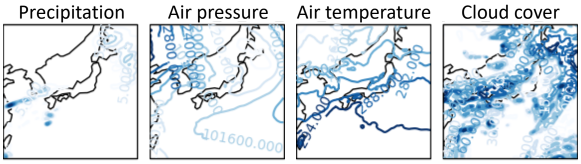
Abstract

The task of generating weather-forecast comments from meteorological simulations has the following requirements: (i) the changes in numerical values for various physical quantities need to be considered, (ii) the weather comments should be dependent on delivery time and area information, and (iii) the comments should provide useful information for users. To meet these requirements, we propose a data-to-text model that incorporates three types of encoders for numerical forecast maps, observation data, and meta-data. We also introduce *weather labels* representing weather information, such as sunny and rain, for our model to explicitly describe useful information. We conducted automatic and human evaluations. The results indicate that our model performed best against baselines in terms of informativeness. We make our code and data publicly available[1].

1 Introduction

Numerical weather prediction (NWP), a method for weather forecasting that uses mathematical models of the atmosphere, oceans, and observations, has become a mainstream tool for supporting today's weather forecasts around the world. Weather forecasters obtain numerical outputs from the simulation models and use their scientific knowledge and historical data to come up with forecast comments such as "*sunny and sometimes cloudy*". However, writing local or personalized weather comments for end users is labor intensive and requires a solid knowledge of meteorology. Therefore, the task of generating weather-forecast comments has traditionally been addressed in the field of data-to-text generation (Goldberg et al., 1994; Belz, 2007).

In this paper, we focus on the task of generating weather-forecast comments from meteorological simulations. While previous studies have mainly focused on database records and tables (Sripada et al., 2004; Liang et al., 2009), which are modified results by experts based on their local knowledge (Reiter et al., 2005), we use *raw* simulation results of NWP models as inputs for text generation. This is closer to the real-world scenarios, in which meteorological specialists describe weather comments by interpreting such numerical data. We believe it will be more helpful for less experienced forecasters. There has been little research on generating descriptions from a sequence of raw numerical data even in the data-to-text generation (Gatt and Krahmer, 2018).



Delivery time: 05:51 a.m. on 06 April, Tokyo

Today patches of blue sky will appear, but the sky will become cloudy and it will gradually start to rain in the evening. Please bring an umbrella when you go out, even if it's not raining.

Figure 1: A weather comment written by a meteorological expert and simulation results from NWP models

We illustrate the three characteristic problems of weather-comment generation in Figure 1. The first problem is that a forecaster needs to consider the changes in numerical values for different types of physical quantities. For example, the comment in this figure states that it will be raining in the evening after a sunny spell according to the changes in precipitation and cloud cover. The second problem is that weather-forecast comments are often written on the basis of meta-data such as area (e.g., Tokyo), delivery time (e.g., 05:51 a.m.), and date

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1462–1473
April 19 - 23, 2021.

(e.g., 06 April). For example, weather comments contain expressions that depend on their delivery time and date; comments published in the morning use "*today*", while those posted in the evening usually refer to "*tomorrow*". The third problem is that consumers place a higher priority on informativeness of weather comments and their correctness. In particular, important information such as sunny, rain, and snow should be explicitly mentioned since it will greatly affect the consumers. For example, in Figure 1, although there are several possible types of content to be described such as precipitation, cloud cover, and air pressure, the comment mainly focuses on the information on rain and umbrellas since they can affect the consumers' behavior.

To address these issues, we propose a data-to-text model for generating weather comments from simulation results of NWP models and past observation data. To tackle the first problem, we use a multi-layer perceptron (MLP) or convolutional neural network (CNN) to capture different types of physical quantities and input them to a bidirectional recurrent neural network (Bi-RNN) to take their time scales into account. For the second problem, we incorporate meta-data, such as area information, delivery time, and date, into an encoder for the meta-data. To address the third problem, we introduce *weather labels* representing weather information, such as sunny and rain, to help our model explicitly describe useful information and improve the correctness.

We conducted automatic and human evaluations to evaluate the proposed model on the task of generating Japanese weather comments from simulation results of NWP models and meteorological observation data. The results of both automatic and human evaluations indicate that our model improves the informativeness of generated comments compared with baselines.

2 Related Work

Data-to-text generation, which is the task of automatically producing descriptions from non-linguistic data (Gatt and Krahmer, 2018), has been widely used in various fields such as sports (Wiseman et al., 2017; Puduppully et al., 2019), finance (Murakami et al., 2017; Aoki et al., 2018, 2019), and medical care (Portet et al., 2009; Jing et al., 2018). Neural generation methods have been attracting increased attention in the field of data-to-text generation (Liu et al., 2018; Iso et al., 2019), although rule-based approaches have been the mainstream (Kukich, 1983; Reiter et al., 2005).

The task of generating weather-forecast comments has traditionally been tackled in the field of data-to-text generation (Belz, 2007; Angeli et al., 2010; Mei et al., 2016). For example, there are efforts in generating weather-forecast comments intended for marine shipping or offshore oil facilities (Kittredge et al., 1986; Reiter et al., 2005), as well as local weather forecasts for more general use (Kerpedjiev, 1992; Liang et al., 2009).

Prior research has examined the second and third problems mentioned in Section 1 (Murakami et al., 2017; Puduppully et al., 2019). For the second problem, we need to incorporate information for time and area into a generation model to generate time-dependent expressions. For the third problem, we must carry out content selection to explicitly provide useful information, such as sunny and rain, for consumers. In the table-to-text task, which aims to generate a description from a structured table, there have been recent efforts to improve the correctness of generated texts by implicitly introducing a content-matching constraint (Wang et al., 2020), explicitly specifying the content in the table (Ma et al., 2019) or incorporating copy mechanism (Lebret et al., 2016). Nonetheless, the techniques proposed in the table-to-text task are not directly applicable to datasets consisting of raw numerical data, such as simulation results of NWP models, and texts since they rely on task-specific architectures such as the copy mechanism copying words from tables. In addition, Puduppully et al. (2019) proposed a method for generating summaries of basketball games by using the correspondence between entities in text and input tabular data extracted using the information-extraction method (Wiseman et al., 2017). However, the methods are also not applicable to datasets consisting of raw numerical data and texts because they rely heavily on a word-matching algorithm between input tables and texts. To overcome this limitation, we extract weather labels representing the content of weather information from *only* text on the basis of clue words and use them to explicitly describe the useful information.

3 Weather Data

Weather forecasters obtain the output of NWP models and past weather observations, and interpret them together to come up with weather comments.

To reproduce this, we use two types of meteorological data: a numerical forecast map and meteorological observation data.

