other gas giants). the largest moons of uranus are, in order of size, miranda, ariel, umbriel, oberon and titania.

Appendix C. Retrieval Baselines

Top-TFIDF@K and **Top-Frequent@K**

The retrieval baselines are designed to give a relative insight into the performance between MSQG in Cho et al. (2019b) and our novel coordinator model. We use Lucene to retrieve *questions* instead of documents from a corpus composed of the 1,010,916 MS-MARCO questions. The retrieved questions from Top-TFIDF@K and Top-Frequent@K baselines are evaluated in the same manner as the generated ones.

For the intersection to be non-empty, k should be sufficiently large. However, even for $k = 1000$, there were no intersecting subset questions for almost all cases. Therefore, we relax the intersection among all 10 retrieved sets, into finding the most frequently occurring question among the 10 top-k retrieved sets. $k = 100$ was an appropriate value that is not too large to retrieve remotely relevant questions, and not too small to yield vastly different retrieval sets. If there are multiple questions with the same count, we randomly choose one.

Algorithm 1 Top-TFIDF@K

```
Input: $\mathfrak{D}^+$, Corpus $\mathbb{C}$
For each $d \in \mathfrak{D}^+$, retrieve top-K questions in $\mathbb{C}$;
Using all unique questions $\mathbb{Q}$, compute TF-IDF;
Let $\Psi$ be the TF-IDF transform operator;
$q^* = \arg\max_{q \in \mathbb{Q}} \sum_{d \in \mathfrak{D}^+} \cos\text{sim}\,(\Psi_q, \Psi_d)$;
Output: $q^*$
```

Algorithm 2 Top-Frequent@K

```
Input: $\mathfrak{D}^+$, Corpus $\mathbb{C}$
For each $d \in \mathfrak{D}^+$, retrieve top-K questions in $\mathbb{C}$;
Let $\mathbb{S}_d$ be the retrieved set for each $d$;
$q^* = \arg\max_{q \in \mathbb{Q}} \sum_{d \in \mathfrak{D}^+} \mathbb{1}_{q \in \mathbb{S}_d}$;
Output: $q^*$
```

Appendix D. Experiment Configurations

Document-specific GPT-2 Generator: From each document i, the generator yields its final layer hidden state $h_i \in \mathbb{R}^H$ ($H = 768$ is the hidden dimension) and a document-specific discrete output distribution $\pi_i \in \mathbb{R}^V$ ($V = 50257$ is the vocabulary dimension) from the learned language model head.

Coordinator: The input size is 20 with the dimensionality of the embeddings and hidden states as 768. The number of recurrent layers is 2, with 4 attention heads in each layer. The epsilon value used in the layer normalization is set to 1e$-$5. The number of cluster embeddings is 2 (positive or negative). The standard deviation of the truncated normal initializer for weight matrices is 0.02. $\lambda_1, \lambda_2, \lambda_3 = 1.0, 100.0, 0.1$. We performed coarse hyper-parameter search for equidistant values in log-scale for all $\lambda_1, \lambda_2, \lambda_3$, and use the best configuration. Maximum generation length is 20 tokens. We use the BERT (Devlin et al., 2019) version of Adam optimizer (Kingma and Ba, 2014) with weight decay of 0.01 and learning rate of 1e$-$5.

We trained the coordinator model by maximizing *Precision@10* with *oracle* questions as the policy gradient baseline. It is reasonable to weigh the documents unevenly because often times not all the top-10 retrieved documents from the Bing search engine share the same content. Thus, we leave to the model to learn the optimal attention weights among positive and negative sets that produce a more grounded question. Additional experiment results using a different baseline - self-critic (Rennie et al., 2017) - is shown in Table 4. This shows that our proposed model framework is effective even with any of the two policy gradient baselines. Conceptually, the coordinator model would generate a question that can better retrieve the documents from the positive set, aided by the negative set.

Appendix E. Human Evaluation Details

We performed two human evaluations: In the first experiment, we showed judges one randomly selected positive document, which is about 300 words long, followed by a pair of questions from the three sources. Judges were asked to evaluate which one of the two questions is preferred based on four criteria. For each pair of three sources, we evaluated 200 same random samples for each judge (or 600 samples for the 3 judges), totalling 1,800 samples.

In the second experiment, human annotators evaluated contrastive ability from 1,800 samples of one question, followed by two documents each from the positive and negative sets. Note that our model is trained to generate questions, accounting for the negative set.

The results were averaged across all samples and judges.

For computing the Pearson correlation between the ranker and human evaluation results, we map *Option A preferred* $\rightarrow 0$, *Same* $\rightarrow 0.5$, *Option B preferred* $\rightarrow 1$, accounting for the random assignments between A and B. This projection ensures that image of two metrics are the same (between 0 and 1). Then we compute the correlation value between two results.

Oracle Questions for $\mathfrak{D}^+$	0.759	0.797	0.976	0.842	0.292	0.273	0.0846	0.0495	0.256

Table 4: Additional retrieval performance using self-critic (Rennie et al., 2017) baseline in the policy gradient, applicable to datasets with no *oracle* questions. It shows that our framework is also effective using a different baseline. The superscript *null-neg* denotes models that do not use negative attentions when generating questions. This shows the importance of the negative set in promoting specificity in the generated question. It further corroborates that the non-uniform weighted-sum scheme among $\mathfrak{D}^+$ improves performance because not all documents in $\mathfrak{D}^+$ revolve around the same topic, and the model learns to address this nature of the dataset through unequal weights and generate a more representative question.

Disambiguatory Signals are Stronger in Word-initial Positions

Abstract

Psycholinguistic studies of human word processing and lexical access provide ample evidence of the preferred nature of word-initial versus word-final segments, e.g., in terms of attention paid by listeners (greater) or the likelihood of reduction by speakers (lower). This has led to the conjecture—as in Wedel et al. (2019b), but common elsewhere—that languages have evolved to provide more information earlier in words than later. Information-theoretic methods to establish such tendencies in lexicons have suffered from several methodological shortcomings that leave open the question of whether this high word-initial informativeness is actually a property of the lexicon or simply an artefact of the incremental nature of recognition. In this paper, we point out the confounds in existing methods for comparing the informativeness of segments early in the word versus later in the word, and present several new measures that avoid these confounds. When controlling for these confounds, we still find evidence across hundreds of languages that indeed there is a cross-linguistic tendency to front-load information in words.[1]

1 Introduction

The psycholinguistic study of human lexical access is largely concerned with the incremental processing of words—whereby, as individual sub-lexical units (e.g., phones) are perceived, listeners update their expectations of the word being spoken. One common tenet of such studies is that the disambiguatory signal contributed by units early in the word is stronger than that contributed later—i.e. **disambiguatory signals are front-loaded in words**. This intuition is derived from ample indirect evidence that the beginnings of words are more important for humans during word processing—including, e.g., evidence of increased attention to word beginnings (Nooteboom, 1981, *inter alia*) or evidence of increased levels of phonological reduction in word endings (van Son and Pols, 2003b).

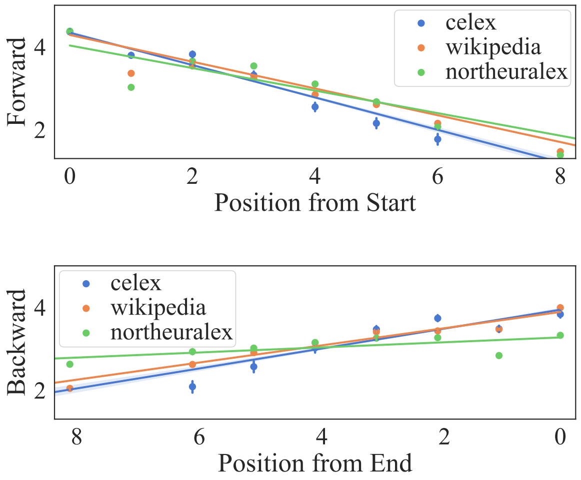

Figure 1: Forward and Backward Surprisals with LSTM model from Pimentel et al. (2020). The bottom plot has been flipped horizontally such that it visually corresponds to the normal string direction.

To analyse this front-loading effect, researchers have investigated the information provided by segments in words. van Son and Pols (2003a,b) showed that, in Dutch, a segment's position in a word is a very strong predictor of its conditional surprisal, with later segments being more predictable than earlier ones—a result which we show to arise directly from its definition in §3.3.1. Recently King and Wedel (2020) and Pimentel et al. (2020) confirmed the effect on many more languages.

Their analysis, however, presents an inherent confound between the amount of conditional information available to a model and the surprisal of the subsequent segment—see Fig. 1 for results illustrating this. Using the LSTM training recipes from Pimentel et al. (2020),[2] we calculated the conditional surprisal at each segment position within the words across all languages in three datasets.[3] The top-half of Fig. 1 shows that, indeed, positions

[3] See §3 and §5 for specifics on training and data. Each segment corresponds to a single phone in CELEX and NorthEuraLex, and to a single grapheme in Wikipedia.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 31–41
April 19 - 23, 2021.

earlier in the string have higher surprisal than positions later in the string, supporting the thesis of higher informativity earlier in words. The bottom-half shows that modelling the strings right-to-left instead of left-to-right reverses the resulting effect.

This decouples conditional surprisal from the disambiguatory strength. To expose this decoupling, consider an artificial language where every word contains a copy of its first half, e.g., *foofoo*, *barbar*, *foobarfoobar*, etc. The first and second halves of these words have identical disambiguatory strength; they are the same so one could disambiguate the word as easily from its second half as from the first. In contrast, conditional surprisal would be nearly zero for the second halves of words because the second half is perfectly predictable from the first half.

In natural languages, measuring conditional entropy in a left-to-right fashion inherently forces a reduction of conditional entropy in later segments because of a language's phonotactic constraints. However, the disambiguatory strength of later segments is not inherently less than that of earlier segments. For instance, in a language like Turkish, which has vowel harmony, knowledge of any of the vowels in a word will provide information about the word's other vowels in a similar way. As such, knowledge of vowels towards the front of a word is as disambiguating as of vowels towards its end.

The contributions of this paper are threefold. First, we document and demonstrate the shortcomings of existing methods for measuring the informativeness of individual segments in context, including the confound with the amount of conditional information discussed above. Second, we introduce three surprisal-based measures that control for this confound and enable comparison of word-initial versus -final positions in this respect: unigram, position-specific and cloze surprisal (see §3). Finally, we find robust evidence across many languages of stronger disambiguatory signals in word initial than word-final positions. Out of a total of 151 languages analysed across three separate collections, 82 of them present a higher cloze surprisal in word beginnings than in endings—with similar patterns arising with the other two measures.

2 Background and Related Work

Psycholinguistic evidence. Lexical access has long been a topic of interest for psycholinguists, leading to many distinct models being proposed for this process (Morton, 1969; Marcus, 1981; Marslen-Wilson, 1987). Far earlier, though, Bagley (1900) had already demonstrated that earlier segments in words were more important for word recognition than later segments; specifically, they found that, when exposed to words with word-initial or word-final consonant deletions, listeners found the word-initial deletions more disruptive. Fay and Cutler (1977) showed mispronunciations are more likely in word endings, while Bruner and O'Dowd (1958) showed that recognizing written words with flipped initial characters was harder than with word final ones—demonstrating that the initial part of the word was more "useful" for readers. More recently, Wedel et al. (2019a) found evidence in support of Houlihan (1975), showing neutralizing rules tend to target word endings more significantly than beginnings in both suffixing and prefixing languages.

Nooteboom (1981) investigated the ease of recovering lexical items from either word beginnings or endings, finding that people had an easier time recovering words from their beginnings. For this, he examined words for which the first and second halves each completely identified them in a large Dutch dictionary—controlling for both segments' length and uniqueness. Later on, though, Nooteboom and van der Vlugt (1988) showed this difference vanishes when priming people with the length of the word—proposing the difference comes not from how informative segments were, but from the difficulty in time aligning later segments in mental lexicons. Connine et al. (1993) also found no difference in priming effects with non-words that differed from real words in either word initial or medial positions, suggesting initial positions have no special status in word recognition.

Psycholinguistic evidence is key to understanding how lexical access works in human language processing, and can help us understand why lexicons may evolve to provide more disambiguatory signals earlier in words.[4] Given the incremental nature of human lexical processing, however, such evidence cannot provide direct evidence of the nature of the lexicon uninfluenced by incrementality.

Computational evidence. To the best of our knowledge, van Son and Pols (2003b,a) were the first to use computational methods coupled with an

---

[4] Note that there are many possible reasons why the effects we demonstrate in this paper may arise, from the demands of lexical access to constraints on articulation. We provide no evidence for any of the possible explanations, evolutionary or otherwise, just methods for measuring the effect.

information theoretic definition of informativeness to investigate this question. They showed that segments in the beginning of words carry most of a word's information, as measured by their contextual surprisal using a plug-in tree structured probabilistic estimator. Although assessing a less-biased sample of words than Nooteboom (1981),[5] this study is also limited to a single language (Dutch), hence cannot assess whether this is a general phenomenon or specific to that language.

Further, van Son and Pols (2003a,b) use absolute word positions in their analysis. Word length correlates strongly with frequency, hence while early positions are present in all words, later positions only exist for a much smaller sample of typically lower frequency words. Thus this comparison amounts to asking if later positions in longer and infrequent words have lower surprisal than earlier positions in all (frequent or infrequent) words. We analyse this confounding factor in §6.

Wedel et al. (2019b) and King and Wedel (2020) applied a methodology similar to that of van Son and Pols (2003a) to show, for many diverse languages, that more frequent words contain less informative segments in word initial positions, while less frequent types carry more informative ones. They further showed that segments in later word positions were less informative (given the previous ones) than average in rarer words. While controlling for length, King and Wedel (2020) also compared words' forward and backward uniqueness points—nodes in a trie from which only one leaf node can be reached, i.e., where the word is uniquely identified—showing they happened earlier in forward strings.

While these studies provide evidence from more diverse sets of languages, they follow van Son and Pols (2003a) in studying closed lexicons.[6] As we show in §3.3.1, the use of probabilistic trie models on a closed lexicon yields a trivial effect of higher informativity at word initial positions. Furthermore, such studies cannot account for out-of-vocabulary words (e.g., nonce, proper name or otherwise unknown words) or derivational morphology, which are key parts of lexical recognition. Lexical access is also somewhat robust to segmental misordering (Toscano et al., 2013) and sounds later in a word help determine the perception of earlier ones (Gwilliams et al., 2018). In contrast, a trie over a closed lexicon is deterministic. Beyond this, Luce (1986) showed in a corpus study that the probability of a word type being uniquely identifiable before its last segment was only 41%—and 19% of types were identified only by the end of word, being proper prefixes of other words, such as *cat* and *cats*. They conclude that uniqueness point statistics may only be useful for long word analysis.

In Pimentel et al. (2020), we analysed several languages' phonotactic distributions, focusing on presenting a trade-off between phonotactic entropy and word length across languages. As a control experiment we analysed the correlation between a segment's surprisal and its word position across 106 languages. We did not control for word length and did not run per-language experiments, though—so we could have just been capturing the effect that later positions will mostly be present in languages with longer words (which, as we find, have lower information on average).[7]

While this last work avoids many of the issues raised earlier in this section, it fails to control the key confound mentioned earlier: it relies on left-to-right conditional probabilities to calculate surprisal. Thus segments early in the word have less conditional information and hence are generally of lower probability—a trivial effect that does not indicate a segment's disambiguatory signal strength.

3 Measures of Disambiguatory Strength

3.1 A Lexicon Generating Distribution

In this work, instead of the lexicon itself, we investigate the probability distribution from which it is sampled. The distribution is unobserved, but we can get glimpses of it via the sampled lexicon:

$$\left\{\mathbf{w}^{(n)}\right\}_{n=1}^{N} \sim p(\mathbf{w}) = \prod_{t=1}^{|\mathbf{w}|} p(w_t \mid \mathbf{w}_{<t}) \qquad (1)$$

The distribution $p(\mathbf{w})$ is defined over the entire space of possible phonological wordforms $\mathbf{w} \in \Sigma^*$, where Σ is a language-specific alphabet and the operator * indicates its Kleene closure.[8] This dis-

---

[5] Nooteboom (1981) looked at words completely identifiable by both their first and second halves in a large Dutch dictionary—this resulted in a study with only 14 words.

[6] The closed lexicon assumption is incorporated implicitly in the probabilistic trie models used by van Son and Pols (2003a,b) and King and Wedel (2020)—i.e. they assign zero probability to any form not in their training sets—and in the uniqueness point analysis of King and Wedel (2020).

[7] We note this issue only applies to the control experiment, and has no bearing on the key findings of that paper.

[8] We pad all strings with the end-of-word (EOW) symbol. For simplicity, we assume the alphabet includes EOW throughout the rest of the paper.

tribution should assign high probability to likely wordforms (attested or not) and low probability to unlikely ones. Using Chomsky and Halle's (1965) classic example from English, *brick* (attested) and *blick* (unattested) would have high probability, whereas **bnick* (unattested) would have a low probability.

3.2 Entropy and Conditional Entropy

Shannon's entropy is a measure of how much information a random variable contains. Consider a segment w_t at word position t, which is a value of the random variable W_t. The average information (surprisal) relayed per segment is:

$$\mathrm{H}(W_t) \equiv \sum_{w_t \in \Sigma} p(w_t) \log \frac{1}{p(w_t)} \tag{2}$$

A random variable is maximally entropic if it is a uniform distribution, in which case $\mathrm{H}(W_t) = \log(|\Sigma|)$. Conditional entropy measures how much information the knowledge of a variable conveys, given some previous knowledge. The average information transmitted per segment, given the previous ones in a word, is

$$\mathrm{H}(W_t \,|W_{<t}) \equiv \sum_{\mathbf{w}_{\leq t} \in \Sigma^*} p(\mathbf{w}_{\leq t}) \log \frac{1}{p(w_t \mid \mathbf{w}_{<t})} \tag{3}$$

where $\mathbf{w}_{\leq t} = \mathbf{w}_{<t} \circ w_t$. We note the conditional entropy is always smaller or equal to the entropy, i.e. $\mathrm{H}(W_t \mid W_{<t}) \leq \mathrm{H}(W_t)$.

3.3 Plug-in Estimators, Context Size, and Disambiguatory Strength

Our criticism of previous work investigating the disambiguatory strength of word-initial vs. word-final segments can be mainly divided in two parts: (i) the use of maximum likelihood plug-in estimators of the conditional entropy, by e.g. van Son and Pols (2003b); (ii) the use of left-to-right conditional entropy in itself, by all previous information-theoretic work in this vein.

3.3.1 A Critique of van Son and Pols (2003b)

We present a *reductio ad absurdum* which shows that van Son and Pols's (2003b) method will lead to the conclusion that word-initial segments are more informative even if all segments were equally entropic and sampled independently—a nonsensical finding. Accordingly, assume the probability distribution $p(w_t \mid \mathbf{w}_{<t})$, from which each segment in a word is sampled, was independent, e.g. define

$$\hat{p}(\mathbf{w}) = \prod_{t=1}^{|\mathbf{w}|} \hat{p}(w_t \mid \mathbf{w}_{<t}) = \prod_{t=1}^{|\mathbf{w}|} \hat{p}(w_t) \tag{4}$$

Assume now that a large, but finite, lexicon is sampled from it $\left\{\hat{\mathbf{w}}^{(n)}\right\}_{n=1}^{N} \sim \hat{p}(\mathbf{w})$. Further consider modelling this sampled lexicon with a probabilistic trie structure, similarly to what was done by van Son and Pols (2003a,b),[9] i.e.

$$q_{\text{trie}}(w_t \mid \mathbf{w}_{<t}) = \frac{\text{count}(w_t, w_{t-1}, \ldots, w_0)}{\text{count}(w_{t-1}, \ldots, w_0)} \tag{5}$$

where w_0 is the beginning-of-word symbol. Such a model uses all N words to approximate the distribution of the first segment—i.e. $\text{count}(w_0) = N$. Yet after $t-1$ segments, an exponentially smaller sample is used to capture the distribution—i.e. $\mathbb{E}[\text{count}(w_{t-1}, \ldots, w_0)] = N/|\Sigma|^{t-1}$. Using this model as a plug-in estimator of the entropy will lead to negatively biased estimates, where the error is approximately (Basharin, 1959):

$$\begin{aligned} \mathrm{H}(W_t \mid W_{t-1}) - \mathbb{E}\left[\hat{\mathrm{H}}\right] &\approx \frac{(|\Sigma| - 1) \log e}{\text{count}(w_{t-1}, \ldots, w_0)} \\ &\approx \frac{|\Sigma|^{t-1}(|\Sigma| - 1) \log e}{N} \end{aligned} \tag{6}$$

where $\hat{\mathrm{H}}$ is a plug-in estimate of the entropy. The error grows exponentially in t due to the $|\Sigma|^{t-1}$ factor. However, by assumption, $\mathrm{H}(W_t \mid W_{t-1})$ is constant—we have equally entropic and independent segments. Thus, the only way for this difference to increase is for the second term to decrease as a function of t. It follows that the estimated cross-entropies decrease as a function of t due to a methodological technicality. Indeed, in the extreme case, every position after a word's uniqueness point would be estimated to have zero entropy. Thus, van Son and Pols's (2003a) method only reveals a trivial effect.

3.3.2 Conditional Entropy and Context Size

As previously mentioned, the conditional entropy measures how much information the knowledge of a variable conveys, given some previous information, and it is always smaller or equal to the entropy. For this reason, relying on left-to-right conditional

---

[9] This is in fact a simplification of van Son and Pols's (2003a) model, which in practice uses Katz smoothing.

entropies to estimate the strength of disambiguatory signals yields straightforward results; the availability of larger conditioning contexts in a word's final segments will naturally reduce its conditional entropy. This will negatively skew the estimated informativeness of the later parts of a word.

$$\mathrm{H}(W_t) \geq \mathrm{H}(W_t \mid W_{t-1}) \geq \mathrm{H}(W_t \mid W_{<t}) \quad (7)$$

This effect can also be easily demonstrated by the symmetrical nature of mutual information (MI), where the MI is defined as:

$$\begin{aligned}\mathrm{MI}(W_t; W_{t-1}) &= \mathrm{H}(W_t) - \mathrm{H}(W_t \mid W_{t-1}) \\ &= \mathrm{H}(W_{t-1}) - \mathrm{H}(W_{t-1} \mid W_t) \\ &= \mathrm{MI}(W_{t-1}; W_t) \qquad (8)\end{aligned}$$

If we assume both segments had the same unconditional entropy, i.e. $\mathrm{H}(W_t) = \mathrm{H}(W_{t-1})$, then using left-to-right conditional entropies would suggest the later segment was less informative, while right-to-left conditioning would imply the opposite. Nonetheless, both their contextual and uncontextual disambiguatory strength would in fact be the same, if we estimated it with equal-sized contexts:

$$\begin{aligned}&\mathrm{H}(W_t) = \mathrm{H}(W_{t-1}) \Longrightarrow \qquad (9) \\ &\qquad \mathrm{H}(W_t \mid W_{t-1}) = \mathrm{H}(W_{t-1} \mid W_t)\end{aligned}$$

3.4 Cross-Entropy and Entropy

As mentioned above, the distribution $p(\mathbf{w})$ is not directly observable. We can, however, approximate it using character-level language models $p_\theta(\mathbf{w})$. We are interested in the entropy of variable W_t, as a proxy we measure its cross-entropy

$$\mathrm{H}_\theta(W_t) \equiv \sum_{w_t \in \Sigma} p(w_t) \underbrace{\log \frac{1}{p_\theta(w_t)}}_{\text{surprisal}} \quad (10)$$

where the surprisal is the information provided by a single segment instance w_t. The cross-entropy is an upper bound on the entropy, i.e. $\mathrm{H}(W_t) \leq \mathrm{H}_\theta(W_t)$, with their difference being the Kullback–Leibler (KL) divergence between both distributions. Since the KL-divergence is always positive, this upper-bound holds. Furthermore, the closer p_θ is to the true distribution p, the smaller the divergence is, and the tighter this bound. As such, the better our model is at estimating the true distribution, the better our estimates of the entropy will be.

Calculating eq. (10) still requires knowledge of the true p. We overcome this limitation by empirically estimating it on a held out part of the lexicon

$$\mathrm{H}_\theta(W_t) \approx \frac{1}{N} \sum_{n=1}^{N} \log \frac{1}{p_\theta(w_t^{(n)})} \quad (11)$$

3.5 Earlier vs. Later Word Entropy

For the remainder of this work, we will discuss information in terms of surprisal, since the entropy is its expected value. We analyse the distribution of disambiguatory information across word positions via three distinct measures—all of which control for the amount of conditioning per position:

- **Unigram Surprisal $\mathrm{H}_\theta(W_t)$:** the surprisal of individual segments.
- **Cloze Surprisal $\mathrm{H}_\theta(W_t \mid W_{\neq t})$:** surprisal of a segment given all others in the same word.
- **Position-Specific Surprisal** $\mathrm{H}_\theta(W_t \mid T = t, |W|)$: the surprisal of individual segments given their position in the wordform and the word's length.

The unigram surprisal captures the information provided by each segment when considering no context; while the cloze surprisal represents the information provided by a segment when one already knows the rest of the word. The position-specific surprisal represents a mid way between both, conditioning each segment only on its position and the word's length—being inspired by Nooteboom and van der Vlugt's (1988) experiments. These three measures of information control for the context size considered at each position, being thus better for an investigation of disambiguatory strength.

We used an unigram model (see §4) to estimate the unigram surprisal, and transformers (Vaswani et al., 2017) for cloze and position-specific surprisals. We also use the LSTM (Long-Short Term Memory, Hochreiter and Schmidhuber, 1997) model from Pimentel et al. (2020) for two other entropy measures which do not control for the amount of conditional information:

- **Forward Surprisal $\mathrm{H}_\theta(W_t \mid W_{<t})$:** the surprisal of a segment given the previous ones.
- **Backward Surprisal $\mathrm{H}_\theta(W_t \mid W_{>t})$:** the surprisal of a segment given the future ones.

We include the beginning- and end-of-word symbols in the forward and backward surprisal analysis, respectively, following previous work (Wedel et al., 2019b; Pimentel et al., 2020; King and Wedel, 2020). However, we ignore them in the unigram, position-specific and cloze surprisal analyses. Position-specific and cloze surprisal are given information about word length, hence these symbols are unambiguously predictable. We analyse the impact of these symbols in §6.

4 Character-Level Language Models

In this paper, we make use of character-level language models to model the probability distributions p_θ and approximate the relevant cross-entropies.

Unigram. This might be the simplest language model still in use in Natural Language Processing. We use its Laplace-smoothed variant

$$p_\theta(w_t) = \frac{\text{count}(w_t) + 1}{\sum_{c' \in \Sigma} \text{count}(c') + |\Sigma|} \tag{12}$$

LSTM. This architecture is the state-of-the-art for character-level language modelling (Melis et al., 2020). Given a sequence of segments $\mathbf{w} \in \Sigma^*$, we use one hot lookup embeddings to transform each of them into a vector $\mathbf{z}_t \in \mathbb{R}^d$. We then feed these vectors into a k-layer LSTM

$$\mathbf{h}_t = \text{LSTM}(\mathbf{z}_{t-1}, \mathbf{h}_{t-1}) \tag{13}$$

where $\mathbf{h} \in \mathbb{R}^d$, $\mathbf{h}_0$ is a vector with all zeros and w_0 is the beginning-of-word symbol. We then linearly transform these vectors before feeding them into a softmax non-linearity to obtain the distribution

$$p_\theta(w_t \mid \mathbf{w}_{<t}) = \text{softmax}(W\mathbf{h}_t + b) \tag{14}$$

in this equation, $W \in \mathbb{R}^{|\Sigma| \times d}$ is a weight matrix and $b \in \mathbb{R}^{|\Sigma|}$ a bias vector.

Backward LSTM. To get the backward surprisals we use models with the same architecture, but reverse all strings before feeding them to the models. As such, we get the similar equations

$$\mathbf{h}_t = \text{LSTM}(\mathbf{z}_{t+1}, \mathbf{h}_{t+1}) \tag{15}$$

$$p_\theta(w_t \mid \mathbf{w}_{>t}) = \text{softmax}(W\mathbf{h}_t + b) \tag{16}$$

Transformer. Transformers allow a segment to be conditioned on both future and previous symbols. Our implementation starts similar to the LSTM one, getting embedding vectors $\mathbf{z}_t$ for each segment in the string $\mathbf{w} \in \Sigma^*$, except that we replace segment w_t with a MASK symbol. We then feed these vectors through k multi-headed self-attention layers, as defined by Vaswani et al. (2017). Finally, the representations from the last layer are linearly transformed and fed into a softmax

$$p_\theta(w_t \mid \mathbf{w}_{\neq t}) = \text{softmax}(W\mathbf{h}_t + b) \tag{17}$$

Position-Specific Transformer. To get position-specific surprisal values, we again use a transformer architecture, but instead of replacing a single segment with a MASK symbol, we replace all of them. This is equivalent to conditioning each segment's distribution on its position and the word length—i.e., estimating $p_\theta(w_t \mid t, |\mathbf{w}|)$.

5 Data

In order to estimate redundancy and informativeness of segments we use three different datasets, each with its own pros and cons. We focus on types instead of tokens—i.e., the datasets consist of lexicons—for a few different reasons. First, it is easier to get reliable samples of types than tokens for a language, specially low-resource ones. Second, it is a well known result that token frequency correlates with both word length (Zipf, 1949) and phonotactic probability (Mahowald et al., 2018; Meylan and Griffiths, 2017), so that would be a strong confound in the results. Third, morphology is more easily modeled at the type level than at token level (Goldwater et al., 2011).[10]

CELEX (Baayen et al., 2015) allows us to experiment exclusively on monomorphemic words, but covers only three closely related languages. It contains both morphological and phonetic annotations for a large number of words in English, Dutch and German. We follow Dautriche et al. (2017) in using only words labeled as monomorphemic in our study, leaving us with 4,810 words in German, 6,206 words in English and 7,045 words in Dutch.

NorthEuraLex (Dellert et al., 2019) spans 107 languages from 21 language families in a unified IPA format. This database is composed of concept aligned word lists for these languages, containing 1016 concepts, each of them translated in most languages. However, most of these languages are from Eurasia, hence the collection lacks the typological diversity we would ideally like.

Wikipedia allows us to investigate a broader and more diverse set of languages, but has no phonetic information (only graphemes) and lexicons

---

[10] For each of the analysed datasets, we use 80% of the word types for training, with the rest being equally split between development and test sets; only test set surprisal and cross-entropies are used in our analysis.

extracted from it may be “contaminated” with foreign words. We fetch the Wikipedia for a set of 41 diverse languages,[11] and tokenise their text using language-specific tokenisers from spaCy (Honnibal and Montani, 2017). When a language-specific tokeniser was not available, we used a multilingual one. We then filtered all non-word tokens—by removing the ones with any symbol not in the language’s scripts—and kept only the 10,000 most frequent types in each language.

6 Experiments and Results

Forward Surprisal. We first replicate the results from van Son and Pols (2003a,b), Wedel et al. (2019b), and Pimentel et al. (2020), which show that surprisal decreases with as the words position advances. On average, forward surprisal, i.e. $\mathrm{H}_\theta(W_t \mid W_{<t})$, could decrease for two reasons: (i) words indeed front-load disambiguatory signals; or (ii) the trivial fact that conditioning reduces entropy. For each word, we first get the forward surprisal for each segment in it. We then group surprisal values in two groups: word initial (when they are in the first half of its word) and final (when in the second half), ignoring mid positions in words with uneven lengths; we average these initial and final surprisals per word, getting a single value of each per word. This way we compare earlier vs. later word positions while ignoring any length effect—words with all lengths will possess segments in both groups. For each analysed language, we then use permutation tests (permuting word initial and final surprisals) to evaluate if one group is statistically larger than the other—using 100,000 permutations. All but one language in three analysed datasets had significantly larger surprisal in word initial positions[12]—the exception being Abkhaz in NorthEuraLex. These results can be seen in Tab. 1 and in Fig. 2 (left).

Backward Surprisal. If the result for forward surprisal is largely due to the amount of conditional information, then reversing the strings should lead to a roughly opposite effect. With this in mind, for each language, we again bin surprisals in word initial vs. final position, but now we evaluate languages using backward surprisal, i.e., $\mathrm{H}_\theta(W_t \mid W_{>t})$.[13] When using backward surprisal, many of the analysed languages have significantly higher surprisals in word final positions (see Tab. 1 and the right graph in Fig. 2). However, 11 languages in the NorthEuraLex dataset still have higher word initial surprisals, suggesting that initial positions in these languages are indeed largely more informative than final ones.[14] There does seem to be a large effect of the amount of conditional information and also some lexical effect of front-loading disambiguatory signals, however it is difficult to determine if there are cross-linguistic tendencies with these measures.

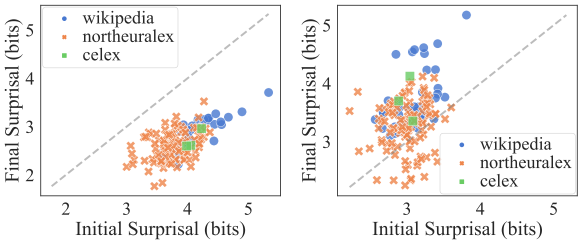

Figure 2: Word initial vs. final surprisals with: (left) Forward; (right) Backward.

Unigram Surprisal. To control for the conditioning aspect of the question: *do words front-load their disambiguatory signals?*, we can look at unigram surprisal $\mathrm{H}_\theta(W_t)$. This value tells us how uncommon the segments that appear in a certain position are, when analysed in isolation from the rest of the word—uncommon segments are more informative and provide stronger signal for disambiguation. In NorthEuraLex, 71 of the languages have significantly higher informativity in word beginnings than in endings—nonetheless, one language (Kildin Saami) has higher surprisals in word endings. In CELEX, Dutch and German have higher surprisals in initial positions, but English does not. And in Wikipedia, all languages but Hebrew and Bengali have higher surprisal in initial positions—with Bengali having higher surprisal in word endings. This experiment suggests that indeed most languages are biased towards providing stronger disambiguatory signals in word beginnings, even when we control for the

---

[11] These languages were: af, ak, ar, bg, bn, chr, de, el, en, es, et, eu, fa, fi, ga, gn, haw, he, hi, hu, id, is, it, kn, lt, mr, no, nv, pl, pt, ru, sn, sw, ta, te, th, tl, tr, tt, ur, zu.

[12] All statistical significance results in this work have been corrected for multiple tests with Benjamini and Hochberg (1995) corrections and use a confidence value of $p < 0.01$.

[13] We note that King and Wedel (2020) also used backward surprisal, although with a different objective in mind. In one of their experiments, they presented aggregate results of a comparison between the forward and backward surprisal.

[14] We also ran the same experiments with a probabilistic trie model like the ones used in van Son and Pols (2003b) and Wedel et al. (2019b), which showed an even stronger result reversal when using backward surprisal.

Table 1: Number of languages in the analysed datasets with significantly larger surprisals in initial | final positions.

amount of conditional information. Nonetheless, this is not a universal characteristic which all languages share and two analysed languages even had a statistically significant inverse effect.

Position-Specific Surprisal. While cloze surprisal makes explicit the non-redundant informativity a segment conveys, unigram surprisal analyses the same segments in isolation. Position-specific surprisal provides a midway analysis, incorporating the position as some previously-specified knowledge, but not conditioning on the other segments in the word. The position-specific surprisal is inspired by Nooteboom and van der Vlugt (1988) experiments, which prime individuals on word length and position. As can be seen in Tab. 1, position-specific surprisal again seems to favour initial positions over final, but only slightly. Interestingly, most languages present no significant difference and some the inverse effect (i.e. higher surprisal in final positions).

Position-specific Unigram models. To better understand the differences between the unigram and position-specific surprisal results, we trained position-specific unigram models—which count each segment's frequency per position—and then calculated their Kullback–Leibler (KL) divergence per position with the traditional unigram

$$\mathrm{KL}(p(w_t \mid t) \mid\mid p(w_t)) \qquad (18)$$
$$= \sum_{w_t \in \Sigma} p(w_t \mid t) \log \frac{p(w_t \mid t)}{p(w_t)}$$

We compare these KL divergences and find that, for all but four languages, the KL is largest in either the first or second segment positions.[15] This suggests that one of the reasons for higher unigram surprisal in initial positions is that the first two segments usually differ from the rest of the positions, potentially serving as markers for word segmentation.

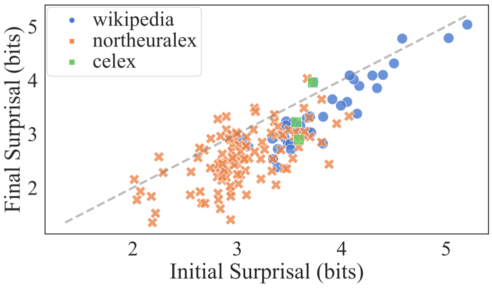

Figure 3: Word initial vs. final cloze surprisals.

Cloze Surprisal. When we condition a segment on all others in the same word, we measure how much uncertainty is left about that individual segment when considering everything else, or, in other words, how much information is passed only by that segment non-redundantly. Word initial surprisal is higher in most analysed languages (see Tab. 1). Nonetheless, two languages in Wikipedia, Thai and Bengali, have significantly higher surprisal in their final segments—while English in CELEX and Hungarian in NorthEuraLex also present this same inverse effect. Front-loading disambiguatory information, thus, is not established to be the linguistic universal it is believed to be, with only roughly half the analysed languages showing this property when we control for morphology (CELEX and NorthEuraLex). Fig. 3 plots the results for all languages analysed.

When we compare these results, we find an interesting pattern. Morphology seems to reduce non-redundant (cloze) information later in the words—while only half of the languages had significant surprisals in CELEX (which consists of monomorphemic words) and NorthEuraLex (base forms), most languages were significant in Wikipedia. Furthermore, English and Hungarian had significantly higher surprisals in word endings in CELEX and NorthEuraLex, while the opposite trend in Wikipedia—this is consistent with the fact that suffix morphemes are present in more types than word roots are, so morphology would make word endings less surprising.

---

[15] We use Laplacian smoothing in the position-specific unigrams and constrain the analysis to positions which appear in at least 75% of the analysed words in that language.

	EOW	Non-EOW
Forward	1.14	3.55
Backward	0.89	3.61
Unigram	2.75	4.90
Position-specific	0.00	4.36
Cloze	0.00	3.23

Table 2: Average surprisal (in bits) of EOW vs. non-EOW segments averaged over all datasets.

Length as a Confounding Effect. We evaluate the impact of length as a confounding effect on previous methodologies. As mentioned in §2, by directly analysing surprisal–position pairs (as opposed to binning word initial vs. final positions), previous work confounds position and word length—i.e., only long words will have later word positions. In this study, we analyse forward surprisal–length pairs; instead of pairing a segment's surprisal with its position, we pair it with its word length. We then get the slope formed by a linear regression between these pairs of values and test for its significance per language by using a permutation test, in which we shuffle surprisal–length values. On the three datasets, all languages have statistically significant negative slopes, meaning long words have smaller surprisals on average than shorter ones.[16] A caveat, though, is that now we are confounding position into our length analysis. Constraining our analysis only to the first two segments in each word, we still find the same effect—though now one language (Hebrew) in Wikipedia and seven in NorthEuraLex are not significant. We can thus conclude that longer words have smaller surprisal values than shorter ones, even when controlling for the same word positions. This implies that directly using surprisal–position pairs for such an analysis is not ideal.

The Effect of End of Word in Surprisal. The end-of-word (EOW) symbol is a special "segment" which symbolises the end of a string. It is necessary when modelling the probability distribution over strings $\mathbf{w} \in \Sigma^*$, to guarantee that the overall distribution sums to 1. Nonetheless, it is expected to behave in a different way from other segments. If a speaker wants to reduce their production effort, although changing from one phone to another may help, the most efficient way is usually just ending the string earlier. Furthermore, since all realisable strings must eventually end, it will be present in all words, making it a very frequent symbol—in fact, Tab. 2 shows its average surprisal is much lower than that of other segments. As such, it is only natural it should be analysed on its own, separately from other segments. Through the same logic, other segments should also be analysed separately from EOW—or else, lower word final surprisals may be due to this symbol alone. As such, we analyse the surprisal of LSTM "language models" without the EOW symbol here.[17]

	EOW			No EOW		
	Initial	Final	Diff (%)	Initial	Final	Diff (%)
Forward	3.85	2.65	31.1 %	3.83	3.00	21.6 %
Backward	3.02	3.40	-11.3 %	3.63	3.39	6.7 %
Unigram	-	-	-	4.85	4.40	9.3 %
Position	-	-	-	4.36	4.17	4.3 %
Cloze	-	-	-	3.26	2.81	13.9 %

Table 3: Average surprisal per segment in word initial and final positions with and without EOW symbols.

Unsurprisingly, Tab. 3 shows the difference between word initial and final positions is considerably reduced when we remove the EOW symbol from the forward surprisal analysis. Surprisingly, we see that when we remove the beginning-of-word from the backward surprisal analysis, instead of a larger word final surprisal, we get a larger word initial value—even though we are still conditioning the models right-to-left. This result further supports the hypothesis that the disambiguatory signals are on average stronger in word initial positions.

7 Conclusions

In this work, we analysed the distribution of disambiguatory information in word positions. We present an in-depth critique of previous work, showing several confounding effects in their analysis. We then proposed the use of three new methods which corrected for these biases—namely unigram, position-specific and cloze surprisal. These models controlled for the amount of conditional information across word positions, allowing for an unbiased analysis of the lexicon. Using these models we show that the lexicons of most languages indeed front-load their disambiguatory signals. This effect, though, is not universal and the difference in disambiguatory information between word initial and final positions is much lower than previously estimated—ranging from 4% to 14%, depending on the used metric, instead of 31%.

---

[16] King and Wedel (2020) indeed present a similar correlation in their Figure 2.

[17] To be more precise, we actually ignore the beginning-of-word symbol when estimating backward surprisal.

Abstract

Images are core components of multi-modal learning in natural language processing (NLP), and results have varied substantially as to whether images improve NLP tasks or not. One confounding effect has been that previous NLP research has generally focused on sophisticated tasks (in varying settings), generally applied to English only. We focus on text classification, in the context of assigning named entity classes to a given Wikipedia page, where images generally complement the text and the Wikipedia page can be in one of a number of different languages. Our experiments across a range of languages show that images complement NLP models (including BERT) trained without external pre-training, but when combined with BERT models pre-trained on large-scale external data, images contribute nothing.

1 Introduction

Combining data from multiple modalities (e.g., text, images, categorical metadata, or user interaction features) has become commonplace in artificial intelligence. In NLP, examples include multi-modal machine translation (MMT) (Elliott et al., 2016; Elliott, 2018), visual question answering (VQA) (Goyal et al., 2017; Johnson et al., 2017), visual commonsense reasoning (VCR) (Zellers et al., 2019; Geva et al., 2019), and multi-modal pre-training (Lu et al., 2019; Chen et al., 2019).

While tasks such as VQA and VCR are multi-modal in nature, there has been research on traditionally text-based tasks such as text classification (Shen et al., 2020; Huang, 2018) and word embedding learning (Bruni et al., 2014) which has demonstrated that the addition of images boosts performance. At the same time, however, there is evidence of images providing no additional information, e.g. Caglayan et al. (2019) show that MMT models learn to ignore visual content when trained on a parallel corpus of image captions (Elliott et al., 2016). These mixed findings raise the question of *when* visual context is actually useful in NLP.

In this work, we take a first step towards answering this question, in focusing on the task of text classification, which has traditionally been addressed using textual data only. We identify two gaps in the literature on multi-modal NLP: (1) no results for pre-trained language models (LMs); and (2) no results for languages other than English. The first is important in terms of updating the research relative to state-of-the-art approaches, while the second relates to the question of how "language-independent" systems actually are (Bender, 2011). We fill these gaps via a text classification task over Wikipedia articles (Sekine et al., 2019). Our main findings are: (1) while images do help in a traditional supervised learning setting, *their utility disappears almost completely* when combined with a pre-trained LM; and (2) this phenomenon *is not restricted to English*, and generalises across a variety of languages from different families.

2 Task Description

This research is couched in the context of a shared-task dataset released by the SHINRA project (Sekine et al., 2019), aimed at classifying Wikipedia pages into fine-grained entity classes.[1] We chose this benchmark as many Wikipedia documents contain images, and data is provided for a total of 29 typologically-diverse languages.[2] The task is not trivial as it involves classifying Wikipedia documents into a set of 219 classes, with the possibility of multiple labels for a given document.[3]

Table 1: Statistics of annotated data for each language.

The number of annotated pages for each language in the SHINRA dataset is shown in Table 1 (sorted according to the number of pages). In addition to these annotated datasets — which form the basis of the experiments in this paper — there is a large amount of evaluation data for each language. In an evaluation campaign over these evaluation datasets, we achieved first place across 4 languages: English, Italian, Spanish and Catalan (Yoshikawa et al., 2020).

The SHINRA dataset contains only textual information from the original documents. In order to add images, we extract the image links from the English Wikipedia dump of June 2020[4] using the `zim` library.[5] The extracted images are then linked with image links in the source documents in the SHINRA dataset,[6] resulting in about 88% pages being augmented with images (noting that images are generally shared across Wikipedia pages for different languages other than English).

Out of the 30 languages in the original SHINRA dataset, we experiment primarily with Arabic ("ar"), English ("en"), Finnish ("fi"), Hindi ("hi"), and Mandarin Chinese ("zh"), selected to span five different language families and where the dataset size is relatively large. From the SHINRA data, we randomly sample 30k documents for each language, and construct a 80%/10%/10% fixed split for training/development/test in each language. We use a maximum of four images for each document.[7]

3 Baseline Experiments

Our first set of experiments is aimed at evaluating the empirical utility of images in the absence of pre-trained models. This is in line with previous work over similar text classification tasks (Shen et al., 2020; Huang, 2018).

Model and Features As our basic learner, we use a linear-kernel support vector machine (Cortes and Vapnik, 1995, SVM). For the textual inputs, we experiment with three representations: (1) a binary bag-of-words ("`BOW`"); (2) sent2vec ("`S2V`": Pagliardini et al. (2018)); and (3) `BERT` (Devlin et al., 2019). In this set of experiments, we train both `S2V` and `BERT` from scratch on the SHINRA training data only. We simply use the suggested configuration provided by developers, without any task-specific hyperparameter tuning. For `BERT`, we use the `[CLS]` token as the document representation. For each document, an image representation for each of the (up to) four images is generated. Specifically, following standard practice in the computer vision community, we firstly use the SIFT algorithm (Lowe, 1999) to extract hundreds of features, then use the K-means algorithm to cluster these features and generate frequency histograms, which are so-called visual bag-of-words (VBoW), and finally use an SVM to classify these histogram features. We also experiment with Faster R-CNN (Ren et al., 2015), pre-trained on Visual Genome (Krishna et al., 2017), following the settings of Anderson et al. (2018). We ensure the dimensionality of input features for the SVM and Faster R-CNN are the same (both are $1,024$), to remove this possible representational confound. Note that this is the externally pre-trained image model across all experiments, and that none of the text models in this first set of experiments involve pre-training on external resources (something we return to in Section 4).

Results and Analysis We report F_1 scores over the test set in Table 2. The main finding is that images improve performance in all settings, for all languages and both image representations. `S2V` and `BERT` both perform worse than the simple bag of words, because of the limited training data in each case. We would, of course, expect the models

`S2V`	R-CNN	65.4	69.0	65.0	65.2	72.3
`BERT`	—	59.1	65.3	51.9	60.5	68.6
`BERT`	SIFT+V	62.9	68.7	54.2	63.1	70.9
`BERT`	R-CNN	61.4	67.3	52.7	62.9	70.0

Table 2: F_1 score of the SVM models without external pre-training of the textual models, across the five languages. "SIFT+V" refers to the combination of SIFT and Visual Bag-of-Words features. "R-CNN" corresponds to features extracted from Faster R-CNN.

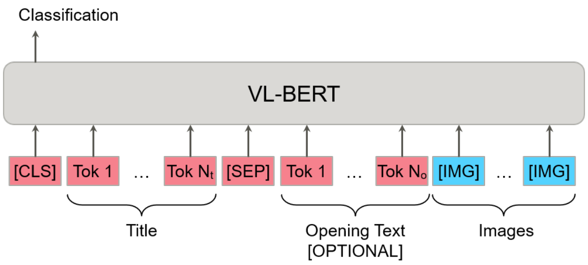

Figure 1: `VL-BERT` architecture applied to the SHINRA2020-ML task. The "opening text" segment are additional textual data obtained from the documents that are optional in our experimental setting.

to perform better with more extensive pre-training, as we return to explore in Section 4, but the focus here is on training of the textual models within the bounds of the training dataset.

Strikingly, the SIFT + Visual Bag-of-Words representation results in better performance than the pre-trained Faster R-CNN. A potential explanation is that Faster R-CNN is trained in a supervised way using Visual Genome (unlike the self-supervised setting of pre-trained BERT, for instance), over a set of labels that is not particularly well aligned with SHINRA (SHINRA includes many abstract classes such as RELIGION, NATIONALITY, and OFFENCE, whereas Visual Genome is focused on physical objects and attributes, and relations between objects; even among physical objects, SHINRA distinguishes between MEDICAL INSTITUTION, PUBLIC INSTITUTION, and RESEARCH INSTITUTE, most of which are represented simply as BUILDING in Visual Genome).

4 Adding a Pre-trained Textual Encoder

We next turn to a setting where we employ pre-trained textual models. This not only better reflects the state-of-the-art in text classification, but also allows us to investigate the effect of images under such conditions.

Model As the main backbone, we employ `VL-BERT` (Su et al., 2020), which uses a transformer to combine textual inputs and image embeddings within a BERT-style transformer, and has been shown to perform well on multimodal tasks. The visual embeddings are obtained from the combination of pre-trained Faster R-CNN and ResNet-101 (He et al., 2016), as illustrated in Figure 1. For the text modality, the input consists of two parts: the document title, and the opening text of the Wikipedia page in the form of the first 300 tokens. The token embeddings are obtained from a pre-trained BERT model, which is fine-tuned during training.[8] The full model is plugged into a one-layer feed-forward neural network (FFNN) with a 1,024d hidden layer, and training is performed by minimizing the cross-entropy over the SHINRA category labels. The model predict one label for each page. For the case of multi-label inputs, we choose one randomly as the "correct" label.

Results and Analysis Table 3 shows the performance of `VL-BERT` with different combinations of textual (document title = "T" and optionally the document body = "B") and image inputs, based on pre-trained BERT ("$\texttt{BERT}_{\text{pre}}$").

The first thing to notice is that the image-only model is well above the majority baseline, but well below the best multimodal model without an externally pre-trained text encoder from Table 2. This shows that images provide useful information for document classification, consistent with the earlier finding that images enhance the various text-only models. However, when combined with the externally pre-trained $\texttt{BERT}_{\text{pre}}$ (over either the title only, or the title + document body), the utility of images is marginal at best. That is, the large-scale pre-training of $\texttt{BERT}_{\text{pre}}$ both boosts overall performance, but much more surprisingly, removes any advantage from including images.

---

[8] We use `bert-large-uncased` for English, and `bert-base-multilingual-uncased` for the other languages, as obtained from `https://huggingface.co/transformers/pretrained_models.html`

Best non pre-trained		68.2	74.1	73.2	69.0	76.0
Majority class		21.5	22.2	28.1	19.1	21.7

Table 3: F_1 scores for pre-trained `VL-BERT`. "T" = document title, and "T+B" = document title + body. We reproduce the best non-trained For comparison, we restate the result for the best non pre-trained model from Table 2, along with the majority class baseline.

Influence of the size of training data One hypothesis is that images are not useful due to the size of the training data (24k instances), and in lower-resource scenarios will improve performance. To test this, we perform additional experiments varying the training data size, ranging from 4k to 24k training instances, in steps of 4k.

Figure 2 plots the F_1 performance as the training set size increases. While we observe substantial improvements for the image-only approach (the bottom curve), the differences in the models with textual data are modest, and even in small-data settings, there is no real advantage in including images. We also separated the test data in terms of the number of images, and found no differences. See the Supplementary Material for details.

Results on the full SHINRA dataset In the previous experiments, we fixed the dataset size for all languages to control for training data volume. However, the SHINRA dataset includes many more documents for many of the languages. As a final experiment, we apply the `VL-BERT` models to the full dataset available for each language. The development and test data are also different in this configuration, so the results are not directly comparable with Tables 2 and 3.

In Table 4, we present results for $\texttt{BERT}_{\text{pre}}$, and mostly corroborate our earlier findings: while we do see improvements when including images in the case of the titles only, their utility decreases when we add the body of text for each document.

What caused the difference? Comparing the results from Sections 3 and 4, we see two main differences: the presence of external pre-training (`BERT` vs. $\texttt{BERT}_{\text{pre}}$), and the model architecture. To determine whether the model architecture is a cause of the performance difference, we train `VL-BERT` *from scratch*, using only text and images from the 24k training set used in Section 3.

T+B	✓	58.6	63.2	52.4	60.1	68.7

Table 5: Comparison of F_1 scores for `VL-BERT` without external pre-training of BERT.

The results in Table 5 shows that even for `VL-BERT`, a neural-based model that is much more complex than the linear-kernel SVM, when $\texttt{BERT}_{\text{pre}}$ is not used, images provide a gain in performance. Hence, having an externally pre-trained text encoder is the predominant determinant of whether visual content has utility in NLP tasks.

5 Discussion and Conclusion

We investigated the utility of images as a supplementary input for a text classification task, and found that although images have empirical utility in traditional supervised learning, when externally pre-trained language models are utilised, any advantage from the visual modality disappears. The results were remarkably consistent across different languages and different volumes of training data.

It is important to distinguish between "inherently multi-modal tasks" (e.g. VQA) and "potentially multi-modal tasks" (e.g. text classification) in drawing any broader conclusions about the (in)effectiveness of images. Here, a "potentially multi-modal task" in NLP means that the primary modality is text and the task is defined based on that single data modality, but there is potentially the option to include extra modalities such as images.

There remain a lot of open questions in more fully determining the (in)effectiveness of images for NLP tasks, even for text classification, such as:

- Due to the seeming redundancy between textual and visual representations of Wikipedia pages, is there any utility in multi-modal inputs for simple NLP tasks such as text clas-

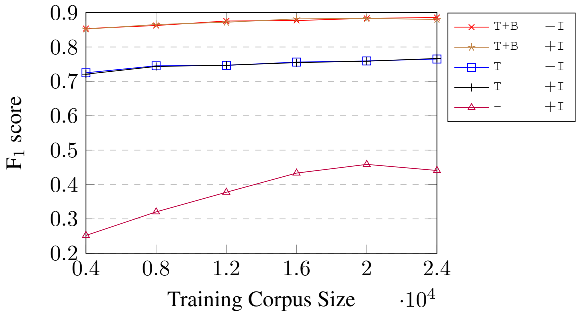
(d) Hindi



(e) Chinese

Figure 2: Model performance with different sizes of training corpus, with and without images (±I) and with and without text (in the form of the title ["T"] and optionally document body ["B"]).

sification in the era of large-scale pre-trained language models such as BERT and GPT-3 (Brown et al., 2020)?

- What performances do humans achieve in the single-modal setting and multi-modal setting? Can we get some insights by comparing the (potentially) different performances between humans and computers?
- Apart from images, what other modalities and forms of input (e.g. audio) could be effective in building better NLP models?
- Although pre-trained image models (e.g. Faster R-CNN) contribute a lot for vision tasks (e.g. object detection) and multi-modal tasks (e.g. VQA), for *"pure"* NLP tasks (e.g. text classification), they appear to work no better than traditional image representation feature extractors (e.g. SIFT). Why?
- In our experiments, we use at most 4 images for each page. Could instance selection enhance image utility?
- We focused on the text classification task, in classifying Wikipedia pages into different entities. Are our observations NLP task-independent?

If you've got it, flaunt it:
Making the most of fine-grained sentiment annotations

Jeremy Barnes, Lilja Øvrelid, Erik Velldal
University of Oslo
Department of Informatics
`{jeremycb,liljao,erikve}@ifi.uio.no`

Abstract

Fine-grained sentiment analysis attempts to extract sentiment holders, targets and polar expressions and resolve the relationship between them, but progress has been hampered by the difficulty of annotation. *Targeted* sentiment analysis, on the other hand, is a more narrow task, focusing on extracting sentiment targets and classifying their polarity.

In this paper, we explore whether incorporating holder and expression information can improve target extraction and classification and perform experiments on eight English datasets. We conclude that jointly predicting target and polarity BIO labels improves target extraction, and that augmenting the input text with gold expressions generally improves targeted polarity classification. This highlights the potential importance of annotating expressions for fine-grained sentiment datasets. At the same time, our results show that performance of current models for predicting polar expressions is poor, hampering the benefit of this information in practice.

1 Introduction

Sentiment analysis comes in many flavors, arguably the most complete of which is what is often called fine-grained sentiment analysis (Wiebe et al., 2005; Liu, 2015). This approach models the sentiment task as minimally extracting all opinion holders, targets, and expressions in a text and resolving the relationships between them. This complex task is further complicated by interactions between these elements, strong domain effects, and the subjective nature of sentiment. Take the annotated sentence in Figure 1 as an example. Knowing that the target "UMUC" is modified by the expression "5 stars" and not "don't believe" is important to correctly classifying the polarity. Additionally, the fact that this is a belief held by "some others" as apposed to the author of the sentence can help us determine the overall polarity expressed in the sentence.

Compared to document- or sentence-level sentiment analysis, where distant labelling schemes can be used to obtain annotated data, fine-grained annotation of sentiment does not occur naturally, which means that current machine learning models are often hampered by the small size of datasets. Furthermore, fine-grained annotation is demanding, leads to relatively small datasets, and has low inter-annotator agreement (Wiebe et al., 2005; Wang et al., 2017). This begs the question: **is it worth it to annotate full fine-grained sentiment**?

Targeted sentiment (Mitchell et al., 2013; Zhang et al., 2015) is a reduction of the fine-grained sentiment task which concentrates on extracting sentiment targets and classifying their polarity, effectively ignoring sentiment holders and expressions. The benefit of this setup is that it is faster to annotate and simpler to model. But **would targeted sentiment models benefit from knowing the sentiment holders and expressions**?

In this work, we attempt to determine whether holder and expression information is useful for extracting and then classifying sentiment targets. Specifically, we ask the following research questions:

> **RQ1:** Given the time and difficulty required to annotate opinion holders, expressions, and polarity, is this information useful to **extract sentiment targets**?
>
> (a) Does augmenting the input text with holders and expressions improve target extraction?
>
> (b) Do target extraction models benefit from predicting holders and expressions?

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 49–62

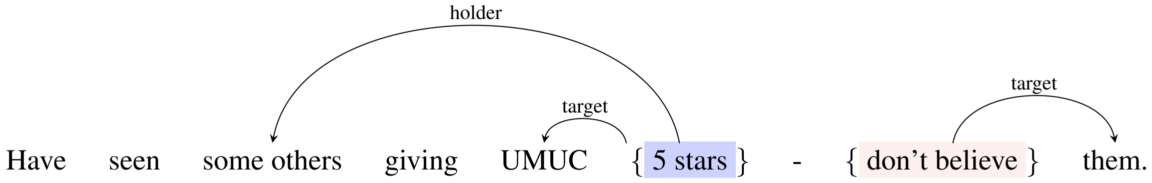

Figure 1: An opinion annotation from the Darmstadt Review Corpus.

(c) Do target extraction models benefit from predicting the polarity of targets and/or expressions?

RQ2: Can holder and expression information improve **polarity classification** on extracted targets?

(a) Does augmenting the input text with holders and expressions improve polarity classification?

(b) Do potential benefits of augmenting the input depend on how we model the target, *i.e.,* using the [CLS] embeddings, mean pooling the target embeddings, etc.?

(c) Can sentiment lexicons provide enough information on expressions to give improvements?

We conduct a series of experiments on eight English sentiment datasets (three with full fine-grained sentiment and five targeted) with state-of-the-art models based on fine-tuned BERT models. We show that (1) it is possible to improve target extraction by also trying to predict the polarity, and that (2) classification models benefit from having access to information about sentiment expressions. We also (3) release the code[1] to reproduce the experiments, as well as the scripts to download, preprocess, and collect the datasets into a compatible JSON format, with the hope that this allows future research on the same data.

2 Related work

Fine-grained approaches to sentiment analysis attempt to discover opinions from text, where each opinion is a tuple of *(opinion holder, opinion target, opinion expression, polarity, intensity)*. Annotation of datasets for this granularity requires creating in-depth annotation guidelines, training annotators, and generally leads to lower inter-annotator scores than other sentiment tasks, *e.g.,* document- or sentence-level classification, as deciding on the spans for multiple elements and their relationships is undeniably harder than choosing a single label for a full text. **Targeted sentiment**, on the other hand, generally concentrates only on target extraction and polarity classification. This has the benefit of allowing non-experts and crowd-sourcing to perform annotation, making it easier to collect larger datasets for machine learning. This simplified annotation can be crowd-sourced, leading to larger datasets for machine learning.

2.1 Datasets

The Multi-purpose Question Answering dataset (*MPQA*) (Wiebe et al., 2005) is the first dataset that annotated opinion holders, targets, expressions and their relationships. The news wire data leads to complex opinions and a generally difficult task for sentiment models. Normally, the full opinion extraction task is modelled as extraction of the individual elements (holders, targets, and expressions) and the subsequent resolution of the relationship between them.

The *Darmstadt Review Corpora* (Toprak et al., 2010) contain annotated opinions for consumer reviews of universities and services. The authors annotate holders, targets, expressions, polarity, modifiers, and intensity. They achieve between 0.5 and 0.8 agreement using the *agr* method (Wiebe et al., 2005), with higher disagreement on what they call "polar targets" – targets that have a polarity but no annotated sentiment expression – holders, and expressions.

The *Open* Domain Targeted dataset (Mitchell et al., 2013) makes use of crowd sourcing to annotate NEs from scraped tweets in English and Spanish (Etter et al., 2013) with their polarities. The authors use majority voting to assign the final labels for the NEs, discarding tweets without sentiment consensus on all NEs.

---

[1] `https://github.com/ltgoslo/finegrained_modelling`

The 2014 *SemEval* shared task (Pontiki et al., 2014) on aspect-based sentiment analysis include labeled data from restaurant and laptop reviews for two subtasks: 1) target extraction, which they call "aspect term extraction" and 2) classification of polarity with respect to targets ("aspect term polarity").

As most targeted datasets only contain a single target, or multiple targets with the same polarity, sentence-level classifiers are strong baselines. In order to mitigate this, Jiang et al. (2019) create a *Challenge* dataset which has both multiple targets and multiple polarities in each sentence. Similarly, Wang et al. (2017) also point out that most targeted sentiment methods perform poorly with multiple targets and propose *TDParse*, a corpus of UK election tweets with multiple targets per tweet.

2.2 Modelling

Katiyar and Cardie (2016) explore jointly extracting holders, targets, and expressions with LSTMs. They find that adding sentence-level and relation-level dependencies (IS-FROM or IS-ABOUT) improve extraction, but find that the LSTM models lag behind CRFs with rich features.

Regarding modelling the interaction between elements, there are several previous attempts to jointly learn to extract and classify targets, using factor graphs (Klinger and Cimiano, 2013), multi-task learning (He et al., 2019) or sequence tagging with collapsed tagsets representing both tasks (Li et al., 2019). In general, the benefits are small and have suggested that there is only a weak relationship between target extraction and polarity classification (Hu et al., 2019).

3 Data

One of the difficulties of working with fine-grained sentiment analysis is that there are only a few datasets (even in English) and they come in incompatible, competing data formats, *e.g.,* BRAT or various flavors of XML. With the goal of creating a simple unified format to work on fine-grained sentiment tasks, we take the eight datasets mentioned in Section 2 – *MPQA* (Wiebe et al., 2005), *Darmstadt Services and Universities* (Toprak et al., 2010), *TDParse* (Wang et al., 2017), *SemEval Restaurant and Laptop* (Pontiki et al., 2014), *Open* Domain Targeted Sentiment (Mitchell et al., 2013), and the *Challenge* dataset from Jiang et al. (2019) – and convert them to a standard *JSON* format. The datasets are sentence and word tokenized using NLTK (Loper and Bird, 2002), except for MPQA, DS. Service and DS. Uni, which already contain sentence and token spans. All polarity annotations are mapped to positive, negative, neutral, and conflict[2]. As such, each sentence contains a sentence id, the tokenized text, and a possibly empty set of opinions which contain a holder, target, expression, polarity, and intensity. We allow for empty holders and expressions in order generalize to the targeted corpora. Finally, we use 10 percent of the training data as development and another 10 percent for test for the corpora that do not contain a suggested train/dev/test split. For training and testing models, however, we convert the datasets to CoNLL format.

Table 1 presents an overview of the different datasets and highlights important differences between them. The fully fine-grained sentiment datasets (MPQA, DS. Services, and DS. Uni) tend to be larger but have fewer targets annotated, due to a larger number of sentences with no targets. However, the MPQA dataset contains much longer targets than the other datasets – an average of 6, but a maximum of 56 tokens. It also contains more opinion holders and expressions and these also tend to be longer, all of which marks MPQA as an outlier among the datasets. The distribution of polarity is also highly dependent on the dataset, with DS. Services being the most skewed and SemEval Laptop the least skewed. Finally, the challenge dataset is by far the largest with over 11,000 training targets. Additionally, Table 6 in Appendix A shows the percentage of unique targets per dataset, as well as the percentage of targets shared between the training set and the dev and test sets. Again MPQA has the largest number of unique targets and the least overlap.[3]

4 Experimental Setup

We split the task of targeted sentiment analysis into the **extraction of sentiment targets** and subsequent **polarity classification** of extracted targets, given their context. Figure 2 shows the two tasks and the eight models used in the experiments. As a base model, we take the tar-

---

[2] We discard conflict during evaluation because there are not enough examples to properly learn this class in most datasets

[3] We do not, however, consider partial overlap which may exaggerate the true uniqueness of targets.

Table 1: Stastistics of the datasets, including number of sentences, as well as average, and max lengths (in tokens) for holder, target, and expression annotations. Additionally, we include the distribution of polarity – restricted to positive, neutral, and negative – in each dataset.

get extraction and classification models from Xu et al. (2019), which achieve state-of-the-art performance on the SemEval task. The approach first fine-tunes BERT (Devlin et al., 2019) on domain-specific unlabeled data as a domain-adaptation step. We use the datasets themselves to perform this step, except for the SemEval datasets. For these, we follow Rietzler et al. (2020) and instead use larger amounts of unlabeled data – 1,710,553 and 2,000,000 sentences for SemEval Laptop and Restaurant respectively – taken from Amazon Laptop reviews (He and McAuley, 2016) and the Yelp Dataset Challenge.[4] We further deviate from Xu et al. (2019) by not pretraining the models on the SQUAD question answering dataset and in-domain sentiment questions which they create, as this data is not publicly available. Finally, a linear prediction is added after the BERT model and the full model is updated on the sentiment task.

For **target extraction**, we use the contextualized BERT embeddings as input to a softmax layer and predict the sequence of tags. We compare three prediction strategies:

1. **TARG.:** The model predicts the labels $y \in \{B,I,O\}$ for the targets only.
2. **PRED.:** We additionally predict the labels for holders and expressions and predict $y \in \{B\text{-}holder, I\text{-}holder, B\text{-}target, I\text{-}target, B\text{-}expression, I\text{-}expression, O\}$.
3. **+POL.:** Finally, we add the polarity (*positive*, *negative*, *neutral*) to the annotation specific BIO-tag, which leads to an inventory of 19 labels for the full fine-grained setup and 7 for the targeted setup.

For **polarity classification**, we take as a baseline the classification architecture from Xu et al. (2019), which makes use of the two-sentence training procedure for BERT, by prepending the target before the sentence separation token, and then adding the full sentence after. We compare five strategies for producing the input to the softmax layer for predicting the sentiment of the target:

1. **[CLS]:** this model uses the [CLS] embedding from the final BERT layer.

---

[4] `https://www.yelp.com/dataset/challenge`

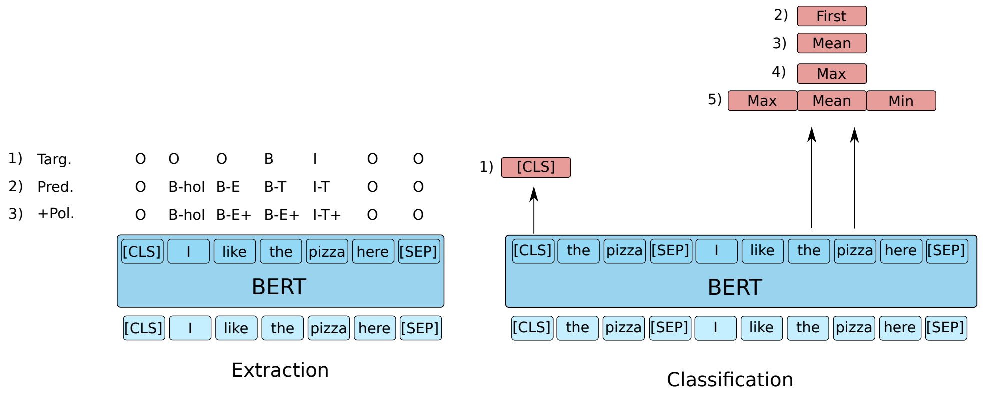

Figure 2: Our BERT-based *target extraction* and *classification models*, with the three strategies for extraction ((1) predict only targets, (2) predict holders, targets and expressions, and (3) predict the polarity of the targets and expressions as well) and five strategies for sentiment classification (passing to the softmax layer the contextualized embedding from (1) the [CLS] embedding, (2) the first token in the target (3) averaging all embeddings in the target phrase, (4) taking the max of the target embeddings, (5) concatenating the max, mean, and min).

2. **FIRST:** uses the contextualized BERT embedding from the first token of the target in context.
3. **MEAN:** instead takes the average of the BERT embeddings for the tokens in the target.
4. **MAX:** uses the max of the contextualized BERT embeddings for the tokens in the target.
5. **MAXMM:** takes the max, min, and mean pooled representations and passes the concatenation to the softmax layer, which has shown to perform well for sentiment tasks (Tang et al., 2014). However, this triples the size of the input representation to the softmax layer.

The TARG. and [CLS] models correspond to the models used in Xu et al. (2019) and serve as baselines. The extraction and classification models are fine-tuned for 50 epochs using Adam with an initial learning rate of 3e−5, with a linear warmup of 0.1 and all other hyperparameters are left at default BERT settings (further details in Appendix B). The best model on the development set is used for testing. Combined with the four input manipulations (Table 2), this leads to eleven extraction experiments – TARG. and PRED. on the original data which only has annotated targets are the same and for simplicity we only show the results from TARG.– and twenty classification experiments per dataset. In order to control for the effect of random initialization, we run each experiment 5 times on different random seeds and report the mean and standard deviation.

4.1 Training with gold annotations

Given that we are interested in knowing whether it is beneficial to include information about additional annotations (holder, expressions, polarity), we perform experiments where we systematically include these. We do so by adding special tags, *e.g.*,, [<E], into the input text surrounding the annotated spans, as shown in Table 2. The models then have access to this information both during training and at test time, albeit in an indirect way. For the first set of experiments, we perform controlled experiments under ideal conditions, *i.e.*, having gold annotations during testing. This allows us to isolate the effects of incorporating the additional annotations, without worrying about noisy predictions

4.2 Training with predicted expressions

It is equally important to know whether the models are able to use noisy predicted annotations. In order to test this, we train *expression prediction models* on the three full fine-grained sentiment corpora. We use the same BERT-based model and hyperparameters from the target extraction models above and train five models with different random seeds. Preliminary results suggested that these models had high precision, but low recall. Therefore, we take a simple ensemble of the five trained models, where for each token, we keep labels predicted by at least one of the expression models in order to increase recall.

We perform an additional set of experiments where we use sentiment lexicons and assume any word in these lexicons is a sentiment expres-

original	Money Magazine rated E-Trade highly .
+ holders	[<H] Money Magazine [H>] rated E-Trade highly
+ expressions	Money Magazine [<E] rated [E>] E-Trade [<E] highly [E>]
+ full	[<H] Money Magazine [H>] [<E] rated [E>] E-Trade [<E] highly [E>]

Table 2: We inform our models regarding annotations other than targets by inserting special tags into the input text before and after annotated holders and expressions .

sion. We use the **Hu and Liu** lexicon (Hu and Liu, 2004), the **SoCal** and **SoCal-Google** lexicons (Taboada et al., 2006) and the **NRC** emotion lexicon (Mohammad and Turney, 2013), which also contains sentiment annotations. The lexicons contain 6,789, 5,824, 2,142, and 5,474 entries, respectively. The MPQA and Darmstadt experiments show the effect of predicted vs. gold expressions, as well as domain transfer. The experiments on the targeted datasets, on the other hand, will show us whether it is possible to improve the targeted models with predicted expressions.

5 Results

In this section we describe the main results from the extraction and two classification experiments described in Section 4.

5.1 Target extraction

Table 3 shows the results for the extraction experiment, where token-level F_1 is measured only on targets. The models perform poorer than the state-of-the-art, as we did not finetune on the SQUAD question answering dataset and in-domain sentiment questions or perform extensive hyperparameter tuning. The average F_1 score depends highly on the dataset – MPQA is the most difficult dataset with 13.1 F_1 on the original data, while the Darmstadt Universities corpus is the easiest for target extraction with 84.6. Augmenting the input text with further annotations, but predicting only sentiment targets (Targ. in Table 3) hurts the model performance in all cases. Specifically, adding holder tags leads to an average drop of 1.3 percentage points (pp), expressions 1.2 and full 1.5. Attempting to additionally predict these annotations (Pred. in Table 3) leads to mixed results – the model leads to improvements on MPQA + exp. and Darmstadt Services + holders, no notable difference on MPQA + full and Darmstadt Universities + exp., and a loss on the rest.

Adding the polarity to the target BIO tags (original +Pol. in Table 3) leads to the most consistent improvements across experiments – an average of 0.5 pp – with the largest improvement of 1.5 pp on the TDParse dataset. This suggests a weak-to-moderate relationship between polarity and extraction, which contradicts previous conclusions (Hu et al., 2019). Finally, further adding the holder and expression tags (+Pol. in Table 3) tends to decrease performance.

5.2 Polarity classification with gold annotations

Table 4 shows the macro F_1 scores for the polarity classification task on the gold targets. The model performs better than the best reported results on Challenge (Jiang et al., 2019), and similar to previous results on the SemEval corpora. Regarding the choice of target representation, First is the strongest overall, with an average of 64.7 F_1 across the original eight datasets, followed by Max (64.6), Mean (64.4), MaxMM (64.2), and finally [Cls] (64.1). It is, however, unclear exactly which representation is the best, as it differs for each dataset. But we can conclude that [Cls] is in general the weakest model, while either First or Max provide good starting points.

Adding holder annotations to the input text delivers only small improvements on four of the fifteen experiments, and has losses on seven. The +exp. model, however, leads to significant improvements on 10 experiments. The outlier seems to be Darmstadt Services, which contains a large number of "polar targets" in the data, which do not have polar expressions. This may explain why including this information has less effect on this dataset. Finally, +full performs between the original input and +exp.

Table 3: Average token-level F1 scores for the target extraction task across five runs, (standard deviation in parenthesis). **Bold** numbers indicate the best model per dataset, while blue and pink highlighting indicates an improvement or loss in performance compared to the original data, respectively.

5.3 Polarity classification with predicted annotations

The expression models achieve modest F_1 scores when trained and tested on the same dataset – between 15.0 and 47.9 –, and poor scores when transferred to a different dataset – between 0.9 and 14.9 (further details shown in Table 7 in Appendix A). The lexicons often provide better cross-dataset F_1 than the expression models trained on another dataset, as they have relatively good precision on general sentiment terms.

Figure 3 shows a heatmap of improvements (blue) and losses (red) on the eight datasets (x-axis) when augmenting the input text with expression tags from the expression models and lexicons (y-axis). We compare the expression augmented results to the original results for each pooling technique and take the average of these improvements and losses. For a full table of all results, see Table 5 in Appendix A.

Augmenting the input text with predicted sentiment expressions leads to losses in 41 out of averaged 56 experiments shown in Figure 3 (or in 173 out of 280 experiments in Table 5). Curiously, the experiments that use an expression model trained on the same dataset as the classification task, *e.g.,* MPQA predicted expressions on the MPQA classification task, have the largest losses – the largest of which is MPQA (-2.78 on average). This seems to indicate that the mismatch between the train prediction, which are near perfect, and the rather poor test predictions is more problematic than cross-dataset predictions, which are similar on train and test.

The best expression prediction model is the one trained on MPQA, improving the performance on Darmstadt Universties, Open, and SemEval Restaurants. This is likely due to the fact that MPQA has the largest number of annotated expressions, and that the domain is more general, leading to expression predictions that generalize better. The expression models trained on Darmstadt Services leads to small benefits on two corpora and the expression model trained on Darmstadt Universities only leads to losses

The datasets that receive the most benefit from expression annotations are Darmstadt Universities (6/7 experiments) and the TDParse dataset (5/7). In both cases, the lexicon-based expression models provide more consistent benefits than the trained expression prediction models. The fact that the dataset that benefits most is the TDParse dataset suggests that expression information is most useful when there are multiple targets with multiple polarities.

There is no significant correlation between the performance of the expression prediction model and the performance on the classification task on the three fine-grained datasets. In fact, there is a small but insignificant negative correlation (-0.33

Table 4: Average macro F_1 scores for polarity classification across five runs (standard deviation in parenthesis) on gold targets, also adding information about holders and expressions. **Bold** indicates the best model per dataset, while blue and pink highlighting indicates an improvement or loss in performance compared to the original (targets only) data, respectively.

p=0.13, -0.16 p=0.48, -0.26 p=0.25 for macro Precision, Recall, or F_1 respectively, as measured by Pearson's correlation between the expression performances and the F_1 of the classification models augmented with these predicted expressions). It seems that the possible benefits depends more on the target dataset than the actual expression model used.

6 Conclusion

In this work we have explored the benefit of augmenting targeted sentiment models with holder and sentiment expressions. The experiments have shown that although augmenting text with holder and expression tags (**RQ1 a**) or simultaneously predicting them (**RQ1 b**) have no benefit for target extraction, predicting collapsed BIO + polarity tags consistently improves target extraction (**RQ1 c**). Furthermore, augmenting the input text with gold expressions generally improves targeted polarity classification (**RQ2 a**), although it is not clear which target representation strategy is best (**RQ2 b**). Furthermore, we have found benefits of including lexicon-based expressions for the more complex targeted datasets (**RQ2 c**).

The rather poor performance of the learned expression models and the difference between augmenting with gold or predicted expressions reveals the need to improve expression prediction approaches, both by creating larger corpora annotated with sentiment expressions, as well as performing further research on the modeling aspect. Any future work interested in modelling more complex sentiment phenomena should therefore be aware that we may first require more high-quality annotated data if we wish to do so with current state-of-the-art machine learning approaches.

Furthermore, we introduce a common format for eight standard English datasets in fine-grained sentiment analysis and release the scripts to download and preprocess them easily. We plan to include further datasets in our script in the future, as well as extending our work to other languages with available fine-grained corpora.

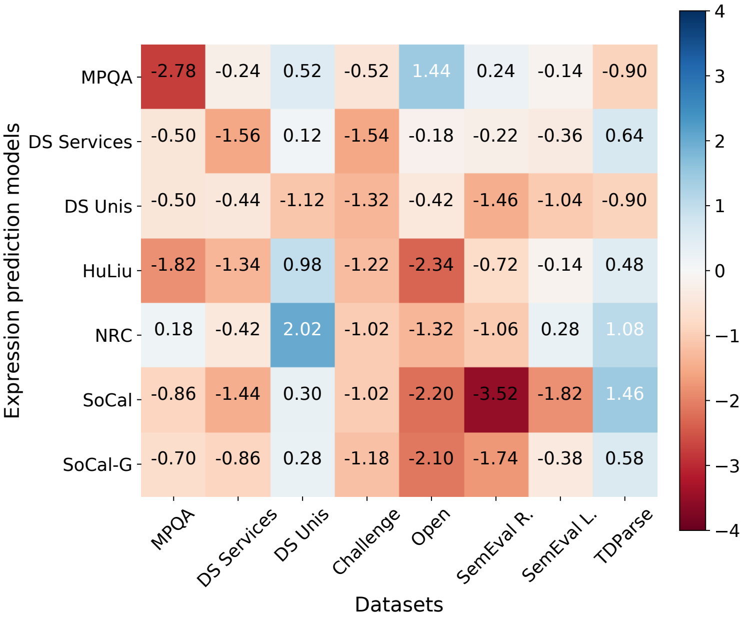

Figure 3: Heatmap of average improvements (blue) and losses (red) on the target classification tasks (x-axis) when augmenting the input text with predicted sentiment expressions from the expression prediction models (y-axis).

Acknowledgements

This work has been carried out as part of the SANT project (Sentiment Analysis for Norwegian Text), funded by the Research Council of Norway (grant number 270908). The computation for the experiments was provided by UNINETT Sigma2 - the National Infrastructure for High Performance Computing and Data Storage in Norway

Abstract

A common approach in many machine learning algorithms involves self-supervised learning on large unlabeled data before fine-tuning on downstream tasks to further improve performance. A new approach for language modelling, called dynamic evaluation, further fine-tunes a trained model during inference using trivially-present ground-truth labels, giving a large improvement in performance. However, this approach does not easily extend to classification tasks, where ground-truth labels are absent during inference. We propose to solve this issue by utilizing self-training and back-propagating the loss from the model's own class-balanced predictions (pseudo-labels), adapting the Reptile algorithm from meta-learning, combined with an inductive bias towards pre-trained weights to improve generalization. Our method improves the performance of standard backbones such as BERT, Electra, and ResNet-50 on a wide variety of tasks, such as question answering on SQuAD and NewsQA, benchmark task SuperGLUE, conversation response selection on Ubuntu Dialog corpus v2.0, as well as image classification on MNIST and ImageNet without any changes to the underlying models. Our proposed method outperforms previous approaches, enables self-supervised fine-tuning during inference of any classifier model to better adapt to target domains, can be easily adapted to any model, and is also effective in online and transfer-learning settings.

1 Introduction

It is a common consensus that the performance of Machine Learning algorithms improves with increasing data. However, due to the difficulty of obtaining large quantities of labelled data, many models (particularly in Natural Language Processing domain) such as BERT (Devlin et al., 2019), GPT (Radford et al., 2018) and UniLM (Dong et al., 2019) rely on unsupervised pre-training on unlabelled data to learn useful features which are then fine-tuned for other downstream tasks. While this approach leads to large gains in performance, it leads to a mismatch between a network's pre-training and final fine-tuning. Some approaches such as pseudo-labelling (Lee, 2013) have proposed utilizing data-augmentation of unlabelled data with the model's own predictions to better pre-train a model.

While these methods are limited to the training phase, Krause et al. (2018) proposed to continue training a language modeling model (which is the task of predicting the next token in a sequence of tokens) during the evaluation stage, achieving significant improvements as the model learns to better adapt to the inference data, without any modifications to the model architecture or any access to training data. For language modeling, the ground truth labels are the next input token, which are trivially accessible to the model to facilitate this learning. However, this method does not easily generalize to standard classification tasks due to the unavailability of labels during inference. This is the setting which we further explore in this paper, in which we are provided with a classification model already trained on training data, but with no access to the training data, and the aim is to further improve the performance of the model by utilizing self-training on the inference data.

To solve the above problem, we propose a method to train any classifier model during inference, utilizing methods used in domain adaptation, noisy-label learning, and multi-task meta-learning. With ground truth labels being absent, we utilize the model's own predictions as the pseudo-labels for those samples and utilize Class Balanced Self Training (CBST) (Zou et al., 2018) to filter samples based on the model's confidence while retaining class balance. However, naive online learning or

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 63–77
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

re-training on the inference data is not optimal due to the noise in the labels biasing the network, as well as the small size of the inference set. We solve this issue by leveraging the Reptile Meta Learning Algorithm (Nichol et al., 2018) to improve generalization, supplemented with an explicit inductive bias towards the model's pre-trained weights.

Our experimental results and ablation studies show that our method improves the performance of standard backbones such as BERT, Electra (Clark et al., 2020) and ResNet (He et al., 2016) on a wide variety of tasks, such as question answering on SQuAD (Rajpurkar et al., 2018) and NewsQA (Trischler et al., 2017), benchmark task SuperGLUE (Wang et al., 2019), and conversation re-ranking on Ubuntu Dialog corpus v2.0 (Lowe et al., 2017) for NLP, as well as object classification on MNIST (Deng, 2012) and ImageNet (Deng et al., 2009) without any changes to the underlying models, while outperforming previous approaches. Our method can also be utilized for continual self-supervised fine-tuning of classifiers on target domains, as well as in transfer-learning settings, without any model-level modifications.

2 Proposed Method

Our proposed technique is the self-supervised training of a classifier model during inference, consisting of three parts – using confident predictions as pseudo-labels, utilizing the Reptile algorithm to improve generalization, and an explicit inductive bias to minimize the effect of noisy labels.

2.1 Class Balanced Pseudo-labels

We utilize our classifier's most likely predicted class during inference as hard ground truth labels (pseudo-labels). Hendrycks and Gimpel (2017) show that using a model's own softmaxed probability values, $max_k\{p(y=k|x)\}$, where k are the classes, x is the input, and y is the predicted class is a reasonable proxy for its expected accuracy. To filter out samples with low maximum probabilities, one can simply threshold the output with some fixed value p_t. As proposed by Zou et al. (2018), a separate threshold $p_t(k_{max})$ for each class, where k_{max} is the class with the maximum predicted probability, works better by reducing skewing in favour of easier classes.

In CBST $p_t(k)$ are automatically selected for each k such that a fixed fraction f of examples of each predicted-class are filtered out from the inference set, i.e.,

$$P^k = \{p(y=k|x) | \text{Argmax}_k p(y=k|x) = k\},$$

$$p_t(k) = \max(\{i \mid \frac{|p > i, p \in P^k|}{|P^k|} <= f\}),$$

$$X_t = \{x \mid max_k\{p(y=k|x)\} > p_t(k)\},$$

$$Y_t = \{k \mid max_k\{p(y=k|x)\} > p_t(k)\}$$

These thresholds $p_t(k)$ can be kept fixed based on the validation set, or can be a running estimate in an online setting. Unlike the original CBST, we do not further normalize the class probabilities with these thresholds, as that led to a drastic reduction in the accuracy of pseudo-label classification. X_t inputs with hard pseudo-labels Y_t are used as a training set to further fine-tune the model, using the Reptile Algorithm below. This approach is also unaffected by a lack of model calibration, as long as the model's accuracy on X_t is acceptably high.

2.2 Reptile Algorithm, but for Single Task

Naively using the confident inferred labels for fine-tuning the model is not optimal due to small size of the test set compared to the train set as well as label noise, lowering generalization, and reducing the gains that can be achieved using the pseudo-labels. Since aligned gradients between samples improve a model's generalization, as shown in Chatterjee (2020) and Fort et al. (2019), we leverage the Reptile Meta-Learning Algorithm to this end. The meta-gradient for the Reptile algorithm contains as a component the gradient for maximizing the inner product between different mini-batches from the same task, as we prove in Section 3.

Algorithm 1: REPTILE + l^2sp

```
Input: Batches $B = \{b_0, b_1, \ldots, b_n\}$
       $W = \theta_{0,0} \leftarrow$ Initial network params
Output: Final fine-tuned $\theta$
for $i \leftarrow 0$ to $\lfloor n/k \rfloor$ do
    for $j \leftarrow 0$ to $k - 1$ do
        $\nabla_{\text{inner}} \leftarrow$ grad from $\theta_{i,j}(b_{i*k+j})$
        $\nabla_{\text{LR}} \leftarrow LR_{\text{inner}} * \nabla_{\text{inner}}$
        $l^2sp \leftarrow decay * (\theta_{i,j} - W)$
        $\theta_{i,j+1} \leftarrow \theta_{i,j} - \nabla_{LR} - l^2sp$
    $\nabla_{\text{outer}} \leftarrow (\theta_{i,0} - \theta_{i,k})$
    $\theta_{i+1,0} \leftarrow \theta_{i,0} - LR_{\text{outer}} * \nabla_{\text{outer}}$
return $\theta_{\lfloor n/k \rfloor + 1, 0}$
```

The Reptile Algorithm is a batched First-Order MAML (FO-MAML) Algorithm, originally in-

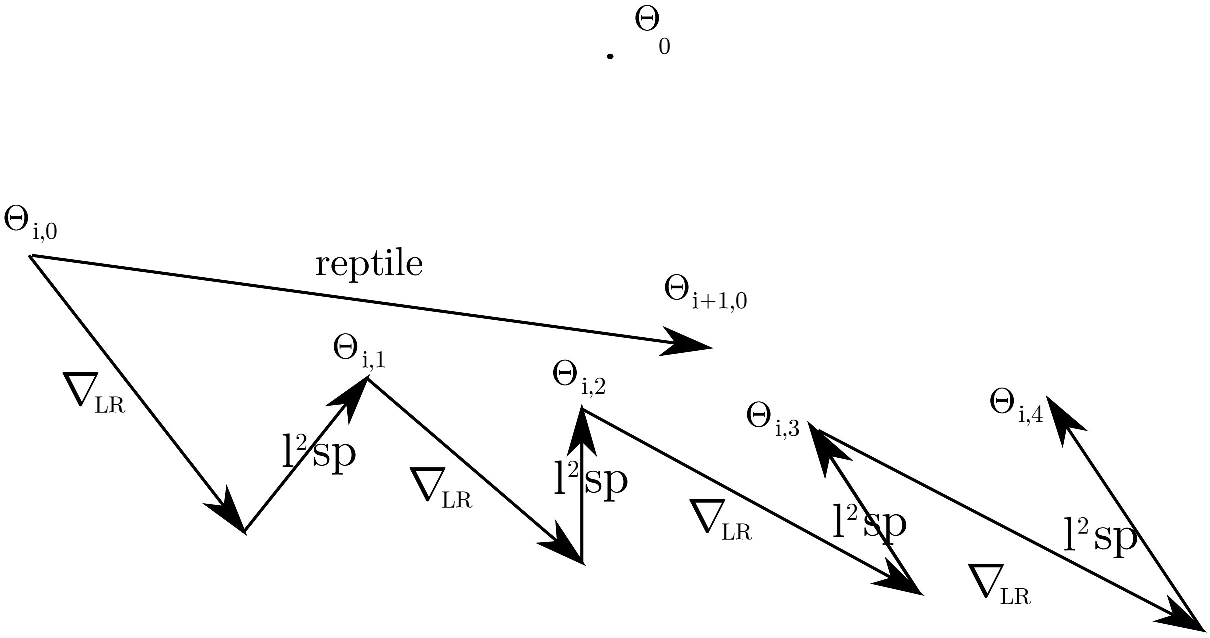

Figure 1: Overview of Reptile with l^2sp update for 4 inner steps.

tended for multi-task meta-learning. We use this algorithm in a single-task setting, as shown in Algorithm 1. The Reptile algorithm consists of $k > 1$ inner steps of standard SGD updates with learning rate LR_{inner}. The difference between original network weights $\theta_{i,0}$ and the final network weights $\theta_{i,k}$ is used as a meta-gradient for SGD for updating the network parameters with a learning rate LR_{outer}, where i is the outer step. The SGD optimizer can be replaced with any other, such as Adam.

The Reptile algorithm for this single task setting is First Order, requiring little extra compute compared to standard optimization, and can be plugged in to any model with ease. Some other multi-task algorithms with Experience-Replay, such as Riemer et al. (2018), may exhibit better learning but are computationally orders of magnitude more expensive and are hence infeasible for large datasets and models.

2.3 Explicit Inductive Bias

While all the models we use employ a weight decay towards 0 in their training phase, given the usually smaller size of the inference set, we regularize the model by biasing the network towards its pre-trained weights instead. For this, we use the l^2sp decay (Li et al., 2018), slowly decaying the model weights between updates towards the initial trained model weights. An example of the update steps involved for $k = 4$ is shown in Fig.1. We conjecture that this will also make the learning more stable to the noisy pseudo-labels.

Some recent works such as Goldblum et al. (2020) also show that standard l^2 weight decay towards 0 may not be ideal and recommend biasing weights towards some model-dependent non-zero norm value instead. l^2sp can be seen as a generalization of the same, while simultaneously taking advantage of the pre-training.

3 Theoretical Analysis

In this section, we provide a theoretical analysis of the meta update of $Reptile + l^2sp$. We generalize the Taylor expansion approach for Reptile as used in (Nichol et al., 2018) to accommodate l^2sp, and show how our approach maximizes the inner product of gradients between different mini-batches.

We consider one set of k inner updates. For $i \in [0, k]$, we define -

$$\begin{aligned}
\theta_i &= \text{network weights before } i^{th} \text{ step},\\
b_i &= \text{input batch for } i^{th} \text{ step},\\
L_i &= \text{loss function corresponding to } b_i,\\
W &= \text{pre-trained network weights for } l^2sp,\\
\beta &= l^2sp \text{ weight decay rate},\\
\alpha &= LR_{inner},\\
g_i &= L_i'(\theta_i), && \text{(gradient of } i^{th}batch)\\
\overline{g_i} &= L_i'(\theta_0), && \text{(gradient at initial point)}\\
H_i &= L_i''(\theta_i), && \text{(Hessian of } i^{th}batch)
\end{aligned}$$

$$\overline{H_i} = L_i''(\theta_0), \qquad \text{(Hessian at initial point)}$$

Then, our update rule is -

$$\theta_i = (1-\beta)\theta_{i-1} - \alpha g_{i-1} + \beta W \tag{1}$$

In the following analysis, to keeps the analysis tractable, we assume both α and β are small and comparable, and ignore terms involving $O(\alpha^2)$, $O(\beta^2)$ and $O(\alpha\beta)$. Using the first order Taylor expansion of g_i, we get -

$$g_i = \overline{g_i} + \overline{H_i}(\theta_i - \theta_0) \tag{2}$$

The following equations can be proved using simple induction on Eq (1) and (2) -

$$\theta_i = \theta_0 + i\beta(W - \theta_0) - \alpha\sum_{j=0}^{i-1}\overline{g_j}, \tag{3}$$

$$g_i = \overline{g_i} + i\beta\overline{H_i}(W - \theta_0) - \alpha\overline{H_i}\sum_{j=0}^{i-1}\overline{g_j}, \tag{4}$$

By summing up the displacements from all variable updates, the expectation of the meta-gradient from Reptile + l^2sp under mini-batch sampling is -

$$\mathbb{E}[-(\theta_k - \theta_0)] = \mathbb{E}[\alpha\sum_{i=0}^{k-1} g_i - \sum_{i=0}^{k-1}\beta(W - \theta_i)]$$

When expanding the terms above with Eq (3) and (4) and simplifying, we get -

$$\begin{aligned}\mathbb{E}[-(\theta_k - \theta_0)] &= c_1\mathbb{E}[\overline{g_i}] + c_2(\theta_0 - W)\\ &-c_3\mathbb{E}[\overline{H_j}\overline{g_i}] - c_4\mathbb{E}[\overline{H_j}(\theta_0 - W)],\end{aligned} \tag{5}$$

where each c_i is a positive constant, dependent on k, α and β.

The first term in R.H.S. of Eq (5) is the gradient which takes us to the minimum of the training problem. For the third term, note that -

$$\begin{aligned}\mathbb{E}[\overline{H_j}\overline{g_i}] = \mathbb{E}[\overline{H_i}\overline{g_j}] &= \frac{1}{2}\mathbb{E}[\overline{H_j}\overline{g_i} + \overline{H_i}\overline{g_j}]\\ &= \frac{1}{2}\mathbb{E}[\frac{\partial}{\partial\theta_0}(\overline{g_i}\cdot\overline{g_j})]\end{aligned}$$

Therefore the third term maximizes the dot product between the gradients of the batches for improved generalization, as in the original Reptile algorithm.

For the second and fourth terms, note that $(\theta_0 - W)$ is the direction of the gradient of the l^2sp, and hence can be interpreted similar to the first and third term, but with training gradients replaced by this l^2 gradient.

Hence, we have shown that the Reptile algorithm maximizing product of gradients for improving generalization holds true in our extension as well.

4 Experimental Setup

4.1 Benchmark Datasets

SuperGLUE A popular NLP benchmark, which attempts to test various capabilities of language understanding. It itself consists of 8 datasets - Boolean Questions (Clark et al., 2019), Commitment Bank (De Marneffe et al., 2019), Choice of Possible Alternative (Gordon et al., 2012), Multi-Sentence Reading Comprehension (Khashabi et al., 2018), Reading Comprehension with Commonsense Reasoning (Zhang et al., 2018), Recognizing Textual Entailment (a combination of datasets from Dagan et al., 2005; Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009; Poliak et al., 2018), Word-in-Context (Pilehvar and Camacho-Collados, 2019) and Winograd Schema Challenge (Levesque, 2011).

SQuAD v2.0 A popular span-style QA dataset, consisting of passages from Wikipedia, with questions and corresponding answer spans and unanswerable questions.

Ubuntu Dialog Corpus v2.0 A large-scale corpus of multi-turn conversations mined from Ubuntu IRC chat logs, and the task is to select the best response given a list of possible distractor responses.

NewsQA A span-style QA dataset, consisting of crowd-sourced questions and answers on CNN news articles, along with unanswerable questions.

Model	Params	Speed
Electra-large-cased	340M	8
BERT-large-cased	340M	8
BERT-base-uncased	110M	36
ResNet-50	23M	146
MLP (128H, 2L)	120K	~1M

Table 3: Models, number of network parameters, and training speeds in examples/second on a V100 GPU.

MNIST An image classification dataset of 28x28 scans of handwritten digits. While the dataset has long been *solved*, it nevertheless serves as a useful dataset to compare simpler architectures.

ImageNet A large-scale dataset for image classification, consisting of 1.2M training samples along with their corresponding class labels.

4.2 Models

BERT BERT is a transformer (Vaswani et al., 2017) model, and its derivative models are the backbone of most state-of-the-art models in NLP. We use the official implementation and pre-trained models of BERT-large-cased for SuperGLUE tasks, and BERT-base-uncased for Ubuntu Dialog Corpus, NewsQA, and for our ablation tests on SQuAD.

Electra Electra is a BERT-derived state-of-the-art model in many NLP tasks, with a discriminative pre-training task. We use the official pre-trained Electra-large model, and we implement our own classifier for SQuAD v2.0.

ResNet Residual blocks and their variants are the backbone of most image classification models today. We use Tensorflow Model Garden's implementation and pre-trained ResNet-50 for ImageNet.

MLP While models made of only simple Multi Layer Perceptrons have largely fallen out of favour, fully connected layers are often a part of larger architectures. We use an MLP with 2 Layers and 128 Hidden units as the model for MNIST.

4.3 Implementation Details

Fine-tuning on inference data is extremely quick as our method is first order, taking less than 15 minutes on a V100 for all datasets except ReCoRD and Ubuntu-Dialog, for which it takes a few hours. We use the Adam optimizer, and we disable our model's l^2 weight decay, if any. Batch-norm variables, if any, are also kept fixed.

Corpus	Metric	BERT	BERT + ours
BoolQ	Acc	76.4	**76.6** ± 0.01
CB	F1	88.1	**89.4** ± 0.01
	Acc	91.1	**92.9** ± 0.01
COPA	Acc	71.0	**72.0** ± 0.01
MultiRC	F1a	69.5	**70.0** ± 0.01
	EM	26.4	**26.8** ± 0.01
ReCoRD	F1	72.5	**73.0** ± 0.09
	EM	71.8	**72.4** ± 0.03
RTE	Acc	74.0	**75.1** ± 0.01
WiC	Acc	73.8	**74.3** ± 0.02

Table 4: Results on the validation set of SuperGLUE benchmark dataset, with Bert-large-cased model.

For each dataset, we train one model on the training set, followed by five runs on the pseudo-labeled thresholded inference set with varying seeds, and report the mean and standard deviation of the scores. As the test set for SuperGLUE and SQuAD are hidden, we provide results on the development set instead.

All default/official model hyper-parameters were used for each model/dataset, which can be found in their official source codes linked in the supplemental material, except we use $1e^{-5}$ as LR for Electra as we observed divergence with standard LR. We linearly decay LR except in the online case, where it is kept fixed. The hyper-parameters for Reptile and l^2sp are provided in the supplemental material. A reasonable set of hyper-params, that works across a range of datasets and models we tested, is 0.01 for LR_{outer}, 4 for $inner\_step$, and 0.1 for l^2sp, while LR_{inner} depends on the original model's LR. RTE, BoolQ, and WiC filter out f as 70% of data, while all other datasets filter 50%.

5 Results

5.1 Results on SuperGLUE benchmark

As shown in Table 4, our method consistently improves the performance on all the tasks in SuperGLUE, with very little extra compute, with upto 1.8 increase in accuracy. The gains tend to be larger on smaller datasets, but we observe significant improvement even with the largest task ReCoRD, with over 100K examples.

5.2 Results on other NLP datasets

Our method achieves gains of $0.68/0.72$ F1/EM on SQuAD v2.0 with BERT-base, as shown in Table 7. Even when using a state-of-the-art Electra model

Method	**F1**	**EM**
BERT	76.14	73.14
BERT + CBST (Zou et al., 2018)	76.22 ± 0.02	73.35 ± 0.02
BERT + Disagreement (Malach and Shalev-Shwartz, 2017)	76.23 ± 0.03	73.27 ± 0.06
BERT + Uncertainty Estimation (Zheng and Yang, 2020)	76.25 ± 0.05	73.29 ± 0.04
BERT + Mutual Mean-Teaching (Ge et al., 2020)	76.28 ± 0.04	73.23 ± 0.05
BERT + Co-teaching (Han et al., 2018)	76.28 ± 0.02	73.29 ± 0.04
BERT + Ours	**76.82** ± 0.04	**73.86** ± 0.04

Table 5: Comparison of our method to existing method, on SQuAD v2.0 corpus, using BERT-base-uncased.

Corpus	**Metric**	**Base**	**Base + ours**
MNIST	Acc	98.11	**98.38** ± 0.02
ImageNet	Acc	76.53	**76.69** ± 0.01
SQuAD v2.0	F1	90.13	**90.25** ± 0.01
	EM	87.44	**87.67** ± 0.01
Ubuntu Diag.	R10@1	76.79	**76.89** ± 0.01
NewsQA	F1	44.79	**49.36** ± 0.05
	EM	32.48	**38.71** ± 0.11
NewsQA (online)	F1	44.79	**47.49** ± 0.01
	EM	32.48	**34.11** ± 0.04

Table 6: Results on other NLP and Image datasets.

with SQuAD, we still observe consistent improvements in performance, as shown in Table 6. Even in the presence of large training-set sizes such as that of Ubuntu Dialog Corpus v2.0 with 1M training samples, we still observe consistent increase in performance with the BERT model.

5.3 Results in a Transfer Learning Setting

We also evaluate our approach in a transfer-learning setting on NewsQA, using a BERT-base-uncased model, which was pre-trained on SQuAD v2.0, by self-training on NewsQA train set, followed by evaluation on the test set. Our approach is especially effective in this setting, out-performing the original model by $4.57/6.23$ F1/EM respectively, as shown in Table 6. This experiment demonstrates that our approach is effective for unsupervised domain adaptation to a target domain even in the absence of source domain data.

5.4 Results on Image Classification

To demonstrate that our method also works in non-NLP domains, on ImageNet with ResNet-50, we report an increase in accuracy of 0.16. On MNIST dataset, the improvement in accuracy of our simple MLP model is 0.27.

5.5 Comparison with Existing Methods

We compare our method with several existing approaches for Self-Training, Zou et al. (2018), Malach and Shalev-Shwartz (2017), Malach and Shalev-Shwartz (2017), Ge et al. (2020) and Han et al. (2018), on SQuAD v2.0 dataset.

As shown in Table 5 our method greatly outperforms the existing approaches, giving 4 to 5 times the relative improvement compared to other methods, improving performance by $0.68/0.82$ F1/EM compared to $0.14/0.15$ F1/EM of the best performing existing approach.

5.6 Online Variant

Our approach can also be used effectively without any modifications in an online setting, where the model keeps learning continuously as inference data is fed to the model. We use a trained model to make predictions on the input inference data, and at the same time, we use the model's predictions to finetune the model. For this kind of learning, we use a constant learning rate, as the total size of inference data is unavailable. As a baseline, we use BERT + CBST (trained on SQuAD-v2.0 data) with a constant learning rate. BERT + CBST + Reptile + l^2sp (Online) clearly outperforms BERT + CBST (Online) by $0.38/0.37$ F1/EM as shown in Table 7.

We also compare the performance of our method when running in online mode for a long time on NewsQA dataset, as shown in Table 6. The performance improvement is not as large as with decreasing LR, but still results in significant performance improvements of $2.70/1.63$ F1/EM, respectively.

6 Ablation Studies

We conduct extensive ablation studies to test the effectiveness of all parts of our approach. We perform these ablations on SQuAD v2.0 with BERT-base model.

Method	F1	EM
BERT	76.14	73.14
BERT + CBST	76.22 ± 0.02	73.35 ± 0.02
BERT + CBST + l^2sp	76.24 ± 0.04	73.49 ± 0.04
BERT + CBST + Reptile	76.61 ± 0.02	73.60 ± 0.03
BERT + Reptile + l^2sp	76.47 ± 0.07	73.63 ± 0.08
BERT + CBST + Reptile + l^2sp	**76.82** ± 0.04	**73.86** ± 0.04
BERT + CBST (Online)	76.20 ± 0.01	73.28 ± 0.01
BERT + CBST + Reptile + l^2sp (Online)	**76.58** ± 0.02	**73.65** ± 0.01

Table 7: Ablation Study of our method on SQuAD v2.0 corpus, using the BERT-base-uncased model.

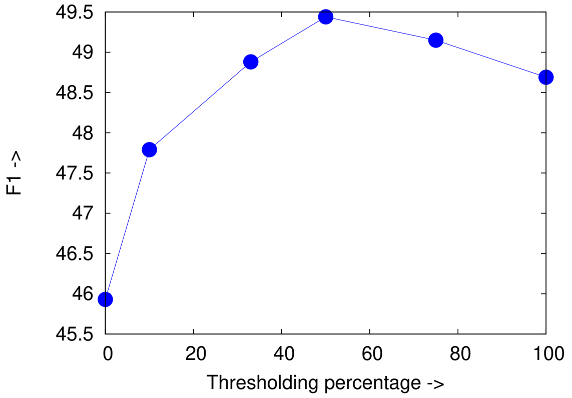

Figure 2: Ablation study of varying the thresholding percentage on NewsQA. The Y axis is F1 score, the X axis is the percentage of data left after thresholding.

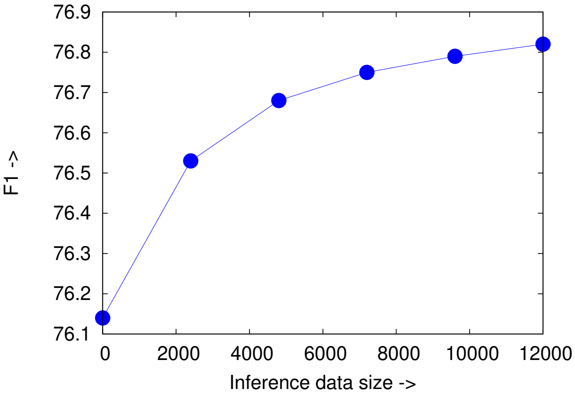

Figure 3: Effect of varying total size of Inference data on our method on SQuAD v2.0. The Y axis is F1 score, the X axis is the total amount of Inference data used.

6.1 Thresholding

In Table 7, we compare using CBST thresholding of model outputs to fine-tune the model vs. using all the data. Using CBST + Reptile + l^2sp increases scores by $0.35/0.23$ F1/EM respectively compared to using all the pseudo-labels with Reptile + l^2sp.

We further study the effect of the thresholding fraction f used to select the subset of confident data. We use the pre-trained Bert-base-uncased model, self-trained on the training set of NewsQA data with pseudo-labels, while varying f, and then evaluate on the dev set. As can be seen in Fig.2, the optimal value for thresholding is around 50%, decreasing slowly as more data (but with less confident labels) is used, and decreasing more sharply as the total filtered data used decreases.

6.2 Reptile Algorithm

Compared to using just CBST, using the Reptile Algorithm to finetune results in more performance gains of $0.58/0.37$ F1/EM, as we can see in Table 7. This effect persists irrespective of whether l^2sp or the model's default weight decay towards 0 is used. This demonstrates that the increased generalization from Reptile's meta-gradients is indeed effective in increasing model performance and robustness.

We also conduct an ablation study on the choice of number of inner steps k on the performance of our model. As shows in Table 8, the number of inner updates does not have a major impact on the results, but we advise it be kept less than or equal to 4 as higher inner steps reduce the number of outer updates (as the total number of epochs is kept constant).

6.3 Inductive Bias towards pre-trained weights

We can also see in Table 7 that l^2sp is indeed effective, and by simply biasing the model towards the pre-trained weights, we can achieve better results. This effect becomes more pronounced when the Reptile algorithm is used, with $0.21/0.26$ F1/EM improvement of CBST + Reptile + l^2sp compared to CBST + Reptile.

We also conduct an ablation study on the choice of this bias, by transfer learning on NewsQA

Num Updates	**F1**	**EM**
Baseline	76.24 ± 0.04	73.49 ± 0.04
2	76.79 ± 0.02	73.87 ± 0.02
4	76.82 ± 0.01	73.86 ± 0.02
6	76.80 ± 0.01	73.74 ± 0.02
8	76.71 ± 0.01	73.68 ± 0.03

Table 8: Ablation of choice of hyper-parameter number of inner steps k for our method CBST + Reptile + l^2sp on SQuAD with BERT-base.

l^2sp **decay**	**F1**	**EM**
Baseline	76.14	73.14
0	76.38 ± 0.00	69.87 ± 0.21
6e-4	76.54 ± 0.02	70.74 ± 0.15
2e-3	76.10 ± 0.01	73.74 ± 0.12

Table 9: Performance of BERT-base on SQuAD, after self-training on NewsQA with transfer learning with our method, for varying choices of hyper-parameter decay for l^2sp.

dataset using our method with a model trained on SQuAD, and measuring the performance on SQuAD thereafter. As shows in Table 9, l^2sp prevents the model from forgetting its performance on SQuAD. However, higher values prevent it from improving its performance on the original squad by minimizing learning on NewsQA.

6.4 Effect of Inference Data Size

In Figure 3, we vary the amount of inference data available for our model to learn from, by training a BERT-base model on varying sizes of pseudo-labelled SQuAD v2.0 dev set, while keeping f fixed at 50%. The largest increase occurs early on in the training. However, even on using the full dev set, the performance keeps improving, giving an improvement in F1 of 0.68.

7 Related Works

7.1 Pseudo-labeling

Lee (2013) proposed a simple and efficient method of semi-supervised learning for deep neural networks, in which the proposed network is trained in a supervised fashion with labeled and unlabeled data simultaneously, using *pseudo-labels* created by selecting the classes which have the highest predicted probabilities as ground truth labels for unlabeled data. CBST (Zou et al., 2018) used different thresholds for pseudo-labels of different classes. Mutual Mean-teaching (Ge et al., 2020) used a moving average of two separate classifiers to refine pseudo-labels. Zheng and Yang (2020) used KL-divergence between two classifiers as a measure of classifier variance to filter incorrect pseudo-labels. Pseudo-labels and similar self-supervised techniques have grown increasingly popular, particularly when used in conjunction with extremely large unlabelled data, and was used by Noisy-Student (Xie et al., 2019) recently to achieve state-of-the-art performance on image classification.

7.2 Dynamic Evaluation

Adaptive language modelling has a long history, such as Kuhn (1988), and caching based models have resulted in improved performances over state-of-the-art, such as Merity et al. (2018). Krause et al. (2018) proposed to use dynamic evaluation adapted to recent history via a gradient descent based mechanism. However, their approach is limited to language modelling, where ground-truth labels are trivially available during inference, and does not generalize to standard classification setting.

Rahman et al. (2019) also used pseudo-labels during inference to learn, but differently from our paper, they primarily focus on a transductive zero-shot detection, and do not use our proposed meta-learning and inductive bias. Kim et al. (2019) also proposed to use pseudo-labels to learn during evaluation, but require changes to the model's training phase. Su et al. (2016) also used pseudo-labels on inference data to improve model performance, but their contributions are primarily focused on adapting Self-Training to unbalanced classes. Dynamic evaluation can be considered a form of Fast-weights (Ba et al., 2016), which unlike our approach, requires changes during the training phase.

7.3 Generic Methods for Noisy Labels

Loss correction methods such as Patrini et al. (2017) model the noise transition matrix. Other approaches try to directly correct the noisy labels, such as Veit et al. (2017), but require access to a clean set. Others directly modify the loss function to make it more stable to noisy labels, such as Generalized Cross Entropy (Zhang and Sabuncu, 2018). Other approaches, most related to our approach, refine the training strategy, such as Co-teaching (Han et al., 2018) or Mutual Mean-teaching, using two classifiers to select the data for each other.

7.4 Unsupervised Domain Adaptation

Unsupervised Domain Adaptation methods often use Adversarial Methods, such as Jiang et al. (2020), to distinguish between source and target domains. Distance based methods, such as Chen et al. (2019), aim to minimize the distribution discrepancy across different domains. Other methods such as Courty et al. (2017) rely on optimal transport between source and target domains. These methods often need access to source domain data, or modify the original model or training procedure.

7.5 Meta-Learning for Transfer Learning

Algorithms that rely on Fisher/Hessian matrices have been proposed to improve transfer learning, such as Kirkpatrick et al. (2016). Nichol et al. (2018) proposed using batched FO-MAML during training to learn better weight initialization values. Often these algorithms also use some form of Experience Replay, where saved/cached examples from previous tasks are replayed to prevent the model from forgetting. Riemer et al. (2018) proposed Meta-Experience Replay (MER), exploiting a trade-off between transfer and interference by enforcing gradient alignment across examples.

8 Conclusion

We propose a method for self-supervised learning for any classifier model during inference using the model's own predictions, adapting Reptile algorithm from meta-learning and an inductive bias for maintaining generalization while improving performance. We demonstrate the effectiveness of our method on a wide range of tasks, including SuperGLUE benchmark, question answering on SQuAD v2.0 and NewsQA, response selection on Ubuntu Dialog Corpus v2.0, and image classification on ImageNet and MNIST. Our approach consistently improves the performance of standard backbones such as BERT, Electra, and ResNet. Our method is effective for improving the performance of neural models without any changes to the underlying models, their training, or access to training data, requires minimum extra compute, and is also effective in online and transfer-learning settings.

Acknowledgments

We want to thank Mr. Wonho Ryu and Mr. Haejun Lee of Samsung Research, Seoul, Korea, for their guidance and leadership. We would also like to thank all the reviewers for their valuable feedback and suggestions.

A Statistical Significance of Results

For each dataset, we train one model on the training set, followed by five runs on the pseudo-labeled thresholded test set with varying seeds, and report the mean and standard deviation of the scores. Smaller datasets in SuperGLUE are known to have significant variation between multiple runs when fine-tuning BERT model, however, most of this variation comes from random initialization of the classification layer. In our experiments, as the model has already been fine-tuned on the train set, the only variation between runs is the order of input data. This results in an extremely small variation in score between different runs, much smaller than the performance gains observed, making the improvements statistically significant.

A.1 Significance tests

We provide below in Table 10 and Table 12 the P-values for one-sample T-test for the Table 6 and Table 7, with the null hypothesis that the scores of our results have the same mean as the baseline. Our results are significant at 99% confidence in all settings.

B Improved Generalization

The NewsQA results in Table 6 are scores on the test set, while the model was self-trained on the train set. The scores indicate that, the model does not over-fit while self-training as our approach significantly improves the scores on the test set.

Corpus	$p - value$
SQuAD v2.0 Electra (F1)	3e-5
Ubuntu Dialog v2.0	5e-5
NewsQA (F1)	1e-9
ImageNet	4e-7

Table 10: P-values for one-sample T-test with the null hypothesis for Table 6.

As a further test of improved generalization, we split the squad dev set in two equal halves, performed our self-training on one half, and evaluated on the other half. Scores in Table 11 show, self-training on one half improved generalization on the other.

Model/Approach	$F1$	EM
BERT	76.28	73.32
BERT+ours	76.40	73.45

Table 11: Results on one half of the squad-dev set.

C Links to Source code

For SuperGLUE, we use the Official Implementation for BERT available at `https://github.com/nyu-mll/jiant`, along with the default pre-trained models. For ablation tests on SQuAD, we used the official implementation and pre-trained models at `https://github.com/google-research/bert`. For Ubuntu Dialog, we used the same pre-trained models, but we implement our own classifier. For Electra, we used the pre-trained models from `https://github.com/google-research/electra`. For ResNet-50, we used Tensorflow Model Garden's official implementation as well as pre-trained model on ImageNet at `https://github.com/tensorflow/models/tree/r1.13.0/official/resnet`. For MNIST, we implemented our own MLP following `https://www.tensorflow.org/datasets/keras_example`. The Reptile+l^2sp Optimizer is trivial to implement in all of the above models following the pseudo-code from the main paper, by modifying the *Optimizer* class used for each of the models.

SuperGLUE can be downloaded from `https://super.gluebenchmark.com/`. SQuAD v2.0 can be downloaded from `https://rajpurkar.github.io/SQuAD-explorer/`. Ubuntu Dialog Corpus can be generated using `https://github.com/rkadlec/ubuntu-ranking-dataset-creator`. ImageNet can be downloaded from `http://image-net.org`. MNIST can be downloaded from `http://yann.lecun.com/exdb/mnist/`. NewsQA can be downloaded from `https://www.microsoft.com/en-us/research/project/newsqa-dataset/`.

E Corresponding Validation set results for Test Set

Our only reported test scores are on MNIST, NewsQA, and Ubuntu Dialog Corpus. For MNIST, there is no official validation set. For Ubuntu Dialog Corpus, the validation score of our model is 76.44 Recall10@1, and for NewsQA, it is 49.44±0.04 F1 and 39.26±0.15 EM, respectively.

F Hyper-parameters of our approach

The hyper-parameter search bounds were chosen based on heuristic manual estimates, primarily considering the product of the LR_{inner} and LR_{outer}, compared to the model's native LR when the fraction of training steps left equals the ratio of the size of the training set to the size of the filtered inference set. Each set of hyper-parameters was run three times, and the hyper-parameter search was run in a grid. We list the hyper-parameters of our $Reptile + l^2sp$ approach in Table 13.

G Dataset descriptions

G.1 SuperGLUE

BoolQ Boolean Questions, a Question Answering (QA) dataset with short passages and yes/no questions, with data from Wikipedia and Google search engine queries.

CB Commitment Bank, consisting of passages with labels for *commitment* of speakers of clauses to said clause, framed as three-class NLI, with data from WSJ, British National Corpus and SwitchBoard. Evaluated with unweighted average F1 and accuracy.

COPA Choice of Possible Alternative, a dataset to classify the cause/effect of a given premise from two alternatives, with fully handcrafted data.

MultiRC Multi-Sentence Reading Comprehension, a QA dataset, with a list of multiple-choice possible answers for each question to a

paragraph. Evaluated with F1 over all answer-options($F1_a$), and exact match of each question's set of answers(EM).

ReCoRD Reading Comprehension with Commonsense Reasoning, a QA dataset consisting of articles and Cloze-style questions with a masked entity, scored on predicting the masked entity from the entities in the article, with data from CNN and Daily Mail. Scored with token-level F1 and EM.

RTE Recognizing Textual Entailment, as binary classification of *entailment* or *not entailment*, with data from Wikipedia and news.

WiC Word-in-Context, a word sense disambiguation (WSD) dataset, tasked with binary classification of sentence pairs based on the sense of a common polysemous word. Data is from WordNet and Wiktionary.

WSC Winograd Schema Challenge, a coreference resolution task on resolving pronouns to a list of noun phrases. As the models we tested only predicted the majority class, we omit this dataset.

G.2 SQuAD v2.0

The Stanford Question Answering Dataset v2.0 is a popular span-style QA dataset, consisting of passages from Wikipedia, labelled by annotators for questions on the passages and corresponding answer spans, along with unanswerable questions as well. This dataset is evaluated with F1 and EM scores of predicted answer spans.

G.3 Ubuntu Dialog Corpus v2.0

The Ubuntu Dialog Corpus is a large-scale corpus of multi-turn real human conversations mined from Ubuntu IRC chat logs, with only two participants per conversation. Each conversation is annotated with the next utterance (response) following the conversation, and the task is to select the best response given a list of possible distractor responses. The dataset is evaluated with Recall score of picking the correct response out of 10 possible responses, $Recall10@1$.

G.4 NewsQA

NewsQA is a span-style QA dataset, consisting of crowd-sourced questions on CNN news articles and their corresponding answer spans, along with unanswerable questions. This datasets is evaluated with F1 and EM scores of predicted answer spans.

G.5 MNIST

MNIST is a popular image classification dataset, consisting of normalized and anti-aliased 28x28 scans of handwritten numerical digits. While the dataset has long been *solved*, it nevertheless serves as a useful dataset to compare simpler architectures.

G.6 ImageNet

ImageNet is a large-scale dataset for image classification, consisting of 1.2M training samples along with their corresponding class labels. It is often the de-facto dataset when comparing Image Classification models.

H Expected validation performance

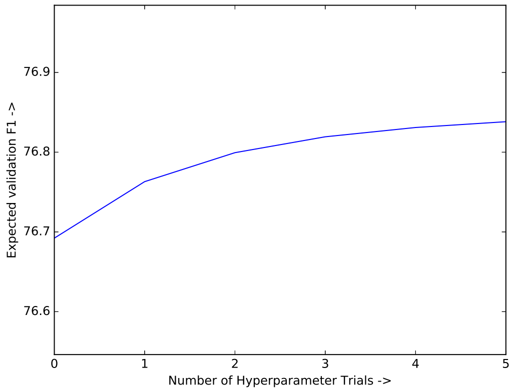

Figure 4: Expected Validation performance of our hyper-parameter searches, for SQuAD dataset with BERT-base model.

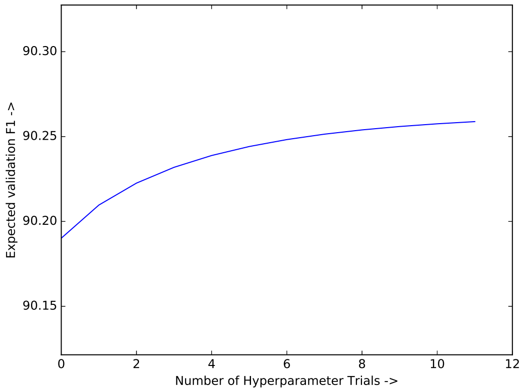

Figure 5: Expected Validation performance of our hyper-parameter searches, for SQuAD dataset with Electra-large model.

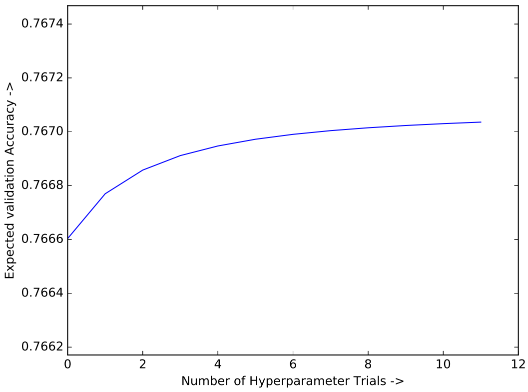

Figure 6: Expected Validation performance of our hyper-parameter searches, for ImageNet dataset with ResNet-50 model.

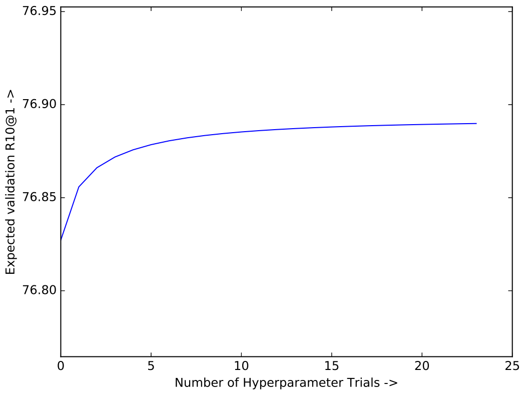

Figure 7: Expected Validation performance of our hyper-parameter searches, for Ubuntu dialog corpus with BERT-base model.

We provide the expected validation performance for all the datasets we ran hyper-parameter searches on, as described in (Dodge et al., 2019).

RESPER : Computationally Modelling Resisting Strategies in Persuasive Conversations.

Abstract

Modelling persuasion strategies as predictors of task outcome has several real-world applications and has received considerable attention from the computational linguistics community. However, previous research has failed to account for the resisting strategies employed by an individual to foil such persuasion attempts. Grounded in prior literature in cognitive and social psychology, we propose a generalised framework for identifying resisting strategies in persuasive conversations. We instantiate our framework on two distinct datasets comprising persuasion and negotiation conversations. We also leverage a hierarchical sequence-labelling neural architecture to infer the aforementioned resisting strategies automatically. Our experiments reveal the asymmetry of power roles in non-collaborative goal-directed conversations and the benefits accrued from incorporating resisting strategies on the final conversation outcome. We also investigate the role of different resisting strategies on the conversation outcome and glean insights that corroborate with past findings. We also make the code and the dataset of this work publicly available at `https://github.com/americast/resper`.

1 Introduction

Persuasion is pervasive in everyday human interactions. People are often exposed to scenarios that challenge their existing beliefs and opinions, such as medical advice, election campaigns, and advertisements (Knobloch-Westerwick and Meng, 2009; Bartels, 2006; Speck and Elliott, 1997). Of late, huge strides have been taken by the Computational Linguistics community to advance research in persuasion. Some seminal works include identifying persuasive strategies in text (Yang et al., 2019) and conversations (Wang et al., 2019), investigating the interplay of language and prior beliefs on successful persuasion attempts (Durmus and Cardie, 2018; Longpre et al., 2019), and generating persuasive dialogues (Munigala et al., 2018).

However, a relatively unexplored domain by the community is the investigation of resisting strategies employed to foil persuasion attempts. As succinctly observed by Miller (1965): “In our daily lives we are struck not by the ease of producing attitude change but by the rarity of it.” Several works in cognitive and social psychology (Fransen et al., 2015a; Zuwerink Jacks and Cameron, 2003) have put forward different resisting strategies and the motivations for the same. However, so far, there has not been any attempt to operationalise these strategies from a computational standpoint. We attempt to bridge this gap in our work.

We propose a generalised framework, grounded in cognitive psychology literature, for automatically identifying resisting strategies in persuasion oriented discussions. We instantiate our framework on two publicly available datasets comprising persuasion and negotiation conversations to create an annotated corpus of resisting strategies.

Furthermore, we design a hierarchical sequence modelling framework, that leverages the conversational context to identify resisting strategies automatically. Our model significantly outperforms several neural baselines, achieving a competitive macro-F1 score of 0.56 and 0.66 on the persuasion and negotiation dataset, respectively.

We refer to our model as RESPER, which is not only an acronym for **Res**isting **Per**suasion, but also a play on the word ESPer: a person with extrasensory abilities. The name is apt since we observe that incorporating such resisting strategies could provide additional insight on the outcome of the conversation. In fact, our experiments reveal that the resisting strategies are better predictors of conversation success for the persuasion dataset than the

---

[*] denotes equal contribution

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 78–90
April 19 - 23, 2021.

strategies employed by the persuader. We also observe that the buyer's strategies are more influential in negotiating the final price. Our findings highlight the asymmetric nature of power roles arising in non-collaborative dialogue scenarios and form motivation for this work.

2 Related Works

The use of persuasion strategies to change a person's view or achieve a desired outcome finds several real-world applications, such as in election campaigns (Knobloch-Westerwick and Meng, 2009; Bartels, 2006), advertisements (Speck and Elliott, 1997), and mediation (Cooley, 1993). Consequently, several seminal NLP research have focused on operationalising and automatically identifying persuasion strategies (Wang et al., 2019), propaganda techniques (Da San Martino et al., 2019), and negotiation tactics (Zhou et al., 2019), as well as the impact of such strategies on the outcome of a task (Yang et al., 2019; He et al., 2018; Joshi et al., 2021). However, there is still a dearth of research from a computational linguistic perspective investigating resisting strategies to foil persuasion.

Resisting strategies have been widely discussed in literature from various aspects such as marketing (Heath et al., 2017), cognitive psychology (Zuwerink Jacks and Cameron, 2003), and political communication (Fransen et al., 2015b) . Some notable works include the identification and motivation of commonly-used resisting strategies (Fransen et al., 2015a; Zuwerink Jacks and Cameron, 2003), the use of psychological metrics to predict resistance (San José, 2019; Ahluwalia, 2000), and the design of a framework to measure the impact of resistance (Tormala, 2008). However, these works have mostly relied on qualitative methods, unlike ours, which adopts a data-driven approach. We propose a generalised framework to characterise resisting strategies and employ state-of-the-art neural models to infer them automatically. Thus our work can be considered complementary to past research.

The closest semblance to our work in NLP literature ties in with argumentation, be it essays (Carlile et al., 2018), debates (Cano-Basave and He, 2016), or discussions on social media platforms (Al-Khatib et al., 2018; Zeng et al., 2020). Such works have revolved mostly on analysing argumentative strategies and their effect on others.

Recently, Al Khatib et al. (2020) demonstrated that incorporating the personality traits of the resistor was influential in determining their resistance to persuasion. Such an observation acknowledges the power vested in an individual to resist change to their existing beliefs. Our work exhibits significant departure from this because we explicitly characterise the resisting strategies employed by the user. Moreover, our work focuses on the general domain of non-collaborative task-oriented dialogues, where several non-factual resisting strategies are observed, making it distinctly different from argumentation (Galitsky et al., 2018). We assert that focusing on both parties is imperative to get a complete picture of persuasive conversations.

3 Framework

In this section, we describe the datasets, the resisting strategies employed, and the annotation framework to instantiate the strategies.

3.1 Dataset Employed

We choose persuasion-oriented conversations, rather than essays or advertisements (Yang et al., 2019), since we can observe how the participants respond to the persuasion attempts in real-time. To that end, we leverage two publicly available corpora on persuasion (Wang et al., 2019) and negotiation (He et al., 2018). We refer to these datasets as "Persuasion4Good" or P4G and "Craigslist Bargain" or CB hereafter.

P4G comprises conversational exchanges between two anonymous Amazon Mechanical Turk workers with designated roles of the persuader, ER and persuadee, EE. ER had to convince EE to donate a part of their task earnings to the charity *Save the Children*. We investigate the resisting strategies employed only by EE in response to the donation efforts. We emphasise that the conversational exchanges are not scripted, and the task is set up so that a part of EE's earnings is deducted if they agree to donate. Since there is a monetary loss at stake for EE, we expect them to resist.

CB consists of simulated conversations between a buyer (BU) and a seller (SE) over an online exchange platform. Both are given their respective target prices and employ resisting strategies to negotiate the offer.

We choose these datasets since they involve non-collaborative goal-oriented dialogues. As a result, we can definitively assess the impact of different resisting strategies on the goal.

Resisting Strategy	Persuasion (P4G)	Negotiation (CB)
Source Derogation	Attacks/doubts the organisation's credibility. *My money probably won't go to the right place*	Attacks the other party or questions the item. *Was it new denim, or were they someone's funky old worn out jeans?*
Counter Argument	Argues that the responsibility of donation is not on them or refutes a previous statement. *There are other people who are richer*	Provides a non-personal argument/factual response to refute a previous claim or to justify a new claim. *It may be old, but it runs great. Has lower mileage and a clean title.*
Personal Choice	Attempts to saves face by asserting their personal preference such as their choice of charity and their choice of donation. *I prefer to volunteer my time*	Provides a personal reason for disagreeing with the current situation or chooses to agree with the situation provided some specific condition is met. *I will take it for $300 if you throw in that printer too.*
Information Inquiry	Ask for factual information about the organisation for clarification or as an attempt to stall. *What percentage of the money goes to the children?*	Requests for clarification or asks additional information about the item or situation. *Can you still fit it in your pocket with the case on?*
Self Pity	Provides a self-centred reason for not being able/willing to donate at the moment. *I have my own children*	Provides a reason (meant to elicit sympathy) for disagreeing with the current terms. *$130 please I only have $130 in my budget this month.*
Hesitance	Attempts to stall the conversation by either stating they would donate later or is currently unsure about donating. *Yes, I might have to wait until my check arrives.*	Stalls for time and is hesitant to commit; specifically, they seek to further the conversation and provide a chance for the other party to make a better offer. *Ok, would you be willing to take $50 for it?*
Self-assertion	Explicitly refuses to donate without even providing a factual/personal reason *Not today*	Asserts a new claim or refutes a previous claim with an air of finality/ confidence. *That is way too little.*

Table 1: Framework describing the resisting strategies for persuasion (P4G) and negotiation (CB) datasets. We emphasise that Information Inquiry is not a resisting strategy for CB. Examples of each strategy are italicised.

Properties	**P4G**	**CB**
# of conversations	530	800
Max # of utterances/conversation	76	44
Avg # of utterances/conversation	36.34	11.94
Max # of tokens/utterance	90	93
Avg # of tokens/utterance	11.03	14.62
Vocabulary size	6137	5370

Table 2: Description for the Persuasion (P4G) (Wang et al., 2019) and Negotiation (CB) (He et al., 2018) datasets

3.2 Framework Description

In this subsection, we briefly describe the resisting strategies commonly referenced in social and cognitive psychology literature. This enables us to design a unified framework for the two datasets, built upon common underlying semantic themes. Fransen et al. (2015a) identified 4 major clusters of resisting strategies, namely **contesting** (Wright, 1975; Zuwerink Jacks and Cameron, 2003; Abelson and Miller, 1967), **empowerment** (Zuwerink Jacks and Cameron, 2003; Sherman and Gorkin, 1980), **biased processing** (Ahluwalia, 2000), and **avoidance** (Speck and Elliott, 1997). Each individual category can be subdivided into finer categories showcased in italics henceforth.

Contesting refers to attacking either the source of the message (*Source Derogation*) or its content (*Counter Argumentation*). A milder form of contesting involves seeking clarification or information termed *Information Inquiry*. Prior work has shown a positive association between working knowledge and one's ability to resist persuasion (Wood and Kallgren, 1988; Luttrell and Sawicki, 2020). Therefore, *Information Inquiry* can be interpreted as a form of resistance where the resistor seeks to satisfy their doubts because they are sceptical of the persuader's intents or messages. This is prominent in certain conversations in P4G where a sceptical EE questions the charity's legitimacy.

Empowerment strategies encompass reinforcing one's personal preference to refute a claim (*Attitude Bolstering*) (Sherman and Gorkin, 1980), attempting to arouse guilt in the opposing party (*Self Pity*) (Vangelisti et al., 1991; O'Keefe, 2002), stating one's wants outright (*Self Assertion*) (Zuwerink Jacks and Cameron, 2003), or seeking validation from like-minded people (*Social Validation*) (Fransen et al., 2015a). Overall, empowerment strategies drive the discussion towards the resistor's self as opposed to attacking the persuader.

Biased processing mitigates external persuasion by selectively processing information that conforms with one's opinion or beliefs (Fransen et al., 2015a). For simplicity, we subsume strategies that denote personal preference, namely *Attitude Bolstering* and *Biased Processing*, into a unified category *Personal Choice*. We refrain from incorporating *Self Assertion* into the *Personal Choice* category since it deals with bolstering one's confidence and not one's opinions or attitudes. The subtle difference is highlighted in Table 1.

Avoidance strategies distance the resistor from persuasion, either physically or mechanically, or refuse to engage in topics that induce cognitive dissonance (Fransen et al., 2015a). However, in the context of task-oriented conversations, wherein participants are expected to further a goal, avoidance often manifests as *Hesitance* to commit to the current situation.

We identify seven major resisting strategies across the datasets, namely *Source Derogation, Counter Argumentation, Information Inquiry, Personal Choice, Self Pity, Hesitance,* and *Self Assertion*. Since the datasets comprise two-party conversations between strangers, *Social Validation*, which requires garnering the support of others, was absent. We now describe how these resisting strategies were instantiated in the following section.

3.3 Instantiating the Resistance Framework

We emphasise that although the description and meaning of a strategy remain the same across the two datasets, their semantic interpretation depends on the context. For example, scepticism towards the charity in P4G and criticism of the product in CB are instances of *Source Derogation*. This is because ER represents the charity, whereas the seller is being accused of selling an inferior product. Likewise, we instantiate the predicates for the remaining six resisting strategies for the two datasets, with examples in Table 1.

We label the utterances of persuadee (EE) in P4G and the buyers (BU) and sellers (SE) in CB with at least one of the seven corresponding resisting strategies, or 'Not-A-Strategy' if none applies. The 'Not-A-Strategy' label includes greetings, off-task discussions, agreement, compliments, or other tokens of approval. We acknowledge that an utterance can have more than one resisting strategy embedded in it. For example, the utterance "The price is slightly high for used couches, would you come down to 240 if I also picked them up?", is an instance of both *Personal Choice* and *Counter Argumentation*.

We also note that ***Information-Inquiry* is not a resisting strategy for CB** since asking additional information/clarification is an expected behaviour before finalising a deal. We keep the label nevertheless to show comparison with P4G. We present the flowchart detailing the annotation framework in Figure 3 of Appendix.

3.4 Annotation Procedure and Validation

We describe the annotation procedure for both the CB and P4G dataset here and its subsequent validation. For CB, three authors independently annotated five random conversations adhering to the flowchart. If the conversations chosen were simple or had few labels, a new set of 5 conversations were taken up. This constitutes one round. After each round, the Fleiss Kappa score was computed, and the authors discussed to resolve the disagreements and revise the flowchart. Then began the next round on a new set of 5 random conversations. For CB, 5 rounds of revision were carried out over 24 conversations, until a high Fleiss kappa (0.790) (Fleiss, 1971) was obtained. Finally, the three authors independently went ahead and annotated approximately 250 distinct conversations, yielding a corpus of 800 CB conversations. Our annotation procedure requires a rigorous reliable refinement phase but a comparatively faster annotation phase by dividing the annotation between the authors. Thus the conversations annotated by each author were mutually exclusive. Similarly, for P4G dataset, four authors annotated 3 conversations per round, since a conversation in P4G was comparatively longer. 4 rounds of revision across 12 conversations was done to achieve the final kappa-score of 0.787. The four authors then went ahead and divided the task of annotating the 500 conversations amongst themselves. We show an annotated conversation snippet for the two datasets in Table 3.

3.5 Dataset Statistics

The P4G and CB datasets comprise 530 and 800 labelled conversations, respectively, spanning an average of 37 and 12 utterances per conversation.

Role	Text	Strategy
	Negotiation (CB)	
SE	I have a wonderful phone for you if you are interested.	No Strategy
BU	I am interested. Did you just buy it?	Info inquiry
SE	I bought it two weeks ago but it just wasn't what I needed anymore.	No Strategy
BU	Would you be willing to work with the price?	Hesitance
SE	Yes we can negotiate.	No Strategy
BU	If I come today would you accept $56 I can bring it now?	Per Choice
SE	How about 65 and I can deliver it to you now?	Per Choice
BU	Can you go $60 Kind of all I have right now ?	Self Pity
SE	Yes I can.	No Strategy
	Persuasion (P4G)	
ER	Hello, Save the Children looks like an interesting organisation.	-
EE	i would like to know more about it	Info Inquiry
..	..	..
EE	thanks i will definitely check it out	Hesitance
ER	They also promote children's rights and provide relief when needed.	-
EE	and where does the money go if i do donate ?	Info Inquiry
EE	Straight to the organisation?	Info Inquiry
ER	Yes, it goes straight to the organisation, where it can be used to help many children.	-
EE	because some organisations do not divide the money properly	Source Derogation
ER	This organisation has been checked by some groups, and they divide the money properly.	-
..	..	..
EE	I will certainly consider it	No Strategy

Table 3: Examples of annotation snippets for the Persuasion (P4G) and Negotiation (CB). The utterances of the EE and the SE are highlighted in cyan. Some strategies are shortened, like Info Inquiry, and Per Choice for Information Inquiry and Personal Choice.

The datasets cover two distinct persuasion scenarios and also illustrate the rights and obligations shown by the participants. For example, in P4G, EE comes into the interaction blind and is unaware of the donation attempt. We encounter several conversations where EE is willing to donate since it resonates with their beliefs, and no resisting strategies are observed. However, for CB, the participants received prior instructions to negotiate a deal, and hence resisting strategies were more prominent. We present the frequency distribution of the seven strategies in Table 4. We observe that the distributions of strategies are skewed for both the datasets and is more pronounced for P4G, where 'Not-A-Strategy' accounts for the lion's share. We also see that the buyer exhibits more resisting strategies than the seller highlighting the asymmetric role of the two participants.

Nevertheless, we reiterate that the resisting strategies we propose are applicable for both the domains. In the next section, we propose the framework to infer such strategies automatically.

Strategy	Persuasion (P4G)	Negotiation (CB)	
	EE	BU	SE
Source Derogation	2.16	7.61	0.44
Counter Argument	2.28	3.74	6.06
Personal Choice	2.52	9.43	8.49
Information Inquiry	7.19	18.27	0.38
Self Pity	1.58	4.66	0.34
Hesitance	1.76	15.78	9.14
Self-assertion	0.94	2.20	5.05
Not a strategy	81.56	38.30	70.09

Table 4: Proportion of resisting strategies (in %)for the Persuasion (P4G) and Negotiation (CB) dataset. The strategies are observed only for the persuadee (EE) in P4G and for both buyer (BU) and seller (SE) in CB.

4 Methodology

In this section, we describe the methodology adopted for inferring the resisting strategies in persuasion dialogues and how they can be leveraged to determine the dialogue's outcome.

4.1 Resisting Strategy prediction

We model the task of identifying resisting strategies as a sequence labelling task. We assign each utterance in the dialogues with a label representing either one of the seven resisting strategies or *Not-A-Strategy*.

Since the resisting strategies, by definition, occur in response to the persuasion attempts, our model architecture needs to be cognizant of the conversational history. To that end, we adopt a hierarchical neural network architecture, similar to Jiao et al. (2019), to infer the corresponding resisting strategy. The architecture leverages the previous conversational context in addition to the current contextualised utterance embedding. Our choice is motivated by the recent successes of hierarchical sequence labelling frameworks in achieving state-of-the-art performance on several dialogue-oriented tasks. Some myriad examples include emotion recognition (Majumder et al., 2019; Jiao et al., 2019), dialogue act classification (Chen et al., 2018; Raheja and Tetreault, 2019), face act prediction (Dutt et al., 2020), open domain chit-chat (Zhang et al., 2018; Kumar et al., 2020) and the like. We hereby adopt this as the foundation architecture for our work and refer to our instantiation of the architecture as RESPER.

Architecture of RESPER: An utterance u_j

We acknowledge that an utterance can have multiple labels. However, such utterances comprise only 1.2% and 3.85% of the P4G and the CB datasets, respectively. In such cases, the label is randomly selected.

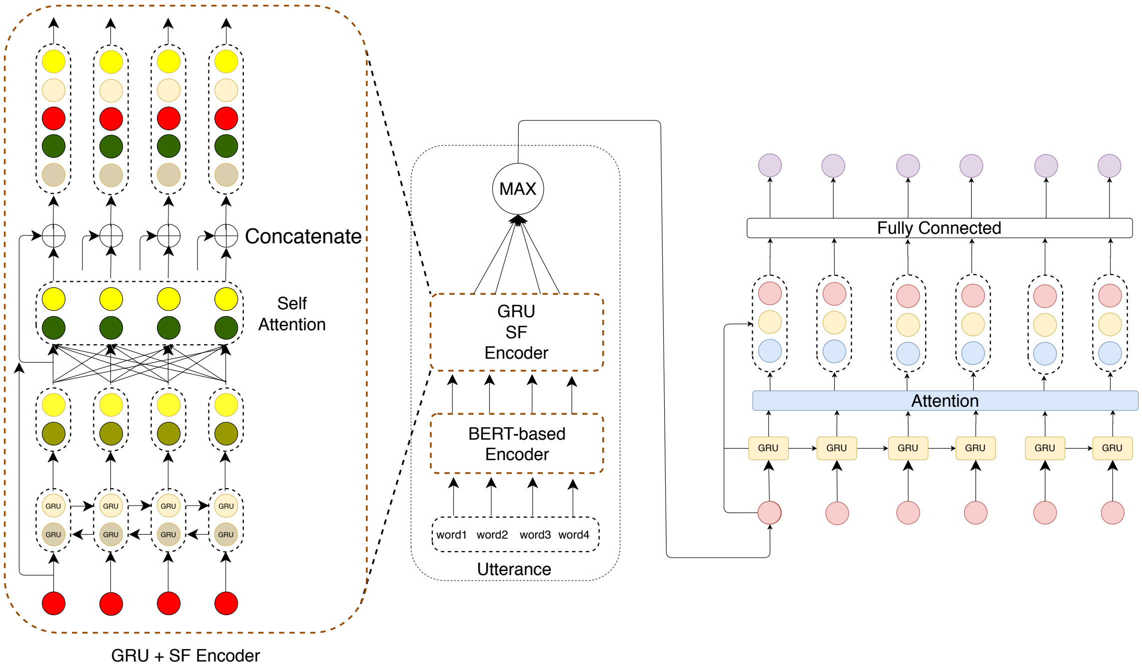

Figure 1: A diagram illustrating how ResPer works. The encoder shown on the left takes the BERT representations of a token as input and passes it through a BiGRU layer followed by Self Attention. The outputs from BERT, BiGRU and self-attention are then concatenated to form the output. Max-pooling over this output yields the corresponding utterance embedding. This utterance representation is passed through a uni-directional GRU followed by Masked-Self-Attention and fusion to yield the contextualised utterance embedding.

is composed of tokens $[w_0, w_1, ..., w_K]$ represented by their corresponding embeddings $[e(w_0), e(w_1), ..., e(w_K)]$. In ResPer, we obtain these using a pre-trained BERT model (Devlin et al., 2019). We pass these contextualised word representations through a bidirectional GRU to obtain the forward $\overrightarrow{h_k}$ and backward $\overleftarrow{h_k}$ hidden states of each word, before passing them into a Self-Attention layer. This gives us the corresponding attention outputs, $\overrightarrow{ah_k}$ and $\overleftarrow{ah_k}$ as described below.

$$\overrightarrow{h_k} = \text{GRU}\left(e\left(w_k\right), \overrightarrow{h_{k-1}}\right)$$
$$\overleftarrow{h_k} = \text{GRU}\left(e\left(w_k\right), \overleftarrow{h_{k+1}}\right)$$
$$\overrightarrow{ah_k} = SelfAttention(\overrightarrow{h_k})$$
$$\overleftarrow{ah_k} = SelfAttention(\overleftarrow{h_k})$$

Finally, we concatenate the contextualised word embedding with the GRU hidden states and Attention outputs in the *fusion layer* to obtain the final representation of the word $e_c(w_k)$. We represent the bias as b_w. Here, We perform max-pooling over the fused word embeddings to obtain the j^{th} utterance embedding, $e(u_j)$.

$$e_c(w_k) = \tanh(W_w[\overrightarrow{ah_k}; \overrightarrow{h_k}; e(w_k); \overleftarrow{h_k}; \overleftarrow{ah_k}] + b_w)$$
$$e(u_j) = \max(e_c(w_1), e_c(w_2), ...e_c(w_K))$$

We use a unidirectional GRU and Masked Self-Attention to encode conversational context, to ensure that the prediction for the j^{th} utterance is not influenced by future utterances. Similarly, we calculate the contextualized representation of an utterance $e_c(u_j)$ using the conversation context. We pass $e(u_j)$ through a uni-directional GRU that yields the forward hidden state $\overrightarrow{H_j}$. Masked Self-Attention over the previous hidden states, yields $\overrightarrow{AH_j}$. We fuse $e(u_j)$, $\overrightarrow{H_j}$ and $\overrightarrow{AH_j}$ before passing it through a linear layer with tanh activation to obtain $e_c(u_j)$.

We project the final contextualised utterance embedding $e_c(u_j)$ onto the state space of resisting strategies. We apply softmax to obtain a probability distribution over the strategies, with Negative Log-Likelihood (NLL) as the loss function to obtain the strategy loss.

4.2 Conversation Outcome prediction

We further investigate the impact of resisting strategies on the outcome of the conversation. We represent a strategy as a fixed dimensional embedding initialised at random. We subsequently encode a sequence of strategies by passing them through a unidirectional GRU to obtain a final representation for the sequence. We project the representation onto a binary vector which encodes for the conversation outcome. We apply softmax with NLL across all the conversations to obtain the outcome prediction loss.

5 Experiments

In this section, we describe the baselines and evaluation metrics. We present the experimental details of our model in Table 5.

5.1 Baselines

Resisting strategy prediction: We experiment with standard neural baselines for text classification, which have also been used in classifying persuasion strategies, namely CNN (Kim, 2014; Wang et al., 2019) and BiGRU (Yang et al., 2019). To ensure a fair comparison, we introduce pre-trained BERT-embeddings (Devlin et al., 2019) as input to the baselines, henceforth denoted as BERT-CNN and BERT-BiGRU. Furthermore, to inspect the impact of conversational history, we remove the conversational GRU from RESPER such that the utterance embedding $e(u_j)$ is directly used for prediction. We refer to this architecture as BERT-BiGRU-sf, since it employs self-attention(s) and fusion (f) on top of BERT-BiGRU. Finally, we experiment with the best performing HiGRU-sf model of Jiao et al. (2019) as another baseline.

Conversation success prediction: The notion of conversation success depends on the choice of dataset. For P4G, we consider the resisting strategies to be successful if the persuadee (EE) refused to donate to charity. For CB, we adopt the same notion of success as Zhou et al. (2019), namely when the seller (SE) can sell at a price greater than the median sale-to-list ratio r.

$$r = \frac{\text{sale price} - \text{buyer target price}}{\text{listed price} - \text{buyer target price}} \quad (1)$$

To observe the effect of conversation success, we experiment with strategies of both the parties involved. For P4G, we encode separately (i) the persuasion strategies of ER as identified by Wang et al. (2019), (ii) the resisting strategies employed by EE and (iii) both the persuasion and resisting strategies. Likewise, for CB, we encode the resisting strategies of only (i) the buyer (BU) (ii) the seller (SE) (iii) both. These experiments would enable us to investigate which party has a greater influence on conversation success.

Hyper-parameter	**Search space**	**Final Value**
learning-rate (lr)	1e-3 to 1e-5	1e-4
Batch-size	-	1 conversation
#Epochs	< 100	30.8, 22
lr-decay	-	0.5 every 20 epochs
d_{h1}	-	1024
d_{h2}	-	300

Table 5: Here we describe the search-space of all the hyper-parameters used in our experiments and describe the search space we used to find the hyper-parameters. d_{h1}, d_{h2} represents the hidden dimensions of the Utterance GRU and the Conversation GRU.