Numerical Forecast Maps A numerical forecast map is composed of a sequence of 2D surface data extracted from the simulation results of an NWP model, which is a mathematical model of the atmosphere and oceans. In this study, we used numerical forecast maps around Japan simulated using the global spectral model (GSM), which is an NWP model, provided by the Japan Meteorological Agency[2]. The maps are updated four times a day at 0000, 0600, 1200, and 1800 Japan Standard Time. The prediction of physical quantities such as humidity and temperature up to 84 hours ahead is available and is suitable for roughly determining weather trends over a few days. In the maps, grid points are set every 20 km in the range of 20 to 50 degrees north latitude and 120 to 150 degrees east longitude. Therefore, the maps are composed of 151 × 121 grid points, where each point contains simulation results of the physical quantities corresponding to the area, such as 1021.01 hPa for air pressure.

Observation Data Since weather-forecast comments are often written in comparison with past weather (e.g., the day before), we also introduce meteorological observation data provided by the automated meteorological data acquisition system (AMeDAS), managed by Japan Meteorological Agency[3]. Specifically, we use four physical quantities: precipitation, air temperature, wind speed, and sunshine duration. These quantities are sequential data observed every ten minutes at about 1300 stations across Japan.

4 Weather-Forecast Generation

We consider weather-forecast generation as a task of generating a description from a sequence of 2D data, which is a forecast map. Since this can be viewed as video captioning (Yao et al., 2015; Long et al., 2018), we first introduce an encoder-decoder model (Sutskever et al., 2014) with an attention mechanism (Bahdanau et al., 2015).

Figure 2 shows an overview of our proposed model. It takes three types of input data: a sequence of numerical forecast maps $\boldsymbol{g} = (g_i)_{i=1}^{|\boldsymbol{g}|}$, observation data $\boldsymbol{a} = \{a_i\}_{i=1}^{|\boldsymbol{a}|}$, and meta-data for comments such as delivery time and area $\boldsymbol{m} = \{m_i\}_{i=1}^{|\boldsymbol{m}|}$. Here, g_i, a_i, and m_i represent a forecast map, a numeric vector for a certain physical quantity (e.g., precipitation), and an embedding vector for specific information (e.g., area name), respectively. The output of our proposed model is a weather-forecast comment $\boldsymbol{w} = (w_i)_{i=1}^{|\boldsymbol{w}|}$ and weather labels $\boldsymbol{l} = \{l_i\}_{i=1}^{|\boldsymbol{l}|}$, where w_i and l_i are a word and a weather label, respectively.

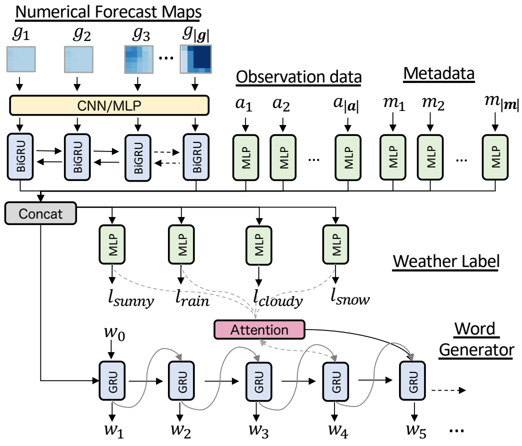

Figure 2: Neural network architecture of proposed model. For simplicity, attention mechanism for three types of input data is omitted.

For the numerical maps, we use either an MLP or CNN to extract numeric features related to physical quantities, such as air pressure, and input each map to a Bi-RNN to take their sequential information into account. We also incorporate meteorological observation data $\boldsymbol{a}$ and meta-data $\boldsymbol{m}$ by encoding with an MLP. We use the MLP to predict weather labels $\boldsymbol{l}$ from the output of the encoders. We use the RNN language model (RNNLM) (Mikolov et al., 2010) to generate words $\boldsymbol{w}$.

We explain our proposed model and how we introduce meta-data and weather labels into it in the following sections.

4.1 Extracting Numerical Maps for Areas

A weather forecaster writes a weather comment for a specific area by referring to weather data corresponding to the area. With this in mind, we extract a g_i for each area, which has 5 × 5 grid points, from an larger map that has 151 × 121 grid points on the basis of latitude and longitude. The extracted map will be a map of 100 square kilometers around the area. Thus, a sequence of numerical forecast maps $\boldsymbol{g}$, for a specific area (e.g., Tokyo) can be acquired, as shown in Figure 3, which shows changes for ten

---

[3] `http://www.jma.go.jp/en/amedas/`

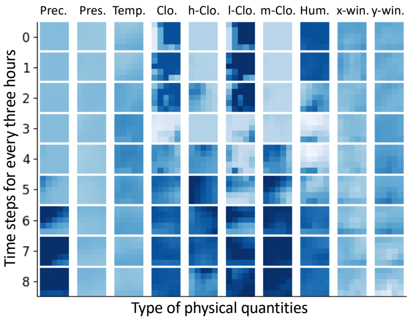

Figure 3: Sequence of numerical forecast maps for specific area, extracted from larger map. Types of physical quantities are as follows: precipitation (Prec), air pressure (Pres), air temperature (Temp), cloud cover (Clo), high-level cloud cover (h-Clo), low-level cloud cover (l-Clo), medium-level cloud cover (m-Clo), humidity (Hum), and wind direction (x-win, y-win).

types of physical quantities (such as precipitation and cloud cover) predicted with an NWP model every three hours up to 24 hours ahead.[4]

4.2 Encoding Numerical Forecast Maps

The task of generating text from sequences of 2D data can be regarded as video captioning. Thus, we use either a CNN or MLP to capture the numeric features of forecast maps. We compared the following two encoders in our experiments.

CNN-based Encoding A CNN is widely used in video captioning to extract visual features from each frame of a video. For example, the CNN encoder for color images has three channels for red, green, and blue. We used ten channels, each channel corresponds to one of the physical quantities (e.g., precipitation), shown in Figure 3, to take the relationships among them into consideration.

MLP-based Encoding In image recognition, a CNN has an advantage over an MLP in terms of translation invariance. However, since we use a map for a specific area, which is extracted from a larger map and whose center is always that area, we hypothesize that a model that takes into account the absolute position on the map is more suitable. Therefore, we use an MLP, which has $10 \times 5 \times 5$ units, to extract the features from forecast maps.

By applying the encoding method to a g_i for each time-step t, we obtain an output vector h^g_i. Next, we sequentially input vector h^g_i to a Bi-RNN to capture value changes for physical quantities in the sequence. As a result, we have the output vector h^g that represents time-series changes in $\boldsymbol{g}$ by concatenating the hidden states of the Bi-RNN:

$$h^g = [h^g_1; h^g_{|\boldsymbol{g}|}], \tag{1}$$

where $[;]$ represents a vector concatenation.