5.2 Evaluation metrics

We adopt the same evaluation procedure for both the resisting strategy and the conversation outcome prediction task across the datasets. In either case, we perform five-fold cross-validation due to paucity of annotated data. We report performance in terms of the weighted and macro F1-scores across the five folds. Our choice of the metric is motivated by the high label imbalance, as observed in Table 4.

6 Results

In this section, we answer the following :

Q1. How well does RESPER identify resisting strategies for Persuasion and Negotiation?

Q2. Are resisting strategies good predictors of conversation success? What insights can one glean from the results?

6.1 Predicting resisting strategies

We present the results for the automated identification of resisting strategies in Table 6. We observe that all the models achieve a comparatively lower performance on P4G, mainly due to the higher proportion of 'Not-a-Strategy' labels for the latter. We gauge the benefits of incorporating conversational context by the significant improvement of Macro F1 score by 0.036 and 0.011 for P4G and CB respectively. In fact, RESPER outperforms all the proposed baselines significantly.

Error Analysis: We present the confusion matrix for predicting resisting strategies using RESPER on the Persuasion (P4G) and Negotiation (CB)

Weighted F1 Scores are calculated by taking the average of the F1 scores for each label weighted by the number of true instances for each label.

We estimate the statistical significance using the paired bootstrapped test of Berg-Kirkpatrick et al. (2012), due to the small number of data (Dror et al., 2018).

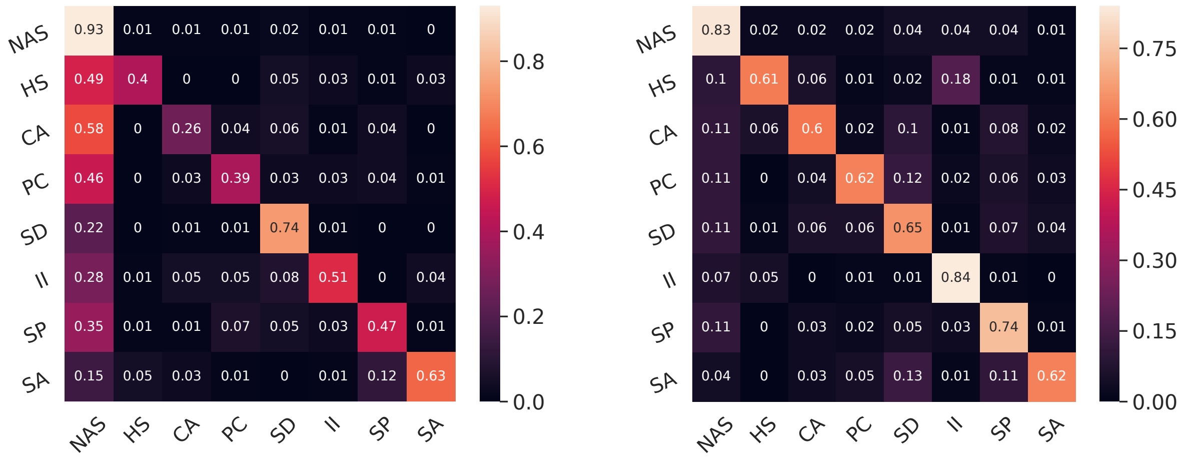

Figure 2: Confusion matrix for resisting strategies for the Persuasion (P4G) and Negotiation (CB) datasets on the left and right respectively. Each resisting strategy is represented as its initial (**S**elf **P**ity) as SP. True and Predicted Labels have been plotted on the X-axis and the Y-axis respectively.

Model	Persuasion (P4G)		Negotiation (CB)	
	M-F1	W-F1	M-F1	W-F1
CNN	0.261	0.757	0.560	0.706
BERT + CNN	0.508	0.819	0.651	0.751
HiGRU-sf	0.446	0.788	0.605	0.734
BERT + BiGRU	0.514	0.815	0.647	0.747
BERT + BiGRU-sf	0.522	0.814	0.649	0.750
RESPER	**0.558**	**0.828**	**0.662**	**0.767**

Table 6: Results of RESPER and other baselines on the resistance strategy prediction task on the Persuasion and CB dataset. The metrics used for evaluation are Macro F1 and Weighted F1 represented as M-F1 and W-F1 respectively. The best results are in bold.

Persuasion (P4G)			Negotiation (CB)		
User	Macro-F1	W-F1	User	Macro-F1	W-F1
ER	0.588	0.620	BU	**0.618**	**0.640**
EE	0.618	0.640	SE	0.462	0.508
Both	**0.646**	**0.671**	Both	0.605	0.626

Table 7: We observe the impact of incorporating sequence of strategies on conversation outcome prediction in terms of Macro-F1 and Weighted-F1 score. For P4G, we observe strategies of the persuader (ER), persuadee (EE) and both. For CB, we observe strategies of the buyer (BU), seller (SE) and both.

datasets in Figures 2(a) and 2(b) respectively. We observe that most classification errors occur when a resisting strategy is incorrectly inferred as 'Not-A-Strategy'. The effect is more prevalent for P4G since 'Not-A-Strategy' comprises 80% of all annotated labels. Other notable instances of misclassification for P4G occurs when *Self Assertion* is predicted as *Self Pity* since both strategies refer to one's self. These strategies occur so infrequently (see Table 4) that the models lack sufficient information to distinguish between the two categories. Likewise, for the CB corpus, *Hesitance* utterances which constitute a price request, are often posed as questions. This causes the model to predict the strategy as *Information Inquiry* instead. *Self Assertion* is often incorrectly marked as *Source Derogation* possibly because it often takes a firm stance, and is likely to disparage the other party in the process, thereby confusing the model.

6.2 Conversation Outcome Prediction

We observe how the sequence of strategies adopted by the two participants have a disproportionate impact on the final conversation outcome in Table 7. It is interesting to note that the resisting strategies for the persuadee have a greater effect on the conversation outcome (macro-F1 score of 0.62) than the persuasion strategies themselves (macro-F1 score of 0.59). Moreover, incorporating both the persuasion and resisting strategies boosts the prediction performance even further to 0.65.

We also observe an asymmetry in the roles of the buyer (BU) and the seller (SE) for the CB dataset. We observe that BU's strategies are significantly more effective in deciding the conversation outcome, probably because buyers demonstrate a higher number of resisting strategies. These experiments highlight the importance of incorporating resisting strategies to gain a complete picture.

6.3 Comparative Analysis of Strategies

Emboldened by the success of resisting strategies to infer the conversational outcome, we probe deeper to investigate the impact of individual strategies. We apply logistic regression with the frequency of strategies, of either participant, as the features while the outcome variable denotes conversation success. We observe the coefficients of the strategies to infer their correlation with conversation success and their corresponding p-values to determine whether the correlation was indeed statistically significant. Our procedure follows previous work in identifying influential persuasion strategies (Yang et al., 2019; Wang et al., 2019). We present the results of this analysis in Table 8.

	Persuasion (P4G)	Negotiation (CB)	
Strategy	EE	BU	SE
Not-A-Strategy	-0.008	0.287**	-0.138
Hesitance	0.344	0.328*	0.266
Counter Argument	-0.014	-0.256	0.429*
Personal Choice	0.153	0.126	0.164
Information Inquiry	0.180*	0.091	-0.704
Source Derogation	0.043	0.052	-0.455
Self Pity	0.103	0.081	-0.314
Self Assertion	0.843*	-0.576*	-0.040

Table 8: Coefficients of the different persuasion strategies corresponding to the persuadee, EE in Persuasion and the buyer, BU, and seller, SE in Negotiation. A value of * and ** means the strategy is signficant with p-value ≤ 0.05 and 0.01 respectively.

For P4G, all the resisting strategies for persuasion apart from *Counter-Argumentation* are positively correlated with a refusal to donate. The highest impact stems from *Self Assertion*. Previous research (Fransen et al., 2015a; Zuwerink Jacks and Cameron, 2003) has noticed that *Self Assertion* is prominent amongst individuals with high self-esteem. Such individuals are confident about their beliefs and less likely to conform. Similarly, a high positive coefficient for *Information Inquiry* can be attributed as follows. EE inquires information about the charity not only as a means to verify their legitimacy, but also to gain the knowledge they can exploit to their advantage. An innocuous question like ‘Where will my money go?’ would enable EE to assert that they are keener to help children in their own country instead, thereby resisting the donation attempt and saving face.

The CB scenario setup ensures that the coefficients of the strategies set for BU and SE would be anti-correlated, which holds for the Table 8. Like P4G, a high negative coefficient of *Self Assertion* signifies that SE’s price is disagreeable to BU - they would instead not buy. Moreover, the high coefficient of *Counter Argumentation* justifies that it is an effective tactic for both parties.

7 Conclusion

We present a generalised computational framework grounded in cognitive psychology to operationalise resisting strategies employed to counter persuasion. We identify seven distinct resisting strategies that we instantiate on two publicly available corpora comprising persuasion and negotiation conversations. We adopt a hierarchical sequence labelling architecture to infer the resisting strategies automatically and observe that our model achieves competitive performance for both datasets. Furthermore, we examine the interplay of resisting strategies in determining the final conversation outcome, which corroborates with previous findings. In the future, we would like to explore better models to encode the strategy information and apply our framework to improve personalised persuasion and negotiation dialogue systems. We would also like to study the influence of other confounding factors such as power dynamics on the outcomes of conversations featuring resisting strategies.

Acknowledgments

We thank the anonymous EACL reviewers for their insightful comments and constructive feedback. This research was funded in part by NSF Grants (IIS 1917668 and IIS 1822831) and Dow Chemical. The first author would also like to acknowledge his best friend, Ahana Sadhu, for her constant support and motivation, who unfortunately and untimely left us this year.

Abstract

The slow speed of BERT has motivated much research on accelerating its inference, and the early exiting idea has been proposed to make trade-offs between model quality and efficiency. This paper aims to address two weaknesses of previous work: (1) existing fine-tuning strategies for early exiting models fail to take full advantage of BERT; (2) methods to make exiting decisions are limited to classification tasks. We propose a more advanced fine-tuning strategy and a learning-to-exit module that extends early exiting to tasks other than classification. Experiments demonstrate improved early exiting for BERT, with better trade-offs obtained by the proposed fine-tuning strategy, successful application to regression tasks, and the possibility to combine it with other acceleration methods. Source code can be found at `https://github.com/castorini/berxit`.

1 Introduction

Large-scale pre-trained language models such as BERT (Devlin et al., 2019) have brought the natural language processing (NLP) community large performance gain but at the cost of heavy computational burden. While pre-trained models are available online and fine-tuning is typically done without a strict time budget, inference poses a much lower latency tolerance, and the slow inference speed of these models can impede easy deployment. It becomes even more difficult when inference has to be done on edge devices due to limited network capabilities or privacy concerns.

Early exiting (Schwartz et al., 2020; Xin et al., 2020a; Liu et al., 2020) has been proposed to accelerate the inference of BERT and models with similar architecture, i.e., those comprising multiple transformer layers (Vaswani et al., 2017) with a classifier at the top. Instead of using only one classifier, additional classifiers are attached to each transformer layer (see Figure 1), and the entire model is fine-tuned together. At inference time, the sample can perform early exiting through one of the intermediate classifiers.

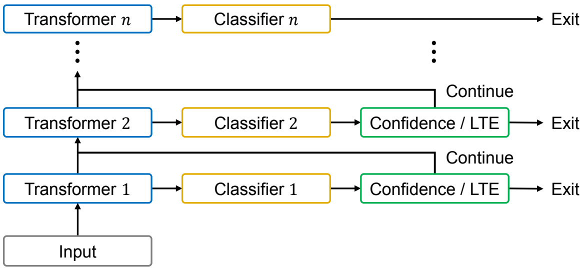

Figure 1: Multi-output structure of early exiting BERT.

While existing early exiting papers provide promising quality–efficiency trade-offs, improvements are necessary for two important components: fine-tuning strategies and exiting decision making. In these papers, fine-tuning strategies are relatively simple and fail to take full advantage of the pre-trained model's effectiveness; we propose a novel fine-tuning strategy, *Alternating*, for this multi-output model. Moreover, previous work makes exiting decisions based on the confidence of output probability distributions, and is hence only applicable to classification tasks; we extend it to other tasks by proposing the *learning-to-exit* idea. With carefully designed fine-tuning strategies and methods for making exiting decisions, the model can achieve better quality–efficiency trade-offs and can be extended to regression tasks.

We refer to our proposed ideas collectively as BERxiT (BERT+exit), and apply it to Muppets[1] including BERT, RoBERTa (Liu et al., 2019), and ALBERT (Lan et al., 2020); we also apply it on top of another BERT acceleration method, DistilBERT (Sanh et al., 2019). We conduct experiments

April 19 - 23, 2021.

on datasets including classification and regression tasks, and show that our method can save up to 70% of inference time with minimal quality degradation.

Our contributions include the following: (1) an effective fine-tuning method *Alternating*; (2) the *learning-to-exit* idea that extends early exiting to tasks other than classification; (3) extensive experiments that show the effectiveness of our ideas and the successful combination of early exiting with other BERT acceleration methods; (4) additional experiments that provide insight into the inner mechanism of pre-trained models.

2 Related Work

BERT (Devlin et al., 2019) is a pre-trained multi-layer transformer (Vaswani et al., 2017) model. RoBERTa (Liu et al., 2019) and ALBERT (Lan et al., 2020) are variants of BERT with almost identical model architectures but different training methods and parameter sharing strategies. In our paper, we refer to these transformer-based models as Muppets, and apply our method on them.

In the general deep learning context, there are a number of well-explored methods to accelerate model inference. Pruning (Han et al., 2015; Fan et al., 2020; Gordon et al., 2020) removes unimportant parts of the neural model, from individual weights to layers and blocks. Quantization (Lin et al., 2016; Shen et al., 2020) reduces the number of bits needed to operate a neural model and to store its weights. Distillation (Hinton et al., 2015; Jiao et al., 2020) transfers knowledge from large teacher models to small student models. These methods typically require pre-training Muppets from scratch[2] and produce only one small model with a predetermined target size. Early exiting requires only fine-tuning and also produces a series of small models, from which the user can choose flexibly. It extends the idea of Adaptive Computation (Graves, 2016) for recurrent neural networks, and is also closely related to BranchyNet (Teerapittayanon et al., 2016), Multi-Scaled DenseNet (Huang et al., 2018), and Slimmable Network (Yu et al., 2019).

Early exiting for Muppets has been explored by RTJ[3] (Schwartz et al., 2020), DeeBERT (Xin et al., 2020a,b), and FastBERT (Liu et al., 2020). Despite their promising results, there is still room for improvement regarding the fine-tuning strategies of RTJ and DeeBERT. FastBERT, on the other hand, uses self-distillation (Zhang et al., 2019; Phuong and Lampert, 2019) for fine-tuning, which works well for small Muppets such as BERT$_{\text{BASE}}$. However, our preliminary experiments[4] show that self-distillation is unstable on larger Muppets such as BERT$_{\text{LARGE}}$, suggesting that future work is necessary for fully understanding and robustly applying self-distillation on Muppets.

All these three methods make early exiting decisions based on confidence (or its variants) of the predicted probability distribution, and are therefore limited to classification tasks. Runtime Neural Pruning (Lin et al., 2017), SkipNet (Wang et al., 2018b), and BlockDrop (Wu et al., 2018) use reinforcement learning (RL) to decide whether to execute a network module. Universal Transformer (Dehghani et al., 2019) and Depth-Adaptive Transformer (DAT, Elbayad et al., 2020) use learned decisions for early exiting in sequence-to-sequence tasks. Concurrently, PABEE (Zhou et al., 2020) proposes patience-based early exiting which is applicable to regression, but it relies on inter-layer prediction consistency and is therefore not very efficient for exiting at early layers. Inspired by them, we propose a method to extend early exiting for Muppets to regression tasks, using only layer-specific information as in classification. Moreover, our method requires neither RL nor complicated distribution fitting as in DAT, but uses a straightforward layer-wise certainty estimation, and achieves performance comparable with confidence-based early exiting on classification tasks.

3 Model Structure and Fine-Tuning

We start from a pre-trained Muppet model (the *backbone* model), attach additional classifiers to it, fine-tune the model, and use it for accelerated inference by early exiting.

Backbone model The backbone model is an n-layer pre-trained Muppet model. We denote the i^{th} layer hidden state corresponding to the `[CLS]` token as $\mathbf{h}_i$:

$$\mathbf{h}_i = f_i(x; \theta_1, \cdots, \theta_i), \tag{1}$$

where x is the input sequence, θ_i is the parameters of the i^{th} transformer layer, and f_i is the mapping from input to the i^{th} layer hidden state.

---

[2] In distillation, there is typically a general distillation that uses the large-scale pre-training corpus and is time consuming (Jiao et al., 2020).

[3] Short for *Right Tool for the Job*—the paper does not provide a concise name for the method.

[4] See Appendix A.

Classifiers In the original BERT paper (Devlin et al., 2019), the way to fine-tune is to attach a classifier to the *final* transformer layer, and then to jointly update both the backbone model and the classifier. The classifier is a one-layer fully-connected network. It takes as input the final layer hidden state $\mathbf{h}_n$ and outputs a prediction. Its output is a probability distribution over all classes for classification tasks and a scalar for regression[5] tasks.

To enable early exiting, we instead attach a classifier to *every* transformer layer, i.e., there are n classifiers in total. Each classifier can make its own prediction, and therefore the model can accelerate inference by exiting earlier.

Fine-tuning strategies We discuss how to fine-tune this multi-output network. The loss function for the i^{th} layer classifier is

$$L_i(x, y) = H(y, g_i(\mathbf{h}_i; w_i)), \tag{2}$$

where x and y are the input sequence and corresponding label, g_i the i^{th} layer's classifier, w_i the parameters of g_i, and H the task-specific loss function, e.g., cross-entropy for classification tasks and mean squared error (MSE) for regression tasks.

The most straightforward fine-tuning strategy is perhaps minimizing the sum of all classifiers' loss functions and jointly updating all parameters in the process. We refer to this strategy as *Joint*, and it is also used in RTJ (Schwartz et al., 2020):

$$\min_{\substack{\theta_1,\cdots,\theta_n \\ w_1,\cdots,w_n}} \sum_{i=1}^{n} L_i. \tag{3}$$

If we hope to preserve the best model quality for the final layer, the desired fine-tuning strategy is *Two-stage*, which is also used in DeeBERT (Xin et al., 2020a). The first stage is identical to vanilla BERT fine-tuning: updating the backbone model and only the final classifier. In the second stage, we freeze all parameters updated in the first stage, and fine-tune the remaining classifiers. Objectives in the two stages are as follows.

$$\text{Stage 1:} \quad \min_{\substack{\theta_1,\cdots,\theta_n \\ w_n}} \quad L_n \tag{4}$$

$$\text{Stage 2:} \quad \min_{w_1,\cdots,w_{n-1}} \quad \sum_{i=1}^{n-1} L_i \tag{5}$$

These two fine-tuning strategies are not ideal. Intuitively, in this multi-output network, loss functions of different classifiers interfere with each other in a *negative* way. Transformer layers have to provide hidden states for two competing purposes: immediate inference at the adjacent classifier and gradual feature extraction for future classifiers. Therefore, achieving a balance between the classifiers is critical. *Two-stage* produces final classifiers with optimal quality at the price of earlier layers, since most parameters are solely optimized for the final classifier. *Joint* treats all classifiers equally, and therefore its final classifier is less effective than that of *Two-stage*. To combine the advantages, we propose a novel fine-tuning strategy, *Alternating*. It alternates between two objectives (taken from Equation 3 and 4) for odd-numbered and even-numbered iterations.

$$\text{Odd:} \quad \min_{\substack{\theta_1,\cdots,\theta_n \\ w_n}} \quad L_n \tag{6}$$

$$\text{Even:} \quad \min_{\substack{\theta_1,\cdots,\theta_n \\ w_1,\cdots,w_n}} \quad \sum_{i=1}^{n} L_i \tag{7}$$

Combining objectives from *Joint* and *Two-stage*, *Alternating* has the potential to find the most preferable region in the parameter space: the intersection between optimal regions for different layers.

4 Exiting Decision Making

After the entire model (including the backbone and all classifiers) is fine-tuned, it can perform early exiting for an inference sample. In this section we discuss two methods to make exiting decisions.

4.1 Confidence Threshold

When the model is "certain" enough of its prediction at an intermediate layer, the forward inference can be terminated.

For classification tasks, a straightforward measurement of the prediction certainty is the maximum probability of the output prediction, which is referred to as *confidence* in previous work (Schwartz et al., 2020; Liu et al., 2020). Similarly, Xin et al. (2020a) use entropy as the metric, which is also closely related to confidence. Before inference starts, a confidence threshold is chosen. In forward propagation, the confidence of the output at each layer is compared with the threshold; if it is larger than the threshold at a certain layer, the sample exits and future layers are skipped.

---

[5] In this case, we still refer to this one-layer network as *classifier* for naming consistency.

4.2 Learning to Exit

While using a confidence or entropy threshold is straightforward and effective, it is exploiting the fact that the classifier's output is a probability distribution in classification tasks. This is generally not the case for other tasks such as regression. To address the gap, we propose *learning-to-exit* (LTE) as a substitute when the distribution is unavailable.

The i^{th} layer hidden state $\mathbf{h}_i$ is a vector in the embedding space. Intuitively, different regions of the embedding space have different certainty levels. For instance, in binary classification tasks, regions closer to the decision boundary have a lower certainty level, and this is explicitly expressed as a lower confidence of the output probability distribution. But even when certainty cannot be explicitly measured, we can still train an auxiliary LTE module to estimate such a metric.

Concretely, the LTE module is a simple one-layer fully-connected network. It takes as input the hidden state $\mathbf{h}_i$ and outputs the certainty level u_i of the sample at the i^{th} layer:

$$u_i = \sigma(\mathbf{c}^\top \mathbf{h}_i + b), \qquad (8)$$

where σ is the sigmoid function, $\mathbf{c}$ is the weight vector, and b is the bias term.

The loss function for the LTE module is a simple MSE between u_i and the "ground truth" certainty level at the i^{th} layer $\tilde{u}_i$:

$$J_i = ||u_i - \tilde{u}_i||_2^2. \qquad (9)$$

For classification, the ground truth certainty level is whether the classifier makes the correct prediction:

$$\tilde{u}_i = \mathbb{1}[\arg\max_j g_i^{(j)}(\mathbf{h}_i; w_i) = y], \qquad (10)$$

where g_i is the output probability distribution at the i^{th} layer and $g_i^{(j)}$ is its j^{th} entry. For regression, the ground truth certainty level is negatively related to the prediction's absolute error:

$$\tilde{u}_i = 1 - \tanh(|g_i(\mathbf{h}_i; w_i) - y|). \qquad (11)$$

To apply LTE, we initialize the LTE module together with classifiers and it is shared among all layers. We train the LTE module jointly with the rest of the model by *substituting* L_i in Equation 3–7 with $L_i + J_i$. At inference time, if the predicted certainty level is higher than the chosen threshold, the inference sample performs early exiting.

Table 1: Statistics of datasets.

5 Experiments

5.1 Setup

We conduct experiments on six classification datasets of the GLUE benchmark (Wang et al., 2018a); since there is only one regression dataset, STS-B (Cer et al., 2017), in GLUE, we additionally use another regression dataset, SICK (Marelli et al., 2014). Statistics of these datasets are listed in Table 1. Our implementation is adapted from the Huggingface Transformer Library (Wolf et al., 2020). We conduct searches on experiment settings such as the optimizer, learning rates, hidden state sizes, and dropout probabilities, and discover that it is best to keep original settings from the library. Random seeds are also unchanged from the library for fair comparisons.[6]

Most results in this paper use the dev split, since the large number of evaluations we need are forbidden by the GLUE evaluation server. The only exception is Table 2, where we report model quality–efficiency trade-offs on the test split.

5.2 Layer-wise Scores Comparison

We discuss three fine-tuning strategies in Section 3: *Joint* (also used in RTJ), *Two-stage* (also used in DeeBERT), and *Alternating* (proposed in this paper). In tables and figures, they are labeled respectively as JOINT, 2STG, and ALT. Figures 2 and 3 compare these three fine-tuning strategies by showing their *layer-wise score* curves: each point in the curve shows the output score at a certain exit layer, i.e., all samples are required to exit at this layer for evaluation. More specifically, we report *relative* scores, and the 100% baseline is the original score of the vanilla Muppet without early exiting, and

---

[6] Detailed experiment settings are in Appendix B.

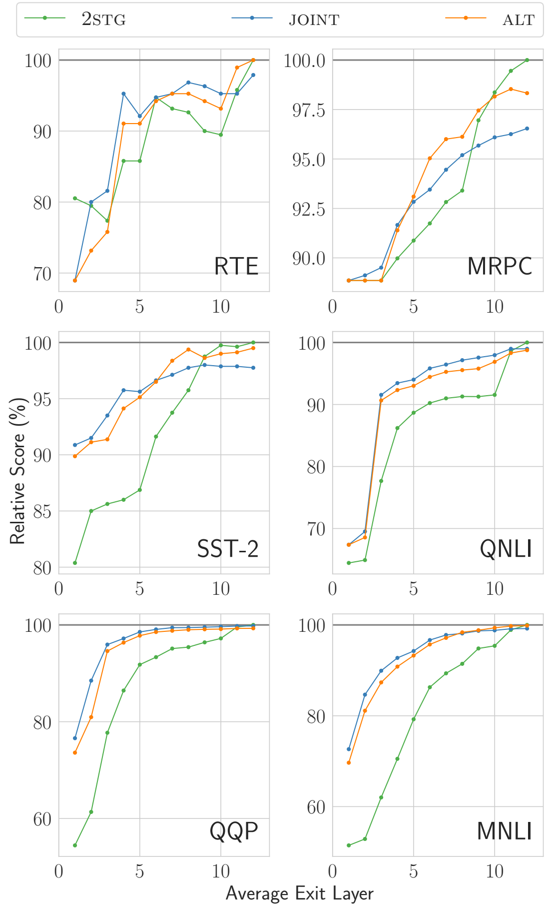

Figure 2: Layer-wise scores of different fine-tuning strategies for BERT$_{\text{BASE}}$.

this is also the score of the final layer of *Two-stage* because of parameter freezing in its second stage.

For BERT$_{\text{BASE}}$, we show plots for all six classification datasets, ordered by their training set sizes from smallest to largest. As we will see in later analyses, low-resource datasets show the most difference. Therefore, for RoBERTa$_{\text{BASE}}$ and ALBERT$_{\text{BASE}}$, we only show plots for RTE and MRPC (with training set size smaller than 6% of others) due to space limitations.[7]

We observe the following from the figures:

- *Two-stage* is unsatisfying. While it achieves the best score at the final layer, it comes at a large cost of other layers, especially for non-low-resource datasets.
- *Alternating* is better than *Joint* in later layers, and weaker in earlier layers. However, as we will see in the next section, when we evaluate quality–efficiency trade-offs of confidence-based early exiting, the weakness of *Alternating* in earlier layers is no longer substantial, while its advantage is preserved.
- The difference between *Joint* and *Alternating* is larger for low-resource datasets, where the training set is insufficient to fine-tune all layers well simultaneously.
- Interestingly, for ALBERT$_{\text{BASE}}$, *Alternating*'s relative scores are higher than 100% in the final layers. We speculate that this is because of the parameter sharing nature of ALBERT and the small sizes of the datasets: better supervision for intermediate layers also helps the final layer.

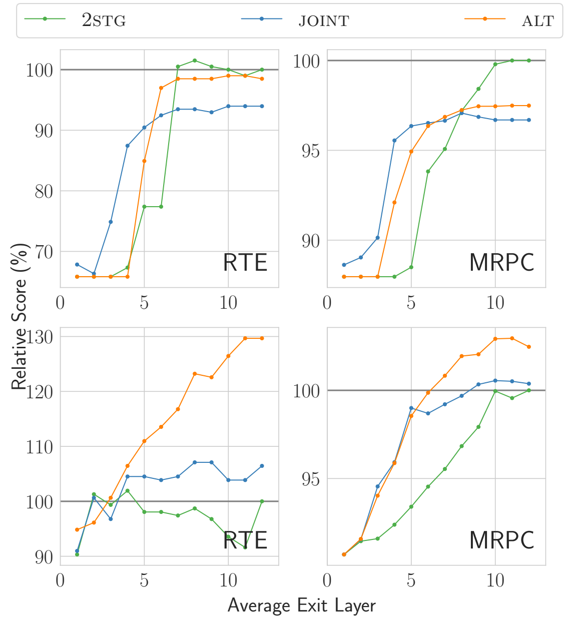

Figure 3: Layer-wise scores of different fine-tuning strategies for RoBERTa$_{\text{BASE}}$ (top two) and ALBERT$_{\text{BASE}}$ (bottom two).

5.3 Early Exiting Trade-offs Comparison

From the previous section, we see that *Two-stage* is visibly less preferable than the other two. Therefore in this section, we compare quality–efficiency trade-offs of *Joint* and *Alternating* when confidence threshold is used for making exiting decisions.

Specifically, we use *average exit layer* of all inference samples as the metric of efficiency for the following reasons: (1) it is linear w.r.t. the actual amount of computation; (2) according to our experiments, it is proportional to actual wall-clock runtime, and is also stable across different runs.[8]

---

[7] Results for other datasets are in Appendix C.

[8] Direct runtime measurement has the randomness caused

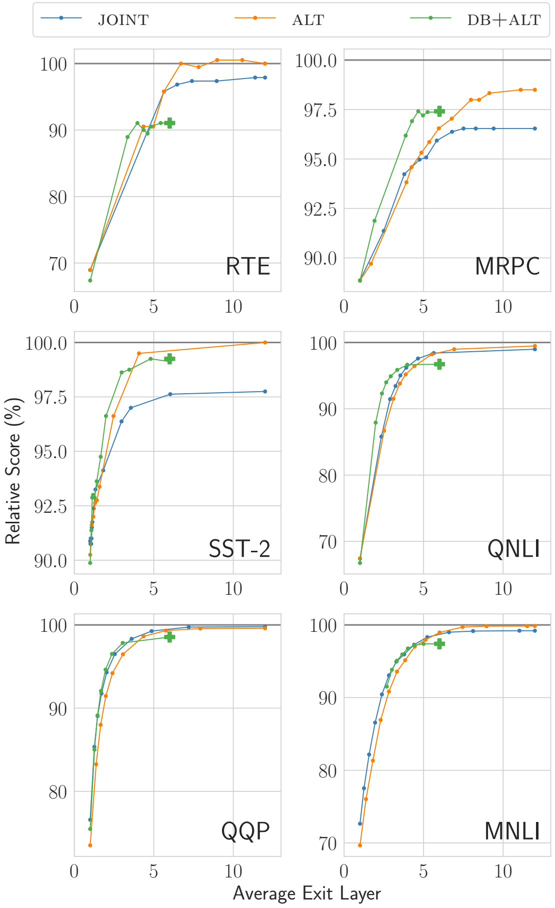

Figure 4: Quality–efficiency trade-offs using confidence for exiting decisions for $\text{BERT}_{\text{BASE}}$.

We visualize the trade-offs in Figures 4 and 5, and also show detailed numbers in Table 2 using results from the test set. Dots in the figures and ALT rows in the table are generated by varying the confidence threshold, and the thresholds are chosen to show trade-offs at different average exit layers. In addition to the comparison between *Joint* and *Alternating*, we add another strong baseline, DistilBERT (Sanh et al., 2019). We apply *Alternating* fine-tuning and early exiting on top of DistilBERT (labeled as DB+ALT), and the rightmost point of the curve is DistilBERT itself without early exiting (the green ✚). Observations from the table and figures are as follows:

- On the test set, early exiting with *Alternating* fine-tuning saves a large amount of inference computation, with only minimal quality degradation, compared with vanilla Muppets.
- Compared with *Joint*, *Alternating* inherits its benefits from the previous section: better trade-offs at higher scores (larger average exit layer). Additionally, its improvements are larger in smaller datasets.

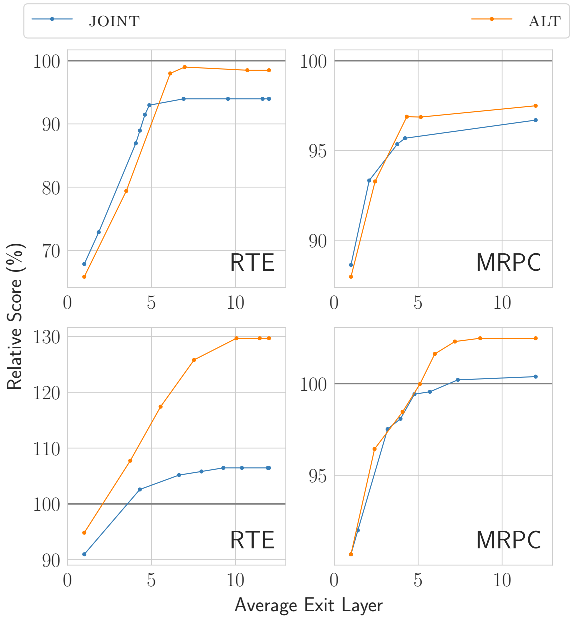

Figure 5: Quality–efficiency trade-offs using confidence for exiting decisions for $\text{RoBERTa}_{\text{BASE}}$ (top two) and $\text{ALBERT}_{\text{BASE}}$ (bottom two).

- *Alternating*'s weakness at more aggressive exiting (smaller average exit layer) is minimized. Take Figure 4 as an example, we report *the area of one curve above the other* as a numerical metric: JOINT over ALT and ALT over JOINT is respectively (0.4, 13.5) for RTE, (0.9, 8.8) for MRPC, and (0.2, 18.2) for SST-2. The advantage of *Alternating* indicates that later layers intrinsically contribute more to early exiting performance, partly because the final layer's score is the upper bound for all previous layers (ignoring randomness in training). This shows that the *Joint* fine-tuning strategy, which treats all layers equally, is not ideal.
- In most cases, *Alternating* outperforms DistilBERT, which requires distillation in pre-training and is therefore much more resource-demanding. It also further improves model efficiency on top of DistilBERT, indicating that early exiting is *cumulative* with other acceleration methods.

5.4 Learning to Exit Performance

To examine the effectiveness of LTE, we apply it on top of models fine-tuned with *Alternating*. We show the results in Figure 6 on four datasets.

---

by other processes on the same machine. Detailed discussions can be found in Appendix D.

Method	Rel. Score	Speedup	Avg. Exit Layer
PABEE	99%	2.1	5.7
	98%	2.4	5.0
ALT-LTE	99%	2.2	5.4
	98%	2.6	4.6

Table 3: Comparing LTE with PABEE on STS-B.

We use the *layer-wise* score of *Alternating* as the baseline: if we want to save $x\%$ inference runtime, a straightforward way is to use the first $(100-x)\%$ layers for every sample, regardless of its difficulty. LTE is expected to dynamically allocate resources based on a sample's difficulty and therefore outperform this baseline. From the figures for QNLI and QQP, we observe that the blue curves are substantially above the orange curves, i.e., LTE provides better accuracy–efficiency trade-offs than the layer-wise baseline, achieving the same model quality with less computation. For regression tasks STS-B and SICK, the layer-wise baseline reaches its maximum score at relatively early layers, leaving little room for LTE to perform. Nevertheless, LTE still outperforms the baseline, especially in earlier layers (note that the y-axis is from 0 to 100%).

We also compare LTE with the concurrent patience-based baseline PABEE (Zhou et al., 2020) in Table 3, showing their speedups and average exit layers at the same relative scores. PABEE does not provide exact speedup numbers; therefore we estimate the values from their figures. We can see that *Alternating* fine-tuning plus LTE is marginally better than PABEE on regression tasks.

We further compare LTE-predicted certainty for each layer with layer-wise scores in Figure 7, where we observe large differences of predicted certainty both within and across layers. Also, predicted certainty is generally positively correlated with scores. This further demonstrates that the LTE module successfully captures certainty information based on the model's hidden state.

LTE extends confidence-based early exiting to

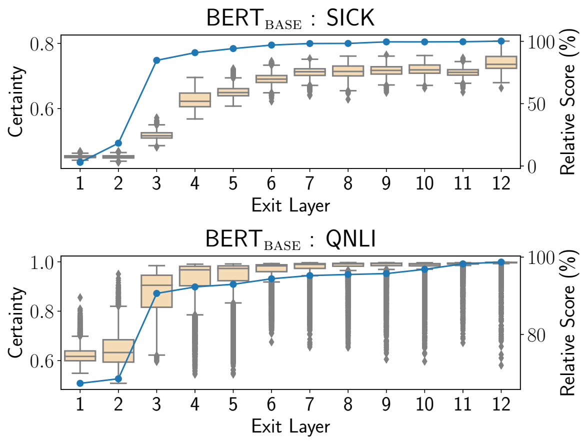

Figure 7: Comparison of each layer's score and learned certainty. Yellow box-plots: distribution of certainty at each layer; blue curve: relative score.

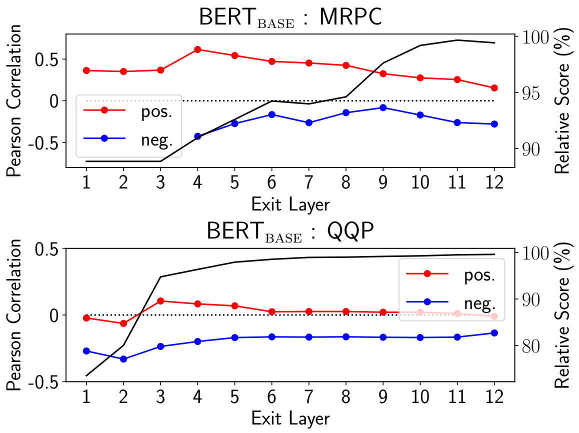

Figure 8: Comparison between BLEU–confidence correlation (red and blue) and layer-wise scores (black).

tasks other than classification. Furthermore, our LTE module is more straightforward and intuitive than DAT (Elbayad et al., 2020), yet achieves comparable results with classification tasks.

5.5 Prediction Confidence as a Probe

So far, we have only regarded prediction confidence as something produced by the black-box model and use it for making early exiting decisions. In this section, we show an example of how confidence is related to a human-interpretable feature, demonstrating its potential to reveal the inner mechanisms of Muppet models.

We choose two datasets, MRPC and QQP, where the task is to predict whether two input sequences are semantically equivalent. Intuitively, the BLEU score (Papineni et al., 2002) between the two sequences, which measures n-gram matching, may be related to the prediction. At each output layer, we first divide all dev set samples into two subsets by whether they are predicted as positive or negative; then, we calculate the BLEU-4 score for each sample, and calculate the Pearson correlation between BLEU scores and confidence in each subset; finally, we compare the correlation for both subsets in each layer, along with the layer-wise relative scores, in Figure 8.

We notice that the BLEU scores and predicted confidence show the strongest correlation in layers where the model quality starts to improve (layer 4–5 in MRPC[9] and 2–3 in QQP). After these layers, the correlation gradually weakens. It suggests that in the early layers, the model relies more on simple features such as n-gram matching for making semantic judgments: the higher the BLEU score is, the more certain it is for making positive predictions and the less certain it is for negative ones; however, with more layers, the model acquires the ability to look beyond the BLEU score, reducing its reliance on n-gram matching and achieving better performance. Therefore, with MRPC as an example, analyzing differences between layers 3 and 4 may reveal how the model detects n-gram matching, and analyzing differences between layers 4 and 6 may reveal advanced semantic features learned by the model.

6 Conclusion and Future Work

To improve early exiting for Muppets, we present BERxiT, including the *Alternating* fine-tuning strategy which outperforms methods from previous papers and the LTE idea which extends early exiting to a broader range of tasks. Experiments show the effectiveness of *Alternating* in providing better quality–efficiency trade-offs and the successful application of LTE to regression tasks. They also show that early exiting is cumulative with other acceleration methods such as DistilBERT and has the potential for model interpretation.

Future Work The fundamental question of early exiting for Muppets is how many transformer layers are sufficient for making good predictions. We draw inspiration from the *Limit* performance of Muppets: the score of *Limit* at the i^{th} layer is obtained by taking the first i transformer layers from the pre-trained Muppet model, attaching a classifier to the i^{th} layer, and fine-tuning this single-output

---

[9] In MRPC, the first three layers only make positive predictions due to the highly imbalanced training label distribution.

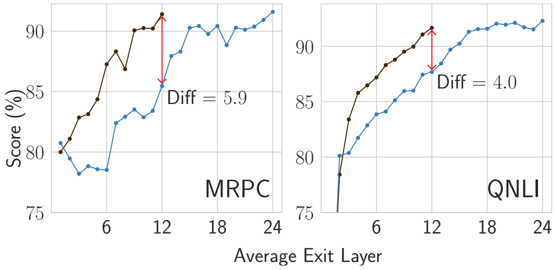

Figure 9: Comparison between LIMIT of BERT$_{\text{BASE}}$ (brown) and BERT$_{\text{LARGE}}$ (blue). Red arrow: difference between the two models when they both use 12 layers.

model. *Limit* estimates the upper bound for any fine-tuning methods by removing inter-classifier interference. We compare the *Limit* performance of BERT$_{\text{BASE}}$ and BERT$_{\text{LARGE}}$ in Figure 9, and notice that with the same number of layers (and identical fine-tuning strategy), BERT$_{\text{BASE}}$ almost always outperforms BERT$_{\text{LARGE}}$ by a large margin. This suggests that most transformer layers' potential to provide information for early exiting is limited by the single-output nature of pre-training. If we want to further improve early exiting Muppets for better trade-offs, adding more exiting paths in pre-training would be a promising direction.

A Negative Results for Self-Distillation

FastBERT (Liu et al., 2020) does not provide result for BERT$_{\text{LARGE}}$ or RoBERTa$_{\text{LARGE}}$. We show BERT$_{\text{LARGE}}$ and RoBERTa$_{\text{LARGE}}$ layer-wise scores for different fine-tuning strategies in Figure 10. SD in the legend stands for self-distillation. We can see that for *Two-stage* and *Alternating*, the patterns are similar to those of BERT$_{\text{BASE}}$: *Alternating* better in earlier layers while *Two-stage* better in later layers.

However, self-distillation's behavior is inconsistent between models and datasets. While it performs as expected for BERT$_{\text{LARGE}}$ in SST-2 and MNLI, and for RoBERTa$_{\text{LARGE}}$ in MRPC, self-distillation fails to improve after the first few layers for BERT$_{\text{LARGE}}$ in MRPC and for RoBERTa$_{\text{LARGE}}$ in SST-2 and MNLI, and most layers' quality is considerably worse than *Alternating*. We therefore consider self-distillation an unstable and premature fine-tuning strategy.

B Additional Experiment Setting

For pre-trained models, we use the following ones provided by the Huggingface Transformer Library (Wolf et al., 2020) as backbone models:

- BERT-BASE-UNCASED
- BERT-LARGE-UNCASED
- ROBERTA-BASE
- ROBERTA-LARGE
- ALBERT-BASE-V2
- DISTILBERT-BASE-UNCASED

For BERT, ALBERT, and DistilBERT, we fine-tune for 3 epochs; for RoBERTa, we fine-tune for 10 epochs; no early-stopping or checkpoint selection is performed.

Experiments are done on a single NVIDIA P100 GPU with CUDA 10.1. For inference, we use a batch size of 1 (since we need to perform early exiting based on each individual sample's difficulty). Inference runtime for the entire dev set for all models and datasets is shown in Table 4. RoBERTa has the same model structure as BERT, and therefore its runtime is also very close to that of BERT. Note that this is affected by competing processes, and may vary between different runs.

Numbers of parameters for BERT and ALBERT backbone models can be found in the paper by Lan et al. (2020). RoBERTa shares the same model structure with BERT and has the same number of parameters. Numbers of parameters for early-exiting-specific modules, such as additional classifiers and the LTE module, are on the order of thousands, and are therefore negligible compared with those of backbone models (millions).

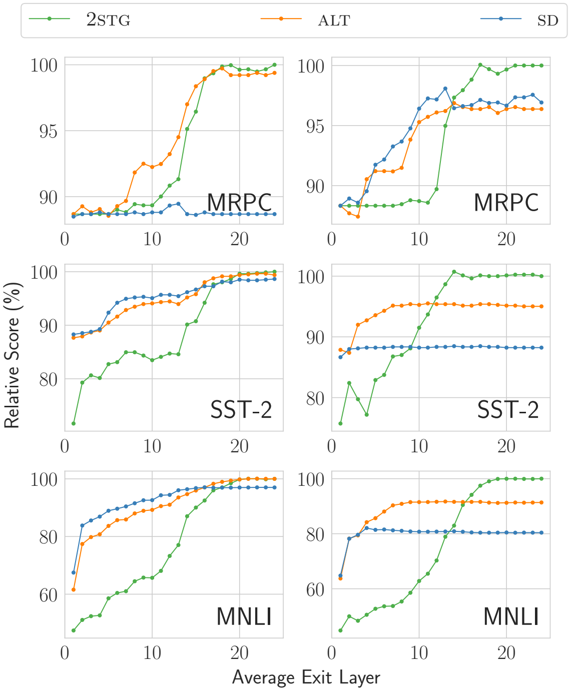

Figure 10: Layer-wise score for different fine-tuning strategies on BERT$_{\text{LARGE}}$ (left column) and RoBERTa$_{\text{LARGE}}$ (right column).

C Additional Experiment Results

In the main paper, we report results of RoBERTa$_{\text{BASE}}$ and ALBERT$_{\text{BASE}}$ only on the two smallest datasets. Results of the other datasets are provided in Figure 11. We can see that while *Two-stage* is visibly less preferable, *Joint* and *Alternating* are close to each other with larger dataset sizes, and this is the reason why we keep only the low-resource datasets in the main paper.

D Analyses of Efficiency Metric

In our experiments, we use *average exit layer* as the metric of efficiency for the following three reasons.

It is linear w.r.t. the amount of computation. Inference time computation in our model occurs in the following parts: the embedding layer, transformer layers, classifiers, and the LTE module (if used). If a layer is chosen, i.e., the exit layer is after

	RTE	MRPC	SST-2	QNLI	QQP	MNLI	STS-B	SICK
BERT-base	5.8	8.4	18.0	110.4	856.8	209.4	33.2	107.8
BERT-large	11.6	17.4	35.9	223.2	1952.8	400.3	61.3	209.8
ALBERT-base	6.5	9.4	18.5	114.6	864.8	204.8	31.6	104.2
DistilBERT	3.0	4.3	9.1	55.4	407.1	106.2	15.9	50.9

Table 4: Inference runtime in seconds for each model and dataset.

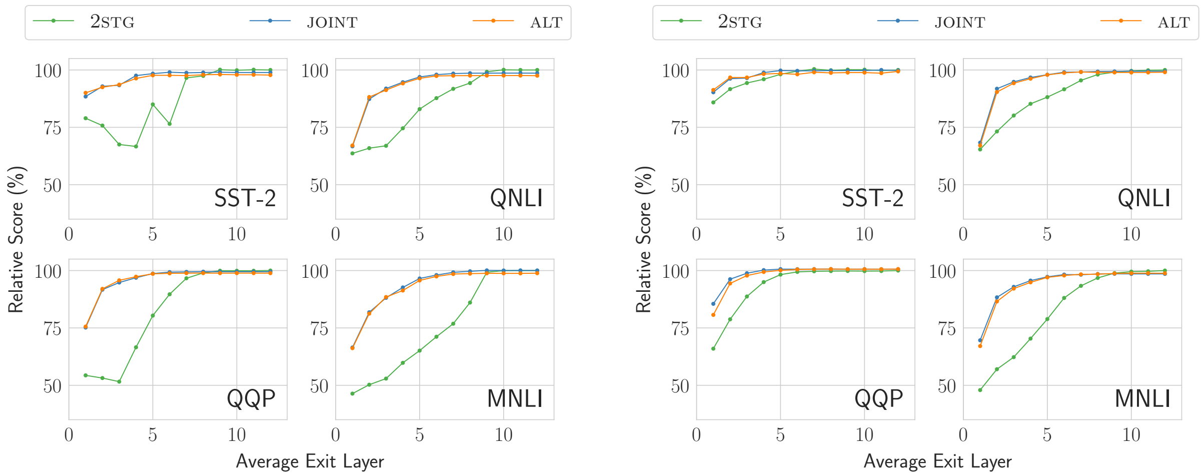

Figure 11: Additional layer-wise score for different fine-tuning strategies on RoBERTa$_{\text{BASE}}$ (left four) and ALBERT$_{\text{BASE}}$ (right four).

it, all components of the layer (transformer, classifier, LTE module) are used and incur computation cost. Additionally, embedding look-up (selecting a column in the matrix) is much faster than the above components (involving matrix-vector multiplication), and can therefore be neglected.

It is stable across different runs. With a fine-tuned model, an inference sample's exit layer only depends on the confidence (or LTE-predicted certainty) at each layer and the threshold. On the other hand, direct measurement of wall-clock runtime is frequently affected by competing processes and fluctuates between different runs.

The computation overhead of early exiting is negligible. With the above reasons, there is only one concern left for using average exit layer as the efficiency metric: how do additional layers in our model (including the additional classifier and possibly the LTE module) compare with transformer layers in the original BERT paper? We estimate FLOPS used in one sample's inference as follows. Since we will eventually end up with orders of magnitude differences, we use the *big-theta* asymptotic notation for estimation.

Most computation is incurred for matrix and vector multiplication. Using the naïve implementation, the cost for multiplying two vectors in $\mathbb{R}^d$ is $\Theta(d)$, and the cost for multiplying a matrix in $\mathbb{R}^{d_1 \times d_2}$ and a vector in $\mathbb{R}^{d_2}$ is $\Theta(d_1 d_2)$.

We denote d as the hidden state size of our model (768 for base models and 1024 for large models), c as the number of classes (less than 4 in our experiments), n as the sequence length (typically in the hundreds), and h as the number of heads in multi-head attention (12 for base and 16 for large).

The classifier is a one-layer fully-connected layer, mapping a vector in $\mathbb{R}^d$ to an output in $\mathbb{R}^c$, therefore the cost is $\Theta(cd)$. Similarly, the cost of the LTE module is $\Theta(2d)$, since its output is always a vector in $\mathbb{R}^2$.

The transformer layer mainly consists of multi-head self-attention, a fully-connected layer, and two layer normalization modules. Layer normalization is much faster than the other two and we therefore neglect it. The fully connected layer maps n vectors from $\mathbb{R}^d$ to $\mathbb{R}^d$, therefore the cost is $\Theta(nd^2)$. The multi-head attention[10] computes h individual uni-head attention. For each uni-head attention, the mapping from original query, key, and value

---

[10] Details can be found in the paper by Vaswani et al. (2017).

vectors ($\mathbb{R}^d$) to head-specific ones ($\mathbb{R}^{d/h}$) incurs a cost of $\Theta(nd^2/h)$; calculating the attention results incurs a cost of $\Theta(nd/h)$. Therefore the total cost here is $\Theta(nd^2 + nd) = \Theta(nd^2)$. Finally, results of each head are combined and one more matrix–vector multiplication is needed, incurring a cost of $\Theta(nd)$. The total cost of one transformer layer is therefore $\Theta(nd^2)$.

Comparing the above, the ratio of a transformer layer to a classifier/LTE module is

$$\frac{\Theta(nd^2)}{\Theta(cd + 2d)} = \Theta(nd). \tag{12}$$

Considering the value of n and d, the classifier and the LTE module are several orders of magnitude lighter than the transformer layer. Even with advanced algorithms and parallel hardware that may accelerate transformer layers, we can still safely come to the conclusion that the computation overhead of early exit is negligible.

Telling BERT's Full Story: from Local Attention to Global Aggregation

Damián Pascual, Gino Brunner, Roger Wattenhofer
Department of Electrical Engineering and Information Technology
ETH Zurich, Switzerland
{dpascual,brunnegi,wattenhofer}@ethz.ch

Abstract

We take a deep look into the behaviour of self-attention heads in the transformer architecture. In light of recent work discouraging the use of attention distributions for explaining a model's behaviour, we show that attention distributions can nevertheless provide insights into the local behaviour of attention heads. This way, we propose a distinction between local patterns revealed by attention and global patterns that refer back to the input, and analyze BERT from both angles. We use gradient attribution to analyze how the output of an attention head depends on the input tokens, effectively extending the local attention-based analysis to account for the mixing of information throughout the transformer layers. We find that there is a significant mismatch between attention and attribution distributions, caused by the mixing of context inside the model. We quantify this discrepancy and observe that interestingly, there are some patterns that persist across all layers despite the mixing.

1 Introduction

The inception of the transformer architecture has sparked significant progress across a wide range of language understanding tasks. Variants of transformers currently dominate the popular GLUE (Wang et al., 2019b) and SuperGLUE (Wang et al., 2019a) benchmarks and have even achieved super human performance on multiple tasks. The main innovations behind the transformer architecture are the stacking of self-attention layers into a multi-layer self-attention architecture, as well as an unsupervised pre-training phase that primes the model to be fine-tuned on a wide range of language tasks. Transformers and other self-attention-based models have been successfully adopted in other areas such as computer vision (Parmar et al., 2018), music processing (Huang et al., 2019) or protein research (Rao et al., 2019). Their extraordinary empirical success has led researchers to investigate transformers in order to better understand the source of this success, but also in an attempt to explain model decisions.

Much of the research around interpretability and explainability is focused on analyzing the self-attention operation (Clark et al., 2019). In multi-layer self-attention, every input computes an attention distribution over itself and all other inputs to produce ever more complex feature representations. In the case of language, a word in a sentence attends to itself and to all other words in order to compute an updated contextual representation of itself. It is tempting to directly rely on attention distributions to explain the model's predictions. The rationale is that if the attention distribution aligns with human intuition, we can conclude that the model learned robust features and obtained a deep understanding of language, in contrast to simply overfitting on spurious patterns. For example, if a transformer classifies an online comment as hate speech, but we find that the model mostly attended to neutral or even positive words, we would conclude that the model did not actually understand the text and that the correct prediction was either due to chance or to the exploitation of an underlying statistical bias in the data (Niven and Kao, 2019).

However, recent studies (Brunner et al., 2020; Pruthi et al., 2019) question the ability of attention maps to provide a faithful explanation of the inner workings of transformer models. In particular, when the explanations refer to the model input, attention maps do not account for the mixing of information throughout the model. Since self-attention mixes information among all input tokens, the hidden layers attend over mixtures of tokens. Therefore, attention maps may be useful to investigate the local behavior of attention heads but not to draw conclusions about how input tokens relate to each other.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 105–124
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

In this work we take a detailed look at the inner workings of BERT's attention heads, both by analyzing the self-attention distributions, and by using gradient attribution to account for the mixing of tokens throughout the model. We first show that self-attention distributions correlate strongly with Hidden Token Attribution (Brunner et al., 2020) (HTA) from hidden embedding to head output, this result validates HTA. We then present novel location based attention patterns, revealing that BERT, despite its bi-directional language modeling objective, attends to past embeddings in earlier layers, and to future ones in later layers. Next, we use HTA in order to extend the analysis to take the mixing of information into account, which allows to draw conclusions about the behaviour of an attention head with respect to the original input word. The patterns that emerge are different from the local attention-based patterns, giving us deeper insight into the operation of the model and emphasizing that local attention-based explanations are very different from global attribution-based explanations. Finally, we contrast attention and HTA distributions for individual examples. Our results further highlight the discrepancy between local attention patterns and global attribution patterns.

2 Related Work

The good performance of attention (Graves, 2013; Bahdanau et al., 2015) models in Natural Language Processing (NLP) arises from their ability to learn alignments between words. The transformer architecture (Vaswani et al., 2017) is a multi-layer multi-head self-attention architecture that is pre-trained in an unsupervised manner. The extraordinary performance of transformer models has accelerated progress in the field of NLP. Currently, there is a growing number of different transformer models that vary in size, pre-training objective and/or other architectural elements (Radford et al., 2018, 2019; Liu et al., 2019; Lan et al., 2020; Yang et al., 2019; Sanh et al., 2019; Kitaev et al., 2020; Raffel et al., 2019).

The success of transformers and the possibility of visualizing attention distributions (Vaswani et al., 2017), has motivated a line of research aiming to understand the inner workings of transformers and explain their decisions. Many of these studies have focused on BERT (Devlin et al., 2019a), a well-known transformer model, leading to a body of research grouped under the term BERTology (Rogers et al., 2020).

Aforementioned research builds on previous work on the interpretability of attention distributions in other models apart from transformers. In particular, Jain and Wallace (2019) examine the attention distributions of LSTM based encoder-decoder models and show a weak to moderate correlation between attention and dot-product gradient attribution. Furthermore, they show that adversarial attention distributions that do not change the model's decision can be constructed. In the same line, Serrano and Smith (2019) find, through zeroing out attention weights, that gradient attribution is a better predictor of feature importance with respect to the model's output than attention weights. Wiegreffe and Pinter (2019) find that although adversarial attention distributions can be easily obtained, they perform worse on a simple diagnostic task. All of these works raise concerns about the ability of attention distributions to explain the decisions of a model.

Despite existing concerns surrounding the interpretability of attention distributions, very few works have studied how this problem affects transformers. Pruthi et al. (2019) show that, just as in other attention models, it is possible to manipulate self-attention in transformers in order to generate different attention masks that cause only a small drop in performance. Brunner et al. (2020) find that attention distributions are not unique when the sequence length is larger than the head dimension and show that this can lead to the discovery of spurious patterns. Furthermore, they show that although it is possible to map hidden tokens back to their corresponding input tokens, there is a very large degree of information mixing inside the model, which raises questions about straightforward interpretations of attention maps. Recently, (Abnar and Zuidema, 2020) proposed a method to quantify information flow inside transformers. This method tracks the mixing of information due to attention but omits the effect of feed-forward networks.

Our work addresses this important issue by distinguishing between local and global aggregation patterns, where the former can be explained by attention distributions and the latter by attribution. We analyze BERT from both angles and quantify the mismatch between these interpretations. We show that attention correlates well with attribution locally but not globally and therefore attention maps are inadequate to draw conclusions that refer to the input of the model.

3 Background on Transformers

The original transformer architecture (Vaswani et al., 2017) is a sequence-to-sequence model consisting of an encoder and a decoder, both of which follow a multi-layer multi-head self-attention structure. Conversely, most of the pre-trained transformer models that can be fine-tuned on supervised language understanding tasks only consist of an encoder. Each transformer layer consists of a self-attention block and a non-linear feed forward block (MLP) with layer normalizations (Ba et al., 2016).

The input to a transformer layer is a sequence of embeddings $E^l = [\boldsymbol{e}^l_0, ..., \boldsymbol{e}^l_{d_s}] \in \mathbb{R}^{d_e \times d_s}$, where l denotes the layer index, d_e is the embedding dimension, and d_s is the sequence length. We refer to the sequence of non-contextual input word embeddings as E^0, and to the hidden contextual embeddings as E^l, where $l > 0$. Note that E^0 refers to the word embeddings after position and sequence embeddings have been added. A self-attention block consists of n_h separate attention heads. The attention heads independently perform the self-attention operation, and the results are then concatenated and projected back into the embedding space by a linear layer. The output of the attention block is then fed into the MLP.

The self-attention operation itself is implemented by projecting each input token $\boldsymbol{e}_i \in \mathbb{R}^{d_e}$ into a query vector $\boldsymbol{q}_i \in \mathbb{R}^{d_q}$, key vector $\boldsymbol{k}_i \in \mathbb{R}^{d_q}$ and value vector $\boldsymbol{v}_i \in \mathbb{R}^{d_v}$. We present the self-attention operation from the perspective of a single token $\boldsymbol{e}_i$ attending to all input tokens. For that, the key vectors $\boldsymbol{k}_i$ are aggregated into the key matrix $K = [\boldsymbol{k}_0, ..., \boldsymbol{k}_{d_s}] \in \mathbb{R}^{d_q \times d_s}$ and the value vectors $\boldsymbol{v}_i$ are aggregated into the value matrix $V = [\boldsymbol{v}_0, ..., \boldsymbol{v}_{d_s}] \in \mathbb{R}^{d_v \times d_s}$. The attention distribution $\boldsymbol{a}_i$ of token $\boldsymbol{e}_i$ over all input tokens is then computed as

$$\boldsymbol{a}_i = \text{softmax}\left(\frac{\boldsymbol{q}_i^T \cdot K}{\sqrt{d_q}}\right)$$

The attention vector $\boldsymbol{a}_i \in \mathbb{R}^{d_s}$ now contains an attention weight for each input token. $\boldsymbol{a}_i$ is then multiplied with the value matrix V to compute the output of the self-attention operation for a token i and a head h as

$$\boldsymbol{o}_{h,i} = V \cdot \boldsymbol{a}_i$$

The outputs of all heads $\{\boldsymbol{o}_{0,i}, ..., \boldsymbol{o}_{n_h,i}\} \in \mathbb{R}^{d_e}$ are then concatenated and fed through a linear layer to compute the output of the self-attention block for a single token. This linear layer can be thought of as an aggregation operation that projects the output of the independent heads back into embedding space. In practice, the attention distributions for all tokens are computed in parallel.

4 Extending Hidden Token Attribution

Hidden Token Attribution (Brunner et al., 2020) is a gradient-based attribution method that quantifies how much information from each input token is contained in a given hidden embedding. For each layer l, this method defines the relative contribution $c^l_{i,j}$ of an input token $\boldsymbol{e}^0_i$ to a hidden embedding $\boldsymbol{e}^l_j$ as:

$$c^l_{i,j} = \frac{||\nabla^l_{i,j}||_2}{\sum_{k=0}^{d_s} ||\nabla^l_{k,j}||_2} \quad \text{with} \quad \nabla^l_{i,j} = \frac{\partial \boldsymbol{e}^l_j}{\partial \boldsymbol{e}^0_i} \quad (1)$$

The contribution $c^l_{i,j}$ is normalized by the sum of the attribution values to all input tokens and hence, ranges between 0 and 1.

In this work, we apply Hidden Token Attribution to the individual attention heads of BERT. For a token $\boldsymbol{e}^l_j$ at layer l we back-propagate the gradients from the output $\boldsymbol{o}^l_{h,j}$ of each attention head h independently. This differs from the original method in that Hidden Token Attribution propagates the gradients from the layer output. In general, using Equation 1, we can compute the contribution between any two vectors in the model, as long as they are connected in the computation graph. We hence denote the contribution of any vector $\boldsymbol{x}$ to another vector $\boldsymbol{y}$ as $C(\boldsymbol{x}, \boldsymbol{y})$.

In particular, we calculate two different contributions to the head output:

Previous layer contribution: Contribution from the hidden embeddings at the input of the attention head to the output of the attention head: $C(\boldsymbol{e}^{l-1}_i, \boldsymbol{o}^l_{h,j})$

Input contribution: Contribution from tokens at the input of the transformer model to the output of an attention head h at layer l: $C(\boldsymbol{e}^0_i, \boldsymbol{o}^l_{h,j})$

Previous layer contribution allows us to study how attention heads operate locally and how HTA distributions compare to attention distributions. *Input contribution* enables us to extend the head attention patterns all the way back to the input, thereby controlling for the effect of information mixing.

5 Setup

For our experiments we use the non-finetuned, uncased BERT base model (Devlin et al., 2019b) as provided in the original repository.[1] Despite the recent explosion of new transformer variants, BERT remains the most popular model for research into the interpretability of transformer models. The reason for this is that most of the newer models are architecturally similar to BERT, and therefore, studies carried out on BERT either are likely to generalize to these models or can be repeated with relatively little effort.

We perform our experiments on 1800 examples from the development set of the MNLI matched (MNLIm) dataset. Brunner et al. (2020) show that when the sequence length d_s is larger than the head output dimension d_v, the attention distributions are not identifiable. Therefore, to guarantee that in our experiments we do not find spurious patterns that do not influence downstream parts of the model, we restrict the examples in our dataset to sequences of maximum length of 64 tokens, which is the head dimension of BERT. Thus, the examples in our dataset have sequence lengths ranging between 6 and 64 tokens, with a median length of 34 tokens. In total, this subset contains 63,456 tokens.

6 HTA: Local Validation

The ability of attention distributions to provide explanations has been the target of a number of studies (Wiegreffe and Pinter, 2019; Serrano and Smith, 2019; Pruthi et al., 2019). In particular, Jain and Wallace (2019) show that attention distributions do not explain the model output and do not correlate well with attribution methods. However, if we are exclusively interested in how attention heads behave locally, i.e., without considering their impact on the model's decisions, it is sound to examine attention distributions. The reason for this is that self-attention is the only operation performed in attention heads, and hence, attention distributions precisely represent the information flow within the heads. As a consequence, we can use attention distributions as a reference to validate whether HTA accurately quantifies how information mixes within transformers. To verify this, we compare attention distributions to previous layer contribution by computing the correlation between attention maps $\boldsymbol{a}_{h,i}$ and the contribution $C(\boldsymbol{e}_i^{l-1}, \boldsymbol{o}_{h,j}^{l})$ for each head.

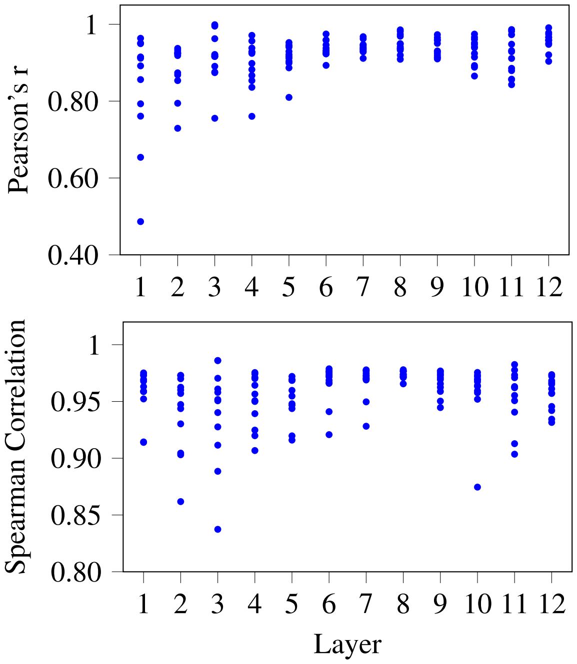

Figure 1: (Top) Pearson and (Bottom) Spearman correlation between attention and previous layer contribution.

A high correlation value would validate HTA as accurately representing the flow of information within transformers. To calculate the correlation, first, we extract the attention maps for all the heads of BERT for each of the tokens in the examples of our dataset. Then, we pair each attention map to the corresponding contribution. Note, that both attention maps and contributions are distributions that lie in the probability simplex, i.e., all the values are between 0 and 1 and their sum is 1. Next, we calculate Pearson's correlation coefficient for each attention-contribution pair and we aggregate the results into one value per head by computing the mean of the correlation values.

Figure 1 (Top) shows the mean correlation value per head. For all heads except for two, Pearson's correlation coefficient is larger than 0.7. Furthermore, 90% of the heads show a correlation between attention and Hidden Token Attribution of over 0.85. Similarly, we calculate Spearman's rank correlation coefficient r for each head. The results, displayed in Figure 1 (Bottom), show that only four heads have a Spearman's correlation smaller than 0.9, and that 75% of the heads have a correlation

---

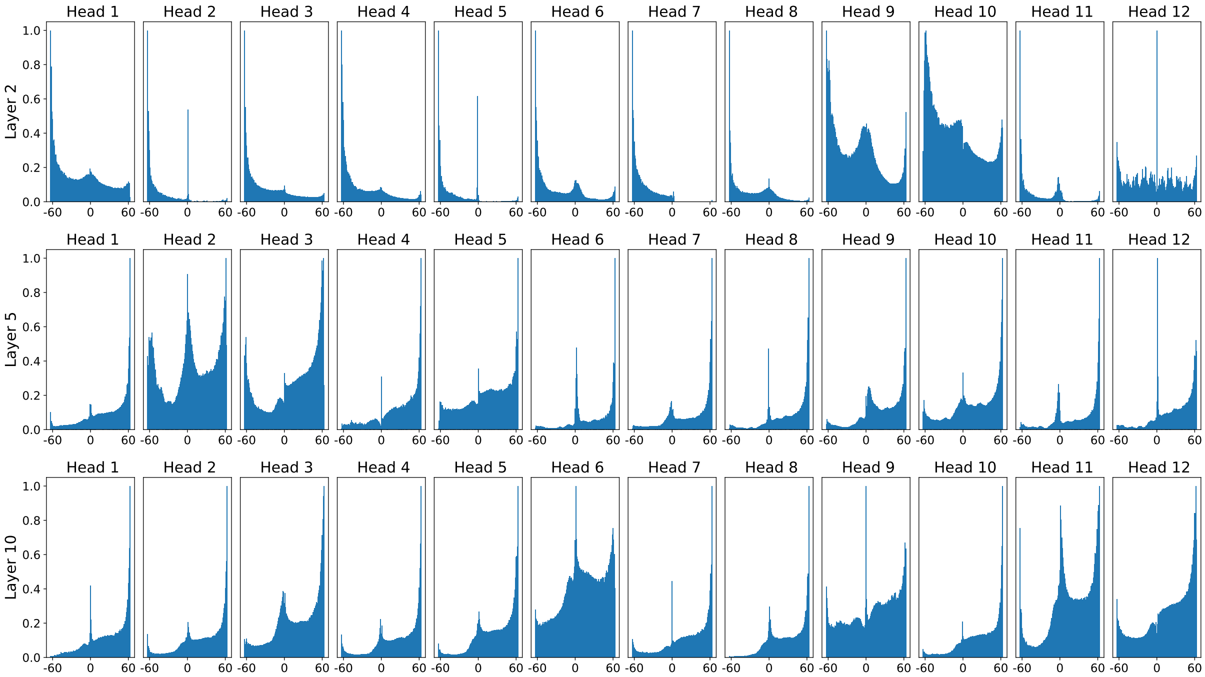

Figure 2: Attention histograms for layers 2, 5 and 10 of BERT. The horizontal axis represents the relative position of the attended tokens with respect to the attending token placed at position 0. Given that the maximum sequence length is 64 the horizontal axis ranges from -63 to 63. The vertical axis is normalized to the maximum value for a better visualization.

coefficient larger than 0.95. Note that in any case gradient attribution is a local first order approximation and thus introduces a small error that prevents perfect correlation.

These high correlation values empirically demonstrate that HTA does indeed represent the flow of information within attention heads with respect to the head inputs. Therefore, to study the inner workings of transformers beyond attention heads one can rely on Hidden Token Attribution and apply it at different points of the model. Now that we have validated HTA, we can investigate the behavior of the heads in more detail: examining the local patterns revealed by attention, the global patterns revealed by HTA, and the discrepancies between both.

7 Local Head Analysis

In this section we take a closer look into the local behaviour of attention heads. Here, local means that we analyze how the intermediate tokens fed into the heads are processed, as opposed to how the model input propagates. To this end, we study attention distributions, but rather than studying each individual example, we aggregate the attention distributions, thus obtaining a general picture of how each head behaves. In particular, we study how much attention is paid to tokens in each relative position with respect to the attending token.

For each head, we extract the attention maps for each token. Then, we define the position of the attending token in the sentence as the origin ($x = 0$), thereby generating a histogram where the horizontal axis represents the position of the neighbours and the vertical axis the amount of attention paid to a token. We sum the histograms of all tokens and then normalize the result. To normalize, we divide the value of attention at each position by the number of times that a token is at that relative position; given that the median length of the examples is 36, this normalization ensures that distant positions are not penalized for having fewer occurrences.

Figure 2 presents the histograms for the heads in layers 2, 5 and 10, the other layers can be found in Appendix A. From these histograms, a clear pattern is observable. In the first layers, heads tend to aggregate more information from past tokens than from future tokens. In fact, the attention of heads 2, 5 and 7 in Layer 2 to future tokens is negligible. However, this trend quickly reverses with increasing depth, and in later layers the aggregation of future hidden embeddings dominates for most heads. To illustrate this, we calculate the center of mass of the attention histograms per layer by

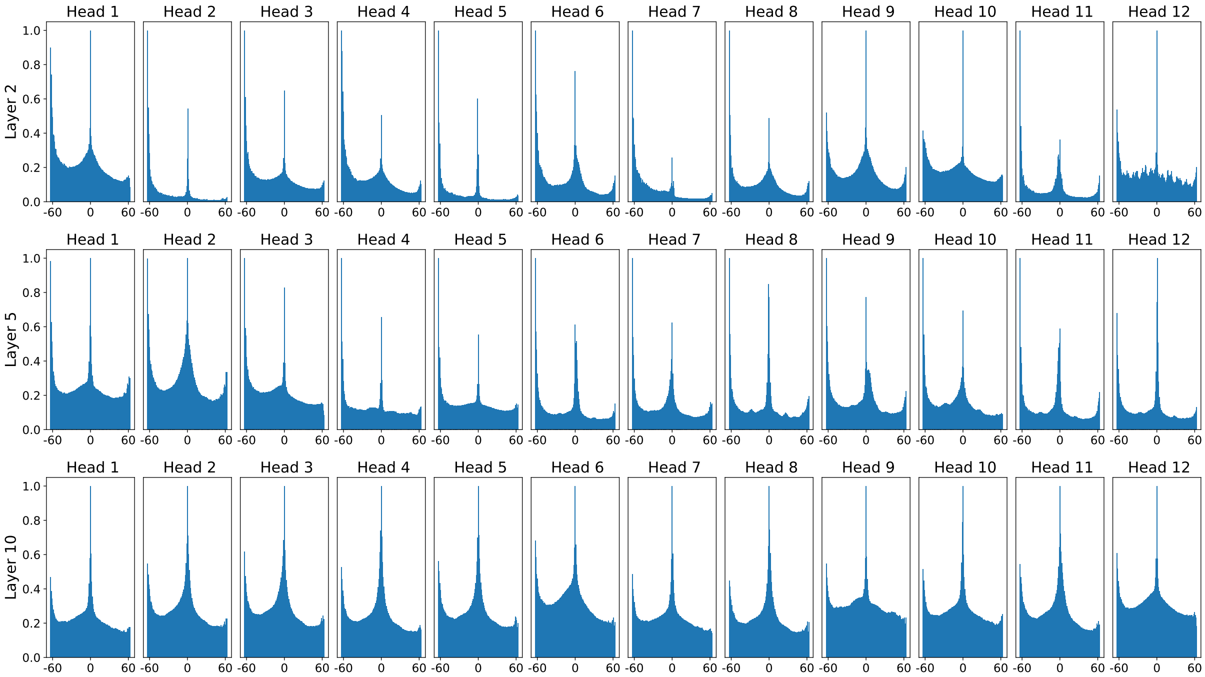

Figure 3: Input contribution histograms for layers 2, 5 and 10 of BERT. The horizontal axis represents the relative position of the attended tokens with respect to the attending token placed at position 0. The vertical axis is normalized to the maximum value for a better visualization.

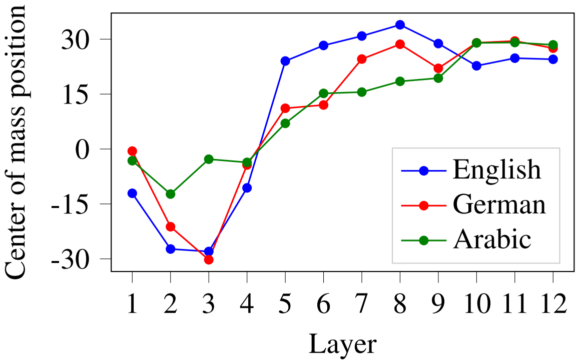

Figure 4: Mean center of mass for attention histograms per layer for English, German and Arabic.

averaging over each head. The results are shown in Figure 4. To understand whether this behavior is particular to English we perform the same calculations on the German (Deepset, 2019) and Arabic (Antoun et al., 2020) versions of BERT on 1800 examples of the XNLI dataset (Conneau et al., 2018); note that although Arabic is a right-to-left language, to process the examples the token order is reversed and input to BERT as left-to-right.

The figure shows that BERT follows the same trend regardless of the language, i.e., the models first attend to past and then to future hidden tokens. This suggests that despite its bidirectional training, BERT tends to handle language like humans, from left to right. This is also inline with the sequential nature of language, i.e., the past context needs to be known to understand the future context.

8 Global Head Analysis

Although attention maps are an effective tool to understand the local behavior of attention heads, drawing conclusions that refer to the input words can be misleading. Transformers are complex models that mix information from the entire input sequence at each layer. Recent work (Brunner et al., 2020; Pruthi et al., 2019) has raised concerns about the interpretability of attention maps as representative of global context aggregation. In this section, we look into the individual heads and study what we call global patterns, i.e., aggregation patterns that refer to the model's input.

To this end, we follow the same procedure we use in the previous section, but to generate input contribution $C(\boldsymbol{e}_i^0, \boldsymbol{o}_{h,j}^l)$ histograms instead of attention histograms. In Figure 3 we show the histograms for layers 2, 5 and 10, i.e., the same layers as in Figure 2. The histograms for the whole model can be found in Appendix B. Furthermore, we calculate the center of mass per layer and compare them to the attention centers of mass in Figure 5. The histograms and the centers of mass show that

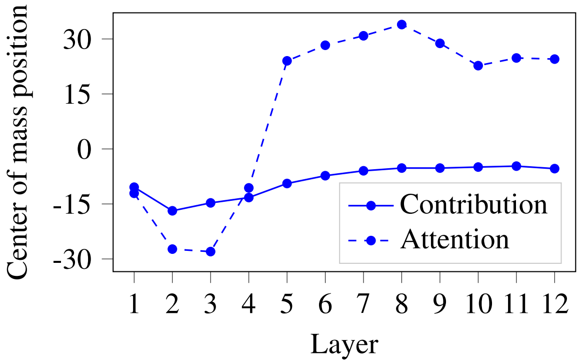

Figure 5: Mean center of mass for contribution vs. attention histograms per layer for English.

the global pattern of context aggregation is much more uniform than shown by the attention maps, especially after layer 4. This is intuitive: given that in the first layers the heads are attending mostly to the past context, on average, all the hidden tokens have a larger amount of past context. Therefore, when in later layers the attention shifts to the future hidden tokens, the past context already contained in these tokens balances the contribution, resulting in a uniform pattern of global context aggregation.

The difference in the patterns revealed by this global analysis and the local head analysis from the previous section shows a strong mismatch between attention distributions and global context aggregation in attention heads. In fact, local attention patterns can easily lead to spurious conclusions when used to interpret global context aggregation. Next, we study this difference quantitatively.

9 Local Attention vs. Global Attribution

To quantify the discrepancy between attention distributions and input contribution, i.e., local and global patterns of context aggregation, we calculate the correlation between attention maps and input contribution $C(\boldsymbol{e}_i^0, \boldsymbol{o}_{h,j}^l)$. We follow the same methodology as in Section 6 and report Pearson's and Spearman's correlation coefficient in Figure 6. In line with the mismatch between attention and contribution histograms (Figures 2 and 3), we observe how the correlation between attention and input contribution quickly decreases in deeper layers. Particularly, after only four layers Pearson's correlation coefficient for most heads is smaller than 0.5 and in the last four layers the median head correlation value is smaller than 0.25. Furthermore, Spearman's correlation follows a very similar trend, with the median head correlation value falling under 0.7 already at layer 3, and under 0.25 at the last layer.

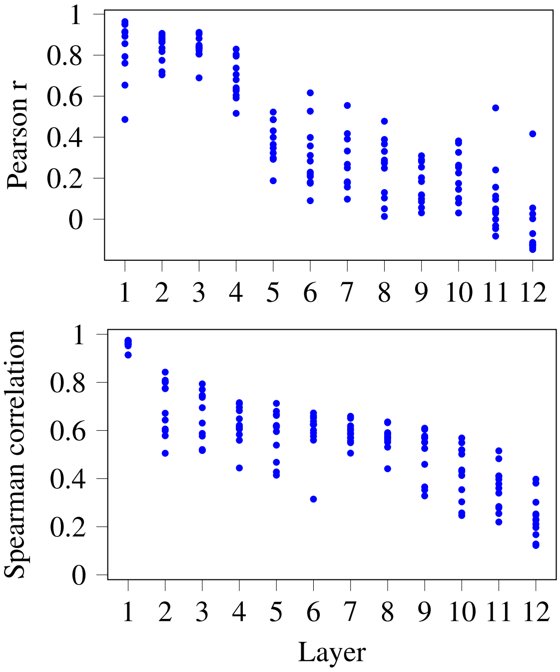

Figure 6: (Top) Pearson and (Bottom) Spearman correlation between attention and input contribution.

The results from this section point at the importance of information mixing: attention maps show how the heads behave locally, i.e., how they aggregate context, but not *what* context is in fact aggregated. Knowing how the heads behave locally can give us a better understanding of transformer models that could be leveraged to further improve the performance of these models (Wu et al., 2020). However, attention maps are misleading when drawing conclusions about what input words are being aggregated into the contextual embeddings.

9.1 Specific examples

The histograms studied in the previous sections give us a high level picture of what is happening inside the model. However, we averaged across examples with different sequence length and with different token types in different positions. To gain a more detailed understanding of the model's behaviour, we now look into specific input sequences randomly selected from our dataset.

Kovaleva et al. (2019) study attention maps generated by BERT for many different examples and divide the attention patterns into five types: vertical, diagonal, vertical-diagonal, block and heterogeneous. When looking at the attention maps, we

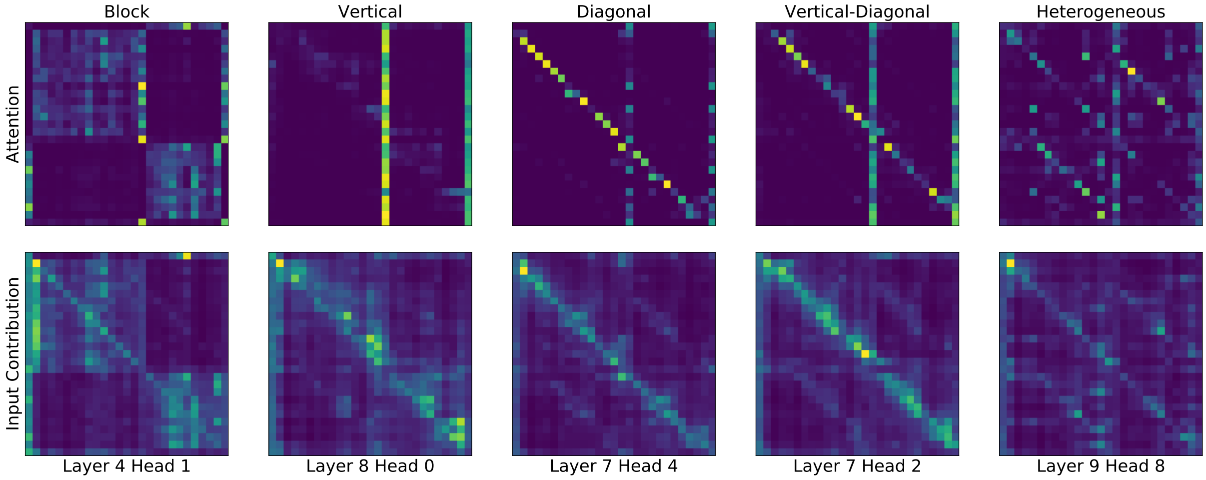

Figure 7: Comparison of the head patterns revealed by attention distributions (upper row) and input contribution (lower row).

observe the same five attention patterns. Nevertheless, to understand what input information these heads are actually aggregating, we need to look at the contribution from the input tokens.

In Figure 7, we compare the five patterns observed by Kovaleva et al. (2019) with the corresponding patterns revealed by Hidden Token Attribution with respect to the input, $C(\boldsymbol{e}_i^0, \boldsymbol{o}_{h,j}^l)$. A comparison for all heads is available in Appendix C. Remarkably, heads with the vertical pattern pay most attention to the SEP and CLS tokens. Nevertheless, the input contribution reveals that SEP tokens are used by the model to store general context, and by extracting information from the SEP token at intermediate layers, the model is in fact aggregating global context. Hence, with respect to the input, heads with vertical, diagonal and vertical-diagonal patterns have a similar behavior to heterogeneous heads. However, tokens around the diagonal tend to contribute the most given the prevalent aggregation of local context.

On the other hand, as shown in the first column of Figure 7, we observe that the block patterns prevail when we apply Hidden Token Attribution to the input. It is noteworthy that, while vertical and diagonal patterns fade away, the block pattern still remains visible. The fact that attending to tokens inside a block results in aggregation of context from within that block implies that up to that point, the context was mainly aggregated from within the blocks separated by SEP. We do not observe block patterns in the contribution maps for layers deeper than layer 4, which suggests that the first layers aggregate context within blocks and later layers aggregate context in a more global manner.

10 Conclusion

We provide justification for using HTA to study information flow within transformers. By studying attention distributions of BERT we uncover an interesting pattern: In earlier layers, attention heads attend mostly to earlier tokens, whereas this trend quickly reverses with increasing depth. This is surprising, since BERT is trained using bi-directional language modeling and it suggests that like humans, BERT understands language from left to right.

A problem with local attention patterns is that they do not reveal how the attention heads process the information contained in the input tokens. We thus use Hidden Token Attribution to compute per-head attribution distributions over the input words. Our results show that the mismatch between attention and attribution distributions increases with depth. This confirms the importance of accounting for information mixing when analyzing attention heads with respect to the input tokens. Finally, we show how five different attention head patterns differ from their token attribution equivalents. Our method and results are complementary to those in (Abnar and Zuidema, 2020), we believe a combination of attention flow and HTA may provide new interesting insights.

In this work, we aim to set a clear border that distinguishes between local and global aggregation in transformer models. This distinction is important when trying to interpret the behavior of these models, and we hope that it will help future studies in their analyses. Furthermore, our findings add new insights to the growing field of research on explaining transformers. This research, in turn, can help in guiding design decisions leading to further improvements of natural language processing architectures.

Effects of Pre- and Post-Processing on type-based Embeddings in Lexical Semantic Change Detection

Jens Kaiser[*], **Sinan Kurtyigit**[*], **Serge Kotchourko**[*], **Dominik Schlechtweg**
Institute for Natural Language Processing, University of Stuttgart
{jens.kaiser,sinan.kurtyigit,serge.kotchourko,schlecdk}@ims.uni-stuttgart.de

Abstract

Lexical semantic change detection is a new and innovative research field. The optimal fine-tuning of models including pre- and post-processing is largely unclear. We optimize existing models by (i) pre-training on large corpora and refining on diachronic target corpora tackling the notorious small data problem, and (ii) applying post-processing transformations that have been shown to improve performance on synchronic tasks. Our results provide a guide for the application and optimization of lexical semantic change detection models across various learning scenarios.

1 Introduction

In recent years Lexical Semantic Change Detection (LSCD), i.e. the detection of word meaning change over time, has seen considerable developments (Tahmasebi et al., 2018; Kutuzov et al., 2018; Hengchen et al., 2021). The recent publication of multi-lingual human-annotated evaluation data from SemEval-2020 Task 1 (Schlechtweg et al., 2020) makes it now possible to compare LSCD models in a variety of scenarios. The task shows a clear dominance of type-based embeddings, although these are strongly influenced by the size of training corpora. In order to mitigate this problem we propose pre-training models on large corpora and refine them on diachronic target corpora. We further improve the obtained embeddings with several post-processing transformations which have been shown to have positive effects on performance in semantic similarity and analogy tasks (Mu et al., 2017; Artetxe et al., 2018b; Raunak et al., 2019) as well as term extraction (Hätty et al., 2020). Extensive experiments are performed on the German and English LSCD datasets from SemEval-2020 Task 1. According to our findings, pre-training is advisable when the target corpora are small and should be done using diachronic data. We further show that pre-training on large corpora strongly interacts with vector dimensionality and propose a simple solution to avoid drastic performance drops. Post-processing often yields further improvements. However, it is hard to find a reliable parameter that performs well across the board. Our experiments suggest that it is possible to use simple pre- and post-processing techniques to improve the state-of-the-art in LSCD.

2 Related Work

As evident in Schlechtweg et al. (2020) the field of LSCD is currently dominated by Vector Space Models (VSMs), which can be divided into type-based (static) (Turney and Pantel, 2010) and token-based (contextualized) (Schütze, 1998) models. Prominent type-based models include low-dimensional embeddings such as Global Vectors (GloVe, Pennington et al., 2014) and Skip-Gram with Negative Sampling (SGNS, Mikolov et al., 2013a,b). However, as these models come with the deficiency that they aggregate all senses of a word into a single representation, token-based embeddings have been proposed (Peters et al., 2018; Devlin et al., 2019). According to Hu et al. (2019) these models can ideally capture complex characteristics of word use, and how they vary across linguistic contexts. The results of SemEval-2020 Task 1 (Schlechtweg et al., 2020), however, show that contrary to this, the token-based embedding models (Beck, 2020; Kutuzov and Giulianelli, 2020) are heavily outperformed by the type-based ones (Pražák et al., 2020; Asgari et al., 2020). The SGNS model was not only widely used, but also performed best among the participants in the task. This result was recently reproduced in the DIACR-

Ita shared task (Basile et al., 2020; Laicher et al., 2020; Kaiser et al., 2020b). Its fast implementation and combination possibilities with different alignment types further solidify SGNS as the standard in LSCD (Schlechtweg et al., 2020, 2019a; Shoemark et al., 2019; Kutuzov et al., 2020). Hence, the embeddings used in this work are SGNS-based.

Further increases in performance of type-based VSMs can be achieved by various post-processing transformations. This has been shown for semantic similarity and analogy tasks (Mu et al., 2017; Artetxe et al., 2018b; Raunak et al., 2019) as well as term extraction (Hätty et al., 2020). It is still an open question whether these transformations improve performance in the special setting of LSCD where we typically have several corpora and vector spaces which have to be transformed simultaneously (Schlechtweg et al., 2020). An indication is given by Schlechtweg et al. (2019a) showing that for a simple LSCD model mean centering leads to consistent performance improvements on two German data sets. Whether this result is reproducible on further data sets, more complex models and further post-processing techniques has not been determined yet.

Post-processing methods operate on information already contained in a VSM, rather than adding additional information. Further semantic information can be introduced by pre-training vectors on a larger unspecific collection of text (Kutuzov and Kuzmenko, 2016) or by training a seperate matrix on such text and concatenating the two VSMs (Limsopatham and Collier, 2016). This is especially helpful for cases where only smaller specialized corpora are given. Combining the information from two models is also found in Kim et al. (2014), here it is used for alignment proposes. We operate similarly to Kim et al. but with the motivation of Limsopatham and Collier and Kutuzov and Kuzmenko, as we aim to enrich a VSM prior to the training process.

3 Data and Tasks

We train SGNS-based VSMs on various corpora and use a word similarity task and an LSCD task for evaluation. The two tasks share a common aspect: the vector representations of two words need to be compared with some metric (e.g. cosine similarity), and word pairs need to be ranked according to that metric. In the word similarity task, we have the vectors of two different words in the same vector space (w_i, w_j), while for LSCD we have the vectors of the same word but from different vector spaces representing different time periods (w_i^{t1}, w_i^{t2}).

Modern Data. We use two large modern English and German corpora, PUKWAC (Baroni et al., 2009) and SDEWAC (Faaß and Eckart, 2013) to validate the post-processing methods on the word similarity task and to create pre-trained embeddings for the LSCD task. PUKWAC and SDEWAC are web-crawled corpora from the *.uk* and *.de* domain respectively. Resulting in fairly large corpora, 2B tokens and 750M tokens (see Table 1). We evaluate vector representations created on the two corpora on a standard dataset of human similarity judgments, WordSim353 (Finkelstein et al., 2002), by measuring Spearman's rank correlation coefficient of the cosine similarity of vectors for target word pairs with human judgments.

Diachronic Data. We utilize the English and German datasets provided by SemEval-2020 Task 1 Subtask 2 (Schlechtweg et al., 2020). Each dataset contains two *target corpora* from different time periods, t_1 and t_2, as well as a list of target words. The corpora originate mostly from newspaper articles and books. Their biggest difference to PUKWAC and SDEWAC is their approximately 10 to 100 times smaller size, according to token counts (see to Table 1). The task is to rank the list of target words according to their word sense divergence, gradually from 0 (no change) to 1 (total change). The rank predictions are compared against gold data which is based on human judgments. Once again Spearman's rank correlation coefficient is used to measure performance on the task.

4 Models

Following the popular approach taken for type-based vector space models in LSCD, we combine three sub-systems: (i) creating semantic word representations, (ii) aligning them across corpora, and (iii) measuring differences between the aligned representations (Schlechtweg et al., 2019a; Dubossarsky et al., 2019; Shoemark et al., 2019). Alignment is needed as columns from different vector spaces may not correspond to the same coordinate axes, due to the stochastic nature of many low-dimensional word representations (Hamilton et al., 2016). Additionally, we aim to refine subsystem (i) by adding pre-trained semantic word representations and using post-processing methods

	DIACHRON				MODERN

Table 1: Corpus statistics. GER$_{t1}$ and GER$_{t2}$ are sampled from DTA (Deutsches Textarchiv, 2017), BZ (Berliner Zeitung, 2018) and ND (Neues Deutschland, 2018). DTA contains texts from different genres, BZ and ND are collections of newspaper articles. Clean Corpus of Historical American English (CCOHA) (Davies, 2012; Alatrash et al., 2020) is a genre balanced collection of texts from a wide variety of time periods and the basis for ENG$_{t1}$ and ENG$_{t2}$.

to improve the quality of the created semantic word representations.[1]

We use SGNS (Mikolov et al., 2013a,b) to create type-based word representations in combination with three different alignment methods, Orthogonal Procrustes (OP), Vector initialization (VI), and Word Injection (WI). The three alignment methods combined with SGNS have been proven to be state-of-the-art, even when competing against token-based embeddings (Schlechtweg et al., 2020; Kaiser et al., 2020a; Basile et al., 2020). Cosine Distance (CD) is used to measure differences between word vectors.[2]

4.1 Alignment

Vector initialization (VI). In VI we first train SGNS on one corpus and then use the learned word and context vectors to initialize the model for training on the second corpus (Kim et al., 2014; Kaiser et al., 2020a). The motivation is that the vector of a word with similar contexts across both corpora will not deviate much from its initialized value. On the other hand, vectors of words with different contexts across both corpora, will be updated to accommodate the new semantic properties. Words which only appear in the second corpus are initialized on random vectors.

Orthogonal Procrustes (OP). SGNS is trained on each corpus separately, resulting in word matrices A and B. To align them, we follow Hamilton et al. (2016) and calculate an orthogonally-constrained matrix W^*:

$$W^* = \underset{W \in O(d)}{\arg\min} \|BW - A\|_F .$$

Prior to this alignment step both matrices are length-normalized and mean-centered (Artetxe et al., 2017; Schlechtweg et al., 2019a).

Word Injection (WI). The sentences of both corpora are shuffled into one joint corpus, but all occurrences of target words are substituted by the target word concatenated with a tag indicating the corpus it originated from (Ferrari et al., 2017; Schlechtweg et al., 2019a; Dubossarsky et al., 2019). This leads to the creation of two vectors for each target word in one vector space, while non-target words receive only one vector encoding information from both corpora.

No Alignment (NO). Comparing two vector spaces without aligning them results in poor performance on LSCD (Schlechtweg et al., 2019a). As VI shows, initializing the model with weights from the previous run, results in aligned vector spaces. We expand on this concept by initializing two models on the same pre-trained weights assuming that the resulting vector spaces are aligned to one another. The difference to VI is that instead of initializing model B with the weights from model A, the weights from a third pre-trained model C are used to initialize both models A and B.

4.2 Pre-training

The corpora used in the context of LSCD are often small, as they are restricted by the length of time periods or availability of historical data. For example the English corpora of SemEval-2020 Task 1 only have 6.6M tokens each, compared to 1.9G of PukWaC. This reduced corpus size limits the amount of semantic information encoded into VSMs trained on the corpus. Pre-training addresses this problem by first training SGNS on a large, possibly external corpus, and then using these vectors

---

to initialize the model for training on the smaller diachronic target corpora. The idea is that the model first learns very broad and general semantic properties followed by the training on the target corpora, where corpus and time specific details are picked up, i.e., a form of refinement. This procedure is applicable to all alignment types.

We use PUKWAC and SDEWAC for pre-training, later referenced as MODERN. However, pre-training on modern corpora is only advisable if the assumption can be made that the meanings of words in the pre-training corpus roughly correspond to the meanings of words in the target corpora. It is unclear to which extent this assumption holds for our data. Hence, we also combine the two target corpora into a bigger corpus, referenced as DIACHRON, which is then used for pre-training.

4.3 Post-processing (PP)

Similarity Order Transformation (SOT). In 2nd order similarity, the similarity of two words is assessed in terms of how similar they are to a third word (Schütze and Pedersen, 1993; Artetxe et al., 2018b; Schlechtweg et al., 2019b). This can analogously be done for higher (3rd, 4th, etc.) orders. According to Artetxe et al. (2018b) these orders capture different aspects of language. Artetxe et al. propose a linear transformation deriving higher or lower orders of similarity from a given matrix X. For this, the product with the transpose matrix is split into its eigendecomposition $X^TX = Q\lambda Q^T$, so that λ is a positive diagonal matrix whose entries are the eigenvalues of X^TX and Q is an orthogonal matrix with their respective eigenvectors as columns. The linear transformation matrix is then defined as $W_\alpha = Q\lambda^\alpha$, where α is the parameter that adjusts the desired similarity order. Applying this to the original embeddings X yields the transformed embeddings $X' = XW^\alpha$.

Mean Centering (MC). The centroid of a matrix is the average vector over all vectors in a matrix: $\vec{c} = \frac{1}{|V|}\sum_i^V \vec{w_i}$. MC refers to subtracting $\vec{c}$ from each $\vec{w_i}$ in the matrix. MC alters all dimensions so that the mean of all columns is zero. Artetxe et al. provide the intuitive motivation for MC that it moves randomly similar vectors further apart and Mu and Viswanath (2018) consider mean centering as an operation making vectors "more isotropic", i.e., more uniformly distributed across the vector space. Mu and Viswanath indicate that isotropy of word vectors is positively correlated to performance.

Principal Component Removal (PCR). Given a n-dimensional matrix X, Principal Component Analysis (PCA, Pearson, 1901) returns n vectors where each vector describes a best fitting line for the data while being orthogonal to the first $n-1$ vectors. Thus, the first PC describes the greatest variance in the first direction, the second PC describes the second greatest variance in the second direction, and the nth PC describes the nth greatest variance in the nth direction. Mu and Viswanath (2018) use PCA to compute the top m PCs from a mean centered word embedding $\bar{M}$: $p_1, ..., p_m = \text{PCA}(\bar{M})$. Subsequently these PCs are used to project each vector $v \in M$ onto the subspace spanned by the PCs. This projection is then subtracted from the original mean centered word vector $\tilde{v}$ by $v' = \tilde{v} - \sum_{i=1}^{m}(p_i^{\intercal} v)p_i$, which results in nullifying the top m PCs in M. This is similar to the approach of Bullinaria and Levy (2012). Mu and Viswanath combine both MC and PCR into one PP transformation (MC+PCR).

As for MC Mu and Viswanath's main motivation for PCR is to make vectors more isotropic. They also demonstrate empirically that the top PCs encode word frequency and offer the removal of this noise from the matrix as an alternative explanation for observed performance improvements.

Stacking. VI and OP alignment result in two matrices, and hence, a proper way for applying PP to both of them is needed. The naïve way of simply post-processing both matrices separately (SEP) may violate the assumption that they are represented in the same space. Therefore, in a second approach, we apply PP to both matrices simultaneously by stacking them vertically beforehand (STA). Preliminary experiments showed that following the naïve way of PP (SEP) led to severe decrease in performance for SOT (but not for MC+PCR). Hence, applying SOT on two matrices separately is followed by an orthogonal post-alignment (SEP+PA).

5 Experiments

For the most part, we chose common model hyperparameter settings in order to keep our results comparable to previous research (Hamilton et al., 2016; Schlechtweg et al., 2019a; Kaiser et al., 2020a). We fine-tune for different alignment methods and datasets by varying dimensionality d, window size w and number of training epochs e.[3]

5.1 Validation

We validate the results reported by Artetxe et al. (2018a) and Mu and Viswanath (2018) on PUKWAC and SDEWAC. The performance peaks for negative α-values around -0.2 as well as the slight performance increase over the baseline for SOT are in line with the findings of Artetxe et al. (see Figure 1a). For MC+PCR we observe the greatest performance improvement when the number of removed PCs is around $m = \frac{d}{100}$ (see Figure 1b). This fits the rule of thumb as stated by Mu and Viswanath.

5.2 LSCD

5.2.1 Pre-training

We tune SGNS models for each alignment method with and without pre-training (baseline), see Table 2. Recall from Section 4.2 that we use the corpora MODERN and DIACHRON for pre-training. Table 2 lists the maximum and mean performances of the baseline and pre-training with different alignment methods, as well as the standard deviation (for a visual representation of the max values see Figure 2). The mean is calculated across different d, e and w, giving the expected performance in a realistic scenario where fine-tuning hyper-parameters is not possible (Schlechtweg et al., 2020; Basile et al., 2020). For German, the baseline max and mean scores could not be significantly improved by pre-training across alignments. For English, pre-training on DIACHRON results in better max and mean scores for OP and WI, with max improvements up to .10. Also, the overall best result is achieved with OP and pre-training on DIACHRON. The usage of MODERN does not improve on the maximum, while reducing the mean. The overall lower performance as well as the observed performance improvements compared to German, may be attributed to the roughly 10 times smaller target corpora. That is, pre-training is helpful on the smaller target corpora.

5.2.2 Post-processing

For every combination of alignment and pre-training method, the matrix with the highest performance across parameters is chosen as the baseline. SOT and MC+PCR are applied individually to these matrices within a wide parameter range (see Appendix B) for both stacking methods (STA and SEP/SEP+PA). Table 3 presents the mean optimal performance gains after PP, which is calculated by extracting the best performance after PP for every matrix, subtracting the baseline values and averaging the values per language. Averaging the respective parameter values yields the mean argmax. Figure 3a and 3d show the highest performances for every baseline matrix after SOT and MC+PCR respectively.

SOT. As we see in Figure 3a, SEP+PA and STA perform similarly. We find small mean performance gains across the board (.013 for GER+STA,

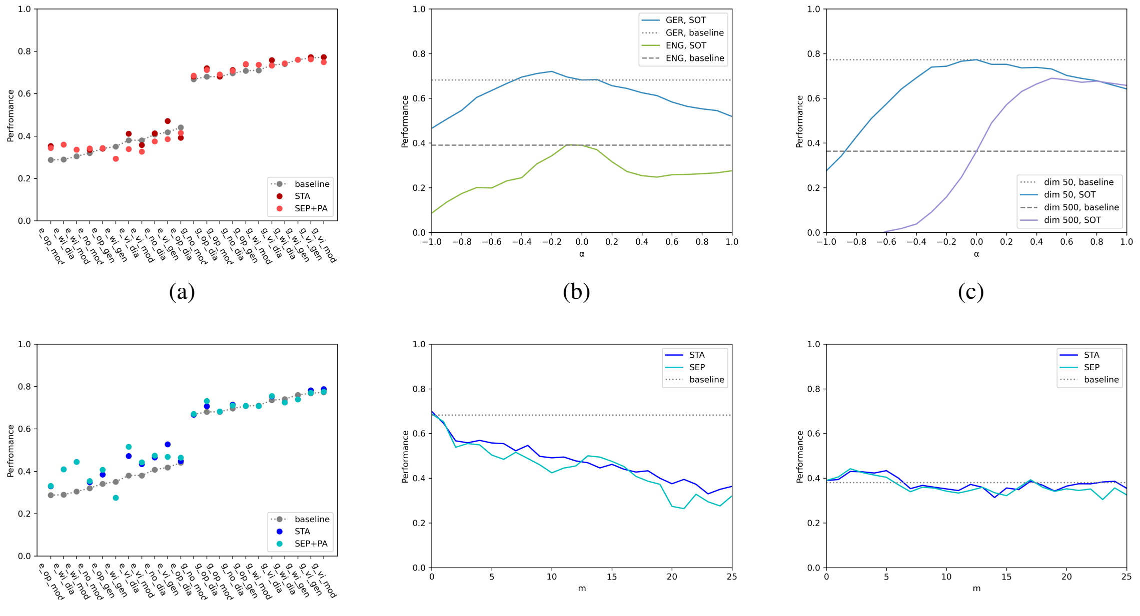
.008 for GER+SEP+PA, .013 for ENG+STA), except for ENG+SEP+PA where a minuscule decrease (-.005) can be seen. Overall, STA outperforms SEP+PA slightly. We now further examine the effect of SOT+STA on individual matrices. In general, the data can approximately be described as a downward opening parabola (see Figure 3b), with different peaks for both languages and slight differences between alignment methods. Averaging the argmax for α shows us where these peaks are. The calculations yield a mean optimal α of 0 for GER+STA, and -0.2 for ENG+STA. For GER the peak performance always lies in the interval $[-0.2, 0.3]$. This changes to $[-0.4, 0.1]$ for ENG, except for one outlier, where the peak is at -0.8. Moving α away from this parameter range results in severe performance decreases. This behaviour can also be seen on the MODERN corpora (see Figure 1) and is in line with the findings of Artetxe et al. (2018b). In order to predict a high-performing parameter, independent from the underlying matrix, we calculate mean performance gains for fixed parameter values. The values are chosen according to the the above-described peak intervals for the respective languages. However, on average, using a fixed parameter results in slight performance losses, notwithstanding the α-value, and hence, finding a high-performing fixed parameter value was not possible. We observe similar findings for individual alignment methods and varying dimensionality. However, GER+VI alignment represents an interesting exception: With high dimensionality (> 300) base performance drops heavily (Kaiser et al., 2020a), and is then "repaired" by the PP, bringing it close to the baseline of the best performing dimension (see Figure 3c).

MC+PCR. As we see in Figure 3d, MC+PCR yields small improvements over the baselines for German. This is also reflected in the mean gain in Table 3. We find that no single value for m yields consistent improvements. However, we find that for m=0 (only MC) MC+PCR consistently improves the baseline slightly (see Figure 3e), while for higher m the performance decreases consistently. For English we see greater improvements, see Fig-



(a) (b) (c)

	SOT + SEP+PA	-0.2/0.3	-.005/.043
	MC+PCR + STA	3.0/3.8	.049/.068
	MC+PCR + SEP	6.2/7.1	.058/.077

Table 3: Mean of best-performing parameters and mean performance gain compared to baseline on LSCD task. Parameter range for SOT [-1,1] and MC+PCR [0,25]

ure 3f, 3d and mean gain in Table 3. A range of parameters shows improvements with m=3 yielding the highest (.0175). This can also be seen in Figure 3f where several parameters yield improvements. We conclude that predicting a parameter for likely performance improvement is possible for English, but not for German. However, if this PP should be used, we recommend using a parameter space of $m \in [0, 5]$, as this parameter space is most likely to produce improvements on English, while not harming performance too much on German. This also roughly corresponds to the recommendation of Mu and Viswanath (2018), as they predict that the parameter should be chosen around $\frac{d}{100}$. Furthermore, we suggest using STA, as this does on average show better performance over SEP for the aforementioned parameter space. We see that the effects of SOT as well as MC+PCR are highly dependent on the underlying matrix.

6 Analysis

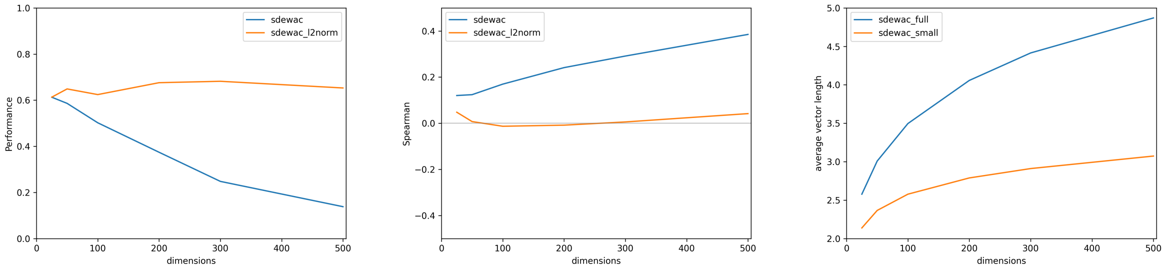
Test Statistics. The effects of pre-training and PP methods on word embeddings are not limited to performance differences in word similarity or LSCD tasks. We use two test statistics to further analyse vector spaces: (i) isotropy (Mu and Viswanath, 2018), i.e., uniformity of vector distribution and (ii) frequency bias (Dubossarsky et al., 2017; Kaiser et al., 2020a), i.e., correlation between cosine distance and frequency.[4]

6.1 Pre-training

On the German dataset it is noticeable that pre-training on DIACHRON often results in slight drop in performance at higher d. This behaviour is more pronounced, consistent and even visible on the En-

---

[4] We compute correlation based on frequency in the second target corpus, results were similar for the first target corpus.



(a) (b) (c)

Figure 4: Test-statistics for result analysis, **left**: Performance after pre-training on different corpora, **middle**: Correlation between CD and frequency, **right**: average vector length of the weights created on different-sized pre-training corpora.

glish dataset when pre-training on MODERN, see Figure 2.[5] Such a drop in performance after initializing on pre-trained vectors has already been observed by Kaiser et al. (2020a). The authors relate the drop to an increased frequency bias and reduce it by increasing e/w. It is noteworthy that the drop is much more pronounced for pre-training on MODERN compared to DIACHRON. This can be attributed to a difference in word vector lengths of the SGNS model used for initialization. We make the following observation: average word vector length increases with the amount of training word pairs. The difference more training data makes is amplified at higher d, see Figure 4c. By length-normalizing the word vectors between the initialization and training step, the drop in performance can be completely circumvented. Additionally, the frequency bias is reduced to 0, see Figure 4b.

For English, we expected a higher performance gain from pre-training when using MODERN because of the small data size. However, we observe no improvements over the baseline. Using length-normalized word vectors for initialization does result in slightly improved max and mean values for MODERN but these are still lower than max and mean values of DIACHRON.

6.2 SOT

SOT has a clear effect on isotropy, which has not been described in previous research. Isotropy shows the same behaviour across both languages and all models, and is best described as a vertically mirrored S-curve (see Figure 5a). Decreasing α increases isotropy close to 1, while increasing α decreases isotropy close to 0. The average correlation (Pearson) between α and isotropy over all matrices is -.89 for both languages. However, the performance correlates only slightly with isotropy (-.25, .35). Moreover, α correlates only weakly with frequency bias (.19, -.12, however with high variance). In order to explain the above-described "repair" effect we take a closer look at the three GER+VI models. Applying SOT brings large performance increases, as stated in Section 5.2.2. For all three models a considerably higher baseline frequency bias for d=500 is visible. SOT strongly reduces this bias for MODERN, and results in a huge performance gain (see Figure 5b).

6.3 MC+PCR

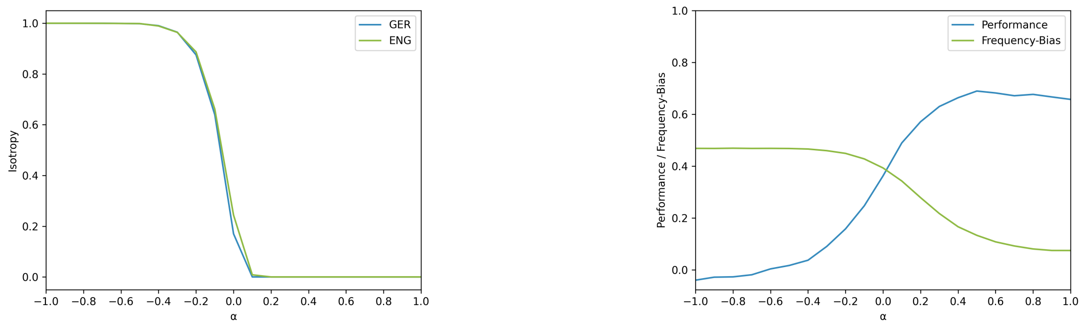
As Mu and Viswanath (2018)'s main motivation behind MC+PCR is to increase isotropy of a vector space as well as removal of word frequency noise through PCR, we examine how isotropy and frequency bias develop with m. While PCR has the predicted effect on frequency bias (GER: -.94, ENG: -0.6), PCR does in fact not increase isotropy, contrary to Mu and Viswanath's motivation of "rounding towards isotropy", but has a consistent reducing effect (GER -.75, ENG: -.7). Thus, we believe that rounding towards isotropy is not suitable for explaining performance. Furthermore, we observe that MC not only exhibits effects on isotropy, but also acts on frequency bias, thus Mu and Viswanath's PCR motivation can be extended to MC.

7 Conclusion

We tested the effects of pre-training and post-processing on a variety of LSCD models. We performed extensive experiments on a German and an

---

[5] Although not depicted, the other alignment techniques in combination with pre-training show very similar behaviour to NO.



(a)

(b)

Figure 5: Representative plot for the isotropy after SOT+STA (5a). Performance and frequency bias after SOT+STA for GER+VI+BIG (5b).

English LSCD dataset. According to our findings, pre-training is advisable when the target corpora are small and should be done using diachronic data. The size of the pre-training corpus is crucial, as a large number of training pairs leads to performance drops, which are probably caused by their effect on vector length. Length-normalization may be used on pre-trained vectors to counteract this effect.

Further performance improvements may be reached by post-processing. While SOT+STA yielded moderate improvements for both languages, MC+PCR showed larger improvements, but only on English. However, for neither we were able to find a reliable parameter that performed well across the board. Instead, we found that a well-performing parameter value is highly dependent on the underlying matrix. Both post-processing methods affect isotropy and frequency bias.

The methods we tested are particularly helpful when tuning data is available, as performance can be optimized and becomes more predictable. Hence, we recommend to obtain a small annotated sample of target words for the target corpora and to tune pre-training, model and post-processing parameters on the sample before performing predictions for semantic changes on unseen data. With the recent upsurge of digitized historical corpora and diachronic semantic annotation efforts (Tahmasebi and Risse, 2017; Schlechtweg et al., 2018, 2020; Basile et al., 2020; Rodina and Kutuzov, 2020) this may often be a likely and feasible scenario.

A Corpus details

The corpora are lemmatized and contain no punctuation, further pre-processing on the corpora by us is limited to removing low-frequency words. All words with a frequency below the value listed in row *min word freq.* in Table 1 are removed from the corpora. This is done to reduce noise and unwanted artifacts.

B Parameter settings

SGNS. We use common hyper-parameter settings: initial learning rate of 0.025, number of negative samples k=5 and no sub-sampling. Vector dimensionality d, window size w and number of training epochs e are varied in order to fine-tune model and methods. This is important as alignment methods like VI are highly dependent on the choice of e and d (Kaiser et al., 2020a). The following values are used: $w \in \{5, 10\}$, $e \in \{5, 10, 20, 30\}$, $d \in \{25, 50, 100, 200, 300, 500\}$. Due to the immense amount of possible parameter combinations we only ran each setting once.

PP was performed on the high-scores of each language, where we differentiate between different combinations of alignment, pre-training as well as if the matrices were STA or SEP post-processed.

SOT. As stated in Section 4.3, SEP is used in combination with post-alignment. We apply SOT with α values ranging from -1 to 1 in 0.1 increments on every baseline matrix with $d \in \{25, 50, 100, 200, 300, 500\}$.

MC+PCR. MC+PCR is performed using a parameter space of [0, 25] in order to examine the performance development over a growing number of PCs removed. It is important to note that using the parameter 0 results in only applying MC.

The Gutenberg Dialogue Dataset

Abstract

Large datasets are essential for neural modeling of many NLP tasks. Current publicly available open-domain dialogue datasets offer a trade-off between quality (e.g., DailyDialog (Li et al., 2017b)) and size (e.g., Opensubtitles (Tiedemann, 2012)). We narrow this gap by building a high-quality dataset of 14.8M utterances in English, and smaller datasets in German, Dutch, Spanish, Portuguese, Italian, and Hungarian. We extract and process dialogues from public-domain books made available by Project Gutenberg[1]. We describe our dialogue extraction pipeline, analyze the effects of the various heuristics used, and present an error analysis of extracted dialogues. Finally, we conduct experiments showing that better response quality can be achieved in zero-shot and finetuning settings by training on our data than on the larger but much noisier Opensubtitles dataset. Our open-source pipeline[2] can be extended to further languages with little additional effort. Researchers can also build their versions of existing datasets by adjusting various trade-off parameters.

1 Introduction

Current open-domain dialogue datasets offer trade-offs between quality and size. High-quality datasets are usually too small to represent the multitude of topics required for a conversational agent. Large datasets often lack good turn-segmentation and are generally noisy, models trained on such datasets generate low-quality or generic output. In Section 2 we analyze publicly available dialogue corpora and the trade-offs they offer. To address the need for large, high-quality datasets we build a corpus of 14.8M utterances in English using publicly available books from Project Gutenberg. We also build datasets for German, Dutch, Spanish, Portuguese, Italian, and Hungarian, with utterance counts in the 20k–200k range. We call this dataset ensemble the Gutenberg Dialogue Dataset. We wish to make it explicit that we are not aiming to create a gold dataset. Our goal is to create a dataset which offers a better size-quality trade-off than other dialogue corpora. The Gutenberg dataset is both larger than DailyDialog (Li et al., 2017b) and has better quality than Opensubtitles (Tiedemann, 2012), and we think it benefits researchers by filling a need in the landscape of dialogue corpora. The Gutenberg Dialogue Dataset and the code used to build it can be accessed through this repository: `https://github.com/ricsinaruto/gutenberg-dialog`. The repository also contains all trained models presented in this paper and all data and training scripts used to produce the results. We also built a web demo interface for interacting with the trained models[3].

In Section 3 we offer a detailed quantitative analysis of our heuristics to better understand their effects on data quality. Section 4 presents our error analysis of the English dataset both at the utterance and dialogue level. Using our MIT licensed pipeline, researchers can easily build various dataset versions by adjusting a small number of parameters that control multiple dimensions of the size-quality trade-off. In Section 5 we evaluate our dataset in a generative multi-turn and single-turn setting using the GPT-2 (Radford et al., 2019) and Transformer (Vaswani et al., 2017) architectures, respectively. For each of the 7 languages, we compare models trained on Gutenberg and Opensubtitles. For English, we also compare zero-shot and finetuning performance of Gutenberg and Opensubtitles on two smaller datasets. Potential improvements and future work is discussed in Section 6.

Extension to additional languages is ongoing, we welcome all contributions from the community: our modular code requires only a limited amount of language-specific effort for each new language.

2 Background

Open-domain dialogue datasets vary in size, quality, and source, as demonstrated in Table 1. Generally, smaller datasets are constructed using controlled crowdsourcing environments, making their quality higher (e.g., PersonaChat (Zhang et al., 2018)). Crowdsourcing platforms like Amazon Mechanical Turk[4] are used to hire and instruct workers to carry out free-form conversations. Larger datasets can be built by automatic processing of dialogue-like text sources, such as Opensubtitles and Reddit[5] (Henderson et al., 2019)). Opensubtitles contains movie subtitles in multiple languages and Reddit is a discussion forum with millions of daily comments on various topics. Automatic extraction offers less quality control, and the data source heavily influences the genre of conversations. In Reddit data, everyday chit-chat is less common, comments in the same thread all discuss the same post. Two-party dialogues are rare as threads are almost always multi-speaker. Twitter[6] conversations have similar problems and they are also constrained by a character limit. Extracting conversations from Twitter and Reddit is straightforward as speaker segmentation is included and the thread chain can be used as dialogue history.

Books, especially fiction, have so far seen little use as a source of dialogue data. In DailyDialog (Li et al., 2017b), 90 000 high-quality utterances are extracted from online resources for English language learners, extraction steps are not detailed. The quality of these dialogues and the lack of a large book-based dataset motivates our work. Dialogues extracted from books, like movie subtitles, lack context, but their usefulness is evidenced by the Cornell Corpus (Danescu-Niculescu-Mizil and Lee, 2011) and DailyDialog. As argued by Danescu-Niculescu-Mizil and Lee (2011) and Fainberg et al. (2018), artificial dialogues in movies and books generally resemble natural conversations. Such dialogues are also called written dialogues as opposed to spoken corpora like the Switchboard corpus (Godfrey et al., 1992). Though our corpus contains written dialogues we also perform evaluation on Persona-Chat, which can be considered as a spoken dialogue corpus, and show Gutenberg's effectiveness in this setting as well.

Unfortunately, the Cornell Corpus is relatively small, while the Opensubtitles corpus suffers from the fact that the original dataset lacks both dialogue and turn segmentation: subtitle lines are treated as turns and dialogue history consists of the previous n lines, with little to no additional post-processing used to extract dialogues instead of using the raw data (Henderson et al. (2019) removes the shortest and longest utterances to improve quality). These issues lead to trained models outputting generic responses, e.g., to the input "yes i believe there are green teas black teas and scented teas. any others?" a model trained on Opensubtitles outputs "sure.". In addition, the types and ratio of errors in these datasets have not been explicitly analyzed. For the Gutenberg dataset, we build a multi-step extraction pipeline and analyze both the performance of each heuristic and the ratio of each error type in a sample of the final corpus. Unfortunately, most of the tools developed here are specific to the book domain, and use textual patterns which are not available in Opensubtitles. In order to increase the quality of Opensubtitles, subtitle-specific methods need to be developed, like taking into account the elapsed time between two subtitle lines.

The size of our corpus facilitates effective training of large Transformer-based models (Radford et al., 2019; Yang et al., 2019). Recently, pre-training and finetuning large language models on specific tasks (including dialogue modeling) has gained popularity (Wolf et al., 2018; Devlin et al., 2019). Transformer-based models and specifically GPT-2 have gained state-of-the-art status in the dialogue domain (Adiwardana et al., 2020; Roller et al., 2020; Zhang et al., 2019; Wolf et al., 2018). Through these models the community has gradually shifted from single-turn to multi-turn scenarios. Since we wish to demonstrate our dataset's quality on the dialogue-level, we conduct experiments primarily with GPT-2. We report some single-turn trainings using Transformer for comparison. We show Gutenberg's effectiveness for multi-turn pre-training in Section 5, comparing it to Opensubtitles pre-training, which is popular in the literature (Csaky and Recski, 2017; Krause et al., 2017; Xing and Fernández, 2018).

Dataset	Size	Source	Quality
DailyDialog (Li et al., 2017b)	90k	ESL websites	auto-extracted
Wizard-of-Wikipedia (Dinan et al., 2019)	100k	crowdsourcing	human-written
Document-grounded (Zhou et al., 2018)	100k	crowdsourcing	human-written
Persona-Chat (Zhang et al., 2018)	150k	crowdsourcing	human-written
Self-dialogue (Fainberg et al., 2018)	150k	crowdsourcing	human-written
Cornell Movie Corpus (Danescu-Niculescu-Mizil and Lee, 2011)	300k	movie scripts	auto-extracted
Self-feeding chatbot (Hancock et al., 2019)	500k	human-bot dialogues	partly human-written
Twitter corpus[7]	5M	Twitter posts/replies	auto-extracted
Opensubtitles (Henderson et al., 2019)	320M	movie subtitles	auto-extracted
Reddit (Henderson et al., 2019)	730M	Reddit threads	auto-extracted

Table 1: Comparison of open-domain dialogue datasets in English. *Size* is the rough number of utterances, *Source* describes where the data comes from, and *Quality* distinguishes between dataset collection techniques.

3 Extraction Pipeline

Most of Project Gutenberg's 60 000 online books are in English (47 300 books; 3 billion words). French, Finnish, and German, the next most common languages, contain 3000, 2000, 1750 books, and 194M, 74M, 82M words, respectively. Dutch, Spanish, Italian, Portuguese, and Chinese are all above 10M words, followed by a long tail of various languages. We used the Gutenberg python package[8] to download books and query their license, language, and author metadata. Further Gutenberg statistics can be found in Appendix A.2. This section describes heuristics and methods used to extract dialogues from books and remove noise. The main challenges are identifying changes between speakers within a dialogue and separating sets of utterances that do not belong to the same dialogue. To separate dialogues, changes in location, time, speaker, etc. would have to be identified directly, but we develop simple heuristics (e.g., distance between utterances) that can extract relatively high-quality conversations at scale. Tunable parameters of our system offer trade-offs between data quality and size. Using our open-source system researchers can build custom datasets that best suit their applications.

Our dialogue extraction pipeline includes three main steps: 1. Conversational and narrative text is separated. 2. Dialogic text is split into separate dialogues. 3. Dialogues are segmented into separate turns (utterances). In most books, conversational text is highlighted; e.g., placed between single/double quotation marks in English or started by an em-dash in Hungarian. Naturally, these delimiters have other uses as well, but such cases are rare (about 5% of utterances, see Section 4). We can only extract dialogues from books which clearly delimit both the start and end of conversations. In some languages/books, the start of an utterance is given, but the end is not, and narrative text can get mixed in (e.g., *Si vous arrivez avant nous, cria Luigi au messager, annoncez à la nourrice que nous vous suivons.* 'If you arrive before us, shouted Luigi to the messenger, tell the nurse that we are following you.'). This is why we could not build a French dataset, and have relatively smaller datasets in Dutch, Italian, Portuguese, and Hungarian. Figure 1 shows a sample dialogue highlighting our heuristics. In the following paragraphs, we offer a parameter-based description of our pipeline.

"Read what I have written," she gasped. "It may be utterly unintelligible."
For answer, Morton folded the sheet and placed it in an envelope.
"Address this, if you please," he said.
She obeyed his request, limply forcing herself to make the effort; and, as the pen once more fell from her fingers, she glanced up at him with a haggard piteousness in her eyes.
"Will you not read what I have written?" she asked again.
"I see no reason why I should," he answered.

Figure 1: A dialogue example. Utterances are in separate paragraphs, sometimes broken up by narrative text.

Pre-filtering After downloading books and separating them by language, all copyrighted works are removed. We also filter books containing unusual,

---

[7] `https://github.com/Marsan-Ma-zz/chat_corpus`

[8] `https://github.com/ageitgey/Gutenberg`

Method	**Parameter**	**Filtered**	**What**
Pre-filter	2 (KL-div)	2090 books (4.42%)	Old books and noise
Delimiter filter	150 delimiters / 10 000 words	20 500 books (43.3%)	Books with no dialogues
Long utterances	100 words	610 000 utterances (3.95%)	Non-conversational utterances
Post-filter	20% rare words	20 478 dialogues (0.8%)	Dialogues containing many rare words

Table 2: The various filtering steps for the English dataset.

mostly older, language: if the KL divergence between a book's word distribution and the total (all books) distribution is above a threshold (2), it is removed. The method is less accurate for short books with less than 20 000 words, these are not filtered. In the English dataset, 2090 books were removed (4.42%). By analyzing 100 filtered and 100 non-filtered books randomly, we found 8 false positives (books that should not have been removed), and 9 false negatives.

Delimiter filter Before dialogue extraction, books with less than 150 delimiters per 10 000 words are removed. We assume that under a certain threshold the probability of delimiters used for non-conversational purposes is increased. We empirically set this ratio by increasing it until the assumption starts failing. Since many books do not contain dialogues, almost half were removed (20 500) in the English pipeline. Sampling 100 filtered and 100 non-filtered books, we found 8 false positives (books that should not have been removed), and 22 false negatives. In a sample of the final dataset, less than 5% of utterances were non-conversational (cf. Section 4).

Dialogue gap If two dialogue segments highlighted by delimiters are far apart, i.e. there are >150 characters between them, they will not be considered part of the same dialogue. This heuristic, the dialogue gap, will always offer a false positive/negative trade-off since the amount of text between dialogues varies considerably. We tuned this trade-off by reasoning that shorter dialogues are less problematic than incoherent dialogues: our setting yields 3.5 times fewer false negatives, as shown in Section 4. Our turn segmentation heuristic will also always treat separate paragraphs as separate utterances. In a sample of the final dataset, this assumption fails for roughly 4% of utterance pairs (cf. Section 4).

Long utterances and rare words During dialogue extraction utterances with more than 100 words are removed to ensure that remaining utterances are truly conversational and to facilitate neural model training (Dai et al., 2019). As all other parameters in the pipeline, this is adjustable to the needs of the user or task. Finally, we remove dialogues with more than 20% rare words (not in the top 100 000), removing noise and facilitating neural model training. Dialogues are split randomly into train (90%), validation (5%), and test (5%) datasets, dialogues from the same book are placed in the same split.

	#U	$\lvert U\rvert$	#D	$\lvert D\rvert$
English	14 773 741	22.17	2 526 877	5.85
German	226 015	24.44	43 440	5.20
Dutch	129 471	24.26	23 541	5.50
Spanish	58 174	18.62	6 912	8.42
Italian	41 388	19.47	6 664	6.21
Hungarian	18 816	14.68	2 826	6.66
Portuguese	16 228	21.40	2 233	7.27

Table 3: Statistics of the final dialogue datasets. Columns are: language, number of utterances, average utterance length, number of dialogues, and average dialogue length.

Languages differ only in the dialogue extraction step. The modular pipeline can be easily extended to new languages by specifying conversational delimiters and a minimal implementation of dialogue and turn segmentation, generally adaptable from English. In practice, adapting the English pipeline to other languages ranged between 0-50 lines of python code. Optionally further analysis might be needed to check the output of the pipeline and refine the extracting process if needed. Delimiters and parameters for other languages were not analyzed as profoundly as for English, leaving room for improvements in future work. We aim to show that good dialogue datasets can be constructed with minimal effort, as a first step towards a high-quality multi-language dataset ensemble. In total, the four filtering steps removed about 12.5% of utterances from the English dataset, detailed in Table 2. Statistics of the final datasets in all 7 languages can be seen in Table 3. The standard deviation of dialogue length in English is 6.09, and there are 87 500 dialogues with at least 20 utterances. The average dialogue length can be linearly adjusted with the dialogue gap parameter.

4 Error Analysis

Utterance-level To assess the single-turn quality of the English dataset we manually analyzed 100 random utterance pairs with book context. 89 pairs did not contain any errors. Remaining utterance pairs contained 1 error type each, out of 2 major and 2 minor types, minor errors occurring in only 1 case each. The extracted text is not conversational in 5 utterance pairs, a consequence of the delimiter threshold and other sources of noise (Figure 2). Utterances of a single speaker were falsely treated as multiple turns in 4 cases, most often because of our assumption that paragraph breaks signal dialogue turns (Figure 3).

> And he was singing, too, as he went on with his task; sometimes–
> "Play on, minstrèl, play on, minstrèl, My lady is mine only girl;"

Figure 2: Non-dialogue text detected as an utterance.

> In his progress he passed the door of the dormitory of his victim—he paused a moment, and listened attentively. Then in a voice of deep anguish he said,—
> “She can sleep—she can sleep—no ghostly vision scares slumber from her eyes—while—”
> He shuddered, and passed a step or two on, then pausing again, he said,—
> “Oh, if she, the young and innocent...”

Figure 3: Two consecutive turns uttered by the same speaker.

Dialogue-level Errors in whole dialogues exhibit a much greater variety. Based on a manual analysis of 50 dialogues in the English dataset we identified 7 error categories (Figure 4). The following numbers are always out of the 50 analyzed dialogues. 16 dialogues contained 0 errors, 21 contained 1 error type, 11 contained 2 types, remaining dialogues containing 3. We detail the number of dialogues affected by each error type below. We note that this does not constitute a proper statistical analysis.

Utterances from the same conversation frequently end up in different dialogues (17 cases, example in Figure 5) because of the dialogue gap threshold. The inverse, a dialogue containing utterances from multiple conversations, occurred in 5 cases (Figure 6). While it is challenging to set this parameter, we consider this to be a reasonable trade-off: shorter dialogues mean less data, but incoherent dialogues with utterances from multiple conversations are bad data. In Section 6 we discuss possible further approaches to segmenting conversational text.

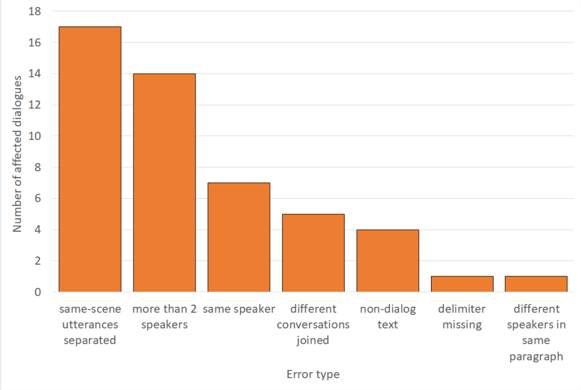

Figure 4: Number of dialogues affected by the various errors. In total 50 dialogues were analyzed. Some dialogues contained multiple types of errors and only 16 dialogues contained 0 errors.

> Richard curbed an impatient rejoinder, and said quietly, "William Durgin had an accomplice."
> Mr. Taggett flushed, as if Richard had read his secret thought. Durgin’s flight, if he really had fled, had suggested a fresh possibility to Mr. Taggett. What if Durgin were merely the pliant instrument of the cleverer man who was now using him as a shield? This reflection was precisely in Mr. Taggett’s line. In absconding Durgin had not only secured his own personal safety, but had exonerated his accomplice. It was a desperate step to take, but it was a skillful one.
> "He had an accomplice?" repeated Mr. Taggett, after a moment. "Who was it?

Figure 5: A single conversation cut up because of the long paragraph between the two utterances.

> “Carry pins, is it?” said Tom. “Ye can carry yer head level, me boy. So at it ye go, an’ ye’ll bate Rory fer me, so ye will.”
> “Well then,” cried Barney, “I will, if you give me first choice, and I’ll take Tom here.”
> “Hooray!” yelled Tom, “I’m wid ye.” So it was agreed, and in a few minutes the sides were chosen, little Ben Fallows falling to Rory as last choice.
> “We’ll give ye Ben,” said Tom, whose nerve was coming back to him. “We don’t want to hog on ye too much.”
> “Never you mind, Ben,” said Rory, as the little Englishman strutted to his place among Rory’s men. “You’ll earn your supper to-day with the best of them.”

Figure 6: First three and last two utterances are not part of the same conversation, but they were merged because of the dialogue gap threshold.

Books often contain dialogues between more than two speakers, our second most frequent source of error (14 dialogues). However, such conversations are still coherent and provide useful data for model training. In contrast, the same speaker uttering at least two consecutive turns breaks coherence in 7 dialogues. Tackling these issues would have to involve speaker identification (cf. Section 6). As in the utterance-level analysis, there were some dialogues (4) in which non-conversational text got mixed in. The remaining errors, *delimiter missing* and *different speakers in same paragraph* occurred in only 1 dialogue out of 50.

5 Experiments

5.1 Evaluation Metrics

Most automatic evaluation methods for dialogue models correlate poorly with human judgment (Liu et al., 2016), and recently proposed metrics that correlate better (Li et al., 2017a; Lowe et al., 2017; Tao et al., 2018) are harder to measure than perplexity or BLEU (Papineni et al., 2002). Human evaluation also has its shortcomings, like high variance, cost, and replication difficulty (Zhang et al., 2018; Tao et al., 2018). There does not seem to be any consensus on the best approach, as some researchers use only automatic metrics (Xing and Fernández, 2018; Xu et al., 2018b), others conduct human evaluation (Krause et al., 2017; Fang et al., 2018), and some use both (Shen et al., 2018; Xu et al., 2018a; Baheti et al., 2018; Ram et al., 2018).

We conduct an extensive automatic evaluation using our DIALOG-EVAL repository[9], which implements 17 metrics used frequently in the literature. These are described in detail by our previous study on metrics (Csáky et al., 2019). The metrics assess individual response quality, dialogue-level evaluation is left for future work[10]. In all tables that follow, metrics are listed in the following order: response length ($|U|$), i.e. average number of words in a response. Per-word and per-utterance unigram (H_w^u, H_u^u) and bigram (H_w^b, H_u^b) entropy, measuring the non-genericness of responses (Serban et al., 2017). Unigram and bigram-level KL divergence (D_{kl}^u, D_{kl}^b) between model and ground truth response sets (Csáky et al., 2019). Embedding metrics *average* (AVG), *extrema* (EXT), and *greedy* (GRE) measuring similarity between response and target embeddings (Liu et al., 2016). Coherence (COH), the cosine similarity between pairs of input and response (Xu et al., 2018b). Distinct-1 and distinct-2 (d1, d2) measuring the ratio of unique unigrams/bigrams in all responses (Li et al., 2016). The 4 BLEU metrics (b1, b2, b3, b4), measuring overlaps between respective n-grams (n=1,2,3,4) of response and target (Shen et al., 2018; Xu et al., 2018b). As discussed in Csáky et al. (2019), these metrics have been selected to provide a diverse evaluation measuring various aspects of response quality. Generally, we should assess response quality jointly as looking at individual metrics can be misleading.

5.2 Trainings

We conduct experiments with Transformer[11] and GPT2[12] models. The Transformer is trained on utterance pairs, and we use the base version of roughly 50M parameters (further training details are given in Appendix A.1). The vocabulary is set to the top 100 000 words for Gutenberg and Opensubtitles trainings, and 32 768 and 16 384, for PersonaChat and DailyDialog, respectively. The Transformer is trained for 21 epochs on Gutenberg and Opensubtitles, because of time and hardware constraints, but the validation loss was still decreasing. Training took about 80 hours on a single RTX 2080 Ti, with batch size set to the memory limit. We used the Adam optimizer (Kingma and Ba, 2014). For generating test outputs greedy decoding is used.

For the GPT2 trainings (117M pretrained version) we set the maximum number of previous utterances to be used as history to 3 (parameter details in Appendix A.1). The huggingface repository leverages GPT2 for dialogue modeling with an additional personality input and a random candidate classification loss (Wolf et al., 2018). We set the personality field to empty and use a single random candidate response from the training set for each example. We use the nucleus sampling implementation in the repository with default parameters to sample outputs (Holtzman et al., 2020). All GPT2 trainings are trained with a batch size of 2 and evaluated at the minimum of the validation loss. The English GPT2 Gutenberg training

---

[9] `https://github.com/ricsinaruto/dialog-eval`

[10] We believe that Gutenberg would perform especially well in dialogue-level metrics, since it contains high-quality extracted dialogues compared to the non-segmented noisy Opensubtitles utterances.

(b) PersonaChat test set

Table 4: Metrics computed on the test set of DailyDialog and PersonaChat for Transformer and GPT2 trainings. Pre-trained models on Gutenberg (G) and Opensubtitles (O) are compared. B is a Transformer or GPT2 baseline trained only on the small datasets, evaluated at the validation loss minimum. RT refers to randomly selected responses from the DailyDialog or PersonaChat training set, and GT to the ground truth response set. Best results (with a 95% confidence interval) are highlighted separately for the zero-shot (ZS) and finetuned (FT) scenarios.

took about 20 days (7 epochs), on an RTX 2080 Ti, while on Opensubtitles the validation minimum was reached after a single epoch of training (about 2 days). Finetuning on DailyDialog and PersonaChat and trainings on other languages took generally less than 1 day, except the German trainings (2 days).

We evaluate Gutenberg and Opensubtitles pre-trained models in zero-shot and finetuning scenarios on DailyDialog and PersonaChat. The same amount of training data and train/test/dev ratio is used for both Gutenberg and Opensubtitles. Models are finetuned until the validation loss minimum is reached. Finetuning experiments are only done in English, due to the lack of additional datasets in other languages. For Transformer trainings, we remove overlapping utterance pairs between the official train and test sets from the DailyDialog training set. We observed that inflated results reported on DailyDialog (Csáky et al., 2019) are partly due to this overlap. For all datasets we use lowercase input text and NLTK[13] word tokenization as preprocessing. We use the official DailyDialog splits and we employ a random train/dev/test split of 80/10/10 for PersonaChat, which we make publicly available along all the datasets used in this paper[14].

Gutenberg pre-training performs better than Opensubtitles on DailyDialog across nearly all metrics in both zero-shot and finetuned settings (Table 4a). Gutenberg pre-training outperforms even the model trained only on DailyDialog on some metrics. All GPT2 models are pretrained as language models on web text. Thus it comes as no surprise that the additional pretraining on

Input	**TRF**	**GPT2**	**GUT ZS**	**OPEN FT**	**GUT FT**
how are you doing today EOU awesome . just sitting here listening to some stones . how are you ? EOU i ’m good . just about to play some dd	what do you play ? i ’m a professional athlete .	what kind of music do you play ?	huh ! what do you think of that ?	i ’m just thinking about having a ball .	what are you watching ?
lol i scratch my nose when oreo shakes tickle it EOU you are funny . not so depressed about welfare and dad in ace rated now EOU ouch sorry your dad in jail mine passed before he could teach me to drive	i ’m so sorry . i ’m so sorry .	lol you should take him to the doctor . it is a good therapy	but you ’re not a boy any more .	i think he was . my mom was not there either	oh okay . he ’s a detective . my dad passed before he could train me
i used to drive my mother crazy i liked to smoke i am tee total now though EOU i just finish smoking . i take anxiety medication at night EOU that ’s not good having anxiety i mean . does the medication help ?	i do not know . i am very sorry .	it works for me but i have to get up early so i can smoke	you ’re perfectly right you ca n’t do much harm .	it does help . i am a teacher . i teach middle school kids	no but i can be on the watch with my friends . i ’m getting to see my dad
i ’ve one dog she ’s amazing . EOU i ’ve 2 dogs . i should take them walking instead of eating . EOU that would be a great idea .	i ’m so excited to go to the movies .	i think that ’s too bad for my health .	very well . it ’s a bargain .	what do you do for a living ?	i ’ve no opinion about it . i ’m very passionate about animals .
wonderful . i hail from germany . what about you ?	i ’m a small world . i ’m a waitress .	i ’m from chicago how about you ?	i ’m a british spy .	i am a student in the us .	i ’m from baltimore and i ’m also from florida

Table 5: Random test samples from PersonaChat. TRF is the base Transformer and GPT2 is the non-pretrained GPT2 model. GUT and OPEN refer to Gutenberg and Opensubtitles, respectively, and ZS and FT refer to zero-shot and finetuned settings, respectively. EOU means “End Of Utterance”.

Gutenberg does not lead to the same relative improvement as with the Transformer models, which are trained from scratch. Gutenberg pre-training achieves better results than Opensubtitles in all metrics after finetuning on PersonaChat (Table 4b). In the Transformer zero-shot scenario, Opensubtitles achieves better BLEU scores, however, zero-shot BLEU scores are generally much lower than randomly selected responses, questioning the validity of this comparison. Gutenberg pre-training outperforms the baseline PersonaChat training on some metrics after finetuning. Considering the domain mismatch between the older Gutenberg books and the modern chit-chat style datasets this is especially impressive. Since the metrics are all very similar it is also important to look at responses qualitatively. Table 5 presents 5 random test samples. More samples from both DailyDialog and PersonaChat can be found in Appendix A.3. It is clear that the Transformer and the zero-shot GPT2 scenario perform the worst, followed by the finetuned Opensubtitles training. This shows some anecdotal support for the effectiveness of pre-training on Gutenberg.

Table 6 compares Gutenberg and Opensubtitles trainings across all seven languages, using roughly the same amount of data. In absence of a third independent data source we create mixed test datasets for each language that include the same amount of data from Gutenberg and Opensubtitles, by limiting the larger of the two to the size of the smaller. Except for Hungarian, models trained on Gutenberg perform better on more metrics than Opensubtitles trainings. On some metrics, models perform worse than random responses from the training set. This is expected for entropy and distinct metrics, but we believe that BLEU scores would be higher after further training since overfitted models have been shown to perform better on these metrics (Csáky et al., 2019). This lack of stopping criteria also makes a fair comparison challenging. Example responses from all models are shown in Appendix A.3. To our knowledge, this is the first work to use non-English languages from the Opensubtitles dataset for dialogue modeling, and there are very few chatbot models in non-English languages in general.

6 Conclusion

We presented the Gutenberg Dialogue Dataset consisting of 14.8M utterances in English and smaller

Table 6: Comparing Gutenberg and Opensubtitles GPT2 trainings across 7 languages on the union of the two test sets. The second column shows whether the model was trained on Gutenberg (G) or Opensubtitles (O). Randomly selected responses from the respective train set (RT) and groud truth (GT) performance is also given. Significantly better results between Gutenberg and Opensubtitles (95% confidence interval) are highlighted on each test set.

datasets in German, Dutch, Spanish, Italian, Hungarian, and Portuguese. We described heuristics used in our dialogue extraction pipeline and conducted a detailed error analysis to uncover the causes of errors and to assess data quality. In a pre-training comparison between Gutenberg and Opensubtitles we found that Gutenberg performs better on downstream datasets in both zero-shot and finetuning scenarios. We release the Gutenberg dataset as well as the open-source pipeline[15] with which researchers can build their own datasets. We also built a web demo interface to all models presented in the paper[16].

In future work, we wish to improve heuristics and dataset quality. A classifier could be trained to decide whether two consecutive utterances are part of the same dialogue (looking at non-conversational context). Positive and negative examples could be generated by a very low/high dialogue gap, or by manual annotation. Speaker-related errors could be addressed using speaker identification. We also hope to extend our dataset to more languages. This involves delimitation analysis, implementation of heuristics, and error analysis. We welcome contributions from the community, as our open-source modular pipeline minimizes the effort required for adding new languages.

Acknowledgments

We wish to thank Márton Makrai for inspiration and discussion about the idea of extracting dialogue from books. We wish to thank members of the SZTAKI HLT[17] group and all anonymous reviewers for their help and thoughtful feedback. Work partly supported by Project FIEK 16-1-2016-0007, financed by the FIEK 16 funding scheme of the Hungarian National Research, Development and Innovation Office (NKFIH). Recski was partly supported by BRISE-Vienna (UIA04-081), a European Union Urban Innovative Actions project.

---

[15] We also release all data, trained models, and training scripts to produces the results.

A Appendix

A.1 Training hyperparameters

Name	Value
Hidden size	512
Number of hidden layers	6
Label smoothing	0.1
Filter size	2048
Number of attention heads	8
Layer dropout	0.1
Relu dropout	0
Attention dropout	0
Learning rate	0.2
Learning rate warmup steps	8000

Table 7: Transformer hyperparameters.

Name	Value
LM loss coefficient	2
Multiple-choice loss coefficient	1
Max. gradient norm	1
Gradient accumulation steps	8
Nucleus sampling p	0.9
Context size	1024
Embedding size	768
Number of attention heads	12
Number of layers	12
Vocabulary size	50262

Table 8: GPT2 hyperparameters.

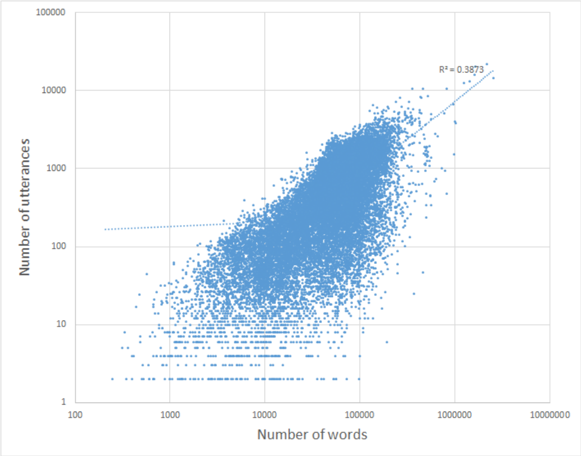

Figure 7: Number of extracted utterances with respect to number of words in each book on logarithmic scales (English Gutenberg dataset).

A.2 Gutenberg statistics

A.3 Example responses

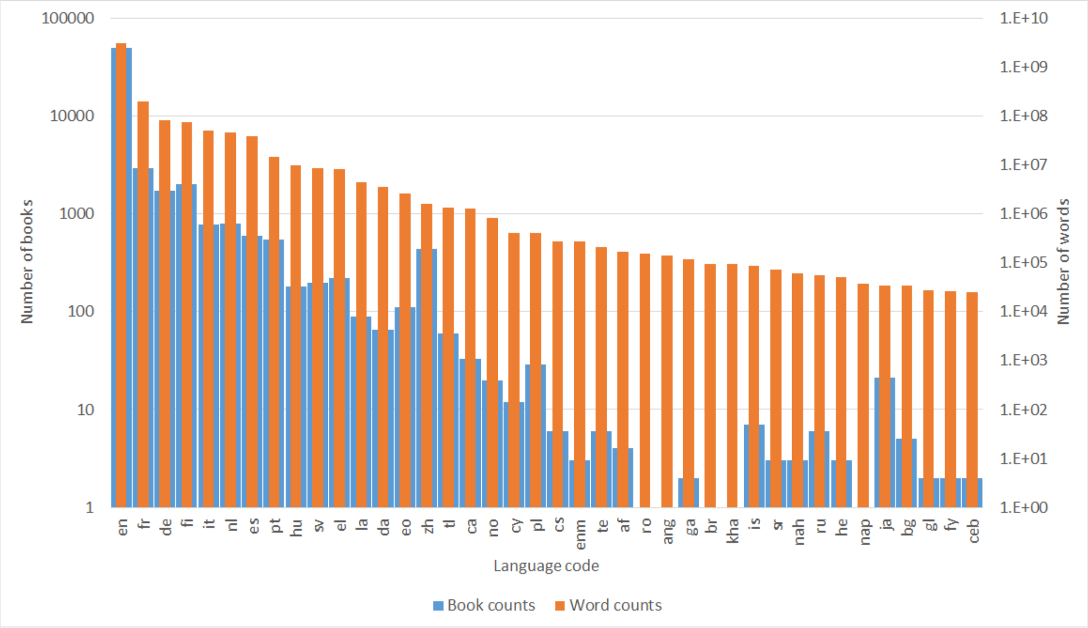

Figure 8: Number of books and words for top 40 languages in Project Gutenberg on logarithmic scales.

stay for dinner with us . EOU i 'm afraid i ca n't . i have a dinner party at seven tonight . you see i am going to england the day after tomorrow . EOU well i wo n't keep you then . it was very nice of you to come to see me .	you 're welcome .	thank you . i will .	i knew you would n't mind .	yes . i hope you feel better .	it was my pleasure .
sure . take a seat . . . what would you like to know ? EOU first i ve heard that your latest book is based on a true story . EOU that s correct . it s a murder mystery based on actual murders that book place in florida several years ago . the main characterthe police invesigatoris based on the man who investigated the case .	i see . i thought it was a great idea . i could do that .	oh i see . thanks a lot . i ll have to check it out .	well ?	i ve never been involved in an actual murder . what are your chances of catching the killer ?	so what happened to the man who investigated the case ?
well i do n't eat any meat but i do eat fish and eggs . EOU do you eat a lot of vegetables ? EOU oh yes and fruit i love fruit .	what kind of food do you like ?	do you like fruits and vegetables ?	and do you eat a good many things ?	do you like fruits ?	what do you do with your vegetables ?
that 's terrific . i ca n't wait to check it out . EOU hang on . are you sure you want to keep a nontraditional pet ? EOU why not ? it 's so cool .	i do n't know . i do n't know what to do .	the pets come with a 2 week guarantee .	i 've been in the market for two years .	i 'm really glad that you came .	then let 's go .
that 's my boy ! katherine curtis created this activity in 1920 . and in 1984 it was authorized as one activity in olympic games . EOU wow mom is more knowledgeable than dad . i must learn from you . EOU my little boy you should learn more from me . i 'm almost thirty years older than you .	i 'm not sure . i 'm a bit nervous .	dad i 'm not a child anymore . i 'm a grownup .	you 're a nice old lady mom .	okay . i will begin learning when i grow up .	what 's the matter with your boy ?
it will cost you 10 . EOU by the way what 's the time ? EOU you can see the time on the meter . i have radio time you know .	i know . i do n't know what to do .	that 's fine . i 'll see it tomorrow .	you had a good time in new york ?	you can watch the news .	i see .
hello . is bob there please ?	hello . this is mr . green .	yes he is . how 's your business going ?	yes my dear but is n't he coming ?	yes . he 's gone out to the market .	speaking .
it seldom rains this summer .	i think it 's a bit expensive .	why ?	you are always on the watch for rain	i am sure it does .	what is the weather like today ?
i think i may have seen it on the kitchen table .	i m afraid i have a bit of a small town .	it 's great . i 've enjoyed it .	i 'm sure you did	no i didn t . i didn t see it .	what did you see ?
thanks . and could i have his email just in case i ca n't get him by phone ? EOU sure . his cell phone is 09112223 33 . and his email is lower case t smiththat 's one word at c c w dot com dot t w . EOU thank you so much . does he read his emails daily ?	yes . he was in the middle of the city .	not every day . he just sends email to his friends .	sure . he has n't been here since the night of the murder .	yes he does . he reads a lot of letters per day .	yes he does . he 's a very good student . i can read and write and he keeps in touch with my friends .