4.3 Encoding Observation Data

With regard to $\boldsymbol{a}$, which are a set of observed values for physical quantities (e.g., sun duration), we use an MLP, which performed best in a study by Murakami et al. (2017). We apply the MLP to each a_i to obtain feature vectors h^a_i. These vectors are concatenated to create the representation that captures the characteristics of meteorological observation data:

$$h^a = [h^a_1; h^a_2; \cdots; h^a_{|\boldsymbol{a}|}]. \tag{2}$$

4.4 Introducing Meta-Data

Since weather forecasters often take their own local knowledge and time information into account when writing weather comments, we incorporate the meta-data for weather comments (such as delivery time) to generate word expressions that depend on the date and time for a comment, e.g., "*today*". Specifically, we create an m_i on the basis of the delivery time and area name (such as *5 a.m.* and *Tokyo*, as shown in Figure 1). We also encode the vector by using the MLP and concatenate its output vector h^m_i. Thus, we obtain a vector h^m that captures the meta-data $\boldsymbol{m}$:

$$h^m = [h^m_1; h^m_2; \cdots; h^m_{|\boldsymbol{m}|}]. \tag{3}$$

Finally, we set the initial hidden state s_0 of both decoders as follows:

$$s_0 = \mathrm{ReLU}(\mathrm{MLP}([h^g; h^a; h^m])). \tag{4}$$

4.5 Weather Labels

In this task, the informativeness of weather comments and their correctness are a key factor. However, since neural-generation models often struggle to capture long-term dependencies, they lose important information included in input data. This shortcoming limits their application to the real world. Thus, we propose a method for explicitly specifying the *content* to be mentioned to help our proposed model correctly describe useful information,

---

[4] The shade of color for physical quantities indicates the magnitude of predicted values. The predicted values are standardized with all values for a year. For example, the dark color for precipitation around 15–18 hours later in Figure 3 indicates that the predicted amount of precipitation is relatively high.

Label	**Clue words**
SUNNY	晴れ (*sunny*), 日差し (*sunlight*), 青空 (*blue sky*)
RAIN	雨 (*rain*), 大雨 (*heavy rain*), にわか雨 (*shower*)
CLOUDY	曇り (*cloudy*), 曇 (*cloudy*), 雲 (*cloud*)
SNOW	雪 (*snow*), 吹雪 (*blizzard*), 小雪 (*light snowfall*)

Table 1: Example weather labels and their corresponding clue words. English translations are given in parentheses. All examples are shown in Appendix A.

inspired by the recent success of faithful data-to-text generation (Ma et al., 2019; Wang et al., 2020) and the controllability of neural models with explicit labels (Aoki et al., 2019). However, since most data-to-text datasets do not typically include content plans, we introduce a simple approach for extracting them from a text as a pseudo reference.

Since consumers are primarily interested in weather information such as sunny and rain, we define such content in weather comments as *weather labels*. Specifically, we introduce four types of weather labels: SUNNY, RAIN, CLOUDY and SNOW. To extract weather labels from weather comments, we define clue words for each weather label, as shown in Table 1. Our strategy is to explicitly match the clue words and words in weather comments. For example, the weather comment in Figure 1 includes the clues words "*blue sky*", "*cloudy*", and "*rain*", so three weather labels, SUNNY, CLOUDY, and RAIN can be associated with the comment. The method for labeling text is very simple, but we found that it works in most cases[5]. The method can also avoid the following two issues in weather-comment generation. First, it is almost impossible to explicitly associate a comment with continuous numerical data such as meteorological data, although the table-to-text task can easily do this, as discussed in Section 2. Second, we need expert knowledge if we annotate content to be mentioned in input data without reference text.

To determine content to be mentioned before text generation begins, we introduce a binary classifier for each weather label, as shown in Figure 2. The classifier is based on an MLP. We train the classifier with the weather labels extracted from comments in the training data. In the inference stage, each classifier predicts each weather label (e.g., l_{sunny}) from the three types of input data ($\boldsymbol{g}$, $\boldsymbol{a}$, $\boldsymbol{m}$). The word generator then generates weather comments $\boldsymbol{w}$ from the input data and those labels.

4.6 Word Generator

The word generator is based on a RNNLM with an attention mechanism. In addition to introducing the attention mechanism into input data (Wiseman et al., 2017; Chen et al., 2019), we also introduce the attention mechanism into the weather labels, as shown in Figure 2. The word generator is designed to take into account weather labels to explicitly describe important information in text generation through this attention mechanism.

In the word generator, the probability of producing a word w_t at t is computed by

$$p(w_t|w_{<t}, \boldsymbol{g}, \boldsymbol{a}, \boldsymbol{m}, \boldsymbol{l}) = \mathrm{softmax}_{\mathrm{w_t}}(W_s s_t^w), \quad (5)$$

$$s_t^w = \mathrm{GRU}(w_{t-1}, s_{t-1}^w, c_t), \quad (6)$$

where w_{t-1} and s_{t-1}^w are an output word and the hidden state of the word decoder at time step $t-1$, respectively. W_s is a weight matrix. Vector c_t represents the context vector at t, which is created by concatenating four context vectors $[c_t^g; c_t^a; c_t^m; c_t^l]$ constructed with the attention mechanism (Bahdanau et al., 2015) for input data $(\boldsymbol{g}, \boldsymbol{a}, \boldsymbol{m})$ and weather labels $\boldsymbol{l}$. For instance, the context vector c_t^l over $\boldsymbol{l}$ at t can be calculated as follows:

$$c_t^l = \sum_{i=1}^{|\boldsymbol{l}|} \alpha_{t,i}^l s_i^l, \quad \alpha_{t,i}^l = \frac{\exp(\eta(s_{t-1}^w, s_i^l))}{\sum_{j=1}^{|\boldsymbol{l}|} \exp(\eta(s_{t-1}^w, s_j^l))}, \quad (7)$$

where s_i^l represents the hidden state of the weather-label classifier for label l_i, and $\alpha_{t,i}^l$ is the alignment probability between the t-th output word and i-th hidden state in the classifier. We use an MLP η as a score function. Note that c_t^g, c_t^a, and c_t^m for the input data ($\boldsymbol{g}$, $\boldsymbol{a}$, $\boldsymbol{m}$) can be derived with Equation (7) in a similar manner.

5 Experiments

5.1 Setup

Dataset We used weather comments from 2014 to 2015 in Japan as the text dataset, which consists of 57,412 comments provided by Weathernews Inc. We separated the dataset into 28,555 comments from 2014 for training, 14,464 and 14,393 comments from 2015 for development and testing. For the numerical forecast maps, we collected 2,715

---

[5] We evaluated correctness of the extracted weather labels by five people on the basis of 100 comments, which are randomly extracted from development set. As a result, 96% of the weather labels were judged to be appropriate.

maps corresponding to the comments from the website[6] of the Research Institute for Sustainable Humanosphere, Kyoto University. We also separated the numerical maps into 1,344 from 2014 for training, 1,326 and 1,329 from 2015 for development and testing, respectively. Their sum does not agree with the total number of maps, 2,715 because the weather comments for development and testing are sampled from 2015, and numerical maps for different areas are often extracted from a single entire map around Japan and are used for them. Note that the weather comments and the corresponding extracted maps are unique for each area, and the comments for development and testing do not overlap with each other.

We used a $\boldsymbol{g}$, which consists of nine steps every three hours up to 24 hours ahead, since the comments treat weather forecasts up to the next day. Referring to delivery date and time of a comment, we aligned each $\boldsymbol{w}$ with the extracted $\boldsymbol{g}$ obtained by following the procedure in Section 4.1. We also used precipitation, air temperature, wind speed, and sunshine duration for the last 24 hours as $\boldsymbol{a}$, where each a_i consists of observed values for 24×6 steps. As $\boldsymbol{m}$, we used delivery date, time, and area name (e.g., *April*, *Monday*, *5 a.m.*, *Tokyo*).

Implementation We used a single-layer MLP and bi-directional gated recurrent unit (Bi-GRU) for the encoders and two-layer GRU for the word generator. Note that we have investigated a transformer-based model (Vaswani et al., 2017), but we found that there were no significant differences between the transformer-based model and the GRU-based model. The hidden states of our model and size of the word embeddings were both 512. We set the dimension size of the hidden vectors for the meta-data h_i^m and observation data h_i^a to 64. The model was trained using the Adam optimizer (Kingma and Ba, 2015). We applied an early stopping strategy with a minimum number of 25 epochs. We stopped training if there was no improvement in validation loss for three consecutive epochs.

Evaluation Metrics For the automatic evaluation, since reference texts written by meteorological experts generally mention important information such as sunny and rain, we used BLEU-4[7] (Papineni et al., 2002) and ROUGE-1[8] (F_1 score) (Lin, 2004) to see whether generated texts properly mention the important information as reference texts do. However, since these metrics based on word overlapping rely on the reference texts, they cannot be used to assess the correctness of the generated texts if their expressions are different from the reference texts. Thus, we also calculated precision, recall and F_1 scores of weather labels, which are extracted from the generated texts, to see how they properly describe important information in comparison with those of the reference texts.

For the human evaluation, we asked five participants to give each generated comment a score from 1 to 3 for informativeness, consistency, and grammar, where 3 is the highest. In the evaluation of informativeness, we showed the participants a human-generated comment as a reference and asked them to compare the generated text and reference. This was done because understanding complicated input data for data-to-text generation is extremely difficult for non-specialists. We randomly selected 40 comments from the test set[9]. Each comment was rated by all five participants. We used Wilcoxon signed rank test (Wilcoxon, 1945) to test the statistical significance of the difference among comparative models. The details for instructing the human raters how to evaluate each comment are provided in Appendix B.

Models We defined five models listed in Table 2 and *w/o Meta*, which does not take meta-data into account, to determine whether each component (e.g., weather label) contributes to the results. Models (1) and (2), which do not take weather labels into account, were regarded as baselines. Model (3) uses the weather labels that we proposed. To further improve the correctness of generated texts, we also introduced model (4) to investigate a content-matching constraint loss (Wang et al., 2020) that aims to constrain an embedding of input data to be close to the corresponding target text embedding. Specifically, we calculated the loss between the output embeddings of the weather-label classifier and the target text embeddings to make their representations close. We also evaluated model (5) that used oracle labels extracted from the reference text to validate the upper bound of improvement in the

correctness of generated text with the labels.

A rule-based system could be also considered as a comparative model, but we could not include it since it is practically impossible to construct their *rules* without expert knowledge in meteorology.

5.2 Results

The results of the automatic evaluation are listed in Table 2. To see how our proposed model can correctly describe the content of weather forecasts, we calculated precision, recall, and F_1 scores of weather labels, which are extracted from their generated texts, by referring to weather labels extracted from human-generated texts as references. Models (3) and (4), which introduce weather labels, outperformed the baselines, which do not take into account the weather labels. In particular, we found that models (3) and (4) significantly improved F_1 scores for the sunny and snow labels by around 5% in comparison to the baselines. This suggests that incorporating the weather labels enables the model to more correctly generate texts.

In terms of BLEU and ROUGE, model (4) outperformed all other models except (5), which can use oracle labels. Interestingly, model (5) significantly improved the correctness of each weather label as in Table 2 since it can use the oracle labels, but the improvement in BLEU and ROUGE scores was limited. This implies that it is difficult to evaluate the correctness of generated texts by relying on only these metrics.

5.3 Contributions of Each Component

Next, we compared the models to investigate how each component contributes to their performance.

Encoder for numerical maps In the comparison between models (1) and (2), which use either a CNN or MLP as an encoder for numerical forecast maps, no significant differences were found.[10] This suggests that either encoder is acceptable, although we had originally expected the MLP encoder that takes into account absolute positions on the maps to be more suitable than a CNN encoder because of its simplicity.

Effect of meta-data With regard to the meta-data such as delivery time and date, for which we expected the model to generate time-dependent expressions (e.g., “*today*”), we conducted an ablation

---

[10] In spite of this, we used an MLP for the models to add other components since it performed slightly better than a CNN in the experiments.

Model	I	C	G	Generated comment
Ref.	–	–	–	今日は、うっすら雲が広がりやすいものの、日差しが届きます。夏至の日差しは強烈なので、紫外線・暑さ対策が欠かせません。 (*Today, the sky will easily become partly cloudy, but it will become sunny. Since the sun this summer is intense, please take precautions against the heat and ultraviolet rays.)*
(2)	2.0	3.0	3.0	今日（月）は日差しが届きますが、段々と雲が広がります。午後はニワカ雨の可能性があるので、折りたたみ傘があると安心です。 (*Today (Monday), it will be sunny then gradually become cloudy. Since there is a chance of rain in the afternoon, it will be a good idea to take a folding umbrella when you go out.)*
(4)	2.8	2.8	3.0	今日（月）は雲が広がりやすいものの、日差しが届く時間もあります。ムシムシとした暑さになるので、熱中症対策を忘れずに。 (*Today (Monday), the sky will become cloudy but will become sunny. Since it will be hot and humid, please remember to take precautions against heatstroke.)*

Table 5: Reference weather comment written by human (Ref.) and those comments generated from models (2) and (4). Weather labels extracted from the reference text are SUNNY and CLOUDY. The reference comment was posted at 00:02 a.m. on Monday June 22, 2015 for the *Toyohashi* area. Columns I, C, and G show average scores for informativeness, consistency, and grammar from human evaluation, respectively. Each example is accompanied by its English translation.

Label	Model(2)			Model(4)			# of cases
	Info.	Con.	Gra.	Info.	Con.	Gra.	
SUNNY	1.92	2.91	2.91	2.10	2.82	2.88	26
RAIN	2.02	2.93	2.92	2.13	2.88	2.90	26
CLOUDY	1.99	2.93	2.94	2.12	2.83	2.89	19
SNOW	1.88	2.95	2.92	1.95	2.91	2.94	13
Overall	1.98	2.92	2.92	2.10	2.86	2.90	40

Table 6: Results of human evaluation. Scores are averages given by five human raters. Columns Info, Con, and Gra represent informativeness, consistency, and grammar, respectively. Differences in informativeness and consistency are statistically significant at $p < 0.05$.

study to investigate whether our proposed model can properly generate these expressions in comparison with w/o Meta that does not take into account such meta-data. Specifically, we calculated F_1 scores for time-dependent expressions by using weather comments written by human as references. Table 3 shows F_1 scores for each expression in the comments generated with model (4) and w/o Meta, respectively. We found that model (4), which takes into account the meta-data, can more accurately provide time-dependent expressions than w/o Meta. This finding suggests that introducing the meta-data into a generation model improve the correctness of meta-data in generated comments.