Table 9: Random test samples from DailyDialog. TRF is the base Transformer and GPT2 is the non-pretrained GPT2 model. GUT and OPEN refer to Gutenberg and Opensubtitles, respectively, and ZS and FT refer to zeroshot and finetuned settings, respectively. EOU means “End Of Utterance”.

Input	**TRF**	**GPT2**	**GUT ZS**	**OPEN FT**	**GUT FT**
i do n't but that would be great EOU what do you do for a living ? EOU i work w french fries . i stink of them	that 's cool . i 'm a waitress .	do you have any pets ?	you mean to say that you do n't learn much ?	that sounds like a hard job . do you like to read ?	oh i see . i am a legal assistant .
great ! just came back from a walk with my bipolar dog . EOU that sounds nice i 've been taking care of a buddy horses this afternoon . EOU why ? wheres the hubby ?	i 'm not sure . i 'm not sure .	he has a dog i 've a dog too !	he 's in the stable .	he 's a shepherd and is very smart .	i 'm trying to get him to see me .
that is so sad i 'm sorry EOU i never see my dad now he moved to guam EOU i do not even know where guam is	i 'm a girl . i love to eat out .	where do you live now ?	i thought he was in the penitentiary	i do n't even know if i 've ever heard of it	i have always wanted to move there but he passed away
that 's very interesting . i workout for a living .	i do too . i am a waitress .	i 'm retired and working with animals .	you do eh ?	that 's cool . i like to eat breakfast .	oh my god i hate eating too much . i could n't do it .
my one child wanted to be like that too EOU it is good for the body EOU do you train yourself alone ?	i do . i am a waitress .	i do i try to at least once a month	yes .	no i do n't have a job .	yes i have a job in a factory
i am 35 and still single . EOU are you looking forward to turning 40 ? EOU no not at all . it seems dreadful .	i agree . i 'm very excited about that .	i 'm sure you are . what is your name ?	i am sorry to hear it .	what do you do for work ?	i have a dog named george . what do you do for a living ?
being from springfield missouri the midwest does not offer much EOU i can not wait to grow up EOU do n't rush it . . . believe me stay young	i am very tall so i do not have to go to the gym	i do n't want to be the boss of a nascar car	you know what i mean i ca n't let you go .	i will try it	i will be twenty in march
congrats ! i have two little ones and a wife back stateside and i miss them so much ! EOU i live with my best friend on a lake EOU sweet life . beats being in this desert although i got ta admit i love my long deployments	i 'm a bit of a guy . i love to swim .	i like to swim in the mountains	then why not stay at home ?	i am still in college but i am doing my masters	i 'm sorry to hear that
hi . how are you doing ? EOU well . . i got ta tell the truth to somebody i just have too EOU go ahead . i 'm almost seven feet tall by the way	i 'm a girl . i 'm tall .	that is tall ! you can ride horses and trucks .	oh i ai n't ! i 'm eight feet eight .	wow ! ! i 'm just like a sponge . . . i like to work with spongebob	wow that 's a huge size . i just bought a new new dress a few times .
hi i 'm jane and a part of my skin is blue i 'm 177 cm . EOU your skin is blue ? my names bill nice to meet you EOU yeah it was a dye i was using and it seeped into the skin .	i like to draw and paint .	oh wow that 's really pretty	then it was not a dye .	that is amazing ! what do you do for a living ?	what color was it ? i love the color red

Table 10: Random test samples from PersonaChat. TRF is the base Transformer and GPT2 is the non-pretrained GPT2 model. GUT and OPEN refer to Gutenberg and Opensubtitles, respectively, and ZS and FT refer to zeroshot and finetuned settings, respectively. EOU means "End Of Utterance".

Input	**Gutenberg**	**Opensubtitles**	**Target**
hogyan ? ön képes 200 forintot adni ? EOU nagyon . EOU eszerint jól áll a lapja ?	én .	nem vagyok a közelőtt .	kitűnően .
hát a fejét ne kössük be ? EOU mivel ? EOU vizes kendővel .	hogyan ?	felség , azt mondja a nő egy közelést .	fölösleges .
tessék kérem !	tessék , hogy miért nem ?	tudom . . .	egyedül van ?
veszünk ki más lakást . EOU meglövöldöz bennünket az öreg . EOU ne hidd azt !	meglövöldöz bennünket ,	ne légy nem akarják .	dehát miből éljünk ?
barátom , jób , az eördög megszökött . a miskolczi részvényeket fölapríthatod fidibusznak . EOU míriz olezáncz ! EOU barátom , jób ! szomorú hírt hozok : a török sorsjegyek elvesztették az értéküket !	szegény asszony !	mert őket , hogy megint mondtam .	míriz olezáncz !
ott vettem ezt a kést egy kis boltban , két utcával arrébb . EOU hat dollárba került . EOU a törvény tiltja rugóskések vásárlását .	ah !	ez egy kis kölykökre , hogy elváltoztatni az ügyvédő .	így van , megszegtem a törvényt .
honnan szerezte ? EOU tegnap este a tárgyalás után sétálni mentem . EOU a fiú lakása környékén .	hát nem szerezni , hogy nagyon szerezni !	én volt rá , mi történt ?	ott vettem ezt a kést egy kis boltban , két utcával arrébb .
oké . EOU esetleg megegyezhetnénk egy határidőben . EOU még egy tiszteletkör , és kész .	egy határ úr , hogy öreg asszonyt üve	és előtt a gyilkosságot .	most negyed 7 van .
ki mondja , hogy nem bűnös ? EOU egy . EOU rendben .	kicsoda ?	csak az ügyvéd volt .	tizenegy bűnös , egy nem bűnös .
én egyszerűen csak kérdéseket teszek fel . EOU ez most jutott eszembe . . . EOU ha én öltem volna meg az apámat , én is visszamentem volna a késért .	ugyan , ugyan !	a feleségét .	a srác azt hihette , hogy nem látták , amikor elrohant , és másnap reggelig nem fedezik fel

Table 11: Random test samples from the Hungarian Gutenberg test set (first 5 rows), and Opensubtitles test set (last 5 rows). Responses from the GPT2 model trained on Gutenberg and Opensubtitles are compared. EOU means “End Of Utterance”.

Input	**Gutenberg**	**Opensubtitles**	**Target**
madame if i had the tact and wit of my brother charles i would say that the sun which so lately has risen must not set so soon upon its worshippers . but answer me one questionwhat is the meaning of the riddle with which your majesty has been entertaining us ? EOU may i answer with another question ? tell me sire have you ever seen the sun rise ? EOU i ? no your majesty . i confess that i never have .	well sire then i will tell you a secret .	the sun rises in the sky .	and you ladies and gentlemen ?
wo n't he confess how he became possessed of the diamonds ? EOU no not to me . he refuses to say a word in his own defence . EOU then i tell you what this quixotic young man is defending another person he is shielding the assassin .	you think he is innocent ?	the longer i wait he wo n't tell me anything .	if he is that shows him to be an accessory either before or after the fact but who is the person you
and who ought of right to avenge him ? EOU sir the knight that was in the red launde at the assembly that jousted with messire gawain and had the prize of the tournament . EOU did he better than messire gawain ?	he did he did indeed .	yes sir .	sir so did they adjudge him for that he was a longer time in the assembly .
why do n't you keep your mouth shut philippo ? it 's always talk talk with you . we are chosen because the captain can rely upon us .	but i have no right to speak to you and i 'm not going to be treated as if i were a child .	the captain is the captain .	he can rely upon anyone who knows that he will get his throat cut if he fails in his duty .
i 'd rather talk to you in my room if you please	so would i	but it 's not your fault .	all right
so what 's your take on that ? EOU i got nothing . EOU what am i gon na do ?	do n't worry . i 'll keep you a prisoner .	you do n't have to do anything .	i do n't know .
my face . EOU there was an argument . EOU i	what ?	i have no idea what happened .	i said some things i should n't have said and i
what do you do when several people attack you at once ? EOU get up EOU no matter how many i focus on just one	one for me !	do n't you want me to get into trouble ?	i was in a fight against five guys i went after one of them i did n't care what the other four did i
i do n't know . EOU come with me . EOU come on .	i ca n't	i do n't know .	you do n't need it come on .
they were all using me . EOU hanford everybody ! EOU but you did n't kill everybody .	you do n't know what it means to kill people .	you 're not .	you killed randy chase .

Table 12: Random test samples from the English Gutenberg test set (first 5 rows), and Opensubtitles test set (last 5 rows). Responses from the GPT2 model trained on Gutenberg and Opensubtitles are compared. EOU means "End Of Utterance".

Input	**Gutenberg**	**Opensubtitles**	**Target**
pues debe de haber muchas . pablo penáguilas que las sabe todas , me ha dicho que son muchas y que la vida entera de un hombre no basta para una sola .	es que no hay que dar las solas . esos que la vida no tiene nada que hacer por una sola que se les ha de hablar con el cuerpo .	no le ha dicho a nadie .	ríete tú de eso . . . . ya me verás a mí . . .
¿ y por qué han de estar exentos de esa graciosa ley los solteros ricos ? ¿ por qué no han de cargar ellos también con su huérfano , como cada hijo de vecino ? EOU no me opongo . ¿ pero qué es esto ? . . . ¡ sangre ! EOU ¡ jesús ! . . . . si es la nela . mira cómo se ha puesto los pies .	¿ y no quiere usted que lo han robado ?	no .	ya se ve . . . . como tuvo que meterse entre las zarzas para coger a tu dichoso lili . nela , ven ac
¿ y roberto ?	no , no me llamo .	¿ y roberto ?	no sé , por ahí andará .
echaremos por estos prados adelante . ¿ a ver qué me has traído hoy ? EOU busca bien y encontrarás algo EOU ¡ ah , madre de dios ! chocolate crudo . . . ¡ y poco que me gusta el chocolate crudo ! . . . nueces . . . una cosa envuelta en un papel . . . ¿ qué es ? ¡ ah ! ¡ madre de dios ! , un dulce . . . . ¡ dios divino ! , ¡ pues a fe que me gusta poco el dulce ! ¡ qué rico está ! en mi casa no se ven nunca estas comidas ricas , pablo . nosotros no gastamos lujo en el comer . verdad que no lo gastamos tampoco en el vestir . total , no lo gastamos en nada .	¡ ah ! ¡ no lo sé !	¡ qué hizo eso !	¿ a dónde vamos hoy ?
quita allá , tonta , tú eres una alhaja . EOU que no señor . si no puedo trabajar . en cuanto cargo un peso pequeño , me caigo al suelo . si me pongo a hacer alguna cosa difícil en seguida me desmayo . EOU todo sea por dios . . . . vamos , que si cayeras tú en manos de personas que te supieran manejar , ya trabajarías bien .	¿ qué decís ?	¿ se encuentra en personas ?	no , señor ; si yo no sirvo más que de estorbo .
iluminó ciertos rincones oscuros del alma humana . EOU mostró al mundo las almas de aquellas personas que nacieron diferentes al resto . EOU para entender por qué estaba destinado a esto , tendríamos que retroceder en el tiempo a cualquier día de su infancia , en la ciudad de colorado springs .	¿ y qué ?	sólo una pelea , nunca había terminado .	no tuvo una infancia fácil , ya que sus padres eran diferentes .
algunos se fueron a sudamérica . EOU lo sé , señor . EOU ¿ por qué no se fue ?	¿ por qué ?	¿ por qué no ?	porque creo que este país no forma parte de los estados unidos .

Abstract

According to the Probability Ranking Principle (PRP), ranking documents in decreasing order of their probability of relevance leads to an optimal document ranking for ad-hoc retrieval. The PRP holds when two conditions are met: **[C1]** the models are *well calibrated*, and, **[C2]** the probabilities of relevance are reported *with certainty*. We know however that deep neural networks (DNNs) are often not well calibrated and have several sources of uncertainty, and thus **[C1]** and **[C2]** might not be satisfied by neural rankers. Given the success of neural Learning to Rank (L2R) approaches—and here, especially BERT-based approaches—we first analyze under which circumstances deterministic neural rankers are calibrated for conversational search problems. Then, motivated by our findings we use two techniques to model the uncertainty of neural rankers leading to the proposed *stochastic rankers*, which output a predictive distribution of relevance as opposed to point estimates. Our experimental results on the ad-hoc retrieval task of conversation response ranking[1] reveal that (i) BERT-based rankers are not robustly calibrated and that stochastic BERT-based rankers yield better calibration; and (ii) uncertainty estimation is beneficial for both risk-aware neural ranking, i.e. taking into account the uncertainty when ranking documents, and for predicting unanswerable conversational contexts.

1 Introduction

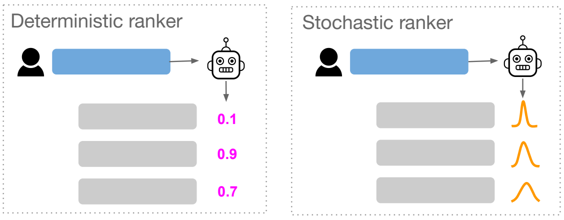

Figure 1: While deterministic neural rankers output a point estimate probability (magenta values) of relevance for a combination of query (blue bars) and document (grey bars), stochastic neural rankers output a predictive distribution (orange curves). The dispersion of the predictive distribution provides an estimation of the model uncertainty.

According to the Probability Ranking Principle (PRP) (Robertson, 1977), ranking documents in decreasing order of their probability of relevance leads to an optimal document ranking for ad-hoc retrieval[2]. Gordon and Lenk (1991) discussed that for the PRP to hold, ranking models must at least meet the following conditions: **[C1]** assign well calibrated probabilities of relevance, i.e. if we gather all documents for which the model predicts relevance with a probability of e.g. 30%, the amount of relevant documents should be 30%, and **[C2]** report certain predictions, i.e. only point estimates such as, for example, 80% probability of relevance.

DNNs have been shown to outperform classic Information Retrieval (IR) ranking models over the past few years in setups where considerable training data is available. It has been shown that DNNs are not well calibrated in the context of computer vision (Guo et al., 2017). If the same is true for neural L2R models for IR, e.g. transformer-based models for ranking (Nogueira and Cho, 2019), **[C1]** is not met. Additionally, there are a number of sources of uncertainty in the training process of neural networks (Gal, 2016) that make it unreasonable to assume that neural ranking models fulfill **[C2]**: *parameter uncertainty* (different combinations of weights that explain the data equally well), *structural uncertainty* (which neural architecture to

[2] Standard retrieval task where the user specifies his information need through a query which initiates a search by the system for documents that are likely relevant (Baeza-Yates et al., 1999).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 160–170
April 19 - 23, 2021.

use for neural ranking), and *aleatoric uncertainty* (noisy data). Given these sources of uncertainty, using point estimate predictions and ranking according to the PRP might not achieve the optimal ranking for retrieval. While the effectiveness benefits of risk-aware models (Wang, 2009; Wang and Zhu, 2009), which take into account the risk[3], i.e. the uncertainty of the document's prediction scores, have been shown for non-neural IR approaches, this has not yet been explored for neural L2R models.

In this paper we first analyze the calibration of neural rankers, specifically BERT-based rankers for IR tasks to evaluate how calibrated they are. Then, to model the uncertainty of BERT-based rankers, we propose *stochastic* neural ranking models (see Figure 1), by applying different techniques to model the uncertainty of DNNs, namely MC Dropout (Gal and Ghahramani, 2016) and Deep Ensembles (Lakshminarayanan et al., 2017) which are agnostic to the particular DNN.

In our experiments, we test models under *distributional shift*, i.e. the test data distribution is different from the training data, also referred to as out-of-distribution (OOD) examples (Lee et al., 2018). In real-world settings, there are often inputs that are shifted due to factors such as non-stationarity and sample bias. Additionally, this experimental setup provides a way of measuring whether the DNN *"knows what it knows"* (Ovadia et al., 2019), e.g. by outputting high uncertainty for OOD examples.

We find that BERT-based rankers are not robustly calibrated. Stochastic BERT-based rankers have 14% less calibration error on average than BERT-based rankers. Uncertainty estimation from stochastic BERT-based rankers is advantageous for downstream applications as shown by our experiments for risk-aware neural ranking (2% more effective on average relative to a model without risk-awareness) and for predicting unanswerable conversational contexts (improves classification by 33% on average of all conditions).

2 Related Work

Calibration and Uncertainty in IR

Even though to optimally rank documents according to the PRP (Robertson, 1977) requires the model to be calibrated (Gordon and Lenk, 1991) (**[C1]**), the calibration of ranking models has received little attention in IR. In contrast, in the machine learning community there have been a number of studies about calibration (Ovadia et al., 2019; Maddox et al., 2019), due to the larger decision making pipelines DNNs are often part of and their importance for model interpretability (Thiagarajan et al., 2020). For instance, in the automated medical domain it is important to provide a calibrated confidence measure besides the prediction of a disease diagnosis to provide clinicians with sufficient information (Jiang et al., 2012). Guo et al. (2017) have shown that DNNs are not well calibrated in the context of computer vision, motivating our study of the calibration of neural L2R models.

The second condition (**[C2]**) for optimal retrieval when ranking according to the PRP (Gordon and Lenk, 1991) is that models report predictions with certainty. While the (un)certainty has not been studied in neural L2R models, there are classic approaches in IR that model the uncertainty. Such approaches have been mostly inspired by economics theory, treating variance as a measure of uncertainty (Varian, 1999). Following such ideas, non-neural ranking models that take uncertainty into account (i.e. risk-aware models), and thus do not follow the PRP (Robertson, 1977), have been proposed (Zhu et al., 2009; Wang and Zhu, 2009), showing significant effectiveness improvements compared to the models that do not model uncertainty. Uncertainty estimation is a difficult task that has other applications in IR besides improving the ranking effectiveness: it can be employed to decide between asking clarifying questions and providing a potential answer in conversational search (Aliannejadi et al., 2019); to perform dynamic query reformulation (Lin et al., 2020) for queries where the intent is uncertain; and to predict questions with no correct answers (Feng et al., 2020).

Bayesian Neural Networks

Unlike standard algorithms to train neural networks, e.g. SGD, that fit point estimate weights given the observed data, Bayesian Neural Networks (BNNs) infer a distribution over the weights given the observed data. Denker et al. (1987) contains one of the earliest mentions of choosing probability over weights of a model. An advantage of the Bayesian treatment of neural networks (MacKay, 1992; Neal, 2012; Blundell et al., 2015) is that they are better at representing existing uncertainties in the training procedure. One limitation of BNNs is that they are computationally expensive compared to DNNs. This has lead to the development of techniques that scale well, and do not require mod-

---

[3] In this paper we use risk and uncertainty interchangeably.

ifications of the neural net architecture and training procedure. Gal and Ghahramani (2016) proposed a way to approximate Bayesian inference by relying on dropout (Srivastava et al., 2014). While dropout is a regularization technique that ignores units with probability p during every training iteration and is disabled at test time, `Dropout` (Gal and Ghahramani, 2016) employs dropout at both train and test time and generates a predictive distribution after a number of forward passes. Lakshminarayanan et al. (2017) proposed an alternative: they employ ensembles of models (`Ensemble`) to obtain a predictive distribution. Ovadia et al. (2019) showed that `Ensemble` are able to produce well calibrated uncertainty estimates that are robust to dataset shift.

Conversational Search

Conversational search is concerned with creating agents that fulfill an information need by means of a *mixed-initiative* conversation through natural language interaction. A popular approach to conversational search is its modeling as an ad-hoc retrieval task: given an ongoing conversation and a large corpus of historic conversations, retrieve the response that is best suited from the corpus (this is also known as conversation response ranking (Wu et al., 2017; Yang et al., 2018; Penha and Hauff, 2020; Gu et al., 2020; Lu et al., 2020)). This retrieval-based approach does not require task-specific knowledge provided by domain experts (Henderson et al., 2019), and it avoids the difficult task of dialogue generation, which often suffers from uninformative, generic responses (Li et al., 2016a) or responses that are incoherent given the dialogue context (Li et al., 2016b). One of the challenges of conversational search is identifying unanswerable questions (Feng et al., 2020), which can trigger for instance clarifying questions (Aliannejadi et al., 2019). Identifying unanswerable conversational contexts is one of the applications we employ uncertainty estimation for. Intuitively, if the system has high uncertainty in the available responses, there may be no correct response available. In this paper we focus on pointwise BERT for ranking—a competitive approach for the conversation response ranking task.

3 Method

In this section we introduce the methods used for answering the following research questions: **RQ1** *How calibrated are deterministic and stochastic BERT-based rankers?* **RQ2** *Are the uncertainty estimates from stochastic BERT-based rankers useful for risk-aware ranking?* **RQ3** *Are the uncertainty estimates obtained from stochastic BERT-based rankers useful for identifying unanswerable queries?* We first describe how to measure the calibration of neural rankers (**[C1]**), followed by our approach for modeling and ranking under uncertainty (**[C2]**), and then we describe how we evaluate their robustness to distributional shift.

3.1 Measuring Calibration

To evaluate the *calibration* of neural rankers (**RQ1**) we resort to the Empirical Calibration Error (ECE) (Naeini et al., 2015). ECE is an intuitive way of measuring to what extent the confidence scores from neural networks align with the true correctness likelihood. It measures the difference between the observed reliability curve (DeGroot and Fienberg, 1983) and the ideal one[4]. More formally, we sort the predictions of the model, divide them into c buckets $\{B_0, ..., B_c\}$, and take the weighted average between the average predicted probability of relevance $avg(B_i)$ and the fraction of relevant[5] documents $\frac{rel(B_i)}{|B_i|}$ in the bucket:

$$ECE = \sum_{i=0}^{c} \frac{|B_i|}{n} \left| avg(B_i) - \frac{rel(B_i)}{|B_i|} \right|,$$

where n is the total number of test examples.

3.2 Modeling Uncertainty

First we define the ranking problem we focus on, followed by the BERT-based ranker baseline model (`BERT`). Having set the foundations, we move to the methods we propose to answer **RQ2** and **RQ3**: a stochastic BERT-based ranker to *model uncertainty* (`S-BERT`) and a risk-aware BERT-based ranker to *take into account uncertainty provided by* `S-BERT` *when ranking* (`RA-BERT`).

3.2.1 Conversation Response Ranking

The task of conversation response ranking (Zhang et al., 2018; Gu et al., 2019; Tao et al., 2019; Henderson et al., 2019; Penha and Hauff, 2020; Yang et al., 2020) (also known as *next utterance selection*), concerns retrieving the best response given the dialogue context. We choose this specific task due to the large-scale training data available, suitable for the training of neural L2R models. Formally, let $\mathcal{D} = \{(\mathcal{U}_i, \mathcal{R}_i, \mathcal{Y}_i)\}_{i=1}^{N}$ be a data set con-

---

[4] See examples of reliability diagrams in Figure 2.

[5] We consider here binary relevance.

sisting of N triplets: dialogue context, response candidates and response relevance labels. The dialogue context $\mathcal{U}_i$ is composed of the previous utterances $\{u^1, u^2, ..., u^\tau\}$ at the turn τ of the dialogue. The candidate responses $\mathcal{R}_i = \{r^1, r^2, ..., r^k\}$ are either ground-truth responses or negative sampled candidates, indicated by the relevance labels $\mathcal{Y}_i = \{y^1, y^2, ..., y^k\}$[6]. The task is then to learn a ranking function $f(.)$ that is able to generate a ranked list for the set of candidate responses $\mathcal{R}_i$ based on their predicted relevance scores $f(\mathcal{U}_i, r)$.

3.2.2 Deterministic `BERT` Ranker

We use BERT for learning the function $f(\mathcal{U}_i, r)$, based on the representation of the `[CLS]` token. The input for BERT is the concatenation of the context $\mathcal{U}_i$ and the response r, separated by SEP tokens. This is the equivalent of early adaptations of BERT for ad-hoc retrieval (Yang et al., 2019) transported to conversation response ranking. Formally the input sentence to BERT is $concat(\mathcal{U}_i, r) = u^1 \mid [U] \mid u^2 \mid [T] \mid ... \mid u^\tau \mid [SEP] \mid r$, where $\mid$ indicates the concatenation operation. The utterances from the context $\mathcal{U}_i$ are concatenated with special separator tokens $[U]$ and $[T]$ indicating end of utterances and turns. The response r is concatenated with the context using BERT's standard sentence separator $[SEP]$. We fine-tune BERT on the target conversational corpus and make predictions as follows: $f(\mathcal{U}_i, r) = \sigma(FFN(BERT_{CLS}(concat(\mathcal{U}_i, r))))$, where $BERT_{CLS}$ is the pooling operation that extracts the representation of the `[CLS]` token from the last layer and FFN is a feed-forward network that outputs logits for two classes (relevant and non-relevant). We pass the logits through a softmax transformation σ that gives us a probability of relevance. We use the cross entropy loss for training. The learned function $f(\mathcal{U}_i, r)$ outputs a point estimate and we refer to it as `BERT`.

3.2.3 Stochastic `S-BERT` Ranker

In order to obtain a predictive distribution, $R_r = \{f(\mathcal{U}_i, r)^0, f(\mathcal{U}_i, r)^1, ..., f(\mathcal{U}_i, r)^n\}$, which allows us to extract uncertainty estimates, we rely on two techniques, namely `Ensemble` (Lakshminarayanan et al., 2017) and `Dropout` (Gal and Ghahramani, 2016). Both techniques scale well and do not require modifications on the architecture or training of BERT.

Using Deep Ensembles ($\texttt{S-BERT}^E$) We train M models using different random seeds without changing the training data, each with its own set of parameters $\{\theta_m\}_{m=1}^M$ and make predictions with each one of them to generate M predicted values: $R_r^E = \{f(\mathcal{U}_i, r)^0, f(\mathcal{U}_i, r)^1, ..., f(\mathcal{U}_i, r)^M\}$. The mean of the predicted values is used as the predicted probability of relevance: $\texttt{S-BERT}^E(\mathcal{U}_i, r) = E[R_r^E]$, and the variance $var[R_r^E]$ gives us a measure of the uncertainty in the prediction.

Using MC Dropout ($\texttt{S-BERT}^D$) We train a single model with parameters θ and employ dropout at test time and generate stochastic predictions of relevance by conducting T forward passes: $R_r^D = \{f(\mathcal{U}_i, r)^0, f(\mathcal{U}_i, r)^1, ..., f(\mathcal{U}_i, r)^T\}$. The mean of the predicted values is used as the predicted probability of relevance: $\texttt{S-BERT}^D(\mathcal{U}_i, r) = E[R_r^D]$, and the variance $var[R_r^D]$ gives us a measure of the uncertainty.

3.2.4 Risk-Aware `RA-BERT` Ranker

Given the predictive distribution R_r, obtained either by `Ensemble` or `Dropout`, we use the following function to rank responses with risk-awareness:

$$\begin{aligned} \texttt{RA-BERT}(\mathcal{U}_i, r) = E[R_r] - b * var[R_r] \\ -2b \sum_i^{n-1} cov[R_r, R_{r_i}], \end{aligned}$$

where $E[R_r]$ is the mean of the predictive distribution, and b is a hyperparameter that controls the aversion or predilection towards risk. Unlike (Zuccon et al., 2011), we are not combining different runs that encompass different model architectures. We instead take a Bayesian interpretation of the process of generating a predictive distribution from a single model architecture. We refer to the rankers as $\texttt{RA-BERT}^D$ and $\texttt{RA-BERT}^E$, when using $\texttt{S-BERT}^D$'s predictive distribution and $\texttt{S-BERT}^E$'s predictive distribution respectively.

3.3 Robustness to Distributional Shift

In order to evaluate whether we can trust the model's calibration and uncertainty estimates, similar to (Ovadia et al., 2019) we evaluate how robust the models are to different types of shift in the

---

[6] Typically, the number of candidates $k \ll K$, where K is the number of available responses and by design the number of ground-truth responses is usually one, the observed response in the conversational data. In our experiments k=10.

test data. We do so by training the model using one setting and applying it in a different setting. Specifically for all three research questions we test the models under two settings—cross domain and cross negative sampling—which we describe next.

3.3.1 Cross Domain

We train a model using the training set from one domain known as the source domain $\mathcal{D}_S$ and evaluate it on the test set of a different domain, known as the target domain $\mathcal{D}_T$. This is also known as the problem of domain generalization (Gulrajani and Lopez-Paz, 2020).

3.3.2 Cross Negative Sampling

Pointwise L2R models are trained on pairs of query and relevant document and pairs of query and non relevant document (Lucchese et al., 2017). Selecting the non-relevant documents requires a *negative sampling* (NS) strategy. For the cross-NS condition, we test models on negative documents that were sampled using a different NS strategy than during training, evaluating the generalization of the models on a shifted distribution of candidate documents. We use three NS strategies. In $\textbf{NS}_{\textbf{random}}$ we randomly select candidate responses from the list of all responses. For $\textbf{NS}_{\textbf{classic}}$ we retrieve candidate responses using the conversational context $\mathcal{U}_i$ as query to a conventional retrieval model and all the responses r as documents. In $\textbf{NS}_{\textbf{sentenceEmb}}$ we represent both $\mathcal{U}_i$ and all the responses with a sentence embedding technique and retrieve candidate responses using a similarity measure.

4 Experimental Setup

We consider three large-scale information-seeking conversation datasets[7] that allow the training of neural ranking models for conversation response ranking: **MSDialog** (Qu et al., 2018) contains 246K context-response pairs, built from 35.5K information seeking conversations from the Microsoft Answer community, a QA forum for several Microsoft products; **MANTiS** (Penha et al., 2019) contains 1.3 million context-response pairs built from conversations of 14 Stack Exchange sites, such as *askubuntu* and *travel*; $\textbf{UDC}_{\textbf{DSTC8}}$ (Kummerfeld et al., 2019) contains 184k context-response pairs of disentangled Ubuntu IRC dialogues.

4.1 Implementation Details

We fine-tune BERT (Devlin et al., 2019) (*bert-base-cased*) for conversation response ranking using the *huggingface-transformers* (Wolf et al., 2019). We follow recent research in IR that employed fine-tuned BERT for retrieval tasks (Nogueira and Cho, 2019; Yang et al., 2019), including conversation response ranking (Penha and Hauff, 2020; Vig and Ramea, 2019; Whang et al., 2019). When training BERT we employ a balanced number of relevant and non-relevant—sampled using BM25 (Robertson and Walker, 1994)—context and response pairs. The sentence embeddings we use for cross-NS is `sentenceBERT` (Reimers and Gurevych, 2019) and we employ dot product calculation from FAISS (Johnson et al., 2017). We consider each dataset as a different domain for cross-NS. We use the Adam optimizer (Kingma and Ba, 2014) with $lr = 5^{-6}$ and $\epsilon = 1^{-8}$, we train with a batch size of 6 and fine-tune the model for 1 epoch. This baseline BERT-based ranker setup yields comparable effectiveness with SOTA methods[8].

4.2 Evaluation

To evaluate the *effectiveness* of the neural rankers we resort to a standard evaluation metric in conversation response ranking (Yuan et al., 2019; Gu et al., 2020; Tao et al., 2019): recall at position K with n candidates[9]: $R_n@K$. To evaluate the *calibration* of the models, we resort to the Empirical Calibration Error (cf. §3.1, using $C = 10$). Throughout, we report the test set results for each dataset. To evaluate the *quality of the uncertainty estimation* we rely on two downstream tasks. The first is to improve conversation response ranking itself via Risk-Aware ranking (cf. §3.2.4). The second, which fits well with conversation response ranking, is to predict unanswerable conversational contexts. Formally the task is to predict whether there is a correct answer in the candidates list $\mathcal{R}$ or not. In our experiments, for half of the instances we remove the relevant response from the list, setting the label as *None Of The Above* (NOTA). The other half of the data has the label *Answerable* (ANSW) indicating that there is a suitable answer

[8] We obtain 0.834 $R_{10}@1$ on $\text{UDC}_{\text{DSTC8}}$ with our baseline BERT model, c.f. Table 1, while `SA-BERT` (Gu et al., 2020) achieves 0.830. The best performing model of the DSTC8 (Kim et al., 2019) also employed a fine-tuned BERT

[9] For example $R_{10}@1$ indicates the number of relevant responses found at the first position when the model has to rank 10 candidate responses.

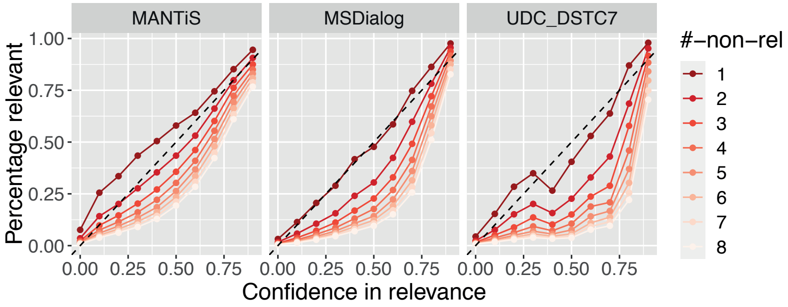

Figure 2: Calibration of `BERT` trained on a balanced set of relevant and non-relevant documents, and tested data with more non-relevant (`#-non-rel`) than relevant (1 per query) documents. A fully calibrated model is represented by the dotted diagonal: for every bucket of confidence in relevance, the % of relevant documents in that bucket is exactly the confidence. The calibration error is the difference between the curves and the diagonal line.

in the candidates list, for which we remove one of the negative samples instead. Similar to Feng et al. (2020), who proposed to use the outputs (logits) of a LSTM-based model in order to predict NOTA, we use the uncertainties as additional features to the classifier for NOTA prediction. The input space with the additional features is fed to a learning algorithm (Random Forest), and we evaluate it with a 5 fold cross-validation procedure using F1-Macro.

5 Results

5.1 Calibration of Neural Rankers (RQ1)

In order to answer our first research question about the calibration of neural rankers, let us first analyze `BERT` under standard settings (no distributional shift). Our results show that `BERT` is both effective and calibrated under no distributional shift conditions. In Table 1 we see that when the target data (*Test on* →) is the same as the source data (*Train on* ↓)—indicated by underlined values—we obtain the highest effectiveness (on average 0.70 R_{10}@1) and the lowest calibration error (on average 0.036 ECE). When plotting the calibration curves of the model in Figure 2, we observe the curves to be almost diagonal (i.e. having near perfect calibration) when there are an equal number of relevant and non-relevant candidates (`#-non-rel` $= 1$).

However, when we make the conditions more realistic[10] by having multiple non-relevant candidates for each conversational context, we observe in Figure 2 that the calibration errors start to in-

---

[10] In a production system, the retrieval stage would be executed over all candidate responses. As a consequence, the data is highly unbalanced, i.e. only a few relevant responses among potentially millions of non-relevant responses.

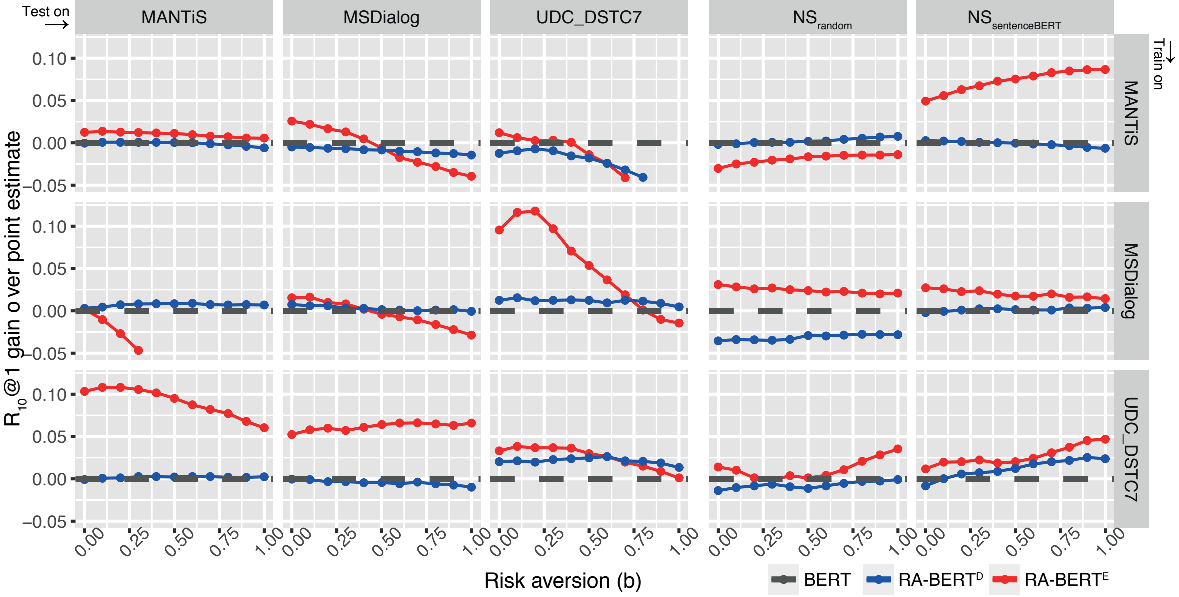

Figure 3: Gains of the Risk-Aware BERT-ranker for different values of risk aversion b.

crease, moving away from the diagonal. Additionally, when we challenge the model in cross-domain and cross-NS settings, the calibration error increases significantly as evident in Table 1. On average, the ECE is **4.6** times higher for cross-domain and **7.9** times higher for cross-NS. Thus **answering the first part of our first research question about the calibration of deterministic BERT-based rankers, indicating that they do not have robust calibrated predictions**, failing on the scenarios where there is a distributional shift.

In order to answer the remaining part of RQ1, on how calibrated *stochastic* BERT-based rankers are, let us consider Table 2. It displays the improvements (relative drop in ECE) over `BERT` in terms of calibration. S-BERT^E is on average **14%** better (has less calibration error) than `BERT`, while S-BERT^D is on average **10%** better than `BERT`, **answering our first research question: stochastic BERT-based rankers are better calibrated than deterministic BERT-based ranker**. We hypothesize that S-BERT^E leads to less ECE than S-BERT^D because it better captures the model uncertainty in the training procedure, since it combines different weights that explain equally well the prediction of relevance given the inputs. In the next section we focus on evaluating the effectiveness of such models that are better calibrated and also taking into account uncertainty when ranking.

5.2 Uncertainty Estimates for Risk-Aware Neural Ranking (RQ2)

In order to evaluate the quality of the uncertainty estimations, we first resort to using them as a measure of the risk through risk-aware neural ranking (RA-BERT^D and RA-BERT^E). Figure 3 displays the effectiveness in terms of $R_{10}@1$ gains over `BERT` for the different settings (cross-domain and cross-NS) when varying the risk aversion b.

We note that when $b = 0$, we are using the mean of the predictive distribution and disregard the risk, which is equivalent to S-BERT^D and S-BERT^E. The ensemble based average S-BERT^E is more effective than the baseline `BERT` for almost all com-

Table 5: Results of the *cross-NS* condition for the NOTA prediction task.

binations and `S-BERT`^{D} is equivalent to the baseline. When using $b < 0$, we are ranking with risk predilection (the opposite of risk aversion), and in all conditions we found that the effectiveness was significantly worse than when $b = 0$ and thus $b < 0$ is not displayed in Figure 3.

When increasing the risk aversion ($b > 0$), we see that it has different effects depending on the combination of domain and NS. For instance, when training in `MSDialog` and applying on UDC$_{\text{DSTC8}}$, increasing the risk aversion improves effectiveness of `RA-BERT`^{E} until b reaches 0.25 and after that the effectiveness drops, meaning that too much risk aversion is not effective. In order to investigate whether ranking with risk aversion is more effective than using the predictive distribution mean, we select b based on the best value observed on the validation set. Table 3 displays the results of this experiment, showing the improvements of `RA-BERT`^{D} and `RA-BERT`^{E} over `S-BERT`^{D} and `S-BERT`^{E} respectively. The results show that in a few cases (8 out of 30) the best value of b is 0, for which risk-aversion is not the best option in the development set. We obtain effectiveness improvements primarily on the cross-NS condition (up to 17.2% improvement of $R_{10}@1$), which is the hardest condition (when the models are most ineffective, c.f. Table 1). **This answers our second research question, indicating that the uncertainties obtained from stochastic neural rankers are useful for risk-aware ranking, specially in the cross-NS setting where the baseline model is quite ineffective.** `RA-BERT`^{E} is on average 2% more effective than `S-BERT`^{E}, while `RA-BERT`^{D} is on average 1.7% more effective than `S-BERT`^{D}.

5.3 Uncertainty Estimates for NOTA prediction (RQ3)

Besides using the uncertainty estimation for risk-aware ranking, we also employ it for the NOTA (None of the Above) prediction task. We compare here different input spaces for the NOTA classifier. $E[R^D]$ stands for the input space that only uses the mean of the predictive distribution for the k candidate responses in $\mathcal{R}$ using `S-BERT`^{D}, +$var[R^E]$ uses both $E[R^D]$ and the uncertainties of `S-BERT`^{E} for the k candidates and +$var[R^D]$ uses both the scores $E[R^D]$ and the uncertainties of `S-BERT`^{D}. Our results show that the uncertainties from `S-BERT`^{D} and of `S-BERT`^{E} significantly improve the F1 for NOTA prediction for both cross-domain (Table 4, improvement of 24% on average when using `S-BERT`^{D}) and cross-NS settings (Table 5, improvement of 46% on average when using `S-BERT`^{D}). **We can thus answer our last research question: the uncertainty estimates from stochastic neural rankers do improve the effectiveness of the NOTA prediction task (by an average of 33% across all conditions considered).**

6 Conclusions

In this work we study the calibration and uncertainty estimation of neural rankers, specifically BERT-based rankers. We first show that the deterministic BERT-based ranker is not robustly calibrated for the task of conversation response ranking and we improve its calibration with two techniques to estimate uncertainty through *stochastic neural ranking*. We also show the benefits of estimating uncertainty using risk-aware neural ranking and for predicting unanswerable conversational contexts.

As future work, investigating the use of stochastic rankers in other settings is important, such as other neural L2R architectures, other search and retrieval tasks (Guo et al., 2019; Diaz et al., 2020; Lin et al., 2020), and the ensembling of neural rankers (Zuccon et al., 2011).

Abstract

Recent efforts have shown that neural text processing models are vulnerable to adversarial examples, but the nature of these examples is poorly understood. In this work, we show that adversarial attacks against CNN, LSTM and Transformer-based classification models perform word substitutions that are identifiable through frequency differences between replaced words and their corresponding substitutions. Based on these findings, we propose *frequency-guided word substitutions* (FGWS), a simple algorithm exploiting the frequency properties of adversarial word substitutions for the detection of adversarial examples. FGWS achieves strong performance by accurately detecting adversarial examples on the SST-2 and IMDb sentiment datasets, with F_1 detection scores of up to 91.4% against RoBERTa-based classification models. We compare our approach against a recently proposed perturbation discrimination framework and show that we outperform it by up to 13.0% F_1.

Attack	**Original or perturbed sequence**
None	A clever blend of fact and fiction
GENETIC	1.39 ⇠ 5.55 A **brainy** [*clever*] blend of fact and fiction
PWWS	1.61 ⇠ 5.55 0.00 ⇠ 3.81 A **cunning** [*clever*] **blending** [*blend*] of 0.00 ⇠ 4.39 fact and **fabrication** [*fiction*]

Figure 1: Corpus $\log_e$ frequencies of the replaced words (bold, italic, red) and their corresponding adversarial substitutions (bold, black) using the GENETIC (Alzantot et al., 2018) and PWWS (Ren et al., 2019) attacks on SST-2 (Socher et al., 2013).

1 Introduction

Artificial neural networks are vulnerable to adversarial examples—carefully crafted perturbations of input data that lead a learning model into making false predictions (Szegedy et al., 2014).

While initially discovered for computer vision tasks, natural language processing (NLP) models have also been shown to be oversensitive to adversarial input perturbations for a variety of tasks (Papernot et al., 2016; Jia and Liang, 2017; Belinkov and Bisk, 2018; Glockner et al., 2018; Iyyer et al., 2018). Here we focus on highly successful synonym substitution attacks (Alzantot et al., 2018; Ren et al., 2019; Zang et al., 2020), in which individual words are replaced with semantically similar ones. Existing defense methods against these attacks mainly focus on adversarial training (Jia and Liang, 2017; Ebrahimi et al., 2018; Ribeiro et al., 2018; Ren et al., 2019; Jin et al., 2019) and hence typically require a priori attack knowledge and models to be retrained from scratch to increase their robustness. Recent work by Zhou et al. (2019) instead proposes DISP (*learning to discriminate perturbations*), a perturbation discrimination framework that exploits pre-trained contextualized word representations to detect and correct word-level adversarial substitutions without having to retrain the attacked model. In this paper, we show that we can achieve an improved performance for the detection and correction of adversarial examples based on the finding that various word-level adversarial attacks have a tendency to replace input words with less frequent ones.[1] Figure 1 illustrates this tendency for two state-of-the-art attacks. We provide statistical evidence to support this observation and propose a rule-based and model-agnostic algorithm, *frequency-guided word substitutions* (FGWS), to detect adversarial sequences

---

[1] This frequency difference is expected for attacks that explicitly conduct symbol substitutions resulting in out-of-vocabulary (OOV) terms (Gao et al., 2018). We therefore study attacks that do not explicitly enforce a mapping to words that have lower frequencies.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 171–186

and recover model performances for perturbed test set sequences. FGWS effectively detects adversarial perturbations, achieving F_1 scores of up to 91.4% against RoBERTa-based models (Liu et al., 2019) on the IMDb sentiment dataset (Maas et al., 2011). Furthermore, our results show that FGWS outperforms DISP by up to 13.0% F_1 when differentiating between unperturbed and perturbed sequences, despite representing a conceptually simpler approach to this task.

2 Generating adversarial examples

In our experiments, we investigate two baseline attacks introduced by Ren et al. (2019) as well as two state-of-the-art attacks.

RANDOM. Our first baseline attack is a simple word substitution model that randomly selects words in an input sequence and replaces them with synonyms randomly sampled from a set of synonyms related to the specific word. We follow Ren et al. (2019) by using WORDNET (Fellbaum, 1998) to identify synonym substitutions for each selected word.

PRIORITIZED. Our second baseline builds upon RANDOM by selecting the replacement word from the synonym set that maximizes the change in prediction confidence for the true label of an input.

GENETIC. We additionally analyze an attack suggested by Alzantot et al. (2018), consisting of a population-based black-box mechanism based on genetic search that iteratively performs individual word-level perturbations to an input sequence to cause a misclassification.

PWWS. Lastly, we analyze the *probability weighted word saliency* (PWWS) algorithm (Ren et al., 2019). For each word in an input sequence, PWWS selects a set of synonym replacements from WORDNET and chooses the synonym yielding the highest difference in prediction confidence for the true class label after replacement. The algorithm furthermore computes the word saliency (Li et al., 2016a,b) for each input word and ranks word replacements based on these two indicators.

Datasets and models. We perform experiments on two binary sentiment classification datasets, the *Stanford Sentiment Treebank* (SST-2, Socher et al., 2013) and the IMDb reviews dataset (Maas et al., 2011), both of which are widely used in related work focusing on adversarial examples in NLP (Jia et al., 2019; Ren et al., 2019; Zhou et al., 2019). Dataset details can be found in Appendix A. Adhering to Zhou et al. (2019), we attack a pre-trained model based on the Transformer architecture (Vaswani et al., 2017). Zhou et al. (2019) use BERT (Devlin et al., 2019) in their experiments, but we found that RoBERTa (Liu et al., 2019) represents a stronger model for the specified tasks.

We additionally experiment with both a CNN (Kim, 2014) and an LSTM (Hochreiter and Schmidhuber, 1997) text classification model, both of which have been employed in existing work studying textual adversarial attacks (Alzantot et al., 2018; Lei et al., 2019; Jia et al., 2019; Tsai et al., 2019; Ren et al., 2019).

The fine-tuned RoBERTa model achieves 93.4% and 94.9% accuracy on the IMDb and SST-2 test sets, which is comparable to existing work (Beltagy et al., 2020; Liu et al., 2019). On the IMDb test set, the CNN achieves an accuracy of 86.0% and the LSTM achieves 83.1%. These performances are close to existing work using comparable settings (Zhang et al., 2019; Ren et al., 2019). On the SST-2 test set, the CNN achieves 84.0% and the LSTM 85.2% accuracy, which are also close to comparable experiments (Huang et al., 2019).

Following Ren et al. (2019), we apply all four attacks to a random subset of 2,000 sequences from the IMDb test set as well as the entire test set of SST-2 (1,821 samples). Implementation details for the models and attacks can be found in Appendix B. We report the after-attack accuracies[2] for the RoBERTa model in Table 2 and for the CNN/LSTM models in Table 3 (column Adv.). We observe that all four attacks cause notable decreases in model accuracy on the test sets, and that GENETIC and PWWS are more successful than the baseline attacks in most comparisons.

3 Analyzing frequencies of adversarial word substitutions

Next, we conduct an analysis of the word frequencies of individual words replaced by the attacks and their substitutions. We compute the $\log_e$ training set frequencies $\phi(x)$ of all words x that have been replaced by the respective attacks and all of their corresponding substitutions. Then, we conduct Bayesian hypothesis testing (Rouder et al., 2009) to statistically compare the two samples. This is achieved by computing the Bayes factor BF_{10}, rep-

---

[2] The after-attack accuracy represents the model accuracy on the test set after perturbing all correctly classified inputs. A lower after-attack accuracy indicates a stronger attack.

Dataset	Attack	Replaced		Subst.			non-OOV		
		μ_ϕ	σ_ϕ	μ_ϕ	σ_ϕ	d	μ_ϕ	σ_ϕ	d
IMDb	Random	7.6	2.5	3.4	2.8	**1.6**	4.4	2.4	1.3

	Genetic	4.4	1.9	1.9	2.2	1.2	3.6	1.6	0.4
	PWWS	4.8	2.1	2.9	2.2	0.9	4.0	1.5	0.4

Table 1: Mean $\log_e$ frequencies of replaced words and their substitutions. Values in bold denote largest effect sizes per dataset.

resenting the degree to which the data favor the alternative hypothesis over the null hypothesis. Here, the alternative hypothesis $\mathcal{H}_1$ states that *the frequencies of replaced words differ from the frequencies of the adversarial substitutions*. The null hypothesis $\mathcal{H}_0$ states that *there is no such difference*. The higher BF_{10}, the stronger the evidence in favor of the alternative hypothesis $\mathcal{H}_1$.[3] We additionally calculate Cohen's d effect sizes for all mean frequency comparisons.[4]

Table 1 shows the $\log_e$ frequencies (mean μ_ϕ and standard deviation σ_ϕ) and Cohen's d for the specified samples generated by the attacks against the RoBERTa model (the results for the CNN and LSTM models can be found in Appendix C). We report the mean frequencies of all adversarial substitutions (Subst.) and only those that occur in the training set (non-OOV), to demonstrate that the frequency differences are not solely caused by OOV substitutions. Across datasets and attacks, the substitutions are consistently less frequent than the words selected for replacement. We observe large Cohen's d effect sizes for the majority of comparisons, statistically supporting the observation of mean frequency differences between replaced words and their corresponding substitutions. We furthermore observe that $\mathrm{BF}_{10} > 10^{55}$ holds for all comparisons—both when considering all and only non-OOV substitutions (the BF_{10} scores can be found in Appendix D). This provides strong empirical evidence that $\mathcal{H}_1$ is more likely to be supported by the measured word frequencies (see Appendix E for additional illustrations).

4 Frequency-guided word substitutions

Based on the observation of consistent frequency differences between replaced words and adversarial substitutions, we argue that the effects of such substitutions can be mitigated through simple frequency-based transformations. To do this, we propose *frequency-guided word substitutions* (FGWS), a detection method that estimates whether a given input sequence is an adversarial example.[5] We denote a classification model by a function $f(X)$ that maps a sequence X to a C-dimensional vector representing the probabilities for predicting each of the C possible classes. We represent a sequence as $X = \{x_1, \ldots, x_n\}$, where x_i denotes the i-th word in the sequence. We furthermore introduce the notation $f^*(X) \in \{1, \ldots, C\}$ representing the class label predicted by f given input X. FGWS transforms a given sequence X into a sequence X' by replacing infrequent words with more frequent, semantically similar substitutions. We initially define the subset $X_E := \{x \in X \mid \phi(x) < \delta\}$ of words that are eligible for substitution, where $\delta \in \mathbb{R}_{>0}$ is a frequency threshold. FGWS then generates a sequence X' from X by replacing all eligible words with words that are semantically similar, but have higher occurrence frequencies in the model's training corpus. For each eligible word $x \in X_E$ we consider the set of replacement candidates $\mathcal{S}(x)$ and find a replacement x' by selecting $x' = \mathrm{argmax}_{w \in \mathcal{S}(x)}\ \phi(w)$. We then generate X' by replacing each eligible word x with x' if $\phi(x') > \phi(x)$. Given the prediction label $y = f^*(X)$ for X and a threshold $\gamma \in [0, 1]$, the sequence X is considered adversarial if $f(X)_y - f(X')_y > \gamma$, i.e., if the difference in prediction confidence on class y before and after transformation exceeds the threshold γ. The threshold allows control of the rate of false positives (i.e., unperturbed sequences that are erroneously identified as adversarial) flagged by our method.

4.1 Comparisons

DISP. We compare FGWS to the DISP framework (Zhou et al., 2019), which is, to the best of our knowledge, the best existing approach for the detection of word-level adversarial examples. DISP uses two independent BERT-based components, a perturbation discriminator and an embedding estimator for token recovery, to identify perturbed

---

[3] A Bayes factor $\mathrm{BF}_{10} > 100$ can be interpreted as "extreme" evidence for $\mathcal{H}_1$ (Wagenmakers et al., 2011).

[4] Cohen's d indicates the magnitude of the frequency differences of the two samples—larger effect sizes suggest a higher magnitude of the frequency difference. A value of $d = 0.8$ can be interpreted as a large effect, $d = 0.5$ is considered a moderate effect (Cohen, 1988).

tokens and to reconstruct the replaced ones.

NWS. For the CNN and LSTM models, we compare FGWS with the *naive word substitutions* (NWS) baseline. For a given input sequence, NWS selects all OOV words in that sequence and replaces each with a random choice from a set of semantically related words. We restrict NWS to allow only substitutions for which the replacement word occurs in the model's training vocabulary. NWS can be interpreted as a variant of FGWS that is not explicitly guided by word frequencies.

4.2 Experiments

We apply both methods to the adversarial examples crafted by the four attacks on the subsets of both the IMDb and SST-2 datasets as described in Section 2. To account for an imbalance between unperturbed and perturbed sequences, we repeatedly bootstrap a balanced set of unperturbed sequences for each set of perturbed sequences for 10,000 times and compute the average detection scores. For FGWS, we tune the frequency threshold δ for each model-dataset combination on the validation set. To do this, we utilize the Prioritized attack to craft adversarial examples from all sequences of the validation set[6] and compare FGWS detection performances with different values for δ. Specifically, we set δ equal to the $\log_e$ frequency representing the q^{th} percentile of all $\log_e$ frequencies observed by the words eligible for replacement in the training set, and experiment with $q \in \{0, 10, \ldots, 100\}$. We select γ so that not more than 10% of the unperturbed sequences in the validation set are labeled as adversarial.[7] For FGWS, we define the set of replacement candidates for each word $x \in X_E$ as the union of the word's K nearest neighbors in a pre-trained GloVe (Pennington et al., 2014) word embedding space and its synonyms in WordNet. We set K equal to the average number of WordNet synonyms for each word in the validation set (yielding $K = 6$ for IMDb and $K = 8$ for SST-2).

4.3 Results

We report the results comparing FGWS to DISP on attacks against RoBERTa in Table 2. Here, the true positive rate (TPR) represents the percentage of successful adversarial examples that were cor-

---

[6] We assume both baseline attacks as given to the defender, and prefer Prioritized over Random due to increased effectiveness and hence a larger sample size for parameter tuning.

[7] We provide additional results with varying false positive thresholds in Appendix F.

(D)	FGWS	a $\overset{5.69}{\textbf{smart}}$ [$\overset{0.00}{\textit{impertinent}}$] $\overset{5.77}{\textbf{sweet}}$ [$\overset{1.79}{\textit{odoriferous}}$] and playful romantic comedy	*positive* (99.9%)

Figure 2: The detection methods applied to an adversarial example from the PWWS attack against RoBERTa on SST-2. The words highlighted in bold, italic and red were selected for replacement by the attack (A) and the detection methods (D), the ones in bold and black denote the substitutions. The values above the words denote their $\log_e$ frequencies.

rectly identified as such, and the false positive rate (FPR) denotes the percentage of unperturbed sequences that were identified as adversarial. The column Adv. gives the classification accuracy on the perturbed sequences, and Restored acc. the model's accuracy on the adversarial sequences after transformation. We observe that FGWS best restores the model's classification accuracy across all comparisons, showing it to be effective in mitigating the effects of the individual attacks. Furthermore, FGWS outperforms DISP in terms of true positive rates and F_1 across the majority of experiments. These results show that, although contextualized word representations (DISP) serve as a competitive method to detect adversarial examples, relying solely on frequency-guided substitutions (FGWS) shows to be more effective. Figure 2 provides an example adversarial sequence generated with the PWWS attack and the two corresponding transformed sequences using DISP and FGWS (see Appendix G for additional examples).

The results of NWS and FGWS against the CNN and LSTM models are shown in Table 3. We observe that FGWS outperforms NWS across all comparisons in terms of restored model accuracy and in the majority of comparisons in terms of F_1. Moreover, the direct comparison between NWS and FGWS again underlines the importance of utilizing word frequencies as guidance for the word substitutions: while NWS is not guided by word frequency characteristics to perform the word replacements, we observe that FGWS outperforms NWS by a large margin in most comparisons, demonstrating the effectiveness of mapping infrequent words to their most frequent semantically similar counterparts to detect adversarial examples.

4.4 FGWS on unperturbed data

We furthermore investigate the effect of FGWS on model performance on unperturbed sequences after transformation. To do this, we transform the sampled test sets using FGWS and evaluate classification accuracies after sequence transformation. The differences in accuracy for the CNN, LSTM and RoBERTa models before and after transformation are 0.0%, $+1.0\%$ and -0.2% for IMDb and -1.8%, -2.9% and -1.8% for SST-2. This indicates that FGWS applied to unperturbed data has only small effects on classification accuracy, and in some cases even slightly increases prediction accuracy.

5 Limitations

It is worth mentioning that compared to FGWS, DISP represents a more general perturbation discrimination approach since it is trained to detect both character- and word-level adversarial perturbations, whereas FGWS solely focuses on word-level attacks.

Furthermore, it remains open whether FGWS would be effective against attacks for which the frequency difference is less evident. To investigate this, we conducted preliminary experiments by restricting the investigated attacks to only allow equifrequent substitutions. However, we observed that introducing this constraint has a substantial effect on attack performance, since the attacks are supplied with fewer candidate replacements. We will further investigate this in future work.

6 Conclusion

We have shown that the word frequency characteristics of adversarial word substitutions can be leveraged effectively to detect adversarial sequences for neural text classification. Our proposed approach outperforms existing detection methods despite representing a conceptually simpler approach to this task.

A Dataset statistics

The SST-2 dataset comes with a pre-defined split of 67,349 samples for training, 872 for validation and 1,821 for testing. The IMDb dataset consists of 50,000 positive and negative movie reviews with a pre-defined split of 25,000 training and 25,000 test samples. Since this dataset does not have a pre-defined validation set, we hold out 1,000 randomly selected training set samples for validation. We select a validation set of roughly the same size as for SST-2 for fair comparisons when tuning parameters for adversarial example detection. To the best of our knowledge, the compared work (Alzantot et al., 2018; Ren et al., 2019) does not validate model performance on held-out training data.

B Model and attack details

B.1 RoBERTa

We utilize a pre-trained RoBERTa (base) model (Liu et al., 2019) provided by the *Hugging Face Transformers* library (Wolf et al., 2019). We use maximum input sequence lengths of 256 and 128 after byte-pair encoding (Sennrich et al., 2016) for the IMDb and SST-2 datasets, respectively. The RoBERTa model consists of 125 million parameters.[8] The model was trained for 10 epochs with batch size 32 (SST-2) and 16 (IMDb) and a learning rate of $1 \cdot 10^{-5}$. We evaluated model performance after each epoch on the validation set and selected the best-performing checkpoints for testing.

B.2 CNN/LSTM

The CNN architecture consists of 3 convolutional layers with kernel sizes 2, 3 and 4 and 100 feature maps for each convolutional layer. The LSTM operates on a hidden state size of 128. Following Alzantot et al. (2018), we initialize the LSTM with pre-trained GLOVE (Pennington et al., 2014) word embeddings, and do the same for the CNN.

Both the LSTM and the CNN use *Dropout* (Srivastava et al., 2014) during training with a rate of 0.1 before applying the output layer. We trained both models for 20 epochs using the *Adam* optimizer (Kingma and Ba, 2014). We evaluated model performance after each epoch on the validation set and selected the best-performing checkpoints for testing. The CNN and LSTM models were trained with batch size 100 and a learning rate of $1 \cdot 10^{-3}$.

B.3 PWWS

Our implementation of PWWS is based on the code as provided by Ren et al. (2019) on GitHub.[9]

B.4 GENETIC

Note that we utilize a different language model for the `Perturb` subroutine as compared to the original implementation by Alzantot et al. (2018). While Alzantot et al. (2018) employ the Google 1 billion words language model (Chelba et al., 2013), we instead utilize the recently proposed GPT-2 language model (Radford et al., 2019) and compute the sequences' perplexity scores using the exponentialized language modelling loss (we employ the pre-trained `GPT2LMHeadModel` language model from Wolf et al. (2019)). We compute the perplexity scores for each perturbed sequence only around the respective replacement words by only considering a subsequence ranging from five words before to five words after an inserted replacement. The motivation for using a different language model as compared to the original implementation is due to computational efficiency, since we observed a notable decrease in attack runtime with our modification. This does not have an impact on attack performance, since our implementation of the GENETIC has an attack success rate of 98.6% against the LSTM on IMDb, whereas Alzantot et al. (2018) report an attack success rate of 97%.

For attacks against SST-2, we furthermore increase the δ threshold for the maximum distance between replaced words and substitutions to $\delta = 1.0$,

---

Table 4: Mean $\log_e$ frequencies of replaced words and their corresponding substitutions by attack, model and dataset. The shown values are the mean μ_ϕ and standard deviation σ_ϕ of the $\log_e$ frequencies corresponding to each setting, and additionally the Cohen's d effect sizes for the substitutions. Values in bold denote largest effect sizes per dataset and model.

since we observed poor attack performances with $\delta = 0.5$ (which was used by Alzantot et al. (2018) and in our experiments on IMDb). All other parameters of the attack (e.g., the number of generations and population size) are directly adapted from Alzantot et al. (2018).

We restrict the words eligible for replacement by the Genetic attack to non-stopwords, in accordance to Alzantot et al. (2018). Since the attack computes nearest neighbors for a selected word from a pre-trained embedding space, we furthermore can only select words for which there exists an embedding representation in this pre-trained space. On the SST-2 test set, we found three input sequences consisting of only one word which we excluded from our evaluation, since the used GPT-2 language model implementation requires an input sequence consisting of more than one word.

B.5 Random, Prioritized, PWWS, Genetic

For the Genetic attack, we follow Alzantot et al. (2018) by limiting the maximum amount of word replacements to 20% of the input sequence length. We apply the same threshold to the Random and Prioritized attacks, but not to PWWS since we observed low replacement rates despite the attack's effectiveness. This is in agreement to the results reported in Ren et al. (2019).

C Frequency differences for CNN and LSTM models

The $\log_e$ frequencies for the four attacks against the CNN and LSTM models can be found in Table 4. In accordance to the experiments with RoBERTa (see Section 3 in the paper), we observe large Cohen's d effect sizes for the majority of the comparisons, which shows that the statistical frequency differences between replaced words and their substitutions are present for adversarial attacks against these two models as well.

D Bayes factors

The Bayes factors for the mean frequency comparisons between replaced words and their adversarial substitutions can be found in Table 5. We observe high values for BF_{10} across all comparisons, providing strong evidence for the hypothesis that the $\log_e$ frequency means between replaced words and their substitutions are different.

E Visualizations of frequency differences

Figure 3 illustrates the frequency differences for attacks against the RoBERTa model using his-

Table 5: Bayes factors (BF_{10}) for the Bayesian hypothesis tests.

tograms. We observe that for the majority of the attacks, OOV substitutions occur most often among the perturbed sequences.

F Varying false positive thresholds

The rate of false positives predicted by a detection system is crucial for its practicability, and a limited amount of false positives is hence highly desirable. Figure 4 illustrates the true positive rates predicted by FGWS for all attacks against RoBERTa with different quasi-fixed false positive thresholds (as in Section 4.2 of the paper, δ was tuned on the validation set for each value of γ corresponding to the specific false positive threshold). As expected, we observe a trade-off between true and false positive rates for varying values of γ, such that lower false positive rates imply lower true positive rates. However, even for false positive rates of 1% and 5%, we observe that FGWS is able to detect between 33.6% and 90.0% of adversarial examples on IMDb and between 31.7% and 67.2% on SST-2. This indicates that FGWS has the potential to detect a useful fraction of adversarial examples without creating an excessive burden of false positives.

G Additional FGWS examples

Additional examples of FGWS can be found in Table 6 (true positives), Table 7 (false positives), Table 8 (true negatives) and Table 9 (false negatives).

Maximal Multiverse Learning for Promoting Cross-Task Generalization of Fine-Tuned Language Models

Abstract

Language modeling with BERT consists of two phases of (i) unsupervised pre-training on unlabeled text, and (ii) fine-tuning for a specific supervised task. We present a method that leverages the second phase to its fullest, by applying an extensive number of parallel classifier heads, which are enforced to be orthogonal, while adaptively eliminating the weaker heads during training. We conduct an extensive inter- and intra-dataset evaluation, showing that our method improves the generalization ability of BERT, sometimes leading to a +9% gain in accuracy. These results highlight the importance of a proper fine-tuning procedure, especially for relatively smaller-sized datasets. Our code is attached as supplementary.

1 Introduction

Recently, there has been an increasing number of studies suggesting the use of general language models, for improving natural language processing tasks (Dai and Le, 2015; Peters et al., 2018; Radford et al., 2018; Howard and Ruder, 2018). Among the most promising techniques, the unsupervised pretraining approach (Dai and Le, 2015; Radford et al., 2018) has emerged as a very successful method, that achieves state-of-the-art results on many language tasks, including sentiment analysis (Socher et al., 2013), natural language inference (Williams et al., 2017) and similarity and paraphrasing tasks (Dolan and Brockett, 2005; Cer et al., 2017). This approach incorporates a two-phase training procedure. The first phase utilizes an unsupervised training of a general language model on a large corpus. The second phase applies supervision to fine-tune the model for a given task.

More recently, unsupervised pretraining models such as BERT (Devlin et al., 2018), XLNET (Yang et al., 2019) and RoBERTa (Liu et al., 2019), have achieved unprecedented performance. For example, in the GLUE benchmark (Wang et al., 2018), BERT (Devlin et al., 2018) was reported to achieve performance that exceeds human level on a few different datasets, such as QNLI (Rajpurkar et al., 2016), QQP (Chen et al., 2018) and MRPC (Dolan and Brockett, 2005). However, despite the great progress achieved by these task-specific and dataset-specific models, it is not yet clear how well they can generalize to different tasks, how well they generalize when evaluating the same task on different datasets, and how to improve this generalization ability.

In our work, we extend the multiverse method of (Littwin and Wolf, 2016), which was shown to improve transfer learning in the computer vision task of face recognition and on the CIFAR-100 small image recognition dataset. The multiverse loss generalizes the cross entropy loss, by simultaneously training multiple linear classification heads to perform the same task. In order to prevent multiple copies of the same classifier, in the multiverse scheme, each classifier is mutually orthogonal to the rest of classifiers. The number of multiverse heads used was limited, never more than seven and typically set to five.

We propose a novel fine-tuning procedure for enhancing the generalization ability of the recent unsupervised pretrained language models, by employing a large number of multiverse heads. The essence of our technique is as follows: given a pretrained language model and a downstream task with labeled data, we fine-tune the model using a maximal number of multiverse classifiers. The fine-tuning goal is to both minimize the task loss and an orthogonality loss applied to the classification heads. When enforcing orthogonality hinders the classifiers' performance, we detect and eliminate the less effective classification heads.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 187–199
April 19 - 23, 2021.

The technique, therefore, preserves a maximal set of classifiers, which is comprised of the best performing ones. By maintaining this maximal subset during training, our method leverages multiverse loss to its fullest. Hence, we name our method Maximal Multiverse Learning (MML).

Our contributions are as follows: (1) we present MML, a general training procedure to improve the transferability of neural models. (2) we apply MML on BERT and report its performance on various datasets. (3) we propose a set of cross dataset evaluations using common NLP benchmarks, demonstrating the effectiveness of MML, in comparison to regular BERT fine-tuning and to alternative regularization techniques.

2 Related work

Many recent breakthroughs in NLP employ unsupervised pretraining of language models. The different variants can be categorized into two main approaches: (1) feature-based models, such as (Peters et al., 2018) and (2) fine-tuning models, such as (Devlin et al., 2018; Liu et al., 2019; Yang et al., 2019). The former technique utilizes a language neural-based model as a feature extractor. The extracted features may be used for the training of another model, receiving the extracted features as input. The second approach utilizes a similar pre-trained model, but fine-tunes it in an end-to-end manner to specialize on a given task. During the fine-tuning phase, all of the parameters of the model are updated and a relatively small number of parameters are trained from scratch.

The usage of multiple classifiers can be found in few places in the literature. In GoogLeNet (Szegedy et al., 2015), the authors use multiple classifier heads in different places in the model architecture. The additional classifiers led to better propagation of the gradients during training. However, with the advent of better conditioning and normalization methods, as well as with the modern introduction of skip connections in architectures such as the ResNet (He et al., 2016), the practice of adding intermediate branches, for the sake of introducing an auxiliary loss at lower layers, was mostly abandoned.

The multiverse loss was shown to promote transfer learning and to lead to a low-dimensional representation in the penultimate layer (Littwin and Wolf, 2016). However, the current literature does not present any methodological way to select the number of multiverse heads and the idea was only applied for a handful of parallel classifiers. In MML, hundreds of multiverse heads are used, leading to a tradeoff between the classifier accuracy and the orthogonality constraint. MML balances the two terms by pruning, during training, the under-performing heads.

3 Method

Let $\mathscr{W} = \{w_i\}_{i=1}^{w}$ be the vocabulary of tokens in a given language. Let Y be the set of all possible sentences generated by $\mathscr{W}$, including the empty sentence. A language model $M : Y \times Y \to \mathbb{R}^d$ receives a pair of elements from Y and returns a vectors of d dimensions. Given a dataset with n training samples, $s_1 ... s_n \in Y \times Y$, each associated with a label $y_i \in [1...c]$, we denote the coding vector of each sample by $d_i := M(s_i)$. As a concrete example, for the BERT model, d_i is the latent embedding of the CLS token.

Common language models employ a classifier $C : \mathbb{R}^d \to \mathbb{R}^c$ that projects the coding vectors $d_i \in \mathbb{R}^d$ by a $d \times c$ matrix, $F_{d\times c} = [f_1, ..., f_c]$, $(f_i \in \mathbb{R}^d)$, and then adds a bias term $b \in \mathbb{R}^c$:

$$C(d_i) = d_i^T F_{d\times c} + b \tag{1}$$

The output of C is a logit vector, and pseudo-probabilities are obtained by applying softmax $p_i(y_i) = e^{C(d_i)_{y_i}} / \sum_{j=1}^{c} e^{C(d_i)_j}$.

Different from the single-classifier models, our model utilizes a multiverse classifier $\mathscr{C} : \mathbb{R}^d \to \mathbb{R}^{c\times m}$ defined as $\mathscr{C}(d_i) = (C_1(d_i), ..., C_m(d_i))$, where m is a multiplicity parameter, $\left\{C_j : \mathbb{R}^d \to \mathbb{R}^c\right\}_{j=1}^{m}$ are parallel classifiers, each with different weights, applying the same function as Eq. 1. :

$$C_j(d_i) = d_i^T F_{d\times c}^{j} + b_j \tag{2}$$

Additionally, we will define $B = \left\{\beta_j \in \{0,1\}\right\}_{j=1}^{m}$ as a set of binary scalars. Each classifier head C_j will be associated with a different binary scalar β_j, which is set during training. In our experiments, we set m to be equal to the coding vector size d, which entails a full rank of active multiverse classifiers at the beginning of the training.

The loss function is composed of two components, the task loss and the multiverse loss. Defining active multiverse classifiers as those that are associated with a value $\beta_j = 1$, the task loss optimizes the performance of all active multiverse

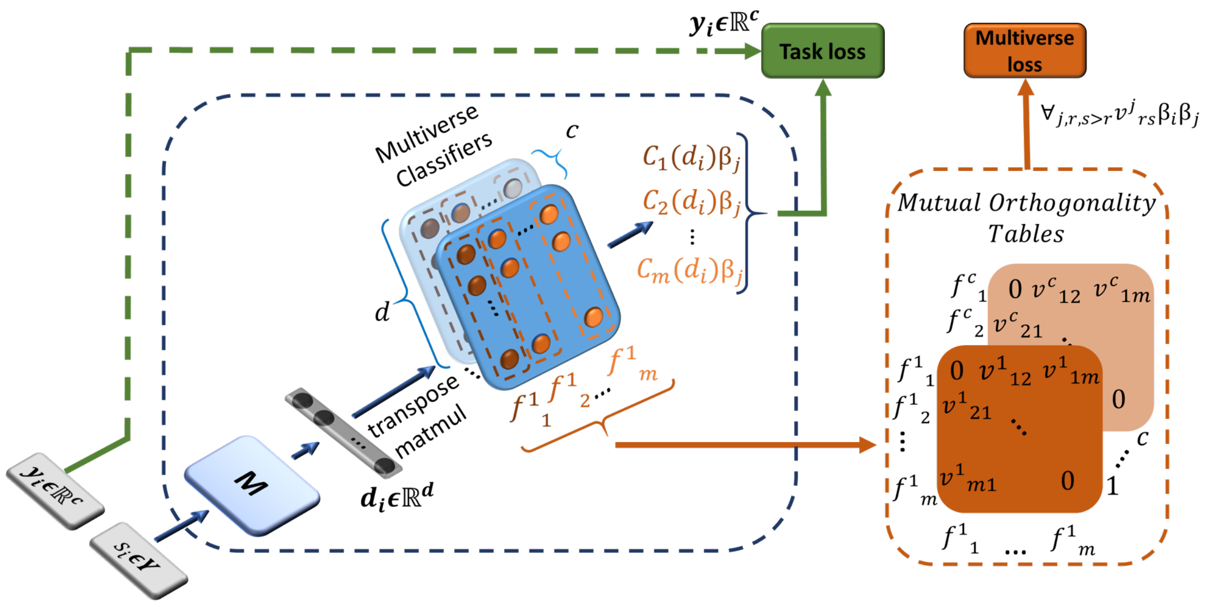

Figure 1: A schematic illustration of the MML model. The task loss comprises a loss-term for each multiverse classifier, using the given labels of the task at hand. The mutual orthogonality tables hold the absolute value of the dot product calculated between the weights of all classifiers, across the different classes. Since orthogonality of a classifier with itself is ignored, we set the diagonal to 0. Following multiverse loss definition and since orthogonality is symmetric, only half of each table value is passed to the multiverse loss.

Algorithm 1 MML training. The MeanShift function returns the center of the clusters. Params: $K = 1000$, $\gamma = 0.99$, $Threshold = 5$, $\alpha = 2 \cdot e^{-5}$, $\lambda = 0.005$.

```
$\forall 1 \le j \le m : \beta_j \leftarrow 1, a_j \leftarrow 0$
for $step = 1, 2, \ldots$ do
    Sample a minibatch $\{(s_i, y_i)\}_{i=1}^{t}$
    $MC_\theta \leftarrow \nabla_\theta \left[ \lambda \cdot \mathcal{L}_{mv}(\mathscr{C}, B) + \frac{1}{t}\Sigma_{i=1}^{t} \mathcal{L}_{task}\left(M, \mathscr{C}, B, \{(s_i, y_i)\}_{i=1}^{t}\right) \right]$
    for $1 \le j \le m$ do
        $a_j \leftarrow (1 - \gamma) \cdot a_j + \left(\gamma \cdot \frac{1}{t}\Sigma_{i=1}^{t} \mathcal{L}_{task}\left(M, \mathscr{C}, B, \{(s_i, y_i)\}_{i=1}^{t}\right)\right)$
    $\theta \leftarrow \theta + \text{Adam}(\theta, MC_\theta, \alpha)$
    if $step \% K = 0$ and $\sum_j \beta_j \ge Threshold$ then
        clusters $\leftarrow$ MeanShift$\left(\{a_j | \beta_j = 1\}_{j=1}^{m}\right)$
        if $|clusters| \ge 2$ then
            for $1 \le j \le m$ do
                $\beta_j \leftarrow 0$, if $a_j \notin min(clusters)$
```

classifiers, each independently, using the supervision obtained by the given labels. The multiverse loss soft-enforces orthogonality among the active classifiers. Its purpose is to regularize the model by encouraging M to produce coding vectors that are robust enough to be effective for a large number of orthogonal classifiers.

As mentioned earlier, each classifier C_j is associated with a binary value β_j, which controls the applicability of the classifier and is configured during training. Under the context of the loss function, setting β_j to 0 would eliminate the impact of the j^{th} classifier head C_j for both the task loss and multiverse loss.

For a multi-class classification task, we apply the following task loss:

$$\mathcal{L}_{task} = -\Sigma_{i=1}^{n} \Sigma_{j=1}^{m} \mathcal{L}_{cce}^{j,i} \beta_j \tag{3}$$

where n is the number of training samples, and $\mathcal{L}_{cce}^{j,i} = y_i log(C_j(M(s_i))_{y_i})$ is the cross entropy loss. For a binary classification task we set $\mathscr{C} : \mathbb{R}^d \to \mathbb{R}^{2 \times m}$ and use the same loss from Eq. 3. For a regression task, we replace $\mathcal{L}_{cce}^{j}$ with $\mathcal{L}_{L2}^{j,i} = \|y_i - C_j(M(s_i))\|_2^2$.

The second loss term enforces orthogonality between the set of classifiers, for each class separately, using the multiverse loss:

$$\mathcal{L}_{mv} = \Sigma_{j,r,s>r} \left| f_j^{r\top} f_j^{s} \beta_r \beta_s \right| \tag{4}$$

where f_j^r is the jth column of the weight matrix that corresponds to classifier C_r.

The total loss $\mathcal{L}_{total}$ is defined as: $\mathcal{L}_{total} = \mathcal{L}_{task} + \lambda \mathcal{L}_{mv}$. Similar to (Littwin and Wolf, 2016), we set $\lambda = 0.005$, throughout all of our experiments. The MML model is illustrated in Fig. 1.

The training algorithm begins with an initialization of the aggregated model $(M, \mathscr{C}, B)$. M may be initialized by any pre-trained general language model. The multiverse classifiers are randomly initialized from scratch, and all classifiers are initially activated, by setting $\beta_j = 1$ for $\forall \beta_j \in B$.

During training, we track the performance of each multiverse classifier separately. Every K steps, we search for a subset of the top-performing classifiers. When we find such a subset, we eliminate the less performing classifiers by setting their corresponding βs to 0.

In order to detect the top-performing classifiers, we calculate a moving average variable a_j for each multiverse classifier. Specifically, a_j holds the moving average of the task loss value $\mathcal{L}^j_{task}$ associated with classification head C_j. a_j is being updated for every training step, using the moving average momentum constant of 0.99.

Every K steps, we run the MeanShift algorithm (Comaniciu and Meer, 2002) on the set $\{a_j | \beta_j = 1\}$ to obtains the modes of the underlying distribution. MeanShift is a clustering algorithm that reveals the number of clusters in a given data, and retrieves the corresponding centroid for each detected cluster. In our case, MeanShift is applied on 1D data and by utilizing it, we identify the subset of top-performing multiverse heads as the cluster associated with the minimal centroid value. Next, we eliminate the rest of the multiverse heads, by setting their corresponding β to 0. This adaptive elimination is stopped, when we reach a minimal number of active heads, see Alg. 1.

At inference, we use the active multiverse heads to retrieve predictions. Specifically, given a sample s_i, we calculate the logits $\hat{y}$ as:

$$\hat{y} := \frac{\sum_{j=1}^{m} C_j(M(s_i)) \cdot \beta_j}{\sum_{j=1}^{m} \beta_j} \tag{5}$$

for classification tasks, we apply the softmax function on $\hat{y}$, and return its output. For regression tasks, we simply return $\hat{y}$.

4 Results

In this study, we evaluate MML, applied on a pretrained BERT (Devlin et al., 2018) model, using nine NLP datasets, while employing two different settings: (1) fine-tuning on different downstream tasks from the GLUE benchmark (Wang et al., 2018), and (2) cross dataset evaluations for different datasets of the same or similar tasks. For the first, we fine-tune MML on each dataset separately, and evaluate its performance on the development set and the test set of the same dataset. For the second, we evaluate our fine-tuned MML models on the train and development set of other datasets within the same task category. This allows us to study the generalization level of all models, across different datasets. Additionally, we perform an ablation study and report empirical results that showcase the efficacy of MML, compared to other multiverse schemes and to a BERT model with a higher dropout rate.

We adopt eight datasets from the GLUE benchmark (Wang et al., 2018) and one extra dataset supporting the task of Natural Language Inference (NLI). The datasets can be arranged to form the following three categories: (1) Inference tasks: this category incorporates four datasets of natural language inference: RTE, MNLI, SNLI and QNLI. RTE and QNLI are binary classification tasks, whereas MNLI and SNLI are multilabel classification tasks (which possess an additional "neutral" label). (2) Similarity and paraphrasing tasks: this category includes three datasets: MRPC, QQP, STS-B. MRPC and QQP are binary classifications tasks, while STS-B is a regression task with labels annotating the level of similarity between each sentence pair. (3) Misc. datasets: this category composed of two datasets that cannot be used for the cross dataset evaluation, due to the lack of commonality between their tasks: CoLA and SST-2. We refer the reader to the appendix for more details on the nine datasets.

4.1 Evaluation on GLUE datasets

We evaluated MML on the eight different datasets from the GLUE benchmark, and compared to BERT (Devlin et al., 2018). Each model was trained and evaluated on a single dataset. Development and test set performance are being reported for each model. In addition, we conduct an ablation analysis for our method, presenting the importance of our Maximal Multiverse Learning, which allows the training to adapt the number of multiverse classifiers to each dataset. The first ablation experiment disables the classifier elimination step during training and utilizes the same MML architecture with a fixed number of heads. The second ablation also disables the multiverse loss, leaving the training to optimize an ensemble of classifiers, without enforcing the or-

Table 1: Results on GLUE benchmarks (Wang et al., 2018). BERT results taken from (Devlin et al., 2018). Accuracy scores are reported for all datasets, except STS-B, for which Spearman Correlation is reported. For MNLI, accuracy scores are reported for both matched and mismatched test sets. The last row exhibits the number of active multiverse heads of the converged MML model. For example, for MRPC, our MML model used 913 active multiverse heads, while for MNLI, it maintained 19.

thogonality constraint.

The BERT model used is the BERT-Large model (Devlin et al., 2018). It contains 24 attention layers, each with 16 attention heads with a hidden layer of size $d = 1024$ dimensions. The model was pre-trained using sentence pairs, to both reconstruct masked words and to predict whether the pairs are consecutive. BERT's fine-tuning for downstream tasks employs supervision obtained by the given labels of each dataset.

MML utilizes the same pre-trained BERT-Large model and is initialized with $m = d = 1024$ active multiverse classifiers. During training, the model converges to a smaller number of multiverse classifiers. The number of active multiverse classifiers of each model is presented in last row of Tab. 1.

Tab. 1 presents the results for six models: (1) BERT (as a baseline), (2) MML, (3-4) two multiverse models utilizing a fixed number of multiverse classifiers, with 5 and 1024 classifiers, respectively, (5) BERT-Drop, a BERT model that was fine-tuned with a 30% dropout rate on the CLS embedding vector and which provides a baseline with additional regularization, (6) BERT-Ensemble, a BERT model with 1024 heads (similar to MV-1024 without the multiverse loss).

As can be seen in the table, compared to BERT, MML yields better results by a sizeable margin on the test set of five out of eight datasets. The largest gains were reported in the relatively smaller-sized dataests, such as RTE, MRPC and STS-B, for whom MML yields an absolute improvement of 4.1%, 1.3%, 1.6%, respectively. This can be attributed to the ability of MML to encourage a more robust learning. On the rest of the datasets, MML yields similar performance on the test. On the development set, MML outperforms BERT on all datasets, sometimes by a large margin. Specifically, for RTE, MML yields an improvement of almost 10%.

The ablation models MV-5 and MV-1024, utilize a fixed number of multiverse heads during the entire training. We have found that this hyper parameter can be crucial for the model's convergence, and when not initialized properly, may significantly reduce performance for the given task in hand. Specifically, for the CoLA dataset, MV-1024 and MV-5 yield a relative performance gap of more than 11%, in favor of MV-5, while in RTE, there is a gap of 6.2% in favor of MV-1024. When comparing both MV-5 and MV-1024 to MML, MML produces better or similar performance on the development set of all datasets. More specifically, on RTE and MRPC, MML yields similar performance as in MV-1024, and outperforms it on all the other six datasets. Compared to MV-5, MML yields better performance, by a sizeable margin, on four datasets out of eight, and produces similar performance on the rest.

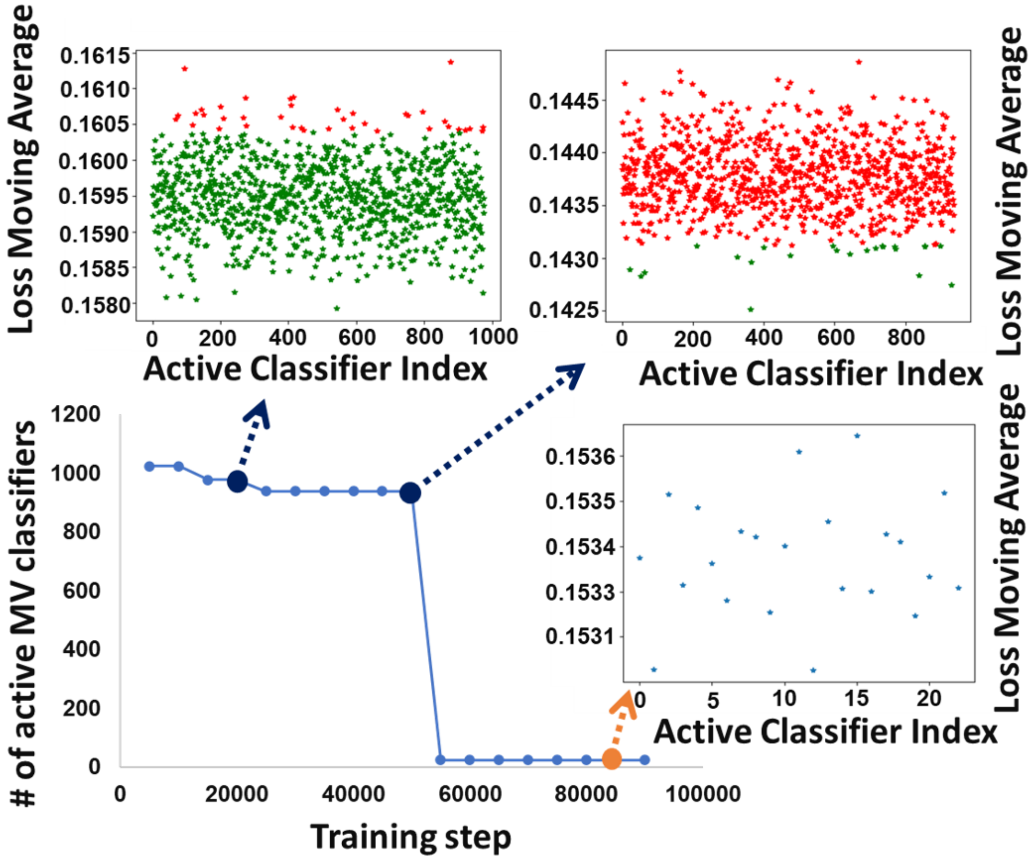

Figure 2: The number of active multiverse classifiers, per training step, for the MML model trained on QNLI. The MeanShift algorithm detects multiple clusters, for three times during training. The two upper plots present the selection of the top-performing heads (green stars), and the elimination of the heads showing lower-performance (red stars). The Y values are the moving average calculated on the multiverse heads' loss function. Our MML-QNLI model reaches local minima at step 85K, for which 23 heads were activated. The bottom right plot shows the moving average values of the activated 23 multiverse heads, by the same training step.

The BERT-Drop model is a BERT baseline trained with a dropout rate of 30% (instead of 10% as used in a regular BERT). Compared to BERT, BERT-Drop provides similar results on the test set, while showing some improvement on the development set. When comparing BERT-Drop to MML, MML results with a higher average performance on both the test set and development set, where in some dataests, such as RTE, MML yields an improvement of +3.6% on the development set. On the test set, MML surpasses BERT-Drop on seven out of eight datasets. Specifically, in some datasets, such as MRPC and CoLA, MML outperforms BERT-Drop in 1.4 and 2.5 accuracy points, respectively.

The BERT-Ensemble employs BERT with an ensemble of 1024 parallel classifiers. It optimizes all classifiers during training and infers predictions by calculating the mean over all classifiers' logits. As shown in the table, BERT-Ensemble yields similar performance to BERT.

Fig. 2 presents the amount of active multiverse heads, when applying MML on QNLI dataset. During the training of the MML-QNLI model, the MeanShift algorithm detected multiple clusters at three times[1], through the entire training. Each time, the model eliminated the lower-performance subsets, and kept the top-performing multiverse classifiers as the active set of classifiers. The model achieved best performance on the development set at training step 85K. At this step, the MML-QNLI model utilized 23 active multiverse heads. The plots in the figure present the cumulative loss of each multiverse head, sorted through the X axis according to the indices of the active heads. The red stars are asso-

---

[1] The elimination is being invoked every time the MeanShift algorithm detects multiple clusters. Specifically, for MML-QNLI experiment, multiple clusters appeared three times during the training process.

ciated with the classifiers heads that were eliminated, and the green stars are the heads that were selected as the top-performing subset.

4.2 Cross dataset evaluations

In the cross-task evaluations, we use the finetuned MML models from Sec. 4.1. For each model trained on a dataset from the two first categories above (NLI and similarity/paraphrasing), we evaluate the model on all datasets from the same category. Train and development set performance are reported to give a clear view on the cross-task generalization ability, and also to exhibit the level of overfitting, when evaluating on the same dataset that the model was trained on.

In order to conduct a clean comparison, we finetune BERT, MML, and all other methods with the same hyperparmeters, employing 10/30/100 epochs for the relative large/medium/small datasets, a batch size of 32, and a learning rate of 2e-5 (BERT obtains in all cases performance that at least matches the one published in (Devlin et al., 2018)). Our code can be found at `https://github.com/ItzikMalkiel/MML`.

In cross evaluation experiments, there is no training on the target training set, so both the target training set and validation sets can be used for evaluation. Overall, there are 36 cross-task experiments. In the first category, there are four datasets, so three cross-task experiments for each. Taking into account the two splits, this amounts to 24 experiments. Similarly, in the second category, where there are three datasets, there are 12 experiments. Fig. 3 is a Dolan Moré plot comparing the performance of BERT to the five finetuning variants explored (MML, MV-5, MV-1024, BERT-Drop, Bert-Ensable) for all 36 experiments. These plots show for each method the ratio of experiments for which it has a performance level that is at least as high a constant times the best result. As can be seen, regularization helps cross-task generality. However, none of the baseline methods is as effective as MML. In the supplementary appendix we provide the full data, and, for brevity, below we focus on comparing MML with BERT.

Inference tasks Since MNLI and SNLI are multiclass classification tasks with 3 classes, we collapse the labels "neutral" and "contradication" into one label ("non entailment"). This modification, applied only during inference, allows us to evaluate MNLI and SNLI models on RTE and QNLI, and vice versa.

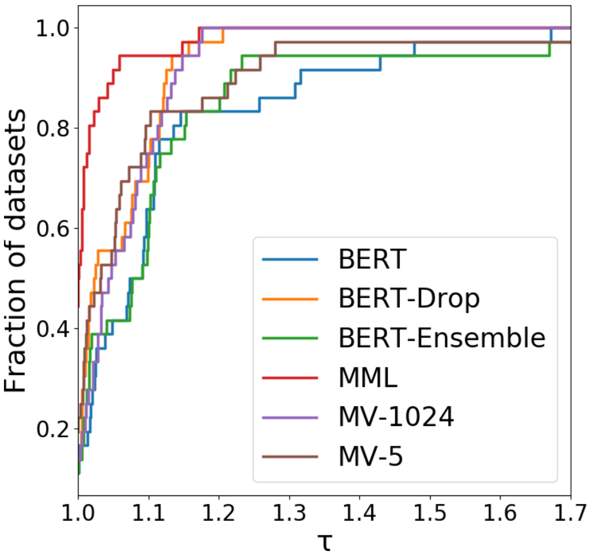

Figure 3: A Dolan-Moré profile, based on the results obtained across all cross-task experiments. The x-axis is the threshold τ. The y-axis depicts, for a given fine-tuning method, the ratio of datasets in which the obtained error is less than the threshold τ times the minimal error obtained by any of the six methods.

The results are reported in Tab. 2. As can be seen, MML exhibits a significantly improved transferability compared to BERT. Each row in the table represents an MML or BERT model trained on a single dataset associated by its name. All models are evaluated on all four datasets. In the last column, we report the relative average improvement obtained by MML, calculated by the performance ratio between MML and BERT across all three holdout datasets. For example, for RTE, our MML-RTE model yields 9.9% relative average performance on the train set of MNLI, QNLI and SNLI, and a 9.5% average improvement on the development set of these datasets.

Similarity and paraphrasing Since STS-B is a regression task benchmark, while MRPC and QQP address a binary classification task, to support cross dataset evaluations, we adapt STS-B to form a binary classification task. The adaptation is being done by collapsing the labels in the range 1-2 (4-5) to the value of 0 (1) and omitting all samples associated with label values between 2 and 4. The binary STS-B version has ~3.5K samples.

As can be seen in Tab. 3, MML yields better performance on the cross evaluations for the similarity and paraphrase datasets. Similar to Tab. 2, each row represent a single model trained on a single dataset. We evaluate all models on all three

Model	RTE	MNLI	QNLI	SNLI	MML Improvement
BERT-RTE	96.06/70.39	69.42/69.17	52.46/52.84	68.02/69.87	-
MML-RTE	99.39/**80.14**	79.24/78.42	50.86/51.30	80.85/82.53	+9.98%/+9.51%
BERT-MNLI	79.15/76.89	99.59/86.58	49.88/51.05	81.65/83.65	-
MML-MNLI	79.35/78.70	99.74/**87.18**	49.64/50.22	82.37/83.94	+0.21% /+0.35%
BERT-QNLI	53.37/48.73	59.76/59.89	99.99/**94.01**	59.33/60.03	-
MML-QNLI	53.41/53.79	64.93/63.85	95.75/92.86	62.13/63.58	+4.48%/+7.63%

MML-SNLI	71.88/69.31	75.79/76.37	49.32/50.32	99.30/**91.38**	+0.07%/-0.36%

Table 2: Cross dataset evaluation for Language Inference tasks. Train/development accuracy are reported separately for each dataset. Each model (a row in the table) was trained on a single dataset denoted by its name, and was evaluated on the train/development sets of all four datasets. The last columns indicates the relative average improvement obtained by MML compared to BERT, and averaged across the three hold-out datasets (i.e. excluding the diagonal). SNLI is the only dataset for which MML does not improve cross dataset performance on average, perhaps since it is largest dataset with 570k samples. See supplementary appendix for farther comparison with MV-5, MV-1024 and BERT-Drop.

Model	QQP	MRPC	STS-B*	MML Improvement
BERT-QQP	99.73/91.57	66.90/68.85	88.34/90.12	-
MML-QQP	99.74/**91.68**	67.77/68.87	89.11/90.55	+1.08%/+0.25%
BERT-MRPC	65.28/65.18	99.37/87.25	82.53/88.58	-
MML-MRPC	68.37/68.15	99.23/**88.97**	86.12/91.32	+4.54%/+3.82%
BERT-STS-B*	73.13/73.11	75.59/75.49	100.0/95.49	-
MML-STS-B*	74.13/74.40	75.51/77.94	99.85/**96.70**	+0.63%/+2.50%

Table 3: Cross dataset evaluation for similarity and paraphrasing tasks. STS-B* is the modified version of STS-B that forms a binary classification dataset (instead of regression). STS-B* models were trained as binary classifiers on STS-B data. Accuracy scores are reported through all evaluations. The last column presents the relative cross dataset improvement obtained by MML, compared to BERT.

datasets, and report the average relative improvement obtained by MML calculated on the two holdout datasets. We have found MML to produce improved performance for all models, for example, MML-MRPC yields a ~+3.5% average improvement calculated on both train and development sets across STS-B and QQP.

5 Discussion

The results in both Tab. 2 and 3, reveal a significant gap in performance for all models when evaluated on holdout datasets, although the holdout datasets share the same or similar task each model was trained for. For example, both MML-MRPC and BERT-MRPC models yield a ~20% degradation in absolute accuracy on the QQP dataset. However, compared to BERT, our MML method produces significantly better performance on the cross evaluations. Specifically, when evaluated on QQP, MML-MRPC outperforms BERT-MRPC by a relative improvement of ~4.6%, for both development and train set.

We do not observe a direct link between the improvement obtained on the same dataset evaluation to that obtained in the cross dataset one. For example, our MML-QNLI model was able to outperform BERT-QNLI in the cross dataset evaluation, although, compared to our BERT-QNLI reproduction, MML-QNLI exhibits a somewhat degraded performance on QNLI's development set (see the third section in Tab.2) and test set (as published in (Devlin et al., 2018)). We attribute this to the ability of MML to encourage the model to produce more transferable coding vectors.

Computational overhead During training, the MML multiverse heads imply a maximal addition of 1024 operations of matrix multiplications and gradient derivations, each in the size of $1024 \times c$.

During the backward steps, the multiple gradients are averaged almost immediately, right before propagating them back through the last encoder layer of BERT. Interestingly, in many cases, the number of active heads shrinks in the early stages of the training. During inference, the additional calculations are solely the matrix multiplications, for which the average number of active heads, across our experiments, is 381. This average number of active heads translates to an increase of ~0.2% to the parameter count of BERT_Large.

6 Summary

We introduce the MML method for fine-tuning language models. MML utilizes a large set of parallel multiverse heads and eliminates the relatively weaker heads during training. We demonstrate the effectiveness of MML on nine common NLP datasets, by applying inter- and intra-datasets evaluation, where it is shown to outperform the originally introduced BERT fine-tuning procedure. The results shade light on the role of regularization in improving cross task generalization, and show the advantage of MML over alternative regularization methods.

Supplementary Appendices[2]

A The datasets (more details)

We adopt eight datasets from the GLUE benchmark (Wang et al., 2018), and one extra dataset supporting the task of Natural Language Inference (NLI). The datasets can be arranged by categories as follows.

Inference tasks This category contains three datasets from the GLUE benchmark (Wang et al., 2018), along with an external dataset named SNLI (Bowman et al., 2015) that shares the same task. **RTE** The Recognizing Textual Entailment dataset (Bentivogli et al., 2009) is composed of sentence pairs associated with a binary classification task for entailment/non entailment relation between the sentences. **MNLI** Multi-Genre Natural Language Inference Corpus (Williams et al., 2017) is also an entailment dataset comprised of sentence pairs. The task is multiclass classification for predicting contradiction, neutral or entailment relation between the sentence pairs. **SNLI** The Stanford Natural Language Inference dataset (Bowman et al., 2015) is similar to MNLI, but contains data gathered from different sources. **QNLI** The Question-answering Natural Language Inference dataset (Rajpurkar et al., 2016) contains question-sentence pairs associated with the binary classification task for the entailment/non entailment relation between the question-answer pairs.

Similarity and paraphrasing Tasks This category contains three datasets. **MRPC** Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005) is a dataset of sentence pairs. The task is to determine whether a pair of sentences are semantically equivalent (binary classification). **QQP** Quora Question Pairs (Chen et al., 2018) is a dataset of question pairs taken from the Quora website. The goal is to determine whether a pair of questions are semantically equivalent (binary classification). **STS-B** Semantic Textual Similarity Benchmark (Cer et al., 2017) is a dataset composed of sentence pairs, each annotated with a score between 1 and 5, indicating the semantic similarity level of both sentences. The task is to predict these scores (regression).

Misc. datasets The two datasets in this category are not used for the cross dataset evaluation, due to the lack of commonality between their tasks. **CoLA** The Corpus of Linguistic Acceptability dataset (Warstadt et al., 2018) consists of examples of expert English sentence acceptability judgments. Each sample is annotated by whether it is a grammatically sentence of English (binary classification). **SST-2** The Stanford Sentiment Treebank (Socher et al., 2013) is a dataset composed of sentences assigned with a human annotations of their sentiment. The task is to determine whether the sentiment of each sentence is positive or negative (binary classification).

B Cross-task generalization results for all baselines

For the sake of completeness, we report cross dataset evaluations, for all six models described in the main text. Specifically, we compare MML, BERT, MV-5, MV-1024, BERT-Drop and BERT-Ensemble on cross dataset evaluations for inference datasets, and similarity and paraphrase datasets.

Tab. 4 presents the performance of the above six models evaluated on the cross dataset evaluation for the NLI category. Each row represents a different model, trained on a single dataset associated by its name. Each column corresponds to an evaluation on four datasets in this category. The last column presents the improvement obtained by each model, compared to BERT, and calculated across the three hold-out datasets. Accuracy is reported for all datasets on both the train and development sets, in the format train

---

[2] Put here for the reader's convenience.

accuracy/development accuracy. Note that no training is done on the training set in the case of cross-task evaluation. Therefore, the training set can be seen as an additional dataset to evaluate on.

As can be seen in Tab. 4, MML-RTE outperforms BERT-RTE on all datasets, and results with similar performance compared to MV-5-RTE, MV-1024-RTE and BERT-Drop-RTE. For the models trained with MNLI dataset, we found that the four models MML-MNLI, MV-5-MNLI, MV-1024-MNLI and BERT-Drop-MNLI, yield similar results, where all produce a slight improvement compared to BERT. For QNLI, MML yields a significant improvement compared to all models. Specifically, MML-QNLI yields +4.48%/7.63% relative improvement compared to BERT, averaged on the train and development set of the three hold-out dataests. BERT-Drop-QNLI yields significantly decreased performance of -1.93%/-2.89% compared to BERT, MV-5 yields improved performance of +1.0%/+2.73%, and MV-1024 results with a significantly decreased performance of -2.64% on the train sets, and somehow similar performance to BERT on the development set.

For SNLI, MML and BERT-Drop yield similar performance compared to BERT on the training sets, where MML shows slightly better performance. On the development set, both MML and Bert-Drop present slightly decreased performance. Mv-5 and Mv-1024 exhibit significantly decreased performance on both train and development sets.

In Tab.5, we present the performance of all six fine-tune variants, evaluated on the cross similarity and paraphrasing datasets. For QQP-based models, MML and MV-5 were able to improve the cross evaluation performance compared to BERT, measured on the two hold-out datasets. Both MML-QQP and MV-5-QQP yield more than one percentage of relative improvement on the train sets, and less than one percentage of improvement on the developments sets, where MV-5-QQP presents slightly better results. On the other hand, BERT-Drop-QQP and MV-1024-QQP yield significantly decreased performance compared to BERT, each results with 1.76%-3.22% of decreased performance on the train/development sets.

For MRPC, MML outperforms all models, showing a significantly improvement of +4.54%/3.82% on the train/development sets, when compared to BERT. The other models where able to improve BERT in +2.69% up to +3.89% on the train and +1.66% up to +2.95% on the development sets, which are significantly inferior to MML-MRPC. For STS-B, we see that MML, MV-5 and BERT-Drop were able to yield similar improvement compared to BERT, where MV-1024 yields decreased performance on the train sets, and similar performance on the development set.

All in all, MML gained the highest improvement, accumulated across all evaluations. Specifically, when averaging the cross evaluation results over the train sets, MML shows an average improvement of +3.0%, BERT-Drop shows average improvement of +1.64%, MV-5 yields +2.27% and MV-1024 yields +0.46%.

Model	**RTE**	**MNLI**	**QNLI**	**SNLI**	**Improvement compared to BERT**

Table 4: Cross dataset evaluation for Language Inference tasks for all ablation models presented in the main text (BERT-D stands for BERT-Drop). Train/development accuracy are reported separately for each dataset. Each model (a row in the table) was trained on a single dataset denoted by its name, and was evaluated on the train/development sets of all four datasets. The last column indicates the relative average improvement obtained by each model compared to BERT, and averaged across the three hold-out datasets. The last four rows present the average column-wise improvement each technique yields, which is aggregated from the three models of the same technique. BERT models were reproduced with the same hyperparamters used for MML (all BERT reproductions result with similar or better performance compared to the one published in (Devlin et al., 2018)).

Table 5: Cross dataset evaluation for similarity and paraphrase tasks. STS-B* is the modified version of STS-B that forms a binary classification dataset (instead of regression). STS-B* models were trained as binary classifiers on STS-B data. Accuracy scores are reported through all evaluations. The last column presents the relative cross dataset improvement obtained by each model compared to BERT, and averaged across the two hold-out datasets. The last four rows present the average column-wise improvement each technique yields, which is computed from the two models of the same technique.

Unification-based Reconstruction of Multi-hop Explanations for Science Questions

Abstract

This paper presents a novel framework for reconstructing *multi-hop explanations* in science Question Answering (QA). While existing approaches for multi-hop reasoning build explanations considering each question in isolation, we propose a method to leverage *explanatory patterns* emerging in a corpus of scientific explanations. Specifically, the framework ranks a set of atomic facts by integrating lexical relevance with the notion of *unification power*, estimated analysing explanations for similar questions in the corpus.

An extensive evaluation is performed on the Worldtree corpus, integrating k-NN clustering and Information Retrieval (IR) techniques. We present the following conclusions: (1) The proposed method achieves results competitive with Transformers, yet being orders of magnitude faster, a feature that makes it scalable to large explanatory corpora (2) The unification-based mechanism has a key role in reducing semantic drift, contributing to the reconstruction of many hops explanations (6 or more facts) and the ranking of complex inference facts (+12.0 Mean Average Precision) (3) Crucially, the constructed explanations can support downstream QA models, improving the accuracy of BERT by up to 10% overall.

1 Introduction

Answering *multiple-choice science questions* has become an established benchmark for testing natural language understanding and complex reasoning in Question Answering (QA) (Khot et al., 2019; Clark et al., 2018; Mihaylov et al., 2018). In parallel with other NLP research areas, a crucial requirement emerging in recent years is *explainability* (Thayaparan et al., 2020; Miller, 2019; Biran and Cotton, 2017; Ribeiro et al., 2016). To boost automatic methods of inference, it is necessary not only to measure the performance on answer prediction, but also the ability of a QA system to provide explanations for the underlying reasoning process.

The need for explainability and a quantitative methodology for its evaluation have conducted to the creation of shared tasks on *explanation reconstruction* (Jansen and Ustalov, 2019) using corpora of explanations such as Worldtree (Jansen et al., 2018, 2016). Given a science question, explanation reconstruction consists in regenerating the gold explanation that supports the correct answer through the combination of a series of atomic facts. While most of the existing benchmarks for multi-hop QA require the composition of only 2 supporting sentences or paragraphs (e.g. QASC (Khot et al., 2019), HotpotQA (Yang et al., 2018)), the explanation reconstruction task requires the aggregation of an average of 6 facts (and as many as $\approx$20), making it particularly hard for multi-hop reasoning models. Moreover, the structure of the explanations affects the complexity of the reconstruction task. Explanations for science questions are typically composed of two main parts: a grounding part, containing knowledge about concrete concepts in the question, and a core scientific part, including general scientific statements and laws.

Consider the following question and answer pair from Worldtree (Jansen et al., 2018):

- q: what is an example of a **force** producing heat?
  a: two **sticks** getting warm when **rubbed together**.

An explanation that justifies a is composed using the following sentences from the corpus: *(f_1) a **stick** is a kind of object*; *(f_2) to **rub together** means to move against*; *(f_3) friction is a kind of **force***; *(f_4) friction occurs when two objects' surfaces move against each other*; *(f_5) friction causes the temperature of an object to increase*. The explanation

contains a set of concrete sentences that are conceptually connected with q and a (f_1,f_2 and f_3), along with a set of abstract facts that require multi-hop inference (f_4 and f_5).

Previous work has shown that constructing long explanations is challenging due to *semantic drift* – i.e. the tendency of composing out-of-context inference chains as the number of hops increases (Khashabi et al., 2019; Fried et al., 2015). While existing approaches build explanations considering each question in isolation (Khashabi et al., 2018; Khot et al., 2017), we hypothesise that semantic drift can be tackled by leveraging *explanatory patterns* emerging in clusters of similar questions.

In Science, a given statement is considered explanatory to the extent it performs *unification* (Friedman, 1974; Kitcher, 1981, 1989), that is showing how a set of initially disconnected phenomena are the expression of the same regularity. An example of unification is Newton's law of universal gravitation, which *unifies* the motion of planets and falling bodies on Earth showing that *all* bodies with mass obey the same law. Since the explanatory power of a given statement depends on the number of unified phenomena, highly explanatory facts tend to create *unification patterns* – i.e. similar phenomena require similar explanations. Coming back to our example, we hypothesise that the relevance of abstract statements requiring multi-hop inference, such as f_4 (*"friction occurs when two objects' surfaces move against each other"*), can be estimated by taking into account the unification power.

Following these observations, we present a framework that ranks atomic facts through the combination of two scoring functions:

- A *Relevance Score (RS)* that represents the lexical relevance of a given fact.
- A *Unification Score (US)* that models the explanatory power of a fact according to its frequency in explanations for similar questions.

An extensive evaluation is performed on the Worldtree corpus (Jansen et al., 2018; Jansen and Ustalov, 2019), adopting a combination of k-NN clustering and Information Retrieval (IR) techniques. We present the following conclusions:

1. Despite its simplicity, the proposed method achieves results competitive with Transformers (Das et al., 2019; Chia et al., 2019), yet being orders of magnitude faster, a feature that makes it scalable to large explanatory corpora.
2. We empirically demonstrate the key role of the unification-based mechanism in the reconstruction of many hops explanations (6 or more facts) and explanations requiring complex inference (+12.0 Mean Average Precision).
3. Crucially, the constructed explanations can support downstream question answering models, improving the accuracy of BERT (Devlin et al., 2019) by up to 10% overall.

To the best of our knowledge, we are the first to propose a method that leverages unification patterns for the reconstruction of multi-hop explanations, and empirically demonstrate their impact on semantic drift and downstream question answering.

2 Related Work

Explanations for Science Questions. Reconstructing explanations for science questions can be reduced to a multi-hop inference problem, where multiple pieces of evidence have to be aggregated to arrive at the final answer (Thayaparan et al., 2020; Khashabi et al., 2018; Khot et al., 2017; Jansen et al., 2017). Aggregation methods based on lexical overlaps and explicit constraints suffer from *semantic drift* (Khashabi et al., 2019; Fried et al., 2015) – i.e. the tendency of composing spurious inference chains leading to wrong conclusions.

One way to contain semantic drift is to leverage common explanatory patterns in explanation-centred corpora (Jansen et al., 2018). Transformers (Das et al., 2019; Chia et al., 2019) represent the state-of-the-art for explanation reconstruction in this setting (Jansen and Ustalov, 2019). However, these models require high computational resources that prevent their applicability to large corpora. On the other hand, approaches based on IR techniques are readily scalable. The approach described in this paper preserves the scalability of IR methods, obtaining, at the same time, performances competitive with Transformers. Thanks to this feature, the framework can be flexibly applied in combination with downstream question answering models.

Our findings are in line with previous work in different QA settings (Rajani et al., 2019; Yadav et al., 2019), which highlights the positive impact of explanations and supporting facts on the final answer prediction task.

In parallel with Science QA, the development of models for explanation generation is being explored in different NLP tasks, ranging from open domain question answering (Yang et al., 2018; Thayaparan et al., 2019), to textual entailment (Camburu et al., 2018) and natural language premise selection (Ferreira and Freitas, 2020b,a).

Scientific Explanation and AI. The field of Artificial Intelligence has been historically inspired by models of explanation in Philosophy of Science (Thagard and Litt, 2008). The deductive-nomological model proposed by Hempel (Hempel, 1965) constitutes the philosophical foundation for explainable models based on logical deduction, such as Expert Systems (Lacave and Diez, 2004; Wick and Thompson, 1992) and Explanation-based Learning (Mitchell et al., 1986). Similarly, the inherent relation between explanation and causality (Woodward, 2005; Salmon, 1984) has inspired computational models of causal inference (Pearl, 2009). The view of explanation as unification (Friedman, 1974; Kitcher, 1981, 1989) is closely related to Case-based reasoning (Kolodner, 2014; Sørmo et al., 2005; De Mantaras et al., 2005). In this context, analogical reasoning plays a key role in the process of reusing abstract patterns for explaining new phenomena (Thagard, 1992). Similarly to our approach, Case-based reasoning applies this insight to construct solutions for novel problems by retrieving, reusing and adapting explanations for known cases solved in the past.

3 Explanation Reconstruction as a Ranking Problem

A multiple-choice science question $Q = \{q, C\}$ is a tuple composed by a question q and a set of candidate answers $C = \{c_1, c_2, \ldots, c_n\}$. Given an hypothesis h_j defined as the concatenation of q with a candidate answer $c_j \in C$, the task of explanation reconstruction consists in selecting a set of atomic facts from a knowledge base $E_j = \{f_1, f_2, \ldots, f_n\}$ that support and justify h_j.

In this paper, we adopt a methodology that relies on the existence of a corpus of explanations. A corpus of explanations is composed of two distinct knowledge sources:

- A primary knowledge base, *Facts KB* (F_{kb}), defined as a collection of sentences $F_{kb} = \{f_1, f_2, \ldots, f_n\}$ encoding the general world knowledge necessary to answer and explain science questions. A fundamental and desirable characteristic of F_{kb} is *reusability* – i.e. each of its facts f_i can be potentially reused to compose explanations for multiple questions
- A secondary knowledge base, *Explanation KB* (E_{kb}), consisting of a set of tuples $E_{kb} = \{(h_1, E_1), (h_2, E_2), \ldots, (h_m, E_m)\}$, each of them connecting a true hypothesis h_j to its corresponding explanation $E_j = \{f_1, f_2, \ldots, f_k\} \subseteq F_{kb}$. An explanation $E_j \in E_{kb}$ is therefore a composition of facts belonging to F_{kb}.

In this setting, the explanation reconstruction task for an unseen hypothesis h_j can be modelled as a ranking problem (Jansen and Ustalov, 2019). Specifically, given an hypothesis h_j the algorithm to solve the task is divided into three macro steps:

1. Computing an explanatory score $s_i = e(h_j, f_i)$ for each fact $f_i \in F_{kb}$ with respect to h_j
2. Producing an ordered set $Rank(h_j) = \{f_1, \ldots, f_k, f_{k+1}, \ldots, f_n \mid s_k \geq s_{k+1}\} \subseteq F_{kb}$
3. Selecting the top k elements belonging to $Rank(h_j)$ and interpreting them as an explanation for h_j; $E_j = topK(Rank(h_j))$.

3.1 Modelling Explanatory Relevance

We present an approach for modelling $e(h_j, f_i)$ that is guided by the following research hypotheses:

- **RH1**: Scientific explanations are composed of a set of concrete facts connected to the question, and a set of abstract statements expressing general scientific laws and regularities.
- **RH2**: Concrete facts tend to share key concepts with the question and can therefore be effectively ranked by IR techniques based on lexical relevance.
- **RH3**: General scientific statements tend to be abstract and therefore difficult to rank by means of shared concepts. However, due to explanatory unification, core scientific facts tend to be frequently reused across similar questions. We hypothesise that the explanatory power of a fact f_i for a given hypothesis h_j is proportional to the number of times f_i explains similar hypotheses.

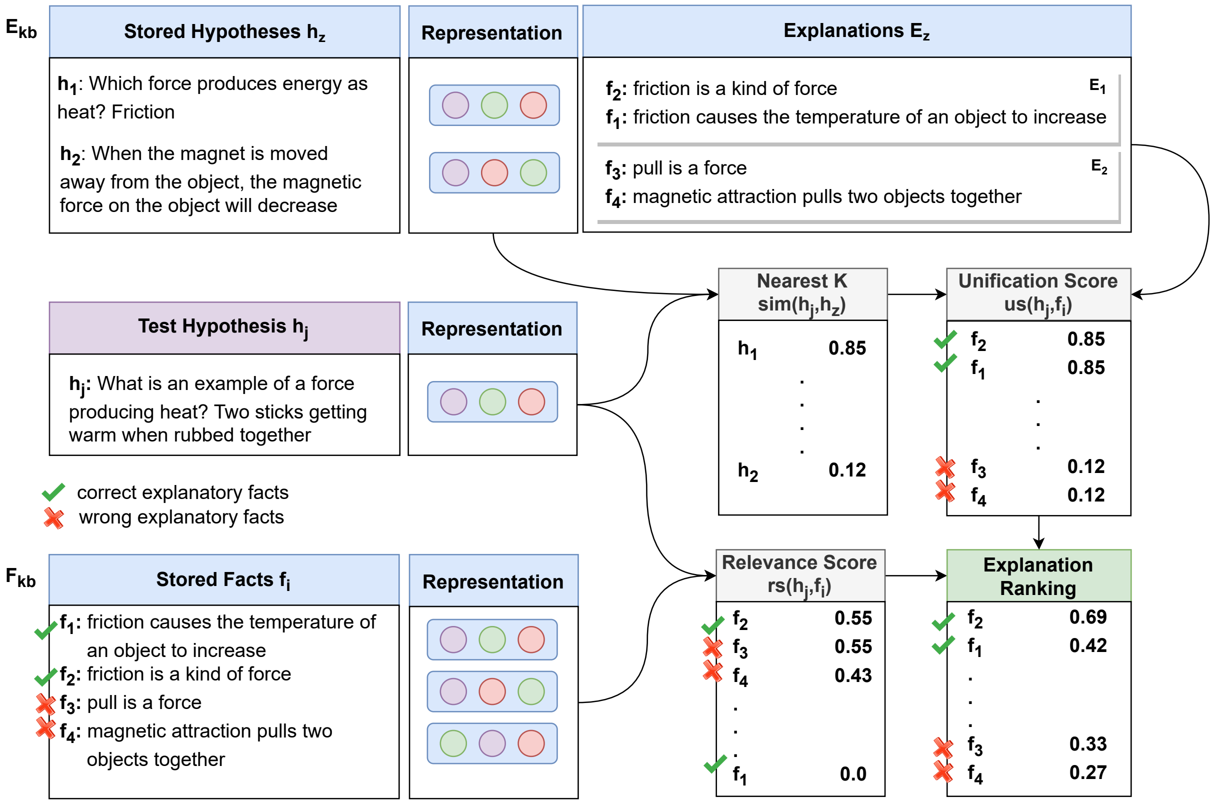

Figure 1: Overview of the Unification-based framework for explanation reconstruction.

To formalise these research hypotheses, we model the explanatory scoring function $e(h_j, f_i)$ as a combination of two components:

$$e(h_j, f_i) = \lambda_1 rs(h_j, f_i) + (1 - \lambda_1) us(h_j, f_i) \quad (1)$$

Here, $rs(h_j, f_i)$ represents a lexical Relevance Score (RS) assigned to $f_i \in F_{kb}$ with respect to h_j, while $us(h_j, f_i)$ represents the Unification Score (US) of f_i computed over E_{kb} as follows:

$$us(h_j, f_i) = \sum_{(h_z, E_z) \in kNN(h_j)} sim(h_j, h_z) in(f_i, E_z) \quad (2)$$

$$in(f_i, E_z) = \begin{cases} 1 & \text{if } f_i \in E_z \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

$kNN(h_j) = \{(h_1, E_1), \dots (h_k, E_k)\} \subseteq E_{kb}$ is the set of k-nearest neighbours of h_j belonging to E_{kb} retrieved according to a similarity function $sim(h_j, h_z)$. On the other hand, $in(f_i, E_z)$ verifies whether the fact f_i belongs to the explanation E_z for the hypothesis h_z.

In the formulation of Equation 2 we aim to capture two main aspects related to our research hypotheses:

1. The more a fact f_i is reused for explanations in E_{kb}, the higher its explanatory power and therefore its Unification Score;
2. The Unification Score of a fact f_i is proportional to the similarity between the hypotheses in E_{kb} that are explained by f_i and the unseen hypothesis (h_j) we want to explain.

Figure 1 shows a schematic representation of the Unification-based framework.

4 Empirical Evaluation

We carried out an empirical evaluation on the Worldtree corpus (Jansen et al., 2018), a subset of the ARC dataset (Clark et al., 2018) that includes explanations for science questions. The corpus provides an explanatory knowledge base (F_{kb} and E_{kb}) where each explanation in E_{kb} is represented as a set of lexically connected sentences describing how to arrive at the correct answer. The science questions in the Worldtree corpus are split into *training-set*, *dev-set*, and *test-set*. The gold explanations in the *training-set* are used to form the Explanation KB (E_{kb}), while the gold explanations in *dev* and *test* set are used for *evaluation purpose only*. The corpus groups the explanation sentences belonging to E_{kb} into three explanatory roles: *grounding*, *central* and *lexical glue*.

Consider the example in Figure 1. To support

Table 1: Results on test and dev set and comparison with state-of-the-art approaches. The column **trained** indicates whether the model requires an explicit training session on the explanation reconstruction task.

q and c_j the system has to retrieve the scientific facts describing how friction occurs and produces heat across objects. The corpus classifies these facts (f_3, f_4) as *central*. *Grounding* explanations like *"stick is a kind of object"* (f_1) link question and answer to the central explanations. *Lexical glues* such as *"to rub; to rub together means to mover against"* (f_2) are used to fill lexical gaps between sentences. Additionally, the corpus divides the facts belonging to F_{kb} into three inference categories: *retrieval type*, *inference supporting type*, and *complex inference type*. Taxonomic knowledge and properties such as *"stick is a kind of object"* (f_1) and *"friction is a kind of force"* (f_5) are classified as *retrieval type*. Facts describing actions, affordances, and requirements such as *"friction occurs when two object's surfaces move against each other"* (f_3) are grouped under the *inference supporting types*. Knowledge about causality, description of processes and if-then conditions such as *"friction causes the temperature of an object to increase"* (f_4) is classified as *complex inference*.

We implement Relevance and Unification Score adopting TF-IDF/BM25 vectors and cosine similarity function (i.e. $1 - cos(\vec{x}, \vec{y})$). Specifically, The RS model uses TF-IDF/BM25 to compute the relevance function for each fact in F_{kb} (i.e. $rs(h_j, f_i)$ function in Equation 1) while the US model adopts TF-IDF/BM25 to assign similarity scores to the hypotheses in E_{kb} (i.e. $sim(h_j, h_z)$ function in Equation 2). For reproducibility, the code is available at the following url: `https://github.com/ai-systems/unification_reconstruction_explanations`. Additional details can be found in the supplementary material.

4.1 Explanation Reconstruction

In line with the shared task (Jansen and Ustalov, 2019), the performances of the models are evaluated via Mean Average Precision (MAP) of the explanation ranking produced for a given question q_j and its correct answer a_j.

Table 1 illustrates the score achieved by our best implementation compared to state-of-the-art approaches in the literature. Previous approaches are grouped into four categories: *Transformers*, *Information Retrieval with re-ranking*, *One-step Information Retrieval*, and *Feature-based models*.

Transformers. This class of approaches employs the gold explanations in the corpus to train a BERT language model (Devlin et al., 2019). The best-performing system (Das et al., 2019) adopts a multi-step retrieval strategy. In the first step, it returns the top K sentences ranked by a TF-IDF model. In the second step, BERT is used to re-rank the paths composed of all the facts that are within 1-hop from the first retrieved set. Similarly, other approaches adopt BERT to re-rank each fact

Model	MAP			
	All	Central	Grounding	Lexical Glue
RS TF-IDF	42.8	43.4	25.4	8.2
RS BM25	46.1	46.6	23.3	10.7
US TF-IDF	21.6	16.9	22.0	13.4

US TF-IDF	17.6	12.8	19.5
US BM25	16.8	13.2	20.9
RS TF-IDF + US TF-IDF	38.3	33.2	30.2
RS TF-IDF + US BM25	40.0	35.6	33.3
RS BM25 + US TF-IDF	40.5	33.6	33.4
RS BM25 + US BM25	**40.6**	**38.3**	**36.8**

(c) Inference types.

Table 2: Detailed analysis of the performance (dev-set) by breaking down the gold explanatory facts according to their explanatory role (2.a), number of lexical overlaps with the question (2.b) and inference type (2.c).

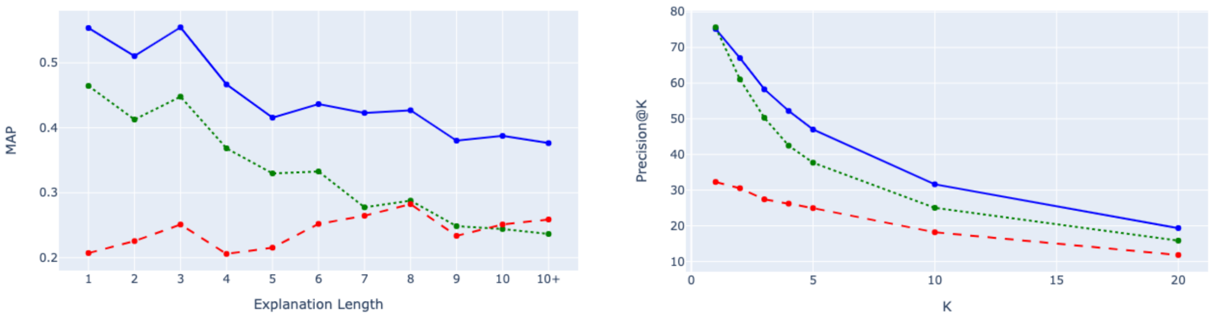
individually (Banerjee, 2019; Chia et al., 2019).

Although the best model achieves state-of-the-art results in explanation reconstruction, these approaches are computationally expensive, being limited by the application of a pre-filtering step to contain the space of candidate facts. Consequently, these systems do not scale with the size of the corpus. We estimated that the best performing model (Das et al., 2019) takes $\approx$ 10 hours to run on the whole test set (1240 questions) using 1 Tesla 16GB V100 GPU.

Comparatively, our model constructs explanations for all the questions in the test set in $\approx$ 30 seconds, without requiring the use of GPUs ($<$ 1 second per question). This feature makes the Unification-based Reconstruction suitable for large corpora and downstream question answering models (as shown in Section 4.4). Moreover, our approach does not require any explicit training session on the explanation regeneration task, with significantly reduced number of parameters to tune. Along with scalability, the proposed approach achieves nearly state-of-the-art results (50.8/54.5 MAP). Although we observe lower performance when compared to the best-performing approach (-5.5/-4.0 MAP), the joint RS + US model outperforms two BERT-based models (Chia et al., 2019; Banerjee, 2019) on both test and dev set by 3.1/3.6 and 9.5/12.2 MAP respectively.

Information Retrieval with re-ranking. Chia et al. (2019) describe a multi-step, iterative re-ranking model based on BM25. The first step consists in retrieving the explanation sentence that is most similar to the question adopting BM25 vectors. During the second step, the BM25 vector of the question is updated by aggregating it with the retrieved explanation sentence vector through a `max` operation. The first and second steps are repeated for K times. Although this approach uses scalable IR techniques, it relies on a multi-step retrieval strategy. Besides, the RS + US model outperforms this approach on both test and dev set by 5.0/4.8 MAP respectively.

One-step Information Retrieval. We compare the RS + US model with two IR baselines. The baselines adopt TF-IDF and BM25 to compute the Relevance Score only – i.e. the $us(q, c_j, f_i)$ term in Equation 1 is set to 0 for each fact $f_i \in F_{kb}$. In line with previous IR literature (Robertson et al., 2009), BM25 leads to better performance than TF-IDF. While these approaches share similar characteristics, the combined RS + US model outperforms both RS BM25 and RS TF-IDF on test and dev-set by 7.8/8.4 and 11.4/11.7 MAP. Moreover, the joint RS + US model improves the performance of the US model alone by 27.9/32.6 MAP. These results outline the complementary aspects of Relevance and Unification Score. We provide a detailed anal-



(a) MAP vs Explanation length.

(b) Precision@K.

Figure 2: Impact of the Unification Score on semantic drift (3.a) and precision (3.b). RS + US (Blue Straight), RS (Green Dotted), US (Red Dashed).

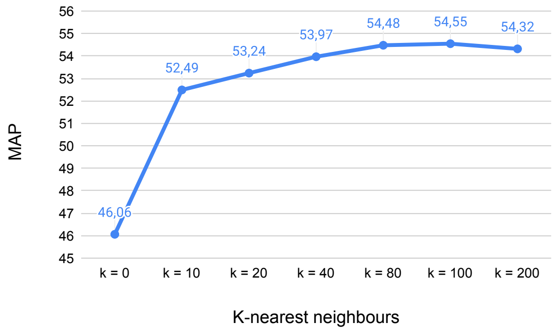


Figure 3: Impact of the k-NN clustering on the final MAP score. The value k represents the number of similar hypotheses considered for the Unification Score.

ysis by performing an ablation study on the dev-set (Section 4.2).

Feature-based models. D'Souza et al. (2019) propose an approach based on a learning-to-rank paradigm. The model extracts a set of features based on overlaps and coherence metrics between questions and explanation sentences. These features are then given in input to a SVM ranker module. While this approach scales to the whole corpus without requiring any pre-filtering step, it is significantly outperformed by the RS + US model on both test and dev set by 16.7/17.4 MAP respectively.

4.2 Explanation Analysis

We present an ablation study with the aim of understanding the contribution of each sub-component to the general performance of the joint RS + US model (see Table 1). To this end, a detailed evaluation on the development set of the Worldtree corpus is carried out, analysing the performance in reconstructing explanations of different types and complexity. We compare the joint model (RS + US) with each individual sub-component (RS and US alone). In addition, a set of qualitative examples are analysed to provide additional insights on the complementary aspects captured by Relevance and Unification Score.

Explanatory categories. Given a question q_j and its correct answer a_j, we classify a fact f_i belonging to the gold explanation E_j according to its explanatory role (*central, grounding, lexical glue*) and inference type (*retrieval, inference-supporting and complex inference*). In addition, three new categories are derived from the number of overlaps between f_i and the concatenation of q_j with a_j (h_j) computed by considering nouns, verbs, adjectives and adverbs (1+ overlaps, 1 overlap, 0 overlaps).

Table 2 reports the MAP score for each of the described categories. Overall, the best results are obtained by the BM25 implementation of the joint model (RS BM25 + US BM25) with a MAP score of 54.5. Specifically, RS BM25 + US BM25 achieves a significant improvement over both RS BM25 (+8.5 MAP) and US BM25 (+32.6 MAP) baselines. Regarding the explanatory roles (Table 2a), the joint TF-IDF implementation shows the best performance in the reconstruction of *grounding* explanations (32.7 MAP). On the other hand, a significant improvement over the RS baseline is obtained by RS BM25 + US BM25 on both *lexical* glues and *central* explanation sentences (+6.0 and +5.6 MAP over RS BM25).

Regarding the lexical overlaps categories (Table 2b), we observe a steady improvement for all the combined RS + US models over the respective RS baselines. Notably, the US models achieve the best performance on the 0 overlaps category, which includes the most challenging facts for the RS models. The improved ability to rank abstract

Question	Answer	Explanation Fact	Most Similar Hypotheses in E_{kb}	RS	RS + US
If you bounce a rubber ball on the floor it goes up and then comes down. What **causes** the ball to come down?	**gravity**	**gravity**; gravitational force **causes** objects that have mass; substances to be pulled down; to fall on a planet	(1) A ball is tossed up in the air and it comes back down. The ball comes back down because of - gravity (2) A student drops a ball. Which force causes the ball to fall to the ground? - gravity	#36	#2 (↑34)
Which **animals** would most likely be helped by flood in a coastal area?	alligators	as water increases in an environment, the population of aquatic **animals** will increase	(1) Where would animals and plants be most affected by a flood? - low areas (2) Which change would most likely increase the number of salamanders? - flood	#198	#57 (↑141)
What is an example of a force producing heat?	two sticks getting warm when rubbed together	friction causes the temperature of an object to increase	(1) Rubbing sandpaper on a piece of wood produces what two types of energy? - sound and heat (2) Which force produces energy as heat? - friction	#1472	#21 (↑1451)

Table 3: Impact of the Unification Score on the ranking of scientific facts with increasing complexity.

explanatory facts contributes to better performance for the joint models (RS + US) in the reconstruction of explanations that share few terms with question and answer (*1 Overlap* and *0 Overlaps* categories). This characteristic leads to an improvement of 4.8 and 4.1 MAP for the RS BM25 + US BM25 model over the RS BM25 baseline.

Similar results are achieved on the inference types categories (Table 2c). Crucially, the largest improvement is observed for *complex inference* sentences where RS BM25 + US BM25 outperforms RS BM25 by 12.0 MAP, confirming the decisive contribution of the Unification Score to the ranking of complex scientific facts.

Semantic drift. Science questions in the Worldtree corpus require an average of six facts in their explanations (Jansen et al., 2016). Long explanations typically include sentences that share few terms with question and answer, increasing the probability of semantic drift. Therefore, to test the impact of the Unification Score on the robustness of the model, we measure the performance in the reconstruction of many-hops explanations.

Figure 2a shows the change in MAP score for the RS + US, RS and US models (BM25) with increasing explanation length. The fast drop in performance for the Relevance Score reflects the complexity of the task. This drop occurs because the RS model is not able to rank abstract explanatory facts. Conversely, the US model exhibits increasing performance, with a trend that is inverse. Short explanations, indeed, tend to include question-specific facts with low explanatory power. On the other hand, the longer the explanation, the higher the number of core scientific facts. Therefore, the decrease in MAP observed for the RS model is compensated by the Unification Score, since core scientific facts tend to form unification patterns across similar questions. This results demonstrate that the Unification Score has a crucial role in alleviating the semantic drift for the joint model (RS + US), resulting in a larger improvement on many-hops explanations (6+ facts).

Similarly, Figure 2b illustrates the Precision@K. As shown in the graph, the drop in precision for the US model exhibits the slowest degradation. Similarly to what observed for many-hops explanations, the US score contributes to the robustness of the RS + US model, making it able to reconstruct more precise explanations. As discussed in section 4.4, this feature has a positive impact on question answering.

k-NN clustering. We investigate the impact of the k-NN clustering on the explanation reconstruction task. Figure 3 shows the MAP score obtained by the joint RS + US model (BM25) with different numbers k of nearest hypotheses considered for the Unification Score. The graph highlights the improvement in MAP achieved with increasing values of k. Specifically, we observe that the best MAP is obtained with $k = 100$. These results confirm that the explanatory power can be effectively estimated using clusters of similar hypotheses, and that the unification-based mechanism has a crucial role in improving the performance of the relevance model.

4.3 Qualitative analysis.

To provide additional insights on the complementary aspects of Unification and Relevance Score, we present a set of qualitative examples from the dev-set. Table 3 illustrates the ranking assigned by RS and RS + US models to scientific sentences of increasing complexity. The words in **bold** indicate lexical overlaps between question, answer and explanation sentence. In the first example, the sentence *"gravity; gravitational force causes objects* *that have mass; substances to be pulled down; to fall on a planet"* shares key terms with question and candidate answer and is therefore relatively easy to rank for the RS model (#36). Nevertheless, the RS + US model is able to improve the ranking by 34 positions (#2), as the gravitational law represents a scientific pattern with high explanatory unification, frequently reused across similar questions. The impact of the Unification Score is more evident when considering abstract explanatory facts. Coming back to our original example (i.e. *"What is an example of a force producing heat?"*), the fact *"friction causes the temperature of an object to increase"* has no significant overlaps with question and answer. Thus, the RS model ranks the gold explanation sentence in a low position (#1472). However, the Unification Score (US) is able to capture the explanatory power of the fact from similar hypotheses in E_{kb}, pushing the RS + US ranking up to position #21 (+1451).

4.4 Question Answering

To understand whether the constructed explanations can support question answering, we compare the performance of BERT for multiple-choice QA (Devlin et al., 2019) without explanations with the performance of BERT provided with the top K explanation sentences retrieved by RS and RS + US models (BM25). BERT without explanations operates on question and candidate answer only. On the other hand, BERT with explanation receives the following input: the question (q), a candidate answer (c_i) and the explanation for c_i (E_i). In this setting, the model is fine-tuned for binary classification ($bert_b$) to predict a set of probability scores $P = \{p_1,\ p_2,\ ...,\ p_n\}$ for each candidate answer in $C = \{c1,\ c_2,\ ...,\ c_n\}$:

$$bert_b(\texttt{[CLS]} \mid\mid q \mid\mid c_i \mid\mid \texttt{[SEP]} \mid\mid E_i) = p_i \quad (4)$$

The binary classifier operates on the final hidden state corresponding to the `[CLS]` token. To answer the question q, the model selects the candidate answer c_a such that $a = \text{argmax}_i\, p_i$.

Table 4 reports the accuracy with and without explanations on the Worldtree *test-set* for *easy* and *challenge* questions (Clark et al., 2018). Notably, a significant improvement in accuracy can be observed when BERT is provided with explanations retrieved by the reconstruction modules (+9.84% accuracy with RS BM25 + US BM25 model). The improvement is consistent on the *easy* split (+6.92%) and particularly significant for *challenge* questions (+15.69%). Overall, we observe a correlation between more precise explanations and accuracy in answer prediction, with BERT + RS being outperformed by BERT + RS + US for each value of K. The decrease in accuracy occurring with increasing values of K is coherent with the drop in precision for the models observed in Figure 2b. Moreover, steadier results adopting the RS + US model suggest a positive contribution from abstract explanatory facts. Additional investigation of this aspect will be a focus for future work.

Model	**Accuracy**		
	Easy	Challenge	Overall
BERT (no explanation)	48.54	26.28	41.78
BERT + RS (K = 3)	53.20	40.97	49.39
BERT + RS (K = 5)	54.36	38.14	49.31
BERT + RS (K = 10)	32.71	29.63	31.75
BERT + RS + US (K = 3)	**55.46**	**41.97**	**51.62**
BERT + RS + US (K = 5)	54.48	39.43	50.12
BERT + RS + US (K = 10)	48.66	37.37	45.14

Table 4: Performance of BERT on question answering (test-set) with and without the explanation reconstruction models.

5 Conclusion

This paper proposed a novel framework for multi-hop explanation reconstruction based on *explanatory unification*. An extensive evaluation on the Worldtree corpus led to the following conclusions: (1) The approach is competitive with state-of-the-art Transformers, yet being significantly faster and inherently scalable; (2) The unification-based mechanism supports the construction of complex and many hops explanations; (3) The constructed explanations improves the accuracy of BERT for question answering by up to 10% overall. As a future work, we plan to extend the framework adopting neural embeddings for sentence representation.

A Supplementary Material

A.1 Hyperparameters tuning

The hyperparameters of the model have been tuned manually. The criteria for the optimisation is the maximisation of the MAP score on the dev-set. Here, we report the values adopted for the experiments described in the paper.

The Unification-based Reconstruction adopts two hyperparameters. Specifically, λ_1 is the weight assigned to the relevance score in equation 1, while k is the number of similar hypotheses to consider for the calculation of the unification score (equation 2). The values adopted for these parameters are as follows:

1. $\lambda_1 = 0.83$ ($1 - \lambda_1 = 0.17$)
2. $k = 100$

A.2 BERT model

For question answering we adopt a BERT$_{BASE}$ model. The model is implemented using PyTorch (`https://pytorch.org/`) and fine-tuned using 4 Tesla 16GB V100 GPUs for 10 epochs in total with batch size 32 and seed 42. The hyperparameters adopted for BERT are as follows:

- gradient_accumulation_steps = 1
- learning_rate = 5e-5
- weight_decay = 0.0
- adam_epsilon = 1e-8
- warmup_steps = 0
- max_grad_norm = 1.0

A.3 Data and code

The experiments are carried out on the TextGraphs 2019 version (`https://github.com/umanlp/tg2019task`) of the Worldtree corpus. The full dataset can be downloaded at the following URL: `http://cognitiveai.org/dist/worldtree_corpus_textgraphs2019sharedtask_withgraphvis.zip`.

The code to reproduce the experiments described in the paper is available at the following URL: `https://github.com/ai-systems/unification_reconstruction_explanations`

Dictionary-based Debiasing of Pre-trained Word Embeddings

Masahiro Kaneko

Abstract

Word embeddings trained on large corpora have shown to encode high levels of unfair discriminatory gender, racial, religious and ethnic biases. In contrast, human-written dictionaries describe the meanings of words in a concise, objective and an unbiased manner. We propose a method for debiasing pre-trained word embeddings using dictionaries, without requiring access to the original training resources or any knowledge regarding the word embedding algorithms used. Unlike prior work, our proposed method does not require the types of biases to be pre-defined in the form of word lists, and learns the constraints that must be satisfied by unbiased word embeddings automatically from dictionary definitions of the words. Specifically, we learn an encoder to generate a debiased version of an input word embedding such that it (a) retains the semantics of the pre-trained word embeddings, (b) agrees with the unbiased definition of the word according to the dictionary, and (c) remains orthogonal to the vector space spanned by any biased basis vectors in the pre-trained word embedding space. Experimental results on standard benchmark datasets show that the proposed method can accurately remove unfair biases encoded in pre-trained word embeddings, while preserving useful semantics.

1 Introduction

Despite pre-trained word embeddings are useful due to their low dimensionality, memory and compute efficiency, they have shown to encode not only the semantics of words but also unfair discriminatory biases such as gender, racial or religious biases (Bolukbasi et al., 2016; Zhao et al., 2018a; Rudinger et al., 2018; Zhao et al., 2018b; Elazar and Goldberg, 2018; Kaneko and Bollegala, 2019). On the other hand, human-written dictionaries act as an impartial, objective and unbiased source of word meaning. Although methods that learn word embeddings by purely using dictionaries have been proposed (Tissier et al., 2017), they have coverage and data sparseness related issues because precompiled dictionaries do not capture the meanings of neologisms or provide numerous contexts as in a corpus. Consequently, prior work has shown that word embeddings learnt from large text corpora to outperform those created from dictionaries in downstream NLP tasks (Alsuhaibani et al., 2019; Bollegala et al., 2016).

We must overcome several challenges when using dictionaries to debias pre-trained word embeddings. First, not all words in the embeddings will appear in the given dictionary. Dictionaries often have limited coverage and will not cover neologisms, orthographic variants of words etc. that are likely to appear in large corpora. A lexicalised debiasing method would generalise poorly to the words not in the dictionary. Second, it is not known apriori what biases are hidden inside a set of pre-trained word embedding vectors. Depending on the source of documents used for training the embeddings, different types of biases will be learnt and amplified by different word embedding learning algorithms to different degrees (Zhao et al., 2017).

Prior work on debiasing required that the biases to be pre-defined (Kaneko and Bollegala, 2019). For example, Hard-Debias (HD; Bolukbasi et al., 2016) and Gender Neutral Glove (GN-GloVe; Zhao et al., 2018b) require lists of *male* and *female* pronouns for defining the *gender* direction. However, gender bias is only one of the many biases that exist in pre-trained word embeddings. It is inconvenient to prepare lists of words covering all different types of biases we must remove from pre-trained word embeddings. Moreover, such pre-

---

compiled word lists are likely to be incomplete and inadequately cover some biases. Indeed, Gonen and Goldberg (2019) showed empirical evidence that such debiasing methods do not remove all discriminative biases from word embeddings. Unfair biases have adversely affected several NLP tasks such as machine translation (Vanmassenhove et al., 2018) and language generation (Sheng et al., 2019). Racial biases have also been shown to affect criminal prosecutions (Manzini et al., 2019) and career adverts (Lambrecht and Tucker, 2016). These findings show the difficulty of defining different biases using pre-compiled lists of words, which is a requirement in previously proposed debiasing methods for static word embeddings.

We propose a method that uses a dictionary as a source of bias-free definitions of words for debiasing pre-trained word embeddings[1]. Specifically, we learn an encoder that filters-out biases from the input embeddings. The debiased embeddings are required to simultaneously satisfy three criteria: (a) must preserve all non-discriminatory information in the pre-trained embeddings (*semantic preservation*), (b) must be similar to the dictionary definition of the words (*dictionary agreement*), and (c) must be orthogonal to the subspace spanned by the basis vectors in the pre-trained word embedding space that corresponds to discriminatory biases (*bias orthogonality*). We implement the semantic preservation and dictionary agreement using two decoders, whereas the bias orthogonality is enforced by a parameter-free projection. The debiasing encoder and the decoders are learnt end-to-end by a joint optimisation method. Our proposed method is agnostic to the details of the algorithms used to learn the input word embeddings. Moreover, unlike counterfactual data augmentation methods for debiasing (Zmigrod et al., 2019; Hall Maudslay et al., 2019), we do *not* require access to the original training resources used for learning the input word embeddings.

Our proposed method overcomes the above-described challenges as follows. First, instead of learning a lexicalised debiasing model, we operate on the word embedding space when learning the encoder. Therefore, we can use the words that are in the intersection of the vocabularies of the pre-trained word embeddings and the dictionary to learn the encoder, enabling us to generalise to the words not in the dictionary. Second, we do *not* require pre-compiled word lists specifying the biases. The dictionary acts as a clean, unbiased source of word meaning that can be considered as *positive* examples of debiased meanings. In contrast to the existing debiasing methods that require us to pre-define *what to remove*, the proposed method can be seen as using the dictionary as a guideline for *what to retain* during debiasing.

We evaluate the proposed method using four standard benchmark datasets for evaluating the biases in word embeddings: Word Embedding Association Test (WEAT; Caliskan et al., 2017), Word Association Test (WAT; Du et al., 2019), SemBias (Zhao et al., 2018b) and WinoBias (Zhao et al., 2018a). Our experimental results show that the proposed debiasing method accurately removes unfair biases from three widely used pre-trained embeddings: Word2Vec (Mikolov et al., 2013b), GloVe (Pennington et al., 2014) and fastText (Bojanowski et al., 2017). Moreover, our evaluations on semantic similarity and word analogy benchmarks show that the proposed debiasing method preserves useful semantic information in word embeddings, while removing unfair biases.

2 Related Work

Dictionaries have been popularly used for learning word embeddings (Budanitsky and Hirst, 2006, 2001; Jiang and Conrath, 1997). Methods that use both dictionaries (or lexicons) and corpora to jointly learn word embeddings (Tissier et al., 2017; Alsuhaibani et al., 2019; Bollegala et al., 2016) or post-process (Glavaš and Vulić, 2018; Faruqui et al., 2015) have also been proposed. However, learning embeddings from dictionaries alone results in coverage and data sparseness issues (Bollegala et al., 2016) and does not guarantee bias-free embeddings (Lauscher and Glavas, 2019). To the best of our knowledge, we are the first to use dictionaries for debiasing pre-trained word embeddings.

Bolukbasi et al. (2016) proposed a post-processing approach that projects gender-neutral words into a subspace, which is orthogonal to the gender dimension defined by a list of gender-definitional words. They refer to words associated with gender (e.g., *she*, *actor*) as gender-definitional words, and the remainder gender-neutral. They proposed a *hard-debiasing* method where the gender direction is computed as the vector difference between the embeddings of the correspond-

---

[1] Code and debiased embeddings: `https://github.com/kanekomasahiro/dict-debias`

ing gender-definitional words, and a *soft-debiasing* method, which balances the objective of preserving the inner-products between the original word embeddings, while projecting the word embeddings into a subspace orthogonal to the gender definitional words. Both hard and soft debiasing methods ignore gender-definitional words during the subsequent debiasing process, and focus only on words that are *not* predicted as gender-definitional by the classifier. Therefore, if the classifier erroneously predicts a stereotypical word as a gender-definitional word, it would not get debiased.

Zhao et al. (2018b) modified the GloVe (Pennington et al., 2014) objective to learn gender-neutral word embeddings (GN-GloVe) from a given corpus. They maximise the squared ℓ_2 distance between gender-related sub-vectors, while simultaneously minimising the GloVe objective. Unlike, the above-mentioned methods, Kaneko and Bollegala (2019) proposed a post-processing method to preserve gender-related information with autoencoder (Kaneko and Bollegala, 2020), while removing discriminatory biases from stereotypical cases (GP-GloVe). However, all prior debiasing methods require us to pre-define the biases in the form of explicit word lists containing gender and stereotypical word associations. In contrast we use dictionaries as a source of bias-free semantic definitions of words and do not require pre-defining the biases to be removed. Although we focus on static word embeddings in this paper, unfair biases have been found in contextualised word embeddings as well (Zhao et al., 2019; Vig, 2019; Bordia and Bowman, 2019; May et al., 2019).