Effect of weather labels In comparison between models (2) and (3), which do not and do use the weather labels, respectively, we found that model (3) significantly improved the F_1 scores for the weather labels extracted from their generated comments than model (2). Specifically, the recall scores significantly improved regarding the weather labels for sunny and snow. This indicates that specifying content to be mentioned, such as weather labels, helps the model to explicitly describe the information.

We also tested a classifier that only predicts weather labels from input data to clarify the upper bound of the improvement in the correctness of each weather label extracted from its generated text. Table 4 presents the results of weather-label prediction by the classifier. According to the comparison between Tables 2 and 4, the scores of weather labels extracted from the generated texts with models (3) and (4) are approaching the upper bound by the classifier, but there is still room for improvement.

Effect of content-matching constraint To investigate the effectiveness of the content-matching constraint loss (Wang et al., 2020) for improving faithfulness of generated texts, we compared model (4), which uses this loss, with model (3), which does not. There was a slight improvement in BLEU and ROUGE scores.

5.4 Human Evaluation

Table 6 lists the results of the human evaluation, where # represents the number of cases, which includes each weather label in the evaluation set. Note that a comment may contain multiple labels. Overall, model (4), which explicitly performs content selection by using weather labels, outperformed model (2), which does not, in terms of informativeness[11]. This indicates that introducing weather labels contributes to the correctness of information included in generated texts, as we also can see from the results of the automatic evalua-

---

[11] Specifically, model (4) was rated more informative than model (2) in 20 of the 40 cases. 10 of them were equivalent.

tion. Model (4), however, was inferior to model (2) in terms of consistency, although the score is still significantly high. This is reasonable because more information makes it more challenging to maintain consistency. To solve this problem, it is necessary to carry out not only content selection but also content planning to specify both *what to say* and *in which order* (Wiseman et al., 2017).

Table 5 shows an example reference and weather comments generated with models (2) and (4). Both models correctly described the information on cloudy weather and sunshine, but model (2) mistakenly described rainy weather compared with the reference. In contrast, model (4) properly described all the information including hot weather and was judged as more informative than model (2). More generation examples are given in Appendix C.

6 Conclusion

In this paper, we addressed the task of generating weather comments from meteorological simulations. We proposed a data-to-text model and incorporated three types of encoders for forecast maps, observation data, and meta-data into the model. In addition, we introduced weather labels representing the content of weather information to explicitly carry out content selection and improve the correctness of information in generated comments. Experiments indicated that our model significantly improved the informativeness of generated comments and outperformed the baselines in both automatic and human evaluations.

A Examples of All Clue Words

To extract weather labels from weather comments, we defined clue words for each weather label, as shown in Table 7. Note that we selected the clue words in reference to the development data.

B Details of Human Evaluation

The following are the instructions presented to evaluation raters during the human evaluation. Each comment was rated by all five participants.

We only showed the raters the weather comments written by human as references to evaluate the generated comments. This was done because understanding complicated data, which is used as input for data-to-text generation, such as numerical forecast maps, is particularly difficult for non-specialists.

Informativeness:

3: This is an ideal weather comment since it appropriately mentions important information.

2: Although some important information is missing, the information included in the comment is appropriate and is acceptable as a weather comment.

1: The information included in the comment is incorrect and inappropriate as a weather comment.

Consistency:

3: The comment is consistent on the whole and it is easy to read.

2: The comment lacks consistency in some parts and is difficult to read.

1: The comment lacks consistency on the whole and is difficult to understand.

Grammar:

3: There are no grammatical errors.

2: There are some grammatical errors, but it is understandable.

1: There are many grammatical errors, and it is difficult to understand.

C More Generation Examples

More generation examples from model (2) and (4) are shown in Table 8 and 9. In this example, we can observe that model (2) was judged as less informative on average by the five raters in comparison with model (4) since the comments generated by model (2) provide incorrect information (e.g., *rain shower* instead of *snow* in Table 8), or lack important information (e.g., *rain* in Table 9). On the other hand, model (4), which is our proposed model, properly describes these important information.

Label	**Clue words**
SUNNY	晴れ (*sunny*), 日差し (*sunlight*), 青空 (*blue sky*), 回復 (*improvement*), 日和 (*perfect day*), 陽気 (*weather*), 秋晴れ (*fine autumn day*), 晴天 (*fine weather*), 晴れ間 (*patch of blue sky*), 晴れる (*clear up*), 太陽 (*sun*), 五月晴れ (*beautiful weather in May*)
RAIN	雨 (*rain*), 大雨 (*heavy rain*), にわか雨 (*shower*), 雷雨 (*thunderstorm*), 暴風雨 (*storm*), 雨風 (*rain and wind*), 荒天 (*stormy weather*), 台風 (*typhoon*), 傘 (*umbrella*)
CLOUDY	曇り (*cloudy*), 曇 (*cloudy*), 雲 (*cloud*)
SNOW	雪 (*snow*), 吹雪 (*blizzard*), 小雪 (*light snowfall*), 吹雪く (*snow blowing*), ふぶく (*snow blowing*)

Table 7: Weather labels and their corresponding clue words we used to extract labels from weather comments. Corresponding English translations are also given in parenthesis.

Abstract

We present SICK-NL (read: *signal*), a dataset targeting Natural Language Inference in Dutch. SICK-NL is obtained by translating the SICK dataset of Marelli et al. (2014) from English into Dutch. Having a parallel inference dataset allows us to compare both monolingual and multilingual NLP models for English and Dutch on the two tasks. In the paper, we motivate and detail the translation process, perform a baseline evaluation on both the original SICK dataset and its Dutch incarnation SICK-NL, taking inspiration from Dutch skipgram embeddings and contextualised embedding models. In addition, we encapsulate two phenomena encountered in the translation to formulate *stress tests* and verify how well the Dutch models capture syntactic restructurings that do not affect semantics. Our main finding is all models perform worse on SICK-NL than on SICK, indicating that the Dutch dataset is more challenging than the English original. Results on the stress tests show that models don't fully capture word order freedom in Dutch, warranting future systematic studies.

1 Introduction

One of the primary tasks for Natural Language Processing (NLP) systems is Natural Language Inference (NLI), where the goal is to determine, for a given premise sentence whether it contradicts, entails, or is neutral with respect to a given hypothesis sentence.

For English, several standard NLI datasets exist, such as SICK (Marelli et al., 2014), SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018). Having such inference datasets available only for English may introduces a bias in NLP research. Conneau et al. (2018) introduce XNLI, a multilingual version of a fragment of the SNLI dataset, that contains pairs for Natural Language Inference in 15 languages and is explicitly intended to serve as a resource for evaluating crosslingual representations. However, Dutch is not represented in any current NLI dataset, a lack that we wish to complement.