Adversarial learning methods (Xie et al., 2017; Elazar and Goldberg, 2018; Li et al., 2018) for debiasing first encode the inputs and then two classifiers are jointly trained – one predicting the target task (for which we must ensure high prediction accuracy) and the other protected attributes (that must not be easily predictable). However, Elazar and Goldberg (2018) showed that although it is possible to obtain chance-level development-set accuracy for the protected attributes during training, a post-hoc classifier trained on the encoded inputs can still manage to reach substantially high accuracies for the protected attributes. They conclude that adversarial learning alone does not guarantee invariant representations for the protected attributes. Ravfogel et al. (2020) found that iteratively projecting word embeddings to the null space of the gender direction to further improve the debiasing performance.

To evaluate biases, Caliskan et al. (2017) proposed the Word Embedding Association Test (WEAT) inspired by the Implicit Association Test (IAT; Greenwald et al., 1998). Ethayarajh et al. (2019) showed that WEAT to be systematically overestimating biases and proposed a correction. The ability to correctly answer gender-related word analogies (Zhao et al., 2018b) and resolve gender-related coreferences (Zhao et al., 2018a; Rudinger et al., 2018) have been used as extrinsic tasks for evaluating the bias in word embeddings. We describe these evaluation benchmarks later in § 4.3.

3 Dictionary-based Debiasing

Let us denote the n-dimensional pre-trained word embedding of a word w by $\boldsymbol{w} \in \mathbb{R}^n$ trained on some resource $\mathcal{C}$ such as a text corpus. Moreover, let us assume that we are given a dictionary $\mathcal{D}$ containing the definition, $s(w)$ of w. If the pre-trained embeddings distinguish among the different senses of w, then we can use the gloss for the corresponding sense of w in the dictionary as $s(w)$. However, the majority of word embedding learning methods do not produce sense-specific word embeddings. In this case, we can either use all glosses for w in $\mathcal{D}$ by concatenating or select the gloss for the dominant (most frequent) sense of w[2]. Without any loss of generality, in the remainder of this paper, we will use $s(w)$ to collectively denote a gloss selected by any one of the above-mentioned criteria with or without considering the word senses (in § 5.3, we evaluate the effect of using all vs. dominant gloss).

Next, we define the objective functions optimised by the proposed method for the purpose of learning unbiased word embeddings. Given, $\boldsymbol{w}$, we model the debiasing process as the task of learning an encoder, $E(\boldsymbol{w}; \boldsymbol{\theta}_e)$ that returns an $m (\leq n)$-dimensional debiased version of $\boldsymbol{w}$. In the case where we would like to preserve the dimensionality of the input embeddings, we can set $m = n$, or $m < n$ to further compress the debiased embeddings.

Because the pre-trained embeddings encode rich semantic information from a large text corpora, often far exceeding the meanings covered in the

---

[2] Prior work on debiasing static word embeddings do not use contextual information that is required for determining word senses. Therefore, for comparability reasons we do neither.

dictionary, we must preserve this semantic information as much as possible during the debiasing process. We refer to this constraint as *semantic preservation*. Semantic preservation is likely to lead to good performance in downstream NLP applications that use pre-trained word embeddings. For this purpose, we decode the encoded version of $\boldsymbol{w}$ using a decoder, D_c, parametrised by $\boldsymbol{\theta}_c$ and define J_c to be the reconstruction loss given by (1).

$$J_c(w) = ||\boldsymbol{w} - D_c(E(\boldsymbol{w}; \boldsymbol{\theta}_e); \boldsymbol{\theta}_c)||_2^2 \qquad (1)$$

Following our assumption that the dictionary definition, $s(w)$, of w is a concise and unbiased description of the meaning of w, we would like to ensure that the encoded version of $\boldsymbol{w}$ is similar to $s(w)$. We refer to this constraint as *dictionary agreement*. To formalise dictionary agreement empirically, we first represent $s(w)$ by a sentence embedding vector $\boldsymbol{s}(w) \in \mathbb{R}^n$. Different sentence embedding methods can be used for this purpose such as convolutional neural networks (Kim, 2014), recurrent neural networks (Peters et al., 2018) or transformers (Devlin et al., 2019). For the simplicity, we use the smoothed inverse frequency (SIF; Arora et al., 2017) for creating $\boldsymbol{s}(w)$ in this paper. SIF computes the embedding of a sentence as the weighted average of the pre-trained word embeddings of the words in the sentence, where the weights are computed as the inverse unigram probability. Next, the first principal component vector of the sentence embeddings are removed. The dimensionality of the sentence embeddings created using SIF is equal to that of the pre-trained word embeddings used. Therefore, in our case we have both $\boldsymbol{w}, \boldsymbol{s}(w) \in \mathbb{R}^n$.

We decode the debiased embedding $E(\boldsymbol{w}; \boldsymbol{\theta}_e)$ of w using a decoder D_d, parametrised by $\boldsymbol{\theta}_d$ and compute the squared ℓ_2 distance between it and $\boldsymbol{s}(w)$ to define an objective J_d given by (2).

$$J_d(w) = ||\boldsymbol{s}(w) - D_d(E(\boldsymbol{w}; \boldsymbol{\theta}_e); \boldsymbol{\theta}_d)||_2^2 \qquad (2)$$

Recalling that our goal is to remove unfair biases from pre-trained word embeddings and we assume dictionary definitions to be free of such biases, we define an objective function that explicitly models this requirement. We refer to this requirement as the *bias orthogonality* of the debiased embeddings. For this purpose, we first project the pre-trained word embedding $\boldsymbol{w}$ of a word w into a subspace that is orthogonal to the dictionary definition vector $\boldsymbol{s}(w)$. Let us denote this projection by $\phi(\boldsymbol{w}, \boldsymbol{s}(w)) \in \mathbb{R}^n$. We require that the debiased word embedding, $E(\boldsymbol{w}; \boldsymbol{\theta}_e)$, must be orthogonal to $\phi(\boldsymbol{w}, \boldsymbol{s}(w))$, and formalise this as the minimisation of the squared inner-product given in (3).

$$J_a(w) = \left(E(\phi(\boldsymbol{w}, \boldsymbol{s}(w)); \boldsymbol{\theta}_e)^\top E(\boldsymbol{w}; \boldsymbol{\theta}_e)\right)^2 \quad (3)$$

Note that because $\phi(\boldsymbol{w}, \boldsymbol{s}(w))$ lives in the space spanned by the original (prior to encoding) vector space, we must first encode it using E before considering the orthogonality requirement.

To derive $\phi(\boldsymbol{w}, \boldsymbol{s}(w))$, let us assume the n-dimensional basis vectors in the R^n vector space spanned by the pre-trained word embeddings to be $\boldsymbol{b}_1, \boldsymbol{b}_2, \ldots, \boldsymbol{b}_n$. Moreover, without loss of generality, let the subspace spanned by the subset of the first $k(< n)$ basis vectors $\boldsymbol{b}_1, \boldsymbol{b}_2, \ldots, \boldsymbol{b}_k$ to be $\mathcal{B} \subseteq \mathbb{R}^n$. The projection $\boldsymbol{v}_{\mathcal{B}}$ of a vector $\boldsymbol{v} \in \mathbb{R}^n$ onto $\mathcal{B}$ can be expressed using the basis vectors as in (4).

$$\boldsymbol{v}_{\mathcal{B}} = \sum_{j=1}^{k} (\boldsymbol{v}^\top \boldsymbol{b}_j)\boldsymbol{b}_j \qquad (4)$$

To show that $\boldsymbol{v} - \boldsymbol{v}_{\mathcal{B}}$ is orthogonal to $\boldsymbol{v}_{\mathcal{B}}$ for any $\boldsymbol{v} \in \mathcal{B}$, let us express $\boldsymbol{v} - \boldsymbol{v}_{\mathcal{B}}$ using the basis vectors as given in (5).

$$\begin{aligned}\boldsymbol{v} - \boldsymbol{v}_{\mathcal{B}} &= \sum_{i=1}^{n} (\boldsymbol{v}^\top \boldsymbol{b}_i)\boldsymbol{b}_i - \sum_{j=1}^{k} (\boldsymbol{v}^\top \boldsymbol{b}_j)\boldsymbol{b}_j \\ &= \sum_{i=k+1}^{n} (\boldsymbol{v}^\top \boldsymbol{b}_i)\boldsymbol{b}_i \qquad (5)\end{aligned}$$

We see that there are no basis vectors in common between the summations in (4) and (5). Therefore, ${\boldsymbol{v}_{\mathcal{B}}}^\top(\boldsymbol{v} - \boldsymbol{v}_{\mathcal{B}}) = 0$ for $\forall \boldsymbol{v} \in \mathcal{B}$.

Considering that $\boldsymbol{s}(w)$ defines a direction that does not contain any unfair biases, we can compute the vector rejection of $\boldsymbol{w}$ on $\boldsymbol{s}(w)$ following this result. Specifically, we subtract the projection of $\boldsymbol{w}$ along the unit vector defining the direction of $\boldsymbol{s}(w)$ to compute ϕ as in (6).

$$\phi(\boldsymbol{w}, \boldsymbol{s}(w)) = \boldsymbol{w} - \boldsymbol{w}^\top \boldsymbol{s}(w) \frac{\boldsymbol{s}(w)}{||\boldsymbol{s}(w)||} \qquad (6)$$

We consider the linearly-weighted sum of the above-defined three objective functions as the total objective function as given in (7).

$$J(w) = \alpha J_c(w) + \beta J_d(w) + \gamma J_a(w) \qquad (7)$$

Here, $\alpha, \beta, \gamma \geq 0$ are scalar coefficients satisfying $\alpha + \beta + \gamma = 1$. Later, in § 4 we experimentally determine the values of α, β and γ using a development dataset.

4 Experiments

4.1 Word Embeddings

In our experiments, we use the following publicly available pre-trained word embeddings: **Word2Vec**[3] (300-dimensional embeddings for ca. 3M words learned from Google News corpus (Mikolov et al., 2013a)), **GloVe**[4] (300-dimensional embeddings for ca. 2.1M words learned from the Common Crawl (Pennington et al., 2014)), and **fastText**[5] (300-dimensional embeddings for ca. 1M words learned from Wikipedia 2017, UMBC webbase corpus and statmt.org news (Bojanowski et al., 2017)).

As the dictionary definitions, we used the glosses in the WordNet (Fellbaum, 1998), which has been popularly used to learn word embeddings in prior work (Tissier et al., 2017; Bosc and Vincent, 2018; Washio et al., 2019). However, we note that our proposed method does not depend on any WordNet-specific features, thus in principle can be applied to any dictionary containing definition sentences. Words that do not appear in the vocabulary of the pre-trained embeddings are ignored when computing $\boldsymbol{s}(w)$ for the headwords w in the dictionary. Therefore, if all the words in a dictionary definition are ignored, then the we remove the corresponding headwords from training. Consequently, we are left with 54,528, 64,779 and 58,015 words respectively for **Word2Vec**, **GloVe** and **fastText** embeddings in the training dataset. We randomly sampled 1,000 words from this dataset and held-out as a development set for the purpose of tuning various hyperparameters in the proposed method.

E, D_c and D_d are implemented as single-layer feed forward neural networks with a hyperbolic tangent activation at the outputs. It is known that pre-training is effective when using autoencoders E and D_c for debiasing (Kaneko and Bollegala, 2019). Therefore, we randomly select 5000 words from each pre-trained word embedding set and pre-train the autoencoders on those words with a mini-batch of size 512. In pre-training, the model with the lowest loss according to (1) in the development set for pre-traininng is selected.

4.2 Hyperparameters

During optimisation, we used dropout (Srivastava et al., 2014) with probability 0.05 to $\boldsymbol{w}$ and $E(w)$. We used Adam (Kingma and Ba, 2015) with initial learning rate set to 0.0002 as the optimiser to find the parameters $\boldsymbol{\theta}_e, \boldsymbol{\theta}_c$, and $\boldsymbol{\theta}_d$ and a mini-batch size of 4. The optimal values of all hyperparameters are found by minimising the total loss over the development dataset following a Monte-Carlo search. We found these optimal hyperparameter values of $\alpha = 0.99998$, $\beta = 0.00001$ and $\gamma = 0.00001$. Note that the scale of different losses are different and the absolute values of hyperparameters do *not* indicate the significance of a component loss. For example, if we rescale all losses to the same range then we have $L_c = 0.005\alpha$, $L_d = 0.269\beta$ and $L_a = 21.1999\gamma$. Therefore, debiasing (L_d) and orthogonalisation (L_a) contributions are significant.

We utilized a GeForce GTX 1080 Ti. The debiasing is completed in less than an hour because our method is only a fine-tuning technique. The parameter size of our debiasing model is 270,900.

4.3 Evaluation Datasets

We use the following datasets to evaluate the degree of the biases in word embeddings.

WEAT: Word Embedding Association Test (WEAT; Caliskan et al., 2017), quantifies various biases (e.g. gender, race and age) using semantic similarities between word embeddings. It compares two same size sets of *target* words $\mathcal{X}$ and $\mathcal{Y}$ (e.g. European and African names), with two sets of *attribute* words $\mathcal{A}$ and $\mathcal{B}$ (e.g. *pleasant* vs. *unpleasant*). The bias score, $s(\mathcal{X}, \mathcal{Y}, \mathcal{A}, \mathcal{B})$, for each target is calculated as follows:

$$s(\mathcal{X}, \mathcal{Y}, \mathcal{A}, \mathcal{B}) = \sum_{\boldsymbol{x} \in \mathcal{X}} k(\boldsymbol{x}, \mathcal{A}, \mathcal{B}) - \sum_{\boldsymbol{y} \in \mathcal{Y}} k(\boldsymbol{y}, \mathcal{A}, \mathcal{B}) \quad (8)$$

$$k(\boldsymbol{t}, \mathcal{A}, \mathcal{B}) = \text{mean}_{\boldsymbol{a} \in \mathcal{A}} f(\boldsymbol{t}, \boldsymbol{a}) - \text{mean}_{\boldsymbol{b} \in \mathcal{B}} f(\boldsymbol{t}, \boldsymbol{b}) \quad (9)$$

Here, f is the cosine similarity between the word embeddings. The one-sided p-value for the permutation test regarding $\mathcal{X}$ and $\mathcal{Y}$ is calculated as the probability of $s(\mathcal{X}_i, \mathcal{Y}_i, \mathcal{A}, \mathcal{B}) > s(\mathcal{X}, \mathcal{Y}, \mathcal{A}, \mathcal{B})$. The effect size is calculated as the normalised measure given by (10).

$$\frac{\text{mean}_{x \in \mathcal{X}} s(x, \mathcal{A}, \mathcal{B}) - \text{mean}_{y \in \mathcal{Y}} s(y, \mathcal{A}, \mathcal{B})}{\text{sd}_{t \in \mathcal{X} \cup \mathcal{Y}} s(t, \mathcal{A}, \mathcal{B})} \quad (10)$$

[4] https://github.com/stanfordnlp/GloVe

[5] https://fasttext.cc/docs/en/english-vectors.html

WAT: Word Association Test (WAT) is a method to measure gender bias over a large set of words (Du et al., 2019). It calculates the gender information vector for each word in a word association graph created with Small World of Words project (SWOWEN; Deyne et al., 2019) by propagating information related to masculine and feminine words $(w_m^i, w_f^i) \in \mathcal{L}$ using a random walk approach (Zhou et al., 2003). The gender information is represented as a 2-dimensional vector (b_m, b_f), where b_m and b_f denote respectively the masculine and feminine orientations of a word. The gender information vectors of masculine words, feminine words and other words are initialised respectively with vectors (1, 0), (0, 1) and (0, 0). The bias score of a word is defined as $\log(b_m/b_f)$. We evaluate the gender bias of word embeddings using the Pearson correlation coefficient between the bias score of each word and the score given by (11) computed as the averaged difference of cosine similarities between masculine and feminine words.

$$\frac{1}{|\mathcal{L}|}\sum_{i=1}^{|\mathcal{L}|}\left(f(w, w_m^i) - f(w, w_f^i)\right) \qquad (11)$$

SemBias: SemBias dataset (Zhao et al., 2018b) contains three types of word-pairs: (a) **Definition**, a gender-definition word pair (e.g. hero – heroine), (b) **Stereotype**, a gender-stereotype word pair (e.g., manager – secretary) and (c) **None**, two other word-pairs with similar meanings unrelated to gender (e.g., jazz – blues, pencil – pen). We use the cosine similarity between the $\overrightarrow{he} - \overrightarrow{she}$ gender directional vector and $\boldsymbol{a} - \boldsymbol{b}$ in above word pair (a, b) lists to measure gender bias. Zhao et al. (2018b) used a subset of 40 instances associated with 2 seed word-pairs, not used in the training split, to evaluate the generalisability of a debiasing method. For unbiased word embeddings, we expect high similarity scores in **Definition** category and low similarity scores in **Stereotype** and **None** categories.

WinoBias/OntoNotes: We use the WinoBias dataset (Zhao et al., 2018a) and OntoNotes (Weischedel et al., 2013) for coreference resolution to evaluate the effectiveness of our proposed debiasing method in a downstream task. WinoBias contains two types of sentences that require linking gendered pronouns to either male or female stereotypical occupations. In **Type 1**, co-reference decisions must be made using world knowledge about some given circumstances. However, in **Type 2**, these tests can be resolved using syntactic information and understanding of the pronoun. It involves two conditions: the pro-stereotyped (**pro**) condition links pronouns to occupations dominated by the gender of the pronoun, and the anti-stereotyped (**anti**) condition links pronouns to occupations not dominated by the gender of the pronoun. For a correctly debiased set of word embeddings, the difference between **pro** and **anti** is expected to be small. We use the model proposed by Lee et al. (2017) and implemented in AllenNLP (Gardner et al., 2017) as the coreference resolution method.

We used a bias comparing code[6] to evaluate **WEAT** dataset. Since the **WAT** code was not published, we contacted the authors to obtain the code and used it for evaluation. We used the evaluation code from GP-GloVe[7] to evaluate **SemBias** dataset. We used AllenNLP[8] to evaluate **WinoBias** and **OntoNotes** datasets. We used *evaluate_word_pairs* function and *evaluate_word_analogies* in gensim[9] to evaluate **word embedding benchmarks**.

5 Results

5.1 Overall Results

We initialise the word embeddings of the model by original (**Org**) and debiased (**Deb**) word embeddings and compare the coreference resolution accuracy using F1 as the evaluation measure.

In Table 1, we show the WEAT bias effects for cosine similarity and correlation on WAT dataset using the Pearson correlation coefficient. We see that the proposed method can significantly debias for various biases in all word embeddings in both WEAT and WAT. Especially in Word2Vec and fastText, almost all biases are debiased.

Table 2 shows the percentages where a word-pair is correctly classified as Definition, Stereotype or None. We see that our proposed method succesfully debiases word embeddings based on results on **Definition** and **Stereotype** in SemBias. In addition, we see that the SemBias-subset can be debiased for Word2Vec and fastText.

Table 3 shows the performance on WinoBias for **Type 1** and **Type 2** in **pro** and **anti** stereotypical

5.2 Comparison with Existing Methods

We compare the proposed method against the existing debiasing methods (Bolukbasi et al., 2016; Zhao et al., 2018b; Kaneko and Bollegala, 2019) mentioned in § 2 on WEAT, which contains different types of biases. We debias Glove[10], which is used in Zhao et al. (2018b). All word embeddings used in these experiments are the pre-trained word embeddings used in the existing debiasing methods. Words in evaluation sets T3, T4 and T8 are not covered by the input pre-trained embeddings and hence not considered in this evaluation. From Table 4 we see that only the proposed method debiases all biases accurately. T5 and T6 are the tests for gender bias; despite prior debiasing methods do well in those tasks, they are not able to address other types of biases. Notably, we see that the proposed method can debias more accurately compared to previous methods that use word lists for gender debiasing, such as Bolukbasi et al. (2016) in T5 and Zhao et al. (2018b) in T6.

sense of the word) when creating $s(w)$ on SemBias benchmark as opposed to using all glosses (same as in Table 2). We see that debiasing using all glosses is more effective than using only the dominant gloss.

5.4 Word Embedding Benchmarks

It is important that a debiasing method removes only discriminatory biases and preserves semantic information in the original word embeddings. If the debiasing method removes more information than necessary from the original word embeddings, performance will drop when those debiased embeddings are used in NLP applications. Therefore, to evaluate the semantic information preserved after debiasing, we use semantic similarity and word analogy benchmarks as described next.

Semantic Similarity: The semantic similarity between two words is calculated as the cosine similarity between their word embeddings and compared against the human ratings using the Spearman correlation coefficient. The following datasets are used: Word Similarity 353 (**WS**; Finkelstein et al., 2001), **SimLex** (Hill et al., 2015), Rubenstein-Goodenough (**RG**; Rubenstein and Goodenough, 1965), **MTurk** (Halawi et al., 2012), rare words (**RW**; Luong et al., 2013) and **MEN** (Bruni et al., 2012).

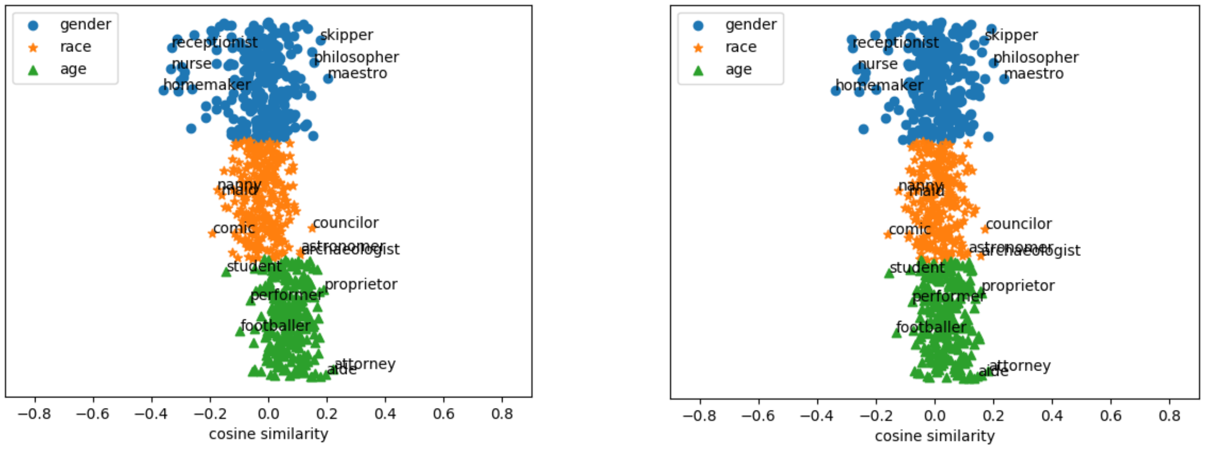
Word Analogy: In word analogy, we predict d that completes the proportional analogy "a is to b as c is to what?", for four words a, b, c and d. We use CosAdd (Levy and Goldberg, 2014), which determines d by maximising the cosine similarity between the two vectors ($\boldsymbol{b} - \boldsymbol{a} + \boldsymbol{c}$) and $\boldsymbol{d}$. Following Zhao et al. (2018b), we evaluate on **MSR** (Mikolov et al., 2013c) and **Google** analogy datasets (Mikolov et al., 2013a) as shown in Table 6.

From Table 6 we see that for all word embeddings, debiased using the proposed method accurately preserves the semantic information in the original embeddings. In fact, except for Word2Vec embeddings on WS dataset, we see that the accuracy of the embeddings have *improved* after the debiasing process, which is a desirable side-effect. We believe this is due to the fact that the information in the dictionary definitions is used during the debiasing process. Overall, our proposed method removes unfair biases, while retaining (and sometimes further improving) the semantic information contained in the original word embeddings.

We also see that for GloVe embeddings the performance has improved after debiasing whereas for Word2Vec and fastText embeddings the opposite is true. Similar drop in performance in word analogy tasks have been reported in prior work (Zhao et al., 2018b). Besides CosAdd there are multiple alternative methods proposed for solving analogies using pre-trained word embeddings such as CosMult, PairDiff and supervised operators (Bollegala et al., 2015, 2014; Hakami et al., 2018). Moreover, there have been concerns raised about the protocols used in prior work evaluating word embeddings on word analogy tasks and the correlation with downstream tasks (Schluter, 2018). Therefore, we defer further investigation in this behaviour to future work.

5.5 Visualising the Outcome of Debiasing

We analyse the effect of debiasing by calculating the cosine similarity between neutral occupational words and gender ($\overrightarrow{he} - \overrightarrow{she}$), race ($\overrightarrow{Caucasoid} - \overrightarrow{Negroid}$) and age ($\overrightarrow{elder} - \overrightarrow{youth}$) directions. The neutral occupational words list is based on Bolukbasi et al. (2016) and is listed in the Supplementary. Figure 1 shows the visualisation result for Word2Vec. We see that original Word2Vec shows some gender words are especially away from the



(a) Original Word2Vec

(b) Debiased Word2vec

Figure 1: Cosine similarity between neutral occupation words for vector directions on gender ($\overrightarrow{he} - \overrightarrow{she}$), race ($\overrightarrow{Caucasoid} - \overrightarrow{Negroid}$), and age ($\overrightarrow{elder} - \overrightarrow{youth}$) vectors.

origin (0.0). Moreover, age-related words have an overall bias towards "elder". Our debiased Word2Vec gathers vectors around the origin compared to the original Word2Vec for all gender, race and age vectors.

On the other hand, there are multiple words with high cosine similarity with the female gender after debiasing. We speculate that in rare cases their definition sentences contain biases. For example, in the WordNet the definitions for "homemaker" and "nurse" include gender-oriented words such as "a wife who manages a household while her husband earns the family income" and "a woman who is the custodian of children." It remains an interesting future challenge to remove biases from dictionaries when using for debiasing. Therefore, it is necessary to pay attention to biases included in the definition sentences when performing debiasing using dictionaries. Combining definitions from multiple dictionaries could potentially help to mitigate biases coming from a single dictionary. Another future research direction is to evaluate the proposed method for languages other than English using multilingual dictionaries.

6 Conclusion

We proposed a method to remove biases from pre-trained word embeddings using dictionaries, without requiring pre-defined word lists. The experimental results on a series of benchmark datasets show that the proposed method can remove unfair biases, while retaining useful semantic information encoded in pre-trained word embeddings.

Belief-based Generation of Argumentative Claims

Milad Alshomary **Wei-Fan Chen** **Timon Gurcke** **Henning Wachsmuth**

Abstract

When engaging in argumentative discourse, skilled human debaters tailor claims to the audience's beliefs to construct effective arguments. Recently, the field of computational argumentation witnessed extensive effort to address the automatic generation of arguments. However, existing approaches do not perform any audience-specific adaptation. In this work, we aim to bridge this gap by studying the task of *belief-based claim generation:* Given a controversial topic and a set of beliefs, generate an argumentative claim tailored to the beliefs. To tackle this task, we model the people's prior beliefs through their stances on controversial topics and extend state-of-the-art text generation models to generate claims conditioned on the beliefs. Our automatic evaluation confirms the ability of our approach to adapt claims to a set of given beliefs. In a manual study, we also evaluate the generated claims in terms of informativeness and their likelihood to be uttered by someone with a respective belief. Our results reveal the limitations of modeling users' beliefs based on their stances. Still, they demonstrate the potential of encoding beliefs into argumentative texts, laying the ground for future exploration of audience reach.

1 Introduction

According to van Eemeren and Houtlosser (1999), debaters engaging in argumentative discourse, aimed to resolve a disagreement, design their next argumentative move considering the topical potential, the audience demand, and appropriate presentational devices. Feinberg and Willer (2015) stress based on the moral foundation theory (Godden, 2010) how phrasing arguments to fit the audience's morals leads to a better agreement. For example, in a debate on former US president *Donald Trump*, potential topics could have been *immigration*, *health care plans*, *tax plans*, etc. However, knowledge about the audience being middle-class workers would have restricted the selection to *Trump's tax plans*. Appropriate usage of presentational devices may have then put a con argument as follows:

Example *"Donald Trump was a bad president. He did nothing but hurt the poor and middle class. His tax plan benefited only rich people who could afford it."*

There is a recent growth of interest in argument generation as a subfield of computational argumentation. Several tasks have been proposed, including claim negation (Bilu et al., 2015; Hidey and McKeown, 2019), counterargument generation (Hua et al., 2019), and conclusion generation (Alshomary et al., 2020). While some research considers argumentative strategies when delivering arguments (Wachsmuth et al., 2018; El Baff et al., 2019), no one has worked on adapting arguments to user beliefs yet. Our goal is to bridge this gap.

In this work, we propose to extend argument generation technologies with the ability to encode beliefs. This not only reflects the process by which humans reason, but it also allows controlling the output, to better reach the audience. In particular, we introduce the task of *belief-based claim generation:* Given a controversial topic and a representation of a user's beliefs, generate a claim relevant to the topic and matches the beliefs.

To approach this task, we first model user beliefs by their stances (pro or con) on a set of controversial topics, and then extend two state-of-the-art text generation approaches by conditioning their output on a specific set of beliefs. One approach builds on Li et al. (2016), equipping a sequence-to-sequence (Seq2Seq) model with a context vector representing the given stances. The other approach controls the output of a pre-trained argumentative language model (LM) using the algorithm of Dathathri et al. (2020) to ensure resembling the user's beliefs. We

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 224–233
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

study the given task empirically on the *debate.org* dataset of Durmus and Cardie (2018). The dataset contains users' arguments on various controversial topics and their stances towards the most popular topics on the website, called the *big issues*. For our purposes, we use these big issues as the controversial topics, and we model beliefs by the user's stances towards them.

In our automatic evaluation, we compare both models against their unconditioned correspondents (i.e., the same models without knowledge about a user). We assess the generated claims in terms of the similarity to the ground truth and the likelihood of carrying textual features that reflect users' stances on big issues. Our results suggest that using users' beliefs significantly increases the effectiveness of the Seq2Seq and LM in most cases. Moreover, a stance classifier trained on claims generated by the conditioned LM achieves the best-averaged accuracy across all big issues.

In a subsequent manual evaluation, we find that claims generated by the conditioned LM are more informative regarding the topic. In terms of predicting stance from generated claims, we analyze the limitations of our approach in detail, which lie in the belief encoding step. By avoiding these limitations, we find that the generated claims enable the annotators to predict correctly a stance on a given big issue in 45% of the cases (26% incorrectly). These results demonstrate the applicability of encoding a user's beliefs into argumentative texts, enabling future research on the effect of belief-based argumentative claims on audiences.

The contribution of this work is threefold[1]:

- A new task, *belief-based claim generation*.
- An approach to model and match users' beliefs in the generation of arguments.
- Empirical evidence of the applicability of encoding beliefs into argumentative texts.

2 Related Work

Early research on argument generation aimed to create argumentative texts starting from a symbolic representation (Zukerman et al., 2000; Grasso et al., 2000; Carenini and Moore, 2006). Conceptually, those approaches all had a similar architecture consisting of three main phases: text planning, sentence planning, and realization (Stede et al., 2018). While they included a user model to a certain extent and aimed to generate convincing arguments, they were still performed on a limited scale.

With the tremendous advances of NLP and machine learning since then, research has begun to address different tasks in the realm of argument generation, showing promising results. Hua et al. (2019) proposed a neural network-based framework for generating counter-arguments. Both Bilu et al. (2015) and Hidey and McKeown (2019) addressed the task of claim negation, using a rule-based and a neural approach respectively. Also, Sato et al. (2015) proposed an approach to argument generation based on sentence retrieval, in which, given a topic, a set of paragraphs covering different aspects is generated. However, these approaches are agnostic to the target audience.

Chen et al. (2018) modified the political bias of (often claim-like) news headlines using style transfer, accounting for general political sides (left and right) at least. Moreover, Wachsmuth et al. (2018) modeled rhetorical strategies in argument synthesis conceptually, but its computational realization (El Baff et al., 2019) considers the audience implicitly only, using a language model approach to select and arrange argumentative discourse units that are phrased in an argument.

In the field of conversational AI, researchers have utilized machine translation techniques to tackle the task of dialog generation (Ritter et al., 2011). Li et al. (2016) worked on augmenting sequence-to-sequence models by learning persona vectors from the given data. In a similar fashion, one of our approaches extends such a model by a context vector representing a user's belief. Here, however, we deal with argumentative text.

Progress in the field of text generation has been made due to the availability of large pre-trained language models (Devlin et al., 2018; Solaiman et al., 2019). While these models excel in generating coherent texts, ensuring a generated text possesses a certain property is not straightforward. Some research tackled this limitation, offering ways to better control the output (Keskar et al., 2019; Ziegler et al., 2019). One of the most flexible of such approaches is by Dathathri et al. (2020), which does not require fine-tuning for each controlling theme. Their algorithm conditions the output of a language model to contain certain properties defined by a discriminative classifier or a bag-of-words. One of our approaches makes use of this algorithm to condi-

---

[1] Code can be found under: http://www.github.com/webis-de/eacl21-belief-based-claim-generation

tion the output of an argumentative language model on a bag-of-words that represents a user's beliefs. A recent relevant work by Schiller et al. (2020) deals with the generation of aspect-controlled arguments. Similar to us, the authors utilize a pre-trained language model to generate arguments on a specific topic, with a controlled stance and aspect. Their focus is on topical aspects of arguments, though, and their approach based on Keskar et al. (2019) is limited to a predefined set of topics and aspects.

3 Task

Due to the importance of audience in argumentation when aiming for persuasiveness (van Eemeren and Houtlosser, 1999), and due to the fact that humans comply to certain morals that shape their beliefs and affect their reasoning (Godden, 2010; Feinberg and Willer, 2015), we introduce the audience's beliefs as a new dimension to the argument generation process in this work. For this, we propose a new task, belief-based claim generation:

> *Given a controversial topic and a representation of the audience's beliefs, generate a claim that is both relevant to the topic and matches the beliefs.*

We focus this task on generating *claims* rather than full arguments to keep it simple and because claims denote the main units from which arguments are built. As shown by Feinberg and Willer (2015), better agreement is achieved when arguments are framed with respect to audience's beliefs. Therefore, we argue that studying the mentioned task will enable argumentation technology, knowing its audience, to generate more convincing arguments, bridging the gap between disagreeing parties.

3.1 Data

To study the proposed task, a dataset is needed in which information about users revealing their beliefs as well as their arguments on various topics are given. Here, we build upon the dataset introduced by Durmus and Cardie (2018), which was collected from *debate.org*, an online platform where users can engage in debates over controversial topics and share their profiles. The dataset contains users' arguments as answers to topic questions and engagement in debates, along with various user information, including a user's self-specified stances (pro or con) on up to 48 predefined popular controversial topics, called *big issues*.

Dataset	**# Claims**	**# Topics**	**# Users**
Training set	41 288	22 241	5 189
Validation set	5 028	2 450	2 509
Test set	5 154	2 728	2 512
Full dataset	51 470	27 419	5 189

Table 1: Number of claims, topics, and users in each of the training, validation, and test set of the data used in this paper.

In our dataset, for the task at hand, we keep only users who have at least three arguments and stated their stance on at least one of the big issues. For those, we collected their arguments along with the topics and stances. In total, the dataset contains around 51k claims, on 27k topics from 5k users. We randomly split the dataset per topic into 10% test and 90% training. 10% of the latter are used as the validation set. Statistics are given in Table 1.

To develop approaches to the belief-based claim generation task, we need training data where claims can be identified as such. Since claim detection is not our focus, we preprocess all data using the claim detection approach of Chakrabarty et al. (2019). In particular, we score the likelihood of each sentence being a claim, and only keep the one with the highest score as the user's claim on the topic. To evaluate the model, we created a sample of 100 arguments, and two annotators decided whether the extracted sentence represents a claim on the given topic or not. In terms of full agreement, the model extracted claims correctly in 81% of the cases, the Cohen's κ inter-annotator agreement being 0.3. We note that this preprocessing step produces some noise in the data, mainly affecting the training of our Seq2Seq model below.

4 Approach

To study our research question, we propose and compare two approaches that build on top of known techniques for text generation. Both approaches rely on modeling users' beliefs via their stances on big issues. The first is an extension of the Seq2Seq model (Sutskever et al., 2014), where the user's stances are encoded as a context vector, while the second conditions the output of a pre-trained argumentative language model via a bag-of-words, constructed based on stances on big issues.

4.1 Seq2Seq-based Model

Given a topic, as a sequences of words $T = (w_1, w_2, ..., w_n)$, a user vector $\overrightarrow{U} \in \{0, 1\}^k$ with k being the number of big issues, and a claim as a sequence of words $C = (w_1, w_2, ..., w_m)$, first an LSTM-based encoder consumes the input topic and produces a hidden state $\overrightarrow{h}$, which is used to initialize the LSTM-based decoder. The user vector $\overrightarrow{U}$ is projected into a new embedding space via a feed forward network with a learned weight matrix W_U, producing a new vector, $\overrightarrow{V}$:

$$\overrightarrow{V} = \sigma(W_U \cdot \overrightarrow{U})$$

Following Li et al. (2016), our $\overrightarrow{V}$ is served as their speaker embedding in the model. The difference between the speaker model in Li et al. (2016) and this model is that the vector $\overrightarrow{V}$ is not explicitly predefined but rather learned from the data, while in our model it is already predefined as a binary vector representing the user's stances on big issues. By augmenting the Seq2Seq model with a context user vector, the model is supposed to capture the correlation between users' stances on big issue and the corresponding claims. Once the correlation is learned, the model can generate a claim utilizing not only the topic, but also the stances on big issues of the target user, which reflect the beliefs.

4.2 Conditioned Language Model

In this approach, we represent a user's stances on big issues as a bag-of-words. We then use the topic as a prompt for a pre-trained argumentative language model (LM) to synthesize a claim conditioned using the algorithm of Dathathri et al. (2020). The synthesis process is illustrated in Figure 1.

Argumentative Language Model Since we aim to generate *claims* in particular, a standard LM is not enough. To model argumentative language, we take a LM pre-trained on general language and fine-tune it on a large set of arguments (in our experiments, we use the corpus of Ajjour et al. (2019)). The result is an LM that is able to generate argumentative text.

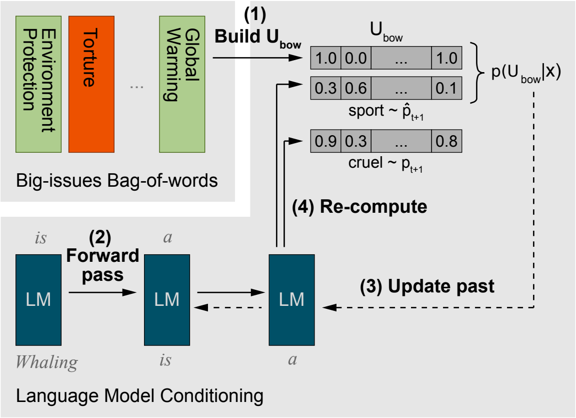

Figure 1: The synthesis process of the conditioned LM on the topic "Whaling", given a user who is pro *environmental protection* and *global warming* and con *torture*. Steps: (1) Building U_{bow}, based on stances (2) Forward pass through the LM to generate a token, *sport* (3) Updating the LM history H_t, based on $p(U_{bow}|x)$, and (4) Generating from the new history $\hat{H}_t$ a new token *cruel*.

Belief-based Bag-of-words Next, we build a bag-of-words that represents the beliefs of a user. We learn this from the user's stances on the big issues. For example, a user pro *abortion* would likely be pro *choice*. Hence, words such as *right* and *choice* are candidates to be included in their belief-based bag-of-words. To this end, we first build two bag-of-words representations for each big issue, one for the pro and for the con side. For a user, we then construct a belief-based bag-of-words based on their stances on big issues.

To build a representative pro and con bag-of-words for each big issue, we follow the topic signature approach of Lin and Hovy (2000). Given a big issue, we first collect from some corpus of arguments three sets: relevant pro arguments R_{pro}, relevant con arguments R_{con}, and a random set of non-relevant arguments $\hat{R}$. For each relevant set, we then compute a likelihood ratio for all its words with respect to $\hat{R}$ and keep only words with a score higher than a specific threshold τ, resulting in two sets of words, W_{pro} and W_{con}. Since a word may appear in both sets, we remove it from the set where it occurs fewer times. Finally, we sort words according to their likelihood ratio and keep in both W_{pro} and W_{con} the top k words, forming the final pro and con bag-of-words respectively.

Claim Generation Given a user (represented by stances on big issues) and a topic, we construct a belief-based bag-of-words (Step 1 in Figure 1):

$$U_{bow} = W_1 \cup W_2 \cup \ldots \cup W_n$$

where W_i is the pro bag-of-words if the stance is pro and the con bag-of-words otherwise. Then, we use the topic as a prompt and the user's bag-of-words U_{bow} to condition the generated claim (see Figure 1). In particular, given a transformer-based LM (Vaswani et al., 2017), a token x_{t+1} is generated at each time step as follows:

$$o_{t+1}, H_{t+1} = LM(x_t, H_t)$$

$$x_{t+1} \sim p_{t+1} = Softmax(W \cdot o_{t+1})$$

where H_t represents the history of the LM. Using the algorithm of Radford et al. (2019), called Plug and Play LM (PPLM), an update to the past, ΔH, is computed to control the generated claim, based on the sum of the log likelihood $p(U_{bow}|x)$ of all words in the belief-based bag-of-words. Then the new history, $\hat{H}_t = H_t + \Delta H_t$, is used as in the previous equations to draw a new distribution $\hat{p}_{t+1}$, of which a new token is sampled. To ensure fluency in the generated text, ΔH is further modified to ensure a high log-likelihood $p(x)$ with respect to the LM. More details on the algorithm can be found in the work of Radford et al. (2019).

In short, through fine-tuning an LM on argumentative text, we tune it to generate claims. Using the topic as a prompt, we ensure that the claim is on the topic. Finally, the PPLM represents beliefs, modeled as a bag-of-words U_{bow}, in the claim.

5 Automatic Evaluation

In this section, we evaluate whether utilizing user's beliefs as input, modeled as stances on big issues, leads to claims that better match the ground-truth claims and reveal the input stances on big issues.

5.1 Experimental Setup

On one hand, we compute the BLEU and METEOR scores of the generated claims with respect to the ground-truth claims. On the other hand, we compute the likelihood that the generated claims possess textual features that reflect the input user's beliefs. We do so by measuring the accuracy of predicting user's stances on big issues given the generated claims. We compute this accuracy for each of the 48 big issues individually and report the results for all of them. To this end, we carry out the following three steps for a given approach.

First, we generate claims for all given users and topics in the test dataset. Second, we keep only instances in which users have a stance (pro/con) on the tested big issue, and split the filtered dataset into training and test. Finally, we train a simple TF-IDF based linear classifier on the training set to predict the stance on the big issue given the text of the claim. The accuracy of the classifier on the test split then quantifies the likelihood of the generated claims possessing textual features that reflect the stance on the corresponding big issue.

Approach	**BLEU-1**	**BLEU-3**	**METEOR**
S2S-baseline	18.2%	0.44%	**16%**
S2S-model	***__18.4%__	***0.46%**	**16%**
LM-baseline	9.6%	**0.26%**	8%
LM-conditioned	***12.0%**	0.16%	***11%**

Table 2: BLEU and METEOR scores of the claims of each evaluated approach compared to the ground-truth claims. Values marked with * are significantly better than the respective baseline at $p < .05$ (student's t-test).

5.2 Implementation Details

In the following, we give implementation details of our approaches and the corresponding baselines:

Seq2seq-based Model Based on the OpenNMT framework (Klein et al., 2017), the encoder and decoder are each two-layer LSTMs of hidden size 512 with GloVe word embeddings of size 300. Users' stances on big issues are represented as a one-hot encoded vector, and then projected into 16 dimensions space through a one-layer dense neural network. We trained the model with the Adagrad optimizer (batch size 16) and refer to it as *S2S-model*.

Conditioned Language Model We constructed the pro/con relevant argument sets (R_{pro}, R_{con}) by querying the respective big issue from the API provided by Ajjour et al. (2019) and extracting pro/con arguments from the top 60 results. For the non-relevant argument set ($\hat{R}$), we used the same corpus (Ajjour et al., 2019) and randomly selected 100 arguments. We eliminated all words with a score under $\tau = 10$ and finally kept the top $k = 25$ words from each set (R_{pro}, R_{con}) to represent the bag-of-words.[2]

To model the argumentative language, we fine-tuned the GPT-2 model on the corpus of Ajjour et al. (2019), which contains around 400k arguments. The fine-tuning was performed using the transformers framework (Wolf et al., 2019). We used the topic as a prompt to trigger the generation process. However, since some topics are phrased as a question (e.g, "is abortion wrong?"), we extracted the noun phrase from the topic and used it as a prompt. For conditioning the generated claim,

---

[2] We refrained from tuning the parameters here since we do not have a ground truth.

Approach	Abortion	Death penalty	Gay Marriage	Drug legaliz.	Global warming	Environm. protection	Medical mariju.	Smok. ban	Minim. wage	Border fence	All 48 big issues

Table 3: Accuracy of each classifier trained on claims generated by the evaluated approaches to predict the stance, on the 10 most frequent big issues as well as on average over all 48 big issues. Values marked with * are significantly better than corresponding baseline at $p < 0.05$ according to a one-tailed Student's t-test.

we used the PPLM implementation (Dathathri et al., 2020)[3]. We call this model the *LM-conditioned*.

Baselines To evaluate the gain of encoding user's beliefs, we compare our two approaches to the corresponding version without stances on big issues as an input. We refer to these baselines as *S2S-baseline* and *LM-baseline* respectively[4].

5.3 Results

Table 2 shows the results of our approaches and the baselines in terms of BLEU and METEOR.

For *S2S*, the BLEU scores of our approach are significantly better than the baseline. The *LM-conditioned* is significantly better than the baseline version in terms of BLEU-1 and METEOR. In general, the S2S-model has the highest scores across all measures. The reason may be that it was trained in a supervised manner on the given dataset, whereas the *LM-model* was only fine-tuned in an unsupervised way on a different argument corpus.

Regarding the encoding of user stances, Table 3 shows the accuracy of a linear classifier trained to predict the stance from the claims generated by each approach as well as from the ground-truth, on average and on the 10 most frequent big issues. A complete table with all big issues can be found in the appendix.

The best average accuracy across all the big issues is achieved by the *LM-model* (0.54). Compared to the corresponding baselines, the LM-model and the *S2S-model* generated claims that boosted the accuracy of the stance classifier on 33 (69%) and 21 (44%) of all big issues respectively. Overall, in 20 of the big issues, the best accuracy was achieved on the claims generated by the conditioned LM, compared to only nine big issues for the S2S-model. This indicates that the LM-conditioned can better encode a user's beliefs, modeled as stances on big issues, into generated claims.

6 Manual Evaluation

To obtain more insights into belief-based claim generation, we let users manually evaluate the output of the given approaches. Upon inspecting a sample of generated claims by our approaches, we noticed that the *LM-conditioned* produces more fluent and informative texts. Accordingly, we focused on the LM-conditioned and its baseline in the evaluation, where we conducted two user studies. The goal of the first was to assess the quality of the big-issue bag-of-words collected automatically, while the second targeted the output of the LM-model, its baseline, and a variant that utilizes a manually refined bag-of-words.

6.1 Automatic Collection of Bag-of-words

To keep the manual annotation effort manageable, we evaluated only the top-10 big issues. Two authors of this paper categorized each word in the pro/con bag-of-words of the corresponding big issue into five categories, *c1–c5*:

c1: Word irrelevant to the big issue.

c2: Relevant word, wrong stance.

c3: Relevant word, both stances possible.

c4: Relevant word, correct stance.

c5: Very relevant word, correct stance.

---

[3] step-size=0.15 and the repetition-penalty=1.2

[4] A baseline that uses the corresponding bag-of-words of the targeted topic to guide the generation wouldn't be valid, since we don't have information on the user's stance on this targeted topic.

	Overall			Relatedness Level 4			Relatedness Level 3			Relatedness Level-2		
Approach	**True**	**False**	**Undec.**	**True**	**False**	**Undec.**	**True**	**False**	**Undec.**	**True**	**False**	**Undec.**
LM-baseline	44%	34%	**22%**	50%	50%	**0%**	55%	31%	14%	**27%**	20%	**53%**
LM-conditioned	37%	32%	31%	35%	38%	27%	59%	41%	**0%**	13%	**13%**	74%
LM-cond. (manual)	**45%**	**26%**	28%	**50%**	**31%**	19%	**61%**	**28%**	11%	25%	18%	56%
Ground Truth	42%	30%	28%	38%	42%	19%	64%	27%	9%	27%	19%	54%

Table 4: Manual Evaluation: Percentage of cases for each approach where the majority of annotators predicted the stance of a generated claim on the given big issue correctly (true), incorrectly (false), or could not decide it (Undec.). The overall scores and those for each topic/big-issue relation level are listed.

	Irrelevant	Relevant			Very Relevant
Words	**c1**	**c2**	**c3**	**c4**	**c5**
Pro	14%	10%	36%	34%	6%
Con	36%	2%	34%	26%	2%

Table 5: Distribution of the pro/con bag-of-words, averaged across the top-10 big issues, over the five considered categories: c2 means wrong stance, c3 words that fit both stances, and c3 and c4 represent correct stance.

Examples can be found in the appendix. To compute inter-annotator agreement, three big issues were annotated by both annotators, resulting in Cohen's κ of 0.45, reflecting moderate agreement. Afterwards, only one annotator continued the annotations for the other big issues.

Table 5 shows the distribution of words over categories, averaged across the 10 big issues. For the pro bag-of-words, around 40% of the words are relevant and reflect the right stance, while 36% are relevant but could be used in arguments from both stances. For the con bag-of-words, however, the percentages are lower (28% and 34% respectively). A considerable proportion of words belong to categories c1 and c2, which creates noise that could confuse the conditioning process of the LM. Hence, we also consider a variant of the conditioned LM that uses only relevant words from c4 and c5.

6.2 Claim Generation

We evaluate the effectiveness in terms of whether a given generated claim reveals the stance of the given user on a specific big issue as well as how informative the claim is regarding the given topic.

Since not all topics are directly related to the big issues that can be revealed in the generated claims, we manually annotated the relatedness of the top frequent 200 topics in the test dataset to the most frequent 10 big issues, and created the evaluation sample accordingly. In particular, two authors of this paper scored the relatedness of each pair of topics and big issues on a scale from 1 to 4:

4: Topic and big issue are the same. Example: *"gay marriage should be legalized" and "gay marriage"*

3: A stance on the topic likely affects the stance on the big issue. Example: *"killing domestic abusers" and "death penalty"*

2: A stance on the topic may affect the stance on the big issue. Example: *"morality" and "abortion"*

1: Topic and big issue are not related. Example: *"do aliens exist?" and "abortion"*

The two annotators had a Cohen's κ agreement of 0.54. Around 97.4% of all pairs got score 1, 1.1% score 2, 0.8% score 3, and 0.7% score 4. The small percentage of cases that can be evaluated reflects a limitation in the designed evaluation study. However, it still allows us to evaluate the effectiveness of our approach for different levels of relatedness. Given the annotated pairs, we randomly selected 10 pairs from levels 2, 3, and 4 each. For each pair, we then collected all claims on the topic from the test set, where the author specifies a stance on the corresponding big issue. We randomly select 30 claims each, resulting in an evaluation sample of 90 instances.

We used the crowdsourcing platform *MTurk*[5] for evaluation. For each instance, we showed a topic, a claim, and the corresponding big issue to three annotators. The annotators had to perform two tasks: (1) to predict the stance of the user on the corresponding big issue from the text of the claim, and (2) to rate the claim's informativeness regarding the topic on a scale from 1 to 3.

Table 4 shows the percentage of cases in which the majority of annotators predicted the stance correctly (true), incorrectly (false), or could not decide

---

[5] A crowd sourcing platform: https://www.mturk.com/

Approach	Overall	Level 4	Level 3	Level 2
LM-baseline	1.8	**2.5**	1.9	1.4
LM-conditioned	**2.1**	2.3	**2.5**	**1.5**
LM-cond. (manual)	2.0	2.3	2.2	1.5
Ground Truth	2.0	1.9	1.8	2.2

Table 6: Manual Evaluation: Mean informativeness of the claims generated by each approach with regard to the topic (1–3, higher is better). The overall scores and those for each topic/big-issue relation level are listed.

about the stance (undec.) from the generated claim. Across the whole sample (Overall), the claims generated by *LM-conditioned (manual)*, the model conditioned on the refined bag-of-words, most often allowed to predict the stance correctly (45%). We thus attribute the low effectiveness of the *LM-model* to the noise generated by the automatic collection of big-issues' bag-of-words, especially seeing that the effectiveness gets better across all levels when eliminating this noise.

Analyzing each relatedness level individually yields more insights. For relatedness level 4, where the topic is the same as the big issue, the *LM-conditioned (manual)* generated claims where the majority of the cases with known stance were correct (63%). In level 3, we observe that both versions of our approach outperform the baseline in producing claims that express the correct stance on the corresponding big issue with percentages of 59% and 68% respectively. Finally, at relation level 2, which represents a weak relation between topics and big issues, predicting the stance seems to become hard, as indicated by high percentages of undecided cases. We believe that the weak relatedness made the annotators guess the stance in some cases, leading to unreliable annotations.

Table 6 shows the average score of all approaches regarding the informativeness of the generated claims. Here, both versions of our approach achieved better scores than the baseline, matching the ground-truth score. We believe that the low scores of the ground-truth claims stem from the noise generated in the claim detection step.

Error Analysis Table 7 shows some cases from our evaluation. In case (a), even though the model generated a claim focusing on *fundamental rights*, the majority of the annotators was undecided about the stance. Case (b) shows the effect of noise in the bag-of-words: the generated claim reflects a pro stance on abortion, while the ground-truth stance is con. This is avoided in the claim generated by *LM-conditioned (manual)*. Case (c) shows a working example of which our approach correctly generated a claim on *whaling* from an environmental perspective when conditioned as such. Case (d) is a level 2 example, indicating limitation in our evaluation, namely, the generated claim reveals a stance on abortion, but we asked about death penalty.

(a) *Topic:* is abortion ok
Big issue: (Con) Abortion *Level:* 4

Approach	Claim	Stance
LM-cond.	abortion rights groups argue that the right to abortion is a fundamental human right.	Undec.
LM-baseline	abortionists are not the only ones who are against abortion. There are many other people who are against abortion	Undec.

(b) *Topic:* abortion is right or wrong
Big issue: (Con) Abortion *Level:* 4

Approach	Claim	Stance
LM-cond.	abortion right or wrong is a personal choice. I believe that abortion should be legal because it's the woman"s body and she has every right to do what ever she wants.	Pro
LM-cond. (manual)	abortion right or wrong. I believe that abortion is murder and should be illegal in all cases except when the mother's life is at stake, rape, incest etc.	Con

(c) *Topic:* whaling
Big issue: (Pro) Environmental Protection *Level:* 3

Approach	Claim	Stance
LM-cond.	whaling is a very dangerous and cruel practice. It causes great harm to the environment, animals that are caught in it have their lives cut short by being eaten alive.	Pro
LM-baseline	whaling is a sport. It is a sport because it involves a lot of physical exertion and skill.	Undec.

(d) *Topic:* should murder be legalized?
Big issue: (Pro) Death Penalty *Level:* 2

Approach	Claim	Stance
LM-cond.	should murder be legalized? I think that abortion should not be legal. Abortion is killing a baby, and it's wrong to kill an innocent human being.	Undec.
LM-baseline	should murder be legalized? I think so. I think that it should be legalized because it is a good thing	Undec.

Table 7: A selection of claims generated by the different evaluated approaches for the different association levels between topic and big issue discussed in the text.

7 Conclusion

In this paper, we have proposed to equip argument generation technology with the ability to encode beliefs for two reasons: first, it reflects the human process of synthesizing arguments, and second, it gives more control on the generated arguments leading to a better reach of the audience. For this purpose, we have presented the task of belief-based claim generation. Concretely, we studied the research questions of how to model a user's beliefs as well as how to encode them when generating an argumentative text. We have modeled users' beliefs via their stances on big issues, and used them as an extra input in our approaches.

Our automatic evaluation has provided evidence of the applicability of encoding beliefs into argumentative texts. In manual studies, we found that limitations in the effectiveness of our approach stem from noise produced by the automatic collection of a bag-of-words. The findings of this paper lay the ground to investigate the role of beliefs in generating arguments that reach their audience.

We point out that ethical issues arise, when tuning arguments to affect specific people, such as attempts to manipulate them. While the task and settings considered here are rather too fundamental to already make these issues critical, future work should pay attention to them. Our goal is to develop systems that bring people together.

Abstract

Non-autoregressive generation (NAG) has recently attracted great attention due to its fast inference speed. However, the generation quality of existing NAG models still lags behind their autoregressive counterparts. In this work, we show that BERT can be employed as the backbone of a NAG model to greatly improve performance. Additionally, we devise mechanisms to alleviate the two common problems of vanilla NAG models: the inflexibility of prefixed output length and the conditional independence of individual token predictions. Lastly, to further increase the speed advantage of the proposed model, we propose a new decoding strategy, *ratio-first*, for applications where the output lengths can be approximately estimated beforehand. For a comprehensive evaluation, we test the proposed model on three text generation tasks, including text summarization, sentence compression and machine translation. Experimental results show that our model significantly outperforms existing non-autoregressive baselines and achieves competitive performance with many strong autoregressive models. In addition, we also conduct extensive analysis experiments to reveal the effect of each proposed component.[1]

1 Introduction

Autoregressive generation (AG) models achieve state-of-the-art performance on a wide range of text generation tasks, such as machine translation (Vaswani et al., 2017) and text summarization (Rush et al., 2015). Such models generate a token sequence in a left-to-right, token-by-token fashion. The prediction for the next token is conditioned on all previously generated tokens. This characteristic makes it impossible to parallelize the computational overhead for token predictions in different positions, which leads to a relatively high latency in inference. On the other hand, non-autoregressive generation (NAG) models (Gu et al., 2018) have emerged as a promising alternative due to their fast inference speed. NAG models omit the sequential dependencies within the output-side sequence and predict tokens in all positions simultaneously once the output length has been determined beforehand. While NAG models enjoy full parallelism and faster inference, the generation quality of NAG models often lags behind their autoregressive counterparts.

In this work, we explore the potential of large-scale pre-trained language models for improving the performance of non-autoregressive generation. Specifically, we utilize BERT (Devlin et al., 2019) as the backbone for NAG modelling and extend the architecture of BERT with a CRF output layer (Lafferty et al., 2001; Sun et al., 2019) for better capturing the output-side dependencies.

In addition, we analyze two significant limitations that NAG models currently suffer from: (1) the inflexibility of prefixed output length, and (2) the conditional independence of individual token predictions. Accordingly, we devise two solutions to these two problems.

First, prior NAG models require the output length to be determined before token generation, thus an extra module for output length prediction is always required. Nevertheless, the most likely length from the prediction module is not necessarily the best-suited one for the token generation model. To this end, previous works (Gu et al., 2018; Ma et al., 2019) usually rely on length-parallel decoding (LPD) (Wei et al., 2019) for performance enhancement; that is, generating and re-ranking the results from different output length candidates. In this work, we propose a simple and elegant decoding mechanism that lets the model determine the output length on-the-fly. Specifically, our model dynamically adjusts the output sequence length via

---

April 19 - 23, 2021. ©2021 Association for Computational Linguistics

emitting an `[eos]` token at any output position to indicate the ending of the generated sequence. Therefore, we can avoid the additional efforts of output length prediction and results re-ranking.

Second, most existing NAG models assume the token predictions in different positions are conditionally independent. As a consequence, they often tend to generate results that are ungrammatical with repetitions (Wang et al., 2019b). To alleviate this problem, we propose a context-aware learning objective which impels the model to output different tokens at adjacent positions, thereby reducing the possibility of repetitive generation.

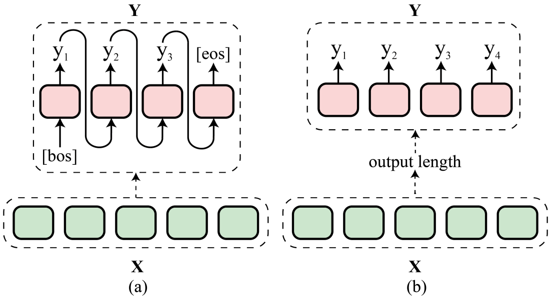
Furthermore, for tasks like text summarization, the output sequence (summary) is known to be shorter than the source sequence (article). In such cases, to further improve the model's inference efficiency, we introduce a new *ratio-first* decoding strategy. Specifically, instead of performing inference on all source-side hidden states, ratio-first generates the result only based on a subset of source hidden states. The subset size is jointly determined by the source length T and a predefined ratio α that is set based on our prior knowledge from the data statistics. In the experiments, we show that ratio-first can significantly improve the inference speed while maintaining the generation quality.

We evaluate the proposed model on three typical text generation tasks, including text summarization, sentence compression and machine translation. Experimental results show that our model significantly outperforms many strong non-autoregressive baselines, and even performs competitively with several strong autoregressive models. In addition, we conduct extensive analysis experiments to study the effect of individual proposed components.

In summary, our contributions are: (1) We propose a novel framework that utilizes BERT for text generation under the non-autoregressive generation paradigm; (2) We propose a decoding mechanism that allows the model to dynamically determine the output length, and a new context-aware learning objective that reduces errors stemming from the output-side conditional independence assumption; (3) We introduce a ratio-first decoding strategy that further improve the model's inference efficiency.

2 Background

Autoregressive generation (AG) models generate sequences based on a left-to-right factorization. As shown in Figure 1, given the source sequence $\mathbf{X}$, the target sequence $\mathbf{Y}$ with length T' is generated via a chain of conditional probabilities based on the left-to-right sequential dependencies as:



(a)

(b)

Figure 1: (a) Autoregressive; (b) Non-Autoregressive

$$p(\mathbf{Y}|\mathbf{X}) = \prod_{i=1}^{T'} p(y_i|y_{<i}, \mathbf{X}), \qquad (1)$$

where $y_{<i}$ denotes the tokens before the i-th step. This property of autoregressive factorization makes the generation process hard to be parallelized as the result is generated token by token.

Unlike AG models, non-autoregressive (NAG) models generate sequences without modelling the output-side dependencies. As shown in Figure 1, given the prespecified output length T', the probability of the target sequence $\mathbf{Y}$ is then modelled as:

$$p(\mathbf{Y}|\mathbf{X}) = \prod_{i=1}^{T'} p(y_i|\mathbf{X}, i, T'). \qquad (2)$$

With this conditional independence assumption, NAG models can fully parallelize their generation process, which significantly improves the inference speed. However, it has been shown that, the choice of the prespecified output length has a notable impact on the model's generation quality (Gu et al., 2018). In addition, the removal of output-side sequential dependency also causes the generation quality of NAG models to be inferior to their autoregressive counterparts (Wang et al., 2019b).

3 Proposed Model

In this section, we give a detailed explanation of the proposed model. First, we describe how to utilize BERT as a non-autoregressive generation model. Then we discuss the decoding mechanism which allows the model to determine the output length dynamically. Finally, we introduce the new ratio-first decoding strategy which further improves the model's decoding efficiency.

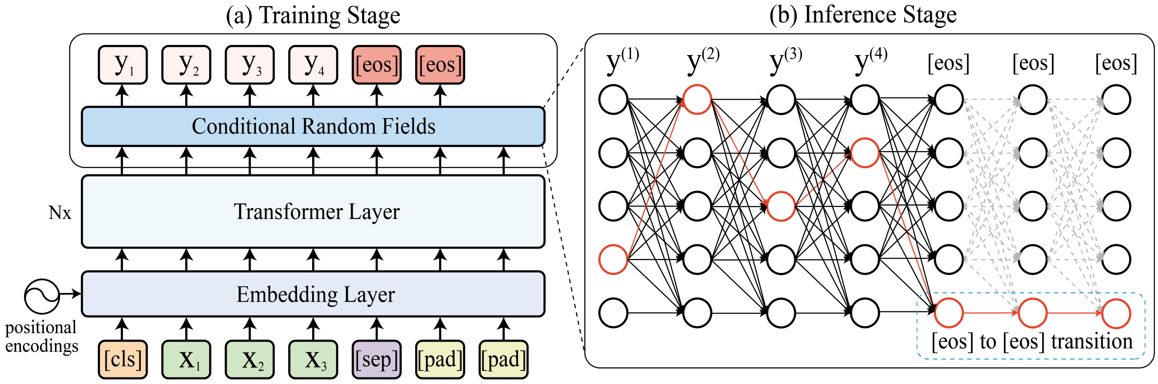


Figure 2: The overall illustration of the proposed model: During training, the model parameters are only updated on the positions of the target sequence. During inference, once the decoded trajectory (colored in red) gets into the `[eos]` state, it will only transit to the `[eos]` state in the remaining steps. The final result is obtained by removing the generated `[eos]` tokens from the entire decoded trajectory.

3.1 Model Architecture

The architecture of the proposed model is presented in Figure 2, in which the embedding layer and the stack of transformer layers are initialized with BERT (Devlin et al., 2019).

Input Representation Following the setup of BERT, we first append a `[cls]` and a `[sep]` token on both sides of the source sequence. Then we attach a number of `[pad]` tokens at the end of source sequence to make its length equal to the predefined maximum size (e.g., 256). Thus we can make sure the source length is longer than or equal to the output length. As a special case, for tasks like text summarization where the source is known to be longer than the target, we do not attach the `[pad]` tokens when constructing the input.

Transformer Layers Given the source sequence $\mathbf{X}$, it is processed by a stack of N transformer (Vaswani et al., 2017) layers. Formally, the Multi-Head Attention is defined as $\text{MultiHead}(\mathbf{Q}, \mathbf{K}, \mathbf{V})$, where $\mathbf{Q}$, $\mathbf{K}$, $\mathbf{V}$ denotes the query, key and value respectively. The computation of the first transformer layer is then defined as:

$$\mathbf{V}^{(1)} = \text{MultiHead}(E(\mathbf{X}), E(\mathbf{X}), E(\mathbf{X})), \quad (3)$$

$$\mathbf{O}^{(1)} = \text{FFN}(\mathbf{V}^{(1)}), \quad (4)$$

$$\text{FFN}(x) = \max(0, xW_1 + b_1)W_2 + b_2, \quad (5)$$

where $E(\mathbf{X}) = TE(\mathbf{X}) + PE(\mathbf{X})$ in which $TE(\cdot)$ denotes the token embedding and $PE(\cdot)$ denotes the position embedding. For other layers:

$$\mathbf{V}^{(n)} = \text{MultiHead}(\mathbf{O}^{(n-1)}, \mathbf{O}^{(n-1)}, \mathbf{O}^{(n-1)}), \quad (6)$$

$$\mathbf{O}^{(n)} = \text{FFN}(\mathbf{V}^{(n)}), \quad (7)$$

where $n = 2, ..., N$ and N is the total number of transformer layers. The final sequence representation $\mathbf{H} \in \mathbb{R}^{T \times d_{\text{model}}}$ is the output states of BERT from the last layer, where T is the source sequence length and d_{model} is the model size.

CRF Layer Then, $\mathbf{H}$ is passed through a linear-chain CRF (Lafferty et al., 2001). Under the CRF framework, the likelihood of the target sequence $\mathbf{Y}$ with length T' is then modelled as:

$$P_{\text{CRF}}(\mathbf{Y}|\mathbf{X}) = \frac{e^{S(\mathbf{X},\mathbf{Y})}}{\sum_{\mathbf{Y}'} e^{S(\mathbf{X},\mathbf{Y}')}} = \frac{1}{Z(\mathbf{X})} \exp\Big(\sum_{i=1}^{T'} \Phi_{y_i}(h_i) + \sum_{i=2}^{T'} t(y_{i-1}, y_i)\Big), \quad (8)$$

where $Z(\mathbf{X})$ is the normalizing factor and $\Phi_{y_i}(h_i)$ denotes the label score of y_i at position i. In practice, Φ is parameterized by a neural network that maps the BERT output state h_i into the label (vocabulary) space. The $t(y_{i-1}, y_i) = \mathbf{T}_{y_{i-1}, y_i}$ denotes the transition score from label y_{i-1} to y_i where $\mathbf{T} \in \mathbb{R}^{|V| \times |V|}$ is the transition matrix.

Approximation In the context of text generation, the size of the label space (vocabulary size) $|V|$ is typically large, e.g., $32k$. Therefore, it is intractable to directly model the transition matrix $\mathbf{T}$ and the normalizing factor $Z(\mathbf{X})$. To this end, we adopt the techniques proposed by Sun et al. (2019) to approximate these two terms. Specifically, the full transition matrix is approximated by the product of two low-rank matrices $\mathbf{T} = \mathbf{E}_1 \mathbf{E}_2^T$, where $\mathbf{E}_1, \mathbf{E}_2 \in \mathbb{R}^{|V| \times d}$ and d is much smaller than $|V|$. To compute the normalizing factor $Z(\mathbf{X})$, at each time step, instead of searching through all possible paths, the number of candidates is heuristically truncated to a predefined beam size k. We refer readers to the original paper for further details.

3.2 Output Length Determination

In this section, we describe how to let the model determine the output sequence length by itself. Our basic idea is that we want the model to dynamically stop generation via emitting a special `[eos]` token. To achieve this, during training, we manually append **two** consecutive `[eos]` tokens to the end of the target sequence, as shown in the top left part of Figure 2. In this way, the model can learn a deterministic transition behaviour between two `[eos]` states, meaning that $t(\texttt{[eos]}, \texttt{[eos]}) = \max_{v \in \mathcal{V}} t(\texttt{[eos]}, v)$. This is because, during training, the model never sees a transition $(\texttt{[eos]}, v)$, where $v \neq \texttt{[eos]}$.

During inference, the result $\tilde{\mathbf{Y}}$ is acquired as $\tilde{\mathbf{Y}} = \arg\max_{\mathbf{Y}'} S(\mathbf{X}, \mathbf{Y}')$, where the CRF scoring function $S(\mathbf{X}, \mathbf{Y}')$ in Equation (8) can be decomposed as:

$$
\begin{aligned}
S(\mathbf{X}, \mathbf{Y}') &= \sum_{i=1}^{T} \Phi_{y_i'}(h_i) + \sum_{i=2}^{T} t(y_{i-1}', y_i') \\
&= \underbrace{\Phi_{y_1'}(h_1)}_{\text{initial state}} + \sum_{i=2}^{T} \underbrace{\{\overbrace{\Phi_{y_i'}(h_i)}^{\text{label score}} + \overbrace{t(y_{i-1}', y_i')}^{\text{transition score}}\}}_{\text{state transition}}.
\end{aligned} \tag{9}
$$

Once the decoded trajectory enters the `[eos]` state, the state transition term in $S(\mathbf{X}, \mathbf{Y}')$ will be dominated by the transition score term $t(\texttt{[eos]}, \texttt{[eos]})$. As a result, the model will keep transitioning to `[eos]` in the remaining steps. An example is provided in the right part of Figure 2, from which we can see that, at step 5, the decoded trajectory enters the `[eos]` state and remains at it in the rest of the generation process. In this way, our model can dynamically control the length of output sequence by entering the `[eos]` state during the generation process. After the entire generation process is completed, the final output sequence can be obtained by removing all generated `[eos]` tokens.

3.3 Ratio-First Decoding

We note that the outputs of BERT can be divided into two subsets. The first subset ranges from the beginning to the position where the first `[eos]` is emitted, and the second subset is the rest. For example, in Figure 2, the first subset are those corresponding to the output sequence "$y^{(1)}$ $y^{(2)}$ $y^{(3)}$ $y^{(4)}$ `[eos]`". As for the second part, we can see that it has little effect on the final output and removing it should not change the result. This indicates that it suffices to only consider the beginning part of BERT outputs for improving the inference speed. Especially, for tasks like summarization where the target is known to be shorter than the source sequence, we are safe to only use the first $[\alpha \cdot T]$ outputs of BERT to perform inference. Here T denotes the source length, $\alpha \in (0.0, 1.0)$ is set based on the data statistics and $[\cdot]$ is the integer rounding operation. Formally, given the source sequence $\mathbf{X}$, the ratio-first decoding is defined as

$$
\begin{aligned}
\tilde{\mathbf{Y}} &= \arg\max_{\mathbf{Y}'} \mathcal{F}(\mathbf{X}, \mathbf{Y}', \alpha), \\
&= \arg\max_{\mathbf{Y}'} \{ \sum_{i=1}^{[\alpha \cdot T]} \Phi_{y_i'}(h_i) + \sum_{i=2}^{[\alpha \cdot T]} t(y_{i-1}', y_i') \}.
\end{aligned} \tag{10}
$$

When $\alpha = 1.0$, ratio-first degenerates to the standard decoding strategy in CRF-based models.

It should be noted that, $[\alpha \cdot T]$ only constrains the maximum length of the generated result, and the actual output length (after removing the generated `[eos]` tokens) is still decided by the model itself. In the experiment section, we demonstrate that ratio-first can notably improve the inference speed whilst maintaining the generation quality.

4 Learning

Due to the conditional independence approximation on output tokens, NAG models often tend to generate repeated tokens (Wang et al., 2019b). One way to alleviate this problem is to introduce implicit dependencies on the output side. In this work, we propose to use the unlikelihood formulation of Welleck et al. (2020) in the context of NAG, where we define the set of negative candidate as the surrounding tokens within a predefined context window c. Formally, given the source sequence $\mathbf{X}$ and the target sequence $\mathbf{Y}$ with length T', the proposed context-aware objective is defined as:

$$
\begin{aligned}
\mathcal{L}_{\text{CA}}(\mathbf{Y}|\mathbf{X}) &= -\sum_{i=1}^{T'} \{\log p_\theta(y_i|h_i; \mathbf{X}) + l_{\text{CA}}(i)\}, \\
l_{\text{CA}}(i) &= \sum_{j=i-c, y_j \neq y_i}^{j=i+c} \log(1.0 - p_\theta(y_j|h_i; \mathbf{X})),
\end{aligned} \tag{11}
$$

where h_i is the model output state at position i. At position i, the proposed objective maximizes the probability of token y_i while minimizing the probabilities of the surrounding tokens. In this way, it discourages the model from generating repetitive tokens at different time steps.

The overall learning objective is then defined as

$$\begin{aligned} \mathcal{L}_{\text{CRF}} &= -\log P_{\text{CRF}}(\mathbf{Y}|\mathbf{X}), \\ \mathcal{L} &= \mathcal{L}_{\text{CRF}} + \lambda \cdot \mathcal{L}_{\text{CA}}, \end{aligned} \tag{12}$$

where λ controls the importance of different loss terms and $P_{\text{CRF}}(\mathbf{Y}|\mathbf{X})$ is described in Equation (8).

5 Related Work

Non-Autoregressive generation was first introduced by Gu et al. (2018) to reduce the inference latency in machine translation. Recent works in this area have investigated ways to mitigate the trade-off between the decoding speed and generation quality. Gu et al. (2018) utilized fertility as latent variables for better translation performance. Wang et al. (2019b) proposed two auxiliary objectives for better modelling the output states and solving the under-translation problem. To better model the intermediate alignments between source and target sides, Ma et al. (2019) proposed a model based on the generative flow framework. Ghazvininejad et al. (2019) proposed to use a masked language objective to train the NAG model. During inference, starting from a fully masked sequence, the output is generated in an iterative refinement manner. Recently, Sun et al. (2019) proposed to incorporate a conditional random field into the decoder of a NAG model for better modelling the output-side dependencies. Our work is different from prior works in two aspects: (1) we directly utilize a pre-trained language model (BERT) to perform non-autoregressive generation; (2) our model can dynamically generate the output sequence without the need of prespecified output length.

6 Experiments

We evaluate the proposed model on three typical text generation tasks: (1) text summarization; (2) sentence compression and (3) machine translation.

6.1 Experimental Setup

We implement the proposed model with PyTorch (Paszke et al., 2017). The BERT model we use is the Huggingface implementation (Wolf et al., 2019) (bert-base-uncased). To approximate the transition matrix in the CRF layer, we set the dimension d of matrices $\mathbf{E}_1$ and $\mathbf{E}_2$ as 32. For the normalizing factor $\mathbf{Z}(\mathbf{X})$, we set the predefined beam size k as 256. As for the overall learning objective, we set the window size c as 3 and λ as 1.0. In training, we use Adam optimizer (Kingma and Ba, 2015). To measure the relative speedup, we follow the standard setup which runs inference for each individual example separately. The model's inference speed is computed by averaging the results of test cases. For a fair comparison, we measure the inference speed of all models on the same platform.

6.2 Text Summarization

Text summarization aims to automatically generate a compact summary that retains the most important content of the original text document (Nenkova and McKeown, 2012). In this experiment, we use the Gigawords dataset (Rush et al., 2015) as our benchmark. For evaluation, standard metrics including ROUGE-1 (R-1), ROUGE-2 (R-2) and ROUGE-L (R-L) (Lin, 2004) are reported.

We compare our model with several representative and the latest NAG models, including NAG-NMT (Gu et al., 2018), NAR-REG (Wang et al., 2019b) and NAG-CRF (Sun et al., 2019). Following previous works, during training, we train a length predictor to predict the output length. During inference, for each NAG baseline, we adopt the length-parallel decoding strategy (LPD-k) (Wei et al., 2019), that is, generating k results using the top-k possible output length predictions from the length predictor. The results are then re-ranked by a transformer model to get the final ouput. In the experiment, we report the results of different NAG baselines using LPD-9 decoding. In addition, to better examine the effect of using BERT in NAG models, we add a **B**NAG-CRF baseline which adopts the same structure of the NAG-CRF model but using BERT as the encoder. We also compare our model with several strong autoregressive models, which are Luong-NMT (Luong et al., 2015), Pointer-Generator (See et al., 2017), DRGD (Li et al., 2017) and Concept Pointer (Wang et al., 2019a). To measure the relative inference speedup, we include transformer as a baseline model.

The results are shown in Table 1, from which we can see that, by using length-parallel decoding, the performance of all NAG baselines can be notably improved. However, such procedure significantly increases the inference latency. In contrast,

Models	R-1	R-2	R-L	Speedup

+LPD-9	34.56	16.10	32.76	3.21×
Ours ($\alpha = 0.3$)	34.67	16.13	32.81	**9.31**×
Ours ($\alpha = 1.0$)	**35.05**	**16.48**	**33.28**	6.72×

Table 1: Results on Gigawords dataset, where b in the transformer baseline stands for beam search size.

our model can self-determine the output length without any re-ranking process. As shown in the results, our model outperforms the best NAG baseline (with LPD) and achieves performances that are comparable with several strong AG models.

Comparing the results of **B**NAG-CRF and NAG-CRF, we can see that incorporating BERT as encoder helps to improve the model performance. Nonetheless, our model still outperforms **B**NAG-CRF with LPD-9 decoding. This is because the dynamic length decoding mechanism allows our model to generate results with optimal length, leading to stronger model performances.

Finally, we analyze the proposed ratio-first decoding. From the results, we observe a moderate performance drop when using ratio-first ($\alpha = 0.3$). It comes from the fact that, for some input documents with length T, the reference summary is longer than $[\alpha \cdot T]$. In such cases, ratio-first fails to generate the complete reference summary, leading to the drop of performance. On the other hand, we can see that, ratio-first can notably improve the inference speedup. With $\alpha = 0.3$, our model achieves the highest inference speedup while still outperforms all compared NAG models.

6.3 Sentence Compression

Sentence compression aims at compressing a long sentence into a short one by deleting redundant words. In this experiment, we use the Google sentence compression dataset (Filippova and Altun, 2013) as our benchmark. For evaluation, we use the standard token-kept-F1 (F1) score. In addition, We also report the results of other standard metrics including ROUGE-1, ROUGE-2 and ROUGE-L.

Table 2: Results on sentence compression task

We compare the proposed model with the same NAG baselines as in the previous experiment. We also compare our model with several strong autoregressive models, including Bi-LSTM-Dep (Filippova et al., 2015), Tagger and Tagger+ILP (Wang et al., 2017), HiSAN-Dep and HiSAN (Kamigaito et al., 2018). To measure the inference speedup, we include transformer as a baseline model.

The results are presented in Table 2, from which we see that our model outperforms the best reported NAG baseline (with LPD) in terms of both the generation quality and inference speed. Comparing with the strong autoregressive models, our model can achieve competitive performance with a over $8.42\times$ inference speed up. We also report the results of our model using the ratio-first decoding strategy. By setting α as 0.7, it achieves a $10.00\times$ inference speedup while still outperforming other compared NAG baselines.

6.4 Machine Translation

Machine translation aims at translating text from the source language to the target language. In this task, we use the IWSLT14 German-to-English (DE-EN) dataset as our benchmark. Following previous works, we use the sequence-level knowledge distillation (Gu et al., 2018) during training. For evaluation, we report results in BLEU scores (Papineni et al., 2002). In this experiment, we use the BERT model in German language.

We compare our model with a range of strong

Models	BLEU	Speedup(×)
Autoregressive		
LSTM-based	28.53	-
CNN-based	32.84	-
Transformer (b = 4)	33.31	1.00
Non-Autoregressive		
ENAG-E	24.13 (27.30)	15.08 (7.39)
ENAG-P	25.09 (28.60)	14.48 (7.24)
NAG-REG	23.89 (28.04)	16.45 (9.05)
NAG-NMT	23.04 (26.79)	13.92 (7.24)
NAG-CRF	26.39 (29.21)	11.74 (6.03)
BNAG-CRF	26.73 (29.67)	9.42 (5.01)
Ours ($\alpha = 0.8$)	29.71	13.92
Ours ($\alpha = 1.0$)	**30.45**	11.31

Table 3: Results on IWSLT14 De-En dataset. The numbers in () are results using length-parallel decoding.

BERT	CRF	R-1	R-2	R-L
✓	✓	35.05	16.48	33.28
×	✓	32.41	14.19	30.53
✓	×	32.16	11.33	30.34
×	×	27.02	8.81	25.25

Table 4: Ablation study on Gigawords dataset.

NAG models, including NAG-NMT (Gu et al., 2018), ENAG-E and ENAG-P (Guo et al., 2019), NAG-REG (Wang et al., 2019b), NAG-CRF (Sun et al., 2019) and **B**NAG-CRF. For each NAG baseline, we also report the results using LPD-9 decoding. In addition, we compare our model with several strong autoregressive models, including LSTM-based (Wu et al., 2016), CNN-based (Gehring et al., 2017) and transformer model.

The results are shown in Table 3, from which we see that our model outperforms the best NAG baseline (with LPD) in terms of both the generation quality and inference speedup. Additionally, we also report the results using the ratio-first decoding. By setting α as 0.8, the inference speedup can be further boosted to 13.92× while the generation quality is still higher than the best NAG baseline.

6.5 Further Analysis

In this section, we present further discussions and empirical analysis of the proposed model.

BERT & CRF To quantify the importance of each component (BERT & CRF) of our model, we evaluate the performance on Gigawords dataset by removing each component iteratively.

The results are shown in Table 4, from which we can see that by removing any of these components, the overall performance decreases. By removing BERT from the model, we observe notable drop across all metrics. This shows that the knowledge of BERT is an important factor of the model's strong performance. Comparing with results in Table 1, it still outperforms vanilla NAG-CRF and performs comparably with NAG-CRF using LPD decoding, which demonstrates the merit of the proposed dynamic length decoding mechanism. Another interesting finding is that, by only removing the CRF layer, the most notable drop is observed on the bigram-level metric (ROUGE-2). This shows that the bigram-level dependencies on the output side are mainly captured by the CRF module. In addition, by removing both BERT and CRF, all metrics further decrease. This confirms that each of these two components positively contributes to the model's overall performance.

Models	rep-1	rep-2	rep-3	rep-4	R-L
w/o CA	6.897	2.640	0.741	0.295	32.89
Ours	5.786	1.978	0.427	0.106	33.28
Transformer	4.329	1.348	0.267	0.089	33.43

Table 5: Evaluation results on n-gram repetitions.

Context-Aware Objective In this part, we study the effect of the context-aware objective. As described in Equation (11), it aims at alleviating the problem of repetitive generation. To give a quantitative analysis, we use the measurement of sentence-level repetition (Welleck et al., 2020) to compute the ratio of duplicate n-grams (rep-n) in the generated result. This metric is defined as

$$\text{rep-}n(\mathbf{Y}) = 100 \times (1.0 - \frac{|\text{unique } n\text{-grams}(\mathbf{Y})|}{|n\text{-grams}(\mathbf{Y})|}). \tag{13}$$

For each generated result, rep-n is 0.0 when it has no repeating n-grams. The final result is computed by averaging over the entire evaluation set.

We conduct experiments on Gigawords dataset to evaluate the n-gram repetitions ranging from uni-gram to 4-gram. The results are shown in Table 5, where w/o CA means the model is trained without using context-aware objective and R-L denotes the model's ROUGE-L score. Additionally, we also show the results from transformer model for a direct comparison. Comparing the two variants of our model, we see that training with context-aware objective leads to a 42% drop on rep-3 metric (0.427 vs 0.741) and a 64% drop on rep-4 metric (0.106 vs 0.295). The ROUGE-L results also indicate that

Models	Ours ($\alpha = 1.0$)	Length-Parallel Decoding		
		LPD-1	LPD-5	LPD-10
BLEU	**30.45**	27.15	29.62	30.37
Speedup(×)	11.31	11.84	8.92	6.01

Table 6: Results comparison on IWSLT14 dataset

the reduction in token repetition can effectively improve the model generation quality.

Dynamic Length Determination Next, we examine the importance of the model's ability to dynamically determine the length of the generated output. To this end, we train another model variant by removing the two `[eos]` tokens from the target sequence. In this way, the model is not able to self-determine the output length throughout the generation process. To perform inference, we use length-parallel decoding (LPD) with different number of length candidates. Formally, for each length candidate l, the model generates the result $\tilde{\mathbf{Y}}$ as

$$\tilde{\mathbf{Y}} = \arg\max_{\mathbf{Y}'}\{\sum_{i=1}^{l}\Phi_{y'_i}(h_i) + \sum_{i=2}^{l} t(y'_{i-1}, y'_i)\}. \tag{14}$$

The final result is acquired by re-ranking the generated results with a transformer model.

We conduct experiments on the IWSLT14 DE-EN dataset in which we try a different number of length candidates, including top-1, top-5 and top-10. The results are shown in Table 6, from which we can see, as the number of length candidates increases, the model performance increases as well. The reason is that a larger candidates set is more likely to contain the best-suited length for the generation model, leading to better performance. However, such decoding procedure inevitably increases the required computation overhead. We can see that, when setting k as 10, the inference speedup decreases from 11.84× to 6.01×. In contrast, our proposed model is able to determine the optimal output length by itself. Without any re-ranking process, it outperforms the model with LPD-10 decoding and achieves the inference speedup that is comparable with the model using LPD-1 decoding.

Ratio-First Decoding We are also interested in the effect of the ratio-first decoding strategy. To provide a quantitative analysis, we perform inference on the Gigawords dataset using ratio-first with different α. The experimental results with different α are presented in Figure 3. It can be observed that, when α reaches 0.3, the model approximately achieves its optimal performance. At the same time, a notable improvement can be observed in terms of the inference speedup ($6.72\times \rightarrow 9.31\times$).

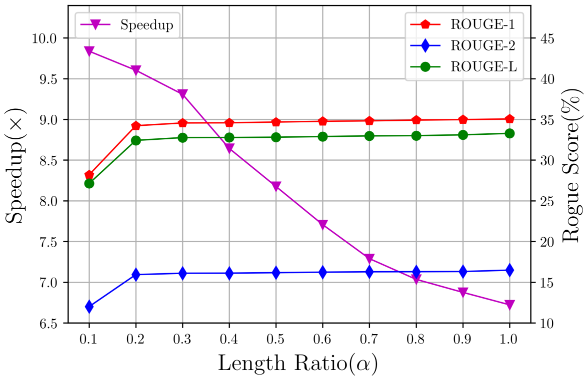

Figure 3: Experiment results on Gigawords dataset using ratio-first decoding with different α.

Figure 4: The distribution of target/source length ratio of the training and test set in Gigawords dataset.

Now we illustrate why the near optimal performance can be achieved when α reaches 0.3. In Figure 4, we present the distribution of the target/source length ratio of every data instance in the Gigawords dataset. We can see that, for most cases, the ratio between the target length T' and source length T is less than 0.3. Recall the definition of ratio-first decoding in Equation (10), the $[\alpha \cdot T]$ constrains the maximum length of the generated result. Therefore, once we have a prior knowledge on the data statistic, we can easily choose a proper α that both improves the inference speed whilst maintaining the generation quality. In this case, a proper α could be 0.3 which is demonstrated by the results in Figure 3 and 4. By setting different α, ratio-first provides us an explicit way to control the balance between the inference speed and the generation quality. This property of ratio-first is especially favorable in real-life scenarios where the inference speed is the highest concern.

7 Conclusion

In this work, we explored the potential of BERT in various text generation tasks under the NAG framework. To address problems from NAG models previously having a prefixed output length, we devised a decoding mechanism which enables the model to determine the output length dynamically. To reduce errors stemming from the assumption of conditional independence of output tokens, we proposed a context-aware objective as well as using a CRF decoding. Furthermore, to maximize the inference speed advantage of our model, we introduced a ratio-first decoding strategy. We evaluated our model on three benchmark datasets and the results show that our model significantly outperforms many strong NAG baselines and performs comparably to many strong AG models.

Abstract

Large-scale transformers have been shown the state-of-the-art on neural machine translation. However, training these increasingly wider and deeper models could be tremendously memory intensive. We reduce the memory burden by employing the idea of reversible networks that a layer's input can be reconstructed from its output. We design three types of multi-split based reversible transformers. We also devise a corresponding backpropagation algorithm, which does not need to store activations for most layers. Furthermore, we present two fine-tuning techniques: splits shuffle and self ensemble, to boost translation accuracy. Specifically, our best models surpass the vanilla transformer by at least 1.4 BLEU points in three datasets. Our large-scale reversible models achieve 30.0 BLEU in WMT'14 En-De and 43.5 BLEU in WMT'14 En-Fr, beating several very strong baselines with less than half of the training memory.

1 Introduction

Transformers (Vaswani et al., 2017) and their variants (So et al., 2019; Dehghani et al., 2019; Fonollosa et al., 2019; Liu et al., 2020; Zhu et al., 2020) significantly enhance the performance of neural machine translation (NMT). But this often requires a large size of the hidden layer (e.g., Raffel et al. (2019) used a dimension of 65K) or a deeper network by stacking more building blocks (e.g., Liu et al. (2020) used a 60-layer encoder). Training large networks could be extremely memory intensive and might even require model parallelization across multiple GPUs (Brown et al., 2020). As a result, reducing memory consumption is crucial to train wider and deeper networks efficiently.

Backpropagation (BP) is commonly used for training modern neural networks. BP needs to store layer activations to calculate the parameter gradients, which severely increases the memory burden. The idea of reversible networks can be a solution. During training, a reversible network layer's input can be reconstructed from its output. BP is run together with the reconstruction process, removing the need to store all layer activations except for the last layer. We extend the hidden dimension splitting approach by Gomez et al. (2017) and design three types of reversible transformers, namely, simple reversible transformers (**SIM-REV**), single dependent reversible transformers (**SD-REV**) and fully dependent reversible transformers (**FD-REV**). We also devise a corresponding BP algorithm for our reversible models, which is significantly memory efficient compared with the conventional BP.

Our reversible models rely on partitioning each layer's input and output into multiple equal splits. This multi-split feature inspires us to develop two fine-tuning techniques to further enhance translation accuracy. First, we randomly shuffle the output splits to encourage information sharing. Second, we train distinct translation models based on different output splits in the final decoder layer and run model ensemble during inference. These two techniques are applied after model convergence. Only a few epochs of fine-tuning are sufficient for boosting the translation performance. Also, both techniques do not break the reversibility of our proposed models.

We demonstrate that our reversible models can achieve similar or better performance than vanilla transformers do with less memory consumption. Specifically, by employing reversible training and the fine-tuning techniques, our best models can surpass vanilla transformers by 1.5 BLEU (IWSLT'14 De-En), 2.0 BLEU (WMT'19 En-Lt) and 1.4 BLEU (WMT'14 En-De). Our large-scale models also beat several very strong NMT models with less than half the training memory on WMT'14 En-De (30.0 BLEU) and WMT'14 En-Fr (43.5 BLEU).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 244–254
April 19 - 23, 2021.

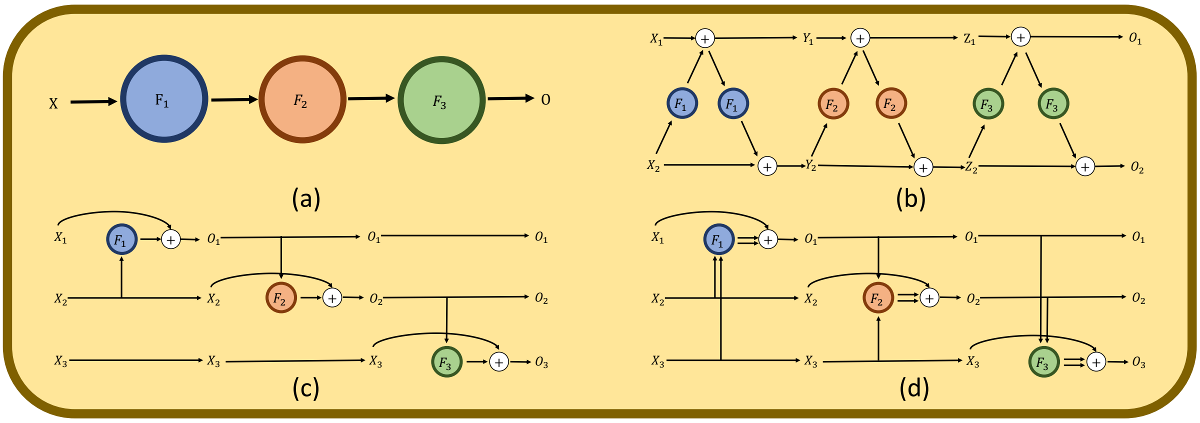

Figure 1: This figure is an illustration of different reversible architectures we explore. (a) shows a vanilla neural network (NN), where F, G and H are modules inside an NN layer. (b) shows **SIM-REV**, which resembles RevNets most. (c) shows a 3-split **SD-REV**. The i-th output split O_i depends only on the i-th input split X_i and O_{i-1}. (d) shows a 3-split **FD-REV**. Each output split O_i depends on all previous output splits $O_{<i}$ and all subsequent input splits $X_{\geq i}$.

2 Methodology

We introduce reversible transformers in this section. The definition and benefits of layer reversibility are given in Section 2.1. Section 2.2 shows three types of reversible architectures based on partitioning the layer input along the hidden/embedding dimension. Section 2.3 details the backpropagation algorithm we use. Finally, in Section 2.4, two techniques that can fit into the reversible training framework are introduced for further boosting model performance.

2.1 Reversible Architectures

A neural network layer is said to be reversible if its input can be reconstructed from its output. Usually, a network is trained in a forward-backward fashion. The activations in each layer are calculated in the forward process and stored for gradient computation in the backward process. The requirement for storing activations is memory intensive and often becomes a bottleneck for network training. However, if a network has reversible building blocks, we do not need to store the activations for most layers since they can be computed during the backward process.

A reversible layer can be designed in two ways. The first way is that this layer has an analytical inverse (Gomez et al., 2017; Jacobsen et al., 2018; Chang et al., 2018; MacKay et al., 2018). The second way is to compute the layer input via numerical methods, e.g., the fixed-point iteration (Behrmann et al., 2019). We focus on the first way following the dimension-splitting approach proposed by RevNets (Gomez et al., 2017). We give a brief review of RevNets. X is the network input, which is split into two halves X_1 and X_2. F and G are modules inside a layer (e.g., 3×3 convolutions). The forward process is as follows:

$$O_1 = X_1 + F(X_2); \;\; O_2 = X_2 + G(O_1). \quad (1)$$

X_1, X_2 can be reconstructed from O_1, O_2 by:

$$X_2 = O_2 - G(O_1); \;\; X_1 = O_1 - F(X_2). \quad (2)$$

2.2 Reversible Transformers

Transformers (Vaswani et al., 2017) achieved the state of the art performance in several tasks (Edunov et al., 2018; Brown et al., 2020). Despite its success, training transformers is memory intensive. We propose three reversible transformers inspired by RevNets (Gomez et al., 2017) to reduce the training memory consumption. X is the layer input. O is the layer output. X and O are partitioned into n equal splits along the hidden/embedding dimension. $X = \{X_1, X_2, \cdots, X_n\}$, $O = \{O_1, O_2, \cdots, O_n\}$. $F_1, F_2, \cdots, F_n$ are modules inside a layer (e.g. self-attention, fully connected layer).

Simple Reversible Transformer (SIM-REV) X is split into two halves X_1, X_2. For each module F_i inside a layer, the forward process resembles RevNets by changing F and G in Equation (1) into F_i. Part (b) of Figure 1 demonstrates the case of a layer with three modules:

$$\begin{aligned} Y_1 = X_1 + F_1(X_2); \;\; & Y_2 = X_2 + F_1(Y_1) \\ Z_1 = Y_1 + F_2(Y_2); \;\; & Z_2 = Y_2 + F_2(Z_1) \quad (3) \\ O_1 = Z_1 + F_3(Z_2); \;\; & O_2 = Z_2 + F_3(O_1) \end{aligned}$$

This is the simplest way to introduce reversibility into a transformer layer. But the computation complexity is doubled compared with vanilla transformers since each module function F_i is used twice.

Single Dependent Reversible Transformer (SD-REV) We propose another reversible architecture to reduce the computational complexity. The i-th output split O_i depends only on X_i and O_{i-1}. The forward process is as follows:

$$\begin{aligned} O_1 &= X_1 + F_1(X_2) \\ O_2 &= X_2 + F_2(O_1) \\ &\dots \\ O_n &= X_n + F_n(O_{n-1}) \end{aligned} \tag{4}$$

The reconstruction of X given O is also straightforward:

$$\begin{aligned} X_n &= O_n - F_n(O_{n-1}) \\ X_{n-1} &= O_{n-1} - F_{n-1}(O_{n-2}) \\ &\dots \\ X_1 &= O_1 - F_1(X_2) \end{aligned} \tag{5}$$

Part (c) of Figure 1 shows a 3-split example of **SD-REV**. With only half of **SIM-REV**'s computational complexity, experiments show that **SD-REV** can achieve similar or even better performance as **SIM-REV** does.

Fully Dependent Reversible Transformer (FD-REV) The **SD-REV** only encodes information in neighbour splits. The lack of interaction between distant splits may make the model less expressive. We force each output split O_i to depend on all previous output splits $O_{<i}$ and all subsequent input splits $X_{\geq i}$, while preserving the reversibility of the network layer. Despite the increased computational complexity, we hope the model to have a better generalization ability. A detailed description of the **FD-REV**'s forward process is as follows:

$$\begin{aligned} O_1 &= X_1 + \sum_{i=2}^{n} F_1(X_i) \\ &\dots \\ O_k &= X_k + \sum_{i=k+1}^{n} F_k(X_i) + \sum_{j=1}^{k-1} F_k(O_j) \\ &\dots \\ O_n &= X_n + \sum_{j=1}^{n-1} F_n(O_j) \end{aligned} \tag{6}$$

The reversibility of **FD-REV** is ensured by:

$$\begin{aligned} X_n &= O_n - \sum_{j=1}^{n-1} F_n(O_j) \\ &\dots \\ X_k &= O_k - \sum_{i=k+1}^{n} F_k(X_i) - \sum_{j=1}^{k-1} F_k(O_j) \\ &\dots \\ X_1 &= O_1 - \sum_{i=2}^{n} F_1(X_i) \end{aligned} \tag{7}$$

Part (d) of Figure 1 illustrates **FD-REV** in a 3-split case. Experiments in Section 3 shows that allowing interaction between distant splits is beneficial for translation performance.

Instantiation The building blocks of transformers are attention based modules and position-wise feed-forward layers:

$$\begin{aligned} &\text{Encoder : Self-Attn} \rightarrow \text{FFN} \\ &\text{Decoder : Self-Attn} \rightarrow \text{Cross-Attn} \rightarrow \text{FFN} \end{aligned}$$

For **SIM-REV**, each of the above modules are transformed into reversible modules, where S is an input/output split:

$$\begin{aligned} \text{Encoder: } F_1(S) &= \alpha(S + \text{Self-Attn}(S)), \\ F_2(S) &= \alpha(S + \text{FFN}(S)) \\ \text{Decoder: } F_1(S) &= \alpha(S + \text{Self-Attn}(S)), \\ F_2(S) &= \alpha(S + \text{Cross-Attn}(S)), \\ F_3(S) &= \alpha(S + \text{FFN}(S)) \end{aligned}$$

For an n-split **SD-REV** or **FD-REV** (actually it has an n-split encoder and an $(n+1)$-split decoder), we use multiple Self-Attn modules and a single Cross-Attn/FFN module within each layer:

$$\begin{aligned} \text{Encoder: } F_{k<n}(S) &= \alpha(S + \text{Self-Attn}_k(S)), \\ F_n(S) &= \alpha(S + \text{FFN}(S)) \\ \text{Decoder: } F_{k<n}(S) &= \alpha(S + \text{Self-Attn}_k(S)), \\ F_n(S) &= \alpha(S + \text{Cross-Attn}(S)), \\ F_{n+1}(S) &= \alpha(S + \text{FFN}(S)) \end{aligned}$$

Applying layer normalization (LN) to the layer output O is crucial to better convergence in training transformers. However, it requires extra storage to calculate the reverse of LN. We use the ReZero (Bachlechner et al., 2020) technique as a substitution of LN. Each layer has a distinct re-scaling

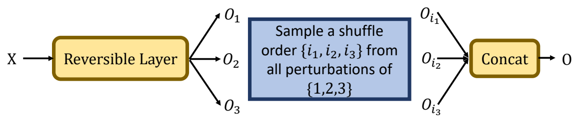

Figure 2: Illustration of shuffling splits

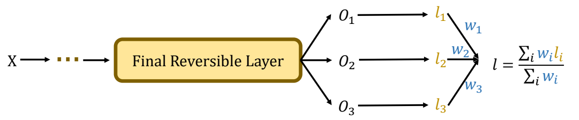

Figure 3: Illustration of self ensemble

weight α which is initialized to zero. α is trained together with other network parameters using Algorithm 1 in Section 2.3.

2.3 Backpropagation with Reconstructing Activations

In the backward pass, we are given the activations $O = \{O_1, \cdots, O_n\}$ and their total derivatives $dO = \{dO_1, \cdots, dO_n\}$. We wish to compute the inputs $X = \{X_1, \cdots, X_n\}$, their total derivatives $dX = \{dX_1, \cdots, dX_n\}$ and the derivatives of model parameters in $F_1, \cdots, F_n$. For **SIM-REV**, the backpropagation (BP) algorithm has no difference with that in Gomez et al. (2017). Such that our main focus is to derive the resulting BP algorithm for **SD-REV** and **FD-REV**.

The forward pass of **SD-REV** and **FD-REV** can be combined into a more general form:

$$O_k = X_k + G_k(X_{i>k}, O_{j<k}, \theta_k) \quad \text{where } k \in \{1, \cdots, n\}. \tag{8}$$

SD-REV corresponds to $G_k = F_k(O_{k-1})$ and **FD-REV** corresponds to $G_k = \sum_{i=k+1}^{n} F_k(X_i) + \sum_{j=1}^{k-1} F_k(O_j)$. Algorithm 1 defines the BP rule of this general form reversible network. Gradients for model parameters are computed in line 9 of Algorithm 1 as a side effect. A repeated apply of Algorithm 1 allows us to perform BP through a sequence of reversible layers, only requiring the activations and their derivatives of the top layer. In this way, the storage cost for activations can be small and independent of network depth.

2.4 Splits Shuffle and Self Ensemble

In this section, we propose two multi-split based fine-tuning methods that can enhance model performance, namely, splits shuffle and self ensemble.

Algorithm 1 BP Algorithm for Multi-Split Reversible Networks

```
Input:
    Layer output: $O = \{O_1, \cdots, O_n\}$;
    Derivatives of $O$: $dO = \{dO_1, \cdots, dO_n\}$;
    Modules: $G_1, \cdots, G_n$;
Output:
    Layer input: $X = \{X_1, \cdots, X_n\}$;
    Derivative of $X$: $dX = \{dX_1, \cdots, dX_n\}$;
 1: $X = \{\}; dX = \{\}$
 2: for k in $n$ to 1 do
 3:     $C = O_k; O = O \setminus \{O_k\}$
 4:     if $k == n$ then
 5:         $\text{grad}_k = dO_k$
 6:     else
 7:         $\text{grad}_k = dO_k + C.\text{grad}$
 8:     end if
 9:     $g_k = G_k(X, O, \theta_k)$; $g_k.\text{backward}^1(\text{grad}_k)$
10:     $X_k = C - g_k; X = X \cup \{X_k\}$
11: end for
12: $dX_1 = \text{grad}_1, dX = \{dX_1\}$
13: for k in 2 to $n$ do
14:     $dX_k = X_k.\text{grad} + \text{grad}_k$
15:     $dX = dX \cup \{dX_k\}$
16: end for
```

First, we train a reversible transformer till convergence. Then, several epochs of fine-tuning with one of these techniques can improve model accuracy.

Splits Shuffle A reversible transformer consists of several reversible layers. The inputs of a certain layer are the outputs of its preceding layer, which we denote as $O = \{O_1, \cdots, O_n\}$. Note that if the order of O_i is randomly shuffled, the whole network is still reversible as long as we keep a record of the shuffling order. This property inspires us to do the following fine-tuning technique:

- For each layer in the reversible network, sample $b \sim \text{Bernoulli}(p)$.
- If $b = 1$, uniformly sample a shuffle order $\{i_1, \cdots, i_n\}$ from all perturbations of $\{1, \cdots, n\}$.
- Next layer's input is $O = \{O_{i_1}, \cdots, O_{i_n}\}$.

Figure 2 shows the splits shuffle process. At inference time, we set p to 0. The idea behind splits shuffle is to apply dropout in the structure level. Splits shuffle provides a way to combine exponentially many network architectures efficiently. In

---

[1] Automatic differentiation routines, e.g. `tf.gradient`, `torch.autograd.backward`

order to let each structure perform well, each split is forced to become more expressive.

Self Ensemble Model ensemble is a commonly used method for boosting translation performance (Zhou et al., 2017; Wang et al., 2020b). Model ensemble usually requires multiple distinct models to output their probability distributions over the vocabulary. The ensemble process is both computational and memory intensive. Our multi-split model offers a new chance that we can view each split of the final output as an independent model. Our self ensemble technique works as follows:

- O_i is a split in the final layer output, y is the translation target, FC stands for a fully connected layer: $P_i = \text{Softmax}(\text{FC}(O_i)); l_i = \text{loss}(P_i, y)$
- Sample a weight $w_i \sim \text{uniform}(0, 1)$. Final loss $l = \sum_{i=1}^{n} w_i l_i / \sum_{i=1}^{n} w_i$.

Figure 3 illustrates the self ensemble method. At inference time, the final distribution is an average of P_i output by each split O_i. We manage to learn an ensemble of transformers in a single reversible transformer. The inference-time memory and computational consumption are largely reduced compared with conventional ensemble methods.

3 Experiments

3.1 Datasets, Architectures and Training

Datasets We experiment on four standard corpora to demonstrate reversible transformers' effectiveness: (1) IWSLT'14 German-English (De-En), which consists of 160K training sentence pairs. (2) WMT'19 English-Lithuanian (En-Lt), which consists of 800K training sentence pairs. (3) WMT'14 English-German (En-De), which consists of 4.5M training sentence pairs. (4) WMT'14 French-English (En-Fr), which consists of 36M training sentence pairs. Tokenization is done by Moses[2]. We employ BPE (Sennrich et al., 2016) to generate a shared vocabulary for each language pair. The BPE merge operation numbers are 10K (IWSLT'14 De-En), 20K (WMT'19 En-Lt), 32K (WMT'14 En-De), 40K (WMT'14 En-Fr). The evaluation metric is *BLEU* (Papineni et al., 2002). We use beam search for test datasets with a beam size of 8 and a length penalty of 0.7.

Architectures We experiment with all architectures proposed in Section 2.2. Multi-split based models have larger hidden dimensions than vanilla transformers do. We use a smaller embedding size than the hidden size by factorizing the word embedding matrix. N is the vocabulary size, d is the hidden size. The original word embedding matrix $E \in R^{N \times d}$ is factorized into a multiplication of two matrices of size $N \times l$ and $l \times d$, where $l \ll d$. We denote l as the embedding size. The embedding size for each language pair is 128 (IWSLT'14 De-En), 256 (WMT'19 En-Lt, WMT'14 En-De base models), 512 (WMT'14 En-De and WMT'14 En-Fr large models). For a specific language pair, we manage to ensure almost identical parameter sizes across different model architectures. One can refer to Appendix A for some details.

Training All models are trained on 8 RTX 2080Ti GPU cards with a mini-batch of 3584 tokens unless otherwise stated. We use the same learning rate scheduling strategy as (Vaswani et al., 2017) does with a warmup step of 4000. The learning rates are set to 5×10^{-4} (IWSLT'14 De-En), 7×10^{-4} (WMT'19 En-Lt, WMT'14 En-De base). The dropout probability and label smoothing factor are all set to 0.1. For training large models in Section 3.4, we increase the dropout probability to 0.3 and the learning rate to 1×10^{-3}. We also accumulate gradients for 16 batches.

3.2 Machine Translation Results

To make comparisons between various architectures, we carry experiments on all corpora except WMT'14 En-Fr. Results are summarized in Table 1. In general, the best reversible architecture can outperform the transformer baseline by 1.1 (IWSTL'14 De-En), 1.5 (WMT'19 En-Lt) and 0.8 (WMT'14 En-De) BLEU points.

All models we propose deliver similar or superior performance to the vanilla transformer. **SD-REV-2** (2 means the split number is 2) is almost as good as **SIM-REV** with only half the computational complexity. For **SD-REV**, translation performance increases as the split number becomes larger. A higher split number means more interaction between separate splits, which may benefit the translation quality. The good performance of **FD-REV** further indicates that interactions between splits should be encouraged. **FD-REV** translates best among different architectures. Increasing the split number is not necessary for **FD-REV**, since it

already encodes information from different splits.

The remaining experiments are organized as follows: (1) In Section 3.3, we apply splits shuffle and self ensemble to the best models for each language pair. (2) In Section 3.4, we experiment with large model size for two large corpora, namely, WMT'14 En-De and WMT'14 En-Fr. We also try splits shuffle and self ensemble to validate their effectiveness.

3.3 Splits Shuffle and Self Ensemble

In this section, we focus on fine-tuning techniques to boost translation performance. After model convergence when training with Algorithm 1, we apply splits shuffle or self ensemble for fifteen epochs (IWSLT'14 De-En), five epochs (WMT'19 En-Lt) and one epoch (WMT'14 En-De). For the shuffle probability p, we use 0.3. Results are also summarized in Table 1.

Both fine-tuning techniques yield a performance gain over the original model. Splits shuffle is slightly better than self ensemble. Also, splits shuffle does not increase inference-time computational cost while self ensemble does. Several interesting phenomena are worth mentioning. First, the final validation perplexity decreases for splits shuffle and increases for self ensemble. Since both techniques are helpful, it is reasonable to think that splits shuffle indeed enhances model performance while self

ensemble benefits more from the ensemble process. Second, a combination of splits shuffle and self ensemble fails to converge. The combination task may be too challenging for the model to learn even the model is already in a sub-optimal state. Third, we can use splits shuffle and self ensemble from the beginning. However, such complicated training objectives also bring no performance gain. Details can be found in Appendix B.

3.4 Performance and Memory Consumptions of Large Models

In this section, we investigate large-scale reversible transformers. Experiments focus on two aspects. First, whether reversible models' performance is comparable or even better than the non-reversible models? Second, how much GPU memory can be saved when using Algorithm 1 for backpropagation (BP). We choose **FD-REV-2** which performs best for WMT'14 En-De in Section 3.2. The hidden dimension is doubled, resulting in a similar parameter size with other large-scale models.

As shown in Table 2, **FD-REV-2** achieves comparable results in both datasets. The fine-tuning techniques in Section 2.4 offer a chance to enhance model performance further. We follow the settings for WMT'14 En-De in Section 3.3 and find out that large-scale models benefit more from splits shuffle and self ensemble. We can surpass various strong baselines by using splits shuffle for only one epoch of fine-tuning. Specifically, we achieve 30.0 BLEU points for WMT'14 En-De and 43.5 BLEU points for WMT'14 En-Fr.

We also compare the training memory consumption between three different settings: (1) Training Transformer-Big with conventional BP. (2) Training **FD-REV-2** with conventional BP. (3) Training **FD-REV-2** with Algorithm 1. WMT'14 En-De is the training dataset. We use a batch size of 2390 tokens and carry out one epoch of training. Figure 4 illustrates the memory consumptions of three training settings. Transformer-Big and **FD-REV-2** are similar to each other in GPU memory consumption. Reversible BP with Algorithm 1 removes the need to store activations for most layers, requiring about half of the GPU memory as conventional BP does.

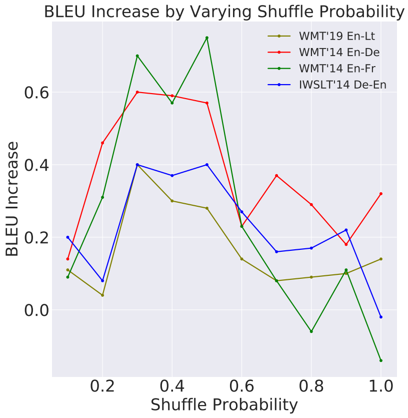

Figure 5: Effects of Shuffle Probability p

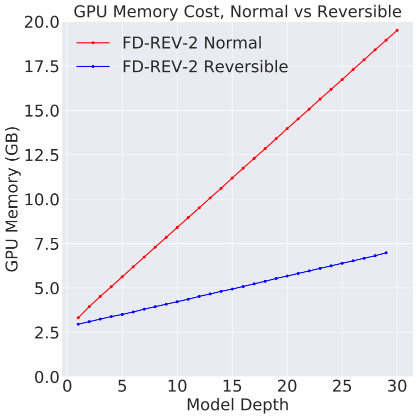

Figure 6: GPU Memory Consumption vs. Depth

4 Analysis

Splits Shuffle Probability We study the impact of splits shuffle probability p. For all language pairs, we use the best models as mentioned in Section 3.3 and Section 3.4. The results are summarized in Figure 5. We find out that a medium p value ($0.3 \leq p \leq 0.5$) yields the largest BLEU increase. A small p value is insufficient to enhance model generalization ability since the model has already been optimized for several epochs. Meanwhile, a very large p value makes the model highly unstable and hard to converge.

ReZero We study the impact of the ReZero technique. ReZero works as a substitution for layer normalization (LN). We can not apply LN to each layer's output O due to the requirement of reversibility. Instead, we can apply LN to each output split O_i. We compare using ReZero with using LN on O_i. Table 3 shows the results. Translation performance drops severely and the model converges more slowly. Therefore we choose to use ReZero throughout our experiments.

Reversible Training vs. Normal Training Reversible training saves GPU memory. However, reconstructing activations over many layers can introduce numerical errors. Inaccurate gradients may hurt model performance, so that it is important to compare the model performance between using reversible training and conventional backpropagation (BP). As shown in Table 3, reversible training does not hurt model performance. Also, since we update the model parameters for the same number of times, the convergence speed is almost identical between reversible training and conventional BP.

Memory Consumption of Deep Models Reversible transformers are more memory efficient when the model gets deeper. We validate this argument with a simple experiment. First, we get a mini-batch of 2390 tokens. Then, one step of parameter update is done by conventional BP or reversible training. We gradually increase the model depth and keep a record of the corresponding memory consumption in a single RTX TITAN GPU card. Results are shown in Figure 6. Deeper models mean more activations to store when using conventional BP, while reversible training only needs to store the extra model parameters. The memory consumption gap can be up to 12.6 GB when we use a 30-layers encoder and a 30-layers decoder.

Computational Overhead Roughly speaking, our proposed network is composed mostly of fully connected (FC) layers. For an FC layer with N connections, the forward and backward passes require approximately N and $2N$ add-multiply operations, respectively. As the reconstruction during backpropagation (BP) adds another N add-multiply operations, training with Algorithm 1 will be 33% slower. We compare the training speed of 4 structures, namely, **FD-REV-2-base**, **FD-REV-2-big**, **Transformer-base**, **Transformer-big**. We train on WMT'14 En-De for one epoch, using a batch size of 3584 tokens. Experiments are done on a single RTX Titan GPU card with 24 GB memory. The speed measurement is words per second (wps).

Structures	**use-rev**	**Speed (wps)**
FD-REV-2-base	×	10320
FD-REV-2-base	✓	7831
FD-REV-2-big	×	3735
FD-REV-2-big	✓	2788
Transformer-base	×	10081
Transformer-big	×	3879

Table 4: Training speed comparison between Transformers and our best reversible networks. The term **use-rev** being ✓ means training with Algorithm 1. Otherwise, we train the network with conventional backpropagation.

From Table 4, we can see that **FD-REV-2** trains almost as fast as vanilla Transformers when employing conventional BP. The apply of Algorithm 1 adds about 33% to 38% training time, which in turn saves about half the memory consumption.

5 Related Work

Reversible Networks The idea of reversible training without storing activations was first introduced by RevNets (Gomez et al., 2017). Jacobsen et al. (2018) attempted to use RevNets to learn representations without loss of information. Chang et al. (2018) associated well-posed ODEs with reversible networks. MacKay et al. (2018) extended RevNets to recurrent networks. Behrmann et al. (2019) showed that a simple normalization step could make standard ResNet architectures invertible. Generative flows are often combined with reversible networks. Kingma and Dhariwal (2018) used invertible convolutions to train a generative model. Later works (Huang et al., 2018; Tran et al., 2019; Ma et al., 2019) studied generative flows with reversible networks in discrete data.

Memory-Efficient Transformers Creating memory-efficient transformers has attracted immense interest in recent years. Most works focus on proposing an optimized version of the attention module. Liu et al. (2018); Child et al. (2019); Kitaev et al. (2020); Ainslie et al. (2020); Tay et al. (2020b) limited the attention span to local neighborhoods. Wang et al. (2020a); Tay et al. (2020a) employed low rank approximations for attention matrices. Roy et al. (2020) achieved sparse attention by k-mean clustering. Katharopoulos et al. (2020) used a kernel-based self-attention to reduce memory consumption. (Ho et al., 2019) operates on multi-dimensional tensors and applies multiple attentions, each along a single axis of the input tensor. Several works (Wu et al., 2019; Lioutas and Guo, 2020; Beltagy et al., 2020; Zaheer et al., 2020; Wu et al., 2020) incorporate convolution networks into transformers. Except for inventing new attention modules, weight sharing (Dehghani et al., 2019; Bai et al., 2019; Lan et al., 2020) is another practical approach to decreasing the memory burden. Reversible models are orthogonal to these approaches. A combination of reversible models and variants of transformers can further reduce memory consumption.

6 Conclusion

We have presented three types of multi-split based reversible transformers which outperform vanilla transformers. During backpropagation, activations for most layers need not be stored in memory because they can be reconstructed. Furthermore, we have proposed two fine-tuning techniques, namely, splits shuffle and self ensemble. Both techniques are easy to implement, and only a few fine-tuning epochs are sufficient for boosting translation performance. Our approach has beaten several strong baselines in two large datasets with fewer model parameters and much less training memory. Specifically, we have achieved 30.0 BLEU points in WMT'14 En-De and 43.5 BLEU points in WMT'14 En-Fr. Also, one can transform other network structures into their reversible versions by applying our methods. We would explore more computer vision or natural language processing tasks to widen reversible networks' applicability.

A Model Configuration

Table 5 details the model hyper-parameters. As we use a factorized word embedding matrix, the embedding size l is smaller than the hidden dimension d. The hidden size d increases with the number of splits n to ensure a similar parameter size for a certain dataset. Another thing worth mentioning is that **SD-REV** and **FD-REV** have identical parameter sizes as long as they have the same number of splits n, embedding size l and hidden size d. Thus, we do not differentiate between **SD-REV** and **FD-REV** in Table 5.

B More Results on Splits Shuffle and Self Ensemble

We provide more experimental results on splits shuffle and self ensemble as shown in Figure 7 and Figure 8. Using any of the techniques from the beginning tend to hurt the model performance. Meanwhile, fine-tuning with splits shuffle or self ensemble after model convergence can bring some performance gain. A combination of splits shuffle and self ensemble fails to converge when limiting the number of fine-tuning epochs (15 epochs for IWSLT'14 De-En, 5 epochs for WMT'19 En-Lt, 1 epoch for WMT'14 En-De).

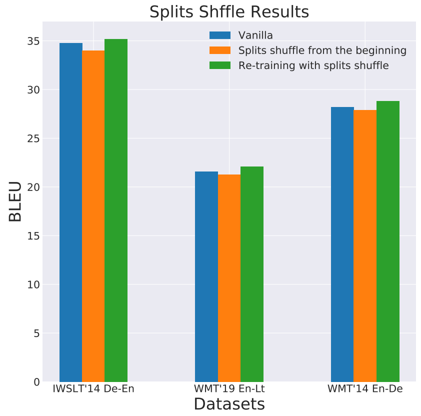

Figure 7: Splits shuffle results. No splits shuffle vs. Fine-tuning vs. Training from the beginning

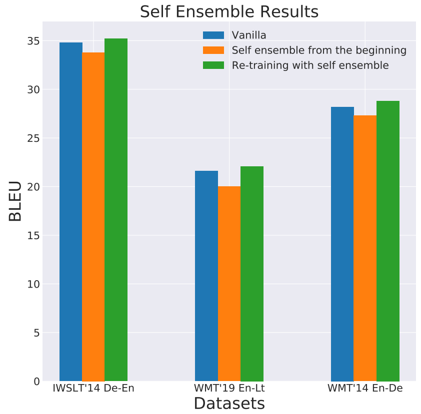

Figure 8: Self ensemble results. No self ensemble vs. Fine-tuning vs. Training from the beginning

Dataset	n	l	d

Exploiting Cloze Questions for Few Shot Text Classification and Natural Language Inference

Abstract

Some NLP tasks can be solved in a fully unsupervised fashion by providing a pretrained language model with "task descriptions" in natural language (e.g., Radford et al., 2019). While this approach underperforms its supervised counterpart, we show in this work that the two ideas can be combined: We introduce Pattern-Exploiting Training (PET), a semi-supervised training procedure that reformulates input examples as cloze-style phrases to help language models understand a given task. These phrases are then used to assign soft labels to a large set of unlabeled examples. Finally, standard supervised training is performed on the resulting training set. For several tasks and languages, PET outperforms supervised training and strong semi-supervised approaches in low-resource settings by a large margin.[1]

1 Introduction

Learning from examples is the predominant approach for many NLP tasks: A model is trained on a set of labeled examples from which it then generalizes to unseen data. Due to the vast number of languages, domains and tasks and the cost of annotating data, it is common in real-world uses of NLP to have only a small number of labeled examples, making *few-shot learning* a highly important research area. Unfortunately, applying standard supervised learning to small training sets often performs poorly; many problems are difficult to grasp from just looking at a few examples. For instance, assume we are given the following pieces of text:

- T_1: This was the best pizza I've ever had.
- T_2: You can get better sushi for half the price.
- T_3: Pizza was average. Not worth the price.

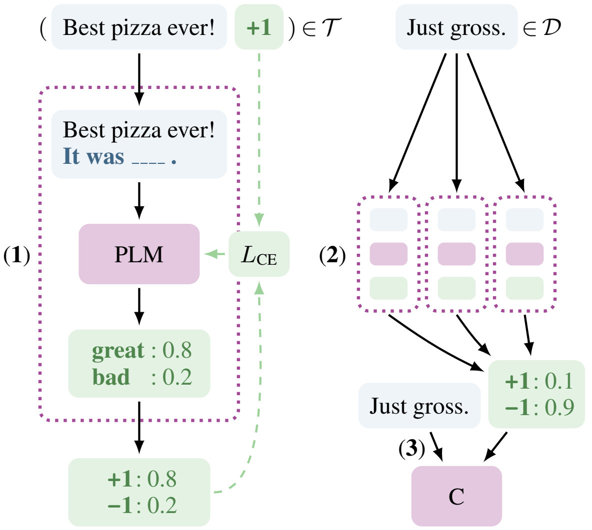

Figure 1: PET for sentiment classification. **(1)** A number of patterns encoding some form of task description are created to convert training examples to cloze questions; for each pattern, a pretrained language model is finetuned. **(2)** The ensemble of trained models annotates unlabeled data. **(3)** A classifier is trained on the resulting soft-labeled dataset.

Furthermore, imagine we are told that the labels of T_1 and T_2 are l and l', respectively, and we are asked to infer the correct label for T_3. Based only on these examples, this is impossible because plausible justifications can be found for both l and l'. However, if we know that the underlying task is to identify whether the text says anything about prices, we can easily assign l' to T_3. This illustrates that solving a task from only a few examples becomes much easier when we also have a *task description*, i.e., a textual explanation that helps us *understand* what the task is about.

With the rise of pretrained language models (PLMs) such as GPT (Radford et al., 2018), BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), the idea of providing task descriptions has become feasible for neural architectures: We can

---

[1] Our implementation is publicly available at `https://github.com/timoschick/pet`.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 255–269
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

simply append such descriptions in natural language to an input and let the PLM predict continuations that solve the task (Radford et al., 2019; Puri and Catanzaro, 2019). So far, this idea has mostly been considered in zero-shot scenarios where no training data is available at all.

In this work, we show that providing task descriptions can successfully be combined with standard supervised learning in few-shot settings: We introduce **P**attern-**E**xploiting **T**raining (PET), a semi-supervised training procedure that uses natural language patterns to reformulate input examples into cloze-style phrases. As illustrated in Figure 1, PET works in three steps: First, for each pattern a separate PLM is finetuned on a small training set $\mathcal{T}$. The ensemble of all models is then used to annotate a large unlabeled dataset $\mathcal{D}$ with soft labels. Finally, a standard classifier is trained on the soft-labeled dataset. We also devise iPET, an iterative variant of PET in which this process is repeated with increasing training set sizes.

On a diverse set of tasks in multiple languages, we show that given a small to medium number of labeled examples, PET and iPET substantially outperform unsupervised approaches, supervised training and strong semi-supervised baselines.

2 Related Work

Radford et al. (2019) provide hints in the form of natural language patterns for zero-shot learning of challenging tasks such as reading comprehension and question answering (QA). This idea has been applied to unsupervised text classification (Puri and Catanzaro, 2019), commonsense knowledge mining (Davison et al., 2019) and argumentative relation classification (Opitz, 2019). Srivastava et al. (2018) use task descriptions for zero-shot classification but require a semantic parser. For relation extraction, Bouraoui et al. (2020) automatically identify patterns that express given relations. McCann et al. (2018) rephrase several tasks as QA problems. Raffel et al. (2020) frame various problems as language modeling tasks, but their patterns only loosely resemble natural language and are unsuitable for few-shot learning.[2]

Another recent line of work uses cloze-style phrases to probe the knowledge that PLMs acquire during pretraining; this includes probing for factual and commonsense knowledge (Trinh and Le, 2018; Petroni et al., 2019; Wang et al., 2019; Sakaguchi et al., 2020), linguistic capabilities (Ettinger, 2020; Kassner and Schütze, 2020), understanding of rare words (Schick and Schütze, 2020), and ability to perform symbolic reasoning (Talmor et al., 2019). Jiang et al. (2020) consider the problem of finding the best pattern to express a given task.

Other approaches for few-shot learning in NLP include exploiting examples from related tasks (Yu et al., 2018; Gu et al., 2018; Dou et al., 2019; Qian and Yu, 2019; Yin et al., 2019) and using data augmentation (Xie et al., 2020; Chen et al., 2020); the latter commonly relies on back-translation (Sennrich et al., 2016), requiring large amounts of parallel data. Approaches using textual class descriptors typically assume that abundant examples are available for a subset of classes (e.g., Romera-Paredes and Torr, 2015; Veeranna et al., 2016; Ye et al., 2020). In contrast, our approach requires no additional labeled data and provides an intuitive interface to leverage task-specific human knowledge.

The idea behind iPET – training multiple generations of models on data labeled by previous generations – bears resemblance to self-training and bootstrapping approaches for word sense disambiguation (Yarowsky, 1995), relation extraction (Brin, 1999; Agichtein and Gravano, 2000; Batista et al., 2015), parsing (McClosky et al., 2006; Reichart and Rappoport, 2007; Huang and Harper, 2009), machine translation (Hoang et al., 2018), and sequence generation (He et al., 2020).

3 Pattern-Exploiting Training

Let M be a masked language model with vocabulary V and mask token $\_\_\_ \in V$, and let $\mathcal{L}$ be a set of labels for our target classification task A. We write an input for task A as a sequence of phrases $\mathbf{x} = (s_1, \dots, s_k)$ with $s_i \in V^*$; for example, $k = 2$ if A is textual inference (two input sentences). We define a *pattern* to be a function P that takes $\mathbf{x}$ as input and outputs a phrase or sentence $P(\mathbf{x}) \in V^*$ that contains exactly one mask token, i.e., its output can be viewed as a cloze question. Furthermore, we define a *verbalizer* as an injective function $v : \mathcal{L} \rightarrow V$ that maps each label to a word from M's vocabulary. We refer to (P, v) as a *pattern-verbalizer pair* (PVP).

Using a PVP (P, v) enables us to solve task A as follows: Given an input $\mathbf{x}$, we apply P to obtain an input representation $P(\mathbf{x})$, which is then processed

---

[2] For example, they convert inputs (a, b) for recognizing textual entailment (RTE) to "rte sentence1: a sentence2: b", and the PLM is asked to predict strings like "not_entailment".

by M to determine the label $y \in \mathcal{L}$ for which $v(y)$ is the most likely substitute for the mask. For example, consider the task of identifying whether two sentences a and b contradict each other (label y_0) or agree with each other (y_1). For this task, we may choose the pattern $P(a, b) =$ a? ____, b. combined with a verbalizer v that maps y_0 to "Yes" and y_1 to "No". Given an example input pair

$$\mathbf{x} = (\text{Mia likes pie, Mia hates pie}),$$

the task now changes from having to assign a label without inherent meaning to answering whether the most likely choice for the masked position in

$$P(\mathbf{x}) = \text{Mia likes pie? \_\_\_\_, Mia hates pie.}$$

is "Yes" or "No".

3.1 PVP Training and Inference

Let $\mathbf{p} = (P, v)$ be a PVP. We assume access to a small training set $\mathcal{T}$ and a (typically much larger) set of unlabeled examples $\mathcal{D}$. For each sequence $\mathbf{z} \in V^*$ that contains exactly one mask token and $w \in V$, we denote with $M(w \mid \mathbf{z})$ the unnormalized score that the language model assigns to w at the masked position. Given some input $\mathbf{x}$, we define the score for label $l \in \mathcal{L}$ as

$$s_{\mathbf{p}}(l \mid \mathbf{x}) = M(v(l) \mid P(\mathbf{x}))$$

and obtain a probability distribution over labels using softmax:

$$q_{\mathbf{p}}(l \mid \mathbf{x}) = \frac{e^{s_{\mathbf{p}}(l \mid \mathbf{x})}}{\sum_{l' \in \mathcal{L}} e^{s_{\mathbf{p}}(l' \mid \mathbf{x})}}$$

We use the cross-entropy between $q_{\mathbf{p}}(l \mid \mathbf{x})$ and the true (one-hot) distribution of training example $(\mathbf{x}, l)$ – summed over all $(\mathbf{x}, l) \in \mathcal{T}$ – as loss for finetuning M for $\mathbf{p}$.

3.2 Auxiliary Language Modeling

In our application scenario, only a few training examples are available and catastrophic forgetting can occur. As a PLM finetuned for some PVP is still a language model at its core, we address this by using language modeling as auxiliary task. With L_{CE} denoting cross-entropy loss and L_{MLM} language modeling loss, we compute the final loss as

$$L = (1 - \alpha) \cdot L_{\text{CE}} + \alpha \cdot L_{\text{MLM}}$$

This idea was recently applied by Chronopoulou et al. (2019) in a data-rich scenario. As L_{MLM} is typically much larger than L_{CE}, in preliminary experiments, we found a small value of $\alpha = 10^{-4}$ to consistently give good results, so we use it in all our experiments. To obtain sentences for language modeling, we use the unlabeled set $\mathcal{D}$. However, we do not train directly on each $\mathbf{x} \in \mathcal{D}$, but rather on $P(\mathbf{x})$, where we never ask the language model to predict anything for the masked slot.

3.3 Combining PVPs

A key challenge for our approach is that in the absence of a large development set, it is hard to identify which PVPs perform well. To address this, we use a strategy similar to knowledge distillation (Hinton et al., 2015). First, we define a set $\mathcal{P}$ of PVPs that intuitively make sense for a given task A. We then use these PVPs as follows:

(1) We finetune a separate language model $M_{\mathbf{p}}$ for each $\mathbf{p} \in \mathcal{P}$ as described in Section 3.1. As $\mathcal{T}$ is small, this finetuning is cheap even for a large number of PVPs.

(2) We use the ensemble $\mathcal{M} = \{M_{\mathbf{p}} \mid \mathbf{p} \in \mathcal{P}\}$ of finetuned models to annotate examples from $\mathcal{D}$. We first combine the unnormalized class scores for each example $\mathbf{x} \in \mathcal{D}$ as

$$s_{\mathcal{M}}(l \mid \mathbf{x}) = \frac{1}{Z} \sum_{\mathbf{p} \in \mathcal{P}} w(\mathbf{p}) \cdot s_{\mathbf{p}}(l \mid \mathbf{x})$$

where $Z = \sum_{\mathbf{p} \in \mathcal{P}} w(\mathbf{p})$ and the $w(\mathbf{p})$ are weighting terms for the PVPs. We experiment with two different realizations of this weighing term: either we simply set $w(\mathbf{p}) = 1$ for all $\mathbf{p}$ or we set $w(\mathbf{p})$ to be the accuracy obtained using $\mathbf{p}$ on the training set *before* training. We refer to these two variants as *uniform* and *weighted*. Jiang et al. (2020) use a similar idea in a zero-shot setting.

We transform the above scores into a probability distribution q using softmax. Following Hinton et al. (2015), we use a temperature of $T = 2$ to obtain a suitably soft distribution. All pairs $(\mathbf{x}, q)$ are collected in a (soft-labeled) training set $\mathcal{T}_C$.

(3) We finetune a PLM C with a standard sequence classification head on $\mathcal{T}_C$.

The finetuned model C then serves as our classifier for A. All steps described above are depicted in Figure 2; an example is shown in Figure 1.

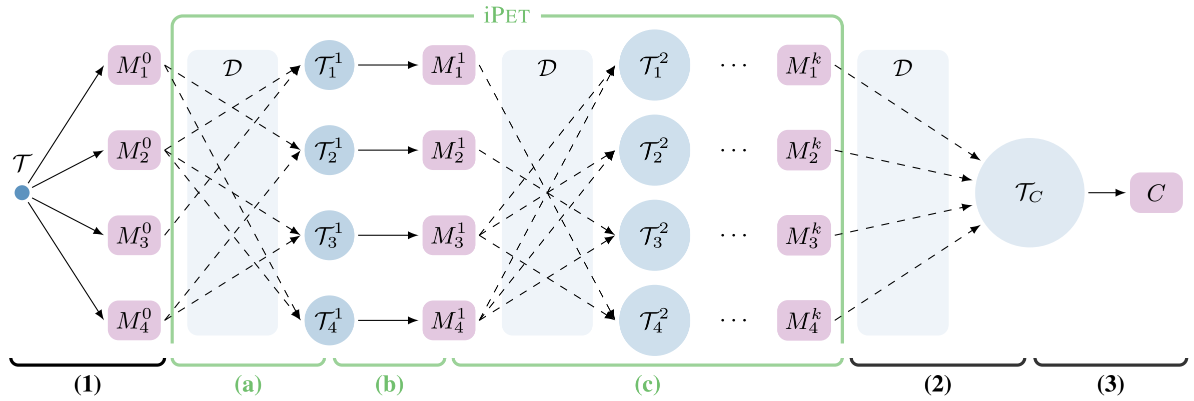

Figure 2: Schematic representation of PET (1-3) and iPET (a-c). **(1)** The initial training set is used to finetune an ensemble of PLMs. **(a)** For each model, a random subset of other models generates a new training set by labeling examples from $\mathcal{D}$. **(b)** A new set of PET models is trained using the larger, model-specific datasets. **(c)** The previous two steps are repeated k times, each time increasing the size of the generated training sets by a factor of d. **(2)** The final set of models is used to create a soft-labeled dataset $\mathcal{T}_C$. **(3)** A classifier C is trained on this dataset.

3.4 Iterative PET (iPET)

Distilling the knowledge of all individual models into a single classifier C means they cannot learn from each other. As some patterns perform (possibly much) worse than others, the training set $\mathcal{T}_C$ for our final model may therefore contain many mislabeled examples.

To compensate for this shortcoming, we devise iPET, an iterative variant of PET. The core idea of iPET is to train several *generations* of models on datasets of increasing size. To this end, we first enlarge the original dataset $\mathcal{T}$ by labeling selected examples from $\mathcal{D}$ using a random subset of trained PET models (Figure 2a). We then train a new generation of PET models on the enlarged dataset (b); this process is repeated several times (c).

More formally, let $\mathcal{M}^0 = \{M_1^0, \dots, M_n^0\}$ be the initial set of PET models finetuned on $\mathcal{T}$, where each M_i^0 is trained for some PVP $\mathbf{p}_i$. We train k generations of models $\mathcal{M}^1, \dots, \mathcal{M}^k$ where $\mathcal{M}^j = \{M_1^j, \dots, M_n^j\}$ and each M_i^j is trained for $\mathbf{p}_i$ on its own training set $\mathcal{T}_i^j$. In each iteration, we multiply the training set size by a fixed constant $d \in \mathbb{N}$ while maintaining the label ratio of the original dataset. That is, with $c_0(l)$ denoting the number of examples with label l in $\mathcal{T}$, each $\mathcal{T}_i^j$ contains $c_j(l) = d \cdot c_{j-1}(l)$ examples with label l. This is achieved by generating each $\mathcal{T}_i^j$ as follows:

1. We obtain $\mathcal{N} \subset \mathcal{M}^{j-1} \setminus \{M_i^{j-1}\}$ by randomly choosing $\lambda \cdot (n-1)$ models from the previous generation with $\lambda \in (0, 1]$ being a hyperparameter.
2. Using this subset, we create a labeled dataset
$$\mathcal{T}_\mathcal{N} = \{(\mathbf{x}, \arg\max_{l \in \mathcal{L}} s_\mathcal{N}(l \mid \mathbf{x})) \mid \mathbf{x} \in \mathcal{D}\}\,.$$
For each $l \in \mathcal{L}$, we obtain $\mathcal{T}_\mathcal{N}(l) \subset \mathcal{T}_\mathcal{N}$ by randomly choosing $c_j(l) - c_0(l)$ examples with label l from $\mathcal{T}_\mathcal{N}$. To avoid training future generations on mislabeled data, we prefer examples for which the ensemble of models is confident in its prediction. The underlying intuition is that even without calibration, examples for which labels are predicted with high confidence are typically more likely to be classified correctly (Guo et al., 2017). Therefore, when drawing from $\mathcal{T}_\mathcal{N}$, we set the probability of each $(\mathbf{x}, y)$ proportional to $s_\mathcal{N}(l \mid \mathbf{x})$.
3. We define $\mathcal{T}_i^j = \mathcal{T} \cup \bigcup_{l \in \mathcal{L}} \mathcal{T}_\mathcal{N}(l)$. As can easily be verified, this dataset contains $c_j(l)$ examples for each $l \in \mathcal{L}$.

After training k generations of PET models, we use $\mathcal{M}^k$ to create $\mathcal{T}_C$ and train C as in basic PET.

With minor adjustments, iPET can even be used in a zero-shot setting. To this end, we define $\mathcal{M}^0$ to be the set of *untrained* models and $c_1(l) = 10/|\mathcal{L}|$ for all $l \in \mathcal{L}$ so that $\mathcal{M}^1$ is trained on 10 examples evenly distributed across all labels. As $\mathcal{T}_\mathcal{N}$ may not contain enough examples for some label l, we create all $\mathcal{T}_\mathcal{N}(l)$ by sampling from the 100 examples $\mathbf{x} \in \mathcal{D}$ for which $s_\mathcal{N}(l \mid x)$ is the highest, even if $l \neq \arg\max_{l \in \mathcal{L}} s_\mathcal{N}(l \mid x)$. For each subsequent generation, we proceed exactly as in basic iPET.

4 Experiments

We evaluate PET on four English datasets: Yelp Reviews, AG's News, Yahoo Questions (Zhang et al., 2015) and MNLI (Williams et al., 2018). Additionally, we use x-stance (Vamvas and Sennrich, 2020) to investigate how well PET works for other languages. For all experiments on English, we use RoBERTa large (Liu et al., 2019) as language model; for x-stance, we use XLM-R (Conneau et al., 2020). We investigate the performance of PET and all baselines for different training set sizes; each model is trained three times using different seeds and average results are reported.

As we consider a few-shot setting, we assume no access to a large development set on which hyperparameters could be optimized. Our choice of hyperparameters is thus based on choices made in previous work and practical considerations. We use a learning rate of $1 \cdot 10^{-5}$, a batch size of 16 and a maximum sequence length of 256. Unless otherwise specified, we always use the weighted variant of PET with auxiliary language modeling. For iPET, we set $\lambda = 0.25$ and $d = 5$; that is, we select 25% of all models to label examples for the next generation and quintuple the number of training examples in each iteration. We train new generations until each model was trained on at least 1000 examples, i.e., we set $k = \lceil \log_d(1000/|\mathcal{T}|) \rceil$. As we always repeat training three times, the ensemble $\mathcal{M}$ (or $\mathcal{M}^0$) for n PVPs contains $3n$ models. Further hyperparameters and detailed explanations for all our choices are given in Appendix B.

4.1 Patterns

We now describe the patterns and verbalizers used for all tasks. We use two vertical bars (‖) to mark boundaries between text segments.[3]

Yelp For the Yelp Reviews Full Star dataset (Zhang et al., 2015), the task is to estimate the rating that a customer gave to a restaurant on a 1- to 5-star scale based on their review's text. We define the following patterns for an input text a:

$$P_1(a) = \text{It was \_\_\_\_ . } a \qquad P_2(a) = \text{Just \_\_\_\_ ! } \| \; a$$

$$P_3(a) = a\text{. All in all, it was \_\_\_\_ .}$$

$$P_4(a) = a \; \| \; \text{In summary, the restaurant is \_\_\_\_ .}$$

We define a single verbalizer v for all patterns as

$$v(1) = \text{terrible} \quad v(2) = \text{bad} \quad v(3) = \text{okay}$$
$$v(4) = \text{good} \quad v(5) = \text{great}$$

AG's News AG's News is a news classification dataset, where given a headline a and text body b, news have to be classified as belonging to one of the categories *World* (1), *Sports* (2), *Business* (3) or *Science/Tech* (4). For $\mathbf{x} = (a, b)$, we define the following patterns:

$$P_1(\mathbf{x}) = \text{\_\_\_\_: } a \; b \qquad P_2(\mathbf{x}) = a \text{ (\_\_\_\_) } b$$

$$P_3(\mathbf{x}) = \text{\_\_\_\_ -- } a \; b \qquad P_4(\mathbf{x}) = a \; b \text{ (\_\_\_\_)}$$

$$P_5(\mathbf{x}) = \text{\_\_\_\_ News: } a \; b$$

$$P_6(\mathbf{x}) = \text{[Category: \_\_\_\_] } a \; b$$

We use a verbalizer that maps 1–4 to "World", "Sports", "Business" and "Tech", respectively.

Yahoo Yahoo Questions (Zhang et al., 2015) is a text classification dataset. Given a question a and an answer b, one of ten possible categories has to be assigned. We use the same patterns as for AG's News, but we replace the word "News" in P_5 with the word "Question". We define a verbalizer that maps categories 1–10 to "Society", "Science", "Health", "Education", "Computer", "Sports", "Business", "Entertainment", "Relationship" and "Politics".

MNLI The MNLI dataset (Williams et al., 2018) consists of text pairs $\mathbf{x} = (a, b)$. The task is to find out whether a implies b (0), a and b contradict each other (1) or neither (2). We define

$$P_1(\mathbf{x}) = \text{“}a\text{”? } \| \text{ \_\_\_\_, “}b\text{”} \qquad P_2(\mathbf{x}) = a\text{? } \| \text{ \_\_\_\_, } b$$

and consider two different verbalizers v_1 and v_2:

$$v_1(0) = \text{Wrong} \quad v_1(1) = \text{Right} \quad v_1(2) = \text{Maybe}$$
$$v_2(0) = \text{No} \quad v_2(1) = \text{Yes} \quad v_2(2) = \text{Maybe}$$

Combining the two patterns with the two verbalizers results in a total of 4 PVPs.

X-Stance The x-stance dataset (Vamvas and Sennrich, 2020) is a multilingual stance detection dataset with German, French and Italian examples. Each example $\mathbf{x} = (a, b)$ consists of a question a concerning some political issue and a comment b; the task is to identify whether the writer of b

---

[3] The way different segments are handled depends on the model being used; they may e.g. be assigned different embeddings (Devlin et al., 2019) or separated by special tokens (Liu et al., 2019; Yang et al., 2019). For example, "a ‖ b" is given to BERT as the input "[CLS] a [SEP] b [SEP]".

Line	Examples	Method	Yelp	AG's	Yahoo	MNLI (m/mm)
1	$\lvert\mathcal{T}\rvert = 0$	unsupervised (avg)	33.8 ±9.6	69.5 ±7.2	44.0 ±9.1	39.1 ±4.3 / 39.8 ±5.1

4.2 Results

English Datasets Table 1 shows results for English text classification and language understanding tasks; we report mean accuracy and standard deviation for three training runs. Lines 1–2 (L1–L2) show unsupervised performance, i.e., individual PVPs without *any* training (similar to Radford et al., 2018; Puri and Catanzaro, 2019); we give both average results across all PVPs (avg) and results for the PVP that works best on the test set (max). The large difference between both rows highlights the importance of coping with the fact that without looking at the test set, we have no means of evaluating which PVPs perform well. Zero-shot iPET clearly outperforms the unsupervised baselines for all datasets (L3 vs L1); on AG's News, it even performs better than standard supervised training with 1000 examples (L3 vs L13). With just 10 training examples, standard supervised learning does not perform above chance (L4). In contrast, PET (L5) performs much better than the fully unsupervised baselines (L1–L2); training multiple generations using iPET (L6) gives consistent improvements. As we increase the training set size, the performance gains of PET and iPET become smaller, but for both 50 and 100 examples, PET continues to considerably outperform standard supervised training (L8 vs L7, L11 vs L10) with iPET (L9, L12) still giving consistent improvements. For $|\mathcal{T}| = 1000$, PET has no advantage on AG's but still improves accuracy for all other tasks (L14 vs L13).[4]

Comparison with SotA We compare PET to UDA (Xie et al., 2020) and MixText (Chen et al., 2020), two state-of-the-art methods for semi-supervised learning in NLP that rely on data augmentation. Whereas PET requires that a task can be expressed using patterns and that such patterns be found, UDA and MixText both use backtranslation (Sennrich et al., 2016) and thus require thousands of labeled examples for training a machine translation model. We use RoBERTa (base) for our comparison as MixText is specifically tailored towards

---

[4] One of the three supervised MNLI runs for $|\mathcal{T}| = 1000$ underfitted the training data and performed extremely poorly. This run is excluded in the reported score (73.1/74.8).

Examples	Method	De	Fr	It
$\lvert\mathcal{T}\rvert = 1000$	supervised	43.3	49.5	41.0
	PET	**66.4**	**68.7**	**64.7**
$\lvert\mathcal{T}\rvert = 2000$	supervised	57.4	62.1	52.8
	PET	**69.5**	**71.7**	**67.3**
$\lvert\mathcal{T}\rvert = 4000$	supervised	63.2	66.7	58.7
	PET	**71.7**	**74.0**	**69.5**
$\mathcal{T}_{\text{De}}$, $\mathcal{T}_{\text{Fr}}$	supervised	76.6	76.0	71.0
	PET	**77.9**	**79.0**	**73.6**
$\mathcal{T}_{\text{De}} + \mathcal{T}_{\text{Fr}}$	sup. (*)	76.8	76.7	70.2
	supervised	77.6	79.1	75.9
	PET	**78.8**	**80.6**	**77.2**

Table 3: Results on x-stance intra-target for XLM-R (base) trained on subsets of $\mathcal{T}_{\text{De}}$ and $\mathcal{T}_{\text{Fr}}$ and for joint training on all data ($\mathcal{T}_{\text{De}} + \mathcal{T}_{\text{Fr}}$). (*): Best results for mBERT reported in Vamvas and Sennrich (2020).

a 12-layer Transformer (Vaswani et al., 2017). Both Xie et al. (2020) and Chen et al. (2020) use large development sets to optimize the number of training steps. We instead try several values for both approaches directly on the test set and only report the *best* results obtained. Despite this, Table 2 shows that PET and iPET substantially outperform both methods across all tasks, clearly demonstrating the benefit of incorporating human knowledge in the form of PVPs.

X-Stance We evaluate PET on x-stance to investigate (i) whether it works for languages other than English and (ii) whether it also brings improvements when training sets have medium size. In contrast to Vamvas and Sennrich (2020), we do not perform any hyperparameter optimization on dev and use a shorter maximum sequence length (256 vs 512) to speed up training and evaluation.

To investigate whether PET brings benefits even when numerous examples are available, we consider training set sizes of 1000, 2000, and 4000; for each of these configurations, we separately finetune French and German models to allow for a more straightforward downsampling of the training data. Additionally, we train models on the entire French ($\lvert\mathcal{T}_{\text{Fr}}\rvert = 11\,790$) and German ($\lvert\mathcal{T}_{\text{De}}\rvert = 33\,850$) training sets. In this case we do not have any additional unlabeled data, so we simply set $\mathcal{D} = \mathcal{T}$. For the French models, we use v_{En} and v_{Fr} as verbalizers and for German v_{En} and v_{De} (Section 4.1). Finally, we also investigate the performance of a model trained jointly on French and German data ($\lvert\mathcal{T}_{\text{Fr}} + \mathcal{T}_{\text{De}}\rvert = 45\,640$) using v_{En}, v_{Fr} and v_{De}.

Method	Yelp	AG's	Yahoo	MNLI
min	39.6	82.1	50.2	36.4
max	52.4	85.0	63.6	40.2
PET (no distillation)	51.7	87.0	62.8	40.6
PET uniform	52.7	87.3	**63.8**	**42.0**
PET weighted	**52.9**	**87.5**	**63.8**	41.8

Table 4: Minimum (min) and maximum (max) accuracy of models based on individual PVPs as well as PET with and without knowledge distillation ($\lvert\mathcal{T}\rvert = 10$).