Dutch counts as a high-resource language, with the sixth largest Wikipedia (2M+ articles), despite having ca. 25M native speakers. Moreover, the syntactically parsed LASSY corpus of written Dutch (van Noord et al., 2013), and the SONAR corpus of written Dutch (Oostdijk et al., 2013) provide rich resources on which NLP systems may be developed. Indeed, Dutch is in the scope of the multilingual BERT models published by Google (Devlin et al., 2019), and two monolingual Dutch BERT models have been published as part of HuggingFace's transformers library (de Vries et al., 2019; Delobelle et al., 2020).

Compared to English, however, the number of evaluation tasks for Dutch is limited. There is a Named Entity Recognition task coming from the CoNLL-2003 shared task (Tjong Kim Sang and De Meulder, 2003); from a one million word hand annotated subcorpus of SONAR (Oostdijk et al., 2013) one derives part-of-speech tagging, Named Entity Recognition and Semantic Role Labelling tasks. More recently a Sentiment Analysis dataset was introduced, based on Dutch Book reviews (van der Burgh and Verberne, 2019). Moreover, Allein et al. (2020) introduce a classification task where a model needs to distinguish between the pronouns *die* and *dat*.

Given the focus on word/token-level tasks in Dutch, we aim to complement existing resources with an NLI task for Dutch. We do so by deriving it from the English SICK dataset, for the following reasons: first, this dataset requires a small amount of world knowledge as it was derived mainly from image captions that are typically concrete descriptions of a scene. Therefore, no world knowledge requirements will be imposed on an NLP model

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1474–1479
April 19 - 23, 2021.

for the task, but rather its ability for reasoning will be assessed. Secondly, due to the structure of the sentences in SICK, the types of inferences can be attributed to particular constructs, such as hypernymy/hyponymy, negation, or choice of quantification. Thirdly, SICK contains 6076 unique sentences and almost 10K inference pairs, making it a sizeable dataset for NLP standards, while deriving a Dutch version is more manageable than with other datasets. We make the dataset, code and derived resources (see Section 5) available online[1].

2 Dataset Creation

We follow a semi-automatic translation procedure to create SICK-NL, similar to the Portuguese version of SICK (Real et al., 2018). First, we use a machine translator to translate all of the (6076) unique sentences of SICK[2]. We review each sentence and its translation in parallel, correcting any mistakes made by the machine translator, and maintaining consistency of individual words' translation, in the process guaranteeing that the meaning of each sentence is preserved as much as possible. Finally, we perform a postprocessing step in which we ensure unique translations for unique sentences (alignment) with as few exceptions as possible. In this way we obtain 6059 unique Dutch sentences, which means that the dataset is almost fully aligned on the sentence level. It should be noted, however, that we can not fully guarantee the same choice of words in each sentence *pair* in the original dataset, as we translate sentence by sentence. In the whole process, we adapted 1833 of the 6076 automatic translations, either because of translation errors or alignment constraints. As we are interested in collecting a comparable and aligned dataset, we maintain the relatedness and entailment scores from the original dataset.

	SICK	**SICK-NL**
No. of tokens	189783	176509
No. of unique tokens	2328	2870
Avg. sentence length	9.64	8.97
Avg. word overlap	66.91%	58.99%

Table 1: Basic statistics of SICK and SICK-NL.

Table 1 shows some statistics of SICK and its Dutch translation. The most notable difference is that the amount of unique words in Dutch is 23% higher than that in English, even though the total number of words in SICK-NL is about 93% of that in SICK. We argue that this is due to morphological complexities of Dutch, where verbs can be separable or compound, leading them to be split up into multiple parts (for example, "*storing*" becomes "*opbergen*", which may be used as "*de man bergt iets op*"). Moreover, Dutch enjoys a relatively free word order, which in the case of SICK-NL means that sometimes the order of the main verb and its direct object may be swapped in the sentence, especially when the present continuous form ("*is cutting an onion*") is preserved in Dutch ("*is een ui aan het snijden*"). Finally, we follow the machine translation, only making changes in the case of grammatical errors, lexical choice inconsistencies, and changes in meaning. This freedom leads to a decrease in relative word overlap between premise and hypothesis sentence, computed as the number of words in common divided by the length of the shortest sentence. From the perspective of Natural Language Inference this is preferable as word overlap often can be exploited by neural network architectures (McCoy et al., 2019).

3 Baseline Evaluation and Results

We evaluate two types of models as a baseline to compare SICK-NL with its English original.

First, we evaluate embeddings that were not specifically trained on SICK. Table 2 shows the correlation results on the relatedness task of SICK and SICK-NL, where the cosine similarity between two independently computed sentence embeddings is correlated with the relatedness scores of human annotators (between 1 and 5).

	SICK		**SICK-NL**
Skipgram	69.49	Skipgram	56.94
BERT$_{cls}$	50.78	BERTje$_{cls}$	49.06
BERT$_{avg}$	61.36	BERTje$_{avg}$	55.55
RoBERTa$_{cls}$	46.62	RobBERT$_{cls}$	43.93
RoBERTa$_{avg}$	62.71	RobBERT$_{avg}$	52.33

Table 2: Pearson r correlation coefficient for the relatedness task of the English SICK dataset (left) and its Dutch translation (right).

To obtain sentence embeddings here, we average skipgram embeddings, or, in the case of contextualised embeddings, we take either the sentence embedding given by the $[CLS]$ token, or

---

[1] `github.com/gijswijnholds/sick_nl`

[2] We used DeepL's online translator `www.deepl.com/translator`

we take the average of the individual word's embeddings. For the skipgram embeddings in English, we use the standard 300-dimensional GoogleNews vectors provided by the `word2vec` package and for Dutch, we use the 320-dimensional Wikipedia trained embeddings of Tulkens et al. (2016).

The relatedness results show that (a) using the $[CLS]$ token embedding as a sentence encoding performs worse than taking the average of word embeddings, and that (b) the Dutch incarnation of SICK is harder than the original English dataset. It may be noted that relatedness scores are less robust then entailment labels, and so our first result may not be enough support for the claim that SICK-NL poses a more challenging task. For example, it could be that relatedness scores will differ slightly if we were to ask a number of annotators to re-evaluate the Dutch dataset.

In the second setup, we use BERTje, the Dutch BERT model of de Vries et al. (2019) and RobBERT, the Dutch RoBERTa model of Delobelle et al. (2020), with their corresponding English counterparts, as well as multilingual BERT (mBERT), as sequence classifiers on the Entailment task of SICK(-NL). Here we observe a similar pattern in the results in Table 3: while there are individual difference on the same task, the main surprise is that the Dutch dataset is harder, even when exactly the same model (mBERT) is used.

	SICK		**SICK-NL**
BERT	87.34	BERTje	83.94
mBERT	87.02	mBERT	84.53
RoBERTa	90.11	RobBERT	82.02

Table 3: Accuracy results on the entailment task of the English SICK dataset and its Dutch translation for two Dutch BERT models and their English counterparts. For each model, we report the best score out of 20 epochs of fine-tuning.