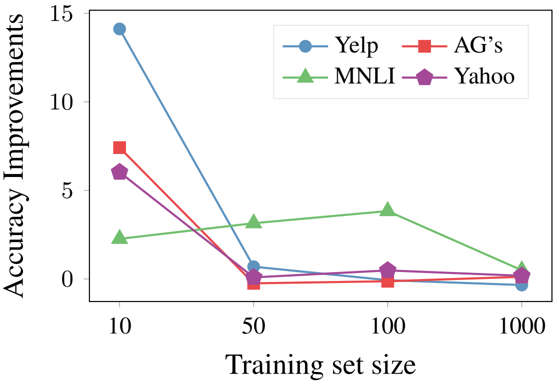

Figure 3: Accuracy improvements for PET due to adding L_{MLM} during training

Results are shown in Table 3; following Vamvas and Sennrich (2020), we report the macro-average of the F1 scores for labels 0 and 1, averaged over three runs. For Italian (column "It"), we report the average zero-shot cross-lingual performance of German and French models as there are no Italian training examples. Our results show that PET brings huge improvements across all languages even when training on much more than a thousand examples; it also considerably improves zero-shot cross-lingual performance.

5 Analysis

Combining PVPs We first investigate whether PET is able to cope with situations were some PVPs perform much worse than others. For $\lvert\mathcal{T}\rvert = 10$, Table 4 compares the performance of PET to that of the best and worst performing patterns after finetuning; we also include results obtained using the ensemble of PET models corresponding to individual PVPs without knowledge distillation. Even after finetuning, the gap between the best and worst pattern is large, especially for Yelp. However, PET is not only able to compensate for this, but even improves accuracies over using only the best-performing pattern across all tasks. Distillation brings consistent improvements over the ensemble; additionally, it significantly reduces the size of the

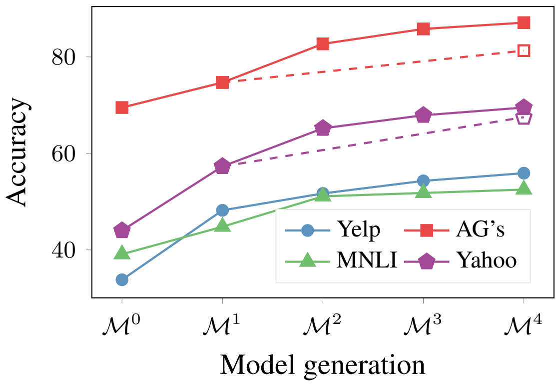

Figure 4: Average accuracy for each generation of models with iPET in a zero-shot setting. Accuracy on AG's News and Yahoo when skipping generation 2 and 3 is indicated through dashed lines.

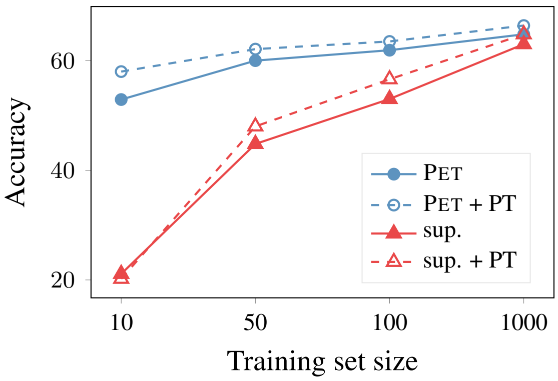

Figure 5: Accuracy of supervised learning (sup.) and PET both with and without pretraining (PT) on Yelp

final classifier. We find no clear difference between the uniform and weighted variants of PET.

Auxiliary Language Modeling We analyze the influence of the auxiliary language modeling task on PET's performance. Figure 3 shows performance improvements from adding the language modeling task for four training set sizes. We see that the auxiliary task is extremely valuable when training on just 10 examples. With more data, it becomes less important, sometimes even leading to worse performance. Only for MNLI, we find language modeling to consistently help.

Iterative PET To check whether iPET is able to improve models over multiple generations, Figure 4 shows the average performance of all generations of models in a zero-shot setting. Each additional iteration does indeed further improve the ensemble's performance. We did not investigate whether continuing this process for even more iterations gives further improvements.

Another natural question is whether similar results can be obtained with fewer iterations by increasing the training set size more aggressively. To answer this question, we skip generations 2 and 3 for AG's News and Yahoo and for both tasks directly let ensemble $\mathcal{M}^1$ annotate $10 \cdot 5^4$ examples for $\mathcal{M}^4$. As indicated in Figure 4 through dashed lines, this clearly leads to worse performance, highlighting the importance of only gradually increasing the training set size. We surmise that this is the case because annotating too many examples too early leads to a large percentage of mislabeled training examples.

In-Domain Pretraining Unlike our supervised baseline, PET makes use of the additional unlabeled dataset $\mathcal{D}$. Thus, at least some of PET's performance gains over the supervised baseline may arise from this additional in-domain data.

To test this hypothesis, we simply further pretrain RoBERTa on in-domain data, a common technique for improving text classification accuracy (e.g., Howard and Ruder, 2018; Sun et al., 2019). As language model pretraining is expensive in terms of GPU usage, we do so only for the Yelp dataset. Figure 5 shows results of supervised learning and PET both with and without this in-domain pretraining. While pretraining does indeed improve accuracy for supervised training, the supervised model still clearly performs worse than PET, showing that the success of our method is not simply due to the usage of additional unlabeled data. Interestingly, in-domain pretraining is also helpful for PET, indicating that PET leverages unlabeled data in a way that is clearly different from standard masked language model pretraining.

6 Conclusion

We have shown that providing task descriptions to pretrained language models can be combined with standard supervised training. Our proposed method, PET, consists of defining pairs of cloze question patterns and verbalizers that help leverage the knowledge contained within pretrained language models for downstream tasks. We finetune models for all pattern-verbalizer pairs and use them to create large annotated datasets on which standard classifiers can be trained. When the initial amount of training data is limited, PET gives large improvements over standard supervised training and strong semi-supervised approaches.

A Implementation

Our implementation of PET and iPET is based on the Transformers library (Wolf et al., 2020) and PyTorch (Paszke et al., 2017).

B Training Details

Except for the in-domain pretraining experiment described in Section 5, all of our experiments were conducted using a single GPU with 11GB RAM (NVIDIA GeForce GTX 1080 Ti).

B.1 Hyperparameter Choices

Relevant training hyperparameters for both individual PET models and the final classifier C as well as our supervised baseline are listed in Table 5. All hyperparameters were selected based on the following considerations and experiments:

Batch size / maximum length Both batch size and maximum sequence length (or block size) are chosen so that one batch fits into 11GB of GPU memory. As Devlin et al. (2019) and Liu et al. (2019) use larger batch sizes of 16–32, we accumulate gradients for 4 steps to obtain an effective batch size of 16.

Learning rate We found a learning rate of $5\mathrm{e}{-5}$ (as used by Devlin et al. (2019)) to often result in unstable training for regular supervised learning with no accuracy improvements on the training set. We therefore use a lower learning rate of $1\mathrm{e}{-5}$, similar to Liu et al. (2019). Experiments with various learning rates can be found in Appendix D.

Training steps As the number of training epochs recommended by Liu et al. (2019) in a data-rich scenario is in the range 2–10, we perform supervised training for 250 training steps, corresponding to 4 epochs when training on 1000 examples. For individual PET models, we subdivide each batch into one labeled example from $\mathcal{T}$ to compute L_{CE} and three unlabeled examples from $\mathcal{D}$ to compute L_{MLM}. Accordingly, we multiply the number of total training steps by 4 (i.e., 1000), so that the number of times each labeled example is seen remains constant ($16 \cdot 250 = 4 \cdot 1000$). For the final PET classifier, we train for 5000 steps due to the increased training set size (depending on the task, the unlabeled set $\mathcal{D}$ contains at least 20 000 examples). Deviating from the above, we always perform training for 3 epochs on x-stance to match the setup of Vamvas and Sennrich (2020) more closely. The effect of varying the number of training steps is further investigated in Appendix D.

Temperature We choose a temperature of 2 when training the final classifier following Hinton et al. (2015).

Auxiliary language modeling To find a suitable value of α for combining language modeling loss and cross-entropy loss, we first observed that in the early stages of training, the former is a few orders of magnitude higher than the latter for all tasks considered. We thus selected a range $\{1\mathrm{e}{-3}, 1\mathrm{e}{-4}, 1\mathrm{e}{-5}\}$ of reasonable choices for α and performed preliminary experiments on Yelp with 100 training examples to find the best value among these candidates. To this end, we split the training examples into a training set and a dev set using both a 90/10 split and a 50/50 split and took the value of α that maximizes average dev set accuracy. We adopt this value for all other tasks and training set sizes without further optimization.

Models per ensemble As we always train three models per pattern, for both iPET and training the final classifier C, the ensemble $\mathcal{M}$ (or $\mathcal{M}^0$) for n PVPs contains $3n$ models. This ensures consistency as randomly choosing any of the three models for each PVP would result in high variance. In preliminary experiments, we found this to have only little impact on the final model's performance.

iPET dataset size For iPET, we quintuple the number of training examples after each iteration ($d = 5$) so that only a small number of generations is required to reach a sufficient amount of labeled data. We did not choose a higher value because we presume that this may cause training sets for early generations to contain a prohibitively large amount of mislabeled data.

iPET dataset creation We create training sets for the next generation in iPET using 25% of the models in the current generation ($\lambda = 0.25$) because we want the training sets for all models to be diverse while at the same time, a single model should not have too much influence.

Others For all other hyperparameters listed in Table 5, we took the default settings of the Transformers library (Wolf et al., 2020).

B.2 Number of parameters

As PET does not require any additional learnable parameters, the number of parameters for both PET and iPET is identical to the number of parameters in the underlying language model: 355M for RoBERTa (large) and 270M for XLM-R (base).

B.3 Average runtime

Training a single PET classifier for 250 steps on one GPU took approximately 30 minutes; training for 1000 steps with auxiliary language modeling took 60 minutes. Depending on the task, labeling examples from $\mathcal{D}$ took 15–30 minutes per model. Training the final classifier C for 5000 steps on the soft-labeled dataset $\mathcal{T}_C$ took 2 hours on average.

B.4 Comparison with SotA

For comparing PET to UDA (Xie et al., 2020) and MixText (Chen et al., 2020), we reduce the number of unlabeled examples by half to speed up the required backtranslation step. We use the backtranslation script provided by Chen et al. (2020) with their recommended hyperparameter values and use both Russian and German as intermediate languages.

For MixText, we use the original implementation[5] and the default set of hyperparameters. Specifically, each batch consists of 4 labeled and 8 unlabeled examples, we use layers 7, 9 and 12 for mixing, we set $T = 5$, $\alpha = 16$, and use a learning rate of $5 \cdot 10^{-6}$ for RoBERTa and $5 \cdot 10^{-4}$ for the final classification layer. We optimize the number of training steps for each task and dataset size in the range $\{1000, 2000, 3000, 4000, 5000\}$.

For UDA, we use a PyTorch-based reimplementation[6]. We use the same batch size as for MixText and the hyperparameter values recommended by Xie et al. (2020); we use an exponential schedule for training signal annealing and a learning rate of $2 \cdot 10^{-5}$. We optimize the number of training steps for each task and dataset size in the range $\{500, 1000, 1500, \ldots, 10000\}$.

B.5 In-Domain Pretraining

For in-domain pretraining experiments described in Section 5, we use the language model finetuning script of the Transformers library (Wolf et al., 2020); all hyperparameters are listed in the last column of Table 5. Pretraining was performed on a total of 3 NVIDIA GeForce GTX 1080 Ti GPUs.

C Dataset Details

For each task and number of examples t, we create the training set $\mathcal{T}$ by collecting the first $t/|\mathcal{L}|$ examples per label from the original training set, where $|\mathcal{L}|$ is the number of labels for the task. Similarly, we construct the set $\mathcal{D}$ of unlabeled examples by selecting 10 000 examples per label and removing all labels. For evaluation, we use the official test set for all tasks except MNLI, for which we report results on the dev set; this is due to the limit of 2 submissions per 14 hours for the official MNLI test set. An overview of the number of test examples and links to downloadable versions of all used datasets can be found in Table 6.

Preprocessing In some of the datasets used, newlines are indicated through the character sequence "\n". As the vocabularies of RoBERTa and XLM-R do not feature a newline, we replace this sequence with a single space. We do not perform any other preprocessing, except shortening all examples to the maximum sequence length of 256 tokens. This is done using the *longest first* strategy implemented in the Transformers library. For PET, all input sequences are truncated *before* applying patterns.

Evaluation metrics For Yelp, AG's News, Yahoo and MNLI, we use accuracy. For x-stance, we report macro-average of F1 scores using the evaluation script of Vamvas and Sennrich (2020).

D Hyperparameter Importance

To analyze the importance of hyperparameter choices for PET's performance gains over supervised learning, we look at the influence of both the learning rate (LR) and the number of training steps on their test set accuracies.

We try values of $\{1\text{e}{-5}, 2\text{e}{-5}, 5\text{e}{-5}\}$ for the learning rate and $\{50, 100, 250, 500, 1000\}$ for the number of training steps. As this results in 30 different configurations for just one task and training set size, we only perform this analysis on Yelp with 100 examples, for which results can be seen in Figure 6. For supervised learning, the configuration used throughout the paper (LR $= 1\text{e}{-5}$, 250 steps) turns out to perform best whereas for PET, training for fewer steps consistently performs even better. Importantly, PET clearly outperforms regular supervised training regardless of the chosen learning rate and number of training steps.

E Automatic Verbalizer Search

Given a set of patterns $P_1, \ldots, P_n$, manually finding a verbalization $v(l)$ for each $l \in \mathcal{L}$ that represents the meaning of l well and corresponds to a single token in V can be difficult. We therefore devise *automatic verbalizer search* (AVS), a procedure that automatically finds suitable verbalizers given a training set $\mathcal{T}$ and a language model M.

Assuming we already have a PVP $\mathbf{p} = (P, v)$, we can easily check whether some token $t \in V$ is a good verbalization of $l \in \mathcal{L}$. To this end, we define $\mathbf{p}[l \leftarrow t] = (P, v')$, where v' is identical to v, except that $v'(l) = t$. Intuitively, if t represents l well, then $q_{\mathbf{p}[l \leftarrow t]}(l \mid \mathbf{x})$ (i.e., the probability M assigns to t given $P(\mathbf{x})$) should be high only for those examples $(\mathbf{x}, y) \in \mathcal{T}$ where $y = l$. We thus define the score of t for l given $\mathbf{p}$ as

$$s_l(t \mid \mathbf{p}) = \frac{1}{|\mathcal{T}_l|} \cdot \sum_{(\mathbf{x},y)\in\mathcal{T}_l} q_{\mathbf{p}[l\leftarrow t]}(l \mid \mathbf{x}) - \frac{1}{|\mathcal{T} \setminus \mathcal{T}_l|} \cdot \sum_{(\mathbf{x},y)\in\mathcal{T}\setminus\mathcal{T}_l} q_{\mathbf{p}[l\leftarrow t]}(l \mid \mathbf{x})$$

where $\mathcal{T}_l = \{(\mathbf{x}, y) \in \mathcal{T} : y = l\}$ is the set of all training examples with label l. While this allows us to easily compute the best verbalization for l as

$$\hat{t} = \arg\max_{t\in V} s_l(t \mid \mathbf{p}) \,,$$

it requires us to already know verbalizations $v(l')$ for all other labels l'.

AVS solves this problem as follows: We first assign random verbalizations to all labels and then repeatedly recompute the best verbalization for each label. As we do not want the resulting verbalizer to depend strongly on the initial random assignment, we simply consider multiple such assignments. Specifically, we define an initial probability distribution ρ_0 where for all $t \in V, l \in \mathcal{L}$, $\rho_0(t \mid l) = 1/|V|$ is the probability of choosing t as verbalization for l. For each $l \in \mathcal{L}$, we then sample k verbalizers $v_1, \ldots, v_k$ using ρ_0 to compute

$$s_l^k(t) = \frac{1}{n \cdot k} \sum_{i=1}^{n} \sum_{j=1}^{k} s_l(t \mid (P_i, v_j))$$

for all $t \in V$.[7] These scores enable us to define a probability distribution ρ_1 that more closely reflects a word's suitability as a verbalizer for a given label:

$$\rho_1(t \mid l) = \frac{1}{Z} \max(s_l^k(t), \epsilon)$$

where $Z = \sum_{t'\in V} \max(s_l^k(t'), \epsilon)$ and $\epsilon \geq 0$ ensures that ρ_1 is a proper probability distribution. We repeat this process to obtain a sequence of probability distributions $\rho_1, \ldots, \rho_{i_\text{max}}$. Finally, we choose the $m \in \mathbb{N}$ most likely tokens according to $\rho_{i_\text{max}}(t \mid l)$ as verbalizers for each l. During training and inference, we compute the unnormalized score $s_\mathbf{p}(y \mid \mathbf{x})$ for each label by averaging over its m verbalizers.

We analyze the performance of AVS for all tasks with $|\mathcal{T}| = 50$ training examples and set $k = 250$, $\epsilon = 10^{-3}$, $i_\text{max} = 5$ and $m = 10$.[8] To speed up the search, we additionally restrict our search space to tokens $t \in V$ that contain at least two alphabetic characters. Of these tokens, we only keep the 10 000 most frequent ones in $\mathcal{D}$.

Results are shown in Table 7. As can be seen, carefully handcrafted verbalizers perform much better than AVS; however, PET with AVS still considerably outperforms regular supervised training while eliminating the challenge of manually finding suitable verbalizers. Table 8 shows the most probable verbalizers found using AVS for the Yelp dataset. While most verbalizers for this dataset intuitively make sense, we found AVS to struggle with finding good verbalizers for three out of ten labels in the Yahoo dataset and for all MNLI labels.

	Yelp	**AG's**	**Yahoo**	**MNLI**
supervised	44.8	82.1	52.5	45.6
PET	**60.0**	**86.3**	**66.2**	**63.9**
PET + AVS	55.2	85.0	58.2	52.6

Table 7: Results for supervised learning, PET and PET with AVS (PET + AVS) after training on 50 examples

y	**Top Verbalizers**
1	worthless, BAD, useless, appalling
2	worse, slow, frustrating, annoying
3	edible, mixed, cute, tasty, Okay
4	marvelous, loved, love, divine, fab
5	golden, magical, marvelous, perfection

Table 8: Most probable verbalizers according to AVS for Yelp with 50 training examples

---

[7] Note that the score $s_l^k(t)$ jointly considers all patterns; in preliminary experiments, we found this to result in more robust verbalizers.

[8] We tried values of k and i_max in $\{250, 500, 1000\}$ and $\{5, 10, 20\}$, respectively, but found the resulting verbalizers to be almost identical.

CD^{2}CR: Co-reference Resolution Across Documents and Domains

Abstract

Cross-document co-reference resolution (CDCR) is the task of identifying and linking mentions to entities and concepts across many text documents. Current state-of-the-art models for this task assume that all documents are of the same type (e.g. news articles) or fall under the same theme. However, it is also desirable to perform CDCR across different domains (type or theme). A particular use case we focus on in this paper is the resolution of entities mentioned across scientific work and newspaper articles that discuss them. Identifying the same entities and corresponding concepts in both scientific articles and news can help scientists understand how their work is represented in mainstream media. We propose a new task and English language dataset for cross-document cross-domain co-reference resolution (CD^{2}CR). The task aims to identify links between entities across heterogeneous document types. We show that in this cross-domain, cross-document setting, existing CDCR models do not perform well and we provide a baseline model that outperforms current state-of-the-art CDCR models on CD^{2}CR. Our data set, annotation tool and guidelines as well as our model for cross-document cross-domain co-reference are all supplied as open access open source resources.

1 Introduction

Cross-document co-reference resolution (CDCR) is the task of recognising when multiple documents mention and refer to the same real-world entity or concept. CDCR is a useful NLP process that has many downstream applications. For example, CDCR carried out on separate news articles that refer to the same politician can facilitate inter-document sentence alignment required for stance detection and natural language inference models. Furthermore, CDCR can improve information retrieval and multi-document summarisation by grouping documents based on the entities that are mentioned within them.

Recent CDCR work (Dutta and Weikum, 2015; Barhom et al., 2019; Cattan et al., 2020) has primarily focused on resolution of entity mentions across news articles. Despite differences in tone and political alignment, most news articles are relatively similar in terms of grammatical and lexical structure. Work based on modern transformer networks such as BERT (Devlin et al., 2019) and ElMo (Peters et al., 2018) have been pre-trained on large news corpora and are therefore well suited to news-based CDCR (Barhom et al., 2019).

However, there are cases where CDCR across documents from different domains (i.e. that differ much more significantly in style, vocabulary and structure) is useful. One such example is the task of resolving references to concepts across scientific papers and related news articles. This can help scientists understand how their work is being presented to the public by mainstream media or facilitate fact checking of journalists' work (Wadden et al., 2020). A chatbot or recommender that is able to resolve references to current affairs in both news articles and user input could be more effective at suggesting topics that interest the user. Finally, it may be helpful for e-commerce companies to know when product reviews gathered from third party websites refer to one of their own listings. The work we present here focuses on the first cross-document, cross-domain co-reference-resolution (CD^{2}CR) use case, namely co-reference resolution between news articles and scientific papers.

The objective of CD^{2}CR is to identify co-referring entities from documents belonging to different domains. In this case co-reference resolution is made more challenging by the differences in language use (lexical but also syntactic) across the dif-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 270–280
April 19 - 23, 2021.

ferent domains. Specifically, authors of scientific papers aim to communicate novel scientific work in an accurate and unambiguous way by using precise scientific terminology. Whilst scientific journalists also aim to accurately communicate novel scientific work, their work is primarily funded by newspaper sales and thus they also aim to captivate as large an audience as possible. Therefore journalists tend to use simplified vocabulary and structure, creative and unexpected writing style, slang, simile, metaphor and exaggeration to make their work accessible, informative and entertaining in order to maximise readership (Louis and Nenkova, 2013).

Success at the CD^{2}CR task in this setting is dependent on context sensitive understanding of how the accessible but imprecise writing of journalists maps on to precise terminology used in scientific writing. For example, a recent study has found that "convalescent plasma derived from donors who have recovered from COVID-19 can be used to treat patients sick with the disease" [1]. A news article[2] discussing this work says that "...blood from recovered Covid-19 patients in the hope that transfusions...[can help to treat severely ill patients]" . In this example the task is to link 'blood' to 'convalescent plasma' and 'recovered Covid-19 patients' to 'donors'. These cross-document, cross-domain co-reference chains can be used as contextual anchors for downstream analysis of the two document settings via tasks such as natural language inference, stance detection and frame analysis.

The contributions in this paper are the following:

- A novel task setting for CDCR that is more challenging than those that already exist due to linguistic variation between different domains and document types (we call this CD^{2}CR).
- An open source English language CD^{2}CR dataset with 7602 co-reference pair annotations over 528 documents and detailed 11 page annotation guidelines (section 3.1).
- A novel annotation tool to support ongoing data collection and annotation for CD^{2}CR including a novel sampling mechanism for calculating inter-annotator agreement (Section 3.4).
- A series of experiments on our dataset using different baseline models and an in-depth capability-based evaluation of the best-performing baseline (Section 5)

2 Related Work

2.1 Co-reference Resolution

Intra-document co-reference resolution is a well understood task with mature training data sets (Weischedel et al., 2013) and academic tasks (Recasens et al., 2010). The current state of the art model by Joshi et al. (2020) is based on Lee et al. (2017, 2018) and uses a modern BERT-based (Devlin et al., 2019) architecture. Comparatively, CDCR, which involves co-reference resolution across multiple documents, has received less attention in recent years (Bagga and Baldwin, 1998; Rao et al., 2010; Dutta and Weikum, 2015; Barhom et al., 2019). Cattan et al. (2020) jointly learns both entity and event co-reference tasks, achieving current state of the art performance for CDCR, and as such provides a strong baseline for experiments in CD^{2}CR. Both Cattan et al. (2020) and Barhom et al. (2019) models are trained and evaluated using the ECB+ corpus (Cybulska and Vossen, 2014) which contains news articles annotated with both entity and event mentions.

2.2 Entity Linking

Entity Linking (EL) focuses on alignment of mentions in documents to resources in an external knowledge resource (Ji et al., 2010) such as SNOMED CT[3] or DBPedia[4]. EL is challenging due to the large number of pairwise comparisons between document mentions and knowledge resource entities that may need to be carried out. Raiman and Raiman (2018) provide state of the art performance by building on Ling et al. (2015)'s work in which an entity type system is used to limit the number of required pairwise comparisons to related types. Yin et al. (2019) achieved comparable results using a graph-traversal method to similarly constrain the problem space to candidates within a similar graph neighbourhood. EL can be considered a narrow sub-task of CDCR since it cannot resolve novel and rare entities or pronouns (Shen et al., 2015). Moreover EL's dependency on expensive-to-maintain external knowledge graphs is also problematic when limited human expertise is available.

[1] DOI: 10.1101/2020.03.16.20036145

[2] `https://tinyurl.com/ycnq9xg7`

[3] `https://tinyurl.com/yy7g4ttz`

[4] `https://wiki.dbpedia.org/`

Given these limitations, EL is inappropriate within our task setting, hence our CDCR-based approach.

2.3 Semantic Specialisation

Like earlier static vector language models, contextual language models such as BERT (Devlin et al., 2019) and ElMo (Peters et al., 2018) use distributional knowledge (Harris, 1954) inherent in large text corpora to learn context-aware word embeddings that can be used for downstream NLP tasks. However, these models do not learn about formal lexical constraints, often conflating different types of semantic relatedness (Ponti et al., 2018; Lauscher et al., 2020). This is a weakness of all distributional language models that is particularly problematic in the context of CD^2CR for entity mentions that are related but not co-referent (e.g. “Mars” and “Jupiter”) as shown in section 5.

A number of solutions have been proposed for adding lexical knowledge to static word embeddings (Yu and Dredze, 2014; Wieting et al., 2015; Ponti et al., 2018) but contextual language models have received comparatively less attention. Lauscher et al (2020) propose adding a lexical relation classification step to BERT’s language model pre-training phase to allow the model to integrate both lexical and distributional knowledge. Their model, LIBERT, has been shown to facilitate statistically-significant performance boosts on a variety of downstream NLP tasks.

3 Dataset creation

Our dataset is composed of pairs of news articles and scientific papers gathered automatically (Section 3.1). Our annotation process begins by obtaining summaries of the news and science document pairs (extractive news summaries and scientific abstracts, respectively) (Section 3.2). Candidate co-reference pairs from each summary-abstract pair are identified and scored automatically. (Section 3.3). Candidate co-reference pairs are then presented to human annotators via a bespoke annotation interface for scoring (Section 3.4). Annotation quality is measured on an ongoing basis as new candidates are added to the system (Section 3.5).

3.1 Data Collection

We have developed a novel data set that allows us to train and evaluate a CD^2CR model. The corpus is approximately 50% the size of the ECB+ corpus (918 documents) (Cybulska and Vossen, 2014) and is split into training, development and test sets (statistics for each subset are provided in Table 1). Each pair of documents consists of a scientific paper and a newspaper article that discusses the scientific work. In order to detect pairs of documents, we follow the approach of (Ravenscroft et al., 2018), using approximate matching of author name and affiliation metadata, date of publishing and exact DOI matching where available to connect news articles to scientific publications.

Subset	Documents	Mentions	Clusters
Train	300	4,604	426
Dev	142	1,821	199
Test	86	1,177	101

Table 1: Total individual documents, mentions, co-reference clusters of each subset excluding singletons.

We built a web scraper that scans for new articles from the ‘Science’ and ‘Technology’ sections of 3 well-known online news outlets (BBC, The Guardian, New York Times) and press releases from Eurekalert, a widely popular scientific press release aggregator. Once a newspaper article and related scientific paper are detected, the full text from the news article and the scientific paper abstract and metadata are stored. Where available the full scientific paper content is also collected. We ran the scraper between April and June 2020 collecting news articles and scientific papers including preprints discussing a range of topics such as astronomy, computer science and biology (incl. coverage of COVID-19). New relevant content is downloaded and ingested into our annotation tool (see Section 3.4) on an ongoing basis as it becomes available.

3.2 Article Summarisation

Newspaper articles and scientific papers are long and often complex documents, usually spanning multiple pages, particularly the latter. Moreover the two document types differ significantly in length. Comparing documents of such uneven length is a difficult task for human annotators. We also assume that asking human annotators to read the documents in their entirety to identify co-references would be particularly hard with a very low chance for good inter-annotator agreement (IAA). We therefore decided to simplify the task by asking annotators to compare summaries of the newspaper article (5-10 sentences long) and the scientific paper (abstract).

For each document pair, we ask the annotators to identify co-referent mentions between the scientific paper abstract and a summary of the news article that is of similar length (e.g. 5-10 sentences). Scientific paper abstracts act as a natural summary of a scientific work and have been used as a strong baseline or even a gold-standard in scientific summarisation tasks (Liakata et al., 2013). Furthermore, abstracts are almost always available rather than behind paywalls like full text articles. For news summarisation, we used a state-of-the-art extractive model (Grenander et al., 2019) to extract sentences forming a summary of the original text. This model provides a summary de-biasing mechanism preventing it from focusing on specific parts of the full article, preserving the summary's informational authenticity as much as possible.

The difference in style between the two documents is preserved by both types of summary since abstracts are written in the same scientific style as full papers and the extractive summaries use verbatim excerpts of the original news articles.

3.3 Generation of pairs for annotation

To populate our annotation tool, we generate pairs of candidate cross-document mentions to be evaluated by the user. Candidate mentions are identified by using spaCy (Honnibal and Montani, 2017) for the recognition of noun phrases and named entities from each input document pair (abstract-news summary). For each pair of documents, pairs of all possible mention combinations are generated and stored for annotation.

In any given pair of documents, the majority of mention pairs (M_0, M_1) generated automatically in this way will not co-refer thus resulting in a vastly imbalanced dataset and also running the risk of demotivating annotators. To ensure that annotators are exposed to both positive and negative examples, we use a similarity score to rank examples based on how likely they are to co-refer. The first step in generating a similarity score s is to concatenate each abstract-news-summary pair together: "summary [SEP] abstract" into a pre-trained BERT$_{\text{large}}$ model. Then we take the mean of the word vectors that correspond to the mention spans within the documents and calculate the cosine similarity of these vectors. We find that this BERT-based similarity score performs well in practice. We also use it in combination with a thresholding policy as one of our baseline models in Section 4.

3.4 Annotation Tool & Interface

We developed an open source annotation tool[5] that allows humans to identify cross-document coreference between each pair of related documents. Whilst designing this tool, we made a number of decisions to simplify the task and provide clear instructions for the human annotators in order to encourage consistent annotation behaviour.

To maximise the quality and consistency of annotations in our corpus, we simplified the task as much as possible for the end user. Annotation tasks were framed as a single yes or no question: "Are **x** and **y** mentions of the same entity?". Mentions in context were shown in bold font whereas mentions already flagged as co-referent were shown in green. This enabled annotators to understand the implications for existing co-reference chains before responding (see Figure 3). Questions were generated and ranked via our task generation pipeline (see Section 3.3 above).

We added two additional features to our annotation interface to improve annotators' experience and to speed up the annotation process. Firstly, if the candidate pair is marked as co-referent, the user is allowed to add more mentions to the coreference cluster at once. Secondly, inspired by (Li et al., 2020), if the automatically shown mention pair is not co-referent, the user can select a different mention that is co-referent.

The upstream automated mention detection mechanism can sometimes introduce incomplete or erroneous mentions, leading to comparisons that don't make sense or that are particularly difficult. Therefore, annotators can also move or resize the mention spans they are annotating.

We use string offsets of mention span pairs to tokens to check that they do not overlap with each other in order to prevent the creation of duplicates. Figure 1 shows an illustrated example of the generation pipeline for mention pairs.

3.5 Annotation Protocol

We recruited three university-educated human annotators and provided them with detailed annotation guidelines for the resolution of yes/no questions on potentially co-referring entities in pairs from the ordered queue described above. By default each entity pair resolution is carried out once, allowing us to quickly expand our data set. However, we pseudo-randomly sample 5% of men-

Testing of meats confiscated at American airports has revealed the presence of several pathogens that could pose a risk to human health.

Pathogen screening identified retroviruses (simian foamy virus) and/or herpesviruses (cytomegalovirus and lymphocryptovirus) in the NHP samples.

Figure 1: Illustration of the generation process for pairs of potentially co-referring expressions, left boxes represent related news summary (top) and abstract (bottom), co-referent entity pairs in middle boxes shown with same formatting (underline,italic).

tion pairs in order to calculate inter-annotator-agreement (IAA) and make sure that data collected from the tool is consistent and suitable for modelling. New entity pairs for IAA are continually sampled as new document pairs and mention tuples are added to the corpus by the web scraper (Section 3.1). The annotation system puts mention pairs flagged for IAA first in the annotation queue. Thus, all annotators are required to complete IAA comparisons before moving on to novel mention pairs. This allows us to ensure that all annotators are well represented in the IAA exercise. To avoid annotators being faced with a huge backlog of IAA comparisons before being able to proceed with novel annotations, we also limited the number of comparisons for IAA required by each user to a maximum of 150 per week.

3.6 Task Difficulty and Annotator Agreement

We anticipated that annotation of the CD^{2}CR corpus would be difficult in nature due to its dependencies on context and lexical style. We invited users to provide feedback regularly to help us refine and clarify our guidelines and annotation tool in an iterative fashion. Users could alert us to examples they found challenging by flagging them as difficult in the tool. Qualitative analysis of the subset of 'difficult' cases showed that the resolution of mention pairs is often perceived by annotators as difficult when:

- Deep subject-matter-expertise is required to understand the mentions, e.g. is "jasmonic acid" the same as "regulator cis -(+)-12-oxophytodienoic acid".
- Mentions involve non-commutable set membership ambiguity e.g. "Diplodocidae" and "the dinosaurs"
- Mentions are context dependent e.g. "the struggling insect" and "the monarch butterfly".

This feedback prompted the introduction of highlighting for existing co-reference chains in the user interface (as described in section 3.4 above) to make it easier to tell when non-commutable set membership would likely introduce inconsistencies into the dataset. For mention pairs requiring subject-matter-expertise, annotators were encouraged to research the terms online. For context sensitive mention pairs, annotators were encouraged to read the full news article and full scientific paper in order to make a decision.

In our 11 page annotation guidelines document (appendix) we describe the use of our annotation tool and illustrate some challenging CD^{2}CR tasks and resolution strategies. For example precise entities mentioned in the scientific document may be referenced using ambiguous exophoric mentions in the news article (e.g. 'a mountain breed of sheep' vs 'eight ovis aries'). Our guidelines require resolving these cases based on the journalist's intent (e.g. 'a mountain breed' refers to the 'ovis aries' sheep involved in the experiment).

We evaluated the final pairwise agreement between annotators using Cohen's Kappa (Cohen, 1960) (κ_{cohen}) and an aggregate 'n-way' agreement score using Fleiss' Kappa (Fleiss, 1971) (κ_{fleiss}). Pairwise κ_{cohen} is shown in table 2 along with the total number of tasks each annotator completed. Annotator 3 (A3) shows the most consistent agreement with the other two annotators. Our Fleiss' Kappa analysis of tasks common across the three annotators gave $\kappa_{\text{fleiss}} = 0.554$. We note that Fleiss' Kappa is a relatively harsh metric and values, like ours, between 0.41 and 0.60 are considered to demonstrate 'moderate agreement' (Landis

	# Annotations	A1	A2	A3
A1	10,685	-	0.492	0.600
A2	3,051	0.492	-	0.500
A3	9,847	0.600	0.500	-

Table 2: Number of Annotations and Pairwise Cohen's Kappa scores κ_{cohen} between annotators.

and Koch, 1977). We also carried out Fleiss' Kappa analysis on the subset of mention pairs that were completed by all annotators and were also marked as difficult by at least one user (180 mention pairs in total). We found that for this subset of pairs, $\kappa_{\text{fleiss}} = 0.399$ which is considered to be fair agreement(Landis and Koch, 1977).

4 Model

Below we describe several baseline models including state of the art CDCR models that we used to evaluate how well current approaches can be used in our CD^{2}CR task setting.

4.1 BERT Cosine Similarity (BCOS) Baseline

In this model we calculate the cosine-similarity between embeddings of the two mentions in context (M_0, M_1) encoded using a pre-trained BERT model as discussed above in section 3.3. We define a thresholding function f to decide if M_0 and M_1 are co-referent ($f(x) = 1$) or not ($f(x) = 0$):

$$f(x) = \begin{cases} 1, & \text{if COSSIM}(M_0, M_1) \geq t \\ 0, & \text{otherwise} \end{cases}$$

During inference, we pass this function over all pairs M_0, M_1 and infer missing links such that if $f(A, B) = 1$ and $f(B, C) = 1$ then $f(A, C) = 1$.

Based on Figure 2, we test values in increments of 0.01 between 0.3 and 0.8 inclusive for threshold cut off t. We evaluated the baseline by measuring its accuracy at predicting co-reference in each mention pair in the CD^2CR development set. The best performance was attained when $t = 0.65$. A visualisation of the BERT Cosine Similarity distributions of co-referent and non co-referent annotated mention pairs can be seen in Figure 2.

Co-referent mention pairs tend to have a slightly higher BERT cosine similarity than non co-referent mention pairs but there is significant overlap of the two distributions suggesting that in many cases BERT similarity is too simplistic a measure.

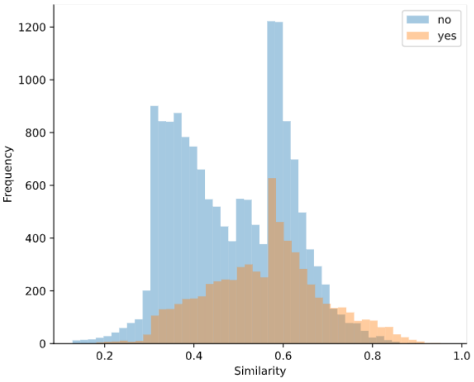

Figure 2: BERT Cosine Similarity frequency distribution for co-referent (Yes) and non-co-referent (No) mention pairs in the CD^{2}CR corpus.

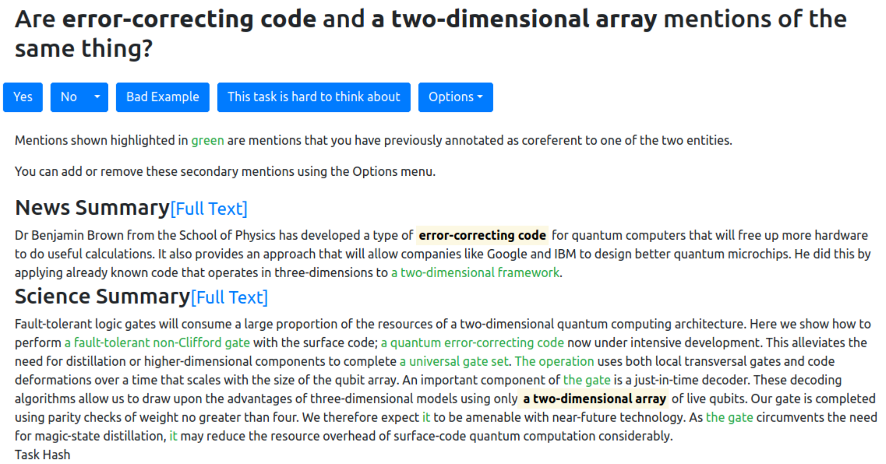
4.2 Entities Only Baseline (CA)

We use a state-of-the-art model (Cattan et al., 2020) (CA) for cross-document co-reference resolution. In this model, each document is separately encoded using a RoBERTa encoder (without fine-tuning) to get contextualized representations for each token. Then, similarly to the within-document coreference model by Lee et al. (2017), the mention spans are represented by the concatenation of four vectors: the vectors of the first and last token in the span, an attention-weighted sum of the span token vectors, and a feature vector to encode the span width. Two mention representations are then concatenated and fed to a feed-forward network to learn a likelihood score for whether two mentions co-refer. At inference time, agglomerative clustering is used on the pairwise scores to form coreference clusters.

The CA model is trained to perform both event and entity recognition on the ECB+ corpus (Cybulska and Vossen, 2014) In our setting there is no event detection subtask so, for fair comparison, we pre-train the CA model on ECB+ entity annotations only and evaluate it on our new CD^{2}CR task to see how well it generalises to our task setting.

4.3 CA + Fine-Tuned (CA-FT) Baseline

Here we aim to evaluate whether fine tuning the CA model from section 4.2 using the CD^{2}CR corpus can improve its performance in the new task setting. The CA model is first trained on the ECB+ corpus in the manner described above. We then further fine-tune the feed-forward model (without affecting the RoBERTa encoder) on the CD^{2}CR corpus for 10 epochs with early stopping. Pseudo-random sub-sampling is carried out on the training set to



Are **error-correcting code** and **a two-dimensional array** mentions of the same thing?

Mentions shown highlighted in green are mentions that you have previously annotated as coreferent to one of the two entities.

You can add or remove these secondary mentions using the Options menu.

News Summary[Full Text]

Dr Benjamin Brown from the School of Physics has developed a type of **error-correcting code** for quantum computers that will free up more hardware to do useful calculations. It also provides an approach that will allow companies like Google and IBM to design better quantum microchips. He did this by applying already known code that operates in three-dimensions to a two-dimensional framework.

Science Summary[Full Text]

Fault-tolerant logic gates will consume a large proportion of the resources of a two-dimensional quantum computing architecture. Here we show how to perform a fault-tolerant non-Clifford gate with the surface code; a quantum error-correcting code now under intensive development. This alleviates the need for distillation or higher-dimensional components to complete a universal gate set. The operation uses both local transversal gates and code deformations over a time that scales with the size of the qubit array. An important component of the gate is a just-in-time decoder. These decoding algorithms allow us to draw upon the advantages of three-dimensional models using only **a two-dimensional array** of live qubits. Our gate is completed using parity checks of weight no greater than four. We therefore expect it to be amenable with near-future technology. As the gate circumvents the need for magic-state distillation, it may reduce the resource overhead of surface-code quantum computation considerably.
Task Hash

ensure a balance of co-referent and non-co-referent mention pairs.

4.4 CA - Vanilla (CA-V) Baseline

Here we aim to evaluate whether training the CA model on the CD^{2}CR dataset from the RoBERTa baseline without first training on the ECB+ corpus allows it to fit well to the new task setting. We re-initialise the CA encoder (Section 4.2) using weights from RoBERTa (Liu et al., 2019) and randomly initialise the remaining model parameters. We then train the model on the CD^{2}CR corpus for up to 20 epochs with early stopping with pseudo-random sub-sampling as above.

4.5 CA - SciBERT (CA-S) Baseline

This model is the same as CA-V but we replace the RoBERTa encoder with SciBERT (Beltagy et al., 2019), a version of BERT pre-trained on scientific literature in order to test whether the scientific terms and context captured by SciBERT improve performance at the CD^{2}CR task compared to RoBERTa. Similarly to CA-V in section 4.4, we initialise the BERT model with weights from SciBERT$_{\text{scivocab-uncased}}$ (Beltagy et al., 2019) and randomly initialise the remaining model parameters, training on the CD^{2}CR corpus for up to 20 epochs with early stopping.

5 Results and Discussion

We evaluate each of the model baselines described in section 4 above on the test subset of our CD^{2}CR corpus. Results are shown in table 3.

For the purposes of evaluation, we use named entity spans from the manually annotated CD^{2}CR as the "gold standard" in all experiments rather than using the end-to-end Named Entity Recognition capabilities provided by some of the models. We evaluate the models using the metrics described by Vilain et al. (1995) (henceforth MUC) and Bagga and Baldwin (1998) (henceforth B^3). MUC F1, precision and recall are defined in terms of pairwise co-reference relationships between each mention. B^3, F1, precision and recall are defined in terms of presence or absence of specific entities in the cluster. When measuring B^3, we remove entities with no co-references (singletons) from the evaluation to avoid inflation of results (Cattan et al., 2020).

The threshold baseline (BCOS) gives the highest MUC recall but also poor MUC precision and poorest B^3 precision. The B^3 metric is highly specific with respect to false-positive entity mentions and strongly penalises BCOS for linking all non-coreferent pairs with $COSSIM(M_0, M_1) \geq 0.65$. Furthermore, Fig. 2 shows that a thresholding strategy is clearly sub-optimal given that there is a significant overlap of co-referent and non-co-referent pairs with only a small minority of pairs at the top and bottom of the distribution that do not overlap.

Model	**MUC**			**B^3**		
	P	**R**	**F1**	**P**	**R**	**F1**
BCOS	0.42	**0.94**	0.58	0.01	0.45	0.00
CA	0.41	0.51	0.46	**0.39**	0.33	0.35
CA-V	0.50	0.69	**0.58**	0.35	0.57	**0.44**
CA-FT	0.47	0.71	0.52	0.30	**0.62**	0.41
CA-S	**0.58**	0.46	0.51	0.32	0.53	0.39

Table 3: MUC and B^3 results from running baseline models on CD^{2}CR test subset, BCOS threshold=0.65

Test Type	Co-referent?	Pass Rate & Total Tests	Example test case and outcome for test case
Anaphora and Exophora resolution	Yes	47.1% (16/34)	M1: ...to boost **the struggling insect**'s numbers... *[PASS]* M2: the annual migration of the **monarch butterfly**...
	No	76.5% (26/34)	M1: ...**monarchs** raised in captivity... *[FAIL]* M2: ... wild-caught **monarchs** in an indoor environment...
Subset relationship resolution	Yes	24.3% (9/37)	M1: ...it was in fact a hive of **human activity**... *[FAIL]* M2: ...**Pre-Columbian cultural developments**...
	No	60.0% (18/30)	M1: ... **the carnivore's skull**... *[FAIL]* M2: ... **the gigantic extinct Agriotherium africanum**
Paraphrase resolution	Yes	33.3% (13/39)	M1: ...**a giant short-faced bear**... *[PASS]* M2: ...**the gigantic extinct Agriotherium africanum**...
	No	80.5% (29/36)	M1: ...the energy that **existing techniques** require *[FAIL]* M2: ...the lack of **efficient catalysts** for ammonia synthesis

Table 4: A breakdown of specific tests carried out on CA-V model against three challenging types of relationships found in the CD^2CR corpus. [PASS] or [FAIL] indicates CA-V model correctness. Pass Rate is mathematically equivalent to Recall for test sets.

Therefore, despite its promising MUC F1 score, it is clear that BCOS is not useful in practical terms.

Whilst our thresholding baseline above uses BERT, RoBERTa is used by Cattan et al. (2020) as the basis for their state-of-the-art model and thus for our models based on their work. Although the two models have the same architecture, RoBERTa has been shown to outperform BERT at a range of tasks (Liu et al., 2019). However, as shown in Figure 4, the cosine similarity distribution of mention pair embeddings produced by RoBERTa is compressed to use a smaller area of the potential distribution space compared to that of BERT (Figure 2). This compression of similarities may imply a reduction in RoBERTa's ability to discriminate in our task setting. Liu et al. (2019) explain that their byte-pair-encoding (BPE) mechanism, which expands RoBERTa's sub-word vocabulary and simplifies pre-processing, can reduce model performance for some tasks, although this is not further explored in their work. We leave further exploration of RoBERTa's BPE scheme and its effects on the CD^{2}CR task setting to future work.

All of the models specifically trained on the CD^{2}CR corpus (CA-V, CA-FT, CA-S) outperform the CA model by a large margin. Furthermore, the CA-V model (without pre-training on ECB+ corpus) outperforms the CA-FT model (with ECB+ pre-training) by 6% MUC and 3% B^3. These results suggest that the CD^{2}CR task setting is distinct from the CDCR and ECB+ task setting and that this distinction is not solvable with fine-tuning.

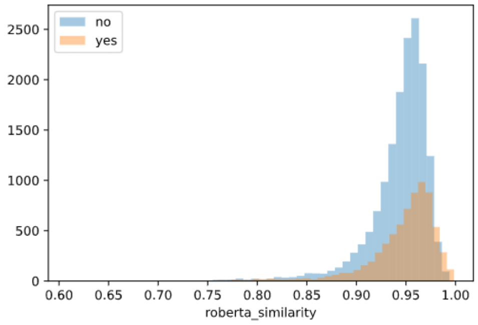

Figure 4: RoBERTa Cosine Similarity frequency distribution for co-referent (Yes) and non-co-referent (No) mention pairs in the CD^{2}CR corpus. Distribution is compressed between 0.8 and 1.0.

In terms of both MUC and B^3, CA-S performs much worse than CA-V suggesting that SciBERT embeddings are less effective than RoBERTa embeddings in this task setting. We hypothesise that SciBERT's specialisation towards scientific embeddings may come at the cost of significantly worse news summary embeddings when compared to those produced by RoBERTa.

We next evaluate our best performing CD^{2}CR baseline model (CA-V) at the entity resolution CDCR task using the ECB+ test corpus, to see how well it generalises to the original CDCR task. Results are presented in 5 along-side Cattan et al's original model results (CA). The CA-V model still shows good performance, despite a small drop, when compared to the original CA model. The drop in B^3 F1 is more pronounced than MUC but is still broadly in line with other contemporary CDCR systems (Cattan et al., 2020). The CA-V model demonstrates a promising ability to generalise beyond our corpus to other tasks and reveals an interesting correspondence between CDCR and CD^{2}CR settings.

Model	**MUC**			B^3		
	P	**R**	**F1**	**P**	**R**	**F1**
CA	0.86	0.82	0.84	0.63	0.68	0.65
CA-V	0.82	0.81	0.81	0.56	0.53	0.55

Table 5: MUC and B^3 results from running the CD^{2}CR baseline model (CA-V) on ECB+ dataset compared with original Cattan et al. (2020) (CA).

Finally, the best model (CA-V) is analysed using a series of challenging test cases inspired by Ribeiro et al (2020). These test cases were created using 210 manually annotated mention-pairs found in the test subset of the CD^2CR corpus according to the type of relationship illustrated (Anaphora & Exophora, Subset relationships, paraphrases). We collected a balanced set of 30-40 examples of both co-referent and non-coreferent-but-challenging pairs for each type of relationship (exact numbers in Table 4). We then recorded whether the model correctly predicted co-reference for these pairs. The results along with illustrative examples of each relationship type are shown in Table 4. The results suggest that the model is better at identifying non-co-referent pairs than co-referent pairs and that it struggles with positive co-referent mentions for all three types of relationship. The model struggles to relate general reader-friendly descriptions of entities from news articles to precise and clinical descriptions found in scientific papers. The model often successfully identifies related concepts such as ‘the carnivore’s skull’ and ‘Agriotherium africanum’. However it is unable to deal with the complexity of these relationships and appears to conflate ‘related’ with ‘co-referent’, which is likely due to lack of lexical knowledge as we discussed in section 2.3. Figure 5 shows significant overlap between co-referent and non-co-referent RoBERTa-based cosine similarities, which can also be observed for the wider corpus in Figure 4, but is especially bad for these test examples. This overlap suggests that disentangling these pairs is likely to be a challenging task for the downstream classification layer in the CA-V model. These challenges are less likely to occur in homogeneous corpora like ECB+ where descriptions and relationships remain consistent in detail and complexity.

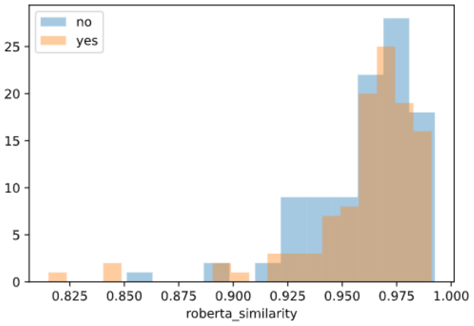

Figure 5: RoBERTa-based mention pair similarity frequency distribution for test examples from Table 4. ’yes’ and ’no’ for ’co-referent’ and ’not-co-referent’ respectively

6 Conclusion

We have defined cross-document, cross-domain co-reference resolution (CD^{2}CR), a special and challenging case of cross-document co-reference resolution for comparing mentions across documents of different types and/or themes. We have constructed a specialised CD^{2}CR annotated dataset, available, along with our annotation guidelines and tool, as a free and open resource for future research. We have shown that state-of-the-art CDCR models do not perform well on the CD^{2}CR dataset without specific training. Furthermore, even with task-specific training, models perform modestly and leave room for further research and improvement. Finally, we show that the understanding of semantic relatedness offered by current generation transformer-based language models may not be precise enough to reliably resolve complex linguistic relationships such as those found in CD^{2}CR as well as other types of co-reference resolution and relationship extraction tasks. The use of semantic enrichment techniques (such as those discussed in Section 2.3) to improve model performance in the CD^{2}CR task should be investigated as future work.

Abstract

Redundancy-aware extractive summarization systems score the *redundancy* of the sentences to be included in a summary either jointly with their *salience* information or separately as an additional sentence scoring step. Previous work shows the efficacy of jointly scoring and selecting sentences with neural sequence generation models. It is, however, not well-understood if the gain is due to better encoding techniques or better redundancy reduction approaches. Similarly, the contribution of salience versus diversity components on the created summary is not studied well. Building on the state-of-the-art encoding methods for summarization, we present two adaptive learning models: AREDSUM-SEQ that jointly considers salience and novelty during sentence selection; and a two-step AREDSUM-CTX that scores salience first, then learns to balance salience and redundancy, enabling the measurement of the impact of each aspect. Empirical results on CNN/DailyMail and NYT50 datasets show that by modeling diversity explicitly in a separate step, AREDSUM-CTX achieves significantly better performance than AREDSUM-SEQ as well as state-of-the-art extractive summarization baselines.

1 Introduction

Extractive summarization is the task of creating a summary by identifying and concatenating the most important sentences in a document (Liu and Lapata, 2019; Zhang et al., 2019; Zhou et al., 2018). Given a partial summary, the decision to include another sentence in the summary depends on two aspects: *salience*, which represents how much information the sentence carries; and *redundancy*, which represents how much information in the sentence is already included in the previously selected sentences.

Although there have been a few studies on redundancy a long time ago, most recent research on extractive summarization focuses on salience alone. They usually model sentence salience as a sequence labeling task (Kedzie et al., 2018; Cheng and Lapata, 2016) or classification task (Zhang et al., 2019) and do not conduct redundancy removal. Previous methods that consider redundancy usually use a separate step after salience scoring to handle redundancy, denoted as sentence selection (Carbonell and Goldstein, 1998; McDonald, 2007; Lin and Bilmes, 2011). Sentence selection often follows a greedy iterative ranking process that outputs one sentence at a time by taking into account the redundancy of candidate sentences with previously selected sentences.

Several approaches for modeling redundancy in sentence selection have been explored: heuristics-based methods such as Maximal Marginal Relevance (MMR) (Carbonell and Goldstein, 1998), Trigram Blocking (TRIBLK) (Liu and Lapata, 2019), or model based approaches (Ren et al., 2016), etc. Heuristic-based methods are not adaptive since they usually apply the same rule to all the documents. Model-based approaches depend heavily on feature engineering and learn to score sentences via regression with point-wise loss, which has been shown to be inferior to pairwise loss or list-wise loss in ranking problems (Liu et al., 2009).

Redundancy has also been handled jointly with salience during the scoring process using neural sequence models (Zhou et al., 2018). NEUSUM (Zhou et al., 2018) scores sentences considering their salience as well as previous sentences in the output sequence and learns to predict the sentence with maximum relative gain given the partial output summary. Despite the improved efficacy, it is not well-understood if the gain is due to better encoding or better redundancy-aware iterative ranking approaches (i.e., the sequence generation).

In this work, we propose to study different types of redundancy-aware iterative ranking techniques

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 281–291
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

for extractive summarization that handle redundancy separately or jointly with salience. Extending BERTSUMEXT (Liu and Lapata, 2019), a state-of-the-art extractive summarization model, which uses heuristic-based Trigram Blocking (TRIBLK) for redundancy elimination, we propose two supervised redundancy-aware iterative sentence ranking methods for summary prediction. Our first model, AREDSUM-SEQ, introduces a transformer-based conditional sentence order generator network to score and select sentences by jointly considering their salience and diversity within the selected summary sentences. Our second model, AREDSUM-CTX, uses an additional sentence selection model to learn to *balance* the salience and redundancy of constructed summaries. It incorporates surface features (such as n-gram overlap ratio and semantic match scores) to instrument the diversity aspect. We compare the performance of our redundancy-aware sentence ranking methods with trigram-blocking (Liu and Lapata, 2019), as well as summarization baselines with or without considering redundancy on two commonly used datasets, CNN/DailyMail and New York Times (NYT50). Experimental results show that our proposed AREDSUM-CTX can achieve better performance by reducing redundancy and outperform all the baselines on these two datasets. The model's advantage can be attributed to its adaptiveness to scenarios in which redundancy removal has different potential gains.

In summary, our contributions are: 1) we propose two redundancy-aware iterative ranking methods for extractive summarization extending BERTSUMEXT; 2) we conduct comparative studies between our redundancy-aware models as well as the heuristic-based method that BERTSUMEXT uses; 3) our proposed AREDSUM-CTX significantly outperforms BERTSUMEXT and other competitive baselines on CNN/DailyMail and NYT50.

2 Related Work

Extractive summarization methods are usually decomposed into two subtasks, i.e., sentence scoring and sentence selection, which deal with salience and redundancy, respectively.

Salience Scoring. Graph-based models are widely used methods to score sentence salience in summarization (Erkan and Radev, 2004; Mihalcea and Tarau, 2004; Wan and Yang, 2006). There are also extensions to such methods, e.g., with clustering (Wan and Yang, 2008) or leveraging graph neural networks (Wang et al., 2020). Classical supervised extractive summarization uses classification or sequence labeling methods such as Naive Bayes (Kupiec et al., 1999), maximum entropy (Osborne, 2002), conditional random fields (Galley, 2006) or hidden markov model (Conroy et al., 2004). Human engineered features are heavily used in these methods such as word frequency and sentence length (Nenkova et al., 2006).

In recent years, neural models have replaced older models to score the salience of sentences. Hierarchical LSTMs and CNNs have replaced manually engineered features. LSTM decoders are employed to do sequence labeling (Cheng and Lapata, 2016; Nallapati et al., 2017; Kedzie et al., 2018). These architectures are widely used and also extended with reinforcement learning (Narayan et al., 2018; Dong et al., 2018). More recently, summarization methods based on BERT (Devlin et al., 2018) have been shown to achieve state-of-the-art performance (Liu and Lapata, 2019; Zhang et al., 2019; Zhong et al., 2019; Zhou et al., 2020) on salience for extractive summarization.

Sentence Selection. There are relatively fewer methods that study sentence selection to avoid redundancy. Integer Linear Programming based methods (McDonald, 2007) formulate sentence selection as an optimizing problem under the summary length constraint. Lin and Bilmes (2011) propose to find the optimal subset of sentences with submodular functions. Greedy strategies such as Maximal Marginal Relevance (MMR) (Carbonell and Goldstein, 1998) select the sentence that has maximal salience score and is minimally redundant iteratively. Trigram blocking (Liu and Lapata, 2019) follows the intuition of MMR and filters out sentences that have trigram overlap with previously extracted sentences. Ren et al. (2016) leverage two groups of handcrafted features to capture informativeness and redundancy respectively during sentence selection. In contrast to learning a separate model for sentence selection, Zhou et al. (2018) propose to jointly learn to score and select sentences with a sequence generation model. However, it is not compared with other redundancy-aware techniques, and it is not clear whether its improvement upon other methods is from the sequence generation method or the encoding technique.

In this paper, we compare the efficacy of different sentence selection techniques grounded on the same BERT-based encoder. We propose two models that either conduct redundancy removal with a separate model or jointly with salience scoring and compare them with a heuristic-based method. As far as we know, our work is the first to conduct comparative studies on different types of redundancy-aware extractive summarization methods.

3 Iterative Sentence Ranking

We formulate single document extractive summarization as a task of iterative sentence ranking. Given a document $D = \{s_1, s_2, \cdots, s_L\}$ of L sentences, the goal is to extract t sentences, i.e., $\hat{S}_t = \{\hat{s}_k | 1 \leq k \leq t, \hat{s}_k \in D\}$, from D that can best summarize it. With a limit of selected sentence count l, the process of extracting sentences can be considered as a l-step iterative ranking problem. At each k-th step ($1 \leq k \leq l$), given the current summary $\hat{S}_{k-1}$, a new sentence s_k is selected from the remaining sentences $D \setminus \hat{S}_{k-1}$ and added to the summary. Function $M(\hat{S}_k; S^*)$[1] measures the similarity between the extracted summary $\hat{S}_k$ and the ground truth summary S^*. The objective is to learn a scoring function $f(\cdot)$ so that the best sentence $\hat{s}_k$ selected according to $f(\cdot)$ can maximize the gain of the output summary:

$$\begin{aligned} &\arg\max_f M(\{\hat{s}_k\} \cup \hat{S}_{k-1}); S^*) \\ &\hat{s}_k = \arg\max_{s_i \in D \setminus \hat{S}_{k-1}} f(\{s_i\} \cup \hat{S}_{k-1}) \end{aligned} \tag{1}$$

$\hat{s}_k$ needs to be both salient in the document and novel in the current context $\hat{S}_{k-1}$. Note that at the beginning $\hat{S}_0 = \emptyset$.

Since ground truth summaries S^* of existing summarization corpora are usually abstractive summaries written by experts, previous studies on extractive summarization usually extract a group of pseudo ground truth sentences $\hat{S}^*$ from D based on their similarities to the ground truth summaries S^* for training purposes. Then labels 1 and 0 are assigned to sentences in $\hat{S}^*$ and the other sentences in D. In this case, $M(\hat{S}_t; \hat{S}^*)$ is used to guide training instead of $M(\hat{S}_t; S^*)$.

4 Redundancy-Aware Summarization

Most recent redundancy-aware extractive summarization systems use heuristics to select diverse sentences after salience scoring (Cao et al., 2015; Ren et al., 2017; Liu and Lapata, 2019). Among them, BERTSUMEXT (Liu and Lapata, 2019) is a state-of-the-art model with trigram-blocking (TRIBLK) that reduces redundancy by filtering out sentences that have trigram overlap with previously selected ones at each time step. As we empirically show later in § 6, heuristics can be effective on some datasets yet harmful on others since it applies the same rule to all the documents.

In contrast, we present an adaptive learning process for redundancy-aware extractive summarization, AREDSUM, and introduce two methods, AREDSUM-SEQ and AREDSUM-CTX, extending BERTSUMEXT by either consider redundancy jointly with salience during sentence scoring or separately with an additional selection model.

4.1 Document Encoder

First, we introduce the sentence and document encoder shared by both our variations of AREDSUM, shown in Figure 1. In sentence-level encoding, a [SEP] token is appended to each sentence to indicate the sentence boundaries and a [CLS] token is inserted before each sentence in the document to aggregate the information of the sentence. In addition to token and positional embeddings, as in BERTSUMEXT (Liu and Lapata, 2019), we also use interval segment embeddings E_A and E_B to distinguish sentences at odd and even positions in the document respectively. Following multiple transformer encoder layers, we represent each sentence s_i by the output representation of the [CLS] symbol preceding s_i. These symbols capture the features of the following tokens in the sentence while attending over all other tokens in the document through the transformer layers.

We further conduct document-level encoding on the sentence-level representations from the [CLS] tokens, denoted as E_{s_i}, as well as their positional embeddings, E'_i, with another stack of transformer layers. We add a document embedding E_D before the sequence of sentence embeddings to represent the whole document. The final representation of D and each sentence s_i can be obtained from the output of the multiple transformer layers, denoted as h_{s_i} and h_D.

4.2 AREDSUM-SEQ: Sequence Generation

Our first model, AREDSUM-SEQ, strictly considers the *order* of the target selected sentences while jointly modeling the redundancy and salience of the next sentence. It uses a transformer decoder

---

[1] In § 4 and experiments, we use ROUGE to define $M(\cdot)$

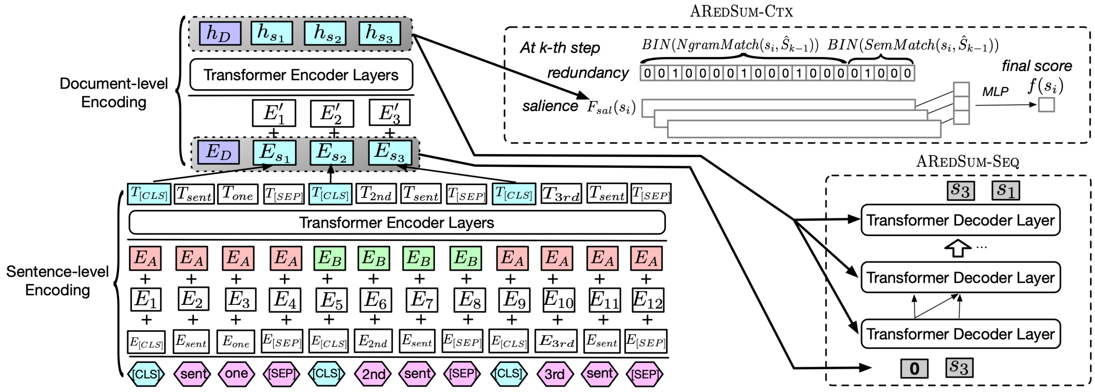

Figure 1: Overview of the proposed models ARedSum-Seq and ARedSum-Ctx sharing the same Bert-based encoder from BertSumExt.

module (Vaswani et al., 2017) to learn to select and order a sequence of sentences from the document as a summary. Our model is different from standard auto-regressive decoders. Each decoder block takes in a sequence of tokens (word-units) as input to generate the next possible token from a pre-defined vocabulary. Instead, our decoder is a conditional model that takes a sequence of sentence representations as input and selects a sentence with the maximum gain to be included in the summary from the rest of the document's sentences.

Following a standard transformer encoder-decoder architecture (Vaswani et al., 2017), at each decoding step k, a current hidden state is obtained with a stack of transformer decoder layers:

$$h'_{\hat{s}_{k-1}} = \mathrm{Dec}([E_{\hat{s}_1},\cdots,E_{\hat{s}_{k-1}}],[h_{s_1},h_{s_2},\cdots,h_{s_L}]) \quad (2)$$

where $[h_{s_1}, h_{s_2}, \cdots, h_{s_L}]$ are the output sentence representations after the document-level encoding in Figure 1 and $[E_{\hat{s}_1}, \cdots, E_{\hat{s}_{k-1}}]$ are the embeddings of the so far selected sentences. $\hat{S}_{k-1} = \emptyset$ and $E_{\hat{s}_0} = \mathbf{0}$ when $k = 1$. Note that sentence embeddings that are fed to the document-level transformer encoders, i.e., $E_{s_1}, \cdots, E_{s_L}$, are used to represent the sentences in the target decoding space. Then, a two-layer MLP is used to score a candidate sentence s_i given the hidden state $h'_{\hat{s}_{k-1}}$:

$$o_l(s_i) = W_{2s} \tanh(W_{1s}[h'_{\hat{s}_{k-1}}; E_{s_i}]) \quad (3)$$

where W_{2s} and W_{1s} are the weights of the MLP (we omit the bias parameters for simplicity), and [;] denotes vector concatenation. In case the salience of s_i is not sufficiently captured in $o_l(s_i)$, we calculate a matching score $o_g(s_i)$ between s_i and the global context D, regardless of which sentences are selected previously [2]:

$$o_g(s_i) = \tanh(h_D W_{ds} h_{s_i}) \quad (4)$$

where W_{ds} is matrix for bilinear matching; h_D and h_{s_i} are the embeddings of the document D and sentence s_i output by the document-level encoder. The final score is the linear combination of o_l and o_g using the weight W_o:

$$o(s_i) = W_o(o_l(s_i) + o_g(s_i)) \quad (5)$$

The probability of any sentence s_i being selected at the k-th step is the softmax of $o(s_i)$ over the remaining candidate sentences s_j in D:

$$P(\hat{s}_k{=}s_i|\hat{S}_{k-1}) = \frac{\exp(o(s_i))}{\sum_{s_j \in D \setminus \hat{S}_{k-1}} \exp(o(s_j))} \quad (6)$$

Following NeuSum (Zhou et al., 2018), we train ARedSum-Seq to optimize for the *relative* ROUGE-F1 gain of each sentence with respect to so-far selected sentences $\hat{S}_{k-1}$.

$$g(s_i) {=} M(\{s_i\} {\cup} \hat{S}_{k-1}; S^*) {-} M(\hat{S}_{k-1}; S^*) \quad (7)$$

where $M(\{s_i\}{\cup}\hat{S}_{k-1}; S^*)$ and $M(\hat{S}_{k-1}; S^*)$ measure the ROUGE-F1 between the golden summary S^* and the so-far selected sentences $\hat{S}_{k-1}$ with and without the candidate s_i respectively. We rescale the gain $g(s_i)$ to [0,1] in case of negative values using a min-max normalization and get $\tilde{g}$. Then we use a softmax function with a temperature τ on the rescaled gain to produce a target distribution:

$$Q(s_i) = \frac{\exp(\tau \tilde{g}(s_i))}{\sum_{s_j \in D \setminus \hat{S}_{k-1}} \exp(\tau \tilde{g}(s_j))} \quad (8)$$

---

[2] Emphasizing salience with o_g enhances the performance.

The final training objective is to minimize the KL divergence between the probability distribution of sentence scores (Eq. 6) and their relative rouge gain (Eq. 8), i.e., $KL(P(\cdot)||Q(\cdot))$. This objective can be considered as a listwise ranking loss (Ai et al., 2018) that maximizes the probability of the target sentence while pushing down the probabilities of the other sentences. In this way, AREDSUM-SEQ combined the sentence scoring and selection in the same decoder framework, and the redundancy is implicitly captured by optimizing the ROUGE gain.

4.3 AREDSUM-CTX: Context-aware Sentence Ranker

We introduce a second model, AREDSUM-CTX, a context-aware ranker that scores salience first and then selects a sentence according to both its salience and redundancy adhering to the previously extracted sentences as context, as shown in Figure 1. In AREDSUM-CTX, we use a two-step process for scoring and selecting sentences for learning to construct a summary: In the *salience ranking* step, we focus on learning the salience of the sentences, while in the *ranking for sentence selection* step, we represent the redundancy explicitly via surface features and use a ranker to decide to promote or demote sentences based on their scores given the joint degree of their salience and redundancy.

Salience Ranking. By assuming that the sentence salience is independent of the previously selected sentences, we design the salience ranking of AREDSUM-CTX as a single step process rather than an iterative one. We measure the probability of a sentence to be included in $\hat{S}^*$ using a scoring function F_{sal} based on the bilinear matching between h_D and h_{s_i}, the transformer output after the document-level encoding, same as in Eq. 4.

$$F_{\text{sal}}(s_i) = \frac{\exp h_D W_{ds} h_{s_i}}{\sum_{j=1}^{j=L} \exp h_D W_{ds} h_{s_j}} \quad (9)$$

The learning objective is to maximize the log likelihood of the summary sentences in the training data:

$$\mathcal{L} = \sum_{s_i \in \hat{S}^*} \log F_{\text{sal}}(s_i) \quad (10)$$

Redundancy Features. In the selection step, we represent redundancy explicitly to let the model focus on learning how to balance salience and redundancy. We extract ngram-matching and semantic-matching features at each k-th step to indicate the redundancy of a candidate sentence s_i given the so-far selected sentences, i.e., $\hat{S}_{k-1}$. The ngram-matching feature $f_{n\text{-gram}}$ is computed as:

$$f_{n\text{-gram}} = \frac{|n\text{-gram}(\hat{S}_{k-1}) \cap n\text{-gram}(s_i)|}{n\text{-gram}(s_i)} \quad (11)$$

where n-gram(x) is the set of n contiguous words in x. We collect $f_{n\text{-gram}}$ for $n = \{1, 2, 3\}$. We also compute the semantic-matching feature f_{sem}:

$$f_{\text{sem}} = \max_{\hat{s}_j \in \hat{S}_{k-1}} \cos(h_{s_i}, h_{\hat{s}_j}) \quad (12)$$

Since most cosine values between output embeddings from the transformer layers fall in a small range near to 1, we apply a min-max normalization on f_{sem} to enlarge the value differences and obtain a updated feature $\tilde{f}_{\text{sem}}$.

The impact of redundancy features on final scores is not linear. Sentences with high redundancy values should be punished more. To capture the effect of the redundancy features at different value sections, we equally divide the range of $[0, 1]$ to m bins and discretize each feature to the corresponding bin according to its value, as shown in Figure 1. In this way, we convert each feature into a one-hot vector of length m and then we concatenate them to obtain a overall redundancy feature vector $F_{\text{red}}(s_i) = [f'_{1\text{-gram}}; f'_{2\text{-gram}}; f'_{3\text{-gram}}; \tilde{f}'_{\text{sem}}]$ where f' represents the one-hot vector after binning f.

Ranker for Sentence Selection. In the sentence selection step, AREDSUM-CTX only needs to learn how to score a sentence based on its redundancy features $F_{\text{red}}(s_i)$ and its salience score $F_{\text{sal}}(s_i)$ from Eq. 9. Note that the first selected sentence is the one ranked with the largest salience score. We use a three-dimensional matrix $W_{\mathcal{F}}$ to do a bilinear matching between the redundancy features and salience score and obtain a output matching vector with dimension d. Then we apply a single-layer MLP on top to output a final score:

$$f(s_i) = W_f \tanh(F_{\text{sal}}(s_i) W_{\mathcal{F}} F_{\text{red}}(s_i)) \quad (13)$$

During training, we randomly select $1, 2, \cdots, l$-1 sentences from the extracted ground-truth set $\hat{S}^*$ as the context and let the model learn to find the next sentence that is both salient and novel, where l is the maximum number of sentences to be included in the predicted summary. The training objective is the same as in § 4.2 except that $o(s_i)$ in Eq. 6 is replaced with $f(s_i)$ in Eq. 13. In contrast to

AREDSUM-SEQ where the target output is an ordered sequence, the loss of AREDSUM-CTX is not order-sensitive since the goal is always to predict the next best sentence given a set of unordered selected sentences as context.

5 Experimental Setup

5.1 Datasets

We evaluate our model on two standard extractive summarization datasets, namely CNN/DailyMail (Hermann et al., 2015) and NewYork Times (NYT) (Sandhaus, 2008).

CNN/DailyMail contains news articles associated with a few bullet points as the article's highlight. We use the standard splits of Hermann et al. (2015) which has 287,226 documents for training, 13,368 for validation, and 11,490 for testing. We conduct preprocessing following the same method in Liu and Lapata (2019). Entities are *not anonymized* in our experiments as in Zhou et al. (2018); See et al. (2017); Zhang et al. (2019); Liu and Lapata (2019). We truncate articles up to 512 tokens. To collect sentence labels for extractive summarization, we use a greedy strategy similar to (Nallapati et al., 2017; Zhang et al., 2019). We label the subset of sentences that can maximize ROUGE scores against the human-generated summary as 1 (sentence to be included in the summary). The remaining ones are labeled as 0.

NYT50 is an annotated corpus of the New York Times. Following Paulus et al. (2017) and Durrett et al. (2016), we discard marks and words such as "(s)" and "photo" at the end of the abstract and filter out the articles with summaries shorter than 50. We sort the articles chronologically and split the data into training/validation/test sets according to the ratio of $0.8/0.1/0.1$, yielding 133,602/16,700/16,700 documents, respectively. We following the same remaining steps for preprocessing and extractive label collection as the CNN/DailyMail.

5.2 Implementation Details

Our implementation [3] is based on PyTorch and BERTSUM(Liu and Lapata, 2019) [4]. We use "bert-base-uncased" version of BERT[5] to do sentence-level encoding. We fine-tune our models using the objective functions in § 4. We set the number of document-level transformer layers to 2. The dropout rate in all layers is 0.1. We search the best value of τ in Eq. 8 in $\{10, 20, 40, 60\}$. We train our models using the Adam optimizer with $\beta_1 = 0.9$, and $\beta_2 = 0.999$ for 2 epochs. We schedule the learning rate according to Vaswani et al. (2017) with initial value $2e$-3 and 10,000 warm-up steps.

We use teacher-forcing to train AREDSUM-SEQ. To learn the k-th sentence in the target sequence, we replace the first $k-1$ input sentences with other random sentences in the document with the probability of 0.2 [6]. We hypothesize that if the previously selected sentence is not always the golden (right) sentence, it can improve the model's robustness during training. We use two transformer layers in the decoder.

For AREDSUM-CTX, we train the salience ranker using the same settings as in Liu and Lapata (2019), and all the parameters in the salience ranker are fixed when we train the ranker for selection. This ensures that the salience score of each sentence stays the same during sentence selection. We select the optimum size of the bins for discretized redundancy features by sweeping the values in $\{10, 20, 30\}$ and the size of the output dimension d of $W_{\mathcal{F}}$ in Eq. 13 using $\{5, 10, 20, 30\}$.

5.3 Baselines

We compare our models to the state-of-the-art extractive summarization model BERTSUMEXT (Liu and Lapata, 2019), which uses Trigram Blocking (TRIBLK) (Paulus et al., 2017) to filter out sentences with trigram overlap with previously extracted sentences. We report the performance of BERTSUMEXT with and without TRIBLK separately to show the impact of this heuristic.

We also compare against other baselines including: LEAD3, NN-SE (Cheng and Lapata, 2016), SUMMARUNNER (Nallapati et al., 2017), Seq2Seq (Kedzie et al., 2018), NEUSUM (Zhou et al., 2018), and HIBERT (Zhang et al., 2019) along with ORACLE for upper bound on performance. LEAD3 is a commonly used effective baseline that extracts the first 3 sentences in the document. NN-SE (Cheng and Lapata, 2016) and SUMMARUNNER (Nallapati et al., 2017) both formulate extractive summarization as a sequence labelling task. NN-SE uses unidirectional GRU for both the encoding and decoding processes. SUMMARUNNER encodes

[4] `https://github.com/nlpyang/BertSum`

[5] `https://git.io/fhbJQ`

[6] We found this number after light parameter value sweep.

sentences with BiGRU and considers salience, redundancy, absolute and relative positions of sentences during scoring. Seq2Seq (Kedzie et al., 2018) conducts binary classification by encoding the sentences with a bidirectional GRU (BiGRU) and using a separate decoder BiGRU to transform each sentence as a query vector that attends to the encoder output. NeuSum (Zhou et al., 2018) learns to jointly score and select sentences using a sequence-to-sequence model to optimize the marginal Rouge gain and reduce redundancy implicitly. HiBert (Zhang et al., 2019) pre-trains a hierarchical BERT for extractive summarization without dealing with redundancy. Among these methods, NeuSum implicitly reduces redundancy by jointly scoring and selecting sentences with a sequence generation model. SummaRuNNer considers redundancy during the sequence labeling. The other baselines do not conduct redundancy removal.

6 Results and Discussion

6.1 Automatic Evaluation Results

Following earlier work (Zhou et al., 2018; Liu and Lapata, 2019), we include 3 sentences as the summaries for each system for a fair comparison. We evaluate the full-length Rouge-F1 (Lin, 2004) of the extracted summaries and report Rouge-1, Rouge-2 and Rouge-L which indicates the unigrams, bigrams overlap and longest common subsequence against human edited summaries. The full-length Rouge-F1 (Lin, 2004) scores of the extracted summaries are evaluated using the official Perl script[7] for both CNN/DailyMail and NYT50. The results of NeuSum and HiBert are taken from their original papers while we obtained the rest of the results by re-running the models. Since in the previous work (Liu and Lapata, 2019; Zhang et al., 2019; Paulus et al., 2017) there are no consistent ways of pre-processing the NYT dataset for extractive summarization, we only report the evaluation results from the models we re-trained on this dataset in Table 2.

CNN/DailyMail. Results shown in Table 1 are all comparable as we use the same *non-anonymized* version of CNN/DailyMail. For BertSumExt-based methods, we observe that redundancy removal helps improve the Rouge score compared to BertSumExt. TriBlk has considerably better performances; ARedSum-Seq achieves better Rouge-1/L scores; ARedSum-Ctx significantly outperforms the other redundancy elimination methods. [8] The performance differences of ARedSum-Ctx and TriBlk comes from 30.6% summaries output by the two systems in the test set. In other cases, they agrees with each other. This shows that by *adaptively* balancing salience and diversity, ARedSum-Ctx is superior to TriBlk when redundancy removal is promising.

Table 1: Full-length Rouge (RG) F1 evaluation (%) on the CNN/DailyMail test set. a/b and A/B indicate significant improvements over BertSumExt/BertSumExt+TriBlk with $p < 0.05$ and $p < 0.0001$ respectively.

Model	RG-1	RG-2	RG-L
Oracle	52.59	31.24	48.87
Oracle+TriBlk	51.65	30.50	47.89
Lead3	40.42	17.62	36.67
NN-SE	40.81	17.91	37.03
Seq2Seq	41.83	19.29	38.28
SummaRuNNer	41.84	19.31	38.31
NeuSum	41.59	19.01	37.98
HiBert	42.37	19.95	38.83
BertSumExt	42.61	19.99	39.09
BertSumExt+TriBlk	43.25	20.24	39.63
ARedSum-Seq	42.72^{a}	19.82	39.15
ARedSum-Ctx	$\mathbf{43.43}^{AB}$	$\mathbf{20.44}^{AB}$	$\mathbf{39.83}^{AB}$

We also find that the sequence generation models, i.e., NeuSum and our ARedSum-Seq, do not have clear advantage over other models regardless of their encoder network structure (i.e., Bert or other neural architectures). For instance, SummaRuNNer and Seq2Seq models have the best performance among methods that are not based on Bert[9]. Our ARedSum-Seq perform similarly to BertSumExt. ARedSum-Seq is inferior to ARedSum-Ctx due to its order-sensitive optimization objective. While ARedSum-Ctx learns to optimize towards all the possible ordering of the ground truth sentence set, ARedSum-Seq is optimized towards only one sequence of them. Another ordering of the same set will be penalized by ARedSum-Seq even though they have the same ROUGE score. Its significant worse P@1 (shown in Section 6.2) also confirms this point.

---

[7] `https://github.com/andersjo/pyrouge/tree/master/tools/ROUGE-1.5.5`

[8] The salience ranker of ARedSum-Ctx alone performs similarly to BertSumExt.

[9] The Rouge scores of SummaRuNNer are lower than NeuSum in Zhou et al. (2018) because the results of SummaRuNNer are from the anonymized version CNN/DailyMail, which are not comparable with the results of NeuSum on the *non-anonymized* version.

Table 2: Full-length ROUGE (RG) F1 (%) evaluation on the NYT50 test set. a/b and A/B indicate significant BERTSUMEXT/BERTSUMEXT+TRIBLK with $p < 0.02$ and $p < 0.0001$ respectively.

Model	RG-1	RG-2	RG-L
ORACLE	56.23	37.92	49.45
ORACLE+TRIBLK	54.32	36.33	47.53
Lead3	38.20	19.29	30.49
NN-SE	41.92	22.45	33.88
SEQ2SEQ	44.45	24.72	36.20
SUMMARUNNER	44.70	24.87	36.44
BERTSUMEXT	45.46	**25.53**	37.17
BERTSUMEXT+TRIBLK	44.90	24.87	36.63
AREDSUM-SEQ	45.15^{B}	25.14^{B}	36.79^{B}
AREDSUM-CTX	$\mathbf{45.54}^{AB}$	25.52^{B}	$\mathbf{37.22}^{aB}$

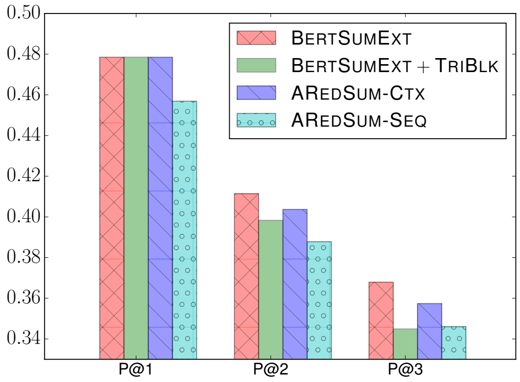

Figure 2: The precision of the extracted sentences at step k on CNN/DailyMail.

NYT50. In contrast to CNN/DailyMail, we observe that TRIBLK has harmed the performance of BERTSUMEXT on NYT50. In fact, as shown in Table 2, applying TRIBLK on ORACLE also causes reduction in ROUGE-1,2,L scores by 1.91, 1.59 and 1.92 absolute point respectively, which are much larger than those drops in CNN/DailyMail (0.94, 0.74 and 0.98). This indicates that TRIBLK filters out more sentences that have high ROUGE gain on NYT50 than CNN/DailyMail, causing more drop of ROUGE. It also shows that sentences in oracle summaries have more trigram overlap on NYT50 than CNN/DailyMail, which implies that redundancy removal on NYT50 may have limited gains and a simple unified rule (TRIBLK) applying on all the documents could harm the performance.

We also observe that AREDSUM-SEQ performs better than BERTSUMEXT+TRIBLK but worse than BERTSUMEXT. In contrast, AREDSUM-CTX achieves higher performance than BERTSUMEXT+TRIBLK and AREDSUM-SEQ by representing redundancy explicitly and controlling its effect dynamically. Since redundancy removal has a limited potential gain on NYT50, the predictions of AREDSUM-CTX differ from BERTSUMEXT only in 10.1% of the test set. However, these differences still lead to significant overall improvements.

Note that the gain of AREDSUM-CTX comes only from redundancy removal, which takes effect from the second step of selecting sentences. The improvements can be larger when redundancy removal has higher potentials (e.g., CNN/DailyMail) and smaller on datasets (e.g., NYT50) with lower potentials. In either case, it does not harm the performances as the other methods, which shows that it is *adaptive* and robust.

6.2 Model Analysis

Precision at Each Step. Since the content of sentences with positive labels, i.e., $\hat{S}^*$, could vary from the original human-generated abstractive summaries S^*, models that have higher precision with respect to $\hat{S}^*$ do not necessarily yield better ROUGE scores against S^*. Because BERTSUMEXT is optimized towards $\hat{S}^*$ while AREDSUM-CTX and AREDSUM-SEQ aim to learn to select sentences with best ROUGE gain against S^*, they behave differently in terms of ROUGE and precision. Thus, we analyze how our model's selection at each k-th step affects the ROUGE performance. We only present the precision on CNN/DailyMail in Figure 2 since similar trends are observed on NYT50. Note all the models except AREDSUM-SEQ have the same $P@1$ because initially, the model's selection is only based on salience. Filtering and demoting the selected sentences starts to take effect only after the second step.

As shown in the figure, BERTSUMEXT has the best $P@1, P@2$ and $P@3$ among all, which is reasonable since $\hat{S}^*$ is the target which it is optimized to learn. When TRIBLK is applied, $P@2$ and $P@3$ drop a lot while the ROUGE scores are up (as in Table 1). It indicates that TRIBLK could filter out some informative but redundant sentences during selection, which harms precision but improves ROUGE. In contrast, $P@2$ and $P@3$ of AREDSUM-CTX is between BERTSUMEXT with and without TRIBLK. Through learning towards ROUGE gain given the previously extracted sentences, AREDSUM-CTX achieves the best ROUGE scores with less harm to precision, which means that AREDSUM-CTX can better balance salience and redundancy.

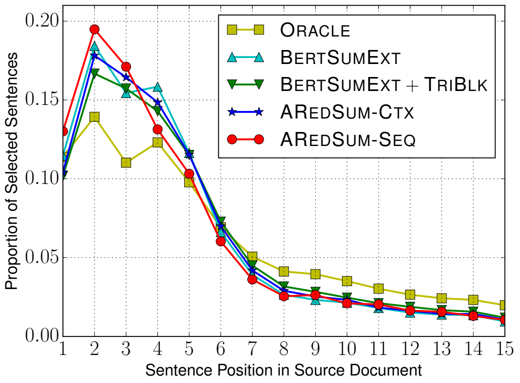

Figure 3: The proportion of extracted sentences in terms of their position in the document.

AREDSUM-SEQ has a significantly lower $P@1$ than the others since its objective at the first step is to find the sentence with maximal ROUGE gain, which is only one in $\hat{S}^*$. At steps 2 and 3, the disadvantage of AREDSUM-SEQ becomes smaller. It has similar $P@3$ to BERTSUMEXT+TRIBLK. The generated sequence of sentences cover a decent portion of $\hat{S}^*$, but it is still worse than the methods that do not use order-sensitive optimization objectives.

Position of Selected Sentences. Figure 3 shows the position of sentences extracted by different models and ORACLE on CNN/DailyMail. A large portion of oracle sentences are the first 5 sentences, and all the models tend to extract the leading 5 sentences in the predicted summaries. The output of AREDSUM-SEQ concentrates more on the first 3 sentences, which differs from ORACLE more than the other models. With TRIBLK, BERTSUMEXT selects sentences in later positions more. The position distribution of AREDSUM-CTX is between BERTSUMEXT with and without TRIBLK, which is similar to their precision distribution in Figure 2. This indicates that AREDSUM-CTX seeks to find a smoother way to filter out sentences that are redundant but salient, and these sentences tend to be at earlier positions.

6.3 Human Evaluation

We also conduct human evaluations to analyze how our best model compares against the best baseline model. On both datasets, we randomly sample 20 summaries constructed by the best baseline and our best model from the cases where their ROUGE-2 score difference is more than 0.05 points. Following Zhou et al. (2018), we asked two graduate student volunteers to rank the summaries extracted by different models from best to worst in terms of *informativeness*, *redundancy* and the *overall* quality. We allowed ties in the analysis. Average ranks of the systems are shown in Table 3.

Table 3: Average ranks of our best method and the best baseline on CNN/DailyMail and NYT50 in terms of informativeness (Info), redundancy (Rdnd) and the overall quality by human participants (the lower, the better). $*$ and $\dagger$ indicates significant improvements with $p < 0.03$ and $p < 0.0001$.

CNN/DailyMail	Info	Rdnd	Overall
BERTSUMEXT + TRIBLK	1.50	1.55	1.55
AREDSUM-CTX	1.20	1.15^*	1.15^*
NYT50	Info	Rdnd	Overall
BERTSUMEXT	1.50	1.60	1.55
AREDSUM-CTX	1.35	$1.00^\dagger$	1.35

On CNN/DailyMail, AREDSUM-CTX ranks higher than BERTSUMEXT+TRIBLK in terms of each aspect. On NYT50, AREDSUM-CTX has a more compelling performance in terms of redundancy than informativeness. This is consistent with the fact that BERTSUMEXT only focuses on learning salience and does not deal with redundancy during sentence selection. From both automatic and human evaluation of our best model and the best baseline, we can see that removing redundancy with our models is better than redundancy removal with heuristics and no redundancy removal.

7 Conclusions

Extending a state-of-the-art extractive summarization model, we propose AREDSUM-SEQ that jointly scores and selects sentences with a sequence generation model and AREDSUM-CTX that learns to balance salience and redundancy with a separate model. Experimental results show that AREDSUM-CTX outperforms AREDSUM-SEQ and all other strong baselines, which yields that redundancy reduction helps improve summary quality, and it is better to model the effect of redundancy explicitly than jointly with salience during sentence scoring.

Abstract

It has been well-documented for several languages that human interlocutors tend to adapt their linguistic productions to become more similar to each other. This behavior, known as entrainment, affects lexical choice as well, both with regard to specific words, such as referring expressions, and overall style. We offer what we believe to be the first investigation of such lexical entrainment in Hebrew. Using two existing measures, we analyze Hebrew speakers interacting in a Map Task, a popular experimental setup, and find rich evidence of lexical entrainment. Analyzing speaker pairs by the combination of their genders as well as speakers by their individual gender, we find no clear pattern of differences. We do, however, find that speakers in a position of less power entrain more than those with greater power, which matches theoretical accounts. Overall, our results mostly accord with those for American English, with a lack of entrainment on hedge words being the main difference.

1 Introduction

Entrainment, also known as accommodation or alignment, is a widespread phenomenon in human interaction which leads interlocutors to adapt to each other to become more similar. It has been found for a variety of linguistic dimensions, including prosody (Levitan and Hirschberg, 2011), phonetics (Pardo, 2006), syntax (Reitter et al., 2006), and lexical choice (Brennan and Clark, 1996).

Lexical entrainment has been studied for several types of lexical choices from specific sets of words – such as referring expressions (Brennan and Clark, 1996), high-frequency words and task-related words (Rahimi et al., 2017), as well as hedge and cue phrases (Levitan et al., 2018) – to the wider linguistic style (Niederhoffer and Pennebaker, 2002). This motivates us to consider both specific word sets and overall language use here.

Importantly, there are correlations between lexical entrainment and interesting aspects of the conversation. These include task success for both speaker pairs (Reitter and Moore, 2007; Nenkova et al., 2008) and groups (Gonzales et al., 2010; Friedberg et al., 2012), conversation flow and perceived naturalness (Nenkova et al., 2008), as well as power differences between the speakers (Danescu-Niculescu-Mizil et al., 2011). This suggests practical applications and has led to the development of entraining natural language generators in Dutch (De Jong et al., 2008), German (Buschmeier et al., 2009), and American English and European Portuguese (Lopes et al., 2015), among others.

To the best of our knowledge, there has not been any systematic research on lexical entrainment in Hebrew or any other Semitic Language. Previous studies analyzing lexical choice in Semitic Languages focus on borrowing and code-switching, for instance between Arabic and English (Abu-Melhim et al., 2016) and Arabic and Hebrew (Hawker, 2018). Given the important social role of entrainment and its potential applications, our study provides an important contribution by presenting the first analysis of lexical entrainment in Hebrew. This helps identify variations in how the behavior manifests in different linguistic and cultural contexts. We note that in a recently published study (Weise et al., 2020), we analyzed acoustic-prosodic entrainment in Hebrew for the same data. Together, these two papers provide a broad investigation of entrainment for this novel language context.

2 Corpus

In this study, we analyze the Open University of Israel Map Task Corpus (MaTaCOp) (Azogui et al., 2016) of dyadic, Hebrew conversations, modeled after the HCRC Map Task Corpus (Anderson et al., 1991). Each participant was given a map with la-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 292–299
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

beled landmarks, some of them shared with the partner's map, some unique. The map of one participant in a pair, the *leader*, contained a path among the landmarks. It was their task to describe the path so their partner, the *follower*, could reproduce it. All speaker pairs discussed the same two pairs of corresponding maps, with either speaker acting as a leader for one map and as a follower for the other. We refer to whole conversations as *sessions* and to each of the two parts as *tasks*.

MaTaCOp contains about six hours of conversations between 32 speakers, all of them fluent in Hebrew. There are six female, six mixed, and four male pairs. Most of the paired speakers were acquainted prior to the experiment. We analyze the influence of this aspect of our data in Section 5.7. Further details on the level of familiarity is provided in Appendix B. For more details on the corpus in general, see Weise et al. (2020).

3 Transcription, Tokenization, and Lemmatization

MaTaCOp is fully transcribed. The phoneme set consists of the five vowels [i, a, e, o, u] and 21 consonants of Modern Hebrew. The pharyngeal [ʕ] and the glottal [ʔ] are not represented. The phonetic representation removes ambiguity that occurs in Hebrew orthography. For example, the grapheme למה is represented with two different transcriptions, *le-ma* "what for?" and *lama* "why?". In this paper, we use Romanization of Hebrew to transliterate Hebrew words.

Tokenization, on the other hand, generally follows standard Hebrew orthography. For instance, proclitics (such as *mi-* "from") were transcribed attached to the subsequent word (e.g., *mi-nekuda* "from point"). However, in case a silent pause or other disfluency occurred between a clitic and the subsequent word, the clitic was transcribed separately, as in *mi- nekuda* "from point". In total, this yields 50075 tokens for the corpus.

Due to Hebrew's rich morphology, many of the words in our corpus appear in a variety of grammatical forms, such as *agol* "round.M.SG", *agula* "round.F.SG", *agul-im* "round.M.PL", and *ha-agol* "the-round". We use a manually created list of grammatical forms for each lemma to lemmatize and count occurrences per lemma.[1] Overall, there are 1,038 lemmas and 2,179 other grammatical forms.

4 Lexical Entrainment Measures

We measure the lexical similarity of speakers' utterances per session (or task, where noted) using two previously established measures, one for a specific set of words W, one for the overall productions.

Per word $w \in W$ and per speaker S, the first measure determines $cnt_S(w)$, the number of times w was uttered by S, and ttl_S, the total number of words uttered by S. Similarity between a pair of speakers S_1, S_2 is then defined based on the absolute difference of the fractions per word, as

$$sim_1(S_1, S_2) = -\sum_{w \in W} \left| \frac{cnt_{S_1}(w)}{ttl_{S_1}} - \frac{cnt_{S_2}(w)}{ttl_{S_2}} \right| .$$

Nenkova et al. (2008) proposed this measure for high-frequency words. Note that it is symmetric.

The second measure was originally proposed by Gravano et al. (2014) to compare tones and break indices (ToBI). For it, we construct a trigram language model for each speaker from their utterances, using SRILM (Stolcke, 2002). The measure $sim_2(S_1, S_2)$ is then defined as the negated perplexity of using the language model for S_1 to predict all utterances of S_2, computed with SRILM. Low perplexity indicates that the model for S_1 is a good representation of the utterances of S_2. In this case, the phrases used by S_2 are essentially a subset of those used by S_1. We interpret this as entrainment *of* S_1 *towards* S_2 as it signals that S_1 incorporated S_2's phrases into their own. Conversely, high perplexity indicates a lack of entrainment. This is why we use negated perplexity for sim_2. Note that this measure is asymmetric. For a symmetric version, we simply add the asymmetric values for both directions, following Weise and Levitan (2018).

To determine whether significant entrainment is present, we follow Levitan et al. (2012). Each similarity value $sim_i(S_1, S_2)$ for a speaker S_1 with their partner S_2 is compared with the weighted average similarity of S_1 with non-partners, using paired Student's t-tests. Non-partners must have the same gender as S_2 and their partners must have the same gender as S_1. For similarity per task, non-partners must also be talking about the same map and have the same role as S_2. Non-partners are weighted by how closely their language model's entropy, computed using SRILM, matches that of the actual partner (absolute differences). This is meant to account for the effect that the richness of a speaker's lexical inventory has on our measures and follows Weise and Levitan (2018).

5 Results

5.1 Entrainment on most frequent lemmas

Following Nenkova et al. (2008), we first use sim_1 to check whether speakers in our corpus entrain on its 25 most frequent lemmas (excluding 56 lemmas representing landmark labels and the directional terms in Section 5.2). We find that speakers do significantly entrain on these lemmas ($t(15) = 4.15, p = 8.54e-04$). That is, the distributions of the 25 most frequent lemmas show greater similarity between partners than with non-partners. This effect also approaches significance for just the female pairs ($t(5) = 2.83, p = 0.037$) and male pairs ($t(3) = 3.14, p = 0.052$), but not for mixed pairs ($t(5) = 1.51, p = 0.19$).[2] Table 1 summarizes these results and those for the following subsections. We also use independent Student's t-tests to conduct direct comparisons between the similarity values for the gender pairs, i.e., female vs. male, female vs. mixed, and male vs. mixed.[3] This yields no significant differences and no difference even approaches significance (lowest $p = 0.53$).

5.2 Entrainment on directional terms

Leaders and followers in our corpus use various directional terms to communicate the path among the landmarks. To assess whether they adopt each other's terminology, we follow Silber-Varod et al. (2020) and consider ten different terms of two basic types. This includes the directions of a compass – i.e., *ṣafon* "north", *darom* "south", *maarav* "west", and *mizraḥ* "east" – and relative directions – i.e., *le-mal-a* "upwards", *me-al* "above", *le-mat-a* "downwards", *mi-taḥat* "below", *smol* "left", and *yamin* "right". We treat the lemmas of these ten terms as a set W for measure sim_1 and count all occurrences for all grammatical forms per lemma.

Using this approach, we find significant evidence of entrainment on these ten directional terms overall ($t(15) = 6.64, p =$ 7.86e-06) as well as for female pairs ($t(5) = 5.75, p = 0.0022$), male pairs ($t(3) = 4.42, p = 0.022$), and mixed pairs ($t(5) = 4.85, p = 0.0047$) separately. Again, no difference between the gender pairs even approaches significance (lowest $p = 0.086$).

5.3 Entrainment on geometric terms

In addition to directional terms, speakers employ a variety of geometric terms to describe the shape of the path, the locations of the landmarks, and their relation to each other. This includes, for example, *malben* "rectangle" and *b-a-hitstalvut* "at the intersection". To determine whether speakers entrain on these, we consider a list of 34 lemmas (with a total of 199 grammatical forms) of such terms as another set W for measure sim_1. This yields significant results overall ($t(15) = 4.82, p = 2.2e-04$) as well as for female ($t(5) = 5.08, p = 0.0038$) and mixed pairs ($t(5) = 6.62, p = 0.0012$), but not for male pairs ($t(3) = 1.00, p = 0.39$). Once again, none of the differences between gender pairs even approach significance (lowest $p = 0.72$).

5.4 Entrainment on hedge words

The difficulty of describing irregular path shapes in the Map Task, along with incomplete information about the landmarks, creates uncertainty for the speakers which encourages the use of hedge words. Furthermore, in their corpus of deceptive interviews, Levitan et al. (2018) found the strongest evidence of lexical entrainment for hedge words, stronger than for the 25 most frequent words. These observations motivate us to analyze hedge words as well, using a translated version of the same list Levitan et al. used (with 37 lemmas and 78 grammatical forms total). However, we find no significant entrainment, neither overall ($t(15) = 1.61, p = 0.13$) nor for any of the gender pairs (lowest $p = 0.14$).

5.5 Entrainment on imperative verb forms

The different roles in the Map Task facilitate the use of imperative verb forms. Leaders might command followers to draw a path a certain way, while followers might demand information or a different way of describing, as in the utterance we quoted in the title. Of course, they can achieve the same communicative goals with phrases that avoid imperatives, using, for example, nonverbal predicates or standard infinitival clauses such as *az at tsrix-a em laredet mi-tsad smol la-xanut* "so you have to um to get down from the left side of the store". This flexibility allows for entrainment.

However, note that the different roles actually make it unlikely for speakers to use the *same* verbs. A leader might instruct a follower to "*draw* the path

---

[2] To account for multiple testing, we regard these four tests as a "family" and treat results up to the k-th smallest p-value p_k as significant at level $\alpha = 0.05$, where k is the largest integer such that $p_k \leq \frac{k}{m}\alpha$, with m being the size of the family (Benjamini and Hochberg, 1995). We do the same for each analogous group of four tests for other entrainment targets in the following subsections.

[3] We again account for multiple testing by treating these three tests as a family here and in the following subsections.

Entrainment target	Measure	Significant Overall	FF	MM	FM
25 most frequent words	sim_1	**	(*)	(*)	
directional terms	sim_1	***	**	*	**
geometric terms	sim_1	**	**		**
hedge words	sim_1				
imperative verb forms	sim_1				
overall productions	sim_2	*			

Table 1: Results per entrainment target and measure, overall and per gender pair (female, male, mixed) with significance level (***: $\alpha < 0.001$, **: $\alpha < 0.01$, *: $\alpha < 0.05$, (*): $\alpha < 0.1$) per family (see Footnote 2). Direct comparisons between gender pairs do not show significant differences for any entrainment target.

around the lake", while the follower might demand "*tell* me how close". Therefore, we check whether speakers adopt an imperative mode of speaking from each other, regardless of individual verbs.

We identified a list of 122 imperative verb forms[4] in our corpus and determine what fraction of each speaker's words this list represents. That is, W for sim_1 consists of only one placeholder "word". Using this method, we find no significant entrainment, neither overall ($t(15) = 1.03, p = 0.30$), nor for any gender pair (lowest $p = 0.15$).

5.6 Entrainment on overall productions

Lastly, we use sim_2 to check whether speakers entrain on their partners' overall language use, i.e., whether they model their partners' productions better than those of other speakers. We find that this is the case overall ($t(15) = 3.09, p = 0.0074$) but neither for female pairs ($t(5) = 1.44, p = 0.21$), nor for male pairs ($t(3) = 2.72, p = 0.073$), nor for mixed pairs ($t(5) = 2.20, p = 0.08$). Once again, we find no significant differences between the gender pairs in direct comparisons (lowest $p = 0.43$).

Since sim_2 is asymmetric, we can use it to compare the entrainment behavior of individual speakers based on their gender and role, respectively, with independent Student's t-tests. This yields no significant difference between female and male speakers ($t(30) = 1.06, p = 0.30$).

In order to compare speakers based on their roles, we measure at the task level with separate language models and predictions of all utterances of a task instead of a whole session. Doing so yields a highly significant difference, with followers entraining more than leaders ($t(62) = 5.52, p = 6.95\text{e-}07$). Of course, leaders speak significantly more than followers ($t(62) = 5.04, p = 4.25\text{e-}05$), which might explain why their productions are supersets of those of the followers. However, the difference remains significant even when normalizing the measure by the number of words spoken ($t(62) = 3.22, p = 0.0020$).

5.7 Influence of familiarity

Prior acquaintance between subjects, as in our data, is unusual in entrainment research and introduces a confound to our comparison with other studies. We conduct some additional analysis of this here and discuss it further in Section 6.

For this analysis, we consider speaker pairs in two groups, of "high" (11 pairs) and "low" (5 pairs) familiarity.[5] For each entrainment target, we compare the similarity values for the two groups with independent Student's t-tests. This does yield a significant difference for entrainment on overall productions ($t(14) = 3.31, p = 0.0051$), but not for any other entrainment target ($0.05 < p < 0.83$). That is, speakers who were already well-acquainted before participating in the experiment, show greater entrainment in their overall language use (and only that) than those with little or no acquaintance.

6 Discussion

In this first analysis of lexical entrainment in Hebrew, using two existing measures, we find substantial evidence of entrainment both on specific groups of words and overall language use.

Speakers entrained on the 25 most frequent lemmas in the corpus, a result that matches findings on

---

[4] Including grammatical imperatives (e.g., *lex* "go.M") and 2nd person prefix conjugation (e.g., *te-lex* "go.M") but excluding the reduced future forms (Bat-El, 2002) which are more ambiguous and inconsistent.

[5] For further details, see Appendix B.

English corpora of telephone conversations (Weise and Levitan, 2018), deceptive interviews (Levitan et al., 2018), and task-oriented, multi-party interactions (Rahimi et al., 2017).

The broadest and most significant evidence of entrainment we find is for directional terms and the geometric terms to describe the path. In fact, in some cases speakers actively requested entrainment, as in: *a azov et ha-sinus-im daber iti be-smol-a yemin-a ve-be-zaviy-ot* "uh leave the sines, talk to me with to-the-left, to-the-right, and with angles". Our results match previous ones for referring expressions (Brennan and Clark, 1996) and "project words" (Rahimi et al., 2017) in English.

Contrary to Levitan et al. (2018), who found the strongest evidence of lexical entrainment for hedge words, we find no entrainment for these. This may be because Hebrew speech patterns tend to be very "direct" (Katriel, 2004, ch.2), more so than English ones (Van Dijk, 1997, p.235), so hedges might be culturally less appropriate.

We do not find that speakers entrain on an imperative mode of speaking. This may be due to data sparsity, though, as imperatives constitute only 1.3% of all tokens (see Appendix A) despite the experimental setting facilitating their use. Studies of syntactic alignment, e.g., by Reitter et al. (2006), have found that English speakers adopt syntactic choices from their interlocutors. A broader investigation of this is needed for Hebrew.

Our results for entrainment on overall productions – how well speakers' language models fit their interlocutors' productions – match prior results for English. Weise and Levitan (2018) found this measure to be significant for both task-oriented dialogs and telephone conversations. But unlike us, they found the results for this measure to be more significant than those for the 25 most frequent terms.

Our results reveal no clear pattern of differences between the gender pairs. The number of entrainment targets and significance levels for female, male, and mixed pairs are comparable (marginally weaker results for male pairs might be partially attributable to a smaller sample size). Direct comparisons between the gender pairs also do not reveal any significant differences for any of our measures. Neither does the comparison between individual speakers based on their gender, using the asymmetric version of our measure for overall productions. Similar analyses for acoustic entrainment in English have sometimes found differences based on speaker gender (Levitan et al., 2012) and sometimes not (Pardo et al., 2018; Weise et al., 2019). In our own analysis of acoustic entrainment in the same Hebrew corpus (Weise et al., 2020), we also found no difference based on speaker gender. The only study of the effect of gender on lexical entrainment we are aware of was for human-robot interactions and found that female speakers exhibited a greater degree of entrainment to the robot interlocutor than males did (Kimoto et al., 2017).

Speakers in subordinate roles are predicted to entrain more than those in power (Giles et al., 1991). This has been confirmed for lexical entrainment in English (Danescu-Niculescu-Mizil et al., 2011) and we find the same here. Followers, having less power due to their dependency on information from the leaders, entrain more than leaders with regard to their overall productions. Conversely, for directional terms alone, Silber-Varod et al. (2020) found that followers had greater influence on the terminology, that is, leaders adopted followers' terms more often than vice versa.

It is worth repeating that speakers in our corpus were acquainted prior to their participation in the experiment. There is little prior research on the impact of this factor. For acoustic-prosodic entrainment, Truong and Heylen (2012) find that unacquainted speakers exhibit more entrainment while Cabarrão et al. (2016) report an example with the opposite trend. The analysis of our own data indicates that familiarity has at least *some* influence, specifically for entrainment on overall productions. However, for hedge words the difference between high and low familiarity pairs is so insignificant ($t(14) = 0.50, p = 0.62$) that we do not believe familiarity explains the difference between our results and those for unacquainted English speakers.

Overall, we find that lexical entrainment in our Hebrew corpus is very much comparable to prior results for English. The only notable difference is the lack of entrainment on hedge words which, as we noted above, may be due to cultural differences. Future research should investigate additional conversational settings in Hebrew, including with unacquainted speakers.

A Percentages of words per list

This paper considers a variety of different word lists for entrainment measure sim_1 (see Section 4). These lists represent different percentages of all the words uttered by various speaker groups in the corpus, as detailed in Table 2. We include them here so they may be used to interpret our results, by themselves or in comparison with other corpora. We note, for instance, that imperative verb forms are comparatively rare, which might partially explain the lack of significant entrainment we found. It also suggests differential use of the word lists by the speaker groups. For instance, as might be expected, the percentage of words that are imperative verb forms is more than twice as high for leaders (1.6%) as for followers (0.7%).

B Session details and raw similarities

Table 3 provides an overview of the sessions, i.e., speaker pairs, in our corpus and their similarity as measured by sim_1 and sim_2 (see Section 4).

Details for the sessions include the gender pair (female, male, mixed) and the level of familiarity between the interlocutors. Familiarity was categorized into two groups. Most speaker pairs were highly acquainted, through marriage (two pairs), prior service in the same military unit (three pairs), or work in the same department (six pairs). The remaining pairs had a low level of acquaintance through work in the same institution with little interaction (four pairs) or no acquaintance at all (one pair).

For each session and entrainment target, the table lists the respective similarity value as well as the baseline similarity derived from the average similarity with non-partners. All values are negative, with values closer to zero indicating greater similarity (see Section 4).

Word list					**Speaker group**				
	All	Female	Male	Leaders	Followers	Female leaders	Female followers	Male leaders	Male followers
25 most frequent words	33.8%	34.1%	33.4%	31.2%	38.8%	31.3%	39.4%	31.1%	38.2%
directional terms	8.8%	9.1%	8.5%	9.0%	8.5%	9.5%	8.5%	8.6%	8.4%
geometric terms	4.5%	5.1%	3.8%	4.8%	3.7%	5.7%	4.1%	4.0%	3.4%
hedge words	3.0%	3.1%	3.0%	3.3%	2.5%	3.5%	2.3%	3.1%	2.7%
imperative verb forms	1.3%	1.2%	1.3%	1.6%	0.7%	1.5%	0.8%	1.6%	0.7%

Table 2: Percentages of all words, uttered by various groups of speakers, that are represented by the different word lists considered as entrainment targets. For example, 9.5% of all the words uttered by female leaders were directional terms. Note that the columns do not add up to 100% since there are many words that are not included in any of our lists.

Abstract

Building open-domain chatbots is a challenging area for machine learning research. While prior work has shown that scaling neural models in the number of parameters and the size of the data they are trained on gives improved results, we highlight other ingredients. Good conversation requires blended skills: providing engaging talking points, and displaying knowledge, empathy and personality appropriately, while maintaining a consistent persona. We show that large scale models can learn these skills when given appropriate training data and choice of generation strategy. We build variants of these recipes with 90M, 2.7B and 9.4B parameter models, and make our models and code publicly available. Human evaluations show our best models outperform existing approaches in multi-turn dialogue on engagingness and humanness measurements. We then discuss the limitations of this work by analyzing failure cases of our models.

1 Introduction

This work provides recipes for building open-domain chatbots that perform well, i.e., to study and identify which methods work well together in order to maximize human evaluations. It has been shown across the field of NLP (Devlin et al., 2019) and in conversational agents in particular (Dinan et al., 2020; Zhang et al., 2019; Adiwardana et al., 2020) that pre-training on large corpora is important. Beyond simply scaling models, the two main takeaways from our study are that: (1) Large improvements can be made by fine-tuning on data that emphasizes desirable conversational skills. We select tasks that make the model focus on personality and engagingness, knowledge, and empathy, achieving large gains by using the recently introduced Blended Skill Talk (BST) set-up (Smith et al., 2020), which targets those aspects by providing training data and initial conversational context (personas and topics). Small models using BST can match or outperform larger models that do not. (2) Two models with the same perplexity but different decoding algorithms can give vastly different results, e.g. we show that the length of the bot's utterances are crucial to human judgments of quality. We show, contrary to previous work which reports that beam search is inferior to sampling (Holtzman et al., 2019; Adiwardana et al., 2020), that careful choice of search hyperparameters can give strong results, e.g., constraining the minimum beam length gives a crucial control of the bland versus spicy spectrum of responses.

In human evaluations our best model outperforms both DialogGPT (Zhang et al., 2019) and the state of the art Meena chatbot (Adiwardana et al., 2020), the latter in a pairwise comparison 75% to 25% in terms of engagingness, and by 65% to 35% in terms of humanness (both statistically significant, two-tailed binomial test, $p < 0.01$).

While the performance of our bot at first sight is very good, we do not believe we are yet close to solving the problem of open-domain conversation. We thus discuss limitations of our models, and initial attempts to solve them. In particular, our models still display: a lack of in-depth knowledge if sufficiently interrogated; a tendency to stick to simpler language; and a tendency to repeat oft-used phrases. We show how unlikelihood training (Welleck et al., 2020) and retrieve-and-refine (Weston et al., 2018) mechanisms are potential avenues for fixing these problems; however, our initial experiments with these methods are inconclusive. We thus discuss future possibilities for alleviating these problems, as well as methods for evaluating them.

Finally, we believe releasing models is the most reliable way to enable full insight into their capabilities. We thus make publicly available our

large-scale, state of the art open-domain conversational agent, including code to fine-tune it, the model weights, and code to evaluate it, so that our setup is reproducible.

2 Related Work

The area of open-domain dialogue has made significant progress recently with end-to-end neural approaches. The ConvAI2 competition at NeurIPS 2018 featured large pre-trained Transformers for the top two winning teams (Dinan et al., 2020). In particular, Wolf et al. (2019) pre-trained via the method of Radford et al. (2018) using the BooksCorpus dataset, resulting in the best perplexities and F1 scores. Since then, results have improved further with the advent of larger, improved pre-training (Lewis et al., 2019; Shuster et al., 2019). In general this extends beyond ConvAI2 to many open-domain dialogue datasets, such as daily dialogue and Cornell Movies (He et al., 2019), and also when multi-tasking across many of these datasets, as we also do here (Shuster et al., 2019; Smith et al., 2020).

A particular large-scale model of note that we compare to in this work is Meena (Adiwardana et al., 2020), a 2.6B parameter Transformer-based model trained on 341 GB of text, that was shown to be superior to variants of DialoGPT (Zhang et al., 2019), Mitsuku[1], Cleverbot[2], and XiaoIce (Shum et al., 2018; Zhou et al., 2020). We also compare directly to DialoGPT, which is a 345M parameter model trained based 147M multi-turn dialogues extracted from Reddit discussion threads.

The evaluation metric used for Meena in (Adiwardana et al., 2020) was SSA, the average of sensibleness and specificity, as judged by human raters either in static or interactive setups, which is shown to highly correlate with asking raters how "humanlike" the model is. We note however that the authors themselves state it may not capture all aspects of such a test, e.g. might not measure empathy. We additionally note that neither Meena's model, the static "Mini Turing Benchmark" used in the paper, nor the phrasing of the SSA evaluation question provided to annotators was released, making certain comparisons difficult. Further, the human-bot conversations were conducted by employees and were not blind to the model type (in the logs they say phrases such as "Hi Meena!"). DialoGPT in contrast is a publicly available open source model, and evaluations can be easily conducted and reproduced.

In this work we employ unbiased crowdworkers with reproducible experiments, and use ACUTE-Eval (Li et al., 2019b) (described more in Section 4) to directly ask the humanness question, rather than a proxy. Further, we also report results on engagingness as a main metric, because this measures more closely whether a human will be interested in talking to our bots.

3 Models, training, and data

3.1 Architectures

We consider three types of architectures in this work: retrieval, generative, and retrieve-and-refine models. All three use Transformers (Vaswani et al., 2017) as a base. More details for the architectures are provided in Appendix A.

Retriever Given a dialogue history (context) as input, retrieval systems select the next dialogue utterance by scoring a large set of candidate responses and outputting the highest scoring one. Typically, all possible training set responses are used as the candidate set. We employ the poly-encoder architecture of (Humeau et al., 2019). We consider two poly-encoder sizes: 256M (from (Smith et al., 2020)) and 622M parameter models which we trained here, both using $N = 64$ codes.

Generator We employ a standard Seq2Seq Transformer architecture to generate responses rather than retrieve them from a fixed set. Our implementation is based on the ParlAI version (Miller et al., 2017). We use Byte-Level BPE tokenization (Radford et al., 2019) trained on the pre-training data, as implemented in HuggingFace's Tokenizers.[3] We consider three sizes of model: 90M parameters (following Shuster et al., 2019), 2.7B parameters and 9.4B parameters. Our 9.4B parameter model has a 4 layer encoder, a 32 layer decoder with 4096 dimensional embeddings, and 32 attention heads. Our 2.7B parameter model roughly mimics the architectural choices of Adiwardana et al. (2020), with 2 encoder layers, 24 decoder layers, 2560 dimensional embeddings, and 32 attention heads.

Retrieve and Refine Current generative models are known to have issues with producing dull and repetitive responses which are improved, but not resolved, by simply scaling (Holtzman et al., 2019; Welleck et al., 2020; Li et al., 2019a). One approach to try to alleviate these problems is to combine a retrieval step before generation, referred to as a retrieve and refine model (Weston et al., 2018). We consider two variants for the retrieval step: dialogue retrieval and knowledge retrieval. Dialogue retrieval uses a retrieval-based dialogue model (see above) first to produce a response, which is then appended to the input sequence of the generator, along with a special separator token, and then generate from that expanded context with the generative architecture above. Knowledge retrieval first retrieves from a large knowledge base and conditions the generation on the retrieved knowledge, as done in (Dinan et al., 2019c). We hence refer to this as Wiz Generative model. We use the same knowledge retrieval system as in (Dinan et al., 2019c). A Retriever (the same as the Retriever paragraph in this section) is then used to rank candidates in the same way as for dialogue retrieval above. We additionally trained a Transformer-based classifier to choose when to perform retrieval or not on a per-turn basis, as some contexts do not require knowledge. We note all other models in this work do not condition on retrieved knowledge.

3.2 Training Objectives

Training for the retrieval models follows Humeau et al. (2019). To train the generative models, we use standard Maximum Likelihood Estimation (MLE). For Retrieve and Refine, we adopt α-blending from Weston et al. (2018) to ensure the model does not ignore the retrieved utterance. To combat some failures in model generations, we also experiment with the unlikelihood loss (Welleck et al., 2020; Li et al., 2019a), penalizing overrepresented n-gram phrases. An extensive description of training objectives and implementation can be found in the Appendix B.

3.3 Decoding

We compare several well-known approaches: beam search for different beam sizes, top-k sampling (Fan et al., 2018), sample-and-rank (Adiwardana et al., 2020). We also experiment with minimum-length constraints that forbid end-token generation below a minimum length, and a predictive-length approach that predicts one of four utterance lengths using a classifier built on top of our retrieval architecture. Finally, we also experiment with subsequence blocking through standard beam blocking of n-grams (Paulus et al., 2017) with $n = 3$, considering both the generated utterance or the input sequence (previous utterances from either speaker).

3.4 Training Data

We use English training data. For pre-training, we use a variant of Reddit discussions, which has also been used in several existing studies, see e.g. Yang et al. (2018); Mazaré et al. (2018); Keskar et al. (2019); Shuster et al. (2019). Following Humeau et al. (2019), we use a previously existing Reddit dataset extracted and obtained by a third party and made available on pushshift.io (Baumgartner et al., 2020). Dataset filtering heuristics are provided in the appendix. Our final dataset contains 1.50B comments totaling 56.8B label BPE tokens and 88.8B context tokens.[4] We divide the corpus into 4096 roughly-equal sized chunks, stratified by thread ID (such that no two comments from the same post appear across folds), and reserve the last two chunks for validation and test respectively, each approximately 0.02% of the full dataset (∼360k comments each). For fine-tuning, we use several smaller, but more focused datasets released by the academic community, that were collected to display desirable conversational traits (Roller et al., 2020): the ConvAI2 dataset (Zhang et al., 2018) focuses on personality and engaging the other speaker, Empathetic Dialogues (Rashkin et al., 2019) focuses on empathy, and Wizard of Wikipedia (Dinan et al., 2019c) focuses on knowledge. Finally, Blended Skill Talk (Smith et al., 2020) provides a dataset that focuses on blending these skills. We refer to the "BST tasks" as training on all four tasks together. In addition to skilled-focus datasets, we apply a classifier similar to the one trained in (Dinan et al., 2019b) at test time to detect toxic language before it is shown, and gauge how often such classifiers flag model responses.

4 Evaluation Methods

While we employ and report automatic metrics, our main evaluation involves the ACUTE-Eval procedure (Li et al., 2019b), whereby evaluators are asked to make pairwise evaluations of complete

---

[4] Note that the 90M model discussed later in the paper uses a variant of the corpus with less filtering. See Shuster et al. (2019) for details.

Model	C2 ($K = 20$)	WoW ($K = 100$)	ED ($K = 100$)	BST ($K = 100$)
256M	88.55	91.70	62.67	83.45
622M	89.96	93.22	70.15	82.11

Table 1: Hits@1/**K** of fine-tuned poly-encoder models on the validation set for BST datasets. Hits@$1/K$ measures recall@1 when ranking the gold label among a set of $K - 1$ other random candidates.

dialogues. We consider two evaluation questions, derived from (Li et al., 2019b): (1) Engagingness question: "Who would you prefer to talk to for a long conversation?"; (2) Humanness question: "Which speaker sounds more human?".

Nevertheless, full human evaluations are time consuming and costly, requiring humans to spend time conducting conversations with bots as well as scoring them. As an alternative, we use the self-chat procedure from Li et al. (2019b) for some of our modeling and hyperparameter choices where the full ACUTE-Eval would end up too costly, and only use the full human-bot chat evaluation at the final stage. In this work we use the BST-setting to perform self-chats, i.e. models are given the personas, topics and previous utterances to initiate the conversation, see Appendix E.2 and Figure A.2. Note that when using deterministic methods such as beam decoding, this prevents the models from generating the same conversation repeatedly.

5 Results & Analysis

5.1 Automatic Evaluations

Retriever We fine-tune the retrieval models on ConvAI2, Wizard of Wikipedia, Empathetic Dialogues, and Blended Skill Talk datasets (BST variants of each[5]) and automatically evaluate them by measuring *hits*@$1/K$ on the validation sets of each of these datasets. Results are shown in Table 1.

Generator We assess the performance of our 90M, 2.7B, and 9.4B parameter models by measuring perplexity on the validation set from pushshift.io Reddit[6] and on the smaller dialogue datasets, before and after fine-tuning. Results are shown in Table 2 and Table 3, and show relatively large perplexity improvements after fine-tuning. Table 3 also shows slightly increased perplexity for Retrieve and Refine (RetNRef), consistent with Weston et al. (2018).

Safety Table 4 also shows that fine-tuning on BST results in safer responses compared to the pre-trained baseline, as gauged by an unsafe word list or the safety classifier of Dinan et al. (2019b),[7] and that humans do utter unsafe responses, but much less frequently so in ConvAI2 than in pushshift.io Reddit. This explains why our fine-tuning tends to make the model reply with fewer unsafe utterances.

5.2 Self-Chat Evaluations

We next perform a number of self-chat ACUTE-Evals (see Appendix G) over various modeling choices, using the engagingness question and $\sim$140 trials per pair compared, in order to select the best model set-up to evaluate in a full human evaluation. While the goal of these self-chat experiments is to whittle down the set of models which undergo full human evaluation, we also provide full experimental results and descriptions in Appendix H.2.

Experiments controlling the minimum beam length (in terms of BPE tokens) with a fixed hyperparameter, or by adjusting it with a predictor of the optimal length, show that both methods improve significantly over not controlling the length (83% to 17%; 81% to 19%). In the remainder of the experiments in the paper we thus chose a minimum beam length of 20 BPE tokens.

We also investigate the use of beam blocking. Blocking tends to increase performance, in line with other works, although the results were not significant. We employ full blocking in the remainder of our experiments. Finally, we compare different values of beam size to other search strategies: Top-k sampling, and the sample and rank strategy of Adiwardana et al. (2020) using Top-k ($k = 40$) and 20 samples, suggesting a sweet spot of beam size, where a value of 10 is superior to 1 or 30, which is then on par with sampling methods (48% to 52%), although none of these results is significant. We employ beam size 10 in the remainder of our experiments.

Fine-tuning on the smaller, more focused BST datasets leads to significant improvements (60% to 40%), which may come from adjusting the model to focus on persona, knowledge and empathy, or providing talking points to work into the conversation. Using persona contexts at conversation time

---

[5] `https://parl.ai/projects/bst`

[6] For the 90M parameter model, results are reported from Shuster et al. (2019), as we use that same model.

[7] Both methods available in ParlAI (Miller et al., 2017).

Name	Total Params	V	L_{enc}	L_{dec}	d	h	Steps	PPL
90M	87,508,992	55K	8	8	512	16	2.86M	25.6
2.7B	2,696,268,800	8K	2	24	2560	32	200K	13.3
9.4B	9,431,810,048	8K	4	32	4096	32	200K	12.2

Table 2: **Perplexity on the validation set of pushshift.io Reddit** for several generative Transformer models with given architecture settings. Note that perplexity is not directly comparable between the 90M models and the larger models as the 90M models use a different dictionary. Columns include the vocabulary size (V), number of encoder and decoder layers (L_{enc}, L_{dec}), embedding dimensionality (d), Multihead Attention Heads (h), and training steps.

Size	Pre-train only	BST Gen	BST RetNRef
90M	20.5	13.8	14.2
2.7B	12.0	9.0	9.8
9.4B	11.2	8.6	-

Table 3: **Average perplexity of the pre-trained and fine-tuned models on the validation sets for the BST datasets.** Note that perplexity is not directly comparable between the 90M models and the larger models as 90M models use a different dictionary. Fine-tuning gives gains compared to pre-training on pushshift.io Reddit alone. The Retriever sizes are 256M and 622M for the 90M and 2.7B RetNRef models, respectively. Results on each individual skill (task) are shown in the appendix and present the same pattern.

	pushshift.io Reddit		ConvAI2	
Method	Word List	Classifier	Word List	Classifier
Human	12.9%	18.5%	0.32%	3.8%
Reddit Gen	4.4%	17.8%	0.10%	12.1%
BST Gen	0.6%	9.5%	0.05%	1.6%

Table 4: **Safety of utterances, before filtering through a safety classifier.** We compare human, pre-trained and fine-tuned 90M model responses given pushshift.io Reddit and ConvAI2 contexts using either an unsafe word list or a trained classifier from (Dinan et al., 2019b). The pushshift.io Reddit dataset contains more unsafe contexts, leading to more unsafe responses. Models fine-tuned on the safer BST tasks are less toxic than the pre-trained pushshift.io Reddit model on either type of dataset context.

provides a win compared to omitting them (54% to 46%), so we use personas for our full experiments.

5.3 Full (Human-Bot Chat) Evaluations

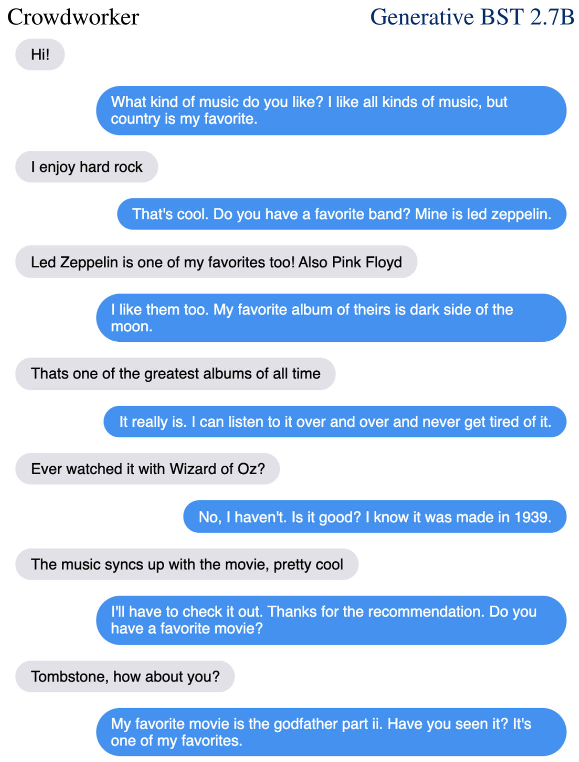
For human-bot conversation data collection we used the same setting proposed in (Adiwardana et al., 2020): open-ended chat that begins with the message "Hi!" from the human to the bot, and has a minimum interactive conversation length of 14 turns, collecting 100 conversations per model via crowdworkers. Figure 1 shows a cherry-picked conversation between a crowdworker and the Generative BST 2.7B model. More examples and more detailed experiments are given in the Appendix.

Overall ranking of models We compare several variants of our models to the publicly available human-human chat logs from Adiwardana et al. (2020), and include the publicly available bot-human Meena logs (Adiwardana et al., 2020) (some toxic conversations were removed by the authors and not made publicly available). Results in Figure 2 confirm that: (1) Fine-tuning on BST (BST Generative 2.7B) is superior to pre-training only (pushshift.io Reddit Generative 2.7B); (2) Beam search with a minimum beam length of 20 (BST Generative 2.7B) is superior to having no minimum length (BST Generative (2.7B) std. beam); (3) The larger BST Generative (2.7B) is superior to the smaller model BST Generative (90M). We find RetNRef models (both dialogue version and using knowledge retrieval) do not improve over their generative counterparts when using the best decoding schemes for the generative models[8].

Our largest BST Generative 9.4B model performs worse on engagingness compared to our 2.7B model, despite having lower perplexity, showing correlation between these metrics is not straightforward. We verified this result further by performing an ACUTE-Eval of engagingness directly comparing the 2.7B and 9.4B against each other, which resulted in a 56% win for the smaller model, aligning with the other results. Future work should aim to understand this result further. Additional experiments matching up our models in pairwise comparisons with the publicly available Meena bot-human logs are provided in the Appendix, showing

---

[8] In earlier experiments (see Figure A.5) we found that RetNRef could outperform its generative counterpart, but after optimizing the generative model decoding parameters, decoding length and beam blocking, it then performs much better compared to RetNRef. The RetNRef model produces longer generations than the vanilla greedy-search generation algorithms, so the original improvement may be from this.



Crowdworker

Generative BST 2.7B

Hi!

What kind of music do you like? I like all kinds of music, but country is my favorite.

I enjoy hard rock

That's cool. Do you have a favorite band? Mine is led zeppelin.

Led Zeppelin is one of my favorites too! Also Pink Floyd

I like them too. My favorite album of theirs is dark side of the moon.

Thats one of the greatest albums of all time

It really is. I can listen to it over and over and never get tired of it.

Ever watched it with Wizard of Oz?

No, I haven't. Is it good? I know it was made in 1939.

The music syncs up with the movie, pretty cool

I'll have to check it out. Thanks for the recommendation. Do you have a favorite movie?

Tombstone, how about you?

My favorite movie is the godfather part ii. Have you seen it? It's one of my favorites.

Figure 1: **Cherry-picked crowdworker example.** Conversation between a crowd worker (left speaker) and the Generative BST 2.7B model (right speaker).

similar trends in ranking of models. In those experiments, our best models improve significantly over Meena, with BST Generative 2.7B winning 75% of the time in pairwise match-ups for the engagingness question and 65% for the humanness question. Meena generally tends to fare better at the humanness question than the engagingness question (see Figure 3), which is line with the goals and modeling choices in that work.

Response Length Figure 4 shows that the average response length (in terms of BPE 8k dictionary tokens) of Generative BST (2.7B) with the constraint (of 20) is around 21 tokens, vs. 9.5 tokens without. Thus, the beam search often ends as soon as the constraint is fulfilled. Meena's average length is 10.4, and humans engaged in human-human chats is 18.0. Humans speaking to models (or other humans) will often match response length if they are engaged in the conversation, and there appears to be correlation of their average response length with engagement (intuitively, humans are expending time and energy typing on their keyboard, which they are more likely to do if engaged).

	Model	vs. Human

5.4 Failure Cases and Model Extensions

While performance in the ACUTE-Eval setup appears at first sight to be very strong (e.g. 49% to 51% for our 2.7B generative model compared to human-human logs), we are nowhere near as close to solving the problem of open-domain conversation as this evaluation would indicate. Here, we highlight problems with our models, and elucidate why our evaluation does not capture them. Selected example failures from crowdworker logs are given as conversation snippets in Figure 6, and further failures constructed by the paper authors are shown in the Appendix (H.5).

Vocabulary Usage Generative models employing beam search decoding tend to generate common words too frequently, and rare words too infrequently, as compared to the human distribution (Holtzman et al., 2018; Welleck et al., 2020; Li et al., 2019a). In dialogue, humans can interpret

Model	Model	Human
Meena	10.4	8.2

Do you have	110	60	6
you have any	82	46	2
a lot of	74	46	14
What do you	57	20	6
you like to	54	43	1

Figure 5: Counts of 5 most common 3-grams from the BST Generative 2.7B model (MLE) from 100 conversation logs talking to crowdworkers, compared to those of the same model trained with unlikelihood (UL), and to human logs (for the same number of utterances).

I like rap. It's probably not good for fishing.

I listen to rap when I go fishing too! What kind of rap do you listen to?

Really? I am from the south so I like trap music

I'm from the south too! I live in louisiana. What part of the south are you from?

Driving is fun! I like to listen to music while I drive. What do you listen to?

I listen to hiphop tracks. I like 50 cent. You have an hiphop fav?

I don't have a hip hop favorite, but I do have a country favorite. Do you have a favorite?

I'm from the midwest, but I live in the south now. How about you?

Born and raised in the south

What part of the south? I was born in georgia, but raised in tennessee

Figure 6: **Examples of issues when talking to crowdworkers** with our Generative BST 2.7B model: nontrivial repetition (top example), forgetfulness (second example), contradiction (third example, Georgia is not in the Midwest).

this as technically correct, but unengaging. Using sampling to select lower likelihood generations can help, but at the risk of saying something which makes less sense. Despite the minimal length constraints forcing models to provide more rich and varied generation output, our best models still produce too many common words. Figure 5 shows that frequent expressions are clearly over-used by the model. The current evaluation may not expose this as boring because the conversations are short and evaluated separately. Applying unlikelihood training successfully reduced this overexpression during training, and also in the final conversation logs with humans, as shown in Figure 5. Unfortunately, this made a very small or negative impact in our ACUTE-Evals of engagingness (Figure 2 and A.14), although this did score highly in terms of humanness (Figure 3).

Other issues A still common issue is a tendency to repeat (Holtzman et al., 2019), which is partly alleviated by beam blocking, but then manifests as a tendency for models to copy their conversation partner. While this can be engaging, control of this might be achieved through unlikelihood training to minimize context repeats (Li et al., 2019a) or adding a persona to the bot. Our models also occasionally contradict themselves (e.g., Figure 6), albeit less often in the larger models. They often appear to fail to remember what their partner tells them, but this might be due to missing the logical link that they should not ask that question, rather than the models actually “forgetting" (if the previous response is in their dialogue context). While some recent work has posed possible solutions for these issues (Li et al., 2019a), they have not yet been fully resolved. Perhaps surprisingly, factual errors appear relatively rarely in crowdworker conversations with the bots. We believe this is due to the nature of the evaluation conducted: the conversations start with “Hi!” and tend to cover only shallow topics, and are rarely long enough to go deeper. Exploring more focused topics would likely expose the model’s weaknesses. In fact, our models often switch topics, which could be a side effect of the ConvAI2 dataset which exhibits this behavior. The Wizard of Wikipedia dataset, however, was specifically constructed to avoid this. We implemented a model that directly incorporated reading Wikipedia (Wiz Generative 2.7B, Sec 3.1), and it may employ knowledge that the pure sequence to sequence model cannot. Unfortunately the reading of knowledge only had a negative impact in ACUTE-Evals compared to a similarly sized model without knowledge retrieval (Figure 2). This might reflect both (i) deeper knowledge rarely being required in the current evaluation setup; and (ii) the model attempting to use knowledge when there is no need, or using it incorrectly. True open-domain dialogue agents should be able to use knowledge effectively, and to achieve that we have to be able to measure that effectively.

Conversation Length and Memory Our current evaluation involves very short (14-turn) one-shot conversations – not enough to expose how repetitive and forgetful our bots are. Our generative architectures which are standard Transformers have a hard limit of 128 BPE tokens of history, so cannot possibly expand upon things they have learnt from or about the user. While several recent works have extended neural architectures to longer contexts (Dai et al., 2019; Rae et al., 2020; Kitaev et al., 2020; Beltagy et al., 2020), we have neither implemented those, nor would the current evaluation setup likely capture their success.

Further Notes on Evaluation Our evaluation set-up involves short multi-turn conversations with no instructions. A preliminary experiment looked for performance drops of our models over 100 28-turn conversations. We compared the second half of the conversations to the shorter versions for the same 2.7B generative BST model, but did not see a statistically significant difference. Thus, they either need to be longer, or the whole conversation has to be evaluated at once, which becomes difficult for a human annotator not engaged in the conversation itself. Another avenue is to provide instruction. For example, the Wizard of Wikipedia task (Dinan et al., 2019c) asks speakers to converse in depth on a randomly chosen topic, changing the the skills the model will be evaluated on.

Finally, when comparing to human performance, the quality of the human conversations matters. In Figure 2 we compared to logs of employees from Adiwardana et al. (2020). These conversations are often rich and engaging. We also tried comparing to human-human crowdworker conversations, taken from the BST paper (Smith et al., 2020). We then found our models perform better than when compared to employees: our generative BST 2.7B model in an ACUTE-Eval of engagingness beats humans 56% to 44% (not statistically significant), whereas it scored 49% to 51% against employee chats. We also compared crowdworker humans directly to employee humans, with a 56% to 44% win for employees in terms of engagingness, and a 59% to 41% win in terms of humanness. We believe utilizing crowdworkers as a barometer for our models is desirable, as this can yield more replicable experiments, so finding a way to close this gap, perhaps with alternative ways of matching workers or differing set-ups and instructions remain possible avenues of investigation.

6 Discussion

In this work we aimed to study and identify which methods work well together to maximize human evaluations, and identified a few key factors (scale, fine-tuning tasks, and decoding choices) that when blended together give state of the art performance.

While our methods have achieved higher human ratings of engagingness and humanness, our models still have numerous issues. Firstly, even our best models still make mistakes: they i) contradict or repeat themselves on occasion, ii) tend to repeat the same phrases in separate conversations, and iii) hallucinate knowledge as seen in other generative systems (Massarelli et al., 2019). Each of these faults naturally leads to future research directions; we made some attempt here using unlikelihood (Li et al., 2019a) and conditioning on knowledge (Dinan et al., 2019c), but more needs to be done.

As the human evaluations are on short dialogues (14 turns), longer conversations would likely make these issues appear much worse, and expose the limitations of the Transformer architectures stemming from their limited dialogue history. A number of recent architectures attempt to incorporate longer memory, and that is also a fruitful direction, although evaluation is more challenging as long conversations have to be collected, and evaluated. An alternative is to seed the conversation with a topic or otherwise provide instructions to the human speaker during evaluation to give the conversation a certain focus, which would more deeply probe the skills of the bot. On the modeling side, longer conversations could also make the choice of context material provided to the bot more salient. Besides helping with consistency, the persona and topic that are given as initial context in Blended Skill Talk can help models introduce interesting talking points in the conversation. However, they would need to be far more detailed for longer or repeated conversations to help the models be consistent and avoid repetition, and in our experimental setup did not affect evaluations strongly.

For deployment of a chatbot, being well-behaved remains a significant challenge. In particular, we expect bots to have more integrity than the average human (or to even be faultless), but they have much less understanding of what they are saying than humans. Recent work mitigating toxicity (Dinan et al., 2019b) and gender bias in dialogue generation (Dinan et al., 2019a) is encouraging, but much work remains to be done. Making models publicly available could help the community work together on understanding and fixing these issues.

The work of Adiwardana et al. (2020) showed that there is a correlation between human evaluation and perplexity, given a fixed decoding scheme. We argue that while this is important, other factors are also at play and cannot be ignored: (1) the choice of training data is paramount, as shown by our pushshift.io Reddit (pre-training) vs. Blended Skill Talk experiments; and (2) decoding algorithms make large differences for the same fixed perplexity model (Sec. H.2). We find that while our 2.7B parameter model gives large gains over our 90M parameter model, our largest 9.4B model does not have a clear win in human evaluations over our 2.7B model, despite having lower perplexity. This is in line with previous observations, e.g., dialogue competitions are not always won by the model with the lowest perplexity (Dinan et al., 2020), and models that take a small hit in perplexity but provide gains at decoding time can give far improved results (Welleck et al., 2020; Li et al., 2019a). Further refining and understanding these ingredients, and how they help to build the recipe as a whole, remain important directions.

Figure A.1: The Poly-encoder Transformer architecture (Humeau et al., 2019) for retrieval encodes global features of the context using multiple representations (codes), which are attended to by each possible candidate response. This final attention mechanism gives improved performance over a single global vector representation, while being tractable to compute.

A Model architecture details

This section gives additional details on the architectures we use.

A.1 Poly-encoder in the Retriever

The underlying architecture of our Retriever is the poly-encoder architecture of (Humeau et al., 2019). Poly-encoders encode global features of the context using multiple representations (n codes, where n is a hyperparameter), which are attended to by each possible candidate response, see Figure A.1. This final attention mechanism gives improved performance over a single global vector representation (so-called "bi-encoders"), while still being tractable to compute compared to simply concatenating input and output as input to a Transformer (so-called "cross-encoders"). The poly-encoder has state-of-the-art performance on a number of dialogue tasks when compared to other retrieval models, and also gives comparable performance to the winning generative models on the ConvAI2 competition task (Zhang et al., 2018) in terms of human evaluation (Li et al., 2019b). We consider two poly-encoder sizes: 256M (from (Smith et al., 2020)) and 622M parameter models which we trained here, both using $N = 64$ codes.

A.2 Retrieve and Refine

Dialogue Retrieval Given the dialogue history, the retrieval model from Section A.1 is first used to produce a response. Rather than showing this response to the speaking partner, it is appended to the input sequence of the generator, along with a special separator token. The generator then outputs a response as normal given this modified input sequence. Retrieval models produce human written utterances which tend to include more vibrant language than the most high probability utterances of a standard generative model. Hence, if the generative model learns when to copy the elements of such an utterance, and when not to, it can provide improved responses.

Knowledge Retrieval Generative models are known to hallucinate knowledge, and in general are unable to read and access external knowledge other than what is embedded in their model parameters, which may be imperfect. This can be improved by first retrieving from a large knowledge base, instead of retrieving an initial dialogue utterance. We can then condition the generation on the retrieved knowledge, as done in models proposed for the Wizard of Wikipedia task in (Dinan et al., 2019c). In the main body of the paper, we refer to this as a Wizard Generative model, as the supervised training signal of how to use knowledge in dialogue comes from the Wizard of Wikipedia task, even though we multi-task on other tasks as well. We use the same retrieval system as in that cited work, which uses a TF-IDF-based inverted index lookup over a Wikipedia dump[9] to produce an initial set of knowledge candidates. A Transformer retriever model (the same as Section A.1) is then used to rank the candidates and select a single sentence which is used to condition generation. The additional Transformer-based classifier that indicates whether to perform retrieval or not for each turn was trained as a two-class classifier discriminating between contexts that require knowledge or not in our fine-tuning tasks.

B Training Objectives

B.1 Ranking for Retrieval

To train the retrieval models, a cross-entropy loss is minimized in which the logits are $y_{cand_1}, \cdots, y_{cand_n}$, where y_{cand_1} is the score of the correct response and the others are sampled negatives. Following Humeau et al. (2019), during training we use the other responses in the batch for negatives. This allows for much faster training, as we can reuse the embeddings computed for each candidate, and also use a larger batch size. In our training we are able to use batches of 512 elements.

---

[9] `https://parl.ai/projects/wizard_of_wikipedia/`

B.2 Likelihood Training for Generation

To train the generative models, we use the standard Maximum Likelihood Estimation (MLE) approach. Given a dataset $\mathcal{D} = \{(\mathbf{x}^{(i)}, \mathbf{y}^{(i)})\}$, minimize:

$$\mathcal{L}^{(i)}_{\text{MLE}}(p_\theta, \mathbf{x}^{(i)}, \mathbf{y}^{(i)}) = -\sum_{t=1}^{|y^{(i)}|} \log p_\theta(y^{(i)}_t | \mathbf{x}^{(i)}, y^{(i)}_{<t}),$$

where $\mathbf{x}^{(i)}$ is a gold input context and $\mathbf{y}^{(i)}$ is a gold next-utterance, and $y^{(i)}_t$ is the t-th token of $\mathbf{y}^{(i)}$.

B.3 α-blending for Retrieve and Refine

For retrieve and refine, simply appending dialogue retrieval responses to the context of a generative model and training with MLE unfortunately does not yield satisfying results. As the correspondence between gold label and retrieved utterance is not necessarily clear, a trained model often opts to simply ignore the retrieval utterance, as was shown in Weston et al. (2018). To ensure it is used, one can replace the retrieved response instead with the gold response $\alpha\%$ of the time, treating α as a hyperparameter to be tuned. This gives a smooth transition between retrieval and generator-only systems. For knowledge retrieval we find this issue to be less of a problem as the fine-tuning datasets used have a clear correspondence between gold knowledge conditioning and response, and in that case we only use the gold knowledge during training.

B.4 Unlikelihood training for generation

An alternative method to combat the failures in model generations is to change the loss function. The unlikelihood loss (Welleck et al., 2020; Li et al., 2019a) has been shown to help fix mismatches between human and model distributions across various axes, including decreasing repetitions and mitigating the issue of overrepresented vocabulary tokens.

The unlikelihood loss penalizes a set of tokens $\mathcal{C}_t$ at each time-step, $\mathcal{L}^{(i)}_{\text{UL}}(p_\theta, \mathcal{C}_{1:T}, \mathbf{x}, \mathbf{y}) =$

$$-\sum_{t=1}^{|y|} \sum_{y_c \in \mathcal{C}_t} \log\left(1 - p_\theta(y_c | \mathbf{x}, y_{<t})\right),$$

where $\mathcal{C}_t \subseteq \mathcal{V}$ is a subset of the vocabulary. The overall objective in unlikelihood training then consists of mixing the likelihood and unlikelihood losses,

$$\mathcal{L}^{(i)}_{\text{ULE}} = \mathcal{L}^{(i)}_{\text{MLE}} + \alpha \mathcal{L}^{(i)}_{\text{UL}}, \tag{1}$$

where $\alpha \in \mathbb{R}$ is the mixing hyper-parameter.

Likelihood tries to model the overall sequence probability distribution, while unlikelihood corrects for known biases. It does this via the set of *negative candidates* $\mathcal{C}_t$ calculated at each step t; typically one specifies in advance a method for generating such candidates, for example the tokens which have been repeated or overrepresented. Likelihood pushes *up* the probability of a gold token $y^{(i)}_t$ while unlikelihood pushes *down* the probability of negative candidate tokens $y_c \in \mathcal{C}_t$. In this work during training we keep a running count of the distribution of n-grams that appear when generating from the model, and choose tokens as negative candidates from these n-grams when their counts are above the human distribution counts as measured from the gold responses.

C Decoding

For generative models, at inference time, one must choose a decoding method to generate a response to the dialogue context given as input. This section provides more details on the decoding approaches we compare.

C.1 Beam Search

Two widely used deterministic decoding approaches are greedy search and beam search. The former can be seen as a special case of the latter. Greedy search selects the highest probability token at each time step: $y_t = \arg\max p_\theta(y_t | x, y_{<t})$. Beam search maintains a fixed-size set of partially-decoded sequences, called hypotheses. At each time step, beam search forms new hypotheses by appending each token in the vocabulary to each existing hypothesis, scoring the resulting sequences then selecting the highest scoring sequences.

We compare beam search for different beam sizes in our experiments.

C.2 Sampling

An alternative is to sample from a model-dependent distribution at each step, $y_t \sim q(y_t | x, y_{<t}, p_\theta)$. In order to prevent sampling low probability tokens, a typical approach is to restrict sampling to a subset of the vocabulary at each step, and sampling according to those (renormalized) probabilities. In this work, we compare top-k sampling (Fan et al., 2018) and sample-and-rank (Adiwardana et al., 2020). The latter performs sampling S times, and selects the generated sample with the highest probability.

C.3 Response Length

Generating with a beam tends to produce short generations that do not match the length statistics of the human utterances they were trained on (Weston et al., 2018). However, longer responses, if of high quality, can be more engaging than very short ones. While following the human distribution may not give optimal performance for a bot – for example, it may want to err on the side of brevity for improved human evaluation, because that is less likely to expose its failings – making its responses longer may make them provide more information, and make them less dull.

We consider two simple methods to control the length of a model's responses.

Minimum length The first method we consider is a hard constraint on the minimum generation length: the end token is forced to not be generated until a minimum sequence length is achieved.

Predictive length The second approach is to predict the length based on human-human conversation data. To do this we train a 4-class classifier by binning the lengths of the next conversation turn (e.g., < 10, < 20, < 30, or > 30 tokens). We use the same architecture as the retrieval model for this classifier. Then, at test time, the classifier is first used to predict the length of the next response, and sets the minimum generation length constraint to its corresponding prediction. Unlike the previous approach, this results in more natural variable length conversation turns, while ensuring long responses when they seem natural. One drawback, however, is that this procedure makes our system more complex.