4 Error Analysis

In order to understand the differences between the Dutch and English language models on the respective tasks, we dive deeper into the classification results. We plot confusion matrices for each model in Table 5, where we separate predictions that the models have in common and the from the predictions that are unique to each model.

In the case of English, performance on classifying contradictions is worse for multilingual BERT and RoBERTa, and RoBERTa also gives highest recall values for the Neutral and Entailment labels. This is all not surprising given that RoBERTa has the overall highest test set accuracy. The surprising results come mainly from the comparison between English and Dutch models. Where BERTje is rather indecisive when it comes to Neutral sentence pairs (it classifies roughly equal numbers as Neutral and Entailment), it classifies 74% of Entailment pairs as Neutral. For multilingual BERT the situation is reversed, with 47% of Neutral entailments classified as Entailment, although for cases of entailment, the classifier did not clearly distinguish Neutral from Entailment. The most surprising pattern was observed in RobBERT: where RoBERTa still has high recall for Neutral and Entailment, its Dutch counterpart RobBERT mistakes most Neutral cases as Entailment and even more so vice versa. For all models, in these four cases of misclassification, in the case of the English task the correct inference was made in at least 99% of the cases.

Following Naik et al. (2018), we inspect these prominent cases of misclassification in Dutch by looking at the number of cases of high overlap (at most four words not in common), and at the number of length mismatches (the difference between sentence length exceeds 4), and set off these distributions against that of the test set, in Table 4.

	BERT (N→E)	**mBERT** (E→N)	**RobBERT** (N→E)	**RobBERT** (E→N)	**Test**
	Word difference				
EN	66%	42%	62%	44%	40%
NL	47%	38%	41%	38%	28%
	Length mismatch				
EN	24 %	17%	25%	17%	27%
NL	30 %	31%	28%	25%	36%

Table 4: Error analysis of prominent misclassifications.

The main finding here is that word overlap does provide a strong cue in the English dataset, especially given that SICK has more cases (1970) overall than SICK-NL (1385), and that in SICK they are more concentrated in cases of Entailment. Length mismatches occur more often in SICK-NL but seem to provide less of a cue to the models to make strong inference decisions.

BERT		**Prediction EN-NL**				**Prediction EN**				**Prediction NL**

5 Stress Testing

One of the potential sources of error could have been the passive form translation of a verb. Such constructions, combined with a prepositional phrase, form an interesting testbed for Dutch as they allow the prepositional phrase to be moved in front of the verb in a sentence without changing the meaning. For example, "*Een vrouw is aan het wakeboarden op een meer*" ("*A woman is wakeboarding on a lake*"), may in Dutch be used interchangeably with "*Een vrouw is op een meer aan het wakeboarden*"). We select all (87) sentences in SICK-NL that contain both the 'aan het' construction and a prepositional phrase, and generate their permutations. Then, we replace all (225) inference pairs with these sentences such that they now contain a sentence with different word order but the exact same meaning and therefore the inference label is preserved. We then verify how the model's predictions do on those inference pairs that were in the test set (116). Additionally, we check whether the models are able to interchange sentences and their rewritten equivalent (i.e. classify as Entailment).

As a second test, we investigate the role of the simple present versus the present continuous. We take all the (383) cases of present continuous in the Dutch dataset and replace them by a simple present equivalent, leading to 1137 pairs, out of which 576 occur in the test data. For example, we turn the sentence "*De man is aan het zwemmen*" into the simple form "*De man zwemt*". We then repeat the same procedure as above, asking how many inference predictions change as a result of this form change, and whether the forms can be used interchangeably for the models.

	present cont. → present simple			
	Before	After	→	←
BERT	84.55	86.63	93.21	92.43
mBERT	86.11	84.90	94.26	94.52
RobBERT	82.81	81.94	86.16	84.33
	prep. phrase order switch			
BERT	81.03	78.45	85.06	85.06
mBERT	87.93	85.34	85.06	80.46
RobBERT	76.72	75.86	72.41	73.56

Table 6: Stress test accuracy. Left: accuracy before and after rewriting. Right: inference between rewritings.

The results in Table 6 indicate that the interchange between present continuous and simple present forms does not make much of a difference to the models' performance, and interchangeability is high except for RobBERT that scores under 90%. However, switching the order of prepositional phrase and verb has a much stronger effect with all models consistently scoring lower on the relevant part of the test set, and mainly the models being particularly poor at interchanging these sentences that are semantically equivalent.

6 Conclusion

In this paper we introduced an NLI dataset for Dutch by semi-automatically translating the SICK dataset. To our knowledge this is the first available inference task for Dutch. Despite the common perception that Dutch is very similar to English, SICK-NL was significantly more difficult to tackle, even for language models that had access to the training data for fine-tuning. We hypothesised that the difference in result may be due to a larger vocabulary in SICK-NL, and a decline in word overlap between inference pairs. In addition we performed two stress tests and found that pretrained models that were exposed to the training data had difficulty detecting semantically equivalent sentences that differ only in word order. Further work will therefore more systematically assess such phenomena.

Acknowledgments

The authors are grateful to the anonymous reviewers for their valuable feedback, which improved the paper. Both authors acknowledge support from the Dutch Research Council (NWO) under the scope of the project "A composition calculus for vector-based semantic modelling with a localization for Dutch" (360-89-070).

Abstract

Non-native speakers show difficulties with spoken word processing. Many studies attribute these difficulties to imprecise phonological encoding of words in the lexical memory. We test an alternative hypothesis: that some of these difficulties can arise from the non-native speakers' phonetic perception. We train a computational model of phonetic learning, which has no access to phonology, on either one or two languages. We first show that the model exhibits predictable behaviors on phone-level and word-level discrimination tasks. We then test the model on a spoken word processing task, showing that phonology may not be necessary to explain some of the word processing effects observed in non-native speakers. We run an additional analysis of the model's lexical representation space, showing that the two training languages are not fully separated in that space, similarly to the languages of a bilingual human speaker.

1 Introduction

Compared to native speakers, non-native speakers perform differently in a variety of tasks related to auditory language processing, both at the phone and at the word level. At the phone level, these tasks usually require speakers to compare individual phones (e.g., phone discrimination or identification), while spoken word processing tasks usually test the implicit activation of a certain word in the memory (e.g., lexical priming, word translation). In some cases, non-native speakers' behavior is consistent across the tasks: lower performance in spoken word processing tasks is directly associated with difficult phone contrasts. For example, upon hearing a word *rock*, Japanese speakers activate both *rock* and *lock* in their lexical memory (Cutler and Otake, 2004), probably because they find it difficult to discriminate the English [ɹ]–[l] phone contrast (Miyawaki et al., 1975). In other cases, however, non-native speakers' behavior in spoken word processing tasks cannot be explained by difficult phone contrasts (Cook et al., 2016; Amengual, 2016; Darcy et al., 2012). For example, in a translation task native English speakers may confuse Russian words *moloko* [məɫʌˈko] ('milk') and *molotok* [məɫʌˈtok] ('hammer'), even though this pair of words does not have a difficult phone contrast (Cook et al., 2016).