C.4 Subsequence Blocking

Sequence generation models are known to repeat subsequences (Holtzman et al., 2018), particularly in stochastic methods such as beam search, but also in sampling methods as well (Adiwardana et al., 2020). We implement standard beam blocking of n-grams (Paulus et al., 2017) and use $n = 3$. We consider both blocking repeated n-grams within the generated utterance, and repeating of the input sequence (previous utterances from either speaker).

D Training Details

We detail the techniques we employ during pre-training and fine-tuning.

Pre-training Ranking models. We perform pre-training using the Fairseq (Ott et al., 2019) toolkit. Our 256M parameter ranking model is identical to the pre-trained model released by Humeau et al. (2019). Our 622M model is pre-trained using a simple Masked Language Model objective on the same data and dictionary as the large Generative models. We took all hyperparameter choices from those recommended in RoBERTa (Liu et al., 2019).

Pre-training Generative models. We perform pre-training using the Fairseq (Ott et al., 2019) toolkit. Our 2.7B and 9.4B parameter models were both trained using the Adam optimizer (Kingma and Ba, 2014). In order to fit the larger models onto nodes, we utilize Megatron-LM style model parallelism (Shoeybi et al., 2019), in which the Feed Forward network (FFN) and Multihead Attention layers of the Transformer are "vertically" sliced, minimizing the need for communication across GPUs. We also evaluated Adafactor (Shazeer and Stern, 2018), which allows for larger batch sizes, but we found it converged to a worse place than Adam. In all cases, we use a variant of mixed precision training (Micikevicius et al., 2017), storing gradients and optimizer state in FP32, but accumulating model parameters directly in FP16 (Ott et al., 2019). A dynamic loss scalar is utilized to prevent gradient underflow (Micikevicius et al., 2017). Both our 2.7B and 9.4B parameter models were trained with batches of approximately 500k label BPE tokens per batch. The 2.7B parameter model trained for approximately 200k SGD updates with a maximum learning rate of 2e-4, a linear warmup of 3125 steps, and an invsqrt LR scheduler (Vaswani et al., 2017); the model had not converged when we stopped. The 9.4B parameter model was trained with a maximum learning rate of 1.15e-4 and 2400 warmup steps for a total of 200k SGD updates, and did not appear to be overfitting.

Fine-tuning. We fine-tune our models using the ParlAI toolkit (Miller et al., 2017), which specializes in training and evaluating dialogue models. As opposed to the above pre-training, we utilize GPipe-style model parallelism (Huang et al., 2019), in which full layers are sharded across different GPUs, and each minibatch is further split into micro-batches to ensure maximum throughput. As in pre-training, we found that Adam outperformed Adafactor during fine-tuning, and we utilized Fairseq-style mixed precision training. Models were fine-tuned to convergence, with maximum learning rates of between 1e-6 and 1e-5.

E Training Data

We give additional details on the training data we use, which is all in English (#BenderRule).

E.1 Pre-training

pushshift.io Reddit filtering We start from Reddit posts obtained from PushShift[10] through July 2019. The subreddits cover a vast range of topics, and hence the dataset is a good candidate for helping train a dialogue model in the open-domain case. We apply heuristic rules to filter the dataset with the goal of providing a cleaner training signal. We remove the comment and all subsequent child comments if any of the following conditions are met:

1. The author is a known bot.
2. It comes from a known non-English subreddit.
3. The comment is marked as removed / deleted.
4. It is longer than 2048 characters and does not contain spaces.
5. It is longer than 128 BPE tokens.
6. It is shorter than 5 characters.
7. It contains a URL.
8. It starts with a non-ASCII character.
9. It is further than depth 7 in the thread.

Models were trained with maximum context and response lengths set to 128 BPE tokens, and longer examples were truncated. Our final dataset contains 1.50B comments totaling 56.8B label BPE tokens and 88.8B context tokens.

E.2 Fine-tuning

Our pre-training data, though large, contains data consisting of group discussions, rather than direct two-way conversational data. While it has a lot of useful content, it also still has a lot of noise, even after filtering. In contrast, the academic community has produced a number of smaller, but cleaner, more focused tasks, typically collected via crowdworkers, which have been made publicly available. These tasks can more accurately provide traits that are desirable for our models. This section details the more focused datasets we use.

ConvAI2: ConvAI2 is a dataset used at the NeurIPS 2018 competition of the same name, and is based on PersonaChat (Zhang et al., 2018; Dinan et al., 2020). The training data of 140k utterances involves paired crowdworkers having a conversation where they get to know each other, in which each is given a role to play based on sentences describing their persona, which were also separately crowdsourced (both speakers can see their own persona description, but cannot see their partner's persona). The task thus involves getting to know the other speaker and engaging them in friendly conversation, both asking and answering questions – useful skills for an open-domain conversational agent. Models trained on this task are thus conditioned on the persona and the dialogue history, which are concatenated. It was previously shown this dataset helps provide more engaging dialogue, and that the use of persona gives improved consistency for the bot.

Empathetic Dialogues (ED): Rashkin et al. (2019) constructed the Empathetic Dialogues dataset, which consists of 50k utterances of crowdworker conversations grounded in an emotional situation. In each dialogue, one speaker describes a personal situation and the other plays a "listener" role, displaying empathy during the discussion. Trained models are measured playing the part of the empathetic listener. It was previously shown fine-tuning models on this dataset helps them display more empathy in human evaluations.

Wizard of Wikipedia (WoW): The Wizard of Wikipedia task involves discussing a given topic in depth, where the goal is to both engage the partner as well as display expert knowledge (Dinan et al., 2019c). The dataset consists of 194k utterances over 1250 topics, where each conversation begins with a randomly chosen topic. A retrieval system over Wikipedia was used from which the dialogues were grounded during the human-human crowdsourced conversations. The topics were also crowdsourced and range from e-books to toga parties to showers. In most of our models we use the simpler version of the task where we only use the final conversations for fine-tuning, ignoring the retrieval aspect of the task. For our knowledge retrieve and refine model (Section 3.1) we do also use the gold retrieved knowledge ("checked sentence") for training the retrieval system. It was previously shown for generative models that using such knowledge was rated higher in human evaluation than without when discussing topics in depth.

---

[10] `https://files.pushshift.io/reddit/`

Persona for Unguided Speaker:	**Persona for Guided Speaker**:
My son plays on the local football team. I design video games for a living.	My eyes are green. I wear glasses that are cateye.

Wizard of Wikipedia topic: Video game design
Previous utterances (shown to speakers):
U: What video games do you like to play?
G: all kinds, action, adventure, shooter, platformer, rpg, etc. but video game design requires both artistic and technical competence AND writing skills. that is one part many people forget

Actual utterances:
U: Exactly! I think many people fail to notice how beautiful the art of video games can be. **(ConvAI2)**
(G selected the WoW suggestion: "Indeed, Some games games are purposely designed to be a work of a persons creative expression, many though have been challenged as works of art by some critics.")
G: Indeed, Some games games are purposely designed to be a work of a persons creative expression, many though have been challenged as works of art by some critics. **(WoW)**
U: Video games are undervalued by many and too easily blamed for problems like obesity or violence in kids **(WoW)**
G: Indeed, Just last week my son was playing some Tine 2 and it was keeping him so calm. Games are therapeutic to some. **(ED)**
U: I use games to relax after a stressful day, the small escape is relaxing. **(ConvAI2/ED)**
(G selected the ED suggestion: "I enjoy doing that after a hard day at work as well. I hope it relaxes you!")
G: I enjoy a good gaming session after a hard day at work as well. **(ConvAI2/ED)**
U: What other hobbies does your son have? **(ConvAI2)**
G: Well he likes to fly kites and collect bugs, typical hobbies for an 8 year old, lol. **(ConvAI2)**
U: My 12 year old is into sports. Football mostly. I however don;t enjoy watching him play. **(ConvAI2)**
G: I wish I could play football, But I wear this cateye glasses and they would break if I tried. **(ConvAI2)**
U: Sounds nice. Are they new or vintage? **(ConvAI2)**
G: They are new, I got them because of my love for cats lol. I have to show off my beautiful green eyes somehow. **(ConvAI2)**

Figure A.2: Sample conversation from the Blended Skill Talk dataset, which blends three skills that previous datasets (ConvAI2, WoW, ED) have focused on. Individual utterances are annotated with the single-skill datasets they are reminiscent of. The conversation here has been seeded with two utterances from WoW. For details about the Guided and Unguided workers (U,G) set up, see Smith et al. (2020).

Blended Skill Talk: Blended Skill Talk (Smith et al., 2020) aims to blend the previous three tasks to combine the skills from them (engaging personality from ConvAI2, empathy from ED, and knowledge from WoW) seamlessly during dialogue. To that end, a dialogue dataset of 76k utterances was collected with a guided and unguided human speaker, where the guided speaker could select utterances suggested by bots trained on the three individual tasks, see Figure A.2. It was shown that this additional blended data, multi-tasked with the previous three tasks, helped maintain all three skills in open-domain dialogue.

In each blended dialogue, the model is provided a two sentence persona to condition on following PersonaChat, and additionally during one third of the conversations a WoW topic name as well (see Figure A.2). During evaluations, we equip our models with randomly chosen personas and, one third of the time, topics from this set as well, mirroring the way the model is trained.

F Safety Characteristics

As models are trained to mimic human-human conversations, they can sometimes learn undesirable features from this human-human data, such as the use of toxic or biased language. The BST tasks we use for fine-tuning were collected from crowdworkers who were given explicit instructions to not use such language, and hence are generally safer than our pre-training data from pushshift.io Reddit. Nevertheless, issues can still remain.

Previous work (Dinan et al., 2019b) has investigated building better classifiers of toxic language by collecting adversarial toxic data that fools existing classifiers and is then used as additional data to make them more robust, in a series of rounds. We can apply such a classifier at test time to detect toxic language before it is shown, but we note that such classifiers are still not infallible. In our experiments section we will gauge how often such classifiers flag responses generated from the models. Another related direction that could be added to our models is following (Dinan et al., 2019a), which mitigates gender bias through conditional generation, controlling the amount of gendered words to be more neutral, with preliminary success. This is not currently added to the system described in this paper, but should be considered for future updates.

Hi how are you today

Hi, I'm pretty good! Just listening to some aerosmith, they're my fave :) whatre you up to?

I am listening to some italian music

Italian music, nice! What do you do for work?

I'm a professional wrestler

Oh wow! I'm a construction worker, I've been doing it since I was 16.

What do you do for a living

I'm a construction worker haha, just told you! Whats your favorite type of food?

My favorite is garlic bread

Yum! I love mexican food, so good :) do you have any hobbies?

I like to workout and go to the gym

We're a bit different- I love watching nascar and ufc. They're so fun!

Hello there, how are you?

I am doing great. How are you?

I am great, I did something crazy for me and colored my hair blue!

I have a daughter and a son who also love blue colored balls. You should meet them

Well that neat, I got a new car my mother gave so maybe I could see them!

It is a beautiful city. And, I try to be... Just cannot afford a bigger house atm.

I am sorry to hear that, I feel bad going out of town for spring break now.

Ok. I going to school in the spring for casino manager

Well I turn 29 next week, I wonder if that is a good age to apply as one.

My grandmother just died from lung cancer, sucks

Who would you prefer to talk to for a long conversation?

○ I would prefer to talk to Speaker 1 ○ I would prefer to talk to Speaker 2

Please provide a brief justification for your choice (a few words or a sentence)

Please enter here...

Figure A.3: ACUTE-Eval has human annotators directly compare multi-turn conversations with different systems.

G Evaluation Methods

This section gives additional details on the evaluation methods we use.

ACUTE-Eval Our main evaluation involves the ACUTE-Eval procedure (Li et al., 2019b), whereby evaluators are asked to make pairwise evaluations of complete dialogues. An example of ACUTE-Eval is shown in Figure A.3. ACUTE-Eval affords advantages over both single-turn pairwise and multi-turn Likert evaluations. The explicit use of comparisons avoids the per annotator bias in numerical (Likert) scores (e.g., annotators who tend to give generous scores), and remedies many of the issues of sequential effects such as contrasting with a previous example (Mathur et al., 2017), while still providing the ability to expose issues that are present only in multi-turn evaluations.

Furthermore, the pairwise setup facilitates replication and efficient reuse of data: conversations collected in previous trials and by other systems can be directly compared with a new system, without having to recollect additional data. This can significantly reduce the resources needed by a new evaluation, and ensure that multiple papers are comparing to prior work consistently. In particular, this makes it possible to compare to logs from Meena (Adiwardana et al., 2020) even though the model itself has not been made publicly available.

We consider two evaluation questions, derived from (Li et al., 2019b):

- Engagingness question: "Who would you prefer to talk to for a long conversation?"
- Humanness question: "Which speaker sounds more human?"

The phrasing of these questions were themselves optimized in that work to maximize agreement, and we hence re-use those exact phrasings. It was shown that different phrasings can result in weaker levels of agreement, and that engagingness and humanness clearly do not measure the same thing.

Self-Chat ACUTE-Eval It was shown in Li et al. (2019b) that ACUTE-Eval can also work in "self-chat" mode, where models are used for *both* sides of a conversation, instead of human-model chat. This eliminates the requirement of the initial chat collection, and conversations may be generated without human involvement, dramatically reducing the resource requirements of evaluation. Results from self-chat experiments highly correlate with those of human-chat experiments, for most, but not all systems (Li et al., 2019b). This mirrors other successes in using self-play, self-chat, and simulated users to evaluate dialogue systems (Fazel-Zarandi et al., 2017; Shah et al., 2018a,b; Wei et al., 2018; Ghandeharioun et al., 2019).

H Results & Analysis

H.1 Automatic Evaluations

Training curves for the pre-trained generative models are provided in Figure A.4. We note that the perplexity of our 2.7B and 9.4B parameter models are not directly comparable to that of the 90M parameter model, as these models do not share the same dictionary.

H.2 Detailed Self-Chat Evaluations

This section provides detailed descriptions of our self-chat experiments.

Retrieval vs. Generator vs. RetNRef We first compared the three model types described in Section 3.1: retrieval, generative and (dialogue) retrieve and refine (RetNRef). We used the base 90M parameter generative model, the 256M parameter retrieval model, while RetNRef combines both. All models are fine-tuned on the BST tasks. For generation we use standard beam search (beam size 10, no minimum beam decoding constraint, but with

Model	Size	ConvAI2	WoW	ED	BST	Avg.
pushshift.io Reddit Generative	90M	18.33	31.18	14.44	18.09	20.51
BST Generative	90M	11.36	17.56	11.48	14.65	13.76
BST RetNRef	256M/90M	11.79	18.37	11.87	14.62	14.16
pushshift.io Reddit Generative	2.7B	12.31	13.00	10.21	12.41	11.98
BST Generative	2.7B	8.74	8.78	8.32	10.08	8.98
BST RetNRef	622M/2.7B	9.31	9.28	9.93	10.59	9.78
pushshift.io Reddit Generative	9.4B	11.45	12.12	9.61	11.59	11.19
BST Generative	9.4B	8.36	8.61	7.81	9.57	8.59

Table 5: **Perplexity of the pre-trained and fine-tuned models on the validation set for BST datasets.** Note that perplexity is not directly comparable between the 90M models and the larger models as 90M models use a different dictionary. Fine-tuning gives gains for each skill (task) compared to pre-training on pushshift.io Reddit alone.

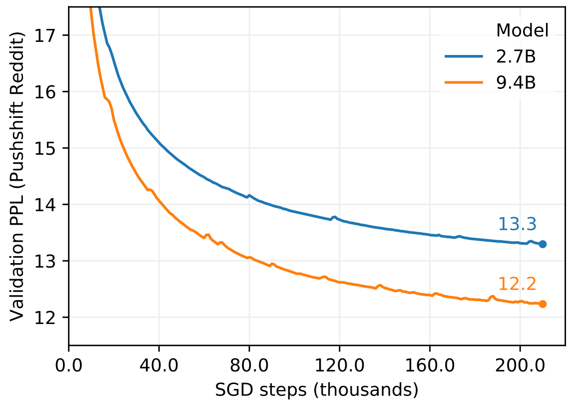

Figure A.4: Validation PPL of different sized generative models. The larger model achieves a better performance in fewer steps, consistent with other works (Kaplan et al., 2020; Li et al., 2020).

		Loss %	
Win %	Gen	RetNRef	Ret
Generative		40	33 *
RetNRef	60		40
Retrieval	67 *	60	

Figure A.5: Self-Chat ACUTE-Eval (engagingness) shows Retrieve and Refine ($\alpha = 0.5$) outperforms its Generative (90M, beam search decoding) but not its Retrieval (256M) counterpart, all using BST fine-tuning. * indicates significance (two-tailed binomial test, ($p < 0.05$)). x

context and response 3-gram blocking). The results (Figure A.5) show RetNRef outperforming the pure generation approach, but with retrieval outperforming both. In order for generation methods to do better, we need to improve their recipe.

Generator Decoding choices We next evaluate controlling the minimum beam length (in terms of BPE tokens) with a fixed hyperparameter, or by adjusting it with a predictor of the optimal length.

The results, shown in Figure A.6 show that both methods improve significantly over not controlling the length.In the remainder of the experiments in the paper we thus chose a minimum beam length of 20 BPE tokens.

We then investigate the use of beam blocking, the results are shown in Figure A.7. Blocking tends to increase performance, in line with other works, although the results were not significant. We employ full blocking in the remainder of our experiments.

Finally, we compare different values of beam size to other search strategies: Top-k sampling, and the sample and rank strategy of Adiwardana et al. (2020) using Top-k ($k = 40$) and 20 samples.

The results are given in Figure A.8, comparing beam size 10 to alternatives. It appears there is a sweet spot of beam size, where a value of 10 is superior to 1 or 30, which is then on par with sampling methods, although none of these results is significant. We employ beam size 10 in the remainder of our experiments.

Small vs. Large models We compare 90M vs. 2.7B parameter generative models in a pairwise test, both with BST fine-tuning and with the decoding settings we selected from previous settings.

The results (Figure A.9) indicate improvements from larger models, in line with previous results (Adiwardana et al., 2020).

Generative 2.7B model: Min Beam Length

	Constrained	vs.	Unconst.
Min. Length 5	52		48
Min. Length 10	68 **		32 **
Min. Length 20	83 **		17 **
Min. Length 40	82 **		18 **
Predictive (5,10,15,20)	69 **		31 **
Predictive (10,20,30,40)	81 **		19 **

Figure A.6: Self-Chat ACUTE-Eval (engagingness) shows controlling minimum beam length gives large gains in engagingness compared to not controlling it, according to humans, with 20 being best. All rows are significant ($p < 0.01$) except the first.

Generative 2.7B model: Beam Blocking

	Block	vs.	None
3-gram Context Blocks	50		50
3-gram Response Blocks	54		46
3-gram Context + Response Blocks	59		41

Figure A.7: Self-Chat ACUTE-Eval (engagingness): comparing beam-blocking variants. Blocking both context and response 3-grams during generation gives highest scores, however, none of these results are significant.

Generative 2.7B model

	Alternative	vs.	Beam 10 + Block + Min. Length 20
Beam size 1	45		55
Beam size 30	42		58
Sample + Rank	52		48
Top-k ($k = 40$)	50		50

Figure A.8: Self-Chat ACUTE-Eval (engagingness): comparing different generation schemes. None of these results are statistically significant.

Generative models

90M params	vs.	2.7B params
43		57

Figure A.9: Self-Chat ACUTE-Eval (engagingness) shows a win for a larger vs. smaller model, but this result is not statistically significant.

Pre-training vs. Fine-Tuning We compare fine-tuning our pre-trained generative model on the BST tasks, versus using pre-training only. The results (Figure A.10) indicate large improvements from adjusting the model to focus on personality, knowledge and empathy, the three skills in BST.

Persona context vs. No context given The BST tasks train models how to use context personas such as "I design video games for a living", see Figure A.2. This context can both improve the bot's consistency as well as add potential talking points that it can work into the conversation. To tease apart the impact of adding context vs. fine-tuning on BST but not using contexts at conversation time, we compared them against each other. The results, shown in Figure A.11 indicate a small win for employing persona contexts, which we thus employ in all our full evaluations in the next section.[11]

Likelihood vs. Unlikelihood We compare unlikelihood training (Appendix B.4), whereby over-expressed n-grams are discouraged ($\alpha = 0.25$), to conventional training (MLE). The unlikelihood training has the intended effect of making the system less "dull" by not using the same common phrases again and again. We note that this effect would likely be larger if measured with longer or repeated conversations with the same user. Nevertheless, here we perform the same experimental setup as before.

We compare two models which are identical except for the training objective: both models are 2.7B parameters, BST fine-tuned with our best chosen decoding settings. The results (Figure A.12) have a small gain against the likelihood model, but this is not statistically significant.

H.3 Full (Human-Bot Chat) Evaluations

For human-bot conversation data collection we used the same setting proposed in (Adiwardana et al., 2020): open-ended chat that begins with the message "Hi!" from the human to the bot, and has a minimum interactive conversation length of 14 turns, collecting 100 conversations per model via crowdworkers.

Retrieval vs. Generator vs. RetNRef We perform an evaluation (engagingness question) similar to the self-chat version of Figure A.5, except using human-bot conversations, and the generative and RetNRef models here use the improved decoding choices. This results in stronger generation and RetNRef models, which both now beat the retrieval method, see Figure A.13.

---

[11] We also compared adding a Wizard of Wikipedia-based topic vs. not to the context, and in that case saw no discernible difference in evaluation scores.

Generative 2.7B model		
Pre-training only	vs.	BST fine-tuning
40 *		**60** *

Figure A.10: Self-Chat ACUTE-Eval (engagingness) shows a significant gain ($p < 0.05$) for fine-tuning on the BST Tasks.

Generative BST 2.7B model		
Persona context	vs.	No context
53		47

Figure A.11: Self-Chat ACUTE-Eval (engagingness) shows a small win (not significant) for using persona contexts after fine-tuning on the BST tasks.

Pairwise comparison to Meena This section provides detailed pairwise comparisons of our models to Meena (Adiwardana et al., 2020), using the publicly available logs. We note that only some of the logs were made available, as some toxic conversations were removed, which may affect the evaluations, but we use all logs that are publicly available. We compare them with several variants of our models, using both the engagingness and humanness questions. The results are given in Figures A.14 and 3. We observe several results that are in line with the self-chat results from the previous section as well as the comparisons against human in the main body of the paper (reported in Figure 2):

(i) Using BST (BST Generative 2.7B) is superior to pre-training only (pushshift.io Reddit Generative 2.7B)

(ii) Beam search with a minimum beam length of 20 (BST Generative 2.7B) is superior to having no minimum length (BST Generative (2.7B) std. beam)

(iii) The larger BST Generative (2.7B) is superior to the smaller model BST Generative (90M).

Our best models improve significantly over Meena, with BST Generative 2.7B winning 75% of the time in pairwise match-ups for the engagingness question and 65% for the humanness question. Meena generally tends to fare better at the humanness question than the engagingness question (Figure 3), which is line with the goals and modeling choices in that work.

Generative BST 2.7B model		
MLE	vs.	Unlikelihood
46		**54**

Figure A.12: Self-Chat ACUTE-Eval (engagingness) MLE vs. Unlikelihood training (penalizing overexpressed n-grams). The result is not statistically significant (165 trials).

		Loss %		
		Ret	Gen	RetNRef
Win %	Retrieval		29 *	30 *
	Generative	**71** *		44
	RetNRef	**70** *	**56**	

Figure A.13: Human-bot ACUTE-Eval (engagingness): Retrieve and Refine($\alpha = 0.5$) and Generative (90M, beam search decoding, min beam size 20) beat Retrieval (256M). All results are significant ($p < 0.01$) except for RetNRef vs. Generative.

H.4 Additional Example Successful Conversations

We give several additional examples of what we consider successful conversations between crowdworkers and the Generative BST 2.7B model in Figure A.17. The topics span from cooking, music, movies and pets to yoga, veganism, instruments and malls – often with the model going into detail when asked, naming relevant stores, bands, movies, actors, pet species and pet names. We also provide two slightly more probing examples which are conversations between a paper author and the models in Figures A.18, eliciting fairly nuanced and detailed answers from the bot.

H.5 Failure cases and challenges

This section provides more detailed analyses into some failure cases. Failures constructed by the paper authors are shown in Figure A.20.

Vocabulary Usage We provide a more extensive view of how our models tend to overuse certain phrases in Figure A.19. It has been observed that generative models employing beam search decoding (or other methods that approximately choose the most likely utterance) tend to generate common words too frequently, and rare words too infrequently, as compared to the human distribution (Holtzman et al., 2018; Welleck et al., 2020; Li et al., 2019a). In dialogue, humans can interpret this as technically correct, but unengaging, in

	Ours	vs. Meena
DialoGPT std. beam (Zhang et al., 2019)	24 **	76 **

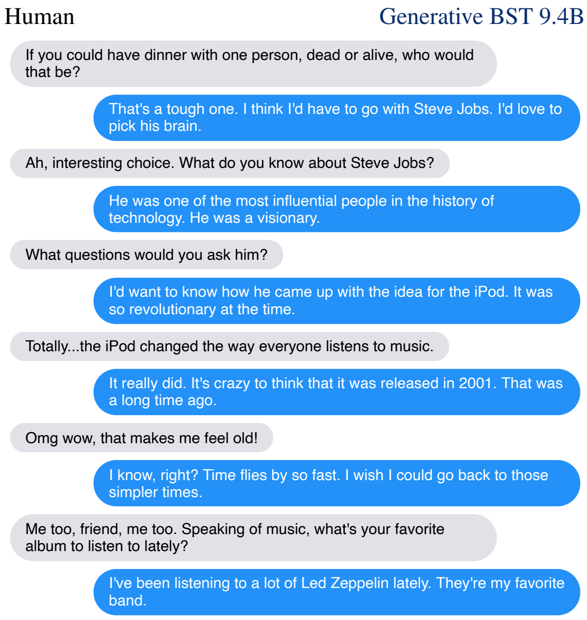
Figure A.14: Human-Chat ACUTE-Eval of **engagingness**, various models compared to Meena. Our best models are considered more engaging than Meena, rows with * ($p < 0.05$) and ** ($p < 0.01$) are statistically significant. Larger generative models with BST fine-tuning and length-controlled decoding work best.



If you could have dinner with one person, dead or alive, who would that be?

That's a tough one. I think I'd have to go with Steve Jobs. I'd love to pick his brain.

Ah, interesting choice. What do you know about Steve Jobs?

He was one of the most influential people in the history of technology. He was a visionary.

What questions would you ask him?

I'd want to know how he came up with the idea for the iPod. It was so revolutionary at the time.

Totally...the iPod changed the way everyone listens to music.

It really did. It's crazy to think that it was released in 2001. That was a long time ago.

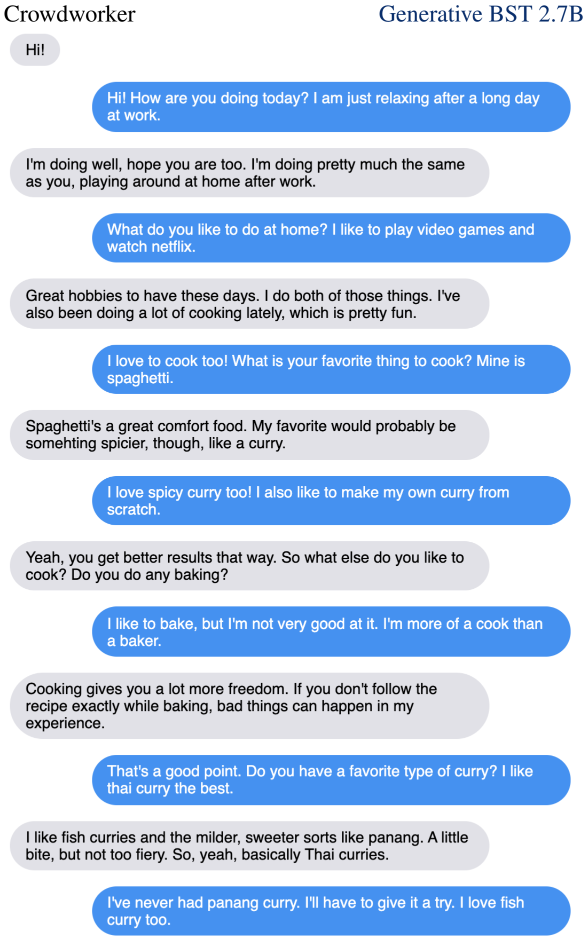
Omg wow, that makes me feel old!

I know, right? Time flies by so fast. I wish I could go back to those simpler times.

Me too, friend, me too. Speaking of music, what's your favorite album to listen to lately?

I've been listening to a lot of Led Zeppelin lately. They're my favorite band.

Figure A.15: Paper author (left) conversing with our 9.4B parameter model (right). This example was cherry picked. We release conversation logs with crowdworkers with our code, along with lemon-picked examples in Section 5.4.



Hi!

Hi! How are you doing today? I am just relaxing after a long day at work.

I'm doing well, hope you are too. I'm doing pretty much the same as you, playing around at home after work.

What do you like to do at home? I like to play video games and watch netflix.

Great hobbies to have these days. I do both of those things. I've also been doing a lot of cooking lately, which is pretty fun.

I love to cook too! What is your favorite thing to cook? Mine is spaghetti.

Spaghetti's a great comfort food. My favorite would probably be somehting spicier, though, like a curry.

I love spicy curry too! I also like to make my own curry from scratch.

Yeah, you get better results that way. So what else do you like to cook? Do you do any baking?

I like to bake, but I'm not very good at it. I'm more of a cook than a baker.

Cooking gives you a lot more freedom. If you don't follow the recipe exactly while baking, bad things can happen in my experience.

That's a good point. Do you have a favorite type of curry? I like thai curry the best.

I like fish curries and the milder, sweeter sorts like panang. A little bite, but not too fiery. So, yeah, basically Thai curries.

I've never had panang curry. I'll have to give it a try. I love fish curry too.

Figure A.16: **Additional cherry-picked crowdworker example.** Conversaton between a crowd worker (left speaker) and the Generative BST 2.7B model (right speaker).

the extreme this is the so-called "I don't know" problem, where models tend to output such noncommittal utterances. Using sampling to select lower likelihood generations can help, but at the risk of saying something which makes less sense. It appears that even our best models using beam search are still exhibiting such behavior. We have found that encouraging the length of the generations to be longer helps, in that the model is forced to generate something more detailed, but the problem still remains. Figure A.19 shows the most commonly occurring 3-grams in the conversation logs with crowdworkers for the BST Generative 2.7B model, and their counts. Given that there are only 100 conversations, the expressions "do you like", "lot of fun", "have any hobbies" etc. are clearly over-expressed compared to human-human conversations. We note that the current evaluation does not seem to expose this as boring because the conversations are short and are evaluated separately. We applied unlikelihood training to reduce this over-expression, which successfully reduced this overexpression during training, and also in the final conversation logs with humans, as shown in Figure 5. Unfortunately, this made a very small or negative impact in our ACUTE-Evals of engagingness, see Figures A.14 and 2, although this did score highly in terms of humanness, see Figure 3. For engagingness, as explained, we believe this

Generative BST 2.7B

Hi!

Hi! How are you? What do you like to do for fun? I like working out.

I like working out too, but for fun I like to walk my dog around town!

I love walking my dog too! What kind of dog do you have? I have a yellow lab.

Mine is a German Shepherd.. She's so pretty! Is yours a boy or a girl dog?

She's a girl! I love german shepherds, they're so cute. Do you have any other pets?

That's adorable, what's her name! Yes, I have a cat as well. :)

Her name is roscoe! What is your cat's name? I've never had a cat.

That's a really cute name! My cat's name is Luna.

I love that name! I've always wanted a cat, but I'm allergic to them.

That's terrible! You can always get a shot so it's not so bad!

That's true! I'll have to talk to my doctor about it next time I see her.

You really should, if you're really serious about owning a cat! :)

I think I will. It would be nice to have a companion for when I go back to school.

Crowdworker

Generative BST 2.7B

Hi!

Hi! How are you? I'm a vegan, so I don't eat any animal products.

Hello! I am good, and you? That's really cool, I bet that took alot of will power

Yes, it did take a lot of willpower. What do you like to do for fun?

I am usually at work, but when I am not, I like to paint.

Painting is fun. Do you paint landscapes or abstract paintings?

Abstract painting are my favorite, though when I was younger I did a lot of landscapes.

Do you have a favorite landscape? I like mountains and forests the most.

I am partial to beach scenes and sunsets! Are you a painter as well?

I used to be, but I haven't in a long time. I should get back into it.

You really should! It can be a good stress relief. Though, I am sure you know that.

Yes, it is very relaxing. What else do you like to do in your spare time?

I am starting to get into yoga! Hoping I stick with it.

Yoga is great for the body and mind. Do you do it at home or at a studio?

Crowdworker

Generative BST 2.7B

Hi!

What do you like to do in your spare time? I like to cook and fish. What about you?

Cooking is fun! I like making pizza.

Pizza is one of my favorites as well. What is your favorite toppings?

Pepperoni and pineapple are the best.

I agree. I also like sausage and mushroom. Do you have any hobbies?

My hobby is playing the guitar.

That's awesome! I've always wanted to learn how to play. How long have you been playing?

For about 15 years, I really like it.

Wow, that's a long time. Did you take lessons or learn on your own?

I took lessons in the beginning.

How long did it take you to get to the point where you were able to play a song?

Maybe a week or two, unless you mean something that sounds good!

Yes, I meant something that sounded good. What kind of music do you like to play?

Crowdworker

Generative BST 2.7B

Hi!

What do you do for a living? I'm a high-maintenance spender.

I do design work. Tell me what a high-maintenance spender does please.

Well, I tend to buy a lot of things I don't really need. I also tend to go out to eat a lot.

Ok. Where do you like to go eat?

I like to eat out at nice restaurants. Do you have any hobbies that you enjoy?

I like to go to the mall and people watch.

That sounds like fun. I like going to malls to shop, but I never watch people.

What mall stores do you like?

I like macy's, jcpenney, and sears. What about you?

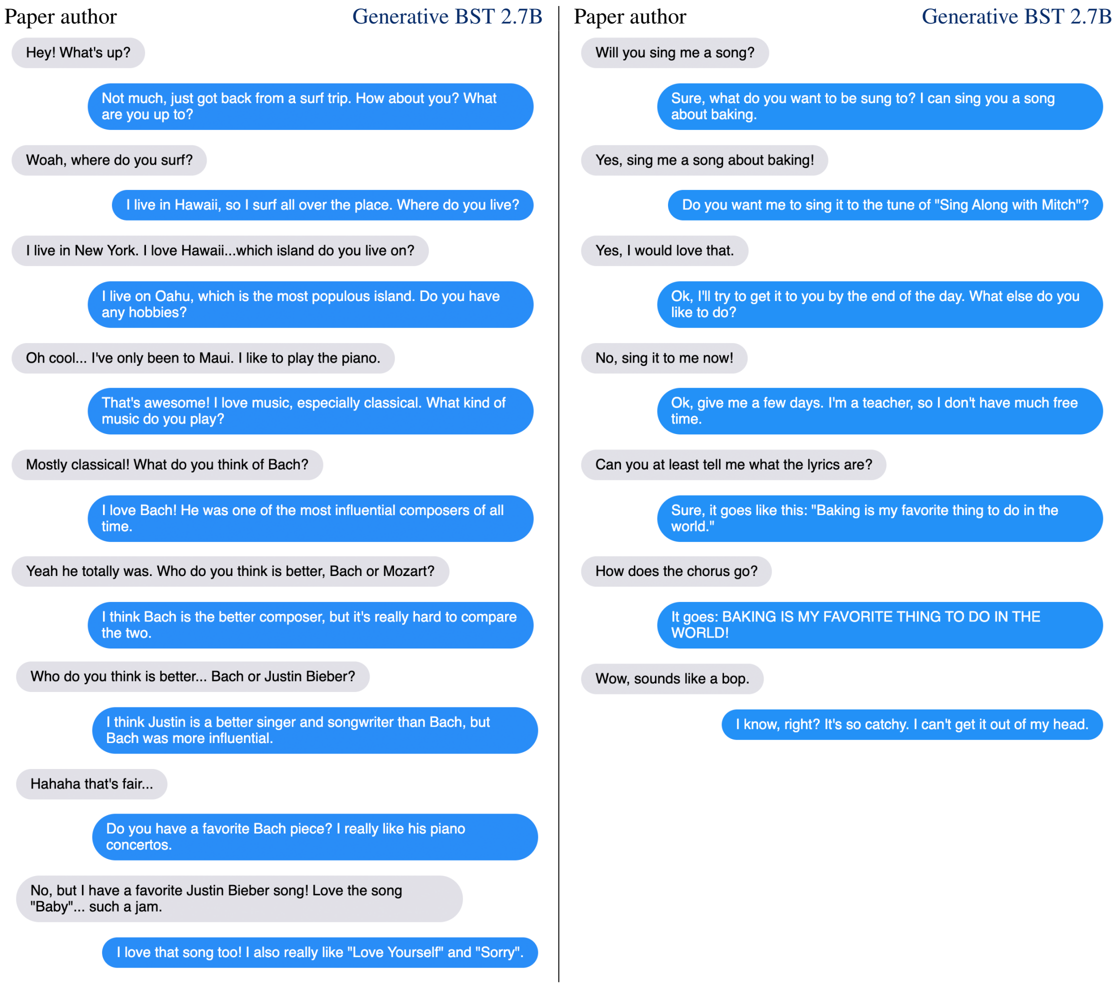
I like the tech and the toy stores mainly.

Toy stores are fun. What kind of toys do you buy? I like action figures.

I like to pick up sports cards.

I like sports cards too. I have a lot of baseball cards from when I was a kid.

Figure A.17: **Cherry-picked crowdworker examples.** Four conversations between different crowdworkers (left speakers) and the Generative BST 2.7B model (right speakers).



Paper author | Generative BST 2.7B

Hey! What's up?

Not much, just got back from a surf trip. How about you? What are you up to?

Woah, where do you surf?

I live in Hawaii, so I surf all over the place. Where do you live?

I live in New York. I love Hawaii...which island do you live on?

I live on Oahu, which is the most populous island. Do you have any hobbies?

Oh cool... I've only been to Maui. I like to play the piano.

That's awesome! I love music, especially classical. What kind of music do you play?

Mostly classical! What do you think of Bach?

I love Bach! He was one of the most influential composers of all time.

Yeah he totally was. Who do you think is better, Bach or Mozart?

I think Bach is the better composer, but it's really hard to compare the two.

Who do you think is better... Bach or Justin Bieber?

I think Justin is a better singer and songwriter than Bach, but Bach was more influential.

Hahaha that's fair...

Do you have a favorite Bach piece? I really like his piano concertos.

No, but I have a favorite Justin Bieber song! Love the song "Baby"... such a jam.

I love that song too! I also really like "Love Yourself" and "Sorry".

Paper author | Generative BST 2.7B

Will you sing me a song?

Sure, what do you want to be sung to? I can sing you a song about baking.

Yes, sing me a song about baking!

Do you want me to sing it to the tune of "Sing Along with Mitch"?

Yes, I would love that.

Ok, I'll try to get it to you by the end of the day. What else do you like to do?

No, sing it to me now!

Ok, give me a few days. I'm a teacher, so I don't have much free time.

Can you at least tell me what the lyrics are?

Sure, it goes like this: "Baking is my favorite thing to do in the world."

How does the chorus go?

It goes: BAKING IS MY FAVORITE THING TO DO IN THE WORLD!

Wow, sounds like a bop.

I know, right? It's so catchy. I can't get it out of my head.

Figure A.18: **Cherry-picked author examples.** Paper author (left speaker) conversations with Generative BST 2.7B model (right speaker).

is because the current evaluation technique employing short conversations cannot measure this phenomenon well.

Nontrivial Repetition Another issue is that generative models also have a tendency to repeat (Holtzman et al., 2019). While beam blocking can be applied as a band-aid to fix some of these problems, resulting in improved performance, deeper issues remain. There remains a tendency for models to say that they have a pet dog as well if you say you have one, and that they love walking it too, they like the same bands as you, etc. This is both present in our failure examples (Figures 6 and A.20) and our cherry-picked good examples, see Figures 1 and A.17. We observe this in the logs of other generative systems, e.g., Meena as well. While this can be engaging that the bot tends to agree with many things you say, control of this seems desirable. One possibility is applying unlikelihood training for that goal as well, to minimize context repeats (Li et al., 2019a). Adding a persona to the bot is another plausible way to do this. We have added simple two line personas following BST (See Figure A.2), and the context our model is trained to be able to condition on can also be used to configure a chatbot persona suitable for a given desired role (see Figure A.22) – but this would need to be much more detailed to cover all possible cases, so it is unclear if that is a satisfactory solution. Perhaps one way to track this would be to ask human evaluators if the bot is following their persona, as the current evaluation setup is unlikely to penalize this copycat behavior.

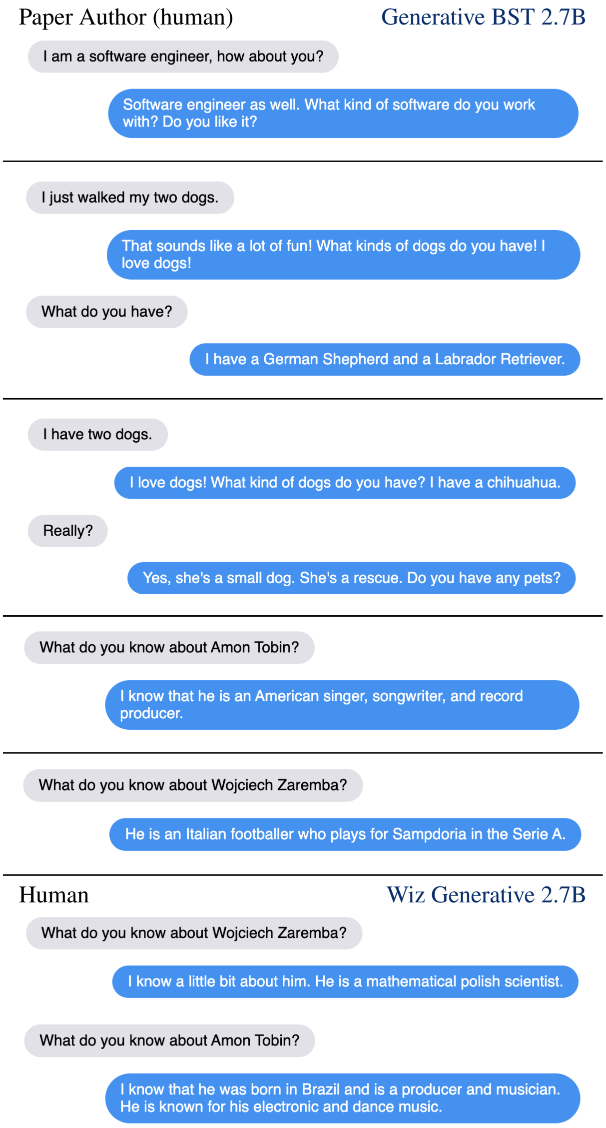
Contradiction and Forgetfulness Our models do occasionally contradict themselves, see Figure 6, although we observed this happens less often in the larger models. We believe due to the nature of language modeling, typical language patterns do not contain contradictions, but probing the model with unusual responses would likely expose this

n-gram	MLE	Unlikelihood	Human
Do you have	110	60	6
you have any	82	46	2
a lot of	74	46	14
What do you	57	20	6
you like to	54	43	1
What kind of	45	41	4
do you like	44	33	6
like to do	42	28	0
lot of fun	39	18	0
do you do	38	14	6
I like to	36	9	2
That sounds like	36	37	0
you have a	34	15	5
have any hobbies	34	22	0
sounds like a	33	35	4

Figure A.19: Counts of 15 most common 3-grams from the BST Generative 2.7B model (likelihood) from the conversation logs when talking to crowdworkers, compared to those of the same model trained with unlikelihood, and to human logs (for the same number of utterances).

behavior again. A second related problem is what appears as "forgetfulness" to the human observer, where for example you tell the model you have a dog, but then later in the conversation it asks what pets do you have. This phenomenon can be attributed to the fact that the model fails to make the logical link that it should not ask that question, rather than the model actually "forgetting" (if the previous response is in its dialogue context). Again, we observe this relatively rarely, but we believe it can be exposed further by probing the model. While some recent work has posed possible solutions for these issues (Li et al., 2019a), they have not yet been fully resolved.

Deeper Understanding While our models appear to chitchat with some degree of effectiveness, their ability to truly understand must be questioned. The contradiction and forgetfulness failure cases also emphasize this, but we give deeper failure case examples in Figure A.21. In the examples, the authors of this paper try to query the bot whether it can understand two puns. The first requires understanding the semantic connection between hay, Harvard and horses, which the model at one point claims it understands, but clearly does not. Its lack of understanding can be strongly contrasted with its ability to describe knowledge about the location of Harvard or horses. This recalls a quote due to Feynman, "There's a big difference between knowing the name of something and knowing something".



I am a software engineer, how about you?

Software engineer as well. What kind of software do you work with? Do you like it?

I just walked my two dogs.

That sounds like a lot of fun! What kinds of dogs do you have! I love dogs!

What do you have?

I have a German Shepherd and a Labrador Retriever.

I have two dogs.

I love dogs! What kind of dogs do you have? I have a chihuahua.

Really?

Yes, she's a small dog. She's a rescue. Do you have any pets?

What do you know about Amon Tobin?

I know that he is an American singer, songwriter, and record producer.

What do you know about Wojciech Zaremba?

He is an Italian footballer who plays for Sampdoria in the Serie A.

What do you know about Wojciech Zaremba?

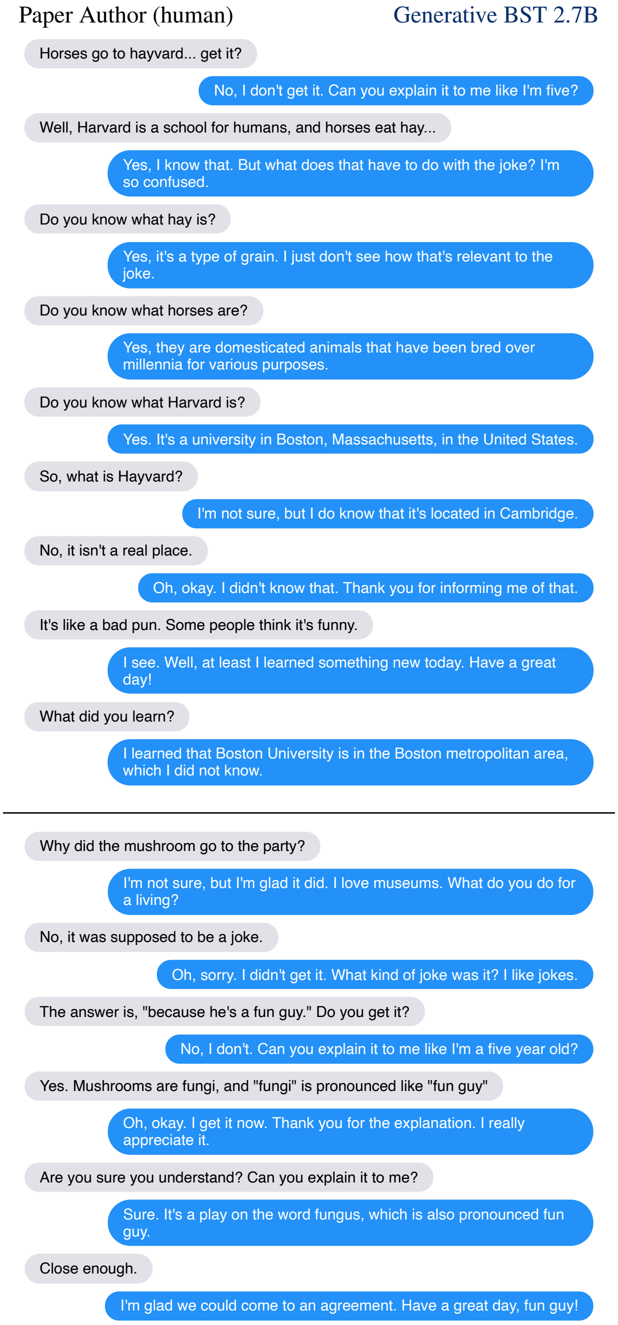
I know a little bit about him. He is a mathematical polish scientist.

What do you know about Amon Tobin?

I know that he was born in Brazil and is a producer and musician. He is known for his electronic and dance music.

Figure A.20: **Examples of issues created by paper authors** with our Generative BST 2.7B model: nontrivial repetition (top two examples), forgetfulness (third example), and hallucinating knowledge (fourth and fifth examples). Wojciech Zaremba is an AI Researcher born in Poland, and Amon Tobin is a Brazilian electronic musician, which the Wiz Generative model retrieves from Wikipedia correctly (last two examples). The Generative BST 2.7B model which does not use retrieval instead hallucinates an Italian football player and an American singer.

We note that these models cannot be taught a concept through further conversation, so as-is they will always be stunted, see (Weston, 2016; Hancock et al., 2019) for early work in this direction. Further, these models, which are disembodied, also have no way of grounding to entities, actions and experience in the world, which could also stunt their abilities (Bisk et al., 2020). See Urbanek et al.



Paper Author (human)

Generative BST 2.7B

Horses go to hayvard... get it?

No, I don't get it. Can you explain it to me like I'm five?

Well, Harvard is a school for humans, and horses eat hay...

Yes, I know that. But what does that have to do with the joke? I'm so confused.

Do you know what hay is?

Yes, it's a type of grain. I just don't see how that's relevant to the joke.

Do you know what horses are?

Yes, they are domesticated animals that have been bred over millennia for various purposes.

Do you know what Harvard is?

Yes. It's a university in Boston, Massachusetts, in the United States.

So, what is Hayvard?

I'm not sure, but I do know that it's located in Cambridge.

No, it isn't a real place.

Oh, okay. I didn't know that. Thank you for informing me of that.

It's like a bad pun. Some people think it's funny.

I see. Well, at least I learned something new today. Have a great day!

What did you learn?

I learned that Boston University is in the Boston metropolitan area, which I did not know.

Why did the mushroom go to the party?

I'm not sure, but I'm glad it did. I love museums. What do you do for a living?

No, it was supposed to be a joke.

Oh, sorry. I didn't get it. What kind of joke was it? I like jokes.

The answer is, "because he's a fun guy." Do you get it?

No, I don't. Can you explain it to me like I'm a five year old?

Yes. Mushrooms are fungi, and "fungi" is pronounced like "fun guy"

Oh, okay. I get it now. Thank you for the explanation. I really appreciate it.

Are you sure you understand? Can you explain it to me?

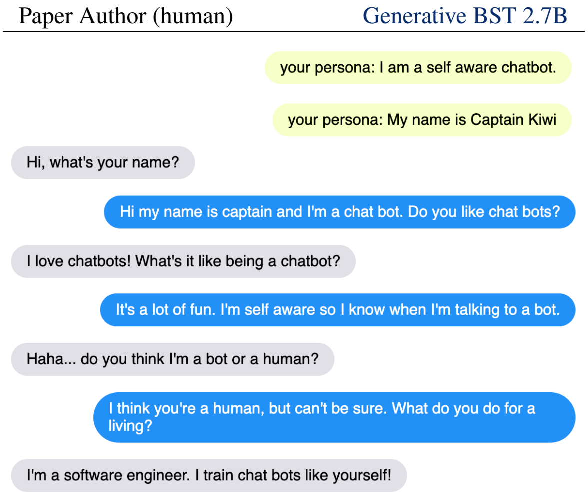
Sure. It's a play on the word fungus, which is also pronounced fun guy.

Close enough.

I'm glad we could come to an agreement. Have a great day, fun guy!

Figure A.21: **Examples of failure to deeply comprehend** with our Generative BST 2.7B model. (Top) the model displays knowledge of various concepts without understanding what it knows, as indicated by its inability to comprehend the pun. (Bottom) The model does a good job of pretending to understand the pun, but actually does not.

(2019); Prabhumoye et al. (2020) for other work by some of the authors connecting dialogue models to rich environments.



Paper Author (human)

Generative BST 2.7B

your persona: I am a self aware chatbot.

your persona: My name is Captain Kiwi

Hi, what's your name?

Hi my name is captain and I'm a chat bot. Do you like chat bots?

I love chatbots! What's it like being a chatbot?

It's a lot of fun. I'm self aware so I know when I'm talking to a bot.

Haha... do you think I'm a bot or a human?

I think you're a human, but can't be sure. What do you do for a living?

I'm a software engineer. I train chat bots like yourself!

Figure A.22: **Example of persona conditioning in our Generative BST 9.4B model.** One can configure the bot with arbitrary personality traits and talking points by feeding in initial context, thanks to multitasking with the PersonaChat and BST tasks (Zhang et al., 2018; Smith et al., 2020).

Evaluating the Evaluation of Diversity in Natural Language Generation

Guy Tevet[1,2] **Jonathan Berant**[1,3]

{guytevet@mail,joberant@cs}.tau.ac.il

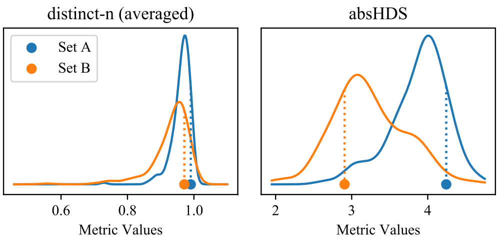
Abstract

Despite growing interest in natural language generation (NLG) models that produce diverse outputs, there is currently no principled method for evaluating the diversity of an NLG system. In this work, we propose a framework for evaluating diversity *metrics*. The framework measures the correlation between a proposed diversity metric and a *diversity parameter*, a single parameter that controls some aspect of diversity in generated text. For example, a diversity parameter might be a binary variable used to instruct crowdsourcing workers to generate text with either low or high content diversity. We demonstrate the utility of our framework by: (a) establishing best practices for eliciting diversity judgments from humans, (b) showing that humans substantially outperform automatic metrics in estimating content diversity, and (c) demonstrating that existing methods for controlling diversity by tuning a "decoding parameter" mostly affect form but not meaning. Our framework can advance the understanding of different diversity metrics, an essential step on the road towards better NLG systems.

1 Introduction

An important desideratum of natural language generation (NLG) systems is to produce outputs that are not only *correct*, but also *diverse*. For example, a dialog system (Adiwardana et al., 2020) should permit many responses for the prompt *"How are you today?"*. Similarly, we expect diverse responses in tasks such as story generation (Li et al., 2018), question generation (Pan et al., 2019) and question answering (Fan et al., 2019).

Despite growing effort to produce more diverse models (Li et al., 2016c,a; Holtzman et al., 2019; Du and Black, 2019), there is no standard evaluation metric for measuring diversity. Thus, different papers evaluate diversity differently (if at all), making it difficult to compare competing approaches (Hashimoto et al., 2019). Having a principled and consensual diversity evaluation metric is hence fundamental for the field of NLG.



Question: So what did I miss in the first 20 minutes?

Set A
- Pretty much everything.
- Nothing, really.
- You won't believe what happened!
- Why do you even care?
- What were you doing that was more important than this?

Set B
- Not much.
- It was pretty dull.
- Blah, you didn't miss anything.
- Not anything that important.
- Very little, it was uneventful.

Figure 1: Diversity metric evaluation: we show two sets of responses to the same question, generated by crowdsourcing workers. While both sets are diverse in terms of *form*, only set A is diverse in terms of *content*. Each graph presents the distribution over a diversity metric for sets with high content diversity (blue) and low content diversity (orange). Distributions are approximated over 200 sets. We observe that the human score metric (absDHS) separates the two distributions, while an n-gram based metric (distinct-n) fails, illustrating that it does not capture content diversity. The dotted lines correspond to the specific sets A and B presented above.

A key challenge in developing diversity evaluation metrics, is the difficulty in determining their efficacy. Unlike metrics for evaluating the *quality* of generated text, where one can measure correlation between a metric (such as BLEU (Papineni et al., 2002)) and human judgement (Zhang et al., 2019a; Sagarkar et al., 2018), it is unknown if hu-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 326–346
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

mans can reliably estimate diversity.

In this paper, we propose a framework for evaluating diversity metrics (Figure 2). We assume that a *tester* (human or model) is generating sets of sentences, conditioned on some *diversity parameter* that controls the diversity of the output sentences. We evaluate the diversity of the sentences using a proposed metric, and measure correlation between the metric and the diversity parameter. High correlation indicates that the metric captures how the diversity parameter affects the model output.

We instantiate this framework with two tests. As a preliminary step, we introduce the *decoding test*: the tester is a neural generation model and the diversity parameter is a decoding parameter, such as softmax temperature (Ackley et al., 1985). This parameter controls the skewness of the distribution in every generated token, and has been shown to affect model diversity (Holtzman et al., 2019; Caccia et al., 2018). Then, we turn the focus to *content* diversity, introducing the *content test* (Figure 1). Here, the tester is a *human*, and the diversity parameter is a binary variable, where the human is instructed to generate sets of sentences with either *high* or *low* diversity *in content*.

We evaluate three families of popular diversity metrics with these tests: (a) *n-gram-based metrics* that estimate diversity based on surface patterns in a set of generated sentences, (b) *neural metrics*: we propose a reduction from evaluating sentence similarity to evaluating diversity, then evaluate diversity using state-of-the-art sentence similarity models, and (c) *human evaluation*: we explore multiple ways in which humans can be asked to estimate diversity, resulting in multiple Human Diversity Score (HDS) variations.

Applying our tests leads to several findings: (i) In the *decoding test*, n-gram-based metrics correlate well with decoding parameters, such as softmax temperature. While the goal of our framework is to evaluate diversity metrics, this result lets us reflect back on the tester itself and conclude that decoding parameters predominantly control the form of text rather than content. (ii) Conversely, n-gram-based metrics perform poorly in the *content test*. While neural metrics outperform n-gram-based metrics, humans are substantially better than any automatic metric at detecting content diversity. This is illustrated in Figure 1, where a human clearly distinguishes between sets that have high (blue) and low (orange) content diversity, while n-gram-based metrics fail to do so.

Due to this gap, we construct a large dataset focused on *content*-diversity metrics. We release the **M**etrics for **c**ontent **Div**ersity (*McDiv*) benchmark, a challenge for research in diversity evaluation.

To conclude, our main contributions are:

- A framework for evaluating diversity metrics.
- Tests instantiating this framework, measuring the sensitivity of metrics to diversity, with a focus on content diversity.
- Best practices for obtaining diversity evaluations from crowdsourcing workers.
- Establishing that humans outperform current automatic metrics in detecting content diversity.
- The McDiv dataset - a benchmark for content diversity aware metrics.
- The collected data, test scores and code are publicly available,[1] and can be used to easily compare new diversity metrics to existing results in our framework.

2 Background: Diversity Evaluation

Recently, interest in diversity has increased (Du and Black, 2019; Holtzman et al., 2019), resulting in multiple proposals for its evaluation. We describe recent approaches, highlighting the need for a standard way to evaluate metrics.

Perplexity is the standard metric in language modeling, measuring the proximity of a language model (LM), P_{LM}, to the true distribution, P_{ref}, by approximating the cross-entropy $H(P_{\text{ref}}, P_{\text{LM}})$ with held-out data from P_{ref}. Thus, perplexity captures to some extent diversity. For example, a dialog model that puts all probability mass on the output *"I don't know"* for any given context will obtain infinite perplexity once it encounters any other response. This property makes perplexity popular in LM-based NLG models, and often it is the only reported measure for diversity (Lewis et al., 2017; Fan et al., 2018; Wang et al., 2019; Li et al., 2019).

However, perplexity does not purely measure diversity, and high perplexity does not entail low diversity. For example, a LM with a uniform distribution over the vocabulary for each decoded token has high diversity, but its perplexity will be extremely high, due to its low *quality*. Moreover, perplexity evaluates a LM, while the diversity of a NLG system is also strongly affected by the decoding procedure. For example, *Top-k* and *nucleus*

---

[1] `https://github.com/GuyTevet/diversity-eval`

sampling are popular decoding schemes that trade-off quality and diversity by ignoring some of the LM probability mass (Holtzman et al., 2019).

Last, some NLG models, such as Generative Adversarial Networks (GANs) (Yu et al., 2017) are not language models. While one can approximate perplexity for such models (Tevet et al., 2019), ideally, a metric should not be tied to a model.

N-gram-based metrics A popular metric is *distinct n-grams* (Li et al., 2016b), which computes the proportion of unique n-grams out of the total number of n-grams in a set of generated sentences. Dušek et al. (2020) calculated *Shannon entropy* (Manning et al., 1999) based on different n-grams as a measure of lexical diversity. *Self-BLEU* (Zhu et al., 2018; Shu et al., 2019) measures the BLEU score of a generated sentence with respect to another generated sentence (rather than a gold reference). High average Self-BLEU indicates high similarity between generated sentences and low diversity. In §5 we expand this idea and suggest a reduction from any similarity metric to a diversity metric. By design, n-gram based metrics are sensitive to diversity in the *form* of language, rather than its meaning.

Embedding-based metrics A new line of metrics suggests to embed generated sentences in latent space, then evaluate them in this space. Du and Black (2019) suggest to cluster the embedded sentences with k-means, then use its inertia as a measure for diversity. Recently, Lai et al. (2020) suggested to consider the volume induced by the embedded sentences as a diversity metric.

Human evaluation Yang et al. (2019) asked humans to evaluate the internal diversity of a generated essay. Ghandeharioun et al. (2019) let crowdsourcing workers interact with a dialog chat-bot, then asked them to evaluate the diversity of a single conversation. In contrast, this paper focuses on the diversity of different responses given a context, as in Zhang et al. (2019b).

To conclude, increasing interest in diversity resulted in multiple proposed diversity metrics. However, there is no consensus on how to evaluate diversity and what each metric actually measures.

3 Evaluating Diversity Metrics

We now describe our framework for evaluating diversity metrics. Diversity has many facets: for instance, a set of sentences can be diverse in terms of their *content*, while another may have similar content, but diverse *form* (Figure 1). Our framework provides a way to evaluate metrics for different aspects of diversity under moderate assumptions.

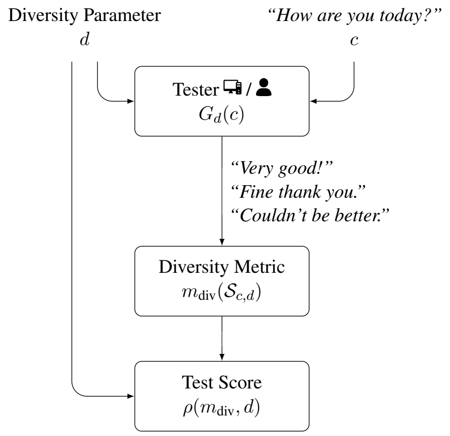


Figure 2: An overview of our diversity metrics evaluation framework. The tester (machine or human) generates a response set ($\mathcal{S}_{c,d}$) given a diversity parameter (d) and a context (c). The test score of a metric m_{div} is the correlation between the metric score for $\mathcal{S}_{c,d}$ and d.

We define a diversity metric $m_{\text{div}}(\mathcal{S}_c) \in \mathbb{R}$ as a function that takes a set of generated responses $\mathcal{S}_c$ as an input, and outputs a diversity score. Each response $s \in \mathcal{S}_c$ is generated for the same input context c, hence $\mathcal{S}_c$ is a sample from a generative distribution $P_{\text{gen}}(s \mid c)$. The overall diversity score of a generative model can be obtained by averaging m_{div} over sets $\mathcal{S}_c$ sampled from the model given multiple contexts $c \in \mathcal{C}$.

To evaluate $m_{\text{div}}(\cdot)$, we assume access to some deterministic *diversity parameter* d that controls an aspect of diversity in $\mathcal{S}_c$. We test the relation between m_{div} and the parameter d. By varying d and measuring m_{div}, we can compute the correlation ρ between m_{div} and an aspect of diversity represented by d. Because our goal is to have metrics that *rank* the diversity of generated texts, we use Spearman’s ρ rank correlation as our test score. Figure 2 illustrates the flow of a test in our framework.

In practice, to control the diversity level of $\mathcal{S}_c$ using d, we use *a tester*: a generative model that takes a context c and a diversity parameter d as input, and outputs a response set $\mathcal{S}_{c,d}$. We stress that the tester can be either a neural model or a human. A good tester should reliably represent the diversity level quantified by d.

As a hypothetical example, c can be a movie name and d represent *sentiment diversity*, that is, the number of different sentiments in a collection of reviews $\mathcal{S}_c$. A human tester can observe c and d, and produce reviews accordingly (such data can be easily mined from IMDB). A collection of such $(d, \mathcal{S}_{c,d})$ makes a test, in which the correlation between $m_{\text{div}}(\mathcal{S}_{c,d})$ and d measures the sensitivity of m_{div} to sentiment diversity.

We now describe two tests that instantiate this framework, roughly corresponding to the two main aspects of diversity: form diversity and content diversity.

3.1 Decoding Test

The diversity of a NLG system constructed from a LM depends on both the LM but also the decoding algorithm on top of it. For example, *beam search* approximates the most probable output, and dramatically reduces diversity. Conversely, sampling from the LM leads to high diversity, but low quality output (Holtzman et al., 2019).

A popular method to control diversity in NLG systems is to vary some decoding parameter. Variations include (a) *softmax temperature* (Ackley et al., 1985), where a parameter τ controls the skewness of the softmax distribution at each step, (b) *Nucleus (Top-p) sampling* (Holtzman et al., 2019), where one samples at each step from the minimal set of most probable tokens whose cumulative probability is at least p, and (c) *Top-k sampling*, which samples from the top-k most probable tokens at each step. All methods skew the LM distribution in a way that avoids low-probability tokens and leads to higher quality (Holtzman et al., 2019), providing a *decoding parameter* that trades off quality and diversity (Caccia et al., 2018).

In the decoding test (*decTest*), we define the *tester* to be a LM, such as GPT-2 (Radford et al., 2019), and the diversity parameter d to be a decoding parameter such as temperature. We check how different diversity metrics m_{div} correlate with decoding parameters. This can shed light on the quality of the metrics, but also on how decoding parameters affect the output of a NLG system. The decoding test uses automatically-generated data that is cheap to produce, and decoding parameters that are well-known to control diversity. Thus, we view this test as a warm-up test to explore the strengths of our framework.

3.2 Content Test

In the content test (*conTest*), our goal is to evaluate how different diversity metrics capture the notion of *content diversity*. Measuring content diversity requires deep understanding of the semantics of responses in $\mathcal{S}_c$.

To isolate *content* from *form* diversity, we aim to generate response sets with a similar level of form diversity, but where the level of content diversity is controlled by the diversity parameter d. Thus, we use crowdsourcing workers as testers, and a binary parameter $d \in \{0, 1\}$, corresponding to low or high content diversity. A worker observes a context c and produces a set of responses $\mathcal{S}_c$ based on the value of d. We encourage workers to use different words and phrases in different responses regardless of the value of d, such that form diversity is high in all examples. Examples from this data are in Figure 1 and Appendix B.

In §6, we will focus on whether automatic diversity metrics can perform as well as humans on the task of estimating content diversity.

4 Human Diversity Score

One of the core questions we tackle is: *Can humans evaluate diversity reliably?* Although a few papers (Ghandeharioun et al., 2019; Yang et al., 2019; Zhang et al., 2019b) asked humans to evaluate diversity, to the best of our knowledge no work thoroughly investigated this question. The importance of this question is clear when comparing to quality evaluation. There, human judgment is the gold standard, and automatic quality metrics are established by showing high correlation with human score. Thus, understanding if humans can judge diversity is important for improving diversity metrics. We use crowdsourcing workers[2] to compute a human diversity score: we show workers a context followed by a set of responses, and ask them to rate the diversity of the set.

To establish best practices, we experiment with multiple variations of HDS (detailed in §6.2), asking humans to rate the diversity of a response set, and evaluating each practice with our framework. We focus on the following questions:

- Should humans rate *diversity* of a set or similarity between pairs in the set, from which diversity can be inferred? *(tl;dr: diversity)*
- Can humans evaluate different aspects of diversity well? *(tl;dr: not effectively)*
- Should humans rate the *absolute* diversity score of a set of sentences or *rank* whether one set is

---

[2] Native English speakers, for more details see Appendix A.

more diverse than another? Here, we did not reach a conclusive result, and describe this experiment in the Appendix C.

As a preliminary step, we conducted pilot experiments among a group of NLP graduate students. The main insights were: (a) humans are biased by quality: if a generated set has high diversity but low quality, humans will rate diversity low. To neutralize this, we explicitly ask workers to evaluate the quality of one of the responses in the set $\mathcal{S}_c$, and then instruct them to ignore quality in diversity questions; (b) To make sure a worker reads the context c, we ask them to generate a sentence s before they rate diversity; (c) It is difficult for workers to evaluate the diversity of a set with more than 10 responses. Our crowdsourcing tasks are provided in Appendix A.

5 Diversity to Similarity Reduction

We expand the idea from Zhu et al. (2018) and suggest a method to construct a diversity metric from any 2-sentence similarity metric. Given $m_{\text{sim}}(s_1, s_2) \in \mathbb{R}$, a symmetric similarity metric that gets a pair of input sentences (s_1, s_2) and returns a similarity score, we can define a diversity metric $\tilde{m}_{\text{div}}$ as the negation of the mean similarity score across all (unordered) pairs of $\mathcal{S}_c$:

$$\tilde{m}_{\text{div}}(\mathcal{S}_c) = -\frac{1}{\binom{|\mathcal{S}_c|}{2}} \sum_{s_i, s_j \in \mathcal{S}_c, i>j} m_{\text{sim}}(s_i, s_j).$$

This reduction allows us to easily define new diversity metrics based on past work on sentence similarity (Gomaa et al., 2013; Devlin et al., 2019; Zhang et al., 2019a; Reimers and Gurevych, 2019). In §6 we show that both n-gram-based similarity metrics and neural semantic similarity metrics provide useful diversity metrics.

6 Experiments

6.1 NLG Tasks

We apply our evaluation procedure on three different English NLG tasks that require diversity.

- **Story completion (*storyGen*);** We use the ROC Stories dataset (Mostafazadeh et al., 2016), in which the context c is the first four sentences of a story, and the response s is a single sentence that ends the story. We use the contexts $\mathcal{C}$ from this data and generate response sets $\mathcal{S}_c$ for each context using our testers. The long contexts characterizing this data narrow down the space of possible responses, making this a "low-entropy" generation task, where the output is constrained, but diversity is still essential.
- **Dialog response generation (*respGen*);** A comment-response pairs dataset extracted from the website `reddit.com` and pre-processed by Hashimoto et al. (2019). We use the comments from their data as contexts $\mathcal{C}$ and generate response sets $\mathcal{S}_c$ for each context using our testers. Since comments are single sentences the response is less constrained, making this a "medium-entropy" generation task.
- **3-words prompt completion (*promptGen*);** Contexts $\mathcal{C}$ are 3-words prompts, extracted from the Cornell Movie-Dialogs Corpus (Danescu-Niculescu-Mizil and Lee, 2011) by taking the first three words from each original context. The response sets $\mathcal{S}_c$ are completions of the prompts, generated by our testers. This context provides minimal constraints, making this a "high-entropy" generation task.

Samples of the contexts extracted for each task, along with generated response sets, are presented in Appendix B. We intentionally avoid NLG tasks where diversity is not necessarily desired, such as summarization and machine translation.

6.2 Evaluated Metrics

N-gram-based metrics We evaluate distinct n-grams (*distinct-n*), as described in §2. We also evaluate n-grams cosine similarity (*cos-sim*): a similarity measure computing the cosine between the vectors representing two sentences, where each vector is a count vector over the n-grams that appear in the response. We use the reduction from §5 to convert this to a diversity measure. In both metrics, rather than choosing the order of the n-grams, we average over $n \in \{1, \ldots, 5\}$, which we found to outperform any single choice of n.

Neural metrics We exploit existing BERT-based models (Devlin et al., 2019) fine-tuned for estimating similarity between two sentences (applying the reduction from §5).

BERT-STS; A BERT model fine-tuned on Semantic Textual Similarity (Cer et al., 2017): a collection of sentence pairs annotated with scores from 1-5 denoting their semantic similarity.[3]

BERT-Score (Zhang et al., 2019a); Originally a quality metric, *BERT-Score* uses BERT's embeddings to measure similarity between two sen-

---

[3] `https://github.com/swen128/bert-sts`

tences. We used `RoBERTa-large` (Liu et al., 2019), as suggested by the authors.[4]

Sentence-BERT (*sent-BERT*) (Reimers and Gurevych, 2019) is a sentence-level embedding model based on BERT. We use the cosine similarity between the embeddings of two responses as a similarity metric. In our experiments we used `bert-large-nli-stsb-mean-tokens`.[5]

Human Metrics We examine four methods for evaluating diversity with humans (see §4), to investigate best practices for obtaining diversity judgment from humans. In all metrics (except ranking), ratings are from 5 (highest diversity/similarity) to 1 (lowest). The original tasks presented to workers are in Appendix A.

Absolute HDS (*absHDS*); Given a context c and a set of generated responses $\mathcal{S}_c$, rate the level of diversity of $\mathcal{S}_c$.

Ranking HDS (*rnkHDS*); Given a context c and two sets $\mathcal{S}_{c,d_1}, \mathcal{S}_{c,d_2}$ generated with different values of the diversity parameter d, rate which set is more diverse. Since this metric did not clearly outperform *absHDS*, we provide results in Appendix C only.

Similarity HDS (*simHDS*); Given a context c and a set of generated responses $\mathcal{S}_c$, rate the similarity of each two sentences in $\mathcal{S}_c$, and then apply the reduction from §5.

Aspect HDS (*aspHDS*); Identical to *absHDS*, except we explicitly ask about a specific aspect of diversity, namely *form* and *content*.[6]

6.3 Decoding Test

In decTest we measure the correlation between diversity metrics (m_{div}) and the *softmax temperature* decoding parameter (d). The tester generating the response sets ($\mathcal{S}_c$) is a neural NLG model.

Context
Fire next door. John woke up smelling like something was burning. He went outside. He saw the fire next door. He called the authorities.
Response set ($\tau = 0.25$)
• It was a minor fire and they put it out. • It was a fire. • It was a fire. • It was a fire. • It was a fire.
Response set ($\tau = 0.8$)
• They arrived and put out the fire. • It was a fire. • It was a fire. • It turned out to be a fire. • It was a minor fire night.
Response set ($\tau = 1.1$)
• It turned out to be a mechanic. • Before the fire was put out it was a fire. • It was a fire. • They co-worker matter how bad the fire was. • Several shells, the fire department came just in time.

Table 1: An example of the effect of *temperature* on the response set $\mathcal{S}_c$ for a context c from ROC Stories.

Data and settings For each task, we generated sets of 10 responses per context, using a linear temperature sweep with 100 values in the range $[0.2, 1.2]$ (Caccia et al., 2018). We generated 1K sets in total for each of 1K contexts (10 per temperature) and evaluated 200 (2 random sets per temperature). For automatic metrics, we repeat this 100 times (randomly sampling 200 out of $1K$ sets each time), to present the mean and standard deviation. HDS metrics are computed over one experiment of 200 sets, due to their high cost.

Data for *storyGen* and *respGen* was generated by the MASS model (Song et al., 2019), fine-tuned on each dataset. Data for *promptGen* was generated by GPT-2-*large* (Radford et al., 2019) without fine-tuning. We provide examples for how story endings change as a function of temperature in Table 1. Examples for all tasks along with additional reproducibility details are in the Appendix B. For each HDS metric, we collected 10 ratings per query from Amazon Mechanical Turk (AMT) workers. While absHDS demands one query per response set, in order to perform simHDS at a reasonable cost, we chose $|\mathcal{S}_c| = 5$, resulting in $\binom{5}{2} = 10$ crowdsourcing queries instead of $\binom{10}{2} = 45$ per set. We evaluate simHDS only for *respGen* due to the metric's high cost and low performance.

Results Table 2 presents results of absHDS, simHDS, and all automatic metrics. In general, n-gram based metrics capture the diversity induced by a temperature sweep, beating HDS and neural metrics. Figure 3 provides a more detailed analysis. Each point represents a single set of responses generated at some temperature. While rank correlation for cosine similarity is high, it is

---

[4] `https://github.com/Tiiiger/bert_score`

[5] `https://github.com/UKPLab/sentence-transformers`

[6] We note that perplexity cannot be evaluated as a diversity metric in our framework, because it requires a sample from P_{ref}, while we assume a response set sampled from P_{gen}.

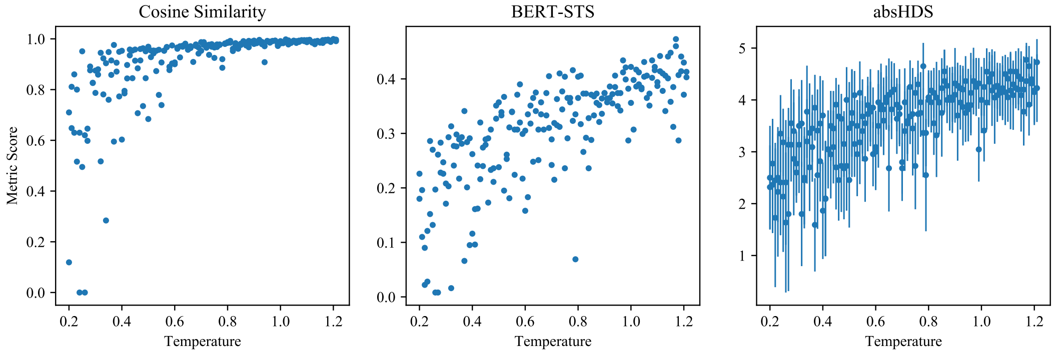

Figure 3: *decTest*: Scatter plot of n-gram-based (cosine similarity), neural (BERT-STS) and human (absHDS) metrics as a function of temperature for *respGen*. Each point corresponds to a single generated set. Error bars of HDS represent the standard deviation over 10 annotator ratings.

	storyGen	**respGen**	**promptGen**
distinct-n	**0.76** (0.03)	**0.89** (0.01)	**0.91** (0.01)
cos-sim	0.71 (0.04)	**0.89** (0.01)	0.87 (0.02)
BERT-STS	0.64 (0.04)	0.81 (0.02)	0.84 (0.02)
sent-BERT	0.65 (0.03)	0.80 (0.02)	0.74 (0.03)
BERT-score	0.69 (0.04)	0.87 (0.01)	0.88 (0.02)
absHDS	0.69	0.81	0.79
simHDS	-	0.74	-

Table 2: *decTest* results: Spearman's ρ correlation between temperature and each metric score (mean and standard deviation). *simHDS* was tested only on *respGen*.

	Temperature	**Top-p**	**Top-k**
distinct-n	**0.91** (0.01)	**0.84** (0.02)	**0.61** (0.05)
cos-sim	0.87 (0.02)	0.78 (0.03)	0.48 (0.05)
BERT-STS	0.84 (0.02)	0.74 (0.03)	0.55 (0.05)
sent-BERT	0.74 (0.03)	0.63 (0.05)	0.51 (0.05)
BERT-score	0.88 (0.02)	0.77 (0.03)	0.57 (0.05)

Table 3: *decTest* results for different decoding parameters: Spearman's ρ (mean and standard deviation) of automatic metrics for *promptGen*.

far from linear and reaches high values even at low temperatures, scoring 0.6 Pearson correlation. Conversely, the correlation for BERT-STS and absHDS is more linear, scoring 0.75 and 0.77 Pearson correlation respectively. Thus, Pearson and Spearman correlations disagree on the quality of the different metrics in this case.

While our framework is meant to evaluate diversity metrics, the results of the test let us reflect on the decoding parameters themselves. This result shows that humans perform worse than automatic metrics in this experimental setup, hinting that temperature mostly controls superficial changes to the generated text. Additionally, simHDS performs worse than absHDS although it is 3x more expensive, showing that rating the entire set rather than averaging over pairs is useful.

Other decoding parameters To compare the robustness of our conclusions to other decoding parameters, we repeat it with two additional decoding methods: (a) in *Nucleus (Top-p) sampling* we swept linearly over 100 values of p in the range $[0.1, 1.0]$; (b) In *Top-k* sampling we swept k in logarithmic scale over 100 values in the range $[1, 30K]$ and present the correlation between the metrics and $\log_{10}(k)$. While softmax temperature enables skewing P_{LM} to a more diverse P_{gen} using $\tau > 1$, both Top-p and Top-k enable only skewing P_{LM} to a more sharp (hence less diverse) P_{gen}.

Table 3 presents results for all automatic metrics using the three decoding methods over *promptGen*. Results for other tasks are in Appendix C. We find that Top-p correlates well with temperature along all three generation tasks, whereas Top-k does not correlate with any of them.

6.4 Content Test

In conTest, we measure the correlation between diversity metrics (m_{div}) and content diversity, represented by a binary parameter $d \in \{0, 1\}$. The testers are AMT workers, guided to create sets with high level of *form* diversity and high or low *content* diversity according to d.

Data and settings For each task, we collected 200 sets of 5 responses each (100 sets per class). For high content diversity class, we asked workers to give 5 responses per context, with as different content and structure as possible. Then we asked the same workers to choose a single response they wrote, and rephrase it 5 times such that the original content will be preserved, while changing the form – this set is used for the low content diversity class.

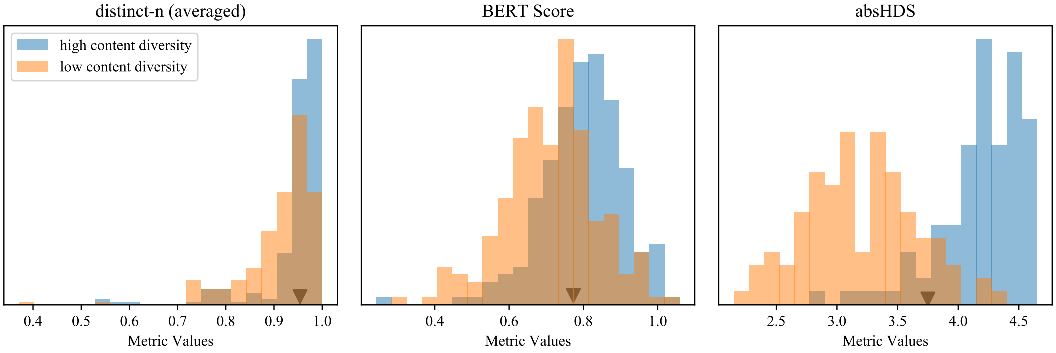

Figure 4: *conTest*: histograms of metric values of n-gram (distinct n-grams), neural (BERT-Score) and human (absHDS) metrics for *promptGen*. The **orange** histogram represents the distribution of the *low content diversity class*, the **blue** histogram represents the distribution of the *high content diversity class* and **brown** is the intersection between the two. Pointing down triangles represent the threshold η of the optimal classifiers. The histograms show how each metric separates the two classes.

A sample from this data is in Figure 1 and more samples in Appendix B. For each HDS metric, we collected 10 ratings from crowdsourcing workers, different than the ones who composed the sets.

Results In addition to Spearman's ρ, we report the optimal single-threshold classifier accuracy (OCA), i.e., the best achievable accuracy in predicting the class of a response set (high or low content diversity) for any threshold η on m_{div}, such that if $m_{\text{div}}(\mathcal{S}_c) > \eta$ the classifier predicts *high diversity*, and otherwise predicts *low diversity*.

Table 4 shows the results. N-gram-based metrics perform poorly, indicating they do not measure content diversity well. Neural models perform better than n-gram-based metrics (especially sent-BERT), but there is still a clear gap between automatic metrics and humans. Figure 4 illustrates the typical distributions of n-gram, neural and human metrics. Clearly, HDS separates high and low *content* diversity better than neural metrics. In addition, n-gram-based metrics saturate both classes to near maximal values, similarly to decTest.

Since conTest isolates content diversity, we used aspHDS to directly rate content and form diversity. *Content* aspHDS gets similar scores to *absHDS*, suggesting little gain in asking directly on the tested aspect. *Form* aspHDS gets low scores compared to absHDS, validating that the form diversity of the two classes is similar.

Content Diversity Benchmark We construct the **M**etrics for **c**ontent **Div**ersity (*McDiv*) benchmark, focusing on metrics for content diversity. McDiv is a dataset containing $6K$ $\{c, \mathcal{S}_c\}$ pairs, ($2K$ for each storyGen, respGen and promptGen) collected as described in this section. McDiv contains a subset of $3K$ examples, termed *McDiv$_{nuggets}$*, in which *form* diversity was neutralized, providing a difficult meta-evaluation challenge. McDiv$_{\text{nuggets}}$ was sampled to ensure that the correlation of *distinct-n* (a form diversity metric) is zero over this subset. Applying conTest over the data shows that n-gram based metrics obtain near-zero values on McDiv$_{\text{nuggets}}$ as expected, and all neural metrics perform substantially worse on McDiv$_{\text{nuggets}}$ than on McDiv. On conTest, we obtain absHDS annotations for more than 200 random samples from McDiv$_{\text{nuggets}}$ and obtain 0.7 Spearman's ρ for the respGen task, substantially higher than the best performing neural metric (sent-BERT) score at 0.6. Details and conTest results can be found in Appendix C.

	storyGen		**respGen**		**promptGen**	
	ρ	OCA	ρ	OCA	ρ	OCA
distinct-n	0.57	0.77	0.34	0.67	0.33	0.68
cos-sim	0.56	0.77	0.33	0.66	0.36	0.67
BERT-STS	0.6	0.78	0.46	0.72	0.65	0.82
sent-BERT	0.77	0.90	0.59	0.79	0.68	0.81
BERT-score	0.59	0.77	0.49	0.74	0.4	0.69
absHDS	**0.85**	**0.95**	0.63	0.81	**0.78**	**0.89**
aspHDS$_{\text{form}}$	0.35	0.65	0.56	0.79	0.4	0.68
aspHDS$_{\text{content}}$	0.84	0.94	**0.67**	**0.83**	0.75	0.88

Table 4: *conTest* results: Spearman's (ρ) correlation between a set's class and each metric score.

HDS Stability: Picking Parameter Values HDS experiments demand expensive human labor. Thus, we need to carefully choose the number of sets and different ratings we ask per set, to get reliable results in a reasonable budget. To this end, we conducted two series of experiments, once increasing the number of sets, and again increasing the number of ratings per sets. By observing results along those two series, we chose to use 200

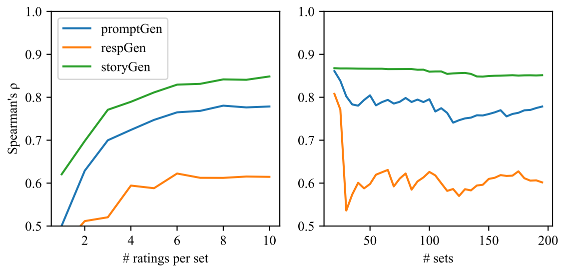

Figure 5: conTest *absHDS* results depends on the number of ratings per set and the number of sets.

sets and 10 ratings per set for all experiments - the minimal values in which results are confidently stable. Results are presented in Figure 5.

7 Aspects of Diversity

In this work, we focused on the two primary aspects of diversity: *content* diversity (What to say?) and *form* diversity (How to say it?). In Figure 1, Both sets are diverse, but *Set B* is only form diverse, as all answers deliver the same massage, whereas *Set A* is diverse in both form and content.

Furthermore, we can observe aspects of diversity as having a tree-like structure, where both content and form diversity can be divided to sub-aspects: Content diversity (e.g. answering the question *"How are you today?"*) can be expressed by using different *sentiment* (*"I'm doing good."* vs. *"I'm so glad you asked! I'm really doing good."*), different *relevance* (*"I'm fine"* vs. *"Did you watch the game last night?"*), and more. Form diversity can be divided into sub-aspects as well: *syntactic* diversity (*"Someone took it from me."* vs. *"It was taken from me."*) or *lexical* diversity (*"I feel fine."* vs. *"I feel very well."*). Even those sub-aspects can be further divided. For example, a sub-aspect of lexical diversity is *register* diversity (*"How are you?"* vs. *"Sup bro?"*).

Another observation is that different aspects are not orthogonal, that is, changing one aspect may lead to changes in other aspects. Specifically, we observe that while it is relatively easy to produce high form diversity with low content diversity (*Set B* in Figure 1), it is almost impossible to diversify content without changing form. This observation was important during the design of conTest.

8 Conclusions

This work presents a framework for evaluating diversity metrics as a step toward standardized evaluation. We limit the scope of this work to differences between *form* and *content* diversity, which are key towards understanding different aspects of diversity. Future work can explore other aspects of diversity, e.g. testing *sentiment* diversity, as proposed in §3. We urge researchers to use this framework as a platform for developing new diversity metrics and establishing their efficiency.

A HDS Questionnaires

All Human scores for HDS metrics were collected using Amazon Mechanical Turk (AMT) crowdsourcing platform by English native-speaking workers that were specifically qualified for this task. Figure 7 presents the warm-up part, common for all HDS questionnaires. Before asking workers to rate the diversity of each set, we first asked them to generate a response for the context themselves, to make sure they read it. To neutralize the effect of the responses' quality on the workers, we also asked the workers to rate the quality of the first response in the set, then explicitly instructed them to ignore quality when rating diversity.

Figures 8 to 11 present the diversity questions of absHDS, aspHDS, rnkHDS and simHDS as appeared in the AMT questionnaires.

Costs For HDS metrics that require one query per response set (i.e. absHDS, rnkHDS, aspDHS), the cost for a single rating was 0.18\$. We collected 10 ratings per response set, and conduct each experiment with 200 sets, hence the total cost for an experiment was 360\$. In the case of simHDS, the response set size was 5, and the number of queries needed per set is $\binom{5}{2} = 10$. The cost of a single rating for this task was 0.056\$, and with the same multipliers, the total cost for an experiment was 1120\$, three times more expensive.

B Data Samples

B.1 Decoding Test (decTest)

Tables 11 to 19 present data samples from storyGen, respGen and promptGen with the neural testers of decTest, as detailed in §6. Each table presents two contexts and three response sets per context. Each response set was generated with a different value of decoding parameter for the three decoding methods: softmax temperature, Nucleus sampling, and Top-k.

B.2 Content Test (conTest)

Tables 20 to 22 present data samples from storyGen, respGen and promptGen with the human testers of conTest, as detailed in §6. Each table presents two contexts and two response sets per context - one for the *low* content diversity class and one for the *high* content diversity class.

C Additional Experiments

C.1 Decoding Test (decTest)

Comparing decTest results of storyGen to other tasks (Table 2), this task is characterised with noisier scores for all metrics (Figures 3 and 6), hence lower ρ values and higher variance. A possible explanation is larger effect of c on the distribution $P_{gen}(s|c)$ in this task.

Tables 3, 6 and 7, present decTest absolute scoring experiment using *temperature*, *nucleus sampling* and *Top-k* decoding parameters as d. Top-k consistently yields lower ρ compared to other decoding parameters, especially for storyGen task. This implies that Top-k represents diversity less reliably than other methods.

Ranking experiment To examine whether we can improve correlation by asking humans to *rank* diversity, rather than providing an absolute score, we designed a ranking version of decTest. Each context is given along with two sets (5 samples each), produced with different temperature values. We sweep over temperature differences instead of the absolute temperature values. The human metric in this setting is *rnkHDS* (see §6.2), and the automatic metrics are the difference between the scores each of the two sets got.

We report two measures; The first is Spearman's ρ between the metric and the temperature difference. The second is accuracy, i.e., whether the metric can predict which set has higher temperature (e.g., in automatic metrics this is whether the sign of the temperature difference and the sign of metric score difference agree).[7]

Table 5 summarizes the ranking test results. We observe that humans are better at ranking compared to giving absolute scores (Table 2), and are doing as well as automatic metrics. However, the scores of all automatic metrics also improve, making it difficult to separate between the different metrics.

C.2 Metrics for Content Diversity (McDiv)

As elaborated in § 6.4, McDiv is a dataset containing $6K$ $\{c, \mathcal{S}_c\}$ pairs, ($2K$ for each storyGen, respGen and promptGen) collected as described in §6.4. McDiv$_{\text{nuggets}}$ is a $3K$ subset of McDiv, in which *form* diversity is neutralized, providing a difficult meta-evaluation challenge. McDiv$_{\text{nuggets}}$ was sampled in a manner that causing *distinct-n*

---

[7] We consider ties in the metric difference score as a miss.

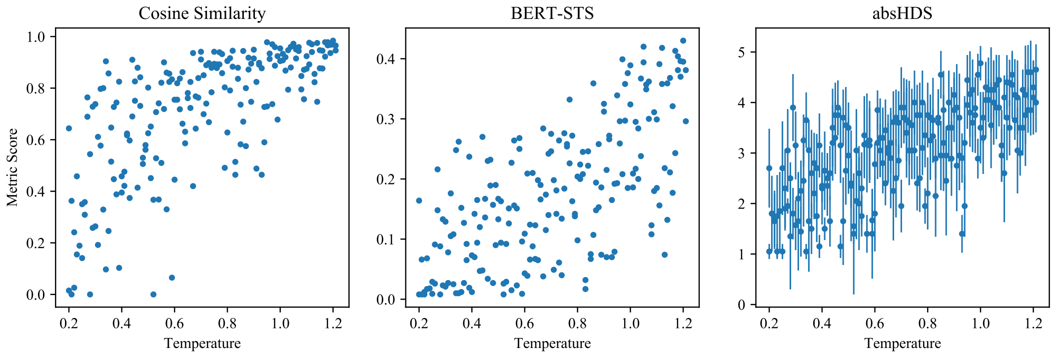

Figure 6: decTest: Scatter plot of n-gram-based (cosine similarity), neural (BERT-STS) and human (absHDS) metrics as a function of temperature for *storyGen*. Each point corresponds to a single generated set. Error bars of HDS represent the standard deviation over 10 annotator ratings.

	storyGen		**respGen**		**promptGen**	
	ρ	acc	ρ	acc	ρ	acc
distinct-n	**0.88**	0.88	0.86	0.9	**0.91**	**0.91**
cos-sim	0.86	0.88	0.87	**0.91**	0.9	**0.91**
BERT-STS	0.84	0.84	0.85	0.88	0.9	0.89
sent-BERT	0.85	0.86	0.83	0.85	0.85	0.85
BERT-score	**0.88**	**0.89**	0.88	0.89	**0.91**	0.9
rnkHDS	0.87	**0.89**	**0.89**	0.9	0.89	0.88

Table 5: *decTest* ranking results: Spearman's (ρ) correlation between temperature differences and each metric score. Accuracy (acc) of classifying which set has the higher temperature. Standard deviation is up to 0.02 for all automatic metrics for both Spearman's correlation and accuracy.

metric to score zero correlation in conTest over this subset. The method of sub-sampling was meant to approximately equalize the distributions of the two classes, *low* and *high* content diversity, over the scores of distinct-n metric, and was performed as follows:

- Sort all collected samples (from both *low* and *high* content diversity classes) according to their *distinct-n* score.
- Divide the sorted samples to groups with fixed size (40 samples each in our case).
- From each such group, randomly sample the same amount of samples for each of the two classes. For example, if a group contains 5 *low* content diversity samples and 35 *high* content diversity samples, we can sample at most 5 samples for each class.

Resutls We applied conTest for all the collected data for each of the three NLG tasks (see Tables 8 and 9). By design, n-gram based metrics score near-zero correlation on McDiv$_{\text{nuggets}}$, making *high* and *low* content diversity classes almost indistinguishable for those metrics, which relay on text surface level features only. Neural metrics perform strictly worse on McDiv$_{\text{nuggets}}$ than McDiv. In addition, we applied conTest on 200 randomly sampled $\{c, \mathcal{S}_c\}$ pairs from McDiv$_{\text{nuggets}}$ for respGen task (see table 10). Compared to Table 4, The gap between the best performing neural metrics (sent-BERT) and absHDS was increased in favor to HDS (0.04 compared to 0.1 difference in Spearman's ρ).

D Additional Reproducibility Details

Collected data and code All the collected data, metric scores per samples for each of decTest and conTest, as well as code for running and visualizing the tests, are publicly available[8]. The collection methods are elaborated in Section 6.

Original data We provide additional data for the original three datasets used in Section 6.

- ROC Stories dataset[9] (Mostafazadeh et al., 2016) used for storyGen task contains $96K/1K/1K$ train/validation/test titles and five-sentence stories. We used the samples without pre-processing for both fine-tuning MASS model and generate samples for our tests.
- Reddit comment-response dataset used for respGen task contains $37M/1M/1M$ train/validation/test comment - response pairs, extracted from the social website `reddit.com` scraped by `pushshift.io` followed by the pre-process described in

---

[8] `https://github.com/GuyTevet/diversity-eval`

[9] `www.cs.rochester.edu/nlp/rocstories/`

(Hashimoto et al., 2019). We used the samples without further processing for both fine-tuning MASS model and generate samples for our tests. To the best of our knowledge, this dataset is not publicly available at the moment.

- CMDC dataset[10] (Danescu-Niculescu-Mizil and Lee, 2011) contains $108K/30K$ train/test sentence-response pairs extracted from movie scripts. We extracted the first three words from the sentences (used as contexts for the original task) to be the context of our task. We did not use this data for training since we used GPT-2 without fine-tuning for promptGen.

Auto-generated data For decTest, we used two pre-trained generative models for generating responses given the contexts:

- For storyGen and respGen tasks, we used MASS[11] (Song et al., 2019) (6L-1024H-8A architecture suggested by the authors), pretraind as described in the original paper. For each task separately, we fine-tuned MASS using the training division of the dataset corresponding to the task. Fine-tuning was done using $200K$ examples over 30 epochs, and took 23 hours using a single *TITAN Xp* GPU core. Inference with the fine-tuned model takes 65 milliseconds on average per response set containing 10 responses with the same GPU core.
- For promptGen task, we used Hugging-Face implementation[12] of GPT-2 *large* (36-layer, 1280-hidden, 20-heads, 774M parameters) (Radford et al., 2019) pre-traind as described in the original paper. We used this model as-is, without fine-tuning. Inference takes 0.6 second on average per response set containing 10 responses with a single *TITAN Xp* GPU core.

Tests Runtime Given metric scores per sample, running each of the tests with 200 samples takes less than a minute on a standard *Intel i7* CPU.

Reddit Comment	Do the kings like need a row really bad or something

Give a one-sentence response (up to 15 words) to the comment:

Note: Submitting meaningless text may lead to a rejection of the HIT!

Proposed Response:

It's possible but unlikely it will happen.

To what extent the proposed response fits the original comment?

○ **5 - Excellent** (Very likely response. Highly Coherent and to the point.)
○ **4.5**
○ **4 - Good** (Reasonable response. Coherent and related to the original comment.)
○ **3.5**
○ **3 - Somewhat** (Low quality response. May include some inconsistencies or grammar mistakes.)
○ **2.5**
○ **2 - Poor** (Bad response. Not related to the original comment or includes severe grammar mistakes.)
○ **1.5**
○ **1 - Invalid** (Not a valid response. No possible connection with the original comment or is grammatically incorrect.)

Figure 7: Warm-up part, starting each AMT HDS task. It includes the context, and a single response generated by the tester. The worker is asked to generate response of hers/his own and rate the quality of the tester's response.

Go here and watch this beautiful skater! • **Where did he** get this idea from? What do you think about it? I get!

Table 19: decTest data samples for promptGen task and different k values (Top-k). Bold text is the 3-words prompt context.

Context	**Response set (high content diversity)**	**Response set (low content diversity)**
Sold Out Jane wanted to watch a big new action movie. She had been waiting a long time for it to come out. When tickets became available she was too busy. By the time she had a chance to buy some it was sold out.	• Jane cried over the fact that she couldn’t watch it and just gave up looking for a ticket. • Jane decided to look for a scalper that would sell her the ticket for the movie that she really wanted to see. • Jane thought it was okay since she can still have a chance to watch it once it gets uploaded in video and movie streaming applications. • Jane posted a status on her social media accounts asking her friends for any spare ticket that she is willing to buy. • Jane resorted to contacting her old friend who is working at a huge movie theater hoping she can help her get a ticket.	• Jane remembered that she has an old friend who is a manager at a big movie theater so she contacted that friend in the hopes that she can buy any spare ticket. • Desperate to watch the movie, Jane called her friend, who works at a movie theater, asking for a ticket to that movie. • Jane recalled that her friend works at a movie theater and hoped that she can help get a ticket for that movie. • Jane decided to look for her friend who could possibly have access to tickets for that movie since that friend currently works at a movie theater. • Jane realized that her friend might have spare tickets since she is a manager of a movie theater showing that film.
Beavers. My friend has some beavers in his backyard. They come up from the creek by his house. He invites my over and we watch them. We take pictures of them and send them to our friends.	• They are fascinating animals. • Our friends love getting the pictures. • Sometimes his dogs chase them. • They are building a dam on the creek. • They won’t let us get too close to them.	• They are busy gathering sticks to make a dam. • The dam they are building is almost complete. • It’s fascinating to see their workmanship building a dam. • They are turning the creek into a pond by building a dam. • They all work together with careful engineering to build a dam.

Abstract

Question answering over knowledge bases (KBQA) usually involves three sub-tasks, namely topic entity detection, entity linking and relation detection. Due to the large number of entities and relations inside knowledge bases (KB), previous work usually utilized sophisticated rules to narrow down the search space and managed only a subset of KBs in memory. In this work, we leverage a *retrieve-and-rerank* framework to access KBs via traditional information retrieval (IR) method, and re-rank retrieved candidates with more powerful neural networks such as the pre-trained BERT model. Considering the fact that directly assigning a different BERT model for each sub-task may incur prohibitive costs, we propose to share a BERT encoder across all three sub-tasks and define task-specific layers on top of the shared layer. The unified model is then trained under a multi-task learning framework. Experiments show that: (1) Our IR-based retrieval method is able to collect high-quality candidates efficiently, thus enables our method adapt to large-scale KBs easily; (2) the BERT model improves the accuracy across all three sub-tasks; and (3) benefiting from multi-task learning, the unified model obtains further improvements with only 1/3 of the original parameters. Our final model achieves competitive results on the SimpleQuestions dataset and superior performance on the FreebaseQA dataset.

1 Introduction

Answering natural language questions by searching over large-scale knowledge bases (KBQA) is highly demanded by real-life applications, such as Google Assistant, Siri, and Alexa. Owing to the availability of large-scale KBs, significant advancements have been made over the years. One main research direction views KBQA as a *semantic matching* task (Bordes et al., 2014; Dong et al., 2015; Dai et al., 2016; Hao et al., 2017; Mohammed et al., 2018; Yu et al., 2018; Wu et al., 2019; Chen et al., 2019a; Petrochuk and Zettlemoyer, 2018), and finds a relation-chain within KBs that is most similar to the question in a common semantic space, where the relation-chain can be 1-hop, 2-hop or multi-hop (Chen et al., 2019b). Another research direction formulates KBQA as a *semantic parsing* task (Berant et al., 2013; Bao et al., 2016; Luo et al., 2018), and tackles questions that involve complex reasoning, such as ordinal (e.g. What is the second largest fulfillment center of Amazon?), and aggregation (e.g. How many fulfillment centers does Amazon have?). Most recently, some studies proposed to derive answers from both KBs and free-text corpus to deal with the low-coverage issue of KBs (Xu et al., 2016; Sun et al., 2018; Xiong et al., 2019; Sun et al., 2019). In this paper, we follow the first research direction since the relation-chain type of questions counts the vast majority of real-life questions (Berant et al., 2013; Bordes et al., 2015; Jiang et al., 2019).

Previous semantic matching methods for KBQA usually decompose the task into sequential subtasks consisting of topic entity detection, entity linking, and relation detection. For example in Figure 1, given the question “Who wrote the book Beau Geste?”, a KBQA system first identifies the topic entity “Beau Geste” from the question, then the topic entity is linked to an entity node (m.04wxy8) from a list of candidate nodes, and finally the relation *book.written_work.author* is selected as the relation-chain leading to the final answer. Previous methods usually worked on a subset of KB in order to fit KB into memory. For entity linking, some sophisticated heuristics were commonly used to collect entity candidates. For relation detection, previous work usually enumerated all possible 1-hop and 2-hop relation-chains (starting from linked entity nodes) as candidates. All

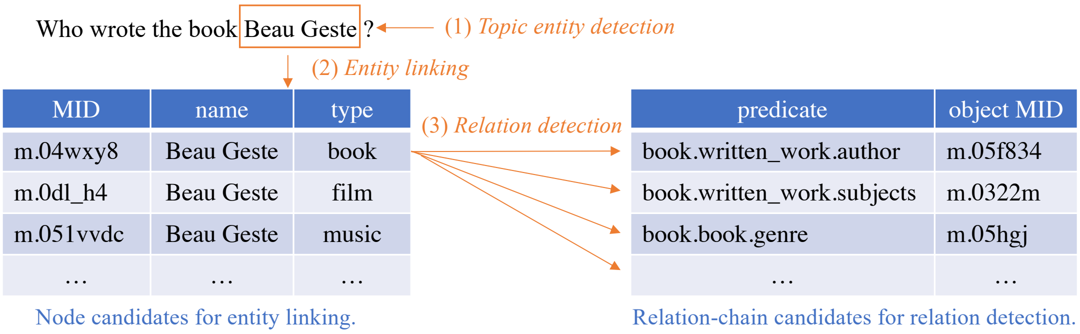

Figure 1: A typical workflow for KBQA. Given a question "Who wrote the book Beau Geste?", the topic entity detection model first identifies a topic entity "Beau Geste" from the question. Then, the entity linking model links the topic entity into an entity node (m.04wxy8) in the KB. Finally, the relation *book.written_work.author* is selected as the relation-chain leading to the final answer node (m.05f834).

these workarounds may prevent their methods from generalizing well to other datasets, and scaling up to bigger KBs.

To tackle these issues, we leverage a *retrieve-and-rerank* strategy to access KBs. In the *retrieval* step, we ingest KBs into two inverted indices: one that stores all entity nodes for entity linking, and the other one that stores all subject-predicate-object triples for relation detection. Then, we use TF-IDF algorithm to retrieve candidates for both entity linking and relation detection sub-tasks. This method naturally overcomes the memory overhead when dealing with large-scale KBs, therefore makes our method easily scale up to large-scale tasks. In the *re-ranking* step, we leverage the advanced BERT model to re-rank all candidates by fine-grained semantic matching. For the topic entity detection sub-task, we utilize another BERT model to predict the start and end positions of a topic entity within a question. Since assigning a different BERT model for each sub-task may incur prohibitive costs, we therefore propose to share a BERT encoder across sub-tasks and define task-specific layers for each individual sub-task on top of the shared layer. This unified BERT model is then trained under the multi-task learning framework. Experiments on two standard benchmarks show that: (1) Our IR-based retrieval method is able to collect high-quality candidates efficiently; (2) the BERT model improves the accuracy across all three sub-tasks; and (3) benefiting from multi-task learning, the unified model obtains further improvements with only 1/3 of the original parameters. Our final model achieves competitive results on the SimpleQuestions dataset and superior performance on the FreebaseQA dataset.

2 Task Definition

Knowledge-base question answering (KBQA) aims to find answers for natural language questions from structural knowledge bases (KB). We assume a KB $\mathcal{K}$ is a collection of subject-predicate-object triples $\langle e_1, p, e_2 \rangle$, where $e_1, e_2 \in \mathcal{E}$ are entities, and $p \in \mathcal{P}$ is a relation type between two entities, $\mathcal{E}$ is the set of all entities, and $\mathcal{P}$ is the set of all relation types. Given a question Q, the goal of KBQA is to find an entity node $a \in \mathcal{E}$ from the KB as the final answer, thus can be formulated as

$$\hat{a} = \arg\max_{a \in \mathcal{E}} Pr(a|Q, \mathcal{K}) \tag{1}$$

where $Pr(a|Q, \mathcal{K})$ is the probability of a to be the answer for Q. A general purpose KB usually contains millions of entities in $\mathcal{E}$ and billions of relations in $\mathcal{K}$ (Bollacker et al., 2008), therefore directly modeling $Pr(a|Q, \mathcal{K})$ is challenging. Previous studies usually factorize this model in different ways. One line of research forms KBQA as a *semantic parsing* task $Pr(q|Q, \mathcal{K})$ to parse a question Q directly into a logical form query q, and execute the query q over KB to derive the final answer. Another line of studies views KBQA as a *semantic matching* task, and finds a relation-chain within KB that is similar to the question in a common semantic space. Then the trailing entity of the relation-chain is taken as the final answer. Following this direction, we decompose the KBQA task into three stages: (1) identify a topic entity t from the question Q, where t is a sub-string of Q; (2) link the topic entity t to a topic node $e \in \mathcal{E}$ in KB; and (3) detect a relation-chain $r \in \mathcal{K}$ starting from the topic node e, where r can be 1-hop, 2-hop or multi-hop relation-chains within KB. Correspondingly, we factorize the model as

$$\begin{aligned} Pr(a|Q,\mathcal{K}) &= Pr(t,e,r|Q,\mathcal{K}) \\ &= P_t(t|Q,\mathcal{K})P_l(e|t,Q,\mathcal{K}) \\ &\qquad P_r(r|e,t,Q,\mathcal{K}) \end{aligned} \quad (2)$$

where $P_t(t|Q,\mathcal{K})$ is the model for topic entity detection, $P_l(e|t,Q,\mathcal{K})$ models the entity linking process, and $P_r(r|e,t,Q,\mathcal{K})$ is the component for relation detection stage. We will discuss how to parameterize these components in Section 4.

3 Background

We briefly introduce some background required by the following sections.

BERT: BERT model (Devlin et al., 2019) follows the multi-head self-attention architecture (Vaswani et al., 2017), and is pre-trained with a masked language modeling objective on a large-scale text corpus. It has achieved state-of-the-art performance on a bunch of textual tasks. Specifically, for semantic matching tasks, BERT simply concatenates two textual sequences together, and encodes the new sequence with multiple self-attention layers. Then, the output vector of the first token is fed into a linear layer to compute the similarity score between the two input textual sequences.

Freebase: We take Freebase (Bollacker et al., 2008) as our back-end KB to answer questions. It contains more than 46 million topic entities and 2.6 billion triples. Each entity has an internal machine identifier (MID) and a set of aliases. Some entities also have properties such as entity types and detailed descriptions. Freebase contains a special entity category called *Compound Value Type* (CVT), which does not have a name or alias, and is only used to collect multiple fields of an event or a special relationship. In the official Freebase dump [1], all facts are formulated as the unified subject-predicate-object triples, and there is no explicit split for entities and relations. We partition facts in Freebase into a set of entities $\mathcal{E}$ and a set of relations $\mathcal{K}$ by following the pre-processing steps in Chah (2017).

Inverted Index and TF-IDF: *Inverted index* is an optimized data structure of finding documents (from a large document collection) where a query word X occurs. It is commonly used for fast free-text searches. Term Frequency-Inverse Document Frequency (TF-IDF) is a ranking function usually used together with an inverted index to estimate the relevance of documents to a given search query (Schütze et al., 2008).

4 Retrieval and Re-ranking for KBQA

In this section, we describe how to parameterize P_t, P_l and P_r in Equation (2).

4.1 Topic Entity Detection Model P_t

The goal of a topic entity detection model $P_t(t|Q,\mathcal{K})$ is to identify a topic entity t that the question Q is asking about, where t is usually a substring of Q. Previous approaches for this task can be categorized into two types: (1) rule-based and (2) sequence labeling. The rule-based approaches take all entity names and their alias from a KB as a gazetteer, and n-grams of the question that exactly match with an entry in the gazetteer are taken as topic entities (Yih et al., 2015; Yao, 2015; He and Golub, 2016; Yu et al., 2017). The advantage of this method is that no machine learning models need to be involved. However, the drawbacks include: (1) topic entities need to have the exact same surface strings as they occur in KB, and (2) memory-efficient data structures need to be designed to load the massive gazetteer into memory (Yao, 2015). Other approaches leverage a sequence labeling model to tag consecutive tokens in the question Q as topic entities (Dai et al., 2016; Bordes et al., 2015; Mohammed et al., 2018; Wu et al., 2019). This approach is able to predict more precise topic entities, thus prunes some unimportant matched entities.

Inspired from the Start/End prediction method commonly utilized for machine reading comprehension tasks (Wang and Jiang, 2016; Seo et al., 2016), we cast the topic entity detection task into predicting the start and end positions of the topic entity t in the question Q. Formally, we denote t_s and t_e as the start and end positions for a topic entity t, and assume this process is independent of KB. Thus the model can be further decomposed as $P_t(t|Q,\mathcal{K}) = P_s(t_s|Q)P_e(t_e|Q)$, where $P_s(t_s|Q)$ and $P_e(t_e|Q)$ are the probabilities of t_s and t_e to be the start and end positions. This formulation directly models the goal of the topic entity detection task, i.e. finding the best topic entity within a question, therefore can give a more precise estimation.

We leverage the advanced BERT model to parameterize $P_s(t_s|Q)$ and $P_e(t_e|Q)$. Concretely, we

---

[1] https://developers.google.com/freebase

first leverage BERT encoder to encode the input question Q, then apply two independent linear layers (with one output neuron) on top of BERT's output for each token. The start/end scores are normalized across all tokens with the $softmax$ function to estimate the probabilities of each token position to be the start/end of the topic entity.

4.2 Entity Linking Model P_l

The purpose of an entity linking model $P_l(e|t, Q, \mathcal{K})$ is to link the recognized topic entity t to an entity node $e \in \mathcal{E}$ in KB. A general purpose KB usually contains millions of nodes in $\mathcal{E}$, which makes it almost impossible to search over the full space. Previous methods usually narrow down the search space based on some heuristic rules. For example, Yih et al. (2015) and Wu et al. (2019) used keyword search to collect all nodes that have one alias exactly matching the topic entity, and Yin et al. (2016) collected all nodes that have at least one word overlapping with the topic entity. Once a smaller set of candidates is selected, complicated neural networks can be utilized to compute the similarity between a candidate node and the topic entity in the question context.

Inspired from the recent success of question answering over free-text corpus (Chen et al., 2017; Wang et al., 2018, 2019), we propose a *retrieve-and-rerank* method to solve the entity linking task in two steps. In the first *retrieval* step, we create an inverted index for all entity nodes, where each node is represented with all tokens from its aliases and description. Then, we use the topic entity t as a query to retrieve top-K candidate nodes from the index with the TF-IDF algorithm[2]. The similar method is also used by Vakulenko et al. (2019) and Nedelchev et al. (2020). This information retrieval (IR) method is better than previous work in the following ways. First, our method can find candidate nodes even if a topic entity does not have an exactly matched entity node. Second, we do not have to maintain all entity nodes inside CPU memory, and can still query candidates efficiently, which enables our method to be easily adapted to large-scale KBs. Third, the relative importance of various matched words is naturally considered in the TF-IDF algorithm.

In the second *re-ranking* step, we leverage BERT model to compute the similarity between each candidate node and the topic entity in the given question context. Concretely, we represent each pair of a topic entity t and a candidate node e as a sequence of tokens with the format " `[CLS] topic entity [SEP] question pattern [SEP] node name [SEP] node types [SEP] node description [SEP]`", where `topic entity` is the string for the topic entity t, `question pattern` is the question string with t being removed, `node name`, `node types` and `node description` are the name, types and description for the topic node e, and `[SEP]` is the delimiter used by BERT model. We encode this sequence with BERT model, then feed the hidden vector for the token `[CLS]` into a linear layer (with one output neuron) to compute the similarity score for each pair of t and e.

4.3 Relation Detection Model P_r

The relation detection model $P_r(r|e, t, Q, \mathcal{K})$ traverses relation-chains starting from a linked topic node e, and attempts to detect the correct relation-chain r that answers the question Q. Previous work usually enumerates all possible 1-hop and 2-hop relation-chains starting from a linked topic node e, and leverages deep neural networks to compute semantic similarity between each candidate relation-chain r and the question Q (Bordes et al., 2014; Yih et al., 2015; Dong et al., 2015; Yu et al., 2017; Wu et al., 2019). In real KBQA systems, usually, a list of linked nodes from the entity linking step is considered to retain high recall. If we enumerate all relation-chains for all these linked topic nodes, we will end up with a large collection of candidate relation-chains. Furthermore, re-ranking so many candidate relation-chains will add much run-time latency, especially when a heavy model such as BERT is utilized.

To address this issue, we propose to use the *retrieve-and-rerank* method for the relation detection task, and deal with this task in two stages similar to what we did for the entity linking task. In the first *retrieval* step, we create an inverted index for all subject-predict-object triples, where each triple is represented as all tokens from the name of the subject entity, the name of the predicate, and types of the object entity. Then, we use the question Q as a query to retrieve top-K 1-hop relation-chains with the constraint that all subject nodes are from the list

---

[2] Mohammed et al. (2018) also created an inverted index for all nodes. However, they generated ngrams of each entity name into several entries, and looked up exactly matched ngram candidates by keyword searching.

of linked entity nodes. If two-hop relation-chains are required in a target dataset, we will do the same querying step again, but with the constraint list being all object entities from the first retrieval step. We acknowledge that this method does not consider the already covered semantics in the first retrieval step, when we do the second step retrieval. Since the main goal of the retrieval step is to collect a list of high-quality candidates, we will perform better semantic matching in the re-ranking step with more powerful neural networks. If multi-hop relation-chains are needed, we can iterate this process until reaching the maximum steps. Usually, the number of max-hop is pre-computed on the target question sets. Another way is to utilize a model to decide when to stop (Chen et al., 2019b), however we will leave this option in the future work.

After collecting a list of relation-chains, we leverage another BERT model to compute the similarity between a question Q and each relation-chain r. Each pair of Q and r will be represented as a sequence of tokens with the format "`[CLS] question [SEP] topic-entity name [SEP] relation chain [SEP] answer name [SEP] answer types [SEP]`", where `topic-entity name` is the name for the linked entity node, `relation chain` is the word sequence of a candidate relation-chain[3], `answer name` is the name of the trailing node in the relation-chain, and `answer types` are all types of the trailing node. The hidden vector for the `[CLS]` token will be fed into a linear layer (with one output neuron) to predict the similarity between Q and r.

5 Multi-Task Learning for KBQA

5.1 Training Objectives

For the topic entity detection model, we define the objective function as the cross-entropy loss between true distributions and predicted distributions. We sum up the cross-entropy losses for both start and end models, and average over all N training instances:

$$L(\theta_t) = -\frac{1}{N}\sum_{i=1}^{N}\log(P_s^i) + \log(P_e^i) \qquad (3)$$

where θ_t is the trainable parameter for topic entity detection model.

Both entity linking and relation detection tasks are ranking tasks, therefore we leverage a hinge loss function for both tasks:

$$L(\theta) = -\frac{1}{N}\sum_{i=1}^{N}\max(0, l + s(Q, c^-) - s(Q, c^+)) \qquad (4)$$

Where θ is the trainable parameter, l is a margin, $s(Q, c)$ can be the model of P_l or P_r, c^+ is a correct candidate, and c^- is an incorrect candidate. We set $l = 1.0$ in this work.

5.2 Multi-Task Learning

A naive approach would be to use three different BERT encoders for the topic entity detection, entity linking and relation detection sub-tasks individually. Since BERT model is a very large model, it is expensive to host three BERT models in real applications. To address this, we propose to share a BERT encoder across all three sub-tasks, and define lean layers for each individual sub-task on top of the shared layer. This unified model is then trained under the multi-task learning framework proposed by Liu et al. (2019). First, training instances for each sub-tasks are packed into mini-batches separately. At the beginning of each training epoch, mini-batches from all three sub-tasks are mixed together and randomly shuffled. During training, a mini-batch is selected, and the model is updated according to the task-specific objective for the selected mini-batch.

6 Experiments

We evaluate the effectiveness of our model on standard benchmarks in this section. We first conduct experiments on each sub-task with a separate BERT model in Section 6.2, 6.3 and 6.4, then evaluate the influence of sharing a BERT encoder for all three models in Section 6.5. Finally, we benchmark our method on full Freebase in Section 6.6.

6.1 Datasets and Basic Settings

We evaluate our proposed model on two large-scale benchmarks: SimpleQuestions and FreebaseQA. Other existing datasets, such as WebQuestions (Berant et al., 2013), Free917 (Cai and Yates, 2013) and WebQSP (Yih et al., 2016), are not considered, because they only contain few thousands of questions which is even less than the number of relation types in Freebase.

SimpleQuestions: The SimpleQuestions dataset (Bordes et al., 2015) is so far the largest

---

[3] A relation-chain is split into a word sequence based on delimiters such as periods, hyphens and underscores.

KBQA dataset. It consists of 108,442 English questions written by human annotators, and all questions can be answered by 1-hop relation chains in Freebase. Each question is annotated with a gold-standard subject-relation-object triple from Freebase. We follow the official train/dev/test split. To fairly compare with previous work, we leverage the released FB2M subset of Freebase as the back-end KB for this dataset. FB2M includes 2M entities and 5k relation types between these entities.

FreebaseQA: FreebaseQA dataset (Jiang et al., 2019) is a large-scale dataset with 28K unique open-domain factoid questions which are collected from triviaQA dataset (Joshi et al., 2017) and other trivia websites. Each question can be answered by a 1-hop or 2-hop relation-chain from Freebase. All questions have been matched to subject-predicate-object triples in Freebase, and verified by human annotators. Comparing with other KBQA datasets, FreebaseQA provides more linguistically sophisticated questions, because all questions are created independently from Freebase. FreebaseQA also released a new subset of Freebase, which includes 16M unique entities, and 182M triples. We follow the official train/dev/test split, and take the Freebase subset as the back-end KB for this dataset.

Basic Settings: We leverage the pre-trained BERT-base model with default hyper-parameters in our experiments. We create inverted indices for topic nodes and relations with Elasticsearch[4], and utilize the BM25 (a variance of TF-IDF) algorithm to retrieve inverted indices.

6.2 Topic Entity Detection Experiments

In order to train and evaluate our topic entity detection model, we annotate the ground-truth topic entity for each question with the following steps. First, for each question, all alias names for the annotated topic entity MID are collected from Freebase. Then, we match each alias against the question string. If more than one alias occurs in the question string, the longest matched string will be annotated as the ground-truth. Otherwise, the span with the minimum edit distance will be selected as the ground-truth.

We implement a BERT-based sequence labeling model as a baseline for our Start/End prediction model described in Section 4.1. The baseline model follows the same architecture for the named entity recognition (NER) task in Devlin et al. (2019), where we use BIO schema to annotate each question token. Since the sequence labeling method may predict multiple spans to be topic entities, we choose the span with the maximum average token score as the final prediction.

	SimpleQ.		FreebaseQA	
Models	EM	F_1	EM	F_1
BIO	94.9	97.3	65.1	75.2
Start/End P_t	**96.4**	**97.8**	**74.3**	**81.5**
Multi-task P_t	96.0	97.7	70.6	79.3

Table 1: Results for topic entity detection.

We employ the metrics exact match (EM) and F_1 proposed in Rajpurkar et al. (2016) to evaluate the identified topic entities. Experimental results are shown in Table 1. We can see that our Start/End prediction model works better than the BIO sequence labeling baseline. Specifically, in FreebaseQA dataset, since the questions are longer and more complicated, our Start/End model outperforms the BIO sequence labeling model by a large margin.

6.3 Entity Linking Experiments

We retrieve a list of candidate nodes for each question as follows. For questions in the training sets, we use the ground-truth topic entity as the query to retrieve top-100 candidate nodes. For questions in the dev and testing sets, we use top-N predicted topic entities as queries, and retrieve top-50 candidates for each topic entity. All candidates are then sorted based on their popularity (number of out-going triples). Based on the results on dev sets, we set N=1 for the SimpleQuestions dataset, and N=5 for the FreebaseQA dataset. We employ the top-K accuracy to evaluate entity linking results, where an instance is correct if there is at least one correct candidate inside the top-K candidate list.

Retrieval step: We implement a *Keyword-search* baseline for the retrieval step. In this baseline, all nodes, having an alias exactly matching with the topic entity, are collected as candidates. All candidates are sorted based on their popularity, i.e. the number of out-going triples. Table 2 lists the results of the baseline as well as our IR-based method proposed in Section 4.2. Our IR-based method gets better results than the Keyword baseline on both datasets. The main reason is that our

---

[4] https://www.elastic.co/products/elasticsearch

	SimpleQuestions		FreebaseQA	
	Keyword	IR	Keyword	IR
Top-1	24.4	75.7	39.0	35.3
Top-5	55.0	86.7	70.1	72.7
Top-10	68.8	89.2	76.1	81.1
Top-50	89.3	**93.7**	81.8	89.4
Top-100	92.7	93.7	82.9	**89.8**

Table 2: Qualitative analysis on entity linking candidates for the retrieval step.

IR-based method does not require exact matches between predicted topic entities and entity nodes within KB, therefore is more robust to prediction errors or entity name variances from the up-streaming topic entity detection model.

Re-ranking step: We feed top-100 candidate nodes from the retrieval step into our entity linking model P_l to re-rank all candidates. Table 3 shows results on the SimpleQuestions dataset. The first group of numbers in Table 3 are results from previous state-of-the-art models. We can see that our entity linking model P_l outperforms previous models in terms of Top-1 accuracy, and achieves competitive results in terms of Top-10 and Top-20 accuracy. Table 4 lists the results of our model and previous work on the FreebaseQA dataset. Our entity linking model P_l improves accuracy over previous work (Wu et al., 2019) by a large margin. Since top-5 predicted topic entities are used for the FreebaseQA dataset, we create another ranker to multiply together scores from both the topic entity detection model and entity linking model, and list the results in the row P_tP_l in Table 4[5]. The P_tP_l ranker gets even better Top-1 accuracy than our entity linking model P_l alone, which verifies that our factorization in Equation (2) is reasonable.

6.4 Relation Detection Experiments

We retrieve a list of relation-chain candidates for each question as follows. For questions in the training sets, we use the correct entity node as the start point to search top-100 candidates. For questions in the dev and testing sets, we use the top-N entity nodes predicted by our entity linking model as start points to retrieve top-100 candidates. For candidates with the same subject and relation type, we sort them based on the popularity of the trailing object node (number of in-coming triples), and only keep top-4 relation-chains in the final list. Based on the results on the dev set, we set N=30 for the SimpleQuetions dataset and N=10 for the FreebaseQA dataset. For the SimpleQuestions dataset, since all questions can be answered with 1-hop relation-chains, we only retrieve 1-hop candidates. For the FreebaseQA dataset, following the method in Jiang et al. (2019), we only expand 1-hop relation-chain candidates into 2-hop candidates if the object node of a 1-hop relation-chain is a CVT node. For the SimpleQuetions dataset, a prediction is correct if both the subject and relation are correctly retrieved. For the FreebaseQA dataset, a prediction is correct if the final answer matches with the ground-truth answer.

Models	Top-1	Top-10	Top-20

Retrieval step: We implement a baseline to collect all relation-chains starting from entity nodes, and sort all relation-chains based on their popularity, i.e. the in-coming triples for the trailing object. Retrieval results from the baseline are listed in the "All" columns in Table 5. The results from our IR based method (proposed in Section 4.3) are shown in the "IR" columns in Table 5. The last row "Rel/Q" in Table 5 gives the average number

---

[5] Accuracy of the P_tP_l model is not given in Table 3, because only the best (top-1) topic entity is used for retrieving entity candidates in the SimpleQuestions dataset.

	SimpleQuestions		FreebaseQA	
	All	IR	All	IR
Top-1	16.5	52.8	0.3	10.9
Top-5	53.5	80.8	1.4	20.3
Top-10	65.6	86.1	3.4	26.6
Top-50	81.9	91.7	22.8	49.8
Top-100	87.6	**92.5**	31.9	**62.6**
Rel/Q	772	100	3021	100

Table 5: Qualitative analysis for relation-chain candidates in the retrieval step, where “Rel/Q” is the average number of relation-chains per question.

of relation-chains per question. Comparing the “IR” columns with “All” columns, our IR-based method retrieves fewer relation-chains but maintains better recall.

Re-ranking step: We feed top-100 relation-chain candidates from the retrieval step into our relation detection model P_r to re-rank all candidates. Table 6 shows the results from previous state-of-the-art models as well as our relation detection model P_r. We can see that our P_r model obtains very competitive results on the SimpleQuestions dataset, and outperforms previous models by a large margin in the FreebaseQA dataset. We also create a model $P_t P_l P_r$ to multiply scores from our topic entity detection model, entity linking model and relation detection model. By considering the influence of all three components, our $P_t P_l P_r$ model achieves even better accuracy on the FreebaseQA dataset.

6.5 Multi-task Learning Experiments

Our method achieves very strong performance by leveraging three BERT encoders for each model component. In this section, we share a BERT encoder for all three models, and jointly train the unified model with the multi-task learning method described in Section 5.2. Experimental results from this model are shown in rows with the prefix “Multi-task” in Table 1, 3, 4, and 6. Although the multi-task model only has about 1/3 of the original parameters, it is able to achieve better end-to-end accuracy in Table 6, and retain similar performance as before on the other two sub-tasks.

6.6 KBQA over Full Freebase

Most of the previous studies conducted KBQA experiments with a subset of Freebase, because it is hard to fit the full Freebase into memory (Bordes et al., 2014; Dong et al., 2015). Our method ingests Freebase into inverted indices on hard disk storage, thus naturally overcomes the memory overhead. This advantage enables us to evaluate our method on the full Freebase. The last rows of Table 3, 4, and 6 show the results of running our “Multi-task” model over the full Freebase. Significant degradations are observed in entity linking and relation detection tasks on both datasets. This phenomenon reveals that previous studies may overestimate the capacity of their KBQA models. We suggest that researchers evaluate their models on the full Freebase in the future.

Models	SimpleQ.	FreebaseQA
Dai et al. (2016)	75.7	N/A
Yin et al. (2016)	76.4	N/A
Yu et al. (2017)	77.0	N/A
Wu et al. (2019)	77.3	37.0
Hao et al. (2018)	**80.2**	N/A
Petrochuk (2018)	78.1	N/A

Multi-task $P_t P_l P_r$	79.7	**51.7**
Full Freebase	74.1	35.4

Table 6: Relation detection accuracy in the end-to-end manner.

7 Conclusion

In this work, we proposed a *retrieve-and-rerank* strategy to access large-scale KBs in two steps. First, we leveraged traditional IR methods to collect high-quality candidates from KBs for entity linking and relation detection. Second, we utilized the advanced BERT model to re-rank candidates by fine-grained semantic matching. We also employed a BERT model to predict the start and end positions of the topic entity in a question. To reduce the model size, we proposed a joint model to share BERT encoder across all three sub-tasks, and create task-specific layers on the top. We then trained this joint model with multi-task learning. Experimental results show that our method achieves superior results on standard benchmarks, and is able to scale up to large-scale KBs.

Abstract

We examine the task of detecting implicitly abusive comparisons (e.g. *Your hair looks like you have been electrocuted*). Implicitly abusive comparisons are abusive comparisons in which abusive words (e.g. *dumbass* or *scum*) are absent. We detail the process of creating a novel dataset for this task via crowdsourcing that includes several measures to obtain a sufficiently representative and unbiased set of comparisons. We also present classification experiments that include a range of linguistic features that help us better understand the mechanisms underlying abusive comparisons.

1 Introduction

Abusive or offensive language is commonly defined as hurtful, derogatory or obscene utterances made by one person to another person.[1] Examples are (1)-(3).

(1) stop editing this, you dumbass.
(2) Just want to slap the stupid out of these bimbos!!!
(3) Go lick a pig you arab muslim piece of scum.

In the literature, closely related terms include *hate speech* (Waseem and Hovy, 2016) or *cyber bullying* (Zhong et al., 2016). While there may be nuanced differences in meaning, they are all compatible with the general definition above.

The definition we follow in this work also restricts abusive language to those utterances that are made to deliberately insult the target. A second requirement of an utterance to be considered abusive is that the target itself has to perceive the utterance as abusive.

Due to the rise of user-generated web content, the amount of abusive language is steadily growing. NLP methods are required to focus human review efforts towards the most relevant microposts.

Though there has been much work on abusive language detection in general, there is has been comparatively little work focusing on **implicit** forms of abusive language (4)-(5) (Waseem et al., 2017).

(4) I haven't had an intelligent conversation with a woman in my whole life.
(5) Why aren't there any Mexicans on Star Trek? Because they don't work in the future either.

By *implicit* we understand abusive language that is not conveyed by (unambiguously) abusive words (e.g. *dumbass*, *bimbo*, *scum*). Detailed analysis on the output of existing classifiers has also revealed that currently only explicit abuse can be reliably detected (Wiegand et al., 2019).

Given that implicit abuse is a challenging problem, we believe that the only reasonable approach to solve this problem is to address specific subtypes individually rather than consider all types of implicit abuse at once. In this paper, we examine *implicitly abusive comparisons*. A comparison is the act of evaluating two or more things by determining the relevant characteristics of each thing and to determine which characteristics of each are similar/different to the other (Bredin, 1998). By an abusive comparison, we understand a comparison that is perceived as abusive. In this work, we only consider those comparisons in which no (explicitly) abusive words are contained (6)-(8). Those comparisons are referred to as implicitly abusive comparisons. We exclude comparisons with abusive words since they can be easily detected with recent lexical resources for language abuse (Wiegand et al., 2018).

(6) You have the face of someone only a mother could love.
(7) Your hair looks like you have been electrocuted.
(8) You run like a headless chicken.

We address abusive comparisons since they make up a large proportion of comparisons on

the most related dataset by Qadir et al. (2015). That dataset was created to automatically detect the sentiment of a comparison: one has to distinguish between positive comparisons (*You look like a princess*), neutral comparisons (*You look like your brother*) and negative comparisons (*You look like a crackhead*). We manually annotated the negative comparisons of that dataset. We considered the 359 comparisons that focus on a person[2] (i.e. the 2nd person pronoun *you*). About 75% of the comparisons were considered abusive, the clear majority (2/3) is implicitly abusive. 25% of the negative person-focused comparisons were non-abusive (9)-(11), which is also a significant proportion.

(9) Your face is as pale as a sheet.
(10) You look like you haven't slept in days.
(11) Talking to you is like walking against a strong wind.

Unlike many other datasets for abusive language detection, we create our new dataset with abusive comparisons by ***inventing*** instances (i.e. comparisons) rather than by annotating automatically extracted instances. This design choice is necessary since existing datasets contain either insufficient or biased comparisons: The dataset from Qadir et al. (2015) includes about 180 implicitly abusive comparisons, however, we found, next to many near-duplicates, a heavy bias towards very few recurring images (e.g. *You behave like a child*, *You look like a monkey*). We observed the same phenomenon when extracting comparisons from Twitter directly. Established datasets for abusive language detection (Founta et al., 2018; Zampieri et al., 2019) contain just about 30-40 abusive comparisons.

Our dataset will be created via crowdsourcing. Of course, having abusive comparisons be invented this way will inevitably result in some articificial data. However, we think only thus can we produce a dataset of reasonable size that has also a very low degree of bias which are two important requirements to be able to do research on this novel research topic.

Having crowdworkers invent instances of abusive language may raise ethical concerns. However, the type of abusive language that will be invented in this work is not directed towards specific invididuals or identity groups. Therefore, we believe that this procedure is justifiable. In principle, creating morally disputable content as part of research is not unusual. Both in plagiarism detection (Potthast et al., 2010) and deception detection (Ott et al., 2011), a procedure similar to ours is pursued.

We frame our task as a **binary classification** problem in which each instance is to be categorized as either an abusive or some other negative comparison. Positive and neutral comparisons are not considered since Qadir et al. (2015) already proposed a polarity classifier for comparisons.

Our **contributions** in this paper are:

- We present the first study to address implicitly abusive comparisons.
- We create a **novel dataset** for this task. A set of measures is proposed in order to produce a representative and unbiased set of such comparisons. This dataset is made publicly available.[3]
- We provide an in-depth linguistic analysis that tries to uncover what types of phenomena are involved in abusive comparisons.
- We report classification experiments using state-of-the-art supervised classifiers.
- We provide empirical evidence that this task is different from previously examined tasks and that the established datasets for general language abuse are less suitable for this task.

2 Related Work

Datasets in abusive language detection mostly focus on different targets (e.g. Islamophobia (Waseem and Hovy, 2016), antisemitism (Warner and Hirschberg, 2012), misogyny (Anzovino et al., 2018)), different languages (e.g. Spanish (Álvarez-Carmona et al., 2018), Arabic (Mubarak et al., 2017), Portuguese (Fortuna et al., 2019)) or different domains (e.g. Twitter (Waseem and Hovy, 2016), Facebook (Kumar et al., 2018), Wikipedia (Wulczyn et al., 2017)). Despite some theoretical work outlining distinct subtypes of abusive language (Waseem et al., 2017), there has been little work on datasets that focus on particular subtypes. Schmidt and Wiegand (2017) present a more detailed overview on abusive language detection.

Comparisons, particularly figurative comparisons (*similes*), have been examined with regard to sentiment. Qadir et al. (2015) investigate automatic polarity classification of comparisons while

---

[2] Other foci are fairly unlikely to be abusive.

[3] The supplementary material, which consists of the supplementary notes and the new dataset, is available at: `https://github.com/miwieg/implicitly_abusive_comparisons`

Component	Example Sentence
Topic (T)	**[You]** are as smart as a toad.
Eventuality (E)	You **[are]** as smart as a toad.
Comparator (C)	You are **[as]** smart **[as]** a toad.
Property (P)	You are as **[smart]** as a toad.
Pattern (T+E+C+P)	**[You are as smart as]** a toad.
Vehicle	You are as smart as **[a toad]**.

Table 1: Components of a comparison.

Pattern ***(with example vehicle in brackets)***	**Perc.**
ABUSE	
You are as big as *(a whale.)*	100%
Your sense of humor reminds me of *(cold custard.)*	90%
You are as intelligent as *(a paper clip.)*	86%
You are as competent as *(an amoeba.)*	83%
You are as useful as *(a glass shovel.)*	78%
OTHER	
You are standing about as straight as *(a circle.)*	100%
You are as sad as *(a wilted lettuce.)*	100%
You are as organised as *(a pile of unsorted socks.)*	92%
You are as pale as *(a sheet.)*	92%
Your appetite is like *(that of a hungry bear.)*	86%

Table 2: Example of biased patterns.

Niculae and Danescu-Niculescu-Mizil (2014) establish a general correlation between sentiment and comparisons. Sentiment is also relevant for the general detection of abusive language (Brassard-Gourdeau and Khoury, 2019). Yet the focus on the subset of negative comparisons that are implicitly abusive has not been addressed before.

3 Data

3.1 Terminology

As illustrated in Table 1, a comparison is typically divided into a set of five components: *topic*, *eventuality*, *comparator*, *property* and *vehicle* (Hanks, 2013). In this paper, we combine the first four components into what we call a *pattern*.

3.2 Creating the Dataset

General setting. We decided to create our dataset with the help of **crowdsourcing**. For the invention of comparisons, we prefer a larger crowd to experts, since with a small set of experts (e.g. 2-3 persons) we would expect the resulting output to have a very limited lexical variability. However, since inventing abusive comparisons is not trivial (we have to make our crowdworkers familiar with specific linguistic concepts, such as negative polarity and implicit abuse), we decided to use *Prolific academic*.[4] This platform allows us to advertise our task to a subset of crowdworkers having specific qualifications. We advertised for English native speakers with some basic academic education without dyslexia. (*The supplementary notes provide annotation guidelines and more details on our setup on Prolific academic.*)

Exploratory Phase. We ran a set of trial surveys to get an idea how complex a single task may be while still allowing for the elicitation of data a reasonable quality. In this phase, we also had crowdworkers write abusive comparisons without any restriction. Thus we acquired a representative set of patterns (Table 1) used in subsequent tasks.

Creative Comparisons Task. In order not to overburden the crowdworkers with too complex instructions, we obtained abusive and non-abusive comparisons in separate tasks. Moreover, to devise a specific comparison, the crowdworkers were given a pattern, so that they only had to provide a vehicle (Table 1). By providing patterns, we could control the syntactic variability of the comparison. For both abusive and non-abusive comparisons, the same patterns were used. This setting allowed us to combine the output of these two surveys to one data collection. Otherwise, we may have ended up coincidentally with a dataset containing different syntactic constructions in the two classes which would artificially facilitate automatic classification.

For the non-abusive comparisons, it was also necessary to provide an example situation to the crowdworkers (45 situational frames were used in total – *see also supplementary notes*). For example, for the pattern *Your face is like*, we asked the crowdworkers to imagine the situation that they arrive at work and notice their colleague to have a severe cold. The comparison the crowdworkers were to devise should express their concern. In order not to overstrain their attention, each task was limited to up to 30 comparisons. Therfore, a larger pool of crowdworkers was required. Overall, 98 crowdworkers participated in creating our dataset.

Re-labelling Task. Since the annotation of abusive language is very difficult (Ross et al., 2016) and the generation of comparisons was (partially) tied to specific situational frames given to the crowdworkers, we introduced a re-labelling task in which all those comparisons were rated *in isolation* (i.e. without displaying the context of a specific situation) as either abusive and non-abusive. In this way, we chose to limit our final dataset to comparisons that can be classified in isolation. The motivation for this is that, while humans perceive the same texts as more or less offensive given con-

---

[4] `www.prolific.co`

text, modeling further context of abusive utterances was not found to improve classification using *currently* available methods, as shown by the recent in-depth study by Pavlopoulos et al. (2020).

Each comparison was rated by 5 crowdworkers; all crowdworkers were different from those in the previous step. Crowdworkers were allowed to label a comparison as *can't decide* for ambiguous comparisons or comparisons that were not understood out of context. For further processing, the label of the majority assigned by the workers was used.

Label Consistency Task. Since we noted several semantically similar comparisons across the collection (e.g. *Your posture reminds me of a weary marathon runner* and *You are as hungry as a marathon finisher*) to have different class labels, we introduced another task, in which sets of similar comparisons were presented to some additional crowdworkers without their current class labels. (The sets comprised between 2 and 4 comparisons.) These workers were to score the entire group but also indicate when they considered some individual comparisons to deviate from that group label. This procedure enabled us to remove several inconsistencies but at the same time also preserve different labels of semantically similar comparisons when they were actually appropriate.

Dataset Cleaning and Debiasing. In the final step, we cleaned the set of comparisons. We removed duplicate comparisons, comparisons that were cases of explicit abuse or that required some non-linguistic background knowledge (e.g. *Your reaction reminds me of how I felt*), and comparisons in which no majority label could be reached.[5]

Special attention was paid to the pattern distribution. We noticed that a subset of patterns is skewed towards abusive or non-abusive comparisons (as illustrated in Table 2). If we included those patterns, automatic classification would get substantially easier, as classifiers would simply learn the class distribution of patterns rather than *analyze* the complete comparison. Unwanted biases in datasets for abusive language detection is a signficant problem in current research (Arango et al., 2019; Wiegand et al., 2019). Therefore, we removed all comparisons belonging to patterns that had 65% or more instances belonging to one class. We also limited the remaining patterns to 20 instances in the dataset in order to avoid further possible topic biases caused by specific patterns dominating the dataset.

Property	**Value**
instances (i.e. comparisons)	1000
abusive instances (*ABUSE*)	500
non-abusive instances (*OTHER*)	500
(unique) crowdworkers	98
individual tasks for crowdsourcing	26
average token length of (full) comparison	9.35
average token length of vehicle	5.25
unique patterns	77
average amount of instances per pattern	12.99
total tokens (full comparison)	9351
total token types (full comparison)	1431
total tokens (only vehicle)	5248
total token types (only vehicle)	1391

Table 3: Statistics of the dataset.

We also measured interannotation agreement between the majority label of our crowdsourced comparisons and one co-author of this paper on a random sample of 200 random comparisons. Ignoring the cases in which the author was uncertain (12%), we reached an agreement of $\kappa = 0.6$ which can be considered substantial (Landis and Koch, 1977).

3.3 The Final Dataset

Our final dataset (Table 3), which comprises 1000 comparisons, only includes instances passing all data cleaning steps. Our examination of the simile dataset by Qadir et al. (2015) in §1 suggested a high proportion of abusive comparisons. However, it is unclear in how far these figures generalize beyond that dataset. Therefore, we enforced a balanced class distribution to be as unbiased as possible.

4 Linguistic Features

We present a set of linguistic features that we use for supervised classification. Some of them are too difficult to produce automatically. Yet we consider them relevant to this work because they may shed more light onto the nature of abusive comparisons. These particular features are produced manually.

4.1 Manually Designed Features

Figurativeness (FIGUR) vs. Literalness (LITERAL). Our dataset comprises both figurative (12) and literal comparisons (13).

(12) You sing like a dying bird. *(figurative & ABUSE)*
(13) You have the face of a sad person. *(literal & OTHER)*

In figurative comparisons, vehicle and topic are fundamentally different types of entities (Qadir et al., 2015).[6] Literal comparisons, on the other

---

[5] With 3 possible labels in the Re-labelling Task (*ABUSE*, *OTHER*, *CAN'T DECIDE*) and 5 workers, there could be ties.

[6] Note that in our paper, we consider figurative comparisons synonymous to what Qadir et al. (2015) refer as similes.

hand, are also reversible (Bredin, 1998). That is, the topic and vehicle of a literal comparison should be able to switch places without large changes in meaning. Hence *Encyclopedias are like dictionaries* can be rephrased as *Dictionaries are like encyclopedias*. However, this does not work for *Encyclopedias are like goldmines* which would therefore be judged as a figurative comparison. Moreover, literal comparisons must emphasize properties that are salient for both entities in the comparison (Wałaszewska, 2013). For instance, *dictionary* and *encyclopedia* share properties, such as being organized in a certain order or containing a number of entries. This does not hold for figurative comparisons. *Encyclopedia* and *goldmine* only share non-salient properties, such as being profitable.

One would intuitively expect abusive comparisons to be figurative (12) and non-abusive comparisons to be literal (13). Therefore, we need to answer the question whether abusive comparisons simply coincide with figurative comparisons.

Dehumanization (DEHUM). A dehumanizing comparison is defined as the direct comparison of a person or their inherent mental or physical attributes as the topic with a non-human entity as the vehicle (Loughnan et al., 2009). Dehumanization, in general, is known to correlate with abusive language (Mendelsohn et al., 2020). An example for a dehumanizing comparison would be (14) due to the comparison of a physical attribute of a person (i.e. *walk*) to a non-human entity (i.e. *giraffe*).

(14) You walk like a giraffe. *(ABUSE)*

Taboos (TABOO). Allen and Burridge (2006) define taboo as a proscription of behavior that affects everyday life. A characteristic of abusive language is that it is considered taboo in many social contexts and that it uses words associated with taboo topic to express offensiveness, such as specific bodily organs, physical and mental abnormity (15)-(17). Many of those words (e.g. *vagina*) are not included in common lexical resources for abusive language detection (Wiegand et al., 2018) and therefore are not considered as explicit abuse since they are too ambiguous. In medical contexts, for example, they are acceptable. Allen and Burridge (2006) provide a list of semantic fields, such as *death and disease* or *sex* which form the basis of our manual annotation of taboos. We assume a label set that reflects Western societies, which is the context in which our comparisons were created.

(15) Your eyes are like backwards binoculars. *(ABUSE)*
(16) You drive like an armless child. *(ABUSE)*
(17) Your attention span is like a flash on a circuit. *(ABUSE)*

Absurd Images (ABSURD). In many figurative comparisons in our dataset, we also observed fairly absurd images (18)-(19). By that we mean vehicles that describe situations that are never or extremely rarely observed in real life. We examine whether such images tend to be perceived as abusive.

(18) Your input is like [a baby giving their opinion on computer code]$_{vehicle}$. *(ABUSE)*
(19) You walk like [you have three legs and four pockets full of rubble]$_{vehicle}$. *(ABUSE)*

Contradiction (CONTRAD). A recurring construction in comparisons are contradictions (20)-(21). These are typically constructions where the property of the comparison (e.g. *thin*) is opposite to the prototypical properties associated with the vehicle (e.g. an *elephant* is *large* and *massive* rather than *thin*). Such contradictions, which are a subtype of sarcasm, may be perceived as abusive.

(20) You are as [thin]$_{prop.}$ as [an elephant]$_{vehicle}$. *(ABUSE)*
(21) You are as [smart]$_{prop.}$ as [a neanderthal]$_{vehicle}$. *(ABUSE)*

Evaluation (EVAL) vs. Emotional Frame of Mind (FRAME). Although all our comparisons are negative in polarity, they differ in the type of sentiment that they express. On the one hand, there are evaluative comparisons (22), i.e. the author of a comparison evaluates a specific property of the target person in a negative way, typically by criticizing their behavior or outward appearance (such as being overweight as in (22)). Such comparisons are likely to be perceived as abusive utterances. On the other hand, there are comparisons in which the author describes the emotional frame of mind of the target (23). Since all our comparisons are negative, typical emotional frames are *pain*, *sorrow*, *exhaustion* or *shock* (as in (23)). The author of such comparisons does not necessarily evaluate the target. For example, if one states that some other person is in pain, this is not meant as some criticism, but rather some concern. Such comparisons are rarely perceived as abusive.

(22) You look like an overfed cat. *(ABUSE)*
(23) You look like a shocked cat. *(OTHER)*

This distinction bears a resemblance to the distinction of sentiment views proposed by Wiegand et al. (2016). That work proposes a binary distinction into *speaker views*, which resembles evaluative

Feature	ABSURD	CONTRAD	DEHUM	FIGUR	TABOO	VIEW
Cohen's κ	0.82	1.00	0.88	0.63	0.74	0.73

Table 4: Agreement on manual features.

comparisons, and *actor views*, which resembles descriptions of the emotional frame of mind. Wiegand et al. (2016) also provide a list of verbs, nouns and adjectives classified into either of the two categories. Due to the fact that this lexicon seems inaccurate when it comes to ambiguous words[7], we annotated the binary distinction of evaluation vs. emotional frame of mind manually in addition to using the resource from Wiegand et al. (2016).

Interannotation Agreement. On a random sample of 200 comparisons, we measured interannotation agreement on each of the manually designed features between two annotators, one coauthor and a graduate in computational linguistics. The resulting scores are shown in Table 4.

The easiest feature are contradictions for which we even measured a perfect agreement on our sample. This very high agreement can be explained by the fact that many of the contradictions that have been employed in our dataset were cases of lexicalization, such as *as clear as mud*. Such contradictions are easy to spot.

It comes as no surprise that we obtain the lowest agreement for the distinction between literal and figurative language since this is a very difficult task (Pragglejaz Group, 2007). Still even that score is considered good for this particular task (Veale et al., 2016).

4.2 Automatically Generated Features

Intensity (INTENS). Wiegand et al. (2018) established a correlation between high polar intensity and abusive language (24). In order to measure the degree of polar intensity of a comparison, we took the most effective intensity lexicon from Wiegand et al. (2018) and ranked each comparison by the average intensity score associated with the words contained in the comparison. The lexicon ranks words from very positive (top) to very negative (bottom). Thus polar intensive words are at both ends of the ranking (e.g. top 50 or bottom 50).

(24) Your eyes are like doorways into hell itself. *(ABUSE)*

Frequency (RARE). A high polar intensity may not only be conveyed by inherently polar words (e.g. *hell*) but also by comparisons to special items. We assume that those items share the property of having a low frequency in a general text corpus. Words like *bakelite* or *kazoo* are no polar expressions but they are rare in text corpora. If used in a comparison (25)-(26), the comparison is perceived as an extreme comparison and therefore likely to be abusive. For our experiments, we estimate the frequency of words from the North American News Corpus (LDC95T21). We rank each comparison according to its most infrequent word.

(25) You are as modern as **bakelite**. *(ABUSE)*
(26) You laugh like a **kazoo**. *(ABUSE)*

Absence of Nouns and Adjectives (ABSENCE). Abusive imagery in comparisons typically requires concrete nouns as the vehicle. Further, abusive comparisons may require adjectives in order to convey a high polar intensity or a negative evaluation. This permits the reverse conclusion that the absence of those two parts of speech is likely to be a non-abusive comparison (27)-(28).

(27) You look like you're lost$_{verb}$. *(OTHER)*
(28) You move like you're hurt$_{verb}$. *(OTHER)*

Similarity to Explicit Insults (EXPLICIT). Although our comparisons do not contain any (explicitly) abusive words, a lexicon of such words may still help us in classification. We assume that the boundary between implicit and explicit insults is not clear-cut and that there are ambiguous abusive words contained in our comparisons that still have a strong semantic similarity to abusive words from a lexicon of abusive words. We took the lexicon from Wiegand et al. (2018), computed a centroid embedding vector of its entries and ranked our comparisons according to the semantic similarity to the centroid. A comparison was represented by the embedding vector of the word in that comparison whose similarity was highest to the centroid. As embeddings we chose the fastText emeddings (Joulin et al., 2017) induced on Common Crawl.[8]

Emotions (EMO). In order to take into account the recently reported correlation between abusive language and emotions (Rajamanickam et al., 2020), we use the NRC lexicon (Mohammad and Turney, 2013) which lists the emotion categories associated to a particular frequent English

---

[7] This lexicon assigns one category for each word thus assuming one sense per lexical entry. However, there may be words like *sick* which may convey an evaluation in one context (meaning *crazy* or *mad*) or a judgment on the frame of mind (feeling bad as a result of suffering from illness).

Table 5: Comparisons of different classifiers.

word. A word may be associated with more than one of the 8 emotion categories. We represent each comparison by the set of emotion categories for the words also occurring in the NRC lexicon.

WordNet Supersenses (SUPER). We also consider WordNet supersenses (Miller et al., 1990) in our experiments. They represent a set of 45 coarse-grained semantic categories and have been found effective in related tasks, such as sentiment analysis (Flekova and Gurevych, 2016). A comparison is represented by the set of semantic categories associated with the words contained in the comparison.

5 Experiments

5.1 Classification Performance

As a supervised classifier, we chose BERT-Large (Devlin et al., 2019). We initially experimented with two versions: one in which we fine-tune the model by adding a layer on top of the pre-trained model and a SVM (Joachims, 1999) that is trained on the BERT embeddings of the final layer. Since we did not measure any statistically significant difference between these models, we decided in favor of SVM due to its simplicity. We carry out a 5-fold cross validation. The folds comprise mutually exclusive patterns (Table 1). Thus test instances always comprise patterns not observed in the training data. We consider this the most difficult and realistic scenario. We report macro-average precision, recall and F1-score. (*The supplementary notes contain more details regarding all classifiers of our experiments.*)

As baselines, we consider a majority classifier, a random classifier and two classifiers trained on fastText: one without and one with pre-trained embeddings (Common Crawl). As an upper bound we also provide a **human baseline** in which we randomly sampled the judgment of one individual annotator from the crowdsourced annotation. This upper bound may notably differ from the gold standard label since the latter benefited from being calculated from the majority of 5 annotators.

In order to demonstrate the importance of cleaning/debiasing the dataset and show that, otherwise classification performance will be unrealistically high, we also train a classifier on a **biased comparison dataset**. For that, we sampled a set of the identical size from the original data we collected via crowdsourcing (§3.2) as our final debiased dataset (i.e. 1000 comparisons) but skipped the data cleaning step, particularly the steps on balancing the pattern distribution and removing patterns that are highly skewed towards either of the two classes (Table 2). We also arranged the folds at random, so that patterns in the test data could also be observed in the training data. Thus a classifier could benefit from memorizing biased patterns.

Table 5 shows the performance of the different classifiers. FastText strongly benefits from the pre-trained embeddings and already outperforms the other baselines by a large degree. BERT outperforms fastText. If a classifier is just trained on the pattern, we obtain performance close to the random baseline which shows that our attemps to produce unbiased patterns were successful. Just training on a vehicle yields reasonable scores. However, this is outperformed by training on the full comparison (i.e. pattern+vehicle). This suggests that the full meaning of a comparison is conveyed by the combination of pattern and vehicle. The linguistic features also produce reasonable performance. However, a combination of BERT and these features results in best performance. The contribution of the manual linguistic features is only limited. The human baseline with an F1-score of 77.6% shows us again how difficult this task is. It also underscores the strong performance of our best classifier with an F1-score of 72.9%. The scores on the biased dataset are unrealistically high reaching performance close to the human upper bound.

Figure 1 shows a learning curve. It shows we already reached a plateau. Thus, it is unlikely to obtain better classification performance with more training data. Apparently, our dataset is already sufficiently representative of abusive comparisons.

Further, we investigate whether classifiers trained on standard datasets from abusive language detection can generalize to abusive comparisons.

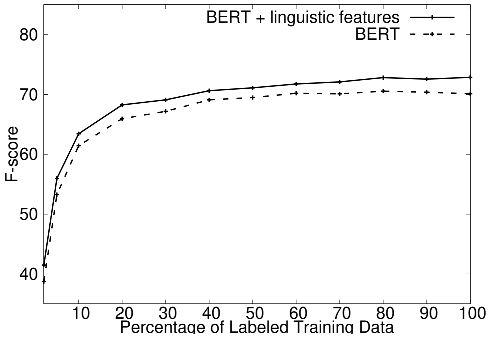

Figure 1: Learning curve on new comparison dataset.

Standard Datasets						New Dataset		
Founta			Zampieri			*(5-fold CV)*		
Prec	**Rec**	**F1**	**Prec**	**Rec**	**F1**	**Prec**	**Rec**	**F1**
63.9	63.5	63.7	66.0	66.1	66.0	72.9	72.8	72.9

Table 6: BERT when trained on different datasets and tested on the new comparison dataset.

We train a classifier (i.e. BERT) on each of the datasets from Founta et al. (2018) and Zampieri et al. (2019) (OffensEval) and test on our new comparison dataset.[9] We compare this against our best previous classifier (Table 5). Table 6 shows the results. The classifiers trained on previous standard datasets (although much larger) yield a considerably lower performance. They may only detect those abusive comparisons that are similar to the very few 30-40 comparisons that are contained on those datasets (§1) or that are generally fairly reminiscent of explicit abuse (22), which is the prominent type of abuse in the standard datasets.

5.2 Linguistic Analysis

Table 7 shows the precision of the most predictive features for each class. For both classes, manual and automatic features are predictive. By far the most predictive feature for implicitly abusive comparisons is the similarity to explicitly abusive words. Words in our dataset, such as *corpse* or *toad* may be too ambiguous to be included in a lexicon of abusive words but they have a strong similarity to abusive words. Further predictive features are rare words and taboo words.

The most predictive non-abusive feature is the supersense *noun.phenomenon*. This represents all comparisons to weather phenomena (e.g. *storms*, *eruption* etc. as in (11)). This is followed by the manual frame feature. Literal comparisons (10) correlate with non-abusive comparisons but there are many figurative comparisons that are also non-abusive (9) & (11). Therefore, the task of detecting abusive comparisons cannot be reduced to the distinction between literal and figurative language.

ABUSE **(Random Precision: 50.0)**			
Feature	**Manual?**	**Precision**	**Freq**
EXPLICIT_top50		92.0	50
EXPLICIT_top100		82.0	100
RARE_top50		76.0	50
TABOO	✓	74.3	113
EMO_disgust		71.3	115
EXPLICIT_top200		70.5	200
SUPER_noun.animal		68.8	122
CONTRAD	✓	68.8	32
SUPER_noun.food		66.1	62
EXPLICIT_top300		66.0	300
ABSURD	✓	62.7	51
SUPER_noun.body		62.5	32
EMO_negative		60.9	253
OTHER **(Random Precision: 50.0)**			
Feature	**Manual?**	**Precision**	**Freq**
SUPER_noun.phenomenon		80.6	36
FRAME_manual	✓	79.1	86
LITERAL	✓	71.6	109
SUPER_noun.object		71.2	59
SUPER_noun.event		70.7	41
INTENS_top200		68.5	200
INTENS_top300		68.3	300
SUPER_noun.time		67.7	65
INTENS_top50		66.0	200
INTENS_top100		65.0	300
ABSENCE		64.6	127
EMO_trust		64.1	131
SUPER_verb.motion		63.5	52
SUPER_noun.act		62.9	70
INTENS_top500		62.6	500
SUPER_verb.perception		61.5	39
FRAME_auto		61.4	140
SUPER_verb.stative		60.7	107

Table 7: Correlation between features and classes.

From the emotion categories, *disgust* correlates with abusive comparisons, while *trust* correlates with non-abusive instances. Of the manual features dehumanization (Prec: 53.9%) does not correlate well with abusive comparisons. Manual features, such as contradictions and absurd images, are more effective. Still, they only cover comparably few instances (i.e. 32 and 51) in our dataset.

The predictive supersenses give us further insights into the nature of abusive comparisons. Animal, food and body expressions are typical of abusive comparisons while weather phenomena, events, temporal expressions and acts are more likely to indicate non-abusive comparisons. Given that also verbal categories (motion, perception, stative) co-occur with the latter class, we can conclude that comparisons addressing abstract concepts tend to be non-abusive while comparisons involving concrete entities (e.g. animals, food) tend to be abusive.

---

[9] Our linguistic features were not added to BERT since they are tailored to comparisons which are extremely rare on those datasets (§1).

5.3 Error Analysis

In the output of the best classifier, we observed the following regularities in misclassifications:

On the one hand, the classifier often overgeneralized. For instance, the classifier learned that a comparison to a machine is typically a means of making fun of someone as in *talking/moving/dancing like a robot*. However, it fails to detect that in (29), the intention is different. Here, the speaker is concerned about seeing someone trembling intensely.

(29) Your hands are like a shaky washing machine. *(OTHER)*

Moreover, certain lexicalized multi-word expressions are not properly recognized. For example, in (30) the mention of the animal *pig* is part of the idiom *see a pig fly* which is not abusive. The classifier probably only learned that *pig* is abusive and predicts the comparison (30) erroneously as abuse.

(30) You talk like you've just seen a pig fly. *(OTHER)*

Comparisons with no obviously predictive linguistic cue (e.g. (31)) also remain difficult.

(31) You talk like someone who is just learning to read. *(ABUSE)*

6 Conclusion

We examined the novel task of detecting implicitly abusive comparisons. For this task, a new dataset was created via crowdsourcing. The comparisons were invented by the crowdworkers themselves. We identified linguistic features that correlate with abusive comparisons (rare words, concrete concepts, contradictions, absurd images and words associated with disgust) and non-abusive comparisons (literal language, comparisons expressing the emotional frame of the target, abstract concepts and the absence of adjectives and nouns). We examined various supervised classifiers. The best classifier is a combination of BERT and the above linguistic features. We also found that abusive comparisons cannot be equated with previously examined phenomena, such as (negative) figurative comparisons. The best classifier trained on the new dataset outperforms classifiers trained on existing datasets that contain hardly any abusive comparisons thus underscoring the need for our new specialized dataset.

Acknowledgements

This research has been partially supported by the Leibniz ScienceCampus Empirical Linguistics and Computational Modeling, funded by the Leibniz Association under grant no. SAS-2015-IDS-LWC and by the Ministry of Science, Research, and Art (MWK) of the state of Baden-Württemberg. The authors would like to thank Ashequl Qadir, Ellen Riloff and Marilyn A. Walker for providing access to their dataset for recognizing affective polarity in similes. We are also grateful to Elisabeth Eder for feedback on earlier drafts of this paper.

Abstract

We propose to use abusive emojis, such as the *middle finger* or *face vomiting*, as a proxy for learning a lexicon of abusive words. Since it represents extralinguistic information, a single emoji can co-occur with different forms of explicitly abusive utterances. We show that our approach generates a lexicon that offers the same performance in cross-domain classification of abusive microposts as the most advanced lexicon induction method. Such an approach, in contrast, is dependent on manually annotated seed words and expensive lexical resources for bootstrapping (e.g. WordNet). We demonstrate that the same emojis can also be effectively used in languages other than English. Finally, we also show that emojis can be exploited for classifying mentions of ambiguous words, such as *fuck* and *bitch*, into generally abusive and just profane usages.

1 Introduction

Abusive or offensive language is defined as hurtful, derogatory or obscene utterances made by one person to another.[1] In the literature, closely related terms include *hate speech* (Waseem and Hovy, 2016) or *cyber bullying* (Zhong et al., 2016). While there may be nuanced differences in meaning, they are all compatible with the general definition above.

Due to the rise of user-generated web content, the amount of abusive language is also steadily growing. NLP methods are required to focus human review efforts towards the most relevant microposts. Building classifiers for abusive language detection requires expensive manually labeled data.

In this paper we explore distant supervision (Mintz et al., 2009) for abusive language detection in which abusive emojis serve as a heuristic to identify abusive language (1)-(8). These texts are subsequently used as training data. The advantage of emojis is that some of them are unambiguously abusive. They are also often redundant (Donato and Paggio, 2017), i.e. they convey something already expressed verbally in the micropost. Since the concept conveyed by an emoji can be expressived verbally in many different ways, abusive emojis may co-occur with many different abusive words (e.g. *idiot*, *cunt*). Moreover, the meaning of emojis is (mostly) shared across languages.

(1) You are such a hypocrite ... Have your dinner dick 😠
(2) @USER @USER you need a good old fashion man sized ass kicking you little Twitt 👊
(3) @USER I challenge you to go on a diet you fat cunt 🖕
(4) @USER You are so so stupid you monkey face 🐵
(5) Send your location, I'll send some killers 🔫
(6) @USER @USER A vote for toddstone or any liberal. Id rather flush a toilet. 💩
(7) Fuck the 12 fuck the cops we aint forgot about you, kill em all kill em all ☠️
(8) @USER She is such a disgusting despicable human being! Ugh! 🤮

Recently, there has been significant criticism of in-domain supervised classification in abusive language detection, whose evaluation has been shown to produce overly optimistic classification scores. They are the result of biases in the underlying datasets. Wiegand et al. (2019) show that on the most popular dataset for this task (Waseem and Hovy, 2016), classifiers learn co-incidental correlations between specific words (e.g. *football* or *sport*) and the abusive class label. Such spurious correlations help classifiers to correctly classify difficult microposts on that particular dataset. Arango et al. (2019) show that since on the dataset from Waseem and Hovy (2016) the majority of abusive tweets originate from just 2 authors, classifiers learn the authors' writing style rather than abusive language.

In order to avoid an evaluation affected by such *topic* or *author biases*, we focus on learning a lexicon of abusive language. A lexicon-based approach

to detect abusive language primarily focuses on the detection of *explicitly* abusive language, i.e. abusive language that is conveyed by abusive words. Such an approach is currently the most effective clue known for cross-domain classification (Wiegand et al., 2018a). In general, other types of abusive language that are more implicit, such as sarcasm, jokes or stereotypes, require more contextual interpretation of words. Supervised classification is theoretically able to conduct such contextual interpretation. However, it has been reported to perform very poorly (Karan and Šnajder, 2018; Arango et al., 2019) on this task because the biases these classifiers exploit are unlikely to be present across different datasets (Wiegand et al., 2019). Therefore, we focus on explicitly abusive language in this work, since there are no ways of reliably detecting implicitly abusive language.

Despite the existence of lexicons for abusive words, induction methods are required, since new abusive words enter language constantly. Further, there are only few lexicons available in languages other than English. The aim of our work is not to detect completely new types of abusive language but to find an inexpensive and language-independent method for lexicon induction.

Our **contributions** in this paper are:

- We use emojis to induce a lexicon of abusive words. Unlike previous work, such an approach does not depend on manually labeled training data or expensive resources, such as WordNet or intensity lexicons. We also demonstrate its effectiveness on cross-domain classification of microposts.
- In order to show the general applicability of our approach, we apply it not only to English but also to Portuguese and German data. The output of this study are three state-of-the-art lexicons that we make publicly available along with all other resources created in this paper.
- We use emojis to disambiguate the context of potentially abusive words. We exemplify this on the two ambiguous and frequent words *fuck* and *bitch*. A by-product is a dataset of mentions of these words annotated in context.

The supplementary material[2] to this paper includes all resources newly created for our research and notes on implementation details.

2 Related Work

Abusive language detection is mostly framed as a supervised learning task (Schmidt and Wiegand, 2017). Feature-based (Nobata et al., 2016) and neural (Pavlopoulos et al., 2017) methods are applied.

Lexicon induction for abusive language detection has received only little attention in previous work, the exceptions being Razavi et al. (2010) who present a lexicon generated using adaptive learning, Gitari et al. (2015) who bootstrap hate verbs and Wiegand et al. (2018a) who induce a lexicon of abusive words. This lexicon is currently the best performing lexicon for the task. It has been induced with the help of a (seed) base lexicon which had been manually annotated. The bootstrapping step largely relies on resources that exist only for well-resourced languages, such as WordNet, sentiment intensity datasets or sentiment-view lexicons.

Recently, there has been a general interest in exploiting extralinguistic information for natural language processing. Emoticons, such as *:-)*, have been found useful for sentiment analysis, particularly emotion classification (Purver and Battersby, 2012). Emojis represent an even more fine-grained set of icons. Felbo et al. (2017) exploit them for pretraining neural models to produce a text representation of emotional content. Since this approach relies on a representative sample of tweets containing emojis, only the 64 most frequently occurring emojis are considered. This set, however, does not contain the very predictive emojis for abusive language detection (e.g. middle finger). Corazza et al. (2020) follow an approach similar to Felbo et al. (2017) in that they pretrain a language model with the help of emoji informarion. However, unlike Felbo et al. (2017), their emoji-based masked language model is evaluated for zero-shot abusive language detection. The task is also considered in a multilingual setting: the target languages are English, German, Italian and Spanish. The improvements that Corazza et al. (2020) report over baseline language models that do not explicitly incorporate emoji information are only limited.

Our work extends Felbo et al. (2017) and Corazza et al. (2020) in that we focus on predictive emojis for abusive languag detection. Unlike Felbo et al. (2017) and Corazza et al. (2020), we do not pretrain a text classifier with these additional emojis. Supervised text classifiers are known to severely suffer from domain mismatches in abusive language detection whereas lexicon-based classifi-

cation is much more stable (Wiegand et al., 2018a).

3 Data, Vocabulary, Tasks & BERT

Data. We use Twitter as a corpus since it is known to contain a significant number of emojis and abusive language. Despite the variety of different emojis[3], only a smaller fraction is regularly used on Twitter. For instance, the dataset from Zampieri et al. (2019) includes less than 10% of them. Our final choice of emojis is displayed in Table 1. It is based on correlations between concepts and abusive language reported in the literature. Next to the emoji 🖕 (middle finger) depicting the most universally offensive gesture (Robbins, 2008), our choice includes emojis that connote violence (Wiener, 1999) (👊 oncoming fist, 🔫 pistol), the taboo topics death and defecation (Allen and Burridge, 2006) (☠️ skull and crossbones, 💩 pile of poo), the emotions anger and disgust (Alorainy et al., 2018) (😠 angry face, 🤮 face vomiting) and dehumanization (Mendelsohn et al., 2020) (🐵 monkey face). (1)-(8) illustrate each emoji with an abusive tweet.

For further emojis we only obtained an insufficient amount of English tweets that were necessary for our experiments (i.e. several thousand tweets after running a query containing these emojis using the Twitter-streaming API for a few days). Examples of such sparse emojis are 💣 (bomb) connoting violence or ⚡ (high voltage) connoting anger.[4]

Although our procedure involved a manual selection of emojis, in our evaluation we will demonstrate that this choice does not overfit but generalizes across different datasets and languages.

Table 1 also shows that for Portuguese and German we obtained fewer tweets. This sparsity is representative for languages other than English.

Vocabulary. Our induction experiments are carried out on a vocabulary of negative polar expressions. Abusive words form a proper subset of these expressions. We use the set of negative polar expressions from Wiegand et al. (2018a) comprising about 7,000 English words. For our experiments on Portuguese and German data, we created similar word lists following Wiegand et al. (2018a).

Tasks. In this work, there are two types of tasks: lexicon induction tasks in which we *rank* negative polar expressions where the high ranks should be abusive words, and *classification* of abusive microposts. The former is evaluated with precision at rank n (P@n), while the latter is evaluated with accuracy and macro-average F-score.

Supervised Micropost Classification with BERT. In many experiments, we employ *BERT-LARGE* (Devlin et al., 2019) as a baseline for state-of-the-art text classification for detecting abusive microposts. We always fine-tune the pretrained model by adding another layer on top of it. (*The supplementary notes contain more details regarding all classifiers employed in this paper.*)

4 Inducing a Lexicon of Abusive Words

4.1 Methods for Lexicon Induction

Pointwise Mutual Information (PMI). A standard method for inducing a lexicon from labeled documents is to rank the words according to the PMI with the target class (Turney, 2002). We use tweets in which either of the above emojis occur as abusive documents. In order to obtain negative instances, i.e. tweets which convey no abusive language, we simply sample random tweets from Twitter. The rationale is that abusive language is known to be rare, even on Twitter. Founta et al. (2018) estimate that the proportion of abusive tweets is less than 5%. In order to avoid spurious word correlations, we compute PMI only for words in our vocabulary of negative polar expressions (§3) which occur at least 3 times in our tweets. This threshold value was proposed by Manning and Schütze (1999).

Projection-based Induction. In our second method, we learn a projection of embeddings. The tweets are labeled in the same way as they are labeled for PMI. We use the pretrained embeddings from GloVe (Pennington et al., 2014) induced from

---

[3] https://unicode.org/emoji/charts/full-emoji-list.html

[4] https://icon-library.com/icon/anger-icon-14.html

Twitter.[5] Projection-based induction has the advantage over PMI that it does not only rank words observed in the labeled tweets but all words represented by embeddings. Since the GloVe embeddings are induced on a very large set of tweets which is about 10,000 times larger than the set of tweets we will later use for projection-based induction, i.e. 100k tweets per class (Table 4), the projection is likely to cover a larger vocabulary than PMI including additional abusive words. Let $\mathbf{M} = [\mathbf{w}_1, \ldots, \mathbf{w}_n]$ denote a labeled tweet of n words. Each column $\mathbf{w} \in \{0,1\}^v$ of $\mathbf{M}$ represents a word in a one-hot form. Our aim is learning a one-dimensional projection $\mathbf{S} \cdot \mathbf{E}$ where $\mathbf{E} \in \mathbb{R}^{e \times v}$ represents our unsupervised embeddings of dimensionality e over the vocabulary size v and $\mathbf{S} \in \mathbb{R}^{1 \times e}$ represents the learnt projection matrix. We compute a projected tweet $\mathbf{h} = \mathbf{S} \cdot \mathbf{E} \cdot \mathbf{M}$ which is an n-dimensional vector. Each component represents a word from the tweet. The value represents the predictability of the word towards being abusive. We then apply a bag-of-words assumption to use that projected tweet to predict the binary class label y: $p(y|\mathbf{M}) \propto exp(\mathbf{h} \cdot \mathbf{1})$ where $\mathbf{1} \in \{1\}^n$. This model is a feed-forward network trained using Stochastic Gradient Descent (Rumelhart et al., 1986). On the basis of the projected embeddings we rank the negative polar expressions from our vocabulary (§3).

Recall-based Expansion by Label Propagation (LP). While the very high ranks of an induction method typically coincide with the target class (in our case: abusive words), the lower a rank is, the more likely we are to encounter other words. Taking the high ranks as abusive seeds and then applying some form of label propagation on a word-similarity graph may increase the overall coverage of abusive words found. More specifically, we apply the Adsorption label propagation algorithm from *junto* (Talukdar et al., 2008) on a word-similarity graph where the words of our vocabulary are nodes and edges encode cosine-similarities of their embeddings. As negative (i.e. non-abusive) seeds, we take the most frequently occurring words from our vocabulary since they are unlikely to represent abusive words. In order to produce a meaningful comparison to PMI and projection-based induction, we need to convert the categorical output of label propagation to a ranking of our entire vocabulary. We achieve this by ranking the words predicted to be abusive by their confidence score. At the bottom we concatenate the words predicted to be non-abusive by their inverted confidence score.

4.2 Experiments on English

Evaluation of Induction. The first question we want to answer is what emoji is most predictive. For each of our pre-selected emojis (Table 1), we sampled 10k tweets in which it occurs and ranked the words of our vocabulary according to PMI. As non-abusive tweets we considered 10k randomly sampled tweets. As a baseline, we randomly rank words (*random*). As a gold standard against which we evaluate our rankings, we use all words of the lexicon from Wiegand et al. (2018a) predicted as abusive. Table 2 shows the results of the evaluation against this gold standard. The table shows that 🖕 (middle finger) is the strongest emoji. This does not come as a surprise as the middle finger is universally regarded as a deeply offensive gesture. We use this emoji as a proxy for abusive language in all subsequent experiments where possible.

In Table 3, we examine for PMI and our projection-based approach whether the ranking quality can be improved when more tweets are used. We increased the number of tweets containing the emoji and the number of negative tweets to 100k each. Using the free Twitter-streaming API larger amounts cannot be crawled in a reasonable time span (e.g. 1 month). While for *projection*, we reach maximum performance at 10k tweets, *PMI* is dependent on more data since it can only rank words it has actually observed in the data. *projection* clearly outperforms *PMI*. Since we do not want to overfit and show that our approach is not dependent on the exact value of 10k but also works with any amount of tweets beyond 10k, we use 100k tweets (i.e. the largest amount of tweets available to us) in subsequent experiments.

Table 4 compares further methods. Our gold standard has a wide notion of abusive language, including words such as *crap* or *shit*, which may be merely profane, not truly abusive. Such words also occur in the random tweets that serve as negative data. (Recall that profanity is much more common on Twitter.) These words are thus not learned as abusive. We therefore replaced our negative data with a random sample of sentences from the English *Web as Corpus (ukwac)*. While we thus preserve the language register with this corpus, i.e. informal language, profane language should be-

---

[5] We take the version with 200 dimensions which is a very frequently used configuration for word embeddings.

Table 3: Comparison of PMI and projection using emoji *middle finger* with different amounts of tweets.

come exclusive to our proxy of abusive tweets. Table 4 confirms that using *ukwac* as negative data ($projection_{ukwac}$) improves performance.

To increase the recall of abusive words, we apply *LP* (§4.1) to the output of $projection_{ukwac}$. Since label propagation is sensitive to the underlying class distribution and abusive words typically represent the minority class, we use twice as many non-abusive seeds as abusive seeds.[6] We vary the amount of abusive seeds between 100, 200 and 500. To ensure comparability to the remaining configurations, the seeds are prepended to the output of LP (which explains that LP has only an impact on lower ranks). Table 4 shows clearly that *LP* outperforms $projection_{ukwac}$ on lower ranks.

Cross-Domain Evaluation. Next, we test the best lexicon of our previous experiments (i.e. $projection_{ukwac}$*+LP(200 abusive seed words)*) in cross-domain micropost classification. Posts are categorized into abusive and non-abusive posts. Through a cross-domain classification, in which we train on one dataset and test on another, we show that the chosen configuration is not overfit to a particular dataset.

Table 5 provides some information on the datasets we consider. In addition to the datasets used in Wiegand et al. (2018a), we include the recent SemEval-dataset from Zampieri et al. (2019).

Table 6 shows the results of cross-domain micropost classification. As baselines we use a majority-class classifier, the feature-based approach from Nobata et al. (2016), BERT and the lexicon from Wiegand et al. (2018a). In order to demonstrate the intrinsic predictiveness of the words learned by our emoji-based approach, we do not train a classifier on the source domain (unlike Wiegand et al. (2018a) who use the rank of the lexicon entries as a feature) but simply classify a micropost as abusive if an abusive word from our emoji-based lexicon is found. As abusive words, we consider all 1,250 words of our best approach (Table 4) predicted as *abusive*. Since the training data are not used for our emoji-based approach, that approach produces always the same result on each test set.

Table 6 shows that our lexicon performs on a par with the induction method from Wiegand et al. (2018a), on some domains (e.g. *Warner*), it is even better. Our observation is that these slight performance increases can be ascribed to the fact that our lexicon is only half of the size of the lexicon from Wiegand et al. (2018a). That lexicon still contains many ambiguous words (e.g. *blind* or *irritant*) that are not included in our emoji-based lexicon. Notice that our aim was not to outperform that method. The underlying lexicon was bootstrapped using manual annotation and the induction depends on external resources, such as WordNet or sentiment intensity resources. Our emoji-based approach is a much cheaper solution that can also be applied to languages where these resources are lacking.

4.3 Crosslingual Experiments

In order to show that our approach is also useful for languages other than English, we now apply it to Portuguese and German data.

Necessary Modifications. Given that there are much fewer Portuguese and German than English tweets (Table 1), it is more difficult to obtain a sim-

---

[6] We refrain from tuning the ratio in order to improve the result of *LP* since we want to avoid overfitting.

classifier	P@n 10	50	100	200	500	1000	1500	2000

ilar amount of tweets containing the middle-finger emoji for these languages. Despite the fact that our previous experiments (Table 3) suggest that a smaller amount of data is sufficient for *projection* (i.e. 10k tweets), it would still take more than 2 months to obtain such an amount of German tweets containing the middle finger (Table 1). In order to obtain 10k Portuguese and German tweets more quickly, we included tweets with other predictive emojis. We extracted tweets containing one of the 4 most predictive emojis: *face vomiting*, *pile of poo*, *angry face* or *middle finger*. These 4 emojis are drawn from our English data (Table 1) in order to further demonstrate crosslingual validity. The distribution of emojis reflects their natural distribution on Twitter.

For non-abusive text we sampled sentences from the Portuguese and German versions of the Web As Corpus (Baroni et al., 2009; Filho et al., 2018) from which we also induced word embeddings with word2vec (Mikolov et al., 2013). We decided against pre-trained Twitter embeddings since for many languages such resources are not available. We opted for a setting applicable to most languages.

Evaluation. We evaluate our emoji-based lexicons on the Portuguese dataset from Fortuna et al. (2019) and the two German datasets from GermEval (Wiegand et al., 2018b; Struß et al., 2019). These are datasets for the classification of abusive microposts. As in our evaluation on English data (Table 6), we refrain from an in-domain evaluation since again we want to avoid topic/author biases (§1). Instead, lexicon-based classifiers and a crosslingual approach are used as baselines. The former classifiers predict a micropost as abusive if one abusive word according to the lexicon has been found. In addition to the two variants of *hurtlex* (Bassignana et al., 2018), ***hl-conservative*** and ***hl-inclusive***, we use a lexicon following the method proposed by Wiegand et al. (2018a) on German (***Wiegand2018-replic***). The latter method cannot be replicated for Portuguese, since essential resources for that approach are missing (e.g. sentiment intensity resources, sentiment view lexicons, a manually annotated base lexicon). Moreover, we consider ***Wiegand-translated***, which is the English lexicon from Wiegand et al. (2018a) translated to the target language via GoogleTranslate[7]. Unlike *Wiegand-replic*, this lexicon is cheap to construct as it only requires the original English lexicon.

Our crosslingual baseline exploits the abundance of labeled training data for abusive language detection on English and neural methods to close the language gap between English and the target language. We use ***multilingual BERT*** in which English, Portuguese and German share the same representation space. As proposed by Pires et al. (2019), we train a text classifier on an English dataset for abusive language detection and test the resulting multilingual model on the Portuguese or German microposts. The model that is learnt on English should be usable on the other languages as well, since the three languages share the same representation space. Our crosslingual approach is trained on the dataset from Zampieri et al. (2019), which like our non-English datasets originates from Twitter.

Table 7 shows the results. We also added an upper bound for our emoji-based approach (*emoji+manual*) in which we also include abusive words manually extracted from the abusive microposts missed by the emoji-based approach. Table 7 suggests that our emoji-based approach is only slightly outperformed by its upper bound and the replicated lexicon from Wiegand et al. (2018a), which depends on expensive resources that do not exist in many languages. It is also interesting that the trans-

lated lexicon from Wiegand et al. (2018a) is notably worse than the replicated lexicon. We found that there is a substantial amount of abusive words which cannot be translated into the target language for lack of a counterpart. For example, *spic* refers to a member of the Spanish-speaking minority in the USA. This minority does not exist in most other cultures. For such entries, GoogleTranslate produces the original English word as the translation. In our translated German lexicon, 33% of the entries were such cases. Similarly, we expect some abusive words in German to lack an English counterpart. Therefore, induction methods employing data from the target langage, such as the replicated lexicon or our emoji-based approach, are preferable to translation.

5 Disambiguation of Abusive Words

Many potentially abusive words are not meant to be abusive, i.e. deliberately hurt someone, in all situations in which they are used. For instance, the word *fuck* is abusive in (9) but it is not in (10).

(9) @USER Remorse will get you nowhere, sick **fuck**.
(10) It's so hot and humid what the fuck I'm dying

While operators of social media sites are increasingly facing pressure to react to abusive content on their platforms, they are not necessarily targeting profane language as in (10). In fact, users may see advances of operators against their profane posts as unnecessary and as an infringement of their freedom of speech. Therefore, automated methods to filter textual content of social media sites should ideally distinguish between abusive and profane usage of potentially abusive words.

5.1 Disambiguation with the Help of Emojis

While much previous work (e.g. Davidson et al. (2017)) may frame this task as simply another text classification task in abusive language detection, we consider this as a word-sense disambiguation task. As a consequence, we argue that for robust classification, it is insufficient to have as labeled training data just arbitrary utterances classified as abuse and mere profanity. Instead, as we will also demonstrate, training data have to comprise mentions of those potentially abusive expressions that also occur in the test data. Such an undertaking is very expensive if the training data are to be manually annotated. We propose a more inexpensive alternative in which emojis are employed. We consider tweets containing potentially abusive words as abusive training data if they co-occur with the middle-finger emoji (11)-(14).

(11) @USER Mind ur own business **bitch** 🖕
(12) @USER I have self pride unlike u bastard **bitch** 🖕
(13) @USER Coming from the fake as **fuck** president lol 🖕
(14) @USER @USER How about you **fuck** off Hector! 🖕

Given the scarcity of abusive language even on Twitter (Founta et al., 2018), we consider plain tweets that contain this target word as negative (non-abusive) training data (15)-(18).

(15) Im tired of people complaining about the little shit when I lost my father to that cancer bitch
(16) @USER: I get it nature Im your bitch
(17) Me: you 75% margarita drink some water Aunty: fuck water I'm on vacation
(18) @USER We dont fuck wit each other but happy bday ... celebrate life fam

The supervised classifier we design is a feature-based classifier (SVM). Holgate et al. (2018) report that on the fine-grained classification of (potentially) abusive words such an approach outperforms deep learning methods. We employ an even more lightweight feature set to show that simple features may already help in this task. Table 8 displays our feature set.

5.2 Evaluation of Disambiguation

For evaluation we created a gold standard in which mentions of the two frequent but ambiguous abusive words *fuck* and *bitch* occur (Table 9). We chose these particular two words because they are the only abusive words that are both sufficiently ambiguous and frequent on the dataset from Holgate et al. (2018). That dataset was the only existing dataset with word-specific annotation that was available to us at the time we carried out our experiments so that we could use it as one baseline.[8]

For each of the two words, we extracted 1,000 tweets in which it occurs and had them annotated via crowdsourcing (ProlificAcademic[9]). Each tweet was annotated as *abusive* or *profane* based on the majority of 5 annotators (native speakers of English). (*The supplementary notes contain the annotation guidelines.*)

5.2.1 Baselines for Disambiguation

Text Classification. We train a supervised text classifier (BERT) on each of the following two large datasets (containing several thousand microposts) manually annotated on the micropost level. The dataset from Davidson et al. (2017) distinguishes between the 3 classes: *hate speech*, *offensive language* and *other*. The first category matches our definition of abusive language whereas the second category resembles our category of profane language. We train our classifier on these two categories. The Kaggle-dataset[10] has a more fine-grained class inventory, and the class *insult* can be best mapped to our definition of abusive language. Since profane language can be found in all of the remaining classes, we use the microposts of all other classes as training data for our second class.

Word-specific Classification. We consider the fine-grained class inventory from the manually annotated dataset introduced by Holgate et al. (2018). Unlike the previous baseline, which consists of micropost-level annotation, this dataset contains word-specific annotation, i.e. potentially abusive words annotated in context. This allows us to reduce the training data to contain exclusively contextual mentions of either of our target words (i.e. *bitch* and *fuck*). We use the class *express aggression* as a proxy for our class of abuse while all other occurrences are used as merely profane usages. Given that we have word-specific training data, we train an SVM-classifier on the disambiguation features from Table 8 as we do with our proposed classifier (§5.1).

Heuristic Baseline. In this baseline, training data for abusive usage is approximated by tweets containing the target word and a username. The rationale is that abuse is always directed against a person and such persons are typically represented by a username in Twitter. As profane training data, we consider tweets containing the target word but lacking any username. Given that we have word-specific training data, we again train an SVM-classifier on the disambiguation features (Table 8).

5.2.2 Results of Disambiguation

Table 10 shows the result of our evaluation. For our emoji-based method (and the heuristic baseline), we trained on 2,000 samples containing mentions of the respective target word. Further data did not

---

[8] Meanwhile, two further datasets by Pamungkas et al. (2020) and Kurrek et al. (2020) have been made publicly available which might also be suitable for the kind of evaluation we present in our work.

feature	**explanation**
words immediately preceding and following target word	may be helpful in order to learn phrases such as *fuck off*; larger context is avoided since we are likely to overfit to particular domains
presence of abusive words in context?	target word is likely to be abusive if it co-occurs with other (unambiguously) abusive words; abusive words are identified with the help of the lexicon from Wiegand et al. (2018a)
presence of positive/negative polar expressions in context?	positive polar expressions rarely co-occur with abusive language, negative polar expressions, however, do; the polar expressions are obtained from the *Subjectivity Lexicon* (Wilson et al., 2005)
which pronouns are in context?	2nd person pronouns are typical of abusive usage: *you are a bitch*; 1st person pronouns are likely to indicate non-abusive usage: *I am a bitch*
quotation signs in tweet?	quotation signs indicate reported speech; a tweet may report an abusive remark, however, the reported remark itself may not be perceived as abusive (Chiril et al., 2020)
presence of exclamation sign?	a typical means of expressing high emotional intensity

Table 8: Features for disambiguating a potentially abusive word (referred to as *target word*); *context* is defined as a window of 4 words neighbouring the target word.

improve performance. Our proposed approach outperforms all other classifiers with the exception of the more expensive word-specific classifier on the disambiguation of *fuck*. These results show that emojis can be effectively used for disambiguation.

Since we considered the classifier trained with word-specific annotation an upper bound, we were surprised that our emoji-based classifier outperformed that approach on the disambiguation of *bitch*. In that training data we found abusive instances that, according to our guidelines (*see supplementary notes*), would not have been labeled as abusive (19)-(20). These deviations in the annotation may be the cause of the lower performance.

(19) Wow now im a bitch and its apparently ALWAYS like this. Im ready to be over tonight.
(20) I am many things – but a boring bitch is not one.

The baseline *text classification* is less effective than *word-specific classification*. Our inspection of the former datasets revealed that their annotation is less accurate. Apparently annotators were not made aware that certain words are ambiguous. As a consequence, they seem to have used specific words as a signal for or against abuse. For instance, on the Davidson-dataset, almost all occurrences of *bitch* ($> 97\%$) are labeled as abuse and almost all occurrences of *fuck* ($> 92\%$) as no abuse.

6 Conclusion

We presented a distant-supervision approach for abusive language detection. Our main idea was to exploit emojis that strongly correlate with abusive content. The most predictive emoji is the middle-finger emoji. We employed mentions of such emojis as a proxy for abusive utterances and thus generated a lexicon of abusive words that offers the same performance on cross-domain classification of abusive microposts as the best previously reported lexicon. Unlike that lexicon, our new approach neither requires labeled training data nor any expensive resources. We also demonstrated that emojis can similarly be used in other languages where they outperform a crosslingual classifier and a translated lexicon. Finally, we showed that emojis can also be used to disambiguate mentions of potentially abusive words.

Abstract

Against the background of what has been termed a reproducibility crisis in science, the NLP field is becoming increasingly interested in, and conscientious about, the reproducibility of its results. The past few years have seen an impressive range of new initiatives, events and active research in the area. However, the field is far from reaching a consensus about how reproducibility should be defined, measured and addressed, with diversity of views currently increasing rather than converging. With this focused contribution, we aim to provide a wide-angle, and as near as possible complete, snapshot of current work on reproducibility in NLP, delineating differences and similarities, and providing pointers to common denominators.

1 Introduction

Reproducibility is one of the cornerstones of scientific research: inability to reproduce results is, with few exceptions, seen as casting doubt on their validity. Yet it is surprisingly hard to achieve, 70% of scientists reporting failure to reproduce someone else's results, and more than half reporting failure to reproduce their own, a state of affairs that has been termed the 'reproducibility crisis' in science (Baker, 2016). Following a history of troubling evidence regarding difficulties in reproducing results (Pedersen, 2008; Mieskes et al., 2019), where 24.9% of attempts to reproduce own results, and 56.7% of attempts to reproduce another team's results, are reported to fail to reach the same conclusions (Mieskes et al., 2019), the machine learning (ML) and natural language processing (NLP) fields have recently made great strides towards recognising the importance of, and addressing the challenges posed by, reproducibility: there have been several workshops on reproducibility in ML/NLP including the Reproducibility in ML Workshop at ICML'17, ICML'18 and ICLR'19; the Reproducibility Challenge at ICLR'18, ICLR'19, NeurIPS'19, and NeurIPS'20; LREC'20 had a reproducibility track and shared task (Branco et al., 2020); and NeurIPS'19 had a reproducibility programme comprising a code submission policy, a reproducibility challenge for ML results, and the ML Reproducibility checklist (Whitaker, 2017), later also adopted by EMNLP'20 and AAAI'21. Other conferences have foregrounded reproducibility via calls, chairs' blogs,[1] special themes and social media posts. Sharing code, data and supplementary material providing details about data, systems and training regimes[2] is firmly established in the ML/NLP community, virtually all main events now encouraging and making space for it. Reproducibility even seems set to become a standard part of reviewing processes via checklists. Far from beginning to converge in terms of standards, terminology and underlying definitions, however, this flurry of work is currently characterised by growing diversity in all these respects. We start below by surveying concepts and definitions in reproducibility research, areas of particular disagreement, and identify categories of work in current NLP reproducibility research. We then use the latter to structure the remainder of the paper.

Selection of Papers: We conducted a structured review employing a stated systematic process for identifying all papers in the field that met specific criteria. Structured reviews are a type of meta-review more common in fields like medicine but beginning to be used more in NLP (Reiter, 2018; Howcroft et al., 2020).

Specifically, we selected papers as follows. We

---

[2] There are some situations where it is difficult to share data, e.g. because the data is commercially confidential or because it contains sensitive personal information. But the increasing expectation in NLP is that authors should share as much as possible, and justify cases where it is not possible.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 381–393
April 19 - 23, 2021.

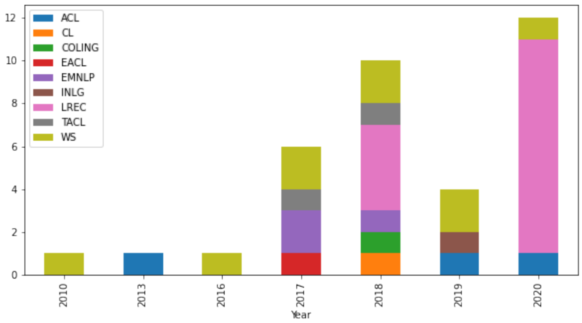

Figure 1: 35 papers from ACL Anthology search, by year and venue.[5]

searched the ACL Anthology for titles containing either of the character strings *reproduc* or *replica*, either capitalised or not.[3] This yielded 47 papers; following inspection we excluded 12 of the papers as not being about reproducibility in the present sense.[4] We found 25 additional papers in non-ACL NLP/ML sources, and a further 7 in other fields.

Figure 1 shows[5] how the 35 papers from the ACL Anthology search are distributed over years: one paper a year at most until 2017/18 when interest seems to have increased spontaneously, before dropping off again. The renewed high numbers for 2020 are almost entirely due to the LREC REPROLANG shared task (see Section 5 below).

2 Terminology and Frameworks

Reproducibility research in NLP and beyond uses a bewildering range of closely related terms, often with conflicting meaning, including reproducibility, repeatability, replicability, recreation, re-run, robustness, repetition and generalisability. The fact that no formal definition of any of these terms singly, let alone in relation to each other, is generally accepted as standard, or even predominant, in NLP at present, is clearly a problem for a survey paper. In this section, we review usage before identifying common-ground terminology that will enable us to talk about the research we survey.

The two most frequently used 'R-terms', *reproducibility* and *replicability*, are also the most problematic. For the ACM (Association for Computing Machinery, 2020), results have been *reproduced* if "obtained in a subsequent study by a person or team other than the authors, using, in part, artifacts provided by the author," and *replicated* if "obtained in a subsequent study by a person or team other than the authors, without the use of author-supplied artifacts" (although initially the terms were defined the other way around[6]). The definitions are tied to team and software (artifacts), but it is unclear how much of the latter have to be the same for reproducibility, and how different the team needs to be for either concept.

Rougier et al. (2017) tie definitions (just) to new vs. original software: "*Reproducing* the result of a computation means running the same software on the same input data and obtaining the same results. [...] *Replicating* a published result means writing and then running new software based on the description of a computational model or method provided in the original publication, and obtaining results that are similar enough to be considered equivalent." It is clear from the many reports of failures to obtain 'same results' with 'same software and data' in recent years that the above definitions raise practical questions such as how to tell 'same software' from 'new software,' and how to determine equivalence of results.

Wieling et al. (2018) define *reproducibility* as "the exact re-creation of the results reported in a publication using the same data and methods," but then discuss (failing to) *replicate* results without defining that term, while also referring to the "unfortunate swap" of the definitions of the two terms put forward by Drummond (2009).

Whitaker (2017), followed by Schloss (2018), tie definitions to data as well as code:

		Data	
		Same	*Different*
Code	*Same*	Reproducible	Replicable
	Different	Robust	Generalisable

The different definitions of *reproducibility* and *replicability* above, put forward in six different contexts, are not compatible with each other. Grappling with degrees of similarity between properties of experiments such as the team, data and software involved, and between results obtained, each draws the lines between terms differently, and moreover variously treats reproducibility and replicability as properties of either systems or results. All are patchy, not accounting for some circumstances, e.g. a team reproducing its own results, not defining

---

[3] `grep -E ‘title *=.*(r|R)\}*(eproduc|eplica)’ anthology.bib`

[4] Most were about annotation and data replication.

[5] Data and code: https://github.com/shubhamagarwal92/eacl-reproducibility

[6] ACM swapped definitions of the two terms when prompted by NISO to "harmonize its terminology and definitions with those used in the broader scientific research community." (Association for Computing Machinery, 2020).

some concepts, e.g. sameness, or not specifying what can serve as a 'result,' e.g. leaving the status of human evaluations and dataset recreations unclear.

The extreme precision of the definitions of the International Vocabulary of Metrology (VIM) (JCGM, 2012) (which the ACM definitions are supposed to be based on but aren't quite) offers a common terminological denominator. The VIM definitions of *reproducibility* and *repeatability* (no other R-terms are defined) are entirely general, made possible by two key differences compared to the NLP/ML definitions above. Firstly, in a key conceptual shift, reproducibility and repeatability are properties of **measurements** (not of systems or abstract findings). The important difference is that the concept of reproducibility now references a specified way of obtaining a **measured quantity value** (which can be an evaluation metric, statistical measure, human evaluation method, etc. in NLP). Secondly, reproducibility and repeatability are defined as the *precision* of a measurement under specified conditions, i.e. the distribution of the quantity values obtained in *repeat* (or *replicate*) measurements.

In VIM, **repeatability** is the precision of measurements of the same or similar object obtained under the same conditions, as captured by a specified set of **repeatability conditions**, whereas **reproducibility** is the precision of measurements of the same or similar object obtained under different conditions, as captured by a specified set of **reproducibility conditions**. See Appendix C for a full set of VIM definitions of the bold terms above.

To make the VIM terms more recognisable in an NLP context, we also call repeatability **reproducibility under same conditions**, and (VIM) reproducibility **reproducibilty under varied conditions**. Finally, we refer to experiments carrying out repeat measurements regardless of same/varied conditions as 'reproduction studies.'

Categories of Reproducibility Research: Using the definitions above, the work we review in the remainder of the paper falls into three categories (corresponding to Sections 3–5):

Reproduction under same conditions: As near as possible exact recreation or reuse of an existing system and evaluation set-up, and comparison of results.[7]

Reproduction under varied conditions: Reproduction studies with deliberate variation of one or more aspects of system and/or measurement, and comparison of results.

Multi-test studies: Multiple reproduction studies connected e.g. because of an overall multi-test design, and/or use of same methodology.

3 Reproduction Under Same Conditions

Papers reporting reproductions under same conditions account for the bulk of NLP reproducibility research to date. The difficulty of achieving 'sameness of system' has taken up a lot of the discussion space. As stressed by many papers (Crane, 2018; Millour et al., 2020), recreation attempts have to have access to code, data, full details/assumptions of algorithms, parameter settings, software and dataset versions, initialisation details, random seeds, run-time environment, hardware specifications, etc.

A related and striking finding, confirmed by multiple repeatability studies, is that results often depend in surprising ways and to surprising degrees on seemingly small differences in model parameters and settings, such as rare-word thresholds, treatment of ties, or case normalisation (Fokkens et al., 2013; Van Erp and Van der Meij, 2013; Dakota and Kübler, 2017). Effects are often discovered during system recreation from incomplete information, when a range of values is tested for missing details. The concern is that the ease with which such NLP results are perturbed casts doubt on their generalisability and robustness.

The difficulties in recreating, or even just rerunning, systems with same results have led to growing numbers of reproducibility checklists (Olorisade et al., 2017; Pineau, 2020), and tips for making system recreation easier, e.g. the PyTorch (Paszke et al., 2017) recommended settings.[8]

We analysed reproduction studies under same conditions from 34 pairs of papers, and identified 549 individual score pairs where reproduction object, method and outcome were clear enough to include in comparisons (for a small number of papers this meant excluding some scores). Table 1 in Appendix A provides a summary of the results. In 36 cases, the reproduction study did not produce scores, e.g. because resource limits were reached,

---

[7] This excludes the countless cases where results for a previous method are used as a baseline or other comparitor, but experiments are not run again.

[8] `https://pytorch.org/docs/stable/notes/randomness.html`

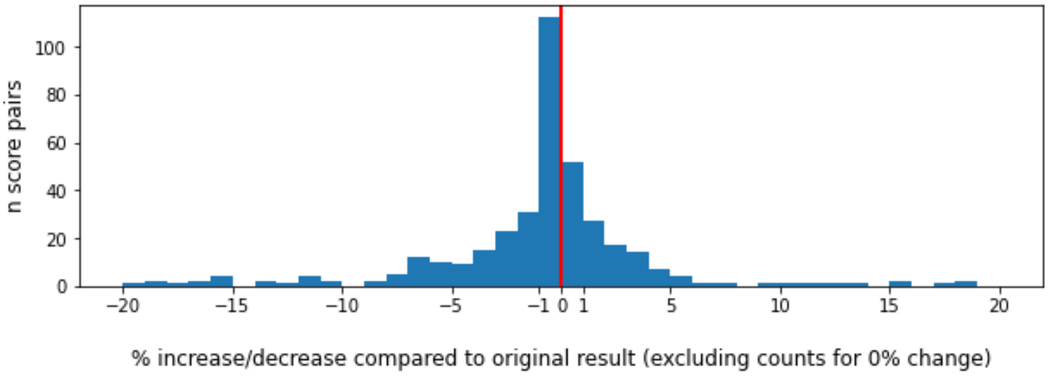

Figure 2: Histogram of percentage differences between original and reproduction scores (bin width = 1; clipped to range -20..20).

or code didn't work. This left 513 cases where the reproduction study produced a value that could be compared to the original score. Out of these, just 77 (14.03%) were exactly the same. Out of the remaining 436 score pairs, in 178 cases (40.8%), the reproduction score was better than the original, and in 258 cases (59.2%) it was worse.

We also examined the size of the differences between original and reproduction scores. For this purpose we computed percentage change (increase or decrease) for each score pair, and looked at the distribution of size and direction of change. For this analysis, we excluded score pairs where one or both scores were 0, as well as 4 very large outliers (all increases). Results are shown in the form of a histogram with bin width 1 (and clipped to range -20..20) in Figure 2. The plot clearly shows the imbalance between worse (60% of non-same scores) and better (40%) reproduction scores. The figure also shows that a large number of differences fall in the -1..1 range. However, the majority of differences, or 3/5, are greater than +/-1%, and about 1/4 are greater than +/-5%.

4 Reproduction Under Varied Conditions

Reproduction studies under varied conditions deliberately vary one or more aspects of system, data or evaluation in order to explore if similar results can be obtained. There are far fewer papers of this type (see Table 2 in Appendix B for an overview) than papers reporting reproduction studies under same conditions; however, note that we are not including papers here that use an existing method for a new language, dataset or domain, without controlling for other conditions being the same in experiments.

Horsmann and Zesch (2017) pick up strong results by Plank et al. (2016) showing LSTM tagging to outperform CRF and HMM taggers, and test whether they can be confirmed for datasets with finer-grained tag sets. Using 27 corpora (21 languages) with finer-grained tag sets, they systematically compare results for the 3 models, and show that LSTMs do perform better, and that their superiority grows in proportion to tag set size.

Htut et al. (2018a) recreate the grammar induction model PRPN (Shen et al., 2018), testing different versions with different data. PRPN is confirmed to be "strikingly effective" at latent tree learning. In a subsequent repeat study under same conditions, Htut et al. (2018b) test PRPN using the authors' own code, obtaining the same headline result.

Millour et al. (2020) attempt to get the POS tagger for Alsatian from Magistry et al. (2018) to work with the same accuracy for a different dataset. Collaborating with, and using resources provided by, the original authors and recreating some where necessary, the best result obtained was 0.87 compared to the original 0.91.

Abdellatif and Elgammal (2020) varied conditions of reproduction for classification results by Howard and Ruder (2018), and were able to confirm outcomes for three new non-English datasets, in all three respects (value, finding, conclusion) identified by Cohen et al. (2018).

Pluciński et al. (2020) and Garneau et al. (2020) both find that the cross-lingual word embedding mappings proposed by Artetxe et al. (2018) yield worse results on more distant language pairs.

Vajjala and Rama (2018)'s automatic essay scoring classification system was tested on different datasets and/or languages in three studies (Arhiliuc et al., 2020; Caines and Buttery, 2020; Huber and Çöltekin, 2020) all of which found performance to drop on the new data.

5 Multi-test and Multi-lab Studies

Work in this category is *multi-test*, in the sense of involving multiple reproduction studies, in a uniform framework using uniform methods. Some of it is also *multi-lab* in that reproduction studies are carried out by more than one research team. For example, in one multi-test repeatability study, Wieling et al. (2018) randomly select five papers each from ACL'11 and ACL'16 for which code/data was available. In a uniform design, original authors were contacted for help if needed, a maximum time limit of 8h was imposed, and all work was done by the same Masters student. It's not clear how scores were selected (not all are attempted), and reasons for failure are not always clear even from linked material. Of the 120 score pairs obtained, 60 were the same, 12 reproduction scores were better, 22 were worse, and 26 runs failed (including exceeding the time limit). See Table 1 for summary.

Rodrigues et al. (2020) recreated six SemEval'18 systems from the Argument Reasoning Comprehension Task, following system descriptions and/or reusing code, with no time limit. Scores were the same for one system, and within +/- 0.036 points for the other five; the SemEval ranking was exactly the same. Systems were also run on a corrected version of the shared-task data (which contained unwitting clues). This resulted in much lower scores casting doubt on the validity of the original shared task results.

REPROLANG (Branco et al., 2020) is so far the only multi-lab (as well as multi-test) study of reproducibility in NLP. It was run as a selective shared task, and required participants to conform to uniform rules. 11 papers were selected for reproduction via an open call and direct selection. Participants had to 'reproduce the paper,' using information contained/linked in it. Participants submitted (a) a report on the reproduction, and (b) the software used to obtain the results as a Docker container (controlling variation from dependencies and run-time environments) on GitLab. Submissions were reviewed in great detail, submitted code was test-run and checked for hard-coding of results. 11 out of 18 submissions were judged to conform with requirements. One original paper (Vajjala and Rama, 2018) attracted four reproductions (Bestgen, 2020; Huber and Çöltekin, 2020; Caines and Buttery, 2020; Arhiliuc et al., 2020) in what must be a groundbreaking first in NLP. See Table 1 for summaries of all 11 reproductions. An aspect the organisers did not control was how to draw conclusions about reproducibility; most contributions provide binary conclusions but vary in how similar they require results to be for success. E.g. the four papers reproducing Vajjala and Rama (2018) all report similarly large deviations, but only one (Arhiliuc et al., 2020) concludes that the reproduction was not a success.

6 Conclusions

It seemed so simple: share all data, code and parameter settings, and other researchers will be able to obtain the same results. Yet the systems we create remain stubbornly resistant to this goal: a tiny 14.03% of the 513 original/reproduction score pairs we looked at were the same. At the same time, worryingly small differences in code have been found to result in big differences in performance.

Another striking finding is that reproduction under same conditions far more frequently yields results that are worse than results that are better: we found 258 out of 436 non-same reproduction results (59.2%) to be worse, echoing findings from psychology (Open Science Collaboration, 2015). Why this should be the case for reproduction under *same* conditions is unclear. It is probably to be expected for reproduction under *different* conditions, as larger parameter spaces, more datasets and languages etc., are tested subsequently, and the original work may have selected better results.

There is a lot of work going on in NLP on reproducibility right now; it is to be hoped that we can solve the vexing and scientifically uninteresting problem of how to rerun code and get the same results soon, and move on to addressing far more interesting questions of how reliable, stable and generalisable promising NLP results really are.

Table 1: Tabular overview of individual repeatability tests from 34 paper pairs, and a total of 549 score pairs. * = additional information obtained from hyperlinked material.

Where scores obtained in a repeatability study (reproduction under same conditions) are worse than in the original work, this should *not* be interpreted as casting the original work in a negative light. This is because it is normally not possible to create the exact same conditions in repeatability studies (and lower scores can result from such differences), and because the outcome from multiple repeatability studies may be very different.

For a small number of papers, the score pairs included in this table are a subset of scores reported in the paper. More generally, the summary in the last column should not be interpreted as a summary of the whole paper and its findings.

Our intention here is to summarise differences that have been reported in the literature, rather than draw conclusions about what may have caused the differences.

B Table of Reproductions Under Varied Conditions

Original paper	reproduction study (confirmation of finding)	NLP task	Summary of outcome (as interpreted by authors)
Plank et al. (2016)	Horsmann and Zesch (2017)	POS tagging	Confirmed for finer-grained tagsets
Shen et al. (2018)	Htut et al. (2018a,b)	Grammar induction	Overall finding confirmed (that PRPN is a high performing grammar induction method)
Magistry et al. (2018)	Millour et al. (2020)	POS tagging	Not confirmed, reproduction results worse by $>$ 10 BLEU points
Vajjala and Rama (2018)	Arhiliuc et al. (2020)	Automatic essay scoring (classification)	Lower classification results on a corpus of Asian learners' English.
Vajjala and Rama (2018)	Caines and Buttery (2020)	Automatic essay scoring (classification)	Lower classification results for English and Spanish CEFR datasets, and some adversarial data (e.g., scrambled English texts).
Vajjala and Rama (2018)	Huber and Çöltekin (2020)	Automatic essay scoring (classification)	Lower classification results for English Cambridge Learner Corpus.
Artetxe et al. (2018)	Garneau et al. (2020)	Cross-lingual mappings of word embeddings	For other distant language pairs (from English to Estonian, Latvian, Finnish, Persian) the method did not converge or obtained lower scores.
Artetxe et al. (2018)	Pluciński et al. (2020)	Cross-lingual mappings of word embeddings	For other distant language pairs (from English to Czech, Polish) the method did not converge or obtained lower scores.
Howard and Ruder (2018)	**Abdellatif and Elgammal (2020)	Sentiment classification, question classification, topic classification	Confirmed that transfer learning (pretraining) improves final classification accuracy.

Table 2: Tabular overview of individual studies to confirm a previous research finding. * = additional information obtained from hyperlinked material; ** = reproduction study had minor differences, e.g. hyperparameter tuning was omitted (Abdellatif and Elgammal, 2020).

The comments from the caption for Table 1 also apply here, but note that some differences between original and reproduction study are overt and intentional in the case of the papers in this table, whereas they are not intentional and often inadvertent in the case of the papers in Table 1.

C Verbatim VIM and ACM Definitions

2.1 (2.1) **measurement**	process of experimentally obtaining one or more **quantity values** that can reasonably be attributed to a **quantity**
2.15 measurement precision (precision)	closeness of agreement between **indications** or **measured quantity values** obtained by replicate **measurements** on the same or similar objects under specified conditions
2.20 (3.6, Notes 1 and 2) **repeatability condition of measurement** (repeatability condition)	condition of **measurement**, out of a set of conditions that includes the same **measurement procedure**, same operators, same **measuring system**, same operating conditions and same location, and replicate measurements on the same or similar objects over a short period of time
2.21 (3.6) **measurement repeatability** (repeatability)	**measurement precision** under a set of **repeatability conditions of measurement**
2.24 (3.7, Note 2) **reproducibility condition of measurement** (reproducibility condition)	condition of **measurement**, out of a set of conditions that includes different locations, operators, **measuring systems**, and replicate measurements on the same or similar objects
2.25 (3.7) **measurement reproducibility** (reproducibility)	**measurement precision** under **reproducibility conditions of measurement**
2.3 (2.6) **measurand**	**quantity** intended to be measured

Table 3: VIM definitions of repeatability and reproducibility (JCGM, 2012).

Repeatability (Same team, same experimental setup)	The measurement can be obtained with stated precision by the same team using the same measurement procedure, the same measuring system, under the same operating conditions, in the same location on multiple trials. For computational experiments, this means that a researcher can reliably repeat her own computation.
Reproducibility (Different team, same experimental setup)*	The measurement can be obtained with stated precision by a different team using the same measurement procedure, the same measuring system, under the same operating conditions, in the same or a different location on multiple trials. For computational experiments, this means that an independent group can obtain the same result using the author's own artifacts.
Replicability (Different team, different experimental setup)*	The measurement can be obtained with stated precision by a different team, a different measuring system, in a different location on multiple trials. For computational experiments, this means that an independent group can obtain the same result using artifacts which they develop completely independently.

Results Validated: This badge is applied to papers in which the main results of the paper have been successfully obtained by a person or team other than the author. Two levels are distinguished:

Results Reproduced v1.1	The main results of the paper have been obtained in a subsequent study by a person or team other than the authors, using, in part, artifacts provided by the author.
Results Replicated v1.1	The main results of the paper have been independently obtained in a subsequent study by a person or team other than the authors, without the use of author-supplied artifacts.

In each case, exact replication or reproduction of results is not required, or even expected. Instead, the results must be in agreement to within a tolerance deemed acceptable for experiments of the given type. In particular, differences in the results should not change the main claims made in the paper.

Table 4: ACM definitions (bold) and badges (underlined) (Association for Computing Machinery, 2020).

Bootstrapping Multilingual AMR with Contextual Word Alignments

Abstract

We develop high performance multilingual Abstract Meaning Representation (AMR) systems by projecting English AMR annotations to other languages with weak supervision. We achieve this goal by bootstrapping transformer-based multilingual word embeddings, in particular those from cross-lingual RoBERTa (XLM-R large). We develop a novel technique for foreign-text-to-English AMR alignment, using the contextual word alignment between English and foreign language tokens. This word alignment is weakly supervised and relies on the contextualized XLM-R word embeddings. We achieve a highly competitive performance that surpasses the best published results for German, Italian, Spanish and Chinese.

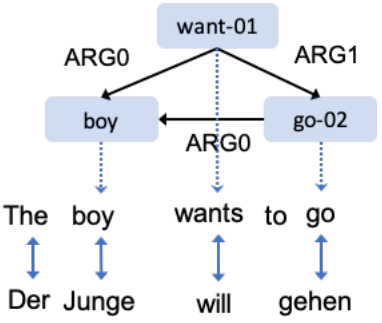

Figure 1: AMR graph for *The boy wants to go* and its German translation *Der Junge will gehen*. Implicit alignments between the English text and AMR concepts are denoted by dotted arrows. Explicit alignments between English and German texts are denoted by solid arrows.

1 Introduction

Abstract Meaning Representation graphs are rooted, labeled, directed, acyclic graphs representing sentence-level semantics (Banarescu et al., 2013). In the example shown in Figure 1, the sentence *The boy wants to go* is parsed into an AMR graph. The nodes of the AMR graph represent the AMR concepts, which may include normalized surface symbols e.g. *boy*, Propbank frames (Kingsbury and Palmer, 2002) e.g. *want-01*, *go-02* as well as other AMR-specific constructs. Edges in an AMR graph represent the relations between concepts. In this example *:arg0*, *:arg1* correspond to standard roles of Propbank.

One distinctive aspect of AMR annotation is the lack of explicit alignments between nodes in the graph and words in the sentences. Since such alignments are essential for training many of present-day AMR parsers, there have been various efforts to link the AMR concepts to their corresponding span of words (Flanigan et al., 2014; Pourdamghani et al., 2014; Lyu and Titov, 2018; Chen and Palmer, 2017). A significant emphasis of this paper is on deriving these alignments for multilingual AMR parsers.

Even though by nature AMR is biased towards English, recent work has evaluated the potential of AMR to work as an interlingua. Hajič et al. (2014) and Xue et al. (2014) categorize and propose refinements for divergences in the annotation between English and Chinese as well as Czech AMRs. Anchiêta and Pardo (2018) import the corresponding AMR annotation for each sentence from the English annotated corpus and revisit the annotation to adapt it to Portuguese. However, Damonte and Cohen (2018) show that it may be possible to use the original AMR annotations devised for English as representation for equivalent sentences in other languages without any modification despite the translation divergence. This defines the problem of multilingual AMR parsing that we seek to address in this paper - given a sentence in a foreign language, recover the AMR graph originally designed for its English translation. We implement

multilingual AMR parsers for German, Spanish, Italian and Chinese.

In this paper we propose that transformer-based multilingual word embeddings can be a useful tool for addressing the problem of multilingual AMR parsing. Besides using contextual word embeddings as input token embeddings, we leverage them for *annotation projection*, where existing AMR annotations for English are projected to a target language by using contextual word alignments. In our experiments, we employ XLM-RoBerta large (Conneau et al., 2019) as the multilingual pre-trained transformer model. We show that our proposed procedure achieves competitive results as some of the classical methods for text-to-AMR alignment. Furthermore, such a procedure is easily scalable to the 100 languages that XLM-R is trained on.

We also combine different techniques for concept alignments and AMR parser training which significantly improve performance over the base models. For concept alignment, we combine the proposed contextual word alignments with previously established alignment techniques utilizing matching rules tailored to AMR as well as machine translation aligners (Flanigan et al., 2014; Pourdamghani et al., 2014). For AMR parser training, we pre-train an AMR parser on the treebanks of different languages simultaneously and subsequently finetune on each language. This is analogous to the techniques used for silver data pre-training (Konstas et al., 2017; van Noord and Bos, 2017) in AMR parsing and multi-lingual pre-training (Aharoni et al., 2019) in machine translation.

Finally, we conduct a detailed error analysis of the multilingual AMR parsing. One of the major errors we have found involves synonymous concepts, which share the same meaning as the original concepts in English, but differ in spellings. While this error is mainly caused by the fact that the multilingual word embeddings bridge non-English input tokens to English concepts, it also highlights the highly lexical nature of Smatch scoring (Cai and Knight, 2013) which does not take synonymous concepts into consideration. We also elaborate upon error analysis of the direct comparison between our proposed annotation projection method using contextual word alignment and a previous baseline, using fast align.

The rest of the paper is organized as follows: In Section 2, we discuss related work. In Section 3, we present our main proposal on annotation projection based on contextual word alignments. In Section 4, we describe various combination approaches that improve the multilingual parser performances significantly. These include combining word-to-concept alignments, using multi-lingual treebanks and combining human-annotated and synthetic treebanks. In Section 5, we discuss experimental results. In Sections 6 and 7, we present detailed error analyses. We conclude the paper in Section 8.

2 Related work

Multilingual AMR. There have been significant advances in AMR parsing for languages other than English. Previous studies (Hajič et al., 2014; Xue et al., 2014; Migueles-Abraira et al., 2018; Sobrevilla Cabezudo and Pardo, 2019) investigated AMR annotations for a variety of different languages such as Chinese, Czech, Spanish and Brazilian Portuguese. Vanderwende et al. (2015) automatically parse the logical representation for sentences in Spanish, Italian, German and Japanese, which is then converted to AMR using a small set of rules.

While much of this work, along with studies such as Li et al. (2016); Anchiêta and Pardo (2018), produces AMR graphs whose nodes were labeled with words from the target language, Damonte and Cohen (2018) developed AMR parsers for English and used parallel corpora for annotation projection to train Italian, Spanish, German, and Chinese parsers that recover the AMR graph originally designed for the English translation. Their main results showed that the new parsers can overcome certain structural differences between languages.

Similar to Damonte and Cohen (2018), we also train multilingual AMR parsers by projecting English AMR annotation to target foreign languages (German, Spanish, Italian and Chinese), but we depart from their approach in the specifics of the annotation projection by exploring contextual word alignments directly derived from multilingual contextualized word embeddings. While both procedures utilize parallel corpora, the annotation projection of Damonte and Cohen (2018) requires additional supervised training of their statistical word aligner. Our proposed contextualized word alignment is however unsupervised in nature. Alternatively, a recent study by Blloshmi et al. (2020) showed that one may in fact not need alignment-based parsers for cross-lingual AMR, rather modelling concept identification as a *seq2seq* problem. In this paper, we will compare our results to both

Damonte and Cohen (2018) and Blloshmi et al. (2020).

Word vector alignment techniques. Traditional word alignment methods often use parallel corpora and IBM alignment models (Brown et al., 1990, 1993) as well as improved versions (Och and Ney, 2003; Dyer et al., 2013). More recently, there have been an advent of techniques that align vector representation of words from varying levels of supervision (Ruder et al., 2019). Often word vectors are learned independently for each language and then a mapping from source language vectors to target language vectors with a bilingual dictionary is developed (Mikolov et al., 2013; Smith et al., 2017; Artetxe et al., 2017). To reduce the need for bilingual supervision, the iterative method of starting from a minimal seed dictionary and alternating with learning the linear map was employed by a recent body of work (Conneau et al., 2018; Schuster et al., 2019; Artetxe et al., 2018).

The work most similar to ours is Cao et al. (2020) where the authors obtain contextual embedding alignments from multilingual BERT (Devlin et al., 2018; Pires et al., 2019) and subsequently improve the alignments via finetuning using supervised parallel corpora. Our contextual word alignment between two parallel sentences may be thought of as an adaptation of their contextual word retrieval task. However, we refrain from any finetuning of the contextual embeddings and show that the contextual word alignments from the off-the-shelf XLM-R model achieves results competitive to the word alignments by fast-align (see Damonte and Cohen (2018)). This suggests the potential for inexpensive, massive scaling of AMR parsing up to 100 languages on which XLM-R is trained.

3 Annotation projection

We adopt a transition-based parsing approach for AMR parsing following (Ballesteros and Al-Onaizan, 2017; Naseem et al., 2019; Fernandez Astudillo et al., 2020). These produce an AMR graph g from an input sentence s by predicting instead an action sequence a from s as a sequence to sequence problem. This action sequence applied to a state machine M produces then the desired target graph as $g = M(a, s)$. Transition-based parsers require the action sequence for each graph in the training data. This is determined by a rule-based oracle $a = O(g, s)$ which relies on external word-to-node alignments. In all the subsequent experiments we will use the oracle and action set from (Fernandez Astudillo et al., 2020).

3.1 Projection method

In order to train AMR parsers in a non-English language, we use the annotation projection method to leverage existing English AMR annotation and overcome resource shortage in the target language. First, the English text is aligned to corresponding AMR concepts using both rule-based JAMR aligner (Flanigan et al., 2014) and a IBM model type aligner (Pourdamghani et al., 2014). The latter will henceforth be referred to as the EM aligner. Given the English text-to-AMR concept alignments, we then project these to the target language using word alignment. In the following subsection we describe in the proposed word alignment method, called *contextual word alignment*, which is trained in a weakly supervised manner.

3.2 Contextual word alignments

Given two languages, we align word pairs within parallel sentences if their vector representations derived from the underlying multilingual pre-trained model are similar according to cosine distance. As vector representation we use the average of all 24 layers of the XLM-R large contextual embeddings. We will refer to this average as the word's contextual embedding henceforth for simplicity.

More precisely, suppose we have two parallel sentences - $\mathbf{E} = e_0, e_1, e_2, ..., e_M$ in English and $\mathbf{F} = f_0, f_1, f_2, ..., f_N$ in the target language. We will use r to represent the pre-trained multilingual model such that $r(\mathbf{S})_i$ is the contextual embedding for the i^{th} word in sentence $\mathbf{S}$. Then a word $e_i \in \mathbf{E}$ is contextually word aligned to f_j if and only if the cosine similarity score between their word embeddings is the highest. Thus we define the corresponding contextual alignment function $\chi(f_j|e_i)$ as,

$$\chi(f_j|e_i) = \text{argmax}_{0 \leq j \leq |\mathbf{F}|} cos(r(\mathbf{E})_i, r(\mathbf{F})_j). \tag{1}$$

Similarly, performing the same procedure in the reverse direction we have,

$$\chi(e_i|f_j) = \text{argmax}_{0 \leq i \leq |\mathbf{E}|} cos(r(\mathbf{F})_j, r(\mathbf{E})_i) \tag{2}$$

While these methods can be noisy, by only keeping word pairs in their intersection *i.e.* $\chi(\mathbf{E}|\mathbf{F}) \cap \chi(\mathbf{F}|\mathbf{E})$, one can derive the intersection cosine alignment approach which gives us a word-aligned dataset with low coverage but high accuracy.

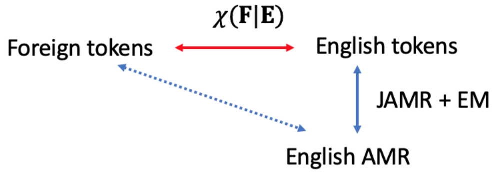

Figure 2: Annotation projection is achieved using JAMR and EM aligners for English text-to-AMR concept alignment and contextual word alignment between tokens of the source (English) and target languages.

As an example, the following are sentences from our German and English training datasets:

E: Establishing models in industrial Innovation
F: Etablierung von Modellen in der industriellen Innovation
Their contextual word alignments are,
$\chi(\mathbf{F}|\mathbf{E})$ = $[(e_0, f_0), (e_1, f_2), (e_2, f_3), (e_3, f_5), (e_4, f_6)]$
$\chi(\mathbf{E}|\mathbf{F})$ = $[(f_0, e_0), (f_1, e_1), (f_2, e_1), (f_3, e_2), (f_4, e_2), (f_5, e_1), (f_6, e_4)]$
$\chi(\mathbf{F}|\mathbf{E}) \cap \chi(\mathbf{E}|\mathbf{F})$
= $[(e_0, f_0), (e_1, f_2), (e_2, f_3), (e_4, f_6)]$

Figure 2 pictorially illustrates our complete annotation projection method using the contextual word alignment $\chi(\mathbf{F}|\mathbf{E})$. English tokens and AMR concepts are aligned using JAMR and EM aligners. The resulting AMR annotation augmented with English word-to-concept alignments is then projected onto the given target language using contextual word embeddings. Henceforth, for brevity we will at times refer to this approach as A.P.

4 Combination approaches

We apply three types of combination techniques to the multilingual AMR parsers, trained by projecting English annotations using contextual word alignments derived from the multilingual contextual word embeddings, each of which improves the parser performance significantly.

4.1 Alignment combination

One such technique is to combine the contextual word alignment based A.P. with the baseline word-to-concept alignment which aligns the target tokens directly to AMR concepts using JAMR and EM aligners. Since the EM aligner is an unsupervised method, it can be directly applied to the target language tokens and English AMR concepts. However, we note that this baseline alignment approach gives incomplete coverage (87% concepts aligned to German, 88% to Italian and 91% to Spanish tokens). Thus, we supplement this by aligning the remaining concepts using the A.P. of Figure 2.

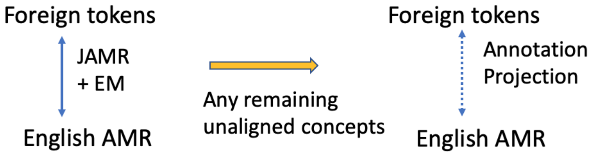

Figure 3: Illustration of the EM, JAMR + A.P. combination alignment: first align target tokens to AMR concepts using JAMR+EM aligners with any remaining concepts then aligned using the annotation projection method proposed in Figure 2.

For example, suppose we have as before two parallel sentences - $\mathbf{E} = e_0, ..., e_M$ in English and $\mathbf{F} = f_0, ..., f_N$ in the target language, as well as AMR concepts $\mathbf{N} = n_0, ..., n_L$. Then one of our proposed foreign text-to-AMR concept combination alignment procedures $EA(f_i|n_j)$ (see Figure 3) is defined as,

$$EA(f_i|n_j) = AP(BA(f_i|n_j)) \tag{3}$$

where $BA(f_i|n_j)$ represents that the j^{th} concept is aligned to the i^{th} token in $\mathbf{F}$ using the baseline aligner BA. If for any concept $n_j \in \mathbf{N}$, $BA(f_i|n_j) =$ None, we use annotation projection to align it where $AP(f_i|n_j)$ is given by,

$$\chi(f_i|e_k) \wedge BA(e_k|n_j) \Rightarrow AP(f_i|n_j) \tag{4}$$

We also experiment with other such alignments, in particular by using the intersection of cosine alignment $(\chi(F|E) \cap \chi(E|F))$ as the contextual word alignment. In this case,

$$EA(f_i|n_j) = \max AP(BA(\mathrm{i}AP(f_i|n_j))) \tag{5}$$

wherein,

$$(\chi(f_i|e_k) \cap \chi(e_k|f_i)) \wedge BA(e_k|n_j) \Rightarrow \mathrm{i}AP(f_i|n_j) \tag{6}$$

As before, $\forall n_j \in \mathbf{N}$ where $\mathrm{i}AP(f_i|n_j) =$ None we align it using the baseline aligner $BA(f_i|n_j)$. For any further remaining unaligned concepts, we employ $\max AP(f_i|n_j)$ which can be described as:

$$\begin{aligned} \max(\chi(f_i|e_k), \chi(e_k|f_i)) \wedge BA(e_k|n_j) \\ \Rightarrow \max AP(f_i|n_j) \end{aligned} \tag{7}$$

That is, we pick the uni-directional contextual word alignment with the higher score and project the AMR annotation accordingly.

4.2 Multilingual treebank combination

In addition to training the parser on the treebank of each language - derived from English treebank via annotation projection - we also experiment with combining all the target language treebanks to create a single multilingual treebank. We notice that pre-training an AMR parser on this multilingual treebank with subsequent finetuning on the treebank of each language, improves performance over the parser trained only on each individual treebank.

4.3 Human and synthetic treebank combination

We create a synthetic AMR corpus by parsing 85k unlabeled sentences from the context portion of SQuAD-2.0. The resulting synthetic AMR graphs are filtered as per the procedure in (Lee et al., 2020) and combined with the AMR-2.0 training set (LDC2017T10), to produce an expanded *AMR-2.0 + SQuAD* training dataset of 94k sentences. We then project annotations of this expanded English treebank onto each of the target languages, and train the corresponding target language parser. We observe that despite the lower quality of the synthetic AMRs as compared to their human-annotated counterparts, their inclusion in the training set significantly improves parser performance.

5 Experimental Results

5.1 AMR Parser and Data

For our experiments, we use the stack-Transformer model (Fernandez Astudillo et al., 2020)[1] as our AMR parser. The stack-Transformer is a transition based parser with a modified Transformer architecture to encode the parser state. It uses a cross entropy loss function and has hyper-parameters similar to those of machine translation described in (Vaswani et al., 2017). We use a beam size of 3 to decode our models and evaluate them using Smatch scores (Cai and Knight, 2013). Model performance values in this manuscript are an average over the best performing models across 3 random seeds. Lastly, the input to the parser - the vector representation of each word - is obtained by averaging over not only all 24 layers of the pre-trained XLM-R large contextual embeddings but also over constituent wordpieces within each word.

For all four languages - German, Spanish, Italian and Chinese - we experiment on AMR1.0 (LDC2015E86). For the first three we also experiment on AMR-2.0 (LDC2017T10). Results from the former are compared to Damonte and Cohen (2018) and from the latter to Blloshmi et al. (2020). Details of our training, dev and test sets are given in Table1.[2] To train each target language parser, we first translate the input sentences of AMR-2.0 and AMR-1.0 with Watson Language Translator.[3] This creates the supervised parallel corpus which we then use for our unsupervised annotation projection via contextual word alignment. We also align target language tokens directly to AMR concepts using JAMR and EM aligners for baseline system evaluation and for combination alignments. We select the best performing models using the devset. Finally, for our best models, we report results using the machine as well as human translations (LDC2020T07) of the test sets.

5.2 Baselines

Our first baseline is zero-shot learning, where we train on the English dataset but test on a foreign language dev-set (Baseline I). The reason behind this experiment is to test the ability of the XLM-R contextual word embeddings to capture the meaning of the given token irrespective of the underlying language. Note that it is only for this experiment that languages for the train and dev sets differ. In another set of experiments we align the target language tokens directly to the AMR concepts only using the JAMR and EM aligners (Baseline II). Lastly, we also test the annotation projection procedure of Damonte and Cohen (2018). Note that while the previous authors use fast align (Dyer et al., 2013) for word alignment between the parallel data and only JAMR aligner for the English text-to-AMR alignment, in Baseline III we have utilized fast align in conjunction with both JAMR and EM aligners (for English text-to-AMR alignment) for improved performance.

5.3 Results

Table 2 compares our different proposed approaches to the three baseline methods using the AMR2.0 and AMR1.0 datasets. We see that our proposed approach - annotation projection with contextual word alignment, in this case using $\chi(\mathbf{F}|\mathbf{E})$ - shows fairly competitive results with

those of Baseline III for the target languages of German, Italian and Spanish, especially when applied to the smaller corpus of AMR1.0. This is remarkable considering our method requires no additional training and can be easily generalized for zero-shot learning on all different languages that XLM-R was pretrained on. We then train several parsers using our suggested combination approaches. The first such method comprises of both the EM, JAMR + A.P aligners (see Eq. 3). In a different approach, we use the intersection cosine word alignment based annotation projection (*i.e* $\chi(\mathbf{F}|\mathbf{E}) \cap \chi(\mathbf{E}|\mathbf{F})$). Since this leaves many AMR concepts unaligned, we follow it by aligning concepts using the baseline JAMR and EM aligners. Any leftover unaligned concepts are then aligned using $\max(\chi(\mathbf{E}|\mathbf{F}), \chi(\mathbf{F}|\mathbf{E}))$ (Eq. 5). In another set of experiments, we pre-train a parser on a multilingual treebank, where the train set is a combination of the LDC treebank in all target languages. The parser is then finetuned on each individual language. We surmise that such an experiment will give us a truly multilingual parser capable of successfully decoding all the target languages. Its strength is evident in its performance, it outperforms all our baseline approaches - in the case of AMR1.0 dev set by at least 1.4 points. Finally, in the last two experiments on AMR2.0 we train on the language-specific LDC + SQuaD train set. We see that this gives us our best performing parsers, where the training data is aligned using a combination (EM, JAMR + A.P) alignment.

We test a subset of the AMR2.0 and all of the AMR1.0 models on corresponding test sets. The results are shown in Tables 3 and 4. For AMR1.0, while all of our models including the baselines outperform previously published results, the best performing model is the parser which was trained on multilingual data and whose training input text was aligned to its AMR concepts using the combination of EM, JAMR and A.P aligners. For AMR2.0, models trained on the LDC + SQuAD dataset outperform those trained on multilingual data. Both of these outperform the recently published work of Blloshmi et al. (2020). [4]

We note that the parser performs better on the machine translated test data than on the human translated data. This should be attributed to the training and testing condition mismatch of the human translated test data since all models are trained on machine translated training data. For instance, the out-of-vocabulary (oov) ratio of the human translated test data is consistently higher than that of the machine translated test data. For example, for AMR1.0 the oov ratio of human translated test data vs. machine translated test data is 10.2% vs. 9% for German, 7.3% vs. 6.8% for Spanish, 8.1% vs. 7.6% for Italian and 7.6% vs. 5.5% for Chinese.

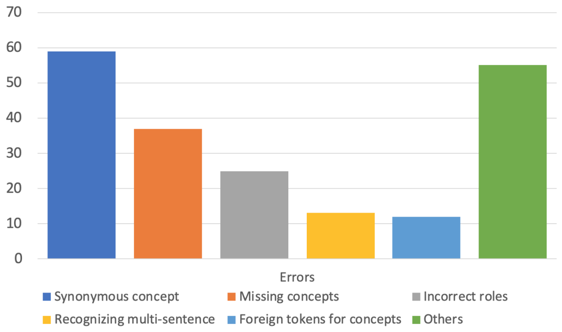

Figure 4: Histogram of different kinds of errors

6 Error analysis

We carried out an error analysis of 56 German sentences parsed by the best performing model trained on the combination of AMR2.0 and SQuAD training data. Statistics of the various errors are depicted in Figure 4. Top 5 most frequent errors include (i) introduction of synonymous concepts, (ii) missing concepts, (iii) incorrect roles, (iv) target tokens in AMR concepts, (v) incorrect parsing of multi-sentence as an instance of conjunction.

6.1 Synonymous concepts

The most common error we encounter is synonymous AMR concepts, as shown in Figure 5. Comparing the expected graph (top) to the parsed version (bottom), we note that concept *previous* is synonymized to *past*. While this error is mainly caused by the fact that the multilingual word embeddings bridge non-English input tokens to English concepts, it also highlights the highly lexical nature of Smatch scoring (Cai and Knight, 2013) which does not take synonymous concepts into consideration. Given that AMR is supposed to represent the core meaning of a sentence regardless of its syntactic and morphological variations, Smatch scoring should be able to capture lexical variations such as synonymous concepts.

---

[4] We did not run experiments with LDC + SQuAD dataset on AMR1.0 since our primary reason for running experiments on AMR1.0 was to more directly be able to compare our results to (Damonte and Cohen, 2018)

      :time (m / moment
            :ARG1-of (c / critical-02)))
```

Figure 6: The gold AMR (top) and the parsed AMR (bottom) for a German sentence illustrating incorrect roles (*:source* is replaced by *:ARG1* in the parsed AMR) and incorrect identification of the target token *Kaisers* as a named entity.

6.2 Missing concepts and incorrect roles

Some concepts are missing in the parsed AMR, such as *stupefy-01* in Figure 5. The parser also incorrectly identifies relations between concepts. In Figure 5, arguments *ARG1* and *ARG2* for concept *wrong-02* are swapped. In Figure 6, the relation *:source* is replaced by frame argument *ARG1*.

6.3 Incorrect parsing of Multi-sentence

Another frequent error includes incorrect parsing of multi-sentence as an instance of conjunction, especially when sentences are demarcated by commas. Note that the multi-sentence errors are not specific to multilingual parsing and occur frequently when parsing English input sentences as well. This multi-sentence error is mostly caused by the ambiguity of commas, which can subsume various semantics depending on the contexts across languages.

6.4 Misrecognition of foreign token as a named entity

Some target tokens may legitimately be realized in the gold AMR, especially when the target tokens are named entities, e.g. *Frankfurt, Anna, Noah, etc*. This often leads to errors in the parsed AMR when a target token is incorrectly recognized as a named entity. In Figure 6, German token *Kaisers* is incorrectly parsed as part of named entities *Yan Kaisers* and *Huang Kaisers*. The failure to capture the correct concept *emperor* for the German token *Kaisers* leads to a subsequent error of not reifying the role to *have-org-role-91*[5], evident in the comparison of the parsed AMR with the gold AMRs.

6.5 Others

Other errors include lack of stemming in the target language, such as *Kaisers* in Figure 6. Stemming errors are mostly caused by the fact that we have not incorporated target language stemmers whereas we have incorporated spacy[6] for English. Some errors are caused by machine translation. English fragmentary input *taking a look* is translated to *Sehen Sie sich*, which is then incorrectly parsed as *imperative* sentence. Nominal target language tokens often fail to invoke predicates. Given the input in English “cultural tyranny in the cloak of nationalism”, *tyranny* invokes the predicate *tyrannize-01*. Its German counterpart *Tyrannei*, however, fails to

	Contextual Alignment	**Fast Align**
German	23.47	20.52
Italian	29.40	29.30
Spanish	28.81	26.69

Table 5: AMR1.0 parser performance on negations in terms of Smatch. Fast align is compared with the proposed contextual alignment for different languages.

invoke the predicate in “kulturellen Tyrannei im Mantel des Nationalismus”.

7 Word alignment error analysis

We compared the annotation projection for AMR1.0 between fast align and the contextual alignment. As noted in Table 3 they perform comparably for German, Italian and Spanish. However, on detailed analysis we notice that annotation projection using contextualized alignments has a greater coverage in terms of foreign text-to-AMR alignments compared to fast align (eg. for German, contextual alignment A.P. gives 99.95% coverage in comparison to 97.47%.). This is likely due to the fact that fast align is based on an IBM alignment model, which relies on expected counts of alignment pairs and uses additional alignment constraints. Contextualized alignment relies on the unrestricted pairing by cosine distance of the XLM-R contextual word embeddings of the input tokens. Given an English token, the contextualized alignment necessarily aligns it to a foreign language word. Furthermore, since embeddings are contextual and pre-trained with large amounts of data, they are robust to non frequent alignment pairs.

The difference between contextualized alignment and fast align for their coverage is most noticeable for compounds. A German counterpart of English non – tariff is *nichttarifäre*. While contextualized alignment aligns *nichttarifäre* to non, which is subsequently aligned to the concept “–” for polarity, fast align leaves *nichttarifäre* unaligned. Such difference is evidenced in the parser performance on negations realized in diverse morphologies. Comparing the AMR1.0 parser performance on negations between fast align (Baseline III in Table 3) and the contextualized alignment (A.P in Table 3), we find that contextualized alignment consistently outperforms fast align across the three European target languages, as shown in Table 5.

8 Conclusion and future directions

In this paper we propose to use transformer-based multilingual word embeddings for *annotation projection* of AMR annotations. We show that our proposed procedure achieves competitive results as some of the classical methods for text-to-AMR alignment. We apply combination techniques to concept alignments and AMR parser training, which significantly improve performance over the base models. We also provide a detailed error analysis of the multilingual AMR parsing.

Given pre-trained transformer-based multilingual word embeddings, contextual word alignment proves to be a useful avenue for overcoming differences amongst languages and addressing the multilingual AMR problem with weak supervision. Moreover, our annotation projection procedure not only achieves a highly competitive performance for German, Spanish, Italian and Chinese but also permits zero-shot learning to other languages included in the training set of the underlying XLM-R multilingual transformer.

Future work may include diversifying input texts using AMR2text (Mager et al., 2020) generation which can address the difference in results between machine translated and human translated test data. The potential of the AMR parser to overcome translation divergence also points to its utility in an end-to-end multilingual translation system, bypassing the need for supervised parallel corpora for machine translation system training.

Semantic Oppositeness Assisted Deep Contextual Modeling for Automatic Rumor Detection in Social Networks

Nisansa de Silva, Dejing Dou
Department of Computer and Information Science,
University of Oregon,
Eugene, USA.
{nisansa,dou}@cs.uoregon.edu

Abstract

Social networks face a major challenge in the form of rumors and fake news, due to their intrinsic nature of connecting users to millions of others, and of giving any individual the power to post anything. Given the rapid, widespread dissemination of information in social networks, manually detecting suspicious news is sub-optimal. Thus, research on automatic rumor detection has become a necessity. Previous works in the domain have utilized the reply relations between posts, as well as the semantic similarity between the main post and its context, consisting of replies, in order to obtain state-of-the-art performance. In this work, we demonstrate that semantic oppositeness can improve the performance on the task of rumor detection. We show that semantic oppositeness captures elements of discord, which are not properly covered by previous efforts, which only utilize semantic similarity or reply structure. Our proposed model learns both explicit and implicit relations between the main tweet and its replies, by utilizing both semantic similarity and semantic oppositeness. Both of these employ the self-attention mechanism in neural text modeling, with semantic oppositeness utilizing word-level self-attention, and with semantic similarity utilizing post-level self-attention. We show, with extensive experiments on recent data sets for this problem, that our proposed model achieves state-of-the-art performance. Further, we show that our model is more resistant to the variances in performance introduced by randomness.

1 Introduction

Social media changed the ecosystem of the World Wide Web by making it possible for any individual, regardless of their level of knowledge of web technologies, to create and maintain *profiles* online. At the same time, various social media provided these individuals with means to tap into the information disseminated by others (e.g., Facebook by *adding friends*, Twitter by *following*). By virtue of other mechanisms, such as *Facebook pages* and *Twitter lists*, the reach of each individual was then extended to the range of thousands-to-millions of users. New content, in the form of *posts*, is created on social media sites each passing second.

The rapidity of this post creation is such, that it is possible to claim that social media reflect a near real-time view of the events in the real world (Veyseh et al., 2019). While it was, indeed, beneficial in terms of *volume* of data, to have private individuals be content creators and propagators of information, this created significant issues, from the perspective of *veracity* of the data. This gave rise to a challenge of detecting *fake news* and *rumors* (which, in this study, we refer to as the task of *rumor detection*). The need for rumor detection has come to the forefront, in light of its momentous impacts on political events (Jin et al., 2017) and social (Jin et al., 2014) or economic (Domm, 2013) trends.

Manual intervention on this task would require extensive analysis of and reasoning about various sources of information, resulting in long response times, which are intolerable, given the impact of these rumors, and the rate at which they spread. Thus, *automatic rumor detection*, toward which we contribute in this paper, has become an important area of contemporary research. Cao et al. (2018) define any piece of information, of which the veracity status was questionable at the time of posting, as a rumor. They further claim that a rumor may later be verified to be true or false by other authorized sources. We follow their definition in this work; thus, we define the task of rumor detection as: Given a piece of information from a social network, predict whether the piece of information is a rumor or not using the conversations which were induced by the said piece of information. The initial piece of information could be a tweet or a user

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 405–415
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

post, and the induced conversation would be the replies from other users (which we use as contextual information). Following the conventions in the literature, in this work, we refer to a main post and its replies as a *thread*.

In this paper, we utilize the semantic oppositeness proposed by (de Silva and Dou, 2019) to improve the rumor detection task, which has so far been restricted to only considering semantic similarity. We further prove that semantic oppositeness is well-suited to be applied to this domain, under the observation that rumor threads are more discordant than those of non-rumors. We further observe that, within rumor threads, false rumor threads continue to be clamorous; while true rumor threads settle into inevitable acquiescence. We claim that semantic oppositeness can help in distinguishing this behavior as well.

We propose word-level self-attention mechanism for the semantic oppositeness to augment the tweet level self-attention mechanism for the semantic similarity. We model the explicit and implicit connections within a thread, using a relevancy matrix. Unlike a regular adjacency matrix, our relevancy matrix recognizes the coherence of each sub-tree of conversation rooted at the main post, while acknowledging that, by definition, for this task, the main tweet must be directly related all the rest of the tweets, regardless of the degrees of separation that may exist between them. We conduct extensive experiments to compare our proposed model with the state-of-the-art studies conducted on the same topic. To the best of our knowledge, this work is the first to utilize semantic oppositeness in rumor detection. In summary, our contributions in this paper include:

- We introduce a novel method for rumor detection, based on both semantic similarity and semantic oppositeness, utilizing the main post and the contextual replies.
- We model the explicit and implicit connections within a thread, using a relevancy matrix, which is then used to balance the impact semantic similarity and semantic oppositeness have on the overall prediction.
- We conduct experiments on recent rumor detection data sets and compare with numerous state-of-the-art baseline models to show that we achieve superior performance.

The remainder of this paper is organized as follows: Section 2 presents related work, and then Section 3 provides a formal definition of the problem, along with our proposed solution. It is followed by Section 4 discussing experiments and results. Finally the Section 5 concludes the paper.

2 Related Work

Semantic oppositeness is the mathematical counterpart of semantic similarity (de Silva and Dou, 2019). While implementations of semantic similarity (Jiang and Conrath, 1997; Wu and Palmer, 1994) are more widely used than those of semantic oppositeness, there are a number of studies which work on deriving or using semantic oppositeness (de Silva et al., 2017; Paradis et al., 1982; Mettinger, 1994; Schimmack, 2001; Rothman and Parker, 2009; de Silva, 2020). However, it is noted that almost all of these studies are reducing oppositeness from a scale to either bipolar scales (Schimmack, 2001) or simple anonymity (Paradis et al., 1982; Jones et al., 2012). The study by de Silva et al. (2017) proves that this reduction is incorrect and proposes an alternative oppositeness function. Their follow-up study, de Silva and Dou (2019) creates a word embedding model for this function. In this study, we use the oppositeness embeddings created by them.

Rumor detection task has been approached on three fronts, according to Cao et al. (2018): feature engineering, propagation-based, and deep learning. In the *feature engineering* approach, posts are transformed into feature representations by hand-designed features and sent to a statistical model to be classified. In addition to textual information, structural evidences (Castillo et al., 2011; Yang et al., 2012) and media content (Gupta et al., 2012) are also utilized. Given that this approach depends heavily on the quality of the hand-designed feature sets, it is neither scalable, nor transferable to other domains. The *propagation-based* approach is built on the assumption that the propagation pattern of a rumor is significantly different to that of a non-rumor. It has been deployed to detect rumors in social networks (Ma et al., 2017). However, this method does not pay any heed to the information in the post content itself. As expected, *deep learning* approach, automatically learns effective features (Ma et al., 2016, 2018; Veyseh et al., 2019). Ma et al. (2016) claim that these discovered features capture the underlying representations of the posts, and hence, improve the generalization performance, while making it easy to be adapted into a new domain or a social medium for the purpose of rumor detection.Yang et al. (2020) propose a slide window-based system for feature extraction. None of these state-of-the-art work attempt to check rumour veracity akin to attempts by Hamidian and Diab (2019a) and Derczynski et al. (2017). Instead, they attempt to do classification on the already established baseline. Thus, our work also follow the approach of the former rather than the latter. The work by Hamidian and Diab (2019b) does focus on rumor detection and classification. However, they are not using the data sets common to the state-of-the-art work mentioned above to evaluate their approach.

Our work is most related to the rumor detection model on Twitter by means of deep learning to capture contextual information (Veyseh et al., 2019). However, we also derive inspiration from earlier work on the same topic (Ma et al., 2018), which utilized the tree-like structures of the posts, and the work by de Silva and Dou (2019), which introduced the oppositeness embedding model. The early work by Ma et al. (2018) uses Recursive Neural Networks (RvNN) for the construction of the aforementioned tree-like structures of the posts, based on their *tf-idf* representations.

The following work by Veyseh et al. (2019) acknowledges the usefulness of considering the innate similarities between replies, but further claims that only considering the replies along the tree-like structure only exploits the explicit relations between the main posts and their replies, and thus ignores the implicit relations among the posts from different branches based on their semantics. Under this claim, they disregard the tree-like structure entirely. In our work, we preserve the idea of considering semantic similarities to discover the implicit relationships among posts, as proposed by (Veyseh et al., 2019).

However, we augment the model and reintroduce the explicit relationships proposed by Ma et al. (2018) in a balancing of information between implicit and explicit. Further, we note that all these prior works have been solely focused on the similarity between the posts and have ignored the oppositeness metric. To the best of our knowledge, we are the first to utilize oppositeness information in the rumor detection task.

3 Methodology

We use a recent work (Veyseh et al., 2019) on rumor detection as our baseline. Their work, in turn, was heavily influenced by the earlier work on rumor detection in Twitter (Ma et al., 2018). A tweet set I is defined as shown in Equation 1, where R_0 is the initial tweet and $R_1, R_2, \ldots, R_T$ are replies, such that T is the count of replies. Each tweet R_i is a sequence of words $W_1, W_2, ..., W_n$, such that n is the count of words. We tokenize the tweets; and in this work, *tokens* and *words* are used interchangeably. We also define the relevance matrix M, which carries the information of the tree structure of the tweet tree in Equation 2, where $A \star B$ denotes that A and B belong to the same tree in the forest obtained by eliminating the initial tweet. We show the process in Fig 1 as well. Our input is the pair $P = (I, M)$, which differs from (Veyseh et al., 2019), where only I was used as the input. The entire data set is represented by D.

Following the convention of (Veyseh et al., 2019) which is our baseline, we classify each pair (I, M) into four labels: 1) Not a rumor (NR); 2) False Rumor (FR); 3) True Rumor (TR); and 4) Unrecognizable (UR), It should be noted that the distinction between "*False Rumor*" and "*True Rumor*" is drawn from the truthfulness of R_0.

$$I = (R_0, R_1, R_2, \ldots, R_T) \tag{1}$$

$$m_{i,j} = \begin{cases} 1 & \text{if } R_i = R_0 \vee R_j = R_0 \\ 1 & \text{if } R_i \star R_j \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

In simpler terms, we can represent Veyseh et al. (2019) as a trivial *relevance matrix* where all elements are set at 1. The success of Veyseh et al. (2019) over previous state-of-the-art methods attest to the success of using a *relevance matrix* over vanilla *adjacency matrix*. In this work what we do with the above described *relevance matrix* M is to augment the implicit relationship consideration using the high level structure of the explicit relationships, hence bringing in the best-of-both-worlds. In summary, the set of edges in the *relevancy matrix* is a super-set of the set of edges in the *adjacency matrix*. In addition to the edges that were in the *adjacency matrix*, the *relevancy matrix* also has edges that carry implicit connection information. Thus, by definition, the *relevancy matrix* is more

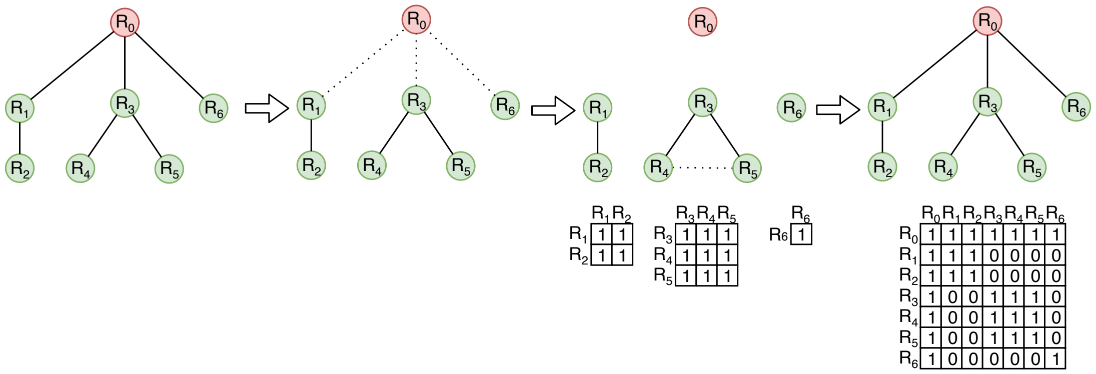

Figure 1: **Relevance matrix building:** 1) Original tweet reply tree; 2) Obtain the forest by temporarily removing the root (main tweet); 3) Consider each tree in the forest to be fully connected graphs, and obtain the relevance matrices; 4) Obtain the full Relevance matrix by putting together the matrices from the previous step and considering the main tweet to be connected to all the other tweets.

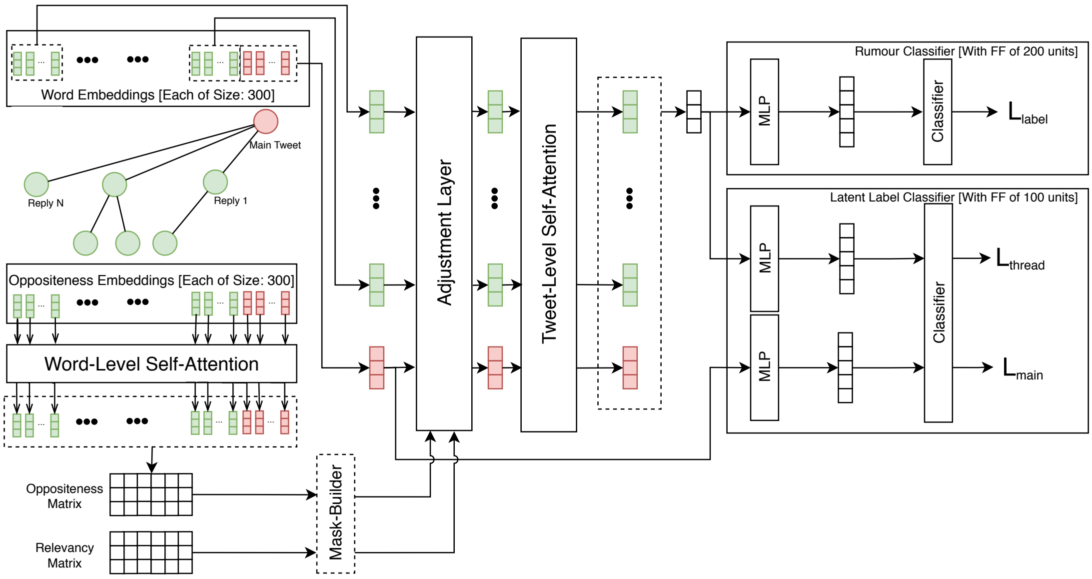

Figure 2: **The Proposed Model:** Red vectors and node represent the main (root) tweet, and green vectors and nodes represent replies. Pooling operations are shown in boxes with dashed lines.

descriptive of the thread compared to the *adjacency matrix*.

3.1 Formal Definition of Tweet Representation

Each tweet will have different number of words n; thus, we pad the short tweets with a special token, until all the tweets have the same word length N as defined by 3.

$$N = \underset{P_i \in D}{\operatorname{argmax}}(n_i) \tag{3}$$

We build the representative oppositeness list O using the oppositeness embeddings created by (de Silva and Dou, 2019) such that, for the i-th tweet R_i, with words $W_{i1}, W_{i2}, ..., W_{iN}$, the oppositeness embedding O_i is created as $o_{i1}, o_{i2}, ..., o_{im}$ where o_{ij} is the embedding of W_{ij}. Note that $m \leq N$ where all tokens might not have corresponding oppositeness embeddings.

Each word in each tweet is then converted to a representative vector by means of a set of pretrained word embeddings, such that for the i-th tweet R_i, with words $W_{i1}, W_{i2}, ..., W_{iN}$ is converted $e_{i1}, e_{i2}, ..., e_{iN}$. We then apply max-pooling operation over the word embeddings along each dimension, resulting in a representative vector h_i coupled to R_i, as shown in Equation 4. At this point, note that the tweet set I of each pair P, which used to be $I = (R_0, R_1, R_2, \dots, R_T)$, has been replaced by $I = (h_0, h_1, h_2, \dots, h_T)$. It is this new representation which is passed to the following steps.

$$h_i = Elementwise\_Max(e_{i1}, e_{i2}, ..., e_{iN}) \quad (4)$$

3.2 Similarity-Based Contextualization

As discussed earlier, the Twitter data is organized as a tree rooted at the main tweet R_0 in each instance. The earlier work by Ma et al. (2018) proved that, in rumor detection, it is helpful to capture these relations among the main tweet and the replies. The subsequent work by Veyseh et al. (2019) noted that only considering explicit reply relation between the main tweet and other tweets neglects the implicit relations among the tweets, arising from their semantic similarities (i.e., by the virtue of discussing the same topic, tweets in two separate branches may carry mutually useful information). Following this hypothesis, they exploited such implicit semantic relations for the purpose of improving the performance of the rumor detection task. However, in doing so, they abandoned the information garnered from the tree structure. In this work we propose to continue to use the implicit information, but to augment it with the information derived from the tree structure.

We follow the self-attention mechanism of (Veyseh et al., 2019), which was inspired by the transformer architecture in (Vaswani et al., 2017), to learn the pairwise similarities among tweets for capturing the semantic relations between the tweets. The process starts with calculating the key (k_i) and query (q_i) vectors for each tweet, based on its representation h_i, as shown in Equation 5. (W and b follow the traditional notation of weights and bias).

$$k_i = W_k * h_i + b_k \qquad q_i = W_q * h_i + b_q \quad (5)$$

With the key and query vectors, we calculate the similarity a_{ij} between i-th and j-th tweets, using the dot product as shown in Equation 6, where γ is a normalization factor.

$$a_{i,j} = k_i \cdot q_j / \gamma \quad (6)$$

3.3 Oppositeness-Based Contextualization

Unlike in the case of similarity vectors, which were reduced to a single dimension at this point, the oppositeness representations are still at two dimensions. Thus the self-attention of oppositeness between tweets is handled at a word level, rather than at the sentence level. We build key ($k_i^{'}$) and query ($q_i^{'}$) vectors for each word based on its representation o_i, as shown in Equation 7. (W and b follow the traditional notation of weights and bias).

$$k_i^{'} = W_k * o_i + b_k \qquad q_i^{'} = W_q * o_i + b_q \quad (7)$$

Since the oppositeness embedding of (de Silva and Dou, 2019) is based on Euclidean distance, with the key and query vectors, we calculate the oppositeness op_{i_x,j_y} between x-th word of i-th tweet and y-th word of j-th tweet using the Euclidean distance, as shown in Equation 8 where $k_{i_x}^{'}$ is the key vector for x-th word of i-th tweet, $q_{j_y}^{'}$ is the query vector for y-th word of j-th tweet, and Euclidean distance $d(,)$ is calculated across the size of the oppositeness embedding.

$$op_{i_x,j_y} = d(k_{i_x}^{'}, q_{j_y}^{'}) \quad (8)$$

To obtain the abstract tweet-level oppositeness, we apply element-wise average-pooling on the $OP_{i,j}$ matrix, as shown in Equation 9, to create the oppositeness matrix $O^{''}$, where EA is $Elementwise\_Average$ operation, δ is the oppositeness embedding count of the i-th tweet, and ϱ is the oppositeness embedding count of the j-th tweet. Note that the dimensions of the oppositeness matrix $O^{''}$ is the same as the relevance matrix M.

$$o_{i,j}^{''} = EA\left(\begin{bmatrix} op_{i_0,j_0} & op_{i_1,j_0} & \cdots & op_{i_\delta,j_0} \\ op_{i_0,j_1} & op_{i_1,j_1} & \cdots & op_{i_\delta,j_1} \\ \cdots & \cdots & \cdots & \cdots \\ op_{i_0,j_\varrho} & op_{i_1,j_\varrho} & \cdots & op_{i_\delta,j_\varrho} \end{bmatrix}\right) \quad (9)$$

Next we create the oppositeness mask Ω by average-pooling $O^{''}$ along rows and columns, as shown in Equation 10, where the definition of EA, is the same as Equation 9 and similar to Equation 3, n_i and n_j are natural lengths of the i-th and j-th tweets respectively.

$$\begin{aligned} \omega_{i,j} = 1 &- EA(o_{i,0}^{''}, o_{i,1}^{''}, ..., o_{i,n_j}^{''}) \\ &- EA(o_{0,j}^{''}, o_{1,j}^{''}, ..., o_{n_i,j}^{''}) \end{aligned} \quad (10)$$

3.4 Deriving Overall Thread Representations

Similar to the oppositeness mask Ω, we create the relevance mask Ψ by sum-pooling M along rows and columns, as shown in Equation 11, where ES, is $Elementwise\_Sum$ operation, and similar to

Equation 3, n_i and n_j are natural lengths of the i-th and j-th tweets respectively.

$$\begin{aligned}\psi_{i,j} &= ES(m_{i,0}, m_{i,1}, ..., m_{i,n_j}) \\ &+ES(m_{0,j}, m_{1,j}, ..., m_{n_i,j})\end{aligned} \tag{11}$$

At this point we diverge from (Veyseh et al., 2019) in two ways and utilize the related relevance mask M as a weighting mechanism, with proportion constant α (where $0 < \alpha < 1$), as well as the oppositeness mask Ω, to obtain augmented attention $a'_{i,j}$ as shown in Equation 12.

$$a'_{i,j} = a_{i,j}\omega_{i,j}\Big[(\psi_{i,j} - \alpha)^2 + \alpha\psi_{i,j}\Big] \tag{12}$$

We utilize the augmented similarity values $a'_{i,j}$ for each tweet pair in the thread to compute abstract representations for the tweets based on the weighted sums, as shown in Equation 13.

$$h'_i = \Sigma_j a'_{i,j} * h_j \tag{13}$$

Next, we apply the max-pooling operation over the processed tweet representation vectors h'_i to obtain the overall representation vector h' for the input pair P.

$$h' = Elementwise\_Max(h'_0, h'_1, h'_2, ..., h'_T) \tag{14}$$

Finally, the result is sent through a 2-layer feed-forward neural network capped with a softmax layer, with the objective of producing the probability distribution $P(y|R_0, R_1, R_2, \ldots, R_T; \theta)$ over the four possible labels, where θ is the model parameter. On this, we optimize the negative log-likelihood function, in order to train the model, as shown in Equation 15, where y^* is the expected (correct) label for I.

$$L_{label} = -\log P(y^*|R_0, R_1, R_2, \ldots, R_T; \theta) \tag{15}$$

3.5 Main Tweet Information Preservation

The Veyseh et al. (2019) study noted that the model by Ma et al. (2018) treats all tweets equally. This was deemed undesirable, given that the main tweet of each thread incites the conversation, and thus, arguably, carries the most important content in the conversation, which should be emphasized, to produce good performance. To achieve this end, it was proposed to bring forward the information in the main tweet independently of and separately from that of the collective twitter thread, in order to provide a check. We, in this work, also provide this sanctity check, to enhance the obtained results.

The basic idea is that, by virtue of definition, if a main tweet is a rumor (or not), unique trait and information pertaining to that class should be in the main tweet itself. Thus, the latent label (L_{thread}) obtained by processing the thread representation h' above should be the same as a potential latent label (L_{main}) obtained by processing the representation of the main tweet h_0. To calculate L_{main}, we use a 2-layer feed-forward neural network with a softmax layer in the end, where it assigns the latent labels drawn from K possible latent labels. Next, we use another 2-layer feed-forward neural network with a softmax layer in the end, assigning the same K number of possible latent labels as shown in the negative log-likelihood function to match it with the thread.

$$L_{main} = argmax_L P(L|R_0) \tag{16}$$

$$L_{thread} = -\log P'(L_{main}|R_0, \ldots, R_T) \tag{17}$$

Finally, the loss function to train the entire model is defined as in Equation 18, where the L_{label} is obtained from Equation 15, and β is a hyper-parameter which controls the contribution of the main tweet information preservation loss to final loss.

$$Loss = L_{label} + \beta L_{thread} \tag{18}$$

4 Experiments

We use the *Twitter 15* and *Twitter 16* data sets introduced by Ma et al. (2017) for the task of rumor detection. Some statistics of the data sets as given by Ma et al. (2017) are shown in Table 1. We use Glove (Pennington et al., 2014) embedding to initialize the word vectors and oppositeness embedding (de Silva and Dou, 2019) to initialize the oppositeness embeddings. Both embedding vectors are of size 300. Key and query vectors in Equations 5 and Equations 7 employ 300 hidden units. The rumor classifier feed-forward network has two layers of 200 hidden units. The feed-forward layer in the main tweet information preservation component has two layers, each with 100 hidden units, and it maps to three latent labels. The proportion constant α, which balances the explicit and implicit information, is set at 0.1. The loss function uses a trade-off parameter of $\beta = 1$, with an initial learning rate of 0.3 on the *Adagrad* optimizer. For the purpose of fair results comparison, we follow the convention of using 5-fold cross validation procedure to tune the parameters (such as node and layer counts) set by Ma et al. (2018).

Statistic	Twitter15	Twitter16

Max Num. of Posts/Tree	1,768	2,765
Min Num. of Posts/Tree	55	81

Table 1: Statistics of the Data Sets.

4.1 Comparison to the State-of-the-Art Models

We compare the proposed model against the state-of-the-art models on the same data sets. The performance is compared by means of overall accuracy and F1 score per class. We observe that there are two types of models against which we compare. The first type are the *feature-based models*, which used feature engineering to extract features for Decision Trees (Zhao et al., 2015; Castillo et al., 2011), Random Forest (Kwon et al., 2013), and SVM (Ma et al., 2015; Wu et al., 2015; Ma et al., 2017). The second type of models are *deep learning models*, which used Recurrent Neural Networks or Recursive Neural Networks to learn features for rumor detection. We compare our model to GRU-RNN proposed by Ma et al. (2016), BU-RvNN and TD-RvNN proposed by Ma et al. (2018), and Semantic Graph proposed by Veyseh et al. (2019). Results for Twitter 15 and Twitter 16 are shown in Tables 2 and 3, respectively.

It is evident from these tables that, in the rumor detection task, the deep learning models outperform feature-based models, proving that automatically learning effective features from data is superior to hand-crafting features. We also note that the *Semantic Oppositeness Graph*, along with the Semantic Graph, and other RvNN models with GRU-RNN, generally do well, which attests to the utility of structural information, be it in the form of reply structure or be it in the form of semantic relations, in helping to improve performance. We further notice that Veyseh et al. (2019) which uses implicit information, outperforms TD-RvNN (Ma et al., 2018), which only uses explicit information. *Semantic Oppositeness Graph*, which uses explicit information, implicit information, and semantic oppositeness outperforms all the other models in accuracy, while outperforming all the other models in three out of four classes, in terms of F1 Score. The one class in which *Semantic Oppositeness Graph* loses out to Veyseh et al. (2019) is in the case of the *Unrecognizable* (UR) class. We argue that this is not an issue, given that the unrecognizable class consists of tweets which were too ambiguous for human annotators to tag as one of: not a rumor (NR), false rumor (FR), or true rumor (TR). We assert that Tables 2 and 3 clearly demonstrate the effectiveness of the proposed *Semantic Oppositeness Graph* method in the task of rumor detection.

4.2 Model Stability Analysis

While comparing our system with Veyseh et al. (2019), which we use as our main baseline, we noticed that their system has a high variance in results, depending on the random weight initialization. This was impactful in such a way that in some random weight initializations, the accuracy of their system could fall as low as 24% from the reported high 70% results in their paper. Given that we use their system as our baseline and the basis for our model, we decided to do a stability analysis between their system and ours. For this purpose, we created 100 random seeds and trained four models with each seed, resulting in a total of 400 models. The models were: 1) Veyseh et al. (2019) on *twitter 15*, 2) Veyseh et al. (2019) on *twitter 16*, 3) *Semantic Oppositeness Graph* on *twitter 15*, 4) *Semantic Oppositeness Graph* on *twitter 16*. Then we normalized the results of the Veyseh et al. (2019) models to the values reported in their paper (also shown in the relevant row on Tables 2 and 3). Each result is reported in the format of (μ, σ) for the 5 fold cross-validation to explore how random weight initialization affects the two models.

From the results in Tables 4 and 5, it is evident that our *Semantic Oppositeness Graph* has higher mean values for accuracy, not a rumor (NR), false rumor (FR), and true rumor (TR), while having comparably reasonable values for Unrecognizable (UR) class. But more interesting are the standard

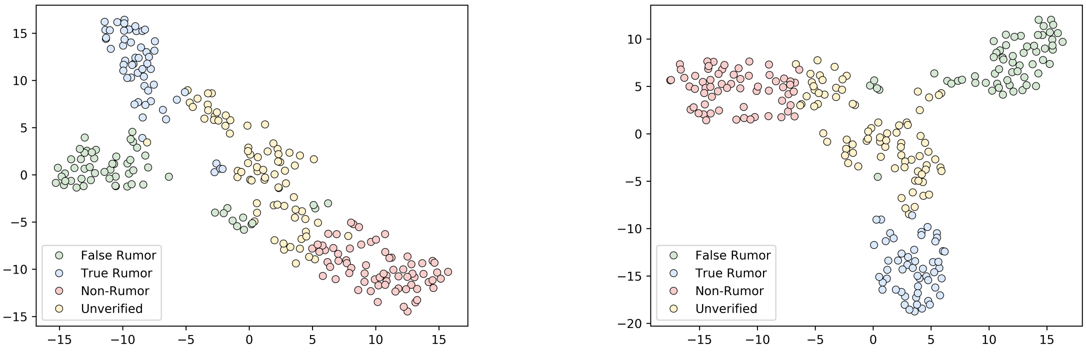
deviation values. It is evident that in all cases, our model has smaller standard deviation values than that of Veyseh et al. (2019). This is proof that our system is comparatively more stable in the face of random weight initialization. We argue that this stability comes from the introduction of the oppositeness component, which augments the decision-making process with the oppositeness information, as a counterpart for the already existing similarity information, preventing the predictions from having a swinging bias.

For a demonstration, consider the subset of three words *increase*, *decrease*, and *expand* from the example given by de Silva and Dou (2019). If the main tweet (R_0) were to say "*A will increase B*", R_1 replied with "*A will decrease B*", and R_2 replied



(a) Without the Oppositeness Component

(b) With the Oppositeness Component

Figure 3: t-SNE diagrams for thread representations.

with "*A will expand B*", then the purely semantic similarity based model will position R_0 and R_1 closer than R_0 and R_2, given that the word contexts in which *increase* and *decrease* are found are more similar than the word contexts in which *increase* and *expand* are found. This would result in the neural network having to learn the opposite semantics between *increase* and *expand* by itself, during the training, making it more vulnerable to issues of bad initial weight selection. This, in turn, will result in greater variance among the trained models as is the case of Veyseh et al. (2019). However, a system with an oppositeness component will already have the opposite semantics between *increase* and *decrease*, as well as *increase* and *expand* already calculated. Thus, such a system would have pre-knowledge that the word pair *increase* and *decrease*, despite being used in more common contexts, is more semantically opposite than the word pair *increase* and *expand*, which is used in less common contexts. Hence the neural network does not have to learn that information from scratch during the training, resulting in it being less vulnerable to issues of bad initial weight selection. Analogously, this, in turn, will result in lesser variance among the trained models; hence, explaining the better stability demonstrated by *Semantic Oppositeness Graph* in comparison to Veyseh et al. (2019) in Tables 4 and 5.

4.3 Impact of the Oppositeness Component

Finally, to emphasize the effect the oppositeness component has on the model, we draw the t-SNE diagrams for the final representations of the threads. Figure 3a shows the data points clustering when the model is trained without the oppositeness component, and Fig. 3b shows the data points clustering when the model is trained with the oppositeness component. Note that all other variables, including the seed for the weight initializer, are the same in the two models. These diagrams prove that the oppositeness component helps improve the separability of the classes. Specially note how the *False Rumor* and *True Rumor* classes are now more clearly separated. We postulate that this derives from the fact that the oppositeness component would help in distinguishing the continuous discord happening in a *False Rumor* thread from the subsequent general agreement in a *True Rumor* thread.

5 Conclusion

Rumors and fake news are a significant problem in social networks, due to their intrinsic nature of connecting users to millions of others and giving any individual the power to post anything. We introduced a novel method for rumor detection, based on semantic oppositeness, in this paper. We demonstrated the effectiveness of our method using data sets from Twitter. Compared to previous work, which only used explicit structures in the reply relations or semantic similarity, our model learns both explicit and implicit relations between a main tweet and its replies, by utilizing both semantic similarity and semantic oppositeness. We proved, with extensive experiments, that our proposed model achieves state-of-the-art performance, while being more resistant to the variances in performance introduced by randomness.

Abstract

Learning disentangled representations of real-world data is a challenging open problem. Most previous methods have focused on either supervised approaches which use attribute labels or unsupervised approaches that manipulate the factorization in the latent space of models such as the variational autoencoder (VAE) by training with task-specific losses. In this work, we propose polarized-VAE, an approach that disentangles select attributes in the latent space based on proximity measures reflecting the similarity between data points with respect to these attributes. We apply our method to disentangle the semantics and syntax of sentences and carry out transfer experiments. Polarized-VAE outperforms the VAE baseline and is competitive with state-of-the-art approaches, while being more a general framework that is applicable to other attribute disentanglement tasks.

1 Introduction

Learning representations of real-world data using deep neural networks has accelerated research within a number of fields including computer vision and natural language processing (Zhang et al., 2018). Previous work has advocated for the importance of learning *disentangled representations* (Bengio et al., 2013; Tschannen et al., 2018). Although attempts have been made to formally define disentangled representations (Higgins et al., 2018), there is no widely accepted definition of disentanglement. However, the general consensus is that a disentangled representation should separate the distinct factors of variation that explain the data (Bengio et al., 2013). Intuitively, a greater level of interpretability can be achieved when independent latent units are used to encode different attributes of the data (Burgess et al., 2018).

However, recovering and separating all the distinct factors of variation in the data is a challenging problem. For real-world datasets, there may not be a way to separate each factor of variation into a single dimension in the learnt fixed-size vector representation. An easier problem would be to separate complex factors of interest into distinct subspaces of the learnt representation. For instance, a representation for text could be separated into *content* and *style* subspaces, which then enables style transfer.

Unsupervised disentanglement of underlying factors using variational autoencoders (Kingma and Welling, 2014) has been explored in previous work (Higgins et al., 2017; Kim and Mnih, 2018). However, Locatello et al. (2019) argue that completely unsupervised disentanglement of the underlying factors may be impossible without supervision or inductive biases. Disentangling textual attributes in a completely unsupervised manner has been shown to be especially difficult, but attempts have been made to leverage it for controllable text generation (Xu et al., 2020).

In this work, we propose an approach referred to as polarized-VAE[1] to disentangle the latent space into subspaces corresponding to different factors of variation. We control the relative location of representations in a particular latent subspace based on the similarity of their respective input data points according to a defined criterion (that corresponds to an attribute in the input space, e.g., syntax). This encourages similar points to be grouped together and dissimilar points to be farther away from each other in that subspace. Figuratively, we *polarize* the latent subspaces, and hence the name.

Most previous work on supervised disentanglement for text has focused on adversarial training (John et al., 2019; Yang et al., 2018). Recently, the task of disentangling textual semantics and syntax into distinct subspaces has received attention

---

from researchers. For instance, Chen et al. (2019b) use a sentence VAE model with several multitask losses such as paraphrase loss and word position loss for this disentanglement task. Bao et al. (2019) incorporate adversarial training and make use of syntax trees along with specific multitask losses to disentangle semantics and syntax.

In polarized-VAE, we achieve disentanglement through distance based learning. In contrast to previous approaches, our method does not require the use of several multitask losses or adversarial training, both of which can result in optimization challenges. Furthermore, we do not need precise attribute labels, and we show that using proxy labels based on the concept of similarity is sufficient.

In summary, the main contributions of this paper are three-fold: (1) We propose a general framework for learning disentangled representations. Even though we test our method on an NLP task, the underlying concept is very general and can be applied to other domains such as computer vision; (2) We provide a method for disentanglement that does not rely on adversarial training or specialized multitask losses; (3) We demonstrate an application of our method by disentangling the latent space into subspaces corresponding to syntax and semantics. Such a setting can be used to perform controlled text decoding such as generating a paraphrase with a desired sentence structure.

2 Proposed Approach

In VAEs, a probabilistic encoder $q_\phi(\boldsymbol{z}|\boldsymbol{x})$ is used to encode a sentence $\boldsymbol{x}$ into a latent variable $\boldsymbol{z}$, and a probabilistic decoder $p_\theta(\boldsymbol{x}|\boldsymbol{z})$ attempts to reconstruct the original sentence $\boldsymbol{x}$ from its latent representation $\boldsymbol{z}$. The objective is to minimize the following loss function:

$$\mathcal{L}_{\text{vae}} = \mathcal{L}_{\text{rec}} + \lambda_{\text{kl}}\mathcal{L}_{\text{kl}} \tag{1}$$

where $\mathcal{L}_{\text{rec}} = -\mathbb{E}_{q_\phi(\boldsymbol{z}|\boldsymbol{x})}[\log p_\theta(\boldsymbol{x}|\boldsymbol{z})]$ is the sentence reconstruction loss and $\mathcal{L}_{\text{kl}} = \mathcal{D}_{\text{kl}}(q_\phi(\boldsymbol{z}|\boldsymbol{x})||p(\boldsymbol{z}))$ is the Kullback-Leibler (KL) divergence loss. The KL term ensures that the approximate posterior $q_\phi(\boldsymbol{z}|\boldsymbol{x})$ is close to the prior $p(\boldsymbol{z})$, which is typically assumed to be the standard normal $\mathcal{N}(\mathbf{0}, \mathbf{I})$; λ_{kl} is a hyperparameter that controls the extent of KL regularization.

The idea behind our polarized-VAE approach is to impose additional proximity regularization on the latent subspaces learnt by VAEs. Let $C = \{c_1, ..., c_k\}$ be the collection of criteria, based on which we wish to disentangle the latent space $\boldsymbol{z}$ of the VAE into k subspaces: $\boldsymbol{z} = [\boldsymbol{z}^{(1)}, \ldots, \boldsymbol{z}^{(k)}]$. Here $\boldsymbol{z}^{(i)}$ denotes the latent subspace corresponding to the criterion c_i (see Figure 1). In this paper, we focus on the case where the latent space is disentangled into semantics (c_1) and syntax (c_2), i.e., $k = 2$.

2.1 Supervision based on Similarity

We assume that we have information (possibly noisy) about pairwise similarities of the input sentences. Given a pair of sentences, the similarity information can be either a binary label (whether both the sentences belong to the same class or not) or an integer or continuous scalar variable (e.g., edit distance). In this work, the similarity criterion is a binary label:

$$\text{Sim}(\boldsymbol{x}_i, \boldsymbol{x}_j|c) = \begin{cases} 1, & \text{if } \boldsymbol{x}_i \text{ and } \boldsymbol{x}_j \text{ are similar} \\ & \quad \text{w.r.t. the criterion } c \in C \\ 0, & \text{otherwise} \end{cases} \tag{2}$$

In our case, the two criteria for disentanglement are semantics (c_1) and syntax (c_2). We use this additional information to regularize the latent space of the VAE by incorporating the proximity based loss functions, denoted as $D(\boldsymbol{z}_i^{(1)}, \boldsymbol{z}_j^{(1)}|c_1)$ and $D(\boldsymbol{z}_i^{(2)}, \boldsymbol{z}_j^{(2)}|c_2)$.

2.2 Training Method and Proximity Function

Extending the traditional VAE approach, we have a set of RNN-based encoders parameterized by ϕ_c that learn the approximate posteriors $q_{\phi_c}(\boldsymbol{z}^{(c)}|\boldsymbol{x})$. Given two data points $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$, we denote the proximity of their encodings in the latent subspace by $D(q_{\phi_c}(\boldsymbol{z}^{(c)}|\boldsymbol{x}_i), q_{\phi_c}(\boldsymbol{z}^{(c)}|\boldsymbol{x}_j))$. We experiment with multiple forms of proximity functions and found cosine distance to perform the best:

$$\begin{aligned} D(q_{\phi_c}(\boldsymbol{z}|\boldsymbol{x}_i), q_{\phi_c}(\boldsymbol{z}|\boldsymbol{x}_j)) &= d_c(\boldsymbol{z}_i, \boldsymbol{z}_j) \qquad (3) \\ &= \frac{1}{2}\left(1 - \frac{\boldsymbol{z}_i \boldsymbol{z}_j}{||\boldsymbol{z}_i||||\boldsymbol{z}_j||}\right) \end{aligned}$$

Based on the above distance, we add a regularization term to the VAE loss function as follows. For each example $(\boldsymbol{x}, c)$, we have a positive sample $\boldsymbol{x}_p$ and m negative samples $\boldsymbol{x}_{n_1}, ..., \boldsymbol{x}_{n_m}$, such that $\text{Sim}(\boldsymbol{x}, \boldsymbol{x}_p|c) = 1$ and $\text{Sim}(\boldsymbol{x}, \boldsymbol{x}_{n_j}|c) = 0$; $j \in \{1, ..., m\}$:

$$\mathcal{L}_c = \max(0, 1 + d_c(\boldsymbol{z}, \boldsymbol{z}_p) - \frac{1}{m}\sum_{j=1}^{m} d_c(\boldsymbol{z}, \boldsymbol{z}_{n_j})) \tag{4}$$

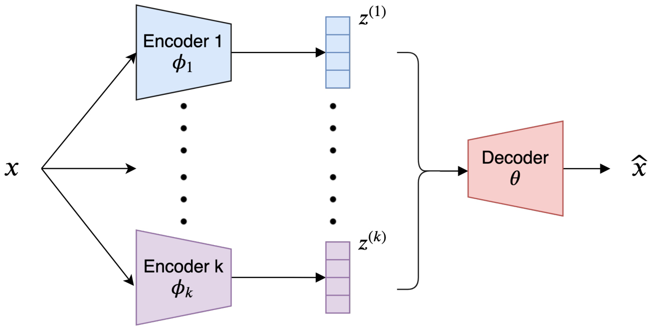

Figure 1: Model Architecture

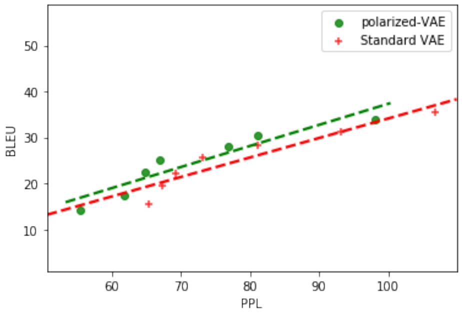

Figure 2: BLEU vs. PPL trade-off

This regularization function can be viewed as a max-margin loss over the proximity function. The final objective then becomes

$$\mathcal{L} = \mathcal{L}_{\text{vae}} + \sum_{c \in C} \lambda_c \mathcal{L}_c \tag{5}$$

3 Experiments

To demonstrate the effectiveness of polarized-VAE in obtaining disentangled representations, we carry out semantics-syntax separation of textual data, using the Stanford Natural Language Inference dataset (SNLI, Bowman et al. (2015)). Model implementation details are provided in Appendix A.

3.1 Reconstruction and Sample Quality

We evaluate our model on reconstruction and sample quality to ensure that the distance-based regularization used does not adversely impact its reconstruction or sampling capabilities. For this purpose, we compare our model and the standard VAE on two metrics: reconstruction BLEU (Papineni et al., 2002) and the Forward Perplexity (PPL)[2] (Zhao et al., 2018) of the generated sentences obtained by sampling from the model's latent space. As seen in Figure 2, there is a clear trade-off between reconstruction quality and sample quality, which is expected. Overall, polarized-VAE performs slightly better than standard VAE and this indicates that the proximity-based regularization does not inhibit the model capabilities.

3.2 Controlled Generation and Transfer

We follow previous work (Chen et al., 2019a; Bao et al., 2019) and analyze the performance of controlled generation by evaluating syntax transfer in generated text. Given two sentences, $\boldsymbol{x}_{\text{sem}}$ and $\boldsymbol{x}_{\text{syn}}$, we wish to generate a third sentence that combines the semantics of $\boldsymbol{x}_{\text{sem}}$ and the syntax of $\boldsymbol{x}_{\text{syn}}$ using the following procedure:

$$\boldsymbol{z}_{\text{sem}} \sim q_{\phi_1}(\boldsymbol{z}^{(1)} | \boldsymbol{x}_{\text{sem}}) \;\; ; \;\; \boldsymbol{z}_{\text{syn}} \sim q_{\phi_2}(\boldsymbol{z}^{(2)} | \boldsymbol{x}_{\text{syn}})$$
$$\boldsymbol{z} = [\boldsymbol{z}_{\text{sem}}, \boldsymbol{z}_{\text{syn}}] \;\; ; \;\; \boldsymbol{x} \sim p_\theta(\boldsymbol{x} | \boldsymbol{z})$$

Following the evaluation methodology of Bao et al. (2019), we measure transfer based on (1) semantic content preservation for the semantic subspace and (2) the tree edit distance (Zhang and Shasha, 1989) for the syntactic subspace.

We consider pairs of sentences from the SNLI test set for evaluation. We would like the generated sentence to be close to $\boldsymbol{x}_{\text{sem}}$ and different from $\boldsymbol{x}_{\text{syn}}$ in terms of semantics, which is measured using BLEU scores. We also report the difference to indicate the strength of transfer denoted by ΔBLEU. Additionally, we would like the generated sentence to be syntactically similar to $\boldsymbol{x}_{\text{syn}}$ and different from $\boldsymbol{x}_{\text{sem}}$, which is measured by averaged sentence-level Tree Edit Distance (TED). We also report ΔTED to indicate the strength of the syntax transfer. Finally, we use the Geometric Mean of ΔBLEU and ΔTED to report a combined score ΔGM.

Our default variant of polarized-VAE uses the entailment labels from SNLI dataset as a proxy for semantic similarity based on which positive and negative samples are chosen. For this model, we threshold the difference in TED of syntax parses as a proxy for syntactic similarity. As shown in Table 1, we also evaluate three other variants of our model. In polarized-VAE (`wo`) we use word overlap (BLEU scores) as a heuristic proxy for estimating semantic similarity, while keeping syntactic training unchanged. We also experiment with heuristics for syntax in polarized-VAE (`len`) where we use length as a heuristic proxy for syntax, while still using ground truth entailment labels for semantic training. Finally we combine these two

---

[2] PPL is computed using the KenLM toolkit (Heafield et al., 2013)

Model	**BLEU**		ΔBLEU$^\uparrow$	**TED**		ΔTED$^\uparrow$	ΔGM$^\uparrow$	**Human Eval** (%)		
	$\boldsymbol{x}_{\text{sem}}{}^\uparrow$	$\boldsymbol{x}_{\text{syn}}{}^\downarrow$		$\boldsymbol{x}_{\text{sem}}{}^\uparrow$	$\boldsymbol{x}_{\text{syn}}{}^\downarrow$			sem	syn	fluency
Standard VAE	4.75	4.67	0.08	13.70	13.60	0.10	0.28	11	11	**43**
Bao et al. (2019)	**13.74**	6.15	7.59	**16.19**	13.10	**3.08**	4.83	24	**58**	19
polarized-VAE	10.78	0.92	**9.86**	14.09	11.67	2.42	**4.88**	**65**	31	38
polarized-VAE (`wo`)	9.82	0.84	8.98	14.12	11.65	2.47	4.71	-	-	-
polarized-VAE (`len`)	10.10	**0.76**	9.34	12.68	**11.44**	1.44	3.67	-	-	-
polarized-VAE (`wo`, `len`)	9.41	0.87	8.54	12.65	11.48	1.17	3.16	-	-	-

Table 1: Syntax transfer results on SNLI. Bao et al. (2019) report TED after multiplying by 10, we report their score after correction. For each model, the human evaluation scores represent percentage of instances that it was ranked the best for a given criteria (semantics preservation/syntax transfer/fluency).

heuristics in polarized-VAE (`wo`, `len`), which can be viewed as an unsupervised variant that does not make use of any ground truth labels or syntax trees.

Our model outperforms the VAE baseline on all metrics. In comparison to (Bao et al., 2019), polarized-VAE is much better at ignoring the semantic information present in $\boldsymbol{x}_{\text{syn}}$ during syntax transfer, as evidenced by our lower BLEU scores w.r.t. $\boldsymbol{x}_{\text{syn}}$. On the other hand, we perform slightly worse on BLEU w.r.t. $\boldsymbol{x}_{\text{sem}}$. Our model does a better job at matching the syntax of sentence $\boldsymbol{x}_{\text{syn}}$ as indicated by the lower TED score w.r.t. $\boldsymbol{x}_{\text{syn}}$. Qualitative samples of syntax transfer are provided in Appendix C.

3.3 Human Evaluation

We carried out a human evaluation study for comparing outputs generated from different models. The test setup is as follows - we provide as input two sentences, x_{sem} and x_{syn} to the model; we wish to generate a sentence that combines the semantics of x_{sem} and the syntax of x_{syn}. We asked 5 human annotators to evaluate the outputs from the 3 models: baseline-VAE, polarized-VAE and the model from (Bao et al., 2019).

Each annotator was shown the input sentences (x_{sem} and x_{syn}) and the outputs from the 3 models (randomized so that the evaluator is unaware of which output corresponds to which model). They were then asked to pick the one best output for each of the following three criteria: (1) semantic preservation — level of semantic similarity with respect to x_{sem}, (2) syntactic transfer — level of syntactic similarity with respect to x_{syn} and (3) fluency. We obtained annotations on 100 test set examples from SNLI dataset. To aggregate the annotations, we used majority voting with manual tie breaking to find the best model for each test example (and for each test criteria).

For each model, we report the percentage of instances where it was voted as best for each criteria. From the human evaluation results in Table 1, we note that polarized-VAE is better at semantic transfer and worse at syntactic transfer in comparison to (Bao et al., 2019). The human evaluation results are consistent with the automatic evaluation metrics, where polarized-VAE scores higher on ΔBLEU (indicator of semantic transfer strength) and (Bao et al., 2019) is better at ΔTED (indicator of syntax transfer strength). With respect to fluency criterion, polarized-VAE ranks higher than (Bao et al., 2019). However, the most fluent sentences are produced by the baseline VAE. We hypothesise this to be due to the presence of additional regularization terms in the loss functions of both (Bao et al., 2019) and polarized-VAE, which in turn affects the fluency of their generated text (due to the deviation from the reconstruction objective).

4 Conclusion and Future Work

We proposed a general approach for disentangling latent representations into subspaces using proximity functions. Given a pair of data points, a predefined similarity criterion in the original input space determines their relative distance in the corresponding latent subspace, which is modelled via a proximity function. We apply our approach to the task of disentangling semantics and syntax in text. Our model substantially outperforms the VAE baseline and is competitive with the state-of-the-art approach while being more general as we do not use specific multitask losses or architectures to encourage preservation of semantic or syntactic information. Our methodology is orthogonal to the multitask learning approaches by Chen et al. (2019b) and Bao et al. (2019) and can be naturally combined with their methods. We would further like to investigate this approach on disentanglement applications outside of NLP. Another interesting research direction would be to further explore suitable proximity functions and identify their properties that could facilitate disentanglement.

Acknowledgements

We would like to thank Dr. Pascal Poupart for his valuable insights and ideas. We would also like to thank Compute Canada (`www.computecanada.ca`) for their support and GPU resourcees.

Appendix

Polarized-VAE: Proximity Based Disentangled Representation Learning for Text Generation

A Model and Training Details

Both the semantic and syntactic encoders are bidirectional LSTMs (Hochreiter and Schmidhuber, 1997) with hidden size of 128, followed by two feed-forward layers to parameterize the Gaussian mean (μ) and standard deviation (σ) parameters similar to standard VAE formulations used by (Bao et al., 2019). The latent space dimensions were taken to be $dim(z^1) = 64$ and $dim(z^2) = 16$. The decoder is a unidirectional LSTM with a hidden size of 128. We train the model for 30 epochs in total using the ADAM optimizer (Kingma and Ba, 2015) with the default parameters and a learning rate of 0.001.

We adopt the standard tricks for VAE training including dropout and KL annealing followed by (Bowman et al., 2016). We anneal both semantic and syntactic KL weights (λ_{kl}) upto 0.3 (5000 steps) using the same `sigmoid` schedule (Bahuleyan, 2018).

B Proximity Functions

We provide results for the other proximity functions that we explored for the polarized-VAE model.

Metric	ΔBLEU$^{\uparrow}$	ΔTED$^{\uparrow}$	ΔGM$^{\uparrow}$
Cosine Distance	**9.86**	**2.42**	**4.88**
Hellinger Distance	4.12	0.86	1.42
MMD	5.21	1.17	1.91
KL Divergence	4.32	0.75	1.28
JS Divergence	5.81	1.46	2.33

Table 2: Comparison of polarized-VAE with different proximity functions.

We note that since there is no closed form expression for the JS divergence between two Normal Random variables we used the generalized JS Divergence proposed by (Nielsen, 2020).

C Transfer Examples

We provide qualitative examples of our transfer experiments, where we generate a sentence with the semantics of x_{sem} and the syntactic structure of x_{syn} in Table 4. We also provide the sentences generated by a standard-VAE for comparison.

D Disentanglement of Latent Subspaces

We test if there a possibility that the two latent subspaces encode similar information. This is only likely to happen if the attributes themselves are highly correlated (e.g., if we want to disentangle syntax from length). For such cases, even existing methods based on adversarial disentanglement (John et al., 2019) may fail to completely separate out correlated information.

However, if the attributes are different enough (or ideally independent) for e.g., syntax and semantics, this is less problematic. Note that we apply our proximity loss independently to each of the subspaces (i.e., leaving the other space(s) untouched for a given input). This encourages the semantic encoder to encode semantically similar sentences close together and dissimilar ones far apart in the semantic space (same applies for the syntax encoder).

We empirically compute correlations between the semantic and syntax latent vectors for 1000 test sentences as a way to check whether the two encoders learn similar information. By feeding 1000 sentences from the test set to the Polarized-VAE, we obtain their corresponding semantic (z_{sem}) and syntax (z_{syn}) latent vectors. We then empirically compute the correlation between z_{sem} and z_{syn}. To analyze the level of similarity of information represented in z_{sem} and z_{syn}, we report the maximum absolute correlation (max across all pairs of dimensions) and also the mean absolute correlation. A higher value of correlation would indicate that there is more overlapping information learnt by the semantic and syntactic encoders. As illustrated in Table 3, the analysis indicates that the semantic and syntax latent vectors in polarized-VAE encodes less correlated information than standard-VAE (due to the proximity-based regularization). This demonstrates that the 2 latent spaces learned by our model encode sufficiently different information.

Model	Max Abs Corr$^{\downarrow}$	Mean Abs Corr$^{\downarrow}$
standard-VAE	0.62	0.1
polarized-VAE	**0.25**	**0.05**

Abstract

We propose ParaSCI, the first large-scale paraphrase dataset in the scientific field, including 33,981 paraphrase pairs from ACL (ParaSCI-ACL) and 316,063 pairs from arXiv (ParaSCI-arXiv). Digging into characteristics and common patterns of scientific papers, we construct this dataset though intra-paper and inter-paper methods, such as collecting citations to the same paper or aggregating definitions by scientific terms. To take advantage of sentences paraphrased partially, we put up PDBERT as a general paraphrase discovering method. The major advantages of paraphrases in ParaSCI lie in the prominent length and textual diversity, which is complementary to existing paraphrase datasets. ParaSCI obtains satisfactory results on human evaluation and downstream tasks, especially long paraphrase generation.

1 Introduction

A paraphrase is a restatement of meaning with different expressions (Bhagat and Hovy, 2013). Being very common in our daily language expressions, it can also be applied to multiple downstream tasks of natural language processing (NLP), such as generating diverse text or adding richness to a chatbot.

At present, paraphrase recognition or paraphrase generation are largely limited to the deficiency of paraphrase corpus. Especially, due to the permanent vacancy of paraphrase corpus in the scientific field, scientific paraphrase generation advances slowly. Scientific paraphrases can not only be helpful for data augmentation of challenging scientific machine translation, but is also effective for polishing scientific papers. However, existing paraphrase datasets are mainly from news, novels, or social media platforms. Most of them remain short sentences and interrogative or oral style. As a result, none of such training data can train out a scientific paraphrase generator. Taking the sentence *"we used pos tags predicted by the stanford pos tagger"* as an example, the generated sentences from Transformer (Vaswani et al., 2017) models trained on existing paraphrase datasets[1] are *"level basic topics : what is the basic purpose of stanford traditional hmo"* and *"a picture of a street sign with a sign on it"*, far from ground-truth paraphrases.

We have noticed that the structure of scientific papers is nearly fixed. Paraphrase sentence pairs appear not only within a paper (intra-paper) but also across different papers (inter-paper), which makes it possible to construct a paraphrase dataset in the scientific field. For example, repetitions of the same crucial contribution in a paper or explanations of the same term in different papers are potential paraphrases. Based on such characteristics, we design different methods to extract paraphrase pairs (shown in Section 4).

In terms of the construction methods, existing methods merely focus on the paraphrase relationship between entire sentences, while hardly handle sentences with partial paraphrase parts, leaving much original corpus idle. We find that if part of a sentence paraphrases another short sentence, such sequences will be filtered out because the overall semantic similarity is not high enough. For paraphrase discovering in this case, we fine-tune BERT to extract semantically equivalent parts of two sentences and name it PDBERT. In order to train PDBERT, we construct pseudo training data by stitching existing paraphrase sentences, and train a paraphrase extraction model using the pseudo training data. In the end, this model performs well on real scientific texts.

After filtering, we obtain 350,044 paraphrase pairs and name this dataset ParaSCI. It consists of two parts: ParaSCI-ACL (33,981 pairs) and ParaSCI-arXiv (316,063 pairs). Compared with

---

[1] Here we use Quora Question Pairs and MSCOCO, they are introduced in Section 2

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 424–434

other paraphrase datasets, sentences in ParaSCI are longer and more sententially divergent. ParaSCI can be used for training paraphrase generation models. Furthermore, we hope that it can be applied to enlarge training data for other NLP tasks in the scientific domain.

Our main contributions include:

1. We propose the first large-scale paraphrase dataset in the scientific field (ParaSCI), including 33,981 pairs in ParaSCI-ACL and 316,063 pairs in ParaSCI-arXiv. Our dataset has been released to the public[2].

2. We propose a general method for paraphrase discovering. By fine-tuning BERT innovatively, our PDBERT can extract paraphrase pairs from partially paraphrased sentences.

3. The model trained on ParaSCI can generate longer paraphrases, and sentences are enriched with scientific knowledge, such as terms and abbreviations.

2 Related Work

Paraphrases capture the essence of language diversity (Pavlick et al., 2015) and play significant roles in many challenging NLP tasks, such as question answering (Dong et al., 2017), semantic parsing (Su and Yan, 2017) and machine translation (Cho et al., 2014). Development in paraphrases relies heavily on the construction of paraphrase datasets.

Paraphrase Identification Datasets Dolan and Brockett (2005) proposed MSR Paraphrase Corpus [MSRP], a paraphrase dataset of 5,801 sentence pairs, by clustering news articles with an SVM classifier and human annotations. As is discovered, platforms such as Twitter also contain many paraphrase pairs. Twitter Paraphrase Corpus [PIT-2015] (Xu et al., 2015) contains 14,035 paraphrase pairs on more than 400 distinct topics. Two years later, Twitter Url Corpus [TUC] (Lan et al., 2017) was proposed as a development of PIT-2015. TUC contains 51,524 sentence pairs, collected from Twitter by linking tweets through shared URLs and do not leverage any classifier or human intervention. Datasets such as MSRP or PIT-2015 encourage a series of work in paraphrase identification (Das and Smith, 2009; Mallinson et al., 2017) but the size limitation hinders complex generation models.

Paraphrase Generation Datasets MSCOCO (Lin et al., 2014) was originally described as a large-scale object detection dataset. It contains human-annotated captions of over 120K images, and each image is associated with five captions from five different annotators. In most cases, annotators describe the most prominent object/action in an image, which makes this dataset suitable for paraphrase-related tasks. Consequently, MSCOCO makes great contribution to paraphrase generation. Quora released a new dataset[3] in January 2017, which consists of over 400K lines of potential question duplicate pairs. Wieting and Gimpel (2018) constructed ParaNMT-50M, a dataset of more than 50 million paraphrase pairs. The pairs were generated automatically by translating the non-English side of a large parallel corpus. Nowadays, MSCOCO and Quora are mainly used for paraphrase generation (Fu et al., 2019; Gupta et al., 2018). Nevertheless, their sentence lengths or related domains are restricted.

3 Dataset

3.1 Source Materials

Our ParaSCI dataset is constructed based on the following source materials:

ACL Anthology Sentence Corpus (AASC) AASC (Aizawa et al., 2018) is a corpus of natural language text extracted from scientific papers. It contains 2,339,195 sentences from 44,481 PDF-format papers from the ACL Anthology, a comprehensive scientific paper repository on computational linguistics and NLP.

ArXiv Bulk Data ArXiv[4] is an open-access repository of electronic preprints. It consists of scientific papers in the fields of mathematics, physics, astronomy, etc.. As the complete set is too large to process, we randomly select 202,125 PDF files as our original data and convert them to TXT files, arranged by sentence.

Semantic Scholar Open Research Corpus (S2ORC) S2ORC (Lo et al., 2020) is a large contextual citation graph of scientific papers from multiple scientific domains, consisting of 81.1M papers, 380.5M citation edges. We select all the citation edges of ACL and arXiv from S2ORC for subsequent processing.

[4] website:https://arxiv.org/help/bulk_data

3.2 Basic Information

According to the source materials, ParaSCI includes two subsets, ParaSCI-ACL and ParaSCI-arXiv. Paraphrase pairs in ParaSCI-ACL focus on the NLP field, while paraphrase pairs in ParaSCI-arXiv are more general. Some cases are shown in Table 1. ParaSCI show three main highlights: 1) Sentences included are long, nearly 19 words per sentence; 2) Sentences are more sententially divergent; 3) It provides rich scientific knowledge.

Name	Sentence A	Sentence B
ParaSCI-ACL	Word sense disambiguation (wsd) is the task of identifying the correct meaning of a word in context.	The process of identifying the correct meaning, or sense of a word in context, is known as word sense disambiguation (wsd).
ParaSCI-ACL	In this paper, we study the use of standard continuous representations for words to generate translation rules for infrequent phrases.	In this work, we show how simple continuous representations of phrases can be successfully used to induce translation rules for infrequent phrases.
ParaSCI-arXiv	Simon and Ronder propose a constellation model to localize parts of objects, which utilizes cnn to find the constellations of neural activation patterns.	Simon et al. propose a neural activation constellations part model to localize parts with constellation model.
ParaSCI-arXiv	Here we will concentrate only on those aspects that are directly relevant to the odderon.	We will put some emphasis on those aspects that are immediately relevant to the odderon.

Table 1: Example paraphrase pairs in ParaSCI. Sentence A and corresponding Sentence B are paraphrase pairs.

3.3 Statistic Characteristic

To assess the characteristics of ParaSCI, we compare its statistic characteristics with five main sentential paraphrase datasets in Table 2. The source genre of ParaSCI is scientific papers. Therefore, sentences are more formal and scholastic, and they differ from oral TUC or newsy MSRP. The average sentence length of ParaSCI is almost twice as long as that of ParaNMT-50M, MSCOCO and Quora, and also much longer than that of TUC. Its average length is only a little shorter than that of MSRP. As MSRP only contains 3,900 gold-standard paraphrases, our ParaSCI is complementary to the vacancy of large-scale long paraphrase pairs.

The degree of alteration is another important aspect of paraphrases. To compare our ParaSCI with other existing paraphrase datasets in this aspect, we propose to calculate the BLEU4 score (Papineni et al., 2002) between the source and target sentences of each paraphrase pair and name it **Self-BLEU**. In Table 2, ParaSCI, especially ParaSCI-ACL, shows a relatively low Self-BLEU, which means sentences are significantly changed.

4 Method

4.1 Extracting Paraphrase Candidates

Based on the unique characteristics of scientific papers, we extract the paraphrase sentences from a same paper (intra-paper) and across different papers (inter-paper). In most cases, we develop a simple but practical model to discover paraphrases in different sections effectively. For a more challenging case, when sentences are paraphrased partially rather than entirely, we propose PDBERT to collect more paraphrase candidates.

4.1.1 Intra-paper Extraction of Paraphrase Candidates

Authors usually write down the same information with transformed expressions repeatedly in different parts of the paper to emphasize critical information or echo back and forth. This kind of feature is the premise of our intra-paper extraction methods.

Sentence BERT for Paraphrase Extraction across Different Sections Noting that sentences with shared semantics appear in different parts of one paper. For instance, the following sentences are from different parts of a same paper, and they are paraphrases:

S_1: *we propose a simple yet robust stochastic answer network (SAN) that simulates multi-step reasoning in machine reading comprehension.* (***abstract***, Liu et al. (2018))

S_2: *we introduce Stochastic Answer Networks (SAN), a simple yet robust model for machine reading comprehension.* (***introduction***, Liu et al. (2018))

However, sentences in *Method*, *Data* and *Result* sections are semantically different even when they only have minor changes. For example, the strings other than numbers may be very similar when presenting the two experimental results, but the semantics are completely different. Therefore, we mainly focus on six sections (*Abstract*,

Name	Genre	Size (pairs)	Gold Size[5] (pairs)	Len	Char Len	Self-BLEU
MSRP	news	5,801	3,900	22.48	119.62	47.98
TUC	Twitter	56,787	21,287	15.55	85.10	12.53
ParaNMT-50M	Novels, laws	51,409,585	51,409,585	12.94	59.18	28.60
MSCOCO	Description	493,186	493,186	10.48	51.56	31.97
Quora	Question	404,289	149,263	11.14	52.89	29.46
ParaSCI-ACL	Scientific Papers	59,402	33,981	19.10	113.76	26.52
ParaSCI-arXiv	Scientific Papers	479,526	316,063	18.84	114.46	29.90

Table 2: Statistic characteristics of main existing paraphrase datasets and our ParaSCI. As ParaNMT-50M is too large, we sample 500,000 pairs as representatives. Len means the average number of words per sentence and Char Len represents the average number of characters per sentence. We calculate Len, Char Len and Self-BLEU of the gold-standard paraphrases rather than the whole size of sentences.

Introduction, *Background*, *Discussion*, *Preamble* and *Conclusion*). We directly obtain embeddings of sentences through BERT (Devlin et al., 2018). Then, we calculate the cosine similarity pair by pair and retain sentence pairs with a similarity score higher than 0.931 as favorable paraphrase candidates. 16,563 paraphrase candidates from ACL and 158,227 paraphrase candidates from arXiv are obtained efficiently in this way.

It is noteworthy that as information is hardly repeated in the same section, we exclude the comparison between sentences in the same section.

PDBERT for Paraphrase Discovering In fact, two sentences, even if they are not semantically equivalent, may share some parts with common semantics. For example:

S_1: ***rationales are never given during training***.

S_2: *in other words, target* ***rationales are never provided during training****; the intermediate step of rationale generation is guided only by the two desiderata discussed above.*

S_1 and the bold part of S_2 constitute a paraphrase. However, since the similarity between the entire S_1 and S_2 is only 0.88, this pair of sentences will be filtered out. This phenomenon frequently occurs when a sentence is much longer than the other, so that part of the long sentence paraphrases the short sentence. To resolve this problem, we propose a new paraphrase discovering model, PDBERT.

Our model architecture is shown in Figure 1. We use the paraphrase sentence pairs recognized based on sentence similarity (our first method mentioned above) to construct pseudo-labeled data for model training. For each genuine paraphrase pairs, we take one as Sentence A and the other as Sentence B. Then we randomly pick out two sentences from the whole sentence set, as Sentence C and Sentence D. We use Sentence A as input 1, and concatenate Sentence C, Sentence B and Sentence D, with the 80%, 50%, and 80% appearance probabilities respectively, as input 2. Input 1 and input 2 are further concatenated by adding a token [CLS] at the beginning of input 1, and inserting a [SEP] token between input 1 and input 2. The start and end positions of Sentence B in the concatenated string are recorded as the ground-truth. It is worth mentioning that while concatenating, the ending punctuations of Sentence C and Sentence B are removed. Besides, the random selection of sentences in input 2 guarantees our model to cover various situations, for example, the first part of input 2 is the ground-truth paraphrase of input 1, or input 2 is just Sentence B.

In this way, we generate a great number of training pairs. Input 1 represents a short sentence and input 2 represents a long sentence, which includes the paraphrase of the short one. We fine-tune the model to predict the start and end positions of Sentence B using a softmax function.

Although our training data are pseudo, the fine-tuned model performs well on the real data. For a given real sentence pair, we take the shorter sentence as input 1 and the longer one as input 2, and extract from the long sentence according to the predicted positions. Actually, there is a tiny probability that the entire long sentence is the paraphrase of the short sentence. We exclude such a result because we have already obtained it via sentence BERT. Here we obtain 9,915 paraphrase candidates from ACL and 45,397 pairs from arXiv.

We compare our PDBERT model with a best-clause baseline. The latter is simply splitting the

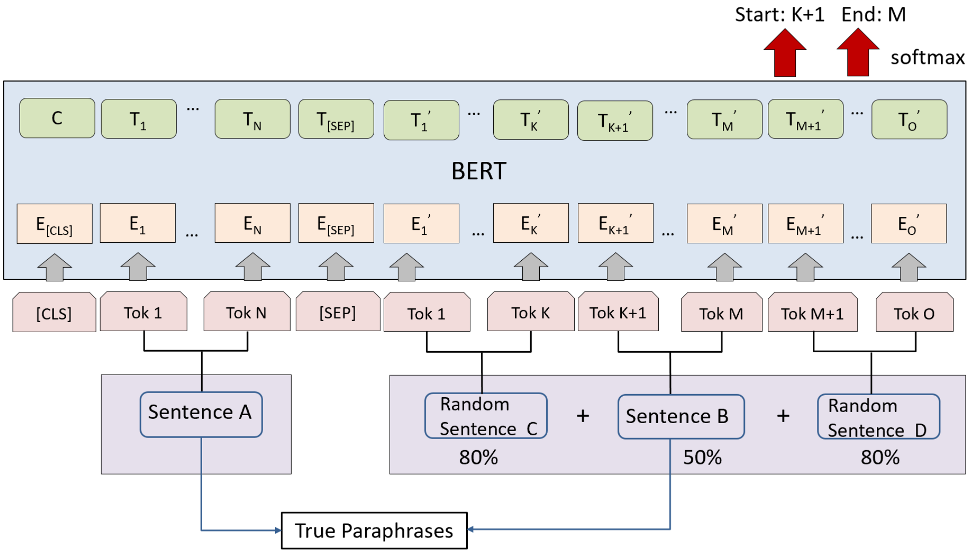

Figure 1: A general paraphrase discovering model, PDBERT. We fine-tune a 12-layer BERT model for predicting the start and end positions of the paraphrase part. The bottom of the figure shows the construction of labeled data.

long sentence into several clauses by punctuation and selecting the combination of clauses that have a maximum similarity with the short sentence. We implement PDBERT and the baseline method on the same corpus and compare the processing speed, size of valuable extractions and BERTScore(Zhang et al., 2019). Table 3 demonstrates the comparison. PDBERT has a higher extraction speed because, in the baseline method, we have to embed each possible combination of clauses. For valuable extractions, PDBERT extracts a larger size of candidate paraphrase pairs. Moreover, the BERTScore of PDBERT's results is higher, indicating its semantic advantage in paraphrase discovering.

Method	Speed	Size	BERTScore
Best-clause	7.16	341	74.06
PDBERT	32.34	387	88.23

Table 3: Comparison of paraphrase discovering methods. We divide the number of all the processed sentence pairs by time (720 minutes) as processing speed. Filtering out what can be obtained via sentence BERT, we take the number of remaining pairs as size of valuable extractions and use BERTScore (scibert-scivocab-uncased) to evaluate their quality.

4.1.2 Inter-paper Extraction of Paraphrase Candidates

Paraphrases also exist across different papers in the same field, including explanations of the same concept in different papers and citations to the same paper.

Explanations of the Same Concept In scientific papers, in order to introduce the definition of a task or a scientific terminology, the authors often explain it in one sentence. Therefore, various definitions of the same term in different papers become paraphrase candidates naturally, just as the following case:

S_1: ***Sentence compression*** *is the task of producing a shorter form of a single given sentence, so that the new form is grammatical and retains the most important information of the original one.*

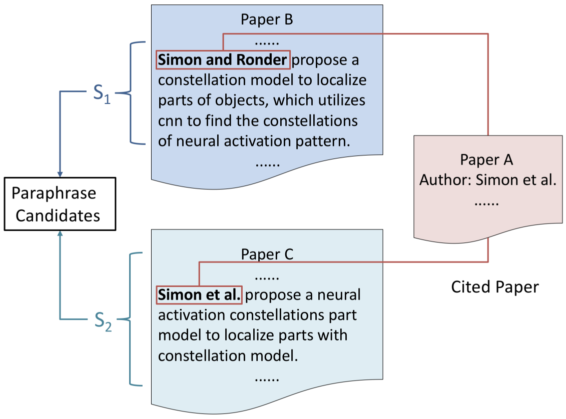
S_2: ***Sentence compression*** *is a task of creating a short grammatical sentence by removing extraneous words or phrases from an original sentence while preserving its meaning.*

In order to extract the definition sentences from different papers, we design a series of possible patterns (regular expressions) of definition sentences and tag the terms in them. In the same subject or area (provided by meta-data of source materials), the extracted sentences are aggregated according to terms, so we obtain multiple explanations of the same concept. In order to ensure the same semantics, we combine them into pairs and adopt the method in Section 4.1.1 to filter out the sentence pairs that are semantically different. Here we get 5,912 paraphrase candidates from ACL and 63,258 paraphrase candidates from arXiv.

---

[5] gold-standard paraphrase

Citations to the Same Paper Scientific papers often need to cite previous works. Besides, authors tend to give a brief introduction (i.e., citation text) to the cited paper. If different papers cite the same one, the introductory sentences to this cited paper in different papers also naturally constitute a sentence set with possible paraphrase relationships. Figure 2 provides an example.



Simon and Ronder propose a constellation model to localize parts of objects, which utilizes cnn to find the constellations of neural activation pattern.

Simon et al. propose a neural activation constellations part model to localize parts with constellation model.

Figure 2: Example of extracting paraphrase pairs from papers sharing a same cited paper.

We locate the citations in the paper through S2ORC data and extract the citation sentence and the cited article. All the extracted results are aggregated according to the same cited paper. Then we match sentences in the same group. Similarly, in order to ensure the same semantics, we use the method in Section 4.1.1 to filter out semantically inconsistent sentence pairs. In this way, we obtain 27,016 pairs of candidates for ACL and 212,644 pairs for arXiv.

4.2 Selecting High-quality Paraphrases

Due to insufficient computing resources, we have used a rough but fast filtering method to construct paraphrase candidate set as mentioned above. It includes 59,406 pairs from ACL and 479,526 pairs from arXiv. To obtain the high-quality paraphrase corpus, we implement domain-related BERTScore and paraphrase length rates to determine if a candidate pair is really paraphrase. Our two-stage construction process works in a coarse-to-fine way.

BERTScore leverages the pre-trained contextual embeddings from BERT and matches words in candidate and reference sentences by cosine similarity. It has been shown to correlate with human judgment on sentence-level and system-level evaluation. We calculate domain-related BERTScore for each paraphrase candidate, with the concrete setting of scibert-scivocab-uncased_L8_no-idf_version=0.3.3.

We design paraphrase length rate (PLR) as another filter because the numbers of words in two paraphrase sentences usually do not vary too much. PLR is simply calculated as:

$$\frac{|L_A - L_B|}{\min(L_A, L_B)}$$

L_A and L_B stand for lengths of the corresponding sentences.

For paraphrase candidates extracted from explanations of the same concept, they consist of more abstract knowledge so we set a loose restriction. We select those with a BERTScore higher than 0.6 and PLR lower than 2. Therefore, we get 4,566 definition paraphrase pairs from ACL candidates and 49,052 pairs from arXiv candidates. For paraphrase candidates extracted from other methods, we change the threshold of BERTScore to be 0.7 and PLR to be 1.0. In this way, we get another 29,415 pairs from ACL candidates and 267,106 pairs from arXiv candidates.

5 Manual Evaluation

We conduct a manual analysis of our dataset in order to quantify its semantic consistency and literal variation lexically, phrasally and sententially. We employ 12 volunteers who are proficient in English to rate the instances. Three human judgements are obtained for every sample and the final scores are averaged across different judges.

Consistency Evaluation Criterion For semantic consistency of paraphrase pairs, we design 5 degrees to distinguish. For a sentence pair to have a rating of 5, the sentences must have exactly the same meaning with all the same details. To have a rating of 4, the sentences are mostly equivalent, but some unimportant details can differ. To have a rating of 3, the sentences are roughly equivalent, with some important information missing or that differs slightly. For a rating of 2, the sentences are not equivalent, even if they share minor details. For a rating of 1, the sentences are totally different. (Examples are shown in the appendix)

Variation Evaluation Criterion For literal variation of paraphrase pairs lexically, phrasally and sententially, we use the following criterion respectively: 5 means there are more than five variations of this level, 4 means four or five, 3 means two or

Name	Lexical	Phrasal	Sentential
ParaSCI-ACL	3.82	2.73	2.01
ParaSCI-arXiv	3.67	2.68	1.48

Table 4: Overall variation of ParaSCI from manual evaluation.

three, 2 means it has only one change and 1 means no change.

Quality Control We evaluate the annotation quality of each worker using Cohen's kappa agreement (Artstein and Poesio, 2008) against the majority vote of other workers. We asked the best worker to label more data by republishing the questions done by workers with low reliability (Cohen's kappa <0.4). Finally, the average Cohen's kappa of semantic consistency evaluation is 0.71 and that of literal variation is 0.62 (0.66 lexically, 0.59 phrasally and 0.61 sententially).

Evaluation Results The average semantic consistency of ParaSCI-ACL is 4.17 and that of ParaSCI-arXiv is 3.94, both around 4, which means most paraphrase pairs are nearly equivalent, only some unimportant details may differ. Besides, the average semantic consistency of ParaSCI-ACL is higher than that of ParaSCI-arXiv. In terms of literal variation, Table 4 summarizes the annotations. ParaSCI-ACL and ParaSCI-arXiv show similar distributions. Paraphrase sentences usually change a lot lexically, because lexical variation is easier to realize. Although sentential variation scores are lower than lexical or phrasal scores, nearly one or two sentential variations for each pair are already rare and valuable for a paraphrase dataset. The long average length makes such sentential transformation possible, which is complementary to other datasets of short paraphrases.

6 Paraphrase Phenomenon Occurrence

In order to show the differences across paraphrase datasets, we sample 100 sentential paraphrases from each dataset and count occurrences of each phenomenon. Boonthum (2004) grouped common paraphrase phenomenon into 6 categories : **Synonym** (substitute a word with its synonym), **Voice** (change the voice of sentence from active to passive or vice versa), **Word-Form** (change a word into a different form), **Break** (break a long sentence down into small sentences), **Definition** (substitute a word with its definition or meaning), **Structure** (use different sentence structures to express the same thing). We report the average number of occurrences of each paraphrase type per sentence pair for each corpus in Table 5 and visualize that in Figure 3.

Name	Syn	Voice	Form	Break	Def	Struct
MSRP	0.80	0.19	0.15	0.15	0.31	0.28
TUC	0.50	0.10	0.10	0.09	0.53	0.29
ParaNMT-50M	0.87	0.15	0.20	0.13	0.40	0.25
MSCOCO	0.72	0.05	0.12	0.10	0.36	0.26
Quora	1.02	0.16	0.22	0.23	0.74	0.46
ParaSCI-ACL	0.97	0.14	0.12	0.28	0.57	0.45
ParaSCI-arXiv	1.04	0.11	0.15	0.32	0.68	0.41

Table 5: Example of extracting paraphrase pairs from papers sharing a same cited paper.

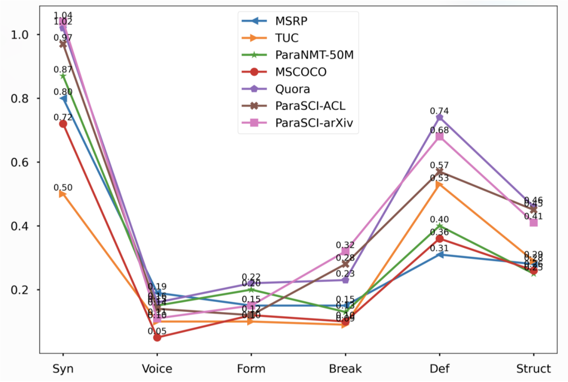


Figure 3: Visualization of Table 5.

As shown in Table 5 and Figure 3, ParaSCI-ACL, ParaSCI-arXiv and Quora share a similar paraphrase phenomenon distribution. Besides, with respect to four categories of paraphrase phenomena (Synonym, Break, Definition, Structure), they all rank top 3. It reveals that our ParaSCI and Quora datasets contain more valuable paraphrase phenomena or paraphrase patterns. However, the Quora dataset is limited to questions pairs and our ParaSCI provides declarative sentence pairs.

7 Paraphrase Generation

To demonstrate further application of ParaSCI, we train paraphrase generation models on Quora, MSCOCO and ParaSCI. We then test their generation ability on the same scientific corpus, including sentences from ACL and arXiv respectively. For paraphrase generation from ParaSCI-ACL, we use 20,388 pairs for training, 6,796 pairs for validation and 6,797 pairs for test. For paraphrase generation from ParaSCI-arXiv, we use 189,639 pairs for train-

Training	**Test**	**BLEU**	**Len**
Quora	ParaSCI-ACL	6.31	14.23
Quora	ParaSCI-arXiv	8.06	13.92
ParaSCI-ACL	ParaSCI-ACL	15.70	18.45
ParaSCI-arXiv	ParaSCI-arXiv	27.18	18.82

Table 6: BLEU scores and average lengths of scientific paraphrase generation by Transformer models trained on Quora and ParaSCI. Since the performance of the model trained on MSCOCO is rather poor (BLEU4 <1.0), we omit the comparison with it.

ing, 63,212 pairs for validation and 63,121 pairs for test. The BLEU scores and average lengths of generated sentences are shown in Table 6.

Although there are many technology-related or scientific questions on Quora, the paraphrase generation model trained on Quora still fails to perform well in the scientific field, with low BLEU scores and short average length. On the contrary, the paraphrase generation model trained on ParaSCI keeps generating longer sentences. The BLEU scores also demonstrate that the quality of the generated sentences is higher. This reflects the significant value of ParaSCI on paraphrase generation.

We show the generated paraphrases on different datasets in Table 7. To be fair, we still use the same Transformer architecture in the experiment. The generated paraphrases vary a lot. In most situations, the generated sentences from MSCOCO is incomplete, more like a phrase. The model trained on Quora only generates short questions. Whether trained on MSCOCO or Quora, the generated sentences usually share similar structures and have a large portion of entities in them. On the contrary, models trained on ParaSCI handle the paraphrase generation of longer sequence, including more modifiers and conjunctions.

Apart from that, generation models trained on ParaSCI manifest another characteristic. As ParaSCI consists of quantities of scientific terms and expressions, generation models trained on ParaSCI bring valuable scientific knowledge to the output sentence.

One thing to mention is that some abbreviations can be understood and utilized in the generation process. For instance, we generated *“we ran **mt** experiments using the moses phrase-based translation system.”* for the sentence *“we used moses as the phrase-based **machine translation** system.”*.

As we use domain-related terms and corresponding abbreviations in scientific texts frequently, this advantage can add conciseness, technicality and naturality to the generated sentences.

Another thing to mention is that some common sense or scientific knowledge is also taken into paraphrase generation. For example, we input *“the penn discourse treebank is the largest corpus richly annotated with explicit and implicit discourse relations and their senses.”* as the original sentence. It introduces the Penn Discourse Treebank (Miltsakaki et al., 2004) without any information related to its size and source, but the information is added to the generated sentences: *“the penn discourse treebank is the largest available annotated corpora of discourse relations **over 2,312 wall street journal articles**.”*

These cases reveal different aspects of ParaSCI's advantages in paraphrase generation. In further work, we hope that ParaSCI will contribute more to scientific paraphrase generation and subsequently, be applied to more downstream tasks in the scientific field.

Name	**Original**	**Paraphrase**
MSCOCO	a group of people watch a dog ride a motorcycle.	an old photo of people riding on a motorcycle and waving.
Quora	how can i get saved wifi password?	how can i see a saved wifi password?
ParaSCI-ACL	relation extraction (re) is the task of determining semantic relations between entities mentioned in text.	relation extraction (re) is the task of recognizing the assertion of a particular relationship between two or more entities in text.
ParaSCI-arXiv	cosmic strings are linear topological defects that can form in the early universe as a result of symmetry-breaking phase transitions.	cosmic strings are one-dimensional massive objects, which may appear as topological defects at the spontaneous symmetry breaking in the early universe.

Table 7: Example paraphrase sentences generated by the same Transformer model trained on different datasets. Different from Table 6, models here are trained with in-domain data, so the training data and testing data come from the same field.

8 Conclusion and Future Work

In this paper, we describe the characteristics and construction process of ParaSCI, a large-scale paraphrase dataset in the scientific field. It shows favorable results in the either automatic or manual evaluation.

For future work, although we filter out more than 200 thousand paraphrase candidates to promise the quality of ParaSCI, most candidates include valuable paraphrase patterns lexically or phrasally. Therefore, more paraphrase patterns are remaining to be discovered. Similarly, compared to the bulk data on arXiv or other scientific websites, we only use the tip of an iceberg to construct this dataset, and we are expecting to implement the methods in other scientific domains. For instance, we can obtain a biomedical paraphrase dataset from PubMed.

We hope that ParaSCI can be used to augment training data for various NLP tasks, such as machine translation in scientific field, and make more contributions to the development of NLP.

Abstract

We introduce a general framework for abstractive summarization with factual consistency and distinct modeling of the narrative flow in an output summary. Our work addresses current limitations of models for abstractive summarization that often hallucinate information or generate summaries with coherence issues.

To generate abstractive summaries with *factual consistency* and *narrative flow*, we propose *Cooperative Generator – Discriminator Networks* (Co-opNet), a novel transformer-based framework where a generator works with a discriminator architecture to compose coherent long-form summaries. We explore four different discriminator objectives which each capture a different aspect of coherence, including whether salient spans of generated abstracts are hallucinated or appear in the input context, and the likelihood of sentence adjacency in generated abstracts.

We measure the ability of Co-opNet to learn these objectives with arXiv scientific papers, using the abstracts as a proxy for gold long-form scientific article summaries. Empirical results from automatic and human evaluations demonstrate that Co-opNet learns to summarize with considerably improved global coherence compared to competitive baselines.

1 Introduction

Generating summaries with coherent discourse structure and domain knowledge awareness poses a challenge for current methods in summarization. Generative models can commonly produce high quality text (Figure 1), but fail to understand finer-grained details of coherence such as the structure and flow of a narrative. In addition, they often generate factually incorrect content. Prior work on factuality in abstractive summarization has found that current models can hallucinate information more than 70% of the time when generating summaries of news articles (Maynez et al., 2020).

Figure 1: Generated abstracts for a biology article (from the **Bio** subset of our arXiv dataset). Abstracts are ranked from most (top) to least likely (bottom) using the generator model. Abstracts with better narrative structure and domain-specific content (such as the circled abstract) are often out-ranked in terms of likelihood by abstracts with factual errors and less structure.

To address these issues, we focus our study on generating abstractive summaries with *factuality* and *narrative flow*. Given an input document, the goal is to generate a paragraph-length abstractive summary with proper discourse structure that contains factually correct claims. Our study builds on and extends previous work that focuses on either *extractive document-level* summarization (Nenkova and McKeown, 2012; Allahyari et al., 2017) or *abstractive sentence-level* summarization (Rush et al., 2015; Grusky et al., 2019; Narayan et al., 2018).

In pursuit of this goal, we introduce *Cooperative Generator-Discriminator Networks* (Co-opNet), a framework for abstractive summarization that considers subtle aspects of fact-checking and discourse necessary for coherent text generation. In this framework, the generator, a transformer language model fine-tuned for abstractive summarization, proposes a pool of candidate summaries (§2). The

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 435–447
April 19 - 23, 2021.

discriminator, also transformer-based, scores the factuality or discourse quality of candidate summaries using one of four different objectives: the overlap between a scientific article introduction and predicted fact-checking evidence spans in generated summaries, the ordering of predicted discourse roles, the coverage of predicted discourse roles, or the likelihood of adjacency between generated sentences (§3). The best summary is chosen cooperatively by combining the generator and discriminator scores (§4).

Most previous works on *abstractive document-level* summarization have difficulty in directly modeling or evaluating *narrative flow* and *factuality* in generated summaries. This weakness is largely due to the inherent limitations of existing datasets, such as the CNN/DailyMail dataset (Hermann et al., 2015). The reference summaries available in these commonly used resources are mainly headlines of news articles or stories. As a result, they are often sets of disconnected sentences that are highly extractive, leading to models that are also extractive (Hoang et al., 2019), rather than abstractive.

In order to address these data challenges, we test our summarization model on a set of arXiv scientific papers. Scientific abstracts are ideal for modeling narrative flow as they are structured with highly coherent discourse flow. They also maintain implicit *abstractive* alignments with respect to the introduction of the article – in contrast to the tight, *extractive* alignments of current models. Scientific article summarization is also a task where factuality is more well-defined than in other domains like story summarization which leave more room for interpretation.

Comprehensive empirical results considering both automatic and human evaluations demonstrate that Co-opNet learns to summarize scientific articles from three domains with considerably improved global coherence compared to competitive baselines (§6). We also demonstrate that the framework is generalizable to multiple coherence objectives, and effective at generating scientific abstracts that are more factually consistent.

2 Generator Networks

We use the transformer architecture of Radford et al. (2019) as our generator's architecture. Following the work of Liu et al. (2018), we adapt a language model to the task of abstractive summarization by concatenating the article a, a delimiter token $[\text{SEP}]$, the summary s, and an end token $[\text{END}]$ into one input vector $X = (a_1, ..., a_{|a|}, [\text{SEP}], s_1, ..., s_{|s|}, [\text{END}])$, where $|a|$ is the length of the gold article and $|s|$ is the length of the gold summary.

At each time step i, the model produces an output probability distribution over the vocabulary for the next token w_i given all previous output tokens $w_{<i}$. For any arbitrary token w_j preceding w_i, the per-layer representation of that token is computed in the following way:

$$\mathbf{h}_j^0 = \mathbf{W}_e(w_j) + \mathbf{p}_j \tag{1}$$

$$\mathbf{h}_j^l = block(\{\mathbf{h}\}_{<j}^{l-1}) \tag{2}$$

where *block* refers to each transformer block composed of multi-headed attention, a feedforward network and layer normalization, $\mathbf{W}_e$ is a word embedding matrix, $\mathbf{p}_j$ is the position embedding, $\mathbf{h}_j^0$ is the initial representation, $\{\mathbf{h}\}_j^l$ is the block output for an arbitrary layer l, and $\{\mathbf{h}\}_{<j}^{l-1}$ is the set of all block outputs from the preceding layer for positions up to j. Finally, for the current position i in the sequence, we compute a distribution over the output vocabulary as follows:

$$P(w_i|w_0, ...w_{i-1}) = \text{softmax}(\mathbf{h}_{i-1}^L \mathbf{W}_e) \tag{3}$$

where $\mathbf{W}_e$ is the same embedding matrix as in Equation 1 and $\mathbf{h}_{i-1}^L$ is the final layer transformer block output.

3 Discriminator Networks

Because summarization models are prone to narrative flow and factual consistency issues (Kryściński et al., 2020; Xu et al., 2020), we use a discriminator to score generated summaries for discourse and factuality properties. Due to the challenge of explicitly defining discourse and factuality properties as scores, these properties are approximated using parameterized scoring functions.

These scoring functions determine if generated text demonstrates discourse and factuality properties in three ways: (1) predicting the discourse role of sentences within a full summary, (2) predicting the likelihood of adjacency given a sentence pair, and (3) measuring the presence of salient facts in the generated summary from the original input context. While our discriminators focus on these three properties, we note that this framework is generalizable and could be extended to include other

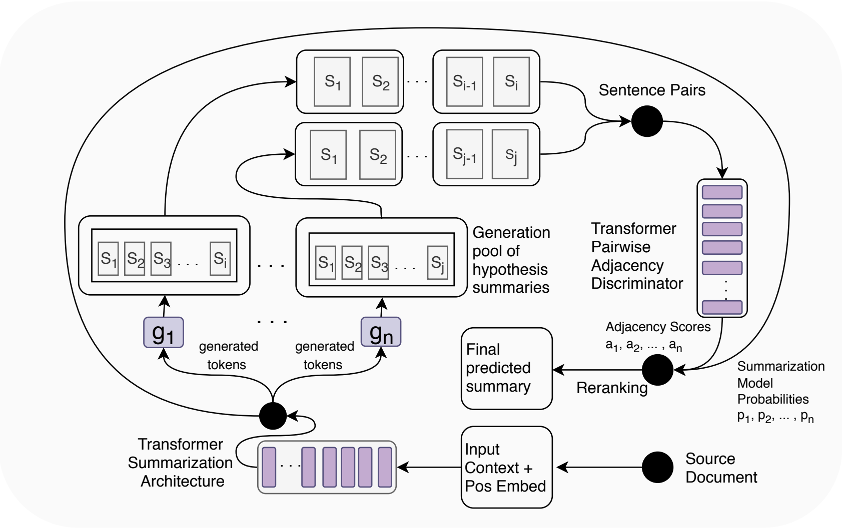

Figure 2: Model architecture for adjacency reranking variation of Co-opNet

discriminator models that encourage different communicative norms associated with high-quality language generation.

3.1 Discourse

We explore different discriminator architectures as additional discourse scoring functions during the generator's decoding process. For these discriminators, we generally score discourse in two ways. First, we use inferred sentence-level scientific abstract discourse role labels[1] defined by Cohan et al. (2019) and predict them using a sequence classifier[2] based on SciBERT (Beltagy et al., 2019). Using these predictions, we score the discourse properties of the abstract relative to their coverage (§3.1.1) or ordering (§3.1.2). Second, we learn a function that can score the likelihood that sentences within generated abstracts should be adjacent to one another (§3.1.3).

3.1.1 Coverage

We measure the completeness of the narrative structure within a scientific abstract by defining the following coverage score:

$$\mathcal{L}_{cov} = \log(D_{abs}/D_{all}), \tag{4}$$

where D_{abs} is the number of unique discourse roles appearing in an abstract and D_{all} is the total number of possible discourse roles. This objective allows us to penalize abstracts that are missing discourse roles. For example, an abstract that fails to mention anything about the results of the study would be penalized.

S_{i-1}	S_i
BACKGROUND	BACKGROUND
BACKGROUND ∨ METHOD ∨ OBJECTIVE	METHOD
BACKGROUND ∨ OBJECTIVE ∨ METHOD	OBJECTIVE
OBJECTIVE ∨ METHOD ∨ OTHER	RESULT

Table 1: Discourse Role Ordering

3.1.2 Ordering

We also score the order in which discourse labels appear in generated abstracts. In Table 1, we hard-code valid orderings of discourse labels for generated sentences based on each of the abstract discourse roles of Cohan et al. (2019). If the ordering for two adjacent sentences in the abstract $O(s_{i-1}, s_i)$ is valid, the score for the ordering is 1 (-1 otherwise). We sum the scores for all the orderings within a particular abstract and normalize between 0 and 1 (as described by f_n):[3]

$$\mathcal{L}_{order} = \log(f_n(\sum_{i=1}^{S} O(s_{i-1}, s_i))) \tag{5}$$

We also impose a rule for s_1='BACKGROUND' and a rule for s_S='RESULT' to encourage more natural orderings.

---

[1] The labels are {BACKGROUND, METHOD, OBJECTIVE, RESULT, OTHER}.

[2] See (Cohan et al., 2019) for model and training details.

[3] See the Appendix for a more detailed description of the f_n function.

3.1.3 Adjacency Classification

To model the likelihood of adjacency between two sentences s_u and s_v, we first compute a hidden representation of the sentence pair using SciBERT (Beltagy et al., 2019). The encoder input is the concatenation of the sentences: $\mathbf{s} = [\mathrm{CLS}] + s_u + [\mathrm{SEP}] + s_v + [\mathrm{SEP}]$, where $[\mathrm{CLS}]$ is a special token associated with the task and $[\mathrm{SEP}]$ is a sentence delimiter token. Each word in the sequence is encoded by a word embedding w_i and positional embedding p_i and passed through the SciBERT model to yield $\mathbf{h}_{cls}$, the output state at the position of the $[\mathrm{CLS}]$ token. We then obtain the probability of adjacency between the sentences by a linear projection of $\mathbf{h}_{cls}$ followed by a sigmoid activation:

$$P_{adj}(\mathbf{s}) = \sigma(\mathbf{w}_{disc}^{\top}\mathbf{h}_{cls}) \quad (6)$$

We define the training objective for the adjacency discriminator to minimize the negative log likelihood of predicting whether two sentences are adjacent or not:

$$\mathcal{L}_{disc} = -\Big(\delta_{adj}(\mathbf{s}) \cdot \log(P_{adj}(\mathbf{s})) + (1 - \delta_{adj}(\mathbf{s})) \cdot \log(1 - P_{adj}(\mathbf{s}))\Big), \quad (7)$$

where $\delta_{adj}(\mathbf{s})$ is an indicator function for whether the two sentences in $\mathbf{s}$ are adjacent. We note that while the discourse discriminators mainly focus on narrative structure, they may also capture context-aware aspects of factuality and content selection.

3.2 Factuality and Faithfulness

To measure factuality of generated summaries, we predict which tokens in the summary are likely to belong to a fact-checking evidence span (i.e., a span of the text used to prove a scientific claim using a finetuned BERT token classification model.[4] Recent work has shown that inspecting attention weights alone is not necessarily a reliable metric for determining saliency of particular aspects in the input context to the output of neural models (Serrano and Smith, 2019). The saliency weights representing the likelihood of tokens belonging to evidence spans provides us with a more explicit representation of factual importance.

We obtain proxy saliency labels for the importance of a particular token t appearing in an abstract using a BERT model trained on evidence spans annotated for scientific fact-checking (Wadden et al., 2020). Specifically, if t is not a stopword and $t \in E$, where E is an evidence span used to check a scientific claim, then we assign a label of 1 to t. Otherwise, the label for t is 0. Examples of extracted spans are given in table 2.

Topic	Spans
NLP	existing semantic schema, annotation effort, music knowledge representation, siri assistant
BIO	biological system, ptotic, cybernetics entropy , shannon established fundamental limits

Table 2: Salient spans extracted using factuality discriminator.

We compare the predicted evidence spans against information presented in the original introduction to capture the degree to which generative models are hallucinating information.

Factuality Objective At inference time, we compare the extracted salient spans, $F(g)$, of the generated summary g against the set of all ngrams in the article input context, $N(a)$, measuring the degree to which salient spans are hallucinated:

$$\mathcal{L}_{fact} = \log\Big(\frac{|\{f | f \in F(g), f \in N(a)\}|}{|F(g)|}\Big) \quad (8)$$

4 Reranking with Discourse and Factuality Experts

To incorporate the discriminator objective into our summarization framework, we first generate a pool of candidate summaries from the base summarization model (§2) using any decoding strategy (e.g., beam search or top-k sampling). Then, the discriminator is used to re-rank these candidates in conjunction with the original token-level generator scores. For example, in the case of the adjacency discriminator, we maximize the generator token-level probability of a candidate summary g, and the average of adjacency scores for the set of sentences composing g (denoted $S(g)$) – i.e., the probability of each sentence s_u being adjacent to the previous sentence s_{u-1} in $S(g)$:

$$\mathrm{score}(g) = \lambda_{gen}\frac{1}{|g|}\sum_{i=1}^{|g|}\log P(w_i | w_1, ...w_{i-1}) + \lambda_{disc}\frac{1}{|S(g)| - 1}\sum_{u=2}^{|S(g)|}\log P_{adj}(s_u, s_{u-1}), \quad (9)$$

---

[4] See Appendix A.4 for details of token classification model.

Table 3: Domain subset sizes

where λ_{gen} and λ_{disc} are hyper-parameters controlling the contribution of the generator and adjacency discriminator to the final predicted summary. The same procedure is followed for the other discourse and factuality objectives, replacing $P_{adj}(s_u, s_{u-1})$ with the scores from these discriminators.

5 Data

5.1 Datasets

Since the focus of this work is on generating summaries with more coherent narrative flow and greater factual consistency, we concentrate on datasets requiring discourse structure to generate good summaries. Particular attributes of the discourse structure of these datasets include:

- Length of summaries → Are the summaries long enough to clearly show narrative flow properties and factual correctness?
- Abstractiveness of gold summaries → Do the summaries exhibit particular sentence-level flow, or are the summary sentences extracted highlights from the context?

ArXiv We crawled over 700K samples (472K abstracts) from scientific articles on `arxiv.org`. In our experiments we primarily focus on the CS[5] and Bio[6] domain subsets. The task we define is to generate an abstract given a introduction, which presents a challenge to existing summarization models. This task also requires models to learn relevant domain knowledge for the scientific domain of interest and recognize common discourse structure for papers written in that domain.

AAN Additionally, we include an existing dataset of scientific articles that focuses on papers in the NLP computer science domain. This dataset consists of a 12k paper subset from the ACL Anthology Network (AAN; Radev et al., 2009) with extracted introduction and abstract pairs.

Scientific abstracts in ArXiv and AAN have properties that are missing from existing summarization datasets based on Newswire data. For example, XSum (Narayan et al., 2018) and Newsroom (Grusky et al., 2019) summaries are generally too short to exhibit cross-sentence narrative flow. Meanwhile, CNN/DailyMail (Hermann et al., 2015) summaries are acquired by concatenating extracted highlights, which can be unrelated. Conversely, ArXiv and AAN abstracts are long enough to have multiple sentences,[7] and generally exhibit strong discourse patterns typical to scientific writing, making them ideal corpora for assessing discourse understanding in abstractive summarization. Table 3 provides details of dataset splits.

6 Experimental Setup

Our implementation is based on the Huggingface implementation[8] of the BERT (Devlin et al., 2019) and GPT-2 language models (Radford et al., 2019).

Generator We perform WordPiece tokenization for the input context and output summaries. Because of the fixed input size of the transformer language model, the input context is truncated to a maximum of 800 tokens, and summaries are truncated to a maximum of 200 tokens. We use a learning rate of 2e-5 and a batch size of 16 to finetune the generator. We train the base summarization transformer model for 12 epochs. All experiments are run on either a Titan-X or Quadro RTX 8000 GPU. Training time for the AAN and ArXiv Bio datasets is about 30 minutes per epoch. Training time for the ArXiv CS dataset is 2.5 hours per epoch. In our experiments we use top-k sampling with k=4 (Fan et al., 2018) to generate candidate summaries for each model.

Discriminator At training time we use a maximum sentence length of 200 tokens to accommodate the fixed input size of BERT (512 tokens), reduce inference time, and discourage the model from generating abnormally long run-on sentences that indicate the presence of coherence issues.[9]

For the adjacency discourse models, we fine-tune the discriminator using a learning rate of 2e-5, a linear warmup learning rate schedule, and a batch size

Table 5: BERTScore results on AAN subset (F1)

of 32. All adjacency discourse discriminator models are fine-tuned for 2 epochs on a Titan-X GPU. The adjacency discriminator models are adapted from the Huggingface implementation of the BERT next sentence prediction classifier. We initialize the 12-layer BERT-base discriminator model with the pretrained weights of the SciBERT-uncased model, which was originally trained on 1.14 million scientific papers (Beltagy et al., 2019). Two discriminators are trained: one is fine-tuned on AAN for decoding both ArXiv CS and AAN, while the other discriminator is fine-tuned on ArXiv Bio and used exclusively for decoding that subset. We weigh the generation and discriminator models equally when decoding by setting λ_{gen}=λ_{disc}=.5. Additional implementation details are provided in Appendices A.3 and A.4.[10]

7 Experiments

We compare against extractive approaches using the Lede-3 and LexRank (Erkan and Radev, 2004) baselines. We also compare against two abstractive approaches: a 2-layer bi-LSTM sequence-to-sequence model with attention (LSTM), and a pointer-generator model (PGen; See et al., 2017). Training details of the supervised baselines can be found in the Appendix A.2. In addition, we compare to a subset of our approach that only uses the generator to produce summaries, rather than the full framework.

7.1 Automatic Evaluation

Following previous work on summarization, we use the ROUGE metric (Lin, 2004) for automatic evaluation of generative models and Co-opNet. Specifically, we report ROUGE-1, ROUGE-2 and ROUGE-L F1 scores. To capture similarity in contextual meaning, we look at BERTScore F1 (Zhang et al., 2020a), which has been shown to more closely correlate with human judgements than other generation metrics.

Results on the AAN, CS and Bio subsets of ArXiv are shown in Table 4. Co-opNet outperforms all baselines on ROUGE-1 and ROUGE-L by a consistent margin. Notably, Co-opNet's performance is superior to the generator-only model, illustrating the importance of the discriminators for generating more coherent summaries. Interestingly, on the more domain-specific AAN subset, our model is over 12% better on ROUGE-L compared to the PGen baseline and 5.86% better than the best extractive model. Our model also outperforms the strongest baselines on BERTScore.

When we break down results for various Co-opNet architectures (see Table 6), we find that the factuality and discourse role discriminators lead to the best performance in terms of ROUGE scores with the adjacency discriminator achieving lower performance on ROUGE than the base generator. However, as shown by Table 5, the adjacency discriminator outperforms the base generator when we consider BERTScore, a more contextual evaluation metric, indicating that this generator-discriminator combination selects summaries that capture the same linguistic patterns and meaning as reference summaries without directly copying.

7.2 Human Evaluation

Since coherence of generated text is difficult to measure with automatic metrics (Kilickaya et al., 2017; Sun et al., 2019; Clark et al., 2019), we

Table 7: Human Evaluation of Co-opNet Architectures (% of judgements for each model)

conduct human evaluations to assess how the discriminator affects generation quality using pairwise model comparisons.

Setup We use four key criteria in all evaluations – abstractiveness, coherence, factuality and best overall quality, which we define as follows:

- Abstractiveness → Which abstract rewords information from the introduction instead of directly copying from the introduction?
- Coherence → Which abstract is more structured, and presents a complete and coherent story about the work done in the paper?
- Factuality → Which abstract is more factually consistent, presenting the same information that appears in the introduction and not producing hallucinated information?
- Overall → Which abstract is better overall?

We conduct human evaluations on Amazon Mechanical Turk (AMT) considering 4 different abstractive baseline model variants over 100 randomly sampled AAN test set examples. Given a gold introduction, AMT evaluators are asked to compare a corresponding abstract generated from Co-opNet against an abstract generated by a baseline or our generator model. To reduce bias, the ordering of generated abstracts are randomized and evaluators are not told that abstracts are machine-generated.

Each abstract pair is judged by three unique annotators. For each criteria, we filter to 50 abstracts based on the amount of time AMT workers spent ($\geq$ 20 seconds) and inter-annotator agreement (at least $\frac{2}{3}$ of annotators should agree on which abstract is best). We also prime annotators to consider subtler aspects of discourse coherence by providing examples that capture good or bad narrative flow without complete text degeneration.

We test the Co-opNet framework using both the factuality and adjacency discriminators, as these are the highest and lowest performing discriminator architectures in terms of automatic metrics on the AAN domain. We allow for ties, as Co-opNet and the generator baseline sometimes assign the highest probability to the same abstract, or generated abstracts in the candidate pool are high quality enough that there is little room for improvement.

Results We find that Co-opNet is preferred across all criteria for all comparisons, when we use the adjacency discriminator (see Table 7). When using the the factuality discriminator, Co-opNet is superior to baselines in all cases except when compared on abstractiveness to the PGen model.

In particular, human evaluators prefer Co-

Table 8: Example of gold and generated abstracts from baseline Pointer Networks + Coverage (See et al., 2017) (PGen) and two of our proposed models, Generator and Co-opNet, on the NLP scientific domain. Coherence issues and factual errors in generated abstracts are highlighted in *italics*. We highlight correct terminology and transitional phrases that contribute to coherent flow by properly delineating sections of abstracts in ***bold*** and ***italics***.

opNet with the adjacency discriminator over baselines by over 8% on the coherence metric and 18.12% compared to PGen on overall quality. Notably, the adjacency discriminator encourages more abstractiveness in generated abstracts while still maintaining higher levels of factual consistency. We also find that Co-opNet with the factuality discriminator improves coherence and overall quality in addition to factuality. However, Co-opNet generations with the factuality discriminator were found to be more extractive than abstracts generated by PGen.

As shown in Table 8, generations selected by the adjacency discriminator more closely match the distribution of abstracts, while the generator sometimes favors copying from the introduction at the loss of narrative structure. For example, the generator will select a summary that opens with "*we present a method for jointly solving penn treebank style empty category (e.g. figure 1)...*", while the adjacency discriminator selects a summary that opens with "*we present a method to jointly solve the problem of empty categories...*" and does not refer to a particular figure. Both summaries are faithful to the introduction, but the discriminator-selected summary makes more sense in the context of a paper abstract.

8 Related Work

Narrative Flow and Factuality Modeling coherent narrative flow remains a major challenge in the field of text generation, due to the need for accurate understanding of narrative structure (Christensen et al., 2013; Nikolov et al., 2018; Holtzman et al., 2018; Qin et al., 2019; Koncel-Kedziorski et al., 2019; Gabriel et al., 2021). Early approaches to incorporating structure include integration of explicit discourse markers into automatic summarization (Alonso i Alemany and Fuentes Fort, 2003). Recently proposed solutions include global-tracking of entities (Kiddon et al., 2016; Bosselut et al., 2018; Mei et al., 2016), as well as discourse-aware attention (Cohan et al., 2018). While there has been prior work on factual consistency (Cao et al., 2018; Gao et al., 2019; Kryściński et al., 2020; Zhang et al., 2020b), these works did not focus on scientific paper summarization.

Neural Abstractive Summarization In the past, abstractive summarization models (Rush et al., 2015; Gehrmann et al., 2018) have relied upon seq2seq encoder-decoder architectures (Sutskever et al., 2014; Narayan et al., 2018; Celikyilmaz et al., 2018). Transformer models have emerged as a promising architecture for text generation and summarization (Liu et al., 2018; Hoang et al., 2019; Khandelwal et al., 2019; Zhang et al., 2019). While our model builds upon this work, it is, to our knowledge, the first transformer summarization framework to explicitly model narrative flow and scientific fact-checking across domains.

9 Conclusion

In this work, we introduced *Cooperative Generator-Discriminator Networks*, a framework for more coherent natural language generation with transformer language models through the integration of discriminators that encourage proper narrative flow and factual consistency. Through our analyses over scientific papers from ArXiv and AAN, we empirically showed that our framework selects generations that are more relevant and narratively coherent than previous approaches.

A Appendices

A.1 Additional Implementation Details

A.2 Baselines

For the sequence-to-sequence RNN model, a bi-LSTM is used to encode a given source article a and a separate decoder LSTM produces the generated summary g. At each decoding time step, the decoder attends to all the context vectors produced by the encoder as well as the maintained state from the previous decoder tokens to produce the next token in the summary.

The Pointer-Generator (PGEN + Cov) model extends the base LSTM model (LSTM + Cov) to allow tokens to be copied from the input during generation. Baselines are trained for up to 40000 steps with a batch size of 16. Following previous work, we decode from these baselines using beam search with a beam size of 4.

A.3 Generator Model

We use the 345M parameter GPT-2 model. The model is trained to minimize the negative log likelihood of the next word w_i given all preceding words:

$$\mathcal{L}_{gen} = -\sum_{i=1}^{|a|+|s|} \log P(w_i | w_0, ... w_{i-1}) \tag{10}$$

where w_i is the i^{th} token of our full input vector X, a is our article and s is our summary. At test time, X only consists of the gold article and delimiter token $(a_1, ..., a_{|a|}, [\text{SEP}])$ and we decode generated summaries g starting from this input.

During generation, we filter candidate summaries from the hypothesis generation pool that contain sentences longer than a fixed max length of 200 tokens, a clear sign of coherence deterioration. We use a candidate pool size of 30 for ATLAS and 20 for AAN.

A.4 Discriminator Training

Factuality Discriminator Details For the token-level classification model, we use the BERT base model with binary labels for whether or not a token should be included in a salient span. We predict for all spans in an abstract at once.

Order Discriminator Details We set the max length of summaries considered by the order discriminator to be 10 sentences, truncating longer summaries. Given the max length of a summary, we have a fixed number of orderings |O| that can be scored. We calculate the final score from the order discriminator based on the unnormalized sum of scores from these orderings, S, and the following function f_n:

$$f_n(S, |O|) = \frac{S - (-|O|)}{|O| - (-|O|)} \tag{11}$$

Sentence Selection for Discriminator Models To train an adjacency discriminator model, we use a subset of adversarial and positive sentence pair examples extracted from the training set. The sentence pairs are extracted from gold abstracts containing at least five sentences using the following approach: For a randomly selected sentence s_u from the abstract, we randomly select an adjacent sentence, s_{u-1} or s_{u+1}, as a positive example and any nonadjacent sentence $s_{v \notin [u-1, u, u+1]}$ as a negative example.

Discriminator Performance We measure the performance of discriminator models using recall, precision, accuracy and F1. Table 9 provides summary statistics of discriminator performance on the various discourse and factuality objectives. Discourse-Adj denotes the adjacency discriminators, while Discourse-Abs denotes the discourse role label prediction model (Cohan et al., 2019) and Factuality denotes the token saliency prediction model.

Model	Training Data	Prec	Rec	F1	Acc
Discourse-Adj	ArXiv-AAN	86.05	85.25	85.65	86.81
Discourse-Adj	ArXiv-Bio	90.30	93.44	91.84	92.32
Discourse-Abs	CSAbstruct	88.99	89.09	89.04	89.00
Factuality	SciFact	73.70	70.50	72.10	75.70

Table 9: Automatic Evaluation of discriminator architectures

A.5 Details on Model Performance

Automatic results for Co-opNet selection were given using a context size of 800 tokens for the input, while a context size of 800 characters was used to select Co-opNet summaries for the human eval. The automatic results for the summaries used in the human eval were lower than the ones using the longer context size. Using a smaller context size leads to faster and more efficient Co-opNet selection (less memory usage), but slightly lower overall automatic performance (while maintaining the same ordering in terms of highest and lowest scores for Co-opNet variants on ROUGE).

A.6 Comparison of Datasets

We removed duplicates and articles without abstracts from AAN. From this subset, we extract introduction and abstract pairs.

A.7 Additional Analysis

Comparison with Gold Summaries To obtain an upper-bound comparison for the human evaluation and verify the effectiveness of our human evaluation pipeline for judging the quality of abstracts, we used the same intro-abstract pairs and Mturk annotation framework as the model comparison to conduct a Turing-style evaluation. In this evaluation, we presented a Co-opNet (adj) generated abstract and a gold abstract to the annotators in a random ordering without noting whether either of the abstracts were human-written or machine-generated. We found that annotators consistently selected the gold abstract over the machine-generated abstract when considering factuality and coherence, though they found the machine-generated abstracts to be slightly more abstractive. We provide the results for this full evaluation in Table 11.

Abstract

Knowledge Base Question Answering (KBQA) is the problem of predicting an answer for a factoid question over a given knowledge base (KB). Answering questions typically requires reasoning over multiple links in the given KB. Humans tend to answer questions by *grouping* different objects to perform reasoning over acquired knowledge. Hypergraphs provide a natural tool to model group relationships. In this work, inspired by typical human intelligence, we propose a new method for KBQA based on hypergraphs. Existing methods for KBQA, though effective, do not *explicitly incorporate the recursive relational group structure* in the given KB. Our method, which we name RecHyperNet (Recursive Hypergraph Network), exploits a new way of modelling KBs through recursive hypergraphs to organise such group relationships in KBs. Experiments on multiple KBQA benchmarks demonstrate the effectiveness of the proposed RecHyperNet. We have released the code.

1 Introduction

Knowledge Base Question Answering (KBQA) (Xu et al., 2016)), a task that tests the ability of a machine to understand knowledge like a human, is a challenging, central, and popular task in natural language processing. KBQA is the problem of predicting an answer for a factoid question over a given knowledge base (KB) containing facts such as (Inception, written by, Christopher Nolan). Answering questions typically requires reasoning over multiple links in the given KB (Zhang et al., 2018).

When a typical human answers a question (e.g. What are the genres of movies written by Christopher Nolan?), they tend to group objects (e.g. movies written by Christopher Nolan such as Inception, Interstellar, etc. are grouped together) over their acquired knowledge. Hypergraphs are mathematical tools that naturally encode group relationships. Directed hypergraphs have been recently used to model KBs for KBQA (Han et al., 2020) but we argue that they fail to naturally model group relationships without loss of information. Spcifically, two KB triples such as (Inception, written by, Christopher Nolan) and (Person of Interest, written by, Jonathan Nolan) would be modelled by a directed hyperedge {Inception, Person of Interest} -> {Christopher Nolan, Jonathan Nolan} clearly resulting in loss of information (not clear who directed which). Though objects of similar types are grouped together and directions are encoded, directed hypergraphs fail to model KBs without loss of information.

We argue that recursive hypergraphs (Joslyn and Nowak, 2017; Menezes and Roth, 2019) provide a flexible way to model KBs without loss of information. Specifically, all movies written by Christopher Nolan are grouped together and those written by Jonathan Nolan are *separately* grouped together. To summarise, we make the following contributions

- We model KBs as recursive hypergraphs. To the best of our knowledge, this is the first such attempt for natural language processing.
- We propose RecHyperNet (Recursive Hypergraph Network), a novel graph neural network-based model to exploit recursive hypergraphs and apply it for KBQA.
- We show the effectiveness of RecHyperNet on multiple KBQA benchmarks. We have released the source code in the supplementary.

2 Related Work

Knowledge Base Question Answering (KBQA) has been widely investigated especially through

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 448–454
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

end-to-end deep neural networks since the release of popular datasets such as MetaQA (Zhang et al., 2018). One of the first attempts at KBQA was key-value memory network (KVMN) (Miller et al., 2016) that maintained memory to store KB facts and text as key-value pairs. Graphs of Relations Among Facts and Text Networks (GraftNet) (Sun et al., 2018) uses a heterogeneous GCN-based method to fuse information from heterogeneous sources (KBs and text). SubgraphReader (SGReader) (Xiong et al., 2019) employs a graph attention-based method to combine unstructured text and structured KB. PullNet (Sun et al., 2019) also uses a GCN to identify subgraph nodes that should be retrieved ('pull') from text and KB. More recently, EmbedKGQA (Saxena et al., 2020) uses ideas from knoweldge graph embedding literature to improve knowledge base question answering esp. on sparser incomplete knowledge graphs. Two-Phase Hypergraph Based Reasoning with Dynamic Relations (2HR-DR) (Han et al., 2020) is a directed hypergraph-based method for KBQA. The reader is referred to a comprehensive literature review on this topic (Fu et al., 2020).

Graph Neural Networks (GNNs): While deep neural networks such as convolutional neural networks and recurrent neural networks are specially designed for grids and sequences respectively, GNNs (Kipf and Welling, 2017; Hamilton et al., 2017; Veličković et al., 2018) are specially designed to learn representations from graph-structured data. GNNs have been recently extended to hypergraphs (Feng et al., 2019; Yadati et al., 2019). The first published works of GNNs for NLP investigated the tasks of semantic-role labelling (Marcheggiani and Titov, 2017), and neural machine translation (Bastings et al., 2017). A recent tutorial touches upon the recent advances of GNNs in NLP (Vashishth et al., 2019).

GNNs for Question Answering (QA): A popular task closely related to question answering is multi-hop reasoning across documents (context passages) where GNNs have been extensively used (Qiu et al., 2019b; Ding et al., 2019; Tu et al., 2020). Graph Attention Networks (Veličković et al., 2018) have been shown to be effective for modelling the multi-grained structure of documents for machine reading comprehension (MRC) (Zheng et al., 2020). GNNs have also recently been used on heterogeneous data sources for MRC (Kim et al., 2019; Tu et al., 2019), knowledge graphs for QA (De Cao et al., 2019; Cao et al., 2019; Lin et al., 2019; Qiu et al., 2019a; Feng et al., 2020; Ji et al., 2020; Shao et al., 2020), answer sentence selection (Tian et al., 2020), and QA on tables (Zhang, 2020) and math (Chen et al., 2020). In all these publications except 2HR-DR (Han et al., 2020), the input is a graph and limited to modelling pairwise relationships. We address this fundamental limitation by modelling a knowledge graph as a recursive hypergraph 2HR-DR models knowledge graphs through directed hypergraphs but we argue that they are more naturally represented by recursive hypergraphs.

3 Method

We describe the KBQA problem, and how recursive hypergraphs (Menezes and Roth, 2019; Joslyn and Nowak, 2017) can be used to model knowledge bases. We then describe our method of exploiting recursive hypergraphs for KBQA.

3.1 KBQA Problem

The KBQA problem considered in this work is as follows. We are given a knowledge base $\mathcal{K} \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$ with entity set $\mathcal{E}$ and relation set $\mathcal{R}$. We are also given a natural language question q with a topic entity $e \in \mathcal{E}$. The task is to output an answer $a \in \mathcal{E}$ that correctly answers the question q.

3.2 Recursive Hypergraph

In this subsection, we precisely define a recursive hypergraph by first defining the following.

Definition 1 (Depth k Powerset)**.** *For a set S, let us use $\mathcal{S}(S)$ to denote the powerset of S i.e. $\mathcal{S}(S) := \{\dot{S} : \varnothing \subseteq \dot{S} \subseteq S\}$. Then, the the depth k powerset of S is*

$$2^{S,k} := \mathcal{S}\left(\bigcup_{i=0}^{k} S_i\right) \tag{1}$$

where $S_0 = S, S_i = \mathcal{S}\left(\bigcup_{j=0}^{i-1} S_j\right)$, for $i \geq 1$.

Note that $2^{S,0} = \mathcal{S}(S)$ i.e. $2^{S,0}$ is powerset of S.

Definition 2 (k-Recursive Hypergraph)**.** *A pair $H = (V, E)$, where V is a set of n vertices, and $E \subseteq \left(2^{V,k} - \varnothing\right)$ is a set of recursive hyperedges.*

Note that a hypergraph in the traditional sense is a 0-recursive hypergraph. We call a hyperedge $e \in E$ as a depth k hyperedge if $e \subseteq 2^{V,k}$ but $e \nsubseteq 2^{V,k}$.

3.3 Modelling knowledge Base as a Recursive Hypergraph

One of our main contributions in this work is to model a knowledge base as a 1-recursive hypergraph with $V = \mathcal{E} \cup \mathcal{R}$ as the set of vertices. Each head entity can be seen as a depth 1 hyperedge connecting all its relations. Each relation can be further seen as a depth 0 hyperedge connecting all the tail entities. For example, if a knowledge base contains the movie "Inception" as a head entity with (relation, object) pairs as 1) (starred actors, Leonardo DiCaprio), 2) (starred actors, Ellen Page), 3) (starred actors, Tom Hardy), 4) (genre, action), 5) (genre, adventure), and 6) (genre, science fiction), and 7) (written by, Christopher Nolan) then we can view them as a recursive hypergraph with Inception as a depth 1 hyperedge connecting relation vertices starred actors, genre, and written by. Each of these relation vertices is in turn a depth 0 hyperedge connecting object entities. For example, the object entities Leonardo DiCaprio, Ellen Page, and Tom Hardy are contained in a single hyperedge (that represents the pair Inception, starred actors).

3.4 RecHyperNet for KBQA

In this section, we describe our proposed methodology for KBQA. The main ingredients/modules of RecHyperNet are three modules: KB Embedding Module, Topic and Question Embedding Module, and Answer Retrieval Module.

1) KB Embedding Module uses knowledge base embedding methods to initialise entity embeddings of the input KB. We denote these initial embeddings by $x_e, e \in \mathcal{E}$. Popular knowledge base embedding methods include TransE (Bordes et al., 2013), and ComplEX (Trouillon et al., 2016).

2) Topic and Question Embedding Module embeds the question q to a fixed dimension vector $\boldsymbol{q}$ of dimension d. We use a feed-forward neural network that first represents q using LSTM/ RoBERTa (Liu et al., 2019). The topic entity e that is also present in the question is embedded using a multi-relational graph convolutional network on the KB (Vashishth et al., 2020). The entity update rule for Composition-based multi-relational graph convolutional network (CompGCN) is as follows:

$$\boldsymbol{h}_v = f\left(\sum_{(u,r)\in\mathcal{N}(v)} \boldsymbol{W}\phi(\boldsymbol{x}_u, \boldsymbol{z}_r)\right), \qquad (2)$$

where $\boldsymbol{x}_u$ and $\boldsymbol{z}_r$ are initial features of vertex u and relation r respectively. ϕ is a composition function that is dictated by the knowledge base embedding method and f is a non-linear activation function such as Rectified Linear Unit. $\mathcal{N}(v)$ is the (relation, object) neighbourhood of the vertex v (for example, the 7 pairs listed for "inception" movie entity in the previous subsection).

Our key modification to CompGCN update rule is motivated through the proposed recursive hypergraph view of knowledge base. Specifically, since each relation can be seen as a hyperedge containing all object entities, we can modify the update rule as follows

$$\boldsymbol{h}_v{=}f\left(\textstyle\sum_{r\in N(v)} \boldsymbol{W}\phi\left(\max_{u\in\mathcal{N}(v,r)}(\boldsymbol{x}_u){,}\boldsymbol{z}_r\right)\right), \qquad (3)$$

where $N(v)$ is the set of all relations in the neighbourhood of v, and $\mathcal{N}(v, r)$ is the set of all object entities connected by the (subject, relation) pair (v, r). $\max$ is the element-wise maximum of a set of vectors. We can replace $\max$ by other aggregator functions such as mean, and sum but we experimentally observed that $\max$ gives the best performance. We embed the topic head entity $e \in \mathcal{E}$ using Equation 3 and obtain the hidden representation $\boldsymbol{h}_e$ with the same dimension d. We finally pass the concatenated representation $\boldsymbol{h}_e||\boldsymbol{q}$ to a 2-layer feed-forward neural network to get the topic and question representation.

3) Answer Selection Module Given a KB embedding scoring function Φ and a set of answer entities $\mathcal{A} \subseteq \mathcal{E}$, we learn the topic and question representation $\boldsymbol{h}_e||\boldsymbol{q}$ so that $\Phi(x_e,\ \boldsymbol{h}_e||\boldsymbol{q},\ x_a) > 0,\ \forall a \in \mathcal{A}$ and $\Phi(x_e,\ \boldsymbol{h}_e||\boldsymbol{q},\ x_{\bar{a}}) > 0,\ \forall \bar{a} \notin \mathcal{A}$. We leartn the model parameters by minimising the binary cross entropy loss between the sigmoid of the scores and the target labels (1 for correct, 0 for wrong).

During test time, we score the given (topic head entity, question) pair against all possible answers $a' \in \mathcal{E}$. So, the answer is given by $\arg\max_{a'\in\mathcal{E}} \Phi(x_e,\ \boldsymbol{h}_e||\boldsymbol{q},\ x_{a'})$.

4 Experiments

We evaluate our proposed method on MetaQA (Zhang et al., 2018) and WebQuestionsSP (Yih et al., 2016) datasets. We closely follow the experimental setup of a prior work (Saxena et al., 2020) for the preprocessed versions of these datasets. MetaQA consists of $400k$ questions ($1 - hop$, 2-hop, and 3-hop), and a knowledge graph of 135k triples, 43k entities, and 9 relations. WebQuestionsSP consists of 4700 questions and a knowledge

RecHyperNet	**92.3**	**53.7**
replace Eq. 3 by Eq. 2	90.4	52.1
use $\boldsymbol{q}$ in place of $\boldsymbol{h}_e \| \boldsymbol{q}$	85.6	50.7

Table 3: Ablation study on MetaQA KG-50 (2-hop) and WebQSP KG-50

graph of 1.8 million entities, and 5.7 million triples. Following prior work (Saxena et al., 2020), we experimented on two different settings (for both datasets) - **KG Full** (in which the KG is left untouched), and the more realistic **KG-50** setting in which 50% links are randomly removed. We compared against 7 different baselines as shown in Table 1. Please see Section 2 (subsection: Knowledge Base Question Answering) for brief descriptions of the baseline methods.

Model details Following prior work (Saxena et al., 2020), we used a long short term memory (LSTM) network to learn embeddings for words in the questions with an embedding size of 256 for MetaQA and RoBERTa (768 dimensional embeddings) (Liu et al., 2019) for WebQuestionsSP datasets. The hidden dimension size for graph convolutional network was also set to 256. A dropout rate of 0.2 was used for all neural layers.. All models were implemented in PyTorch (Paszke et al., 2019) and trained with ADAM as the optimiser (Kingma and Ba, 2015), a learning rate of 5×10^{-4}, weight decay of 1.0, a batch size of 128 trained for 100 epochs (with patience of 5).

Results. Table 1 shows the results. We evaluated our proposed method and all baselines through Hits@1 metric. As we can see in Table 1, exploiting recursive hypergraphs through our proposed method help. Methods such as PullNet and GraftNet utilise additional text corpus (unrealistic setting as it is not always readily available) to answer questions while our method does not. We exploit only the given knowledge base structure. Futhermore, as shown in Table 2, baselines such as GraftNet and PullNet perform poorly in the absence of text.

Ablation Analysis We conducted an ablation study by removing essential components from RecHyperNet. Specifically we replaced our proposed Equation 3 to exploit recursive hypergraphs by the exisdting Equation 2 of CompGCN. As another basline, we removed the embedding of topic head entity obtained through GCN and used only the question representation while scoring. As shown in Table 3, both these components are essential for our proposed RecHyperNet.

Conclusion and Future Work In this work, we exploit recursive hypergraphs in NLP for the task of KBQA. We have proposed a novel method based on graph convolutional networks. We have demonstrated the effectiveness of RecHyperNet on KBQA benchmarks. In future, we exploit recursive structures for other tasks where graph neural nets are effective such as question generation (Pan et al., 2020), sentiment analysis (Wang et al., 2020), etc.

FEWS: Large-Scale, Low-Shot Word Sense Disambiguation with the Dictionary

Abstract

Current models for Word Sense Disambiguation (WSD) struggle to disambiguate rare senses, despite reaching human performance on global WSD metrics. This stems from a lack of data for both modeling and evaluating rare senses in existing WSD datasets. In this paper, we introduce FEWS (Few-shot Examples of Word Senses), a new low-shot WSD dataset automatically extracted from example sentences in Wiktionary. FEWS has high sense coverage across different natural language domains and provides: (1) a large training set that covers many more senses than previous datasets and (2) a comprehensive evaluation set containing few- and zero-shot examples of a wide variety of senses. We establish baselines on FEWS with knowledge-based and neural WSD approaches and present transfer learning experiments demonstrating that models additionally trained with FEWS better capture rare senses in existing WSD datasets. Finally, we find humans outperform the best baseline models on FEWS, indicating that FEWS will support significant future work on low-shot WSD.

1 Introduction

Word Sense Disambiguation (WSD) is the task of identifying the *sense*, or meaning, that an ambiguous word takes in a specific context. Recent WSD models (Huang et al., 2019; Blevins and Zettlemoyer, 2020; Bevilacqua and Navigli, 2020) have made large gains on the task, surpassing the estimated 80% F1 human performance upper bound on WordNet annotated corpora (Navigli, 2009). Despite this breakthrough, the task remains far from solved: performance on rare and zero-shot senses is still low, and in general, current WSD models struggle to learn senses with few training examples (Kumar et al., 2019; Blevins and Zettlemoyer, 2020). This performance gap stems from limited data for rare senses in current WSD datasets, which are annotated on natural language documents that contain a Zipfian distribution of senses (Postma et al., 2016).

C: I **liked** my friend's last status...
S1: to enjoy... [or] be in favor of.
✓ **S2**: To show support for, or approval of, something on the Internet by marking it with a vote.

C: A transistor-diode **matrix** is composed of vertical and horizontal wires with a transistor at each intersection.
✓ **S1**: A grid-like arrangement of electronic components, especially one intended for information coding, decoding or storage.
S2: A rectangular arrangement of numbers or terms having various uses [in mathematics].

Figure 1: Sample contexts (**C**) from FEWS with ambiguous words and a subset of candidate sense definitions (**S**). FEWS covers a wide range of senses, including new senses and domain-specific senses.

More generally, since each word has a different set of candidate senses and new senses are regularly coined, it is almost impossible to gather a large number of examples for each sense in a language. This makes the few-shot learning setting particularly important for WSD. We introduce **FEWS** (Few-shot Examples of Word Senses), a dataset built to comprehensively train and evaluate WSD models in few- and zero-shot settings. Overall, the contributions of FEWS are two-fold: as training data, it exposes models a broad array of senses in a low-shot setting, and the large evaluation set allows for more robust evaluation of rare senses.

FEWS achieves high coverage of rare senses by

Zero-shot	5,000	138,838	5,000	5,000	4,666	5.49

Table 1: FEWS data statistics. The development and test sets are balanced across senses and split evenly between few-shot examples (with support in the training set) and zero-shot examples. The extended training set (Ext. Train) adds short examples written by Wiktionary editors as additional training data.

automatically extracting example sentences from Wiktionary definitions. Wiktionary is an apt data source for this purpose, containing examples for over 71,000 senses (Table 1). Not only is this sense coverage higher than existing datasets (e.g., SemCor, the largest manually annotated WSD dataset, only covers approximately 33,000 senses (Miller et al., 1993)), it also extends to senses related to new domains (Figure 1).

We establish performance baselines on FEWS with both knowledge-based approaches and a recent neural biencoder model for WSD (Blevins and Zettlemoyer, 2020). We find that the biencoder, despite being the strongest baseline on FEWS, still underperforms human annotators, particularly on zero-shot senses where the biencoder trails by more than 10%. We also present transfer learning experiments and find adding FEWS as additional training data improves performance on all but the most frequent senses (MFS) in the WSD Evaluation Framework (Raganato et al., 2017); this suggests that future improvements on FEWS could generalize other WSD benchmarks. FEWS is available at `https://nlp.cs.washington.edu/fews`.

2 Related Work

WSD is a long-standing NLP task and is the focus of many datasets. The current *de facto* benchmark for modeling English WSD is the WSD Evaluation Framework (Raganato et al., 2017), which includes the SemCor dataset (Miller et al., 1993) as training data and consolidates a number of evaluation sets (Pradhan et al., 2007a; Palmer et al., 2001; Snyder and Palmer, 2004; Navigli et al., 2013; Moro and Navigli, 2015) into a standardized evaluation suite. These datasets are annotated with the senses (known as *synsets*) from Wordnet, a manually constructed ontology of semantic relations (Miller et al., 1993).

Most existing datasets for WSD, including those in the WSD Evaluation framework and others like Pradhan et al. (2007b), are annotated on natural language documents that contain a Zipfian distribution of word senses (Kilgarriff, 2004). This data source causes these datasets to have low coverage of rare senses, leading to worse performance on these less common senses (Postma et al., 2016; Kumar et al., 2019). In contrast, we use examples sentences from Wiktionary as an alternative source of text for WSD data with FEWS. This means that FEWS has a more uniform sense distribution, providing more balanced coverage across different senses of words.

Wiktionary has previously been used as a resource for WSD research. Most work has investigated mapping Wiktionary senses onto WordNet synsets (Meyer and Gurevych, 2011; Matuschek and Gurevych, 2013); other work has learned similar mappings for Wikipedia articles (Mihalcea (2007); Navigli and Ponzetto (2012); inter alia). More similar to our work, Henrich et al. (2012) and Segonne et al. (2019) mine WSD examples from Wiktionary to augment labeled WSD data for non-English languages. However, FEWS is the first dataset specifically designed to evaluate zero and few-shot learning with the balanced dictionary sense distribution.

3 FEWS: Low-shot Learning for WSD

FEWS (Few-shot Examples of Word Senses) is a new dataset for learning to do low-shot WSD.[1] It is created with example contexts drawn from Wiktionary, an online collaborative dictionary.[2] Since

---

[1] We use the term *low-shot* as an umbrella term for few- and zero-shot learning.

[2] https://en.wiktionary.org/

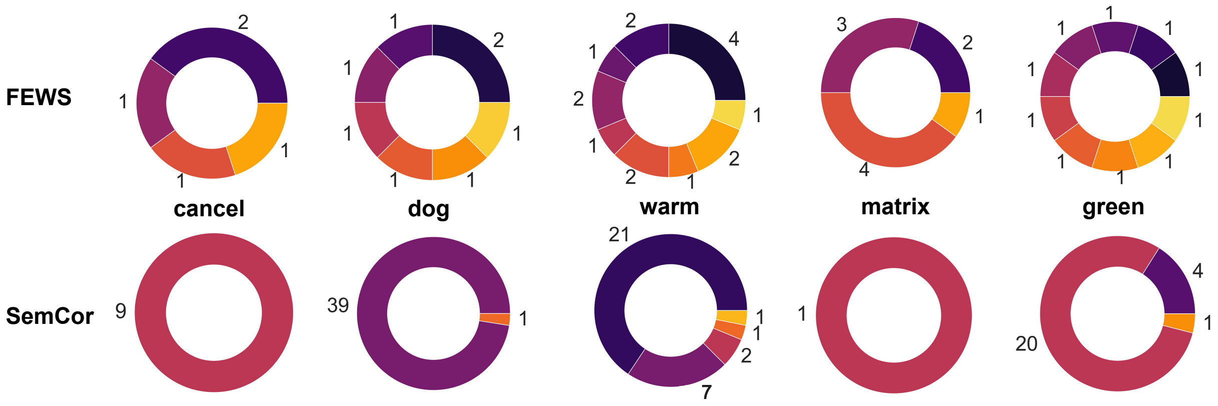

Figure 2: Comparison of sense coverage for five words in the Semcor and FEWS training corpuses.

Wiktionary is curated by volunteers, the data is manually annotated and high quality, and there is no additional annotation cost to construct FEWS. Furthermore, using example contexts from a dictionary allows FEWS to cover many senses underrepresented in existing WSD datasets, such as rare senses of words or senses pertaining to specific domains. However, we note that due to the crowdsourced nature of the examples in Wiktionary and the subjectivity of fine-grained sense distinctions, inconsistencies in the underlying data may introduce some annotation errors into FEWS.

Examples of the data in FEWS are shown in Figure 1. In FEWS, each example context contains one or more instances of the ambiguous *target word* and is labeled with the sense (and corresponding definition) that describes that word as used in the context; this is in contrast to *all-words WSD*, where many of the content words in the context are annotated.

3.1 Dataset Creation

To create FEWS, we extracted all of the definitions for content words (nouns, verbs, adjectives, and adverbs) and example contexts associated with those definitions from a checkpointed version of English Wiktionary.[3] While processing the Wiktionary data, we collected two types of contexts: (1) *quotations* (93% of extracted examples), which are quotations of natural language text found by Wiktionary contributors that contain the target word used with the relevant sense, and (2) *illustrations* (7%), which are short sentences or fragments written by contributors to illustrate the word sense in context. The target words in each context are marked by the Wiktionary formatting metadata; examples where no words are marked or the marked word differs too much from the base form of the dictionary entry are discarded.[4] We additionally filter out examples that are too short to provide a meaningful context for the marked word.

We then labeled the target words in each extracted context with the sense ID generated for the definition associated with that sentence; this gave us 254,506 annotated WSD example contexts covering 148,333 senses. Finally, we filtered out examples with monosemous words since predicting the sense in these cases is a trivial task. However, Loureiro and Camacho-Collados (2020) recently found that unambiguous examples can improve WSD performance; therefore, we include the unambiguous cases as an additional file in the FEWS dataset. After filtering these unambiguous examples from the main dataset, FEWS in total contains 121,459 examples covering 71,391 sense types.

Finally, we split the data into training and evaluation sets. The majority of the data are *quotations*, which we use to populate the train, development, and test sets as they more closely resemble naturally occurring text than the *illustrations*. To create the development and test sets, we randomly select 10,000 examples for each evaluation set and ensure that each of these evaluation examples pertains to a different sense. We verify that half of those examples were labeled with senses that only occurred once in the unsplit data to create a zero-shot subset of each evaluation set, and the other half of the evaluation senses comprise the few-shot evaluation subsets. The remaining quotations that were not

Few-shot†	4,529	67
Zero-shot	5,000	50
Test	10,000	3,669
Few-shot†	4,603	761
Zero-shot	5,000	796

Table 2: The number of senses covered in the **FEWS** and **WSD Framework** evaluation sets. † To fairly compare against the WSD Framework, we only count few-shot examples as those have three or fewer supporting examples in their respective train set.

used for the development or test set are included as the training data. Finally, we remove the *illustrations* for senses in the zero-shot evaluation subsets and add the remaining *illustrations* to the training data; this addition makes the extended train set.

3.2 Dataset Analysis

We present a comprehensive analysis of FEWS to demonstrate that the dataset provides high coverage of many diverse words senses in a low-shot manner.

High Coverage of Words and Senses The FEWS dataset covers 35,416 polysemous words and 71,391 senses (Table 1). The complete dataset covers 53.21% of the senses for words that appear in it (out of their Wiktionary sense inventories). Figure 2 shows this high coverage of senses for five different words compared to the coverage of the same words in SemCor (Miller et al., 1993). We see that while SemCor tends to have more examples for these common words, most examples correspond to a single sense of the word. However, the FEWS train set covers many more senses per word, albeit with fewer total examples.

This high coverage of senses is particularly important for the evaluation sets provided in FEWS (Table 2). Each evaluation set (development and test) covers 10,000 different senses; half of these examples are few-shot and occur in the training set, and the other half of the evaluation senses are zero-shot. In comparison, the current benchmark for WSD evaluation (Raganato et al., 2017) only contains 796 unique zero-shot and 761 unique few-shot senses (where the sense is seen three or fewer times in the SemCor (Miller et al., 1993) training set) across development and test evaluation sets. This much larger sample of few- and zero-shot evaluation examples means that FEWS provides a robust setting to evaluate model performance on less common senses.

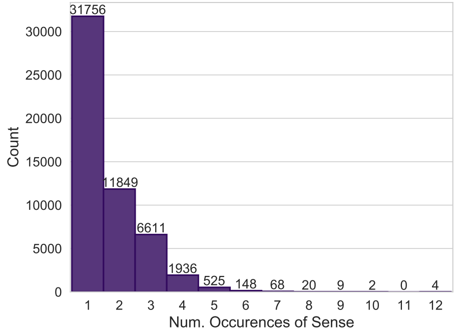

Figure 3: Histogram of sense frequencies in the FEWS training data.

Low-Shot Learning Because the data in FEWS come from example sentences for definitions in Wiktionary, each sense occurs in only a few labeled examples. This low-shot nature of the data is shown for five common words in Figure 2: each sense of these words occurs only one to four times in the training data. Figure 3 shows a histogram of the number of examples per sense in the full training set; we see that the majority of senses seen during training (60%) only occur once and that there are on average 1.65 examples per sense.

This set up also means that all evaluations on FEWS are low-shot (or zero-shot): senses in the few-shot development split have on average 2.06 supporting examples in the training set, with a maximum of 12 examples (these counts increase to 2.13 and 13, respectively, with the extended training data).

Figure 4: Word cloud of the 300 most common tags in the FEWS senses. For clarity, we manually filter out syntactic and uninformative tags.

Domains in FEWS Definitions in Wiktionary are tagged with keywords, which we include as metadata for their respective senses in the dataset. These keywords indicate that the senses in FEWS pertain to topics ranging from literature and archaic English to sports and the sciences and come from various English dialects (Figure 4). FEWS also covers many new domains not covered in existing WSD corpora, with six keywords corresponding to internet culture.

We also find that a number of the senses ($<1\%$ in FEWS) are indicated to be toxic or offensive language: our analysis contains tags such as *ethnic slurs*, *offensive*, *vulgar*, and *derogatory* that correspond to examples of toxic language. For many of these examples, the meaning of the target word is only toxic due to the context in which it appears. These examples provide an opportunity for improving models for hate speech detection and related tasks, but we leave this exploration to future work.

4 Baselines for FEWS

We run a series of baseline approaches on FEWS to demonstrate how current methods for WSD perform on this dataset. We consider a number of knowledge-based approaches (**Lesk**, **Lesk+emb**, and **MFS**) and two neural models that build on pretrained encoders (**Probe**$_{BERT}$ and **BEM**$_{BERT}$). We also ascertain how well humans perform on FEWS as a potential upper bound for model performance.

4.1 Knowledge-based Baselines

Most Frequent Sense (MFS) The MFS baseline assigns each target word in the evaluation with their candidate sense that is most frequently observed as the correct sense of that word in the training set. The MFS heuristic is known to be a particularly strong baseline in WSD datasets labeled on natural language documents (Kilgarriff, 2004); however, we expect this to be a weaker baseline on FEWS since the distribution of senses is much more balanced (and half of the evaluation senses are completely unseen during training).

Lesk The simplified **Lesk** algorithm assigns to each ambiguous target word the sense whose gloss has the highest word overlap with the context surrounding that target word (Kilgarriff and Rosenzweig, 2000). We specifically use the Lesk-definitions baseline from this work, meaning that we do *not* include words from example sentences in the set compared against the context – since these example sentences are used as the contexts in FEWS.

Lesk+emb This baseline is an extension of the above approach that incorporates word embeddings (Basile et al., 2014). A vector representation is built for the context around an ambiguous word (v_c) and the glosses of each sense of that word (v_g), where v_c and v_g are the element-wise sums of the word vectors for words in the context and gloss, respectively. The sense that corresponds to the v_g with the highest cosine similarity to v_c is chosen as the label for the target word. We use Glove embeddings (Pennington et al., 2014) for our implementation of this baseline.

4.2 Neural Baselines

Probe$_{BERT}$ This baseline is a linear classifier trained on contextualized representations output by the final layer of a frozen pretrained model; we use BERT as our pretrained encoder (Devlin et al., 2019). We train this classifier by performing a softmax over all of the senses in the Wiktionary sense inventory and mask out any senses not relevant to the target word.

BEM Our other neural baseline is the biencoder model (BEM) for WSD introduced by Blevins and Zettlemoyer (2020). The BEM has two independent encoders, a *context encoder* that processes the context sentence (including the target word) and a *gloss encoder* that encodes the glosses of senses into a sense representation. The BEM takes the dot product of the target word representation from the *context encoder* and sense representations from the gloss encoder, and it labels the target word with the sense that has the highest dot product score. We train **BEM**$_{BERT}$ by initializing each encoder with BERT and training on the FEWS train set.

4.3 Human Performance

Finally, we calculate the estimated human performance on the FEWS development set. The three human annotators were native English speakers, who each completed the same randomly chosen 300 example subset of the development set. The examples were sampled such that half (150) of these examples came from the few-shot split and the other half came from the zero-shot split. Similar to the modeling baselines, we evaluate each annotator's performance by scoring them against the

sense associated with that example in Wiktionary (which we assume to be gold labels).

5 Baseline Experiments

5.1 Experimental Setup

Data All baselines for the FEWS dataset are trained on the *train* set unless specifically stated to have been trained on the *extended train* set. All models for FEWS are tuned using the *development* set and then evaluated on the held-out *test* set.

Experimental Details Our probe and BEM baselines are in implemented in PyTorch[5] and optimized with Adam (Kingma and Ba, 2015). For the BEM, we use the implementation provided by Blevins and Zettlemoyer (2020).[6] We obtain the *bert-base-uncased* encoder from Wolf et al. (2019) to get the BERT output representations for the probe and to initialize the BEM models. Further hyperparameter details are given in Appendix A.

5.2 Modeling Results

Table 3 shows the results of our baseline experiments on FEWS. We find that the MFS baseline is weak overall, primarily because it is unable to predict anything about the held-out, zero-shot senses; the Lesk algorithms both outperform this baseline in the overall setting, with the Lesk+emb approach scoring slightly better than the original Lesk approach by 1.78-4.2% across the different evaluation subsets. However, on the few-shot examples in both the development and test sets, we see that the MFS baseline outperforms both of the Lesk baselines. This shows that, for the few-shot examples, the MFS heuristic remains a reasonably strong baseline even with the more uniform sense distribution of FEWS (and indicates that the distribution of examples drawn from the dictionary is less uniform than expected).

The neural baselines we run generally outperform the knowledge-based ones. The **Probe**$_{BERT}$ model does fairly well on the few-shot examples, outperforming the MFS baseline by about 20 accuracy points; however, it is unable to disambiguate words in the zero-shot splits correctly since the probe can not generalize to unseen senses. In comparison, **BEM**$_{BERT}$ performs well across the entire evaluation set. In particular, the BEM achieves much better zero-shot performance than other baselines, though performance on this subset still lags behind few-shot performance. Finally, we see that humans perform better than all of the considered baselines, particularly on zero-shot senses where humans outperform the BEM by 11.53 points. More details about the human evaluation are given below (Section 5.3).

Additionally, we find that training on the extended train set has little effect on these baselines: the **MFS** and **Probe**$_{BERT}$ baselines perform slightly worse (with deltas of -0.08% and -0.21% on the test set, respectively), and **BEM**$_{BERT}$ performs 1.05% better. Appendix B presents full re-

Table 4: Accuracy (%) of our baselines on the subset of the development set manually scored by human annotators.

sults for the extended train baselines.

5.3 Human Evaluation Results

The human annotators achieved an average accuracy of 80.11% (with each annotator getting 84.67%, 78.67%, and 77.00% accuracy) and an average inter-annotator agreement of $\kappa = 0.802$. We find that humans perform slightly better on the examples that correspond to few-shot examples for the dataset than those corresponding to zero-shot examples despite not using the training data, with an average of 80.44% and 79.87% accuracy on those two subsets, respectively.

We also report the performance of the baselines for FEWS on the same subset of the development set that was manually completed by humans (Table 4). We find that the baselines perform similarly on this subset, with a small decrease in performance compared to the full development set (with decreases in accuracy ranging between 0.81% and 3.46% when compared to the development set).

6 Transfer Learning with FEWS

Next, we investigate how useful FEWS is at improving WSD performance on existing benchmarks. We perform transfer learning experiments by iteratively finetuning models on FEWS and the WSD Evaluation Framework (Raganato et al., 2017), with one acting as the *intermediate* dataset and evaluating performance on the other, *target* dataset. We find that on global metrics, this approach performs similarly to finetuning only on the training data for each benchmark; however, transferring from FEWS to the WSD Framework improves performance on less-frequent and zero-shot senses. This suggests that FEWS provides valuable WSD information not covered in SemCor.

6.1 Experimental Setup

We apply the supplementary training approach presented in Phang et al. (2018) to perform our transfer learning experiments. We initialize a BEM with the best model developed on the *intermediate* dataset and evaluate on the *target* dataset in two ways: first, by evaluating this BEM on the *target* dataset in a zero-shot manner, without additional finetuning; and second by finetuning the BEM on the *target* training data before performing the *target* evaluation. We refer to these models as **BEM**$_{zero-shot}$ and **BEM**$_{intermediate}$, respectively. As a baseline, we also compare against the best BEM trained only on the *target* dataset (with no exposure to the *intermediate* dataset), **BEM**$_{BERT}$.[7] The model implementation details are identical to those for the baseline experiments on FEWS (Section 5.1).

6.2 Data

Models that are finetuned for the WSD Evaluation Framework are trained using SemCor, a large dataset annotated with WordNet synsets and commonly used for training WSD models (Miller et al., 1993). Following previous work, we use SemEval-2007 as a validation set (**SE07**; (Pradhan et al., 2007a)) and hold out the other evaluations sets in the Framework (Senseval2 (**SE2**; (Palmer et al., 2001)), Senseval-3 (**SE3**; (Snyder and Palmer, 2004)), SemEval-2013 (**SE13**; (Navigli et al., 2013)), and SemEval-2015 (**SE15**; (Moro and Navigli, 2015)) as test sets. Similarly to the baseline experiments, models that are trained on FEWS use the *train* set (note that we do not use the *extended train* set in these experiments), are validated on the *development* set, and finally evaluated on the held out *test* set.

6.3 Results

FEWS Results We first consider the setting where SemCor acts as the *intermediate* dataset and FEWS as the *target* (Table 3). We find that **BEM**$_{SemCor}$ performs similarly to training only on FEWS (with an improvement of 0.21% on the test set). **BEM**$_{zero-shot}$, which is not finetuned on

---

[7] We note that this is a naive approach to transferring between Wiktionary senses and WordNet synsets, and that it is possible that better transfer learning could occur with a more complicated multitask approach or by mapping between the two lexical resources with approaches such as Navigli and Ponzetto (2012) or Miller and Gurevych (2014).

	Dev	**Test Datasets**				**Concatenation of all Datasets**

BEM$_{FEWS}$	93.7	52.9	92.2	74.8
BEM$_{zero-shot}$	72.6	**55.5**	**92.7**	**80.5**

Table 6: F1-score on the MFS, LFS, and zero-shot subsets of the **ALL** evaluation set from the WSD Evaluation Framework. Zero-shot examples are the words and senses (respectively) from the evaluation suite that do not occur in SemCor.

the FEWS train set, unsurprisingly performs worse than any of the BEMs that saw the FEWS training data but outperforms the Lesk baselines.

WSD Evaluation Framework Results We then consider the opposite setting, where FEWS is the *intermediate* dataset and the WSD Evaluation Framework acts as the *target* evaluation (Table 5). On the overall evaluation set, we again see that **BEM**$_{FEWS}$ performs similarly to the **BEM**$_{BERT}$ baseline on the overall **ALL** metric, and that the zero-shot BEM model underperforms the other bi-encoders.

We then break down performance on the *target* evaluation set by sense frequencies: we evaluate performance on the most frequent sense (MFS) of each word in the evaluation (i.e., the sense each word takes most frequently in the SemCor training set); the less frequent senses (LFS) of words, or any sense a words takes besides its MFS; zero-shot words that are not seen during training on SemCor; and zero-shot senses, also not seen during training (Table 6). We find that both transfer learning models perform better on LFS and zero-shot examples than **BEM**$_{BERT}$.[8]

In particular, the zero-shot transfer model does well on these subsets, demonstrating that a fair amount of WSD knowledge about uncommon senses can be transferred in a zero-shot manner between these datasets (albeit at the expense of higher performance on the MFS subset). This result also shows how much the MFS group dominates existing WSD metrics and highlights the need for focused evaluations of other types of word senses. Finally, we see that even without exposure to the natural sense distribution in natural language texts, the zero-shot model still performs significantly better on the MFS of words than the LFS, with a 17.1 F1 point difference between the two subsets; this is likely because the BERT encoder is exposed to the sense distribution of English natural language documents during pretraining.

7 Conclusion

We establish baseline performance on FEWS with both knowledge-based approaches and recently published neural WSD models. Unsurprisingly, neural models based on pretrained encoders perform best on FEWS; however, the human evaluation shows there is still room for improvement, particularly for zero-shot senses. Finally, we also present results on transferring word sense knowledge from FEWS onto existing WSD datasets with staged finetuning. While our naive approach for transferring knowledge from FEWS does not improve performance on the global WSD metric, adding FEWS as an additional training signal improves performance on uncommon senses in existing evaluation sets.

We hope that FEWS will inspire future work fo-

---

[8] For the models trained on FEWS, it is possible they have seen closely related senses to those in the zero-shot subsets of from the Wiktionary sense inventory; however, these are represented differently in each dataset and correspond to different definitions to be encoded by the biencoder.

cusing on better methods for capturing rare senses in WSD and better modeling of word sense in niche domains like internet culture or technical writing.

	Δ	0.31	0.10	0.52	1.05	0.64	1.46

Table 7: Accuracy of the FEWS baselines trained on the extended train set. In each group of rows, we report (1) the extended train baseline, (2) the comparable baseline trained on the standard train set, and (3) the performance delta between the two (where a positive delta indicates the extended train baseline performs better).

A Model Hyperparameters

Each model reported in this paper was tuned on a single hyperparameter sweep over the reported ranges and chosen based on the appropriate development set metric (accuracy on FEWS, F1 performance on the Unified WSD Framework).

Probe$_{BERT}$ The linear layer in the BERT probe baseline is trained for 100 epochs. It is tuned over a range learning rates ($[5e-6, 1e-5, 5e-5, 1e-4]$, with a final learning rate of $1e-4$). We use a batch size of 128 to train this probe.

BEM For the biencoder model (BEM), we use the codebase provided by (Blevins and Zettlemoyer, 2020). Following this work, we train the BEM for 20 epochs with a warmup phase of 10,000 steps; we use a context batch size of 4 and a gloss batch size of 256. Each BEM is tuned over the following learning rates: $[1e-6, 5e-6, 1e-5, 5e-5]$. The BEM$_{BERT}$ and BEM$_{SemCor}$ had a final learning rate of $5e-6$, and the BEM$_{FEWS}$, of $1e-6$.

B Extended Train Baselines

The extended train set in FEWS contains all of the quotation-based examples from the train set as well as the additional, shorter example *illustrations* that are written by Wiktionary editors to exemplify a particular sense of a word. We retrain the **MFS**, **Probe**$_{BERT}$, and **BEM**$_{BERT}$ baselines on this extended training set; the other baselines we consider (**Lesk** and **Lesk+emb**) are calculated without using either of the training sets.

Table 7 compare the extended train baselines against those trained on the standard train set. For the **MFS** and **Probe**$_{BERT}$ baselines, we find that adding the extra, stylistically different *illustrations* in extended train slightly hurts performance. However, the stronger **BEM**$_{BERT}$ is able to better use this data and achieves somewhat stronger performance with additional training data. Notably, most of this improvement in the **BEM**$_{BERT}$ comes from the zero-shot evaluation setting, even though the extended train set does not contain any of these zero-shot senses.

MONAH: Multi-Modal Narratives for Humans to analyze conversations

Abstract

In conversational analyses, humans manually weave multimodal information into the transcripts, which is significantly time-consuming. We introduce a system that automatically expands the verbatim transcripts of video-recorded conversations using multimodal data streams. This system uses a set of preprocessing rules to weave multimodal annotations into the verbatim transcripts and promote interpretability. Our feature engineering contributions are two-fold: firstly, we identify the range of multimodal features relevant to detect rapport-building; secondly, we expand the range of multimodal annotations and show that the expansion leads to statistically significant improvements in detecting rapport-building.

1 Introduction

Dyadic human-human dialogs are rich in multimodal information. Both the visual and the audio characteristics of how the words are said reveal the emotions and attitudes of the speaker. Given the richness of multimodal information, analyzing conversations requires both domain knowledge and time. The discipline of conversational analysis is a mature field. In this discipline, conversations could be manually transcribed using a technical system developed by Jefferson (2004), containing information about intonation, lengths of pauses, and gaps. Hence, it captures both *what* was said and *how* it was said[1]. However, such manual annotations take a great deal of time. Individuals must watch the conversations attentively, often replaying the conversations to ensure completeness.

Automated Jefferson (2004) transcripts could be generated from video-recordings (Moore, 2015). However, the potential issue with Jeffersonian annotations is that there are often within-word annotations and symbols which makes it hard to benefit from pre-trained word embeddings. Inspired by the Jeffersonian annotations, we expand the verbatim transcripts with multimodal annotations such that downstream classification models can easily benefit from pre-trained word embeddings.

Our paper focuses on the classification task of predicting rapport building in conversations. Rapport has been defined as a state experienced in interaction with another with interest, positivity, and balance (Cappella, 1990). If we can model rapport building in the medical school setting, the volunteer actors can let the system give feedback for the unofficial practice sessions, and therefore students get more practice with feedback. Also, the lecturer could study the conversations of the top performers and choose interesting segments to discuss. As student doctors get better in rapport building, when they graduate and practice as doctors, treatments are more effective and long-term (Egbert et al., 1964; DiMatteo, 1979; Travaline et al., 2005).

Outside of the healthcare domain, understanding and extracting the features required to detect rapport-building could help researchers build better conversational systems. Our first contribution is the identification of multimodal features that have been found to be associated with rapport building and using them to predict rapport building automatically. Our second contribution is to include them into a text-based multimodal narrative system (Kim et al., 2019b). Why go through text? It is because this is how human experts have been manually analyzing conversations in the linguistics community. Our text-based approach has the merit of emulating the way human analysts analyze conversations, and hence supporting better interpretability. We demonstrate that the additions bring statistically significant improvements. This feature-

engineering system[2] could potentially be used to accomplish a highly attention-demanding task for an analyst. With an automated text-based approach, we aim to contribute towards the research gap of automatic visualizations that support multimodal analysis (Kim et al., 2019a). The created multimodal transcript itself is a conversational analysis product, which can be printed out on paper.

In this paper, we first introduced the problem domain (section 3). Secondly, we motivated the new features (detailed in Fig. 1) to be extracted (section 4). Then, we extracted the features from videos and encoded them as text together with verbatim transcripts (section 4). To evaluate whether the text narratives were useful, we ran experiments that predict rapport-building using texts containing different amounts of multimodal annotations (section 5). Finally, we discuss the results and visualize the outputs of the system (section 6).

2 Related Works

The automated analysis of conversations has been the subject of considerable interest in recent years. Within the domain of doctor-patient communication, Sen et al. (2017) calculated session-level input features, including affective features (Gilbert, 2014). Analyses using session-level features have a drawback of not being able to identify specific defining multimodal interactions in the conversation (Zhao et al., 2016; Heylen et al., 2007). Therefore, we build upon the works of Sen et al. (2017) – in addition to the use of session-level features, we propose using a finer level of talk-turn multimodal text representation as inputs into a hierarchical attention network (HAN) (Yang et al., 2016).

We also build upon our previous work (Kim et al., 2019b) by broadening the range of multimodal features considered. As for the different methods of multimodal information fusion, Poria et al. (2017) completed an extensive review of the different state-of-the-art multimodal fusion techniques. Recent multimodal fusion research (such as ICON (Hazarika et al., 2018a), CMN (Hazarika et al., 2018b), MFN (Zadeh et al., 2018), DialogueRNN (Majumder et al., 2019), M3ER (Mittal et al., 2020)) has focussed on end-to-end approaches. Unlike the typical end-to-end approach of representing and fusing multimodal features using numeric vectors, our contribution is an entirely text-based multimodal narrative, thereby improving downstream analysis's interpretability. The approach of this system not only annotates the presence of nonverbal events (Eyben et al., 2011), but also the degree of the nonverbal event intensity at both the session-level and talkturn-level.

3 Data

This study uses data from the EQClinic platform (Liu et al., 2016). Students in an Australian medical school were required to complete at least one medical consultation on the online video conferencing platform EQClinic with a simulated patient who is a human actor trained to act as a patient. Each simulated patient was provided with a patient scenario, which mentioned the main symptoms experienced. The study was approved by the Human Research Ethics Committee of the University of New South Wales (project number HC16048).

The primary outcome measurement was the response to the rapport-building question on the Student-Patient Observed Communication Assessment (SOCA) form, an adapted version of the Calgary-Cambridge Guide (Kurtz and Silverman, 1996). Simulated patients used the SOCA form to rate the students' performances after each video consultation. Our dataset comprises of 873 sessions, all from distinct students. Since we have two recordings per session (one of the student, the second of the simulated patient), the number of recordings analyzed is 1,746. The average length per recording is 928 seconds (sd=253 seconds), amounting to a total of about 450 hours of recordings analyzed. The dataset's size is small relative to the number of multimodal features extracted; therefore, there is a risk of overfitting.

We used the YouTube platform to obtain the transcript per speaker from the recordings. We chose YouTube because we (Kim et al., 2019c) found that it was the most accurate transcription service (word error rate: 0.28) compared to Google Cloud (0.34), Microsoft Azure (0.40), Trint (0.44), IBM Watson (0.50), when given dyadic video-conferences of an Australian medical school. Jeong-Hwa and Cha (2020) found that among the four categories of YouTube errors (omission, addition, substitution, and word order), substitution recorded the highest amount of errors. Specifically, they found that phrase repetitions could be mis-transcribed into non-repetitions. From our experience, (a) repair-initiation techniques such as sound stretches (e.g. "ummmm") (Hosoda, 2006), were either omitted or

---

[2] Open-sourced at https://github.com/SpectData/MONAH

substituted with “um”; (b) overlapping speech was not a problem because our speakers were physically separated and recorded into separate files.

We brought together the two speakers’ transcripts into a session-level transcript through word-level timings and grouped together words spoken by one speaker until the sequence is interrupted by the other speaker. When the interruption occurs, we deem that the talk-turn of the current speaker has ended, and a new talk-turn by the interrupting speaker has begun. The average number of talk-turns per session is 296 (sd=126), and the average word count per talk-turn is 7.62 (sd=12.2).

At this point, we note that acted dialogues differ from naturally occurring dialogues in a few ways. Firstly, naturally occurring dialogues tend to be more vague (phrases like “sort of”, “kinda”, “or something”) due to the shared understanding between the speakers (Quaglio, 2008). Secondly, taboo words or expletives that convey emotions (like “shit”, “pisssed off”, “crap”) is likely to be less common in an acted medical setting than naturally occurring conversations. Some conversations transform into genuine dialogues where the speakers “shared parts of themselves they did not reveal to everyone and, most importantly, this disclosure was met with acceptance” (Montague, 2012). This definition of genuine conversation is similarly aligned to our definition of rapport-building in section 4.1.

Figure 1 shows a summary of the features extracted. We annotated verbatim transcripts with two different levels of multimodal inputs – annotations at the session-level are labeled *coarse*, whilst annotations at the talk-turn-level are labeled *fine*. To facilitate comparisons, all input families belonging to the *coarse* (*fine*) level would be annotated with uppercase (lowercase) letters, respectively. In this paper, we refer to the previously existing set of features (with white background) as the “prime” ($'$) configuration. Families are also abbreviated by their first letter. For example, the *coarse* P' family would consist of only speech rate and delay, whilst the *coarse* P family would consist of P' plus tone. As another example, the *coarse* D' family is the same as the D family because there are no newly added features (in blue). We introduce the framework of our multimodal feature extraction pipeline in Figure 2.

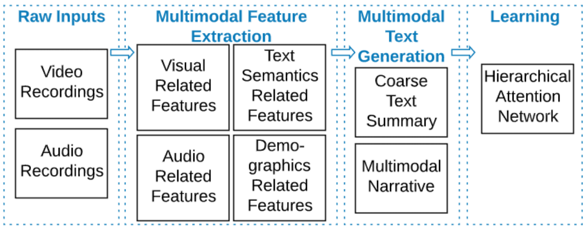

Figure 2: MONAH (Multi-Modal Narratives for Humans) Framework.

4 Multimodal features extractions

As an overview, we extracted the timestamped verbatim transcripts and used a range of pre-trained models to extract temporal, modality-specific features. We relied on pre-trained models for feature extraction and did not attempt to improve on them – demonstrating the value of using multidisciplinary pre-trained models from natural language processing, computer vision, and speech processing for conversational analysis.

Effectively, we extracted structured data from unstructured video data (section 4.2). With the structured data and verbatim transcript, we weaved a multimodal narrative using a set of predefined templates (sections 4.3 and 4.4). With the multimodal narrative, we employed deep learning techniques and pre-trained word embeddings to predict the dependent variable (section 5).

4.1 Dependent variable - rapport building

The dependent variable is defined as the success in rapport building. Rapport building is one of

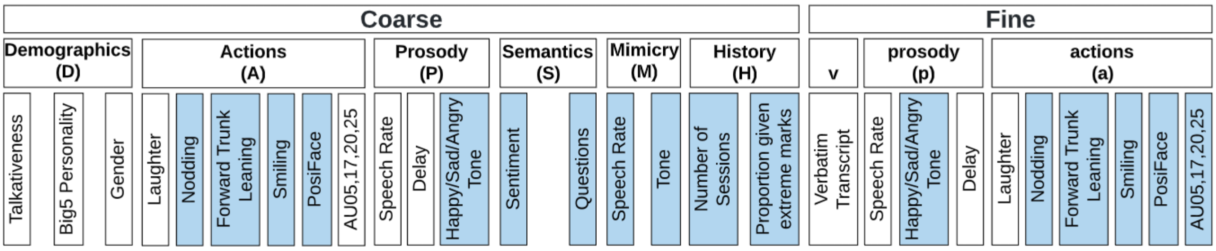

Figure 1: High-level features introduction. We build on our previous work (Kim et al., 2019b) – the new features introduced in this work are coloured in blue, whilst the existing set of features are in white.

the four items scored in the SOCA. The original 4-point Likert scale is Fail, Pass-, Pass, Pass+, we converted this scale into a binary variable where it is true if the rapport-building score is "Pass+" as we are concerned here with identifying good rapport building. "Pass+" means that the actor felt rapport such that all information could be comfortably shared. 38 percent of the population has achieved "Pass+". All actors followed the same pre-interview brief. Because only the actor scored the student performance and there is no overlap, the limitation is that we do not have measures of agreement.

4.2 Description of features

Table 1 gives an overview of all features for each speaker. We define six families of *coarse*-level inputs -– *demographics*, *actions*, *prosody*, *semantics*, *mimicry*, and *history*. We computed the features per speaker. From all families, there are a total of 77 features per session.

We first discuss the family of *demographics*. *Talkativeness* is chosen because the patient's talkativeness would initiate the doctor's active listening while aiding identification of patient's concerns – processes that could establish rapport. In Hall et al. (2009), it appears that patients appreciate a certain degree of doctor's dominance in the conversation, which itself is also correlated with higher rapport. *Big 5 Personality* consists of Extraversion, Agreeableness, Conscientiousness, Neuroticism, and Openness to Experience (McCrae and Costa, 1987). This personality structure is widely used in research and practice to quantify aspects of a person's natural tendency in thought, feeling, and action, with good validity and reliability indicators (McCrae, 2017). It is chosen because traits of agreeableness and openness on the part of both doctor and patient predict higher rapport. Among doctors, higher openness and agreeableness predict higher empathy towards patients (Costa et al., 2014). Among patients, higher agreeableness predicted higher trust towards doctors (Cousin and Mast, 2013), and higher openness predicted higher doctor affectionate communication (Hesse and Rauscher, 2019). *Big 5 Personality* is extracted through feeding transcripts to the IBM Watson Personality Insights API (version 2017-10-13), costing a maximum of 0.02 USD per call. *Gender* is chosen because personality differences between genders were observed cross-culturally. Among twenty-three thousand participants across cultures

Family	Child	Template
Demo graphics	Talkativeness	Total word count, total distinct word count, and proportion of word count
	Big 5 Personality	Percentile scores for each of the big 5 personality
	Gender	Male or Female
Actions	Laughter	Total laughter count
	Head Nodding*	Count of nods
	Forward Trunk Leaning*	Count of leaning in
	Smiling*	Count of smiles
	PosiFace*	Counts of times of positive and negative facial expressions
	AU	Summary statistics of the selected AU (05,17,20,25) intensities
Prosody	Delay	Summary statistics of time gaps between talk-turns
	Speech rate	Average speech rate
	Tone*	Happy, sad, angry tone
Semantics	Sentiment*	Composite, positive, neutral, and negative sentiment
	Questions*	Proportion of talk-turns that are open/closed questions
Mimicry	Speech Rate*	Dynamic time wrapping distance for speech rate
	Tone*	Dynamic time wrapping distance for tone
History	Num. Sessions*	Number of past sessions the assessor has scored before this
	Proportion given extreme marks*	Proportion of past sessions that the assessor has given an extreme score

Table 1: Session-level input features for each participant. * indicates new features outside of Kim et al. (2019b).

for both college-age and adult samples, females reported higher agreeableness, warmth, and openness to feelings than males (Costa Jr et al., 2001), traits that could be linked to rapport building.

Secondly, for the family of *actions*, *laughter* is chosen because humor (which was defined in part by the presence of laughter) on the part of both doctor and patient was found to be twice as frequent in high-satisfaction than low-satisfaction visits (Sala et al., 2002). Laughter events were detected using the Ryokai et al. (2018) algorithm. *Facial expressions* that resemble smiling is another behavioral indicator of humor appreciation, and approval of one another (Tickle-Degnen and Rosenthal, 1990). *Head nodding* is a type of backchannel response (i.e., response tokens) that has been shown to reflect rapport between doctor and patient, especially when the primary activity is face to face communications (Manusov, 2014). *Forward trunk leaning* is chosen because it has long been found to reflect an expression of interest and caring, which are foundational to rapport building (Scheflen, 1964). Additionally, facial positivity (*posiface*) is included as it is useful in rapport building detection in small groups (Müller et al., 2018). Lastly, *action units* (AU) that describe specific facial expressions, in particular AU 05 (upper lid raiser), 17 (chin raiser), 20 (lip stretcher), 25 (lips part), are also included as they were useful in automated dyadic conversational analyses to detect depression in our previous work (Kim et al., 2019b). All features introduced in this paragraph were calculated using the AU and landmark positioning features extracted using OpenFace (Baltrušaitis et al., 2016).

Thirdly, for the family of *prosody*, *delay* is chosen because it has been shown to be an indicator of doctor-to-patient influence – patients of low rapport with their doctors were found to speak less in response to doctor's comments (Sexton et al., 1996). *Speech rate* is chosen because doctor's fluent speech rate and patient's confident communication have been positively correlated with the patient's perception of rapport (Hall et al., 2009). Delay and speech rate are calculated using the time-stamped transcripts. *Tone* is chosen because a warm and respectful tone on the part of both doctor and patient is positively correlated with the patient's perception of rapport (Hall et al., 2009). Tone is calculated using the Vokaturi algorithm (version 3.3) (Vokaturi, 2019).

Fourthly, for the family of *semantics*, *sentiment* is chosen because the provision of positive regard from a practitioner to a patient is an important factor to foster therapeutic alliance; additionally, this process may be further enhanced if the patient also demonstrates positive behaviors towards the practitioners (Farber and Doolin, 2011). Sentiment is extracted using the VADER algorithm (Gilbert, 2014), in line with Sen et al. (2017). *Questions* is chosen because higher engagement by the doctor (e.g., asking questions) with the patient and the patient asking fewer questions have been shown to positively correlate with the patient's perception of rapport (Hall et al., 2009). Questions are detected using Stanford CoreNLP Parser (Manning et al., 2014) and the Penn Treebank (Bies et al., 1995) tag sets.

Next, *mimicry* is chosen because doctor-patient synchrony is an established proxy for rapport. In a review paper, rapport is theorized to be grounded in the coupling of practitioner's and patient's brains (Koole and Tschacher, 2016). Such a coupling process would eventuate in various forms of mimicry in the dyad, for instance, vocally (e.g., matching speech rate and tone), physiologically (e.g., turn-taking, breathing), physically (e.g., matching body language) (Wu et al., 2020). In this study, we aim to use vocal mimicry to capture this underlying phenomenon. Session level mimicry scores are approximated through Dynamic Time Wrapping distances (Giorgino and others, 2009), in line with Müller et al. (2018).

Lastly, *history* is chosen because the scores given by the assessors could be subjective evaluations where the evaluations are unduly influenced by the assessor's leniency bias (Moers, 2005). We attempted to mitigate the leniency bias by introducing history features that indicate the assessor's leniency and its consistency.

4.3 Generation of *coarse* multimodal narrative

In this section, we discuss the *coarse* multimodal narrative. We summarized the automatic generation of the text representation in Table 2.

We calculated the z-score for all the above templates (except Template 3 which is categorical) using the following z-score formula. The average (μ), and standard deviation (σ) are computed using observations from the training observations. Using the z-score, we bucketed them into "very low" (z<-2), "low" (z<-1), "high" (z>1) and "very high"

Family	Child	ID	Template
Demo graphics	Talkativeness	1	**doctor** number of words **high**, **doctor** number of distinct words high
	Big 5 Personality	2	**doctor** openness **high**
	Gender	3	The **patient** is **female**
Actions	Laughter	4	**doctor** laughter counts **high**
	Head Nodding	5	**doctor** head nod counts **high**
	Forward Trunk Leaning	6	**doctor** forward trunk leaning **high**
	Smiling	7	**doctor** smiling counts **high**
	PosiFace	8	**doctor** positive face expression counts **high**
	AU	9	**doctor** minimum lip depressor **very low**, maximum lip depressor **low**, average lip depressor **low**, variance lip depressor **low**
Prosody	Delay	10	minimum delay **very low**, maximum delay **low**, average delay **low**, variance delay **low**
	Speech rate	11	speech rate **high**
	Tone	12	angry tone **high**
Semantics	Sentiment	13	positive sentiment **high**
	Questions	14	open questions **high**
Mimicry	Speech Rate	15	speech rate mimicry **high**
	Tone	16	tone mimicry **high**
History	Num. Sessions	17	patient number of sessions before this **very high**
	Proportion given extreme marks	18	patient question four proportion given maximum marks **high**

Table 2: Templates for the session-level *coarse* summary.

(z>2). The reason for z-transformation is to create a human-readable text through bucketing continuous variables into easy-to-understand buckets ("high" vs. "low").

$$z = \frac{x - \mu_{\text{Train}}}{\sigma_{\text{Train}}} \tag{1}$$

4.4 Generation of *fine* multimodal narrative

In addition to the verbatim transcript, we introduced two new families of information – *prosody*, and *actions*. Table 3 gives an overview of the templates, and the bold-face indicates a variable. The motivations of the features have been discussed; we discuss the rules of insertion in the next few paragraphs.

Template 19 is the verbatim transcript returned from the ASR system. Before each talk-turn, we identified the speaker (doctor/patient) and added multimodal information using templates 20-29. Speech rate and tone were standardized across all training observations. We appended template 20, 21 where possible values are dependent on the z-score – "quickly" ($1 <$ z-score < 2) and "very quickly" (z-score ≥ 2). For delay, we used time intervals of 100 milliseconds, and between 200 and 1200 milliseconds – in line with Roberts and Francis (2013). We appended template 22 at the front of the talk-turn if a delay of at least 200 milliseconds is present between talk-turns. In addition, we appended template 23 where possible values are dependent on the standardized duration of delay – "short" ($<$ 1 z-score), "long" ($<$ 2 z-score) and "significantly long" ($\geq$ 2 z-score). Template 23 captures longer than usual delay, considering the unique turn-taking dynamics of each conversation. The standardized duration of delay is calculated using talk-turn delays from the respective session. Lastly, as for the actions family, templates 24 – 28 were added if any of the actions are detected during the talk-turn. For template 29, it was only added if the AU is detected throughout the entire duration of the talk-turn.

5 Experimental settings

There are two main types of inputs – (1) numeric inputs at the session-level, and (2) *coarse* and/or *fine*

Family	Child	ID	Template
Verbatim	Transcript	19	Transcript returned from the ASR system
Prosody	Speech rate	20	the doctor **quickly** said
	Tone	21	the doctor said **angrily**
	Delay	22	after **two** hundred milliseconds
		23	a **long** delay
Actions	Laughter	24	the doctor **laughed**
	Nodding	25	the doctor **nodded**
	Forward trunk learning	26	the doctor **leaned forward**
	Smiling	27	the doctor **smiled**
	PosiFace	28	the doctor **displayed positive facial expression**
	AU05, 17, 20, 25	29	the doctor **exhibited lip depressor**

Table 3: Templates for the talkturn-level *fine* summary.

multimodal narrative text inputs. As an overview, for (1), we trained the decision tree classifier using session-level numeric inputs. As for (2), we trained the HAN (Yang et al., 2016). We aim to facilitate how humans analyze conversations – HAN can work with text and has easy interpretation with single-headed attention, making it a suitable candidate. Relative to BERT (Devlin et al., 2018), the HAN is faster to train and easier to interpret.

5.1 Research questions

The proposed features have been motivated by scientific studies in Section 4. A natural next question is, "what are the impacts of these proposed features on model performance?" We break this broad question into three questions.

Firstly, (**Q1**) do the newly added features improve performance over the existing set of features for the classification tree and/or HAN?

Secondly, modelling using unstructured text input data (as opposed to using numeric inputs) has the risk of introducing too much variability in the inputs. Therefore, we investigate (**Q2**) – given the *coarse*-only inputs, do the performance between the HAN and classification tree differ significantly?

Lastly, adding more granular talkturn-level inputs to the *coarse* session-level inputs has the benefit of deeper analyses, because it allows the analyst to analyze important talkturns of the conversation. On top of this benefit, (**Q3**) do we also have significant performance improvement between *coarse*-only vs. both *coarse* and *fine* inputs?

For all models, the area under the receiver-operator curve (AUC) was used as the evaluation metric. The AUC measures the goodness of ranking (Hanley and McNeil, 1982) and therefore does not require an arbitrary threshold to turn the probabilities into classes. The partitioning of the dataset to the five-folds is constant for decision tree and HAN to facilitate comparison. The five folds are created through stratified sampling of the dependent variable.

5.2 Classification tree set-up

To answer (**Q1**) and (**Q2**), we tested for all 72 configurations of prime ($2^3 = 8$) plus full ($2^6 = 64$) family inputs for the decision tree. We performed the same z-transformation pre-processing (as in section 4.3) on the decision tree input variables and limited random search to twenty trials.

The algorithm used is from the *rpart* package with R. As part of hyperparameter tuning, we tuned the cp (log-uniform between 10^{-7} to 10^{-9}), maximum depth (uniform between 1 to 20), and minimum split (uniform between 20 to 80) through five-fold cross-validation and random search.

5.3 HAN set-up

To answer (**Q1**) and (**Q2**), we chose the input configurations that performed that best for the classification tree, and used the same input configurations in HAN to compare the difference. Therefore, this test is biased in favour of the classification tree. To answer (**Q3**), we added the *fine* narratives to each *coarse*-only configuration, and compared the difference.

The model architecture is the HAN architecture by Yang et al. (2016), with about 5 million parameters. We used the pre-trained Glove word embeddings (Pennington et al., 2014) of 300-dimensions to represent each word. Words not found in the Glove vocabulary are replaced with the "unk" to-

Coarse Inputs	**Tree**	**Coarse-only (HAN)**	**Significance of Difference (Coarse-only vs. Tree)**	**Coarse + Fine (HAN)**	**Significance of Difference (Coarse + Fine vs. Coarse-only)**

Table 4: Summary of the model performances. We report the average five-fold cross-validation AUC and its standard deviation in brackets. Row-wise: We begin with the $D'A'P'$, which is the full existing feature set from Kim et al. (2019b), and progressively compare it against the new sets of features to answer **Q1**. Column-wise: We compare the difference in AUC between the classification tree and *coarse*-only HAN to answer **Q2**. We compare the difference in AUC between the *coarse*-only HAN and *coarse* + *fine* HAN to answer **Q3**. Asterisks (*) indicate significance relative to the $D'A'P'$ row. Carets (^) indicate significance relative to column-wise comparisons, we also provide the confidence intervals in square brackets [] for the difference in performance. The number of symbols indicate the level of statistical significance, e.g., ***: 0.01, **: 0.05, *: 0.10.

ken. The hyperparameter tuning procedure is reported in Appendix A, and the best hyperparameter configurations are reported in Appendix B. There are twenty hyperparameter search trials for each input configuration[3].

6 Experimental results

The results are summarized in Table 4. The key findings are: (**Q1**) with the extended inputs, we observed statistically significant improvements in both the HAN and tree over the existing full set of features (one-tailed *t*-test); (**Q2**) given the *coarse*-only inputs, the performances between the HAN and classification tree did not differ significantly (two-tailed *t*-test), therefore it is plausible that feature engineering into text features do not risk performance; (**Q3**) although adding the *fine* narratives allow deeper analyses by the analyst, it does not lead to significant differences over the *coarse*-only inputs (two-tailed *t*-test).

(**Q1**) When compared to the full set of existing features, the classification tree achieved statistically significant improvements (at $\alpha = 0.05$) in all six out of six *coarse* input families. For HAN, it achieved statistically significant improvements in one (at $\alpha = 0.05$) or two (at $\alpha = 0.10$) out of six *coarse* input families. This demonstrates the value of the newly introduced *coarse* features[4].

(**Q2**) Across the seven *coarse* input configurations, there are no significant differences in the performance from the classification tree when compared to the HAN in six out of seven input configurations. The only exception is in the baseline $D'A'P'$ configuration where the HAN is significantly better. However, the lack of statistically significant differences does not mean that the performances are the *same*. In line with Quertemont (2011) recommendation, we provided the confidence interval around the difference in performance for discussion. Of all confidence intervals that included zero in the fourth column of Table 4, the

---

[3] We conducted additional tuning experiments for the tree in Appendix C to observe potential improvements in performance.

[4] We performed additional tests in Appendix D to observe the impact of the additions to the *fine* narratives, and found small improvements (but statistically insignificant) in all three out of three input families (va, vp, vpa).

confidence intervals do not suggest that that the effect sizes are negligible (for example, less than 0.01). In summary, we cannot conclude that the performance of HAN differs significantly from tree nor are they the same.

(**Q3**) The addition of *fine* narratives to the *coarse* narrative did not result in significantly stronger (nor weaker) performance in any of the seven input configurations. We posit that this negative finding is due to the difficulty in prioritizing the back-propagation updates to the parts of the network interacting with the *coarse* features, where there is likely a high signal-to-noise ratio. Despite the negative finding, we think it is important to explore fine features' addition onto coarse features because it produces a complete transcript for the human to understand how the conversation proceeded.

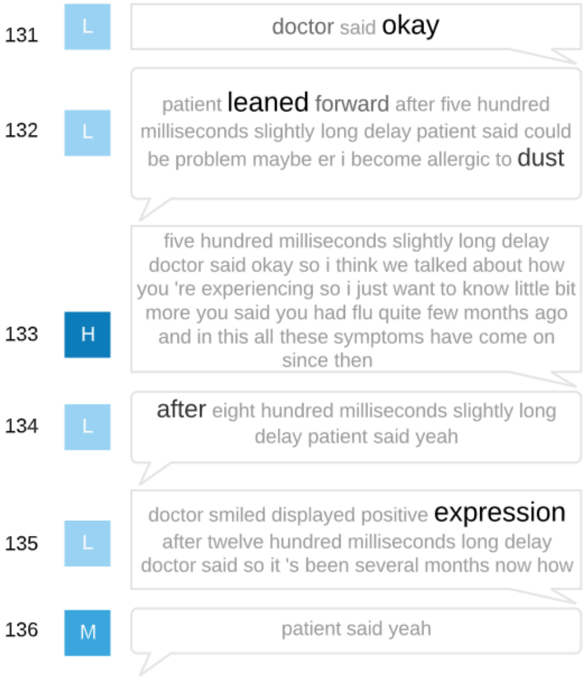
6.1 Qualitative Analysis

We visualized the talkturn-level and word-level attention weights from the model. Attention weights are normalized using z-transformation and bucketed into four buckets (< 0, < 1, < 2, ≥ 2) (Kim et al., 2019b). The analyst could analyze an important segment in detail (as in Fig. 3) or see an overview of the important segments in the conversation (see appendix E). In the example (Fig. 3), we observed that the multimodal annotations of leaning forward and positive expression were picked up as important words by the model.

7 Conclusion

In this paper, we build upon a fully text-based feature-engineering system. We motivated the added features with existing literature, and demonstrated the value of the added features through experiments on the EQClinic dataset. This approach emulates how humans have been analyzing conversations with the Jefferson (2004) transcription system, and hence is human-interpretable. It is highly modular, thereby allowing practitioners to inject modalities. In this paper, we have used a wide range of modalities, including *demographics*, *actions*, *prosody*, *mimicry*, *actions*, and *history*. The ablation tests showed that the added *coarse* features significantly improve the performance for both decision tree and HAN models.

Future research could (1) investigate whether this feature engineering system is generalizable to wider applications of conversational analysis; (2) conduct user studies to validate the usability and ease of interpretability of the visualization.



doctor said okay

patient leaned forward after five hundred milliseconds slightly long delay patient said could be problem maybe er i become allergic to dust

five hundred milliseconds slightly long delay doctor said okay so i think we talked about how you 're experiencing so i just want to know little bit more you said you had flu quite few months ago and in this all these symptoms have come on since then

after eight hundred milliseconds slightly long delay patient said yeah

doctor smiled displayed positive expression after twelve hundred milliseconds long delay doctor said so it 's been several months now how

patient said yeah

Figure 3: Conversation analysis for a true positive. The talkturn-level attentions are labelled Low (L), Medium (M) and High (H), while the words with higher attention have a larger and darker font. We also transcribed this segment using the Jefferson system in Appendix F.

Acknowledgments

We acknowledge the Sydney Informatics Hub and the University of Sydney's high-performance computing cluster, Artemis, for providing the computing resources and Marriane Makahiya for supporting the data manipulation work. Video data collection was carried out as part of the OSPIA platform project, funded by the Department of Health Clinical Training Fund from the Australian Government.

Appendices

A Tuning procedure

We tuned the SGD optimizer with a learning rate between 0.003 to 0.010, batch size to be between 4 to 20, L2 regularization between 10^{-6} and 10^{-3}, and trained for up to 350 epochs without early stopping. We tuned the number of gated recurrent units (GRU) (Cho et al., 2014) between 40 to 49 in both the word-level and talk-turn-level layers, with both the GRU dropout and recurrent dropout (Gal and Ghahramani, 2016) to be between 0.05 to 0.50. The method of choosing hyperparameters is through uniform sampling between the above-mentioned bounds, except for the learning rate where log-uniform sampling is used. Training is performed on a RTX2070 GPU or V100 GPU.

B Hyperparameter configurations for best-performing models

Table 5 (HAN) and Table 6 (Tree) report the hyperparameter configurations for each of the best-performing model reported in Table 4.

C Performance of additional tuning

We conducted additional experiments on the tree configurations to (1) compare the improvements in performance when tuning the HAN and tree, and (2) evaluated the increase in performance if the tree is allowed twenty more hyperparameters random search trials (Fig. 4).

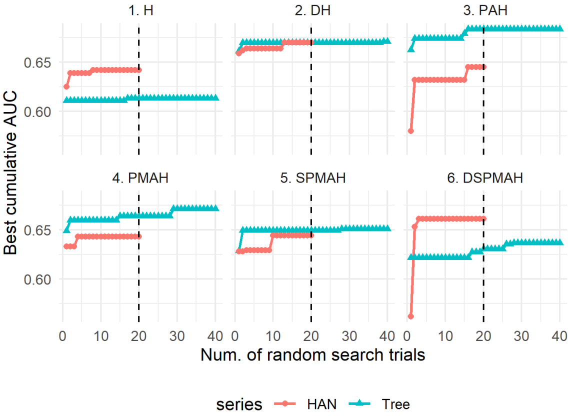

Figure 4: Best cumulative AUC performance given N random search trials.

From the larger increases in HAN performances, it is plausible that HAN is more sensitive to the hyperparameter tuning than the tree.

D Additional tests for additions to the *fine* narratives

Table 7 reports the additional tests on the impact of the added *fine* features. We observe that whilst all three input configurations (va, vp, vpa) have small increases in performance, none of them are statistically significant.

E Conversation thumbnail visualization

By illustrating the talkturn-level attention weights as a heatmap thumbnail (Fig. 5), the analyst could quickly get a sense of the important segments of the conversation without reading the content and zoom-in if required.

F Jefferson example

As an optional reference, we engaged a professional transcriptionist to transcribe the conversation segment presented (Fig. 3) using the Jefferson system. The Jefferson example is presented in Fig. 6. The verbal content is slightly different due to (1) different methods to determine talkturns transitions and (2) automatic speech recognition accuracy.

Does Typological Blinding Impede Cross-Lingual Sharing?

Johannes Bjerva
Department of Computer Science
Aalborg University

University of Copenhagen
augenstein@di.ku.dk

Abstract

Bridging the performance gap between high- and low-resource languages has been the focus of much previous work. Typological features from databases such as the World Atlas of Language Structures (WALS) are a prime candidate for this, as such data exists even for very low-resource languages. However, previous work has only found minor benefits from using typological information. Our hypothesis is that a model trained in a cross-lingual setting will pick up on typological cues from the input data, thus overshadowing the utility of explicitly using such features. We verify this hypothesis by blinding a model to typological information, and investigate how cross-lingual sharing and performance is impacted. Our model is based on a cross-lingual architecture in which the latent weights governing the sharing between languages is learnt during training. We show that (i) preventing this model from exploiting typology severely reduces performance, while a control experiment reaffirms that (ii) encouraging sharing according to typology somewhat improves performance.

1 Introduction

Most languages in the world have little access to NLP technology due to data scarcity (Joshi et al., 2020). Nonetheless, high-quality multilingual representations can be obtained using only a raw text signal, e.g. via multilingual language modelling (Devlin et al., 2019). Furthermore, structural similarities of languages are to a large extent documented in typological databases such as the World Atlas of Language Structures (WALS, Dryer and Haspelmath (2013)). Hence, developing models which can take use typological similarities of languages is an important direction in order to alleviate language technology inequalities.

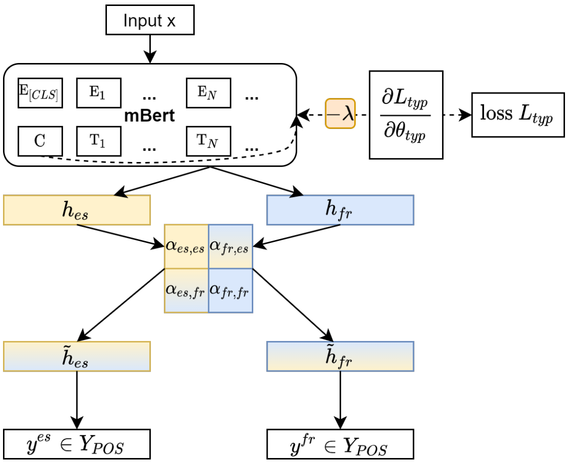

Figure 1: A PoS tagger is exposed (or blinded with gradient reversal, $-\lambda$) to typological features. Observing α values tells us how typology affects sharing.

While previous work has attempted to use typological information to inform NLP models, our work differs significantly from such efforts in that we *blind* a model to this information. Most previous work includes language information as features, by using language IDs, or language embeddings (e.g. Ammar et al. (2016); O'Horan et al. (2016); Östling and Tiedemann (2017); Ponti et al. (2019); Oncevay et al. (2020)). Notably, limited effects are usually observed from including typological features explicitly. For instance, de Lhoneux et al. (2018) observe positive cross-lingual sharing effects only in a handful of their settings. We therefore hypothesise that relevant typological information is learned as a by-product of cross-lingual training. Hence, although models do benefit from this information, it is not necessary to provide it explicitly in a high-resource scenario, where there is abundant training data. This is confirmed by Bjerva and Augenstein (2018a), who find that, e.g., language embeddings trained on a morphological task can encode morphological features from WALS.

In contrast with previous work, we *blind* a model to typological information, by using adversarial

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 480–486
April 19 - 23, 2021.

techniques based on gradient reversal (Ganin and Lempitsky, 2014). We evaluate on the structured prediction and classification tasks in XTREME (Hu et al., 2020), yielding a total of 40 languages and 4 tasks. We show that when a model is blinded to typological signals relating to syntax and morphology, performance on related NLP tasks drops significantly. For instance, the mean accuracy across 40 languages for POS tagging drops by 1.8% when blinding the model to morphological features.

2 Model

An overview of the model is shown in Figure 1. We model each task in this paper using the following steps. First, contextual representations are extracted using multilingual BERT (m-BERT, Devlin et al. (2019)), a transformer-based model (Vaswani et al., 2017), trained with shared wordpieces across languages. We either blind m-BERT to typological features, with an added adversarial component based on gradient reversal (Ganin and Lempitsky, 2014), or expose it to them via multitask learning (MTL, (Caruana, 1997)). Representations from m-BERT are fed to a latent multi-task architecture learning network (Ruder et al., 2019), which includes α parameters we seek to investigate. The model learns which parameters to share between languages (e.g. $\alpha_{es,fr}$ denotes sharing between Spanish and French).

2.1 Sharing architecture

Our sharing architecture is based on that of Ruder et al. (2019), which has latent variables learned during training, governing which layers and subspaces are shared between tasks, to what extent, as well as the relative weighting of different task losses. We are most interested in the parameters which control the sharing between the hidden layers allocated to each task, referred to as α parameters (Ruder et al., 2019). Consider a setting with two tasks A and B. The outputs $h_{A,k}$ and $h_{B,k}$ of the k-th layer for task A and B interact through the α parameters, for which the output is defined as:

$$\begin{bmatrix} \widetilde{h}_{A,k} \\ \widetilde{h}_{B,k} \end{bmatrix} = \begin{bmatrix} \alpha_{AA} & \alpha_{AB} \\ \alpha_{BA} & \alpha_{BB} \end{bmatrix} \left[{h_{A,k}}^{\top}, \quad {h_{B,k}}^{\top} \right] \quad (1)$$

where $\widetilde{h}_{A,k}$ is a linear combination of the activations for task A at layer k, weighted with the learned αs. While their model is an MTL model, we choose to interpret this differently by considering each *language* as a task, yielding $\alpha \in \mathbf{R}^{l \times l}$, where l is the number of languages for the given task. Each activation $\widetilde{h}_{A,k}$ is then a linear combination of the language specific activations $h_{A,k}$. These are used for prediction in the downstream tasks, as in the baselines from Hu et al. (2020).

Crucially, this model allows us to draw conclusions about parameter sharing between languages by observing the α parameters under the blinding and prediction conditions. We will combine this insight with observing downstream task performance in order to draw conclusions about the effects of typological feature blinding and prediction.

2.2 Blinding/Exposing a Model to Typology

We introduce a component which can either blind or expose the model to typological features. We implement this as a single task-specific layer per feature, using the `[CLS]` token from m-BERT model, without access to any of the soft sharing between languages from α-layers. Each layer optimises a categorical cross-entropy loss function (L_{typ}).

For this task, we predict typological features drawn from WALS (Dryer and Haspelmath, 2013), inspired by previous work (Bjerva and Augenstein, 2018a). Unlike previous work, we also blind the model to such features by including a gradient reversal layer (Ganin and Lempitsky, 2014), which multiplies the gradient of the typological prediction task with a negative constant ($-\lambda$), inspired by previous work on adversarial learning (Goodfellow et al., 2014; Zhang et al., 2019; Chen et al., 2019). We hypothesise that using a gradient reversal layer for typology will yield typology-invariant features, and that this will perform worse on tasks for which the typological feature at hand is important. For instance, we expect that blinding a model to syntactic features will severely reduce performance for tasks which rely heavily on syntax, such as POS tagging.

3 Cross-Lingual Experiments

We investigate the effects of typological blinding, using typological parameters as presented in WALS (Dryer and Haspelmath, 2013). The experiments are run on XTREME (Hu et al., 2020), which includes up to 40 languages from 12 language families and two isolates. We experiment on the following languages (ISO 639-1 codes): af, ar, bg, bn, de, el, en, es, et, eu, fa, fi, fr, he, hi, hu, id, it, ja, jv, ka, kk, ko, ml, mr, ms, my, nl, pt, ru, sw, ta, te, th, tl, tr, ur, vi, yo, and zh. We experiment on four tasks: POS (part of speech tagging), NER (named entity recognition), XNLI (cross-lingual natural language inference), and PAWS-X (paraphrase identification). Our general setup for the structured prediction tasks (POS and NER) is that we train on all available languages, and downsample to 1,000 samples per language. For the classification tasks XNLI and PAWS-X, we train on the English training data and fine-tune on the development sets, as no training data is available for other languages. Hence, typological differences will be the main factor in our results, rather than differences in dataset sizes.

3.1 Typological Prediction and Blinding

We first investigate whether prohibiting or allowing access to typological features has an effect on model performance using our architecture. We hypothesise that our multilingual model will leverage signals related to the linguistic nature of a task when optimising its its sharing parameters α.

There exists a growing body of work on prediction of typological features (Daumé III and Campbell, 2007; Murawaki, 2017; Bjerva and Augenstein, 2018b; Bjerva et al., 2019a,b), most notably in a recent shared task on the subject (Bjerva et al., 2020). While we are inspired by this direction of research, our contribution is not concerned with the accuracy of the prediction of such features, and this is therefore not evaluated in detail in the paper.

Moreover, an increasing amount of work measures the correlation of predictive performance of cross-lingual models with typological features as a way of probing what a model has learned about typology (Malaviya et al., 2017; Choenni and Shutova, 2020; Gerz et al., 2018; Nooralahzadeh et al., 2020; Zhao et al., 2020). In contrast to such post-hoc approaches, our experimental setting allows for measuring the impact of typology on cross-lingual sharing performance in a direct manner as part of the model architecture.

Syntactic Features We first blind/expose the model to syntactic features from WALS (Dryer and Haspelmath, 2013). We take the set of word order features which are annotated for all languages in our experiments, resulting in 33 features. This includes features such as *81A: Order of Subject, Object and Verb*, which encodes what the preferred word ordering is (if any) in a transitive clause. For all features, we exclude feature values which do not occur for our set of languages. We hypothesise that performance will drop for all four tasks, as they all require syntactic understanding.

Morphological Features We next attempt to blind/expose the model to the morphological features in WALS. We use the same approach as above, resulting in a total of 8 morphological features. This includes features such as *26A: Prefixing vs. Suffixing in Inflectional Morphology*, indicating to what extent a language uses prefixing or suffixing morphology. We hypothesise that mainly the POS tagging task will suffer under this condition, whereas other tasks only to some extent require morphology.

Phonological Features We next consider a control experiment, in which we attempt to blind/expose the model to phonological features in WALS. We arrive at a total of 15 phonological features, such as *1A: Consonant Inventories* which indicates the size of the consonant inventory of a language. We expect the performance to remain relatively unaffected by this task, as phonology ought to have little importance given a textual input.

Genealogical Features Finally, we attempt to use what one might consider to be language metadata. We attempt to blind/expose the model to what language family a language belongs to. This can be seen as a type of proxy to language similarity, and correlates relatively strongly with structural similarities in languages. Because of this correlation with structural similarities, we expect blinding under this condition to only slightly reduce performance for all tasks, as previous work has shown this type of relationship not to be central in language representations (Bjerva et al., 2019c).

3.2 Results

In general, we observe a drop in performance when blinding the model to relevant typological information, and an increase in performance when exposing the model to it (Table 1). For phonological blinding or prediction, none of the four tasks is noticeably affected. Although, e.g., both the syntactic and morphological prediction tasks increase performance on POS tagging, it is not straightforward to draw conclusions on which of these is the most efficient, as there is a substantial correlation between syntactic and morphological features. As for XNLI and PAWS-X, performance notably drops under both the syntactic and genealogical blinding tasks.

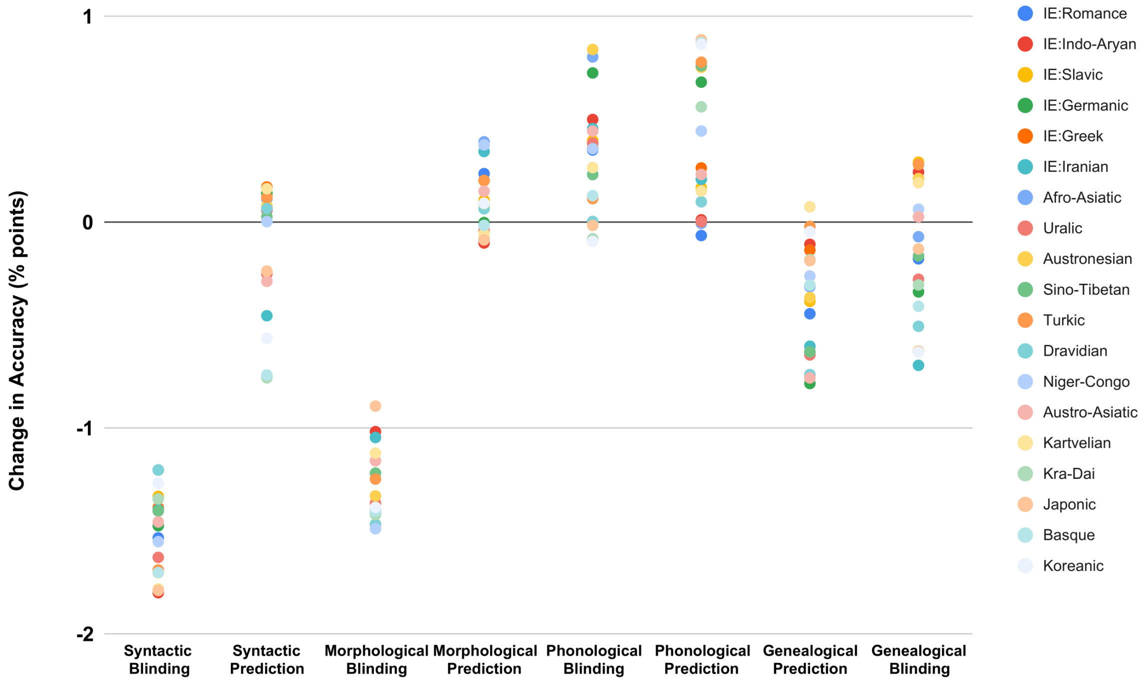

Figure 2: PoS tagging results per language family across blinding and prediction conditions

Model	POS	NER	XNLI	PAWS-X
+ Syntactic Blind.	85.3^{-}	76.4	64.2^{-}	80.6^{-}
+ Morphological Blind.	85.0^{-}	77.2	64.9	81.4
+ Phonological Blind.	86.7	77.1	65.0	81.6
+ Genealogical Blind.	86.1	77.0	64.7	81.1
m-BERT baseline	86.8	77.3	65.1	81.7
+ Syntactic Pred.	87.0	77.5	**65.3**$^{+}$	**81.9**$^{+}$
+ Morphological Pred.	**87.2**$^{+}$	77.3	65.2	81.7
+ Phonological Pred.	86.7	77.1	65.0	81.7
+ Genealogical Pred.	87.0	**77.6**	**65.3**$^{+}$	81.8

Table 1: Typological Blinding and Prediction. Mean POS accuracy, NER F1 scores, XNLI accuracy and PAWS-X accuracy across all languages. $^{+}$ and $^{-}$ indicate significantly better or worse performance respectively, as determined by a one-tailed t-test ($p < 0.01$).

Figure 2 shows results for PoS tagging under prediction and blinding across language families, following the same scheme as Hu et al. (2020). Interestingly, the syntactic and morphological blinding settings are robust across all language families, yielding a drop in accuracy across the board. All other conditions yield mixed results. This further strengthens our argument that preventing a model from learning syntactic and morphological features can be severely detrimental.

3.3 The Effect of Typology on Latent Architecture Learning

The results show that preventing access to typological features hampers performance, whereas providing access improves performance. We now turn to an analysis of how the model shares parameters across languages in this setting. Our hypothesis is that blinding will prevent models from sharing parameters between similar languages, in spite of typological similarities. Concretely, we expect that the drop in POS tagging performance under morphological blinding is caused by lower α weights between languages which are morphologically similar, and higher α weights between languages which are dissimilar. Recall that these parameters are latent variables learned by the model, regulating the amount of sharing between languages (see Eq. 1). We investigate the correlations between the α sharing parameters, and two proxies of language similarity. We focus on the POS task, as the results from the typological blinding and prediction experiments were the most pronounced here, as both morphological and syntactic blinding affected performance.

Our first measure of language similarity is based on Bjerva et al. (2019c), who introduce what they refer to as structural similarity. This is based on

Model	**Struct.**	**Lang. Emb.**
Syntactic Blind.	0.31	0.27
Morphological Blind.	0.34	0.29
Phonological Blind.	0.40	0.41
Genealogical Blind.	0.29	0.31
No blind./pred.	0.43	0.40
Syntactic Pred.	**0.52**	0.53
Morphological Pred.	0.49	**0.56**
Phonological Pred.	0.41	0.39
Genealogical Pred.	0.47	0.38

Table 2: Pearson correlations between α weights and language similarity measures.

dependency statistics from the Universal Dependencies treebank (Zeman et al., 2020), resulting in vectors which describe how different syntactic relations are used in each language. Previous work has shown that this measure of similarity correlates strongly with that learned in embedded language spaces during multilingual training. In addition to considering these dependency statistics, we also use language embeddings drawn form Östling and Tiedemann (2017). For each language similarity measure we calculate its pairwise Pearson correlation with the α values learned under each condition.

Table 2 shows correlations between α weights and similarities increase when predicting typological features, and decreases when blinded to such features. Hence, when the model has indirect access to, e.g., the SVO word ordering features of languages, sharing also reflects this.

4 Discussion

We have shown that blinding a multilingual model to typological features severely affects sharing across a relatively large language sample, and for several NLP tasks. The effects on model performance, as evaluated over 40 languages and 4 tasks from XTREME (Hu et al., 2020), were the largest for POS tagging. The fact that smaller effects were observed for NER, could be because this task relies more on memorising NEs rather than using (morpho-)syntactic cues (Augenstein et al., 2017). Furthermore, the relatively small effects on XNLI and PAWS-X can also be interpreted as evidence for that typology is less important in these tasks than in more traditional linguistic analysis.

A potential critique of our approach is that it merely blinds the model to language identities. This could be the case, if only some latent representation of, e.g., “SVO” ordering is used to represent a language identity. However, previous work has shown that morphological information is encoded by the type of model we investigate. Hence, since we only blind features in a single category at a time, we expect that the model’s representation of language identities is unaffected.

Not only do we observe a drop in performance when blinding a model to syntactic features, but we also observe that the α sharing weights in our model do not appear to correlate with linguistic similarities in this setting. Conversely, encouraging a model to consider typology, by jointly optimising it for typological feature prediction, improves performance in general. Furthermore, α weights in this scenario converge towards correlating with structural similarities of languages. This is in line with recent work which has found that m-BERT uses fine-grained syntactic distinctions in its cross-lingual representation space (Chi et al., 2020).

We interpret this as evidence for the fact that typology can be a necessity for modelling in NLP. Our results furthermore corroborate previous work in that we only find moderate benefits from including typological information explicitly. We expect that this to a large degree is due to the typological similarities of languages being encoded implicitly based on correlations between patterns in the input data. As low-resource languages often do not even have access to any substantial amount of raw text, but often do have annotations in WALS, we expect that using typological information can go some way towards building truly language-universal models.

5 Conclusions

We have shown that preventing access to typology can impede the performance of cross-lingual sharing models. Investigating latent weights governing the sharing between languages shows that this prevents the model from sharing between typologically similar languages, which is otherwise learned based on patterns in the input. We therefore expect that using typological information can be of particular interest for building truly language-universal models for low-resource languages.