This dissociation between the behavior in phone discrimination vs. spoken word processing tasks has been attributed to different kinds of representations involved. On the one hand, thanks to phonetic knowledge, speakers recognize individual phones in a given language. On the other hand, speakers store phonological representations of the words they know in their mental lexicon and use those representations to recognize spoken words (e.g., Pallier et al., 2001). It is often implicitly assumed that any lexical processing effect should be attributed to stored phonological representations of the words (Gor and Cook, 2020; Cook et al., 2016; Cook and Gor, 2015; Darcy et al., 2013, 2012; McQueen et al., 2006). At the same time, *phonetic* effects are not limited to the perception of individual phones:

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1480–1490
April 19 - 23, 2021.

some existing theories argue that phonetic details are encoded in the lexical memory (e.g., Pierrehumbert, 2002; Hawkins, 2003; Port, 2007). This raises the question: can some of the spoken word processing effects normally attributed to phonology be instead explained in terms of phonetic perception?

In this study, we use computational modeling to test a hypothesis that some spoken word processing effects observed in non-native speakers can be explained without involving phonolexical representations—by phonetic perception, which results from phonetic learning, or speakers' attunement to the sounds of their native language (Werker and Tees, 1984). We use a model developed for speech technology applications (Kamper, 2019). Earlier, it was used to simulate early phonetic learning and successfully predicted some infant phone discrimination data (Matusevych et al., 2020b). This model learns from natural speech data that is not segmented at the phone level. It never receives information about individual phones in isolation or about phone-level differences between words. Therefore, the model is not equipped with an explicit mechanism to learn abstract phonolexical representations, making it a good candidate to test our hypothesis: if our model without the knowledge of phonology can correctly predict a particular effect, that effect can at least partially be attributed to phonetic learning. Because our goal is to see whether phonetic perception can explain some of the existing data in principle, even just one phonetic model making correct predictions about the data would be a positive result.

By design, lexical processing tasks require at least minimal knowledge of the target language. That is why they are normally carried out with bilingual speakers (or second language learners: Gor and Cook, 2020; Amengual, 2016; Cook et al., 2016, etc.). In bilingual speakers, the two languages interact at various levels, including lexical (e.g., Weber and Cutler, 2004; Sunderman and Kroll, 2006). To take this into account, we simulate bilingual speakers by training the model on two languages simultaneously.

We present three simulations. The first two show that the model exhibits predictable behaviors in discrimination tasks. In the third one, we present a case study to test whether a lexical processing effect commonly attributed to phonological representations can be explained in terms of phonetic learning alone, without the influence of phonology. In addition, we examine whether the representations in our bilingual model match the pattern observed in bilingual lexical access. Existing studies (Weber and Cutler, 2004; Lagrou et al., 2011; Shook and Marian, 2012, etc.) show that upon the presentation of a word, competitor words in both languages may get activated (non-selective lexical access). We carry out a language classification task with our model, showing that the two languages are not fully separated in its representation space.

2 Method

2.1 Simulations

We train a computational model—a correspondence autoencoder recurrent neural network (CAE-RNN; Kamper, 2019)—on speech data from one or two languages in order to simulate monolingual and bilingual speakers. We then test these different versions of the model on discrimination tasks and compare the observed patterns to those found in human speakers. This general methodological framework is adopted from Schatz et al. (2019).

We run three simulations, described in more detail in the respective sections below. Although it would be ideal to use the same set of languages in each simulation, the choice of languages is limited by available results from studies with human participants. We use language pairs for which human data is available and where our model has previously been tested on the target languages in the monolingual context. In Simulation 1, we look at phone discrimination by infants exposed to two languages (English and Mandarin), showing that the model correctly predicts a discrimination pattern observed in such infants (Kuhl et al., 2003). In Simulation 2, we show that the model can predict discrimination effects at the word level, observed in adult native English speakers and Japanese learners of English (MacKain et al., 1981). In Simulation 3, we show that the result obtained in a translation judgment task with native Russian speakers and English learners of Russian (Cook et al., 2016) can be at least partially explained in terms of phonetic learning, without the effects of phonology.

2.2 Model

The CAE-RNN (Kamper, 2019) is an extension of a recurrent autoencoder (Chung et al., 2016), in which both encoder and decoder are recurrent neural networks. Unlike an autoencoder, the CAE-RNN is trained on pairs of word tokens of the same

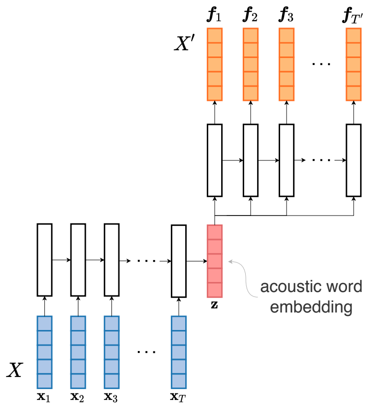

Figure 1: The model learns to reconstruct an acoustic instance of a word, X', from another acoustic instance of the same word, X.

type (e.g., two acoustic instances of the word *apple*). It receives one instance of a word (represented as a speech sequence), encodes it into a vector of a fixed dimensionality (an *acoustic embedding*), and then tries to reconstruct the other instance in the pair, as shown in Figure 1. Formally, each training item is a pair of acoustic words (X, X'). Each word is represented as a sequence of vectors: $X = (\vec{x}_1, \ldots, \vec{x}_T)$ and $X' = (\vec{x}'_1, \ldots, \vec{x}'_{T'})$. The loss for a single training item is:

$$\ell(X, X') = \sum_{t=1}^{T'} ||\vec{x}'_t - \vec{f}_t(X)||^2 \tag{1}$$

where X is the input and X' the target output sequence, and $f_t(X)$ is the t^{th} decoder output conditioned on the embedding $\mathbf{z}$. At inference time, we can encode a sequence of arbitrary duration (e.g., a phone or a word) into a fixed-dimensional acoustic embedding in the model's representation space.

We choose this model because it showed promise for the study of human cognition: it correctly predicted some patterns of infant phonetic learning (Matusevych et al., 2020b), and some of its basic properties are compatible with human auditory cognition and lexical access (Matusevych et al., 2020a). The advantage of this model compared to others (e.g., Schatz et al., 2019) is its ability to represent speech sequences of any duration in a common representation space (the embeddings have a fixed number of dimensions), in which perceptual similarity between sequences can be computed using a simple distance function. The model handles individual phones and acoustic words in exactly the same way, allowing us to easily generalize from phone-level to word-level representations. In addition, the model has been successfully trained on multiple languages for a speech technology application (Kamper et al., 2020a,b), potentially making it a good candidate for simulating bilingual speakers.

Table 1: Corpus samples used in the simulations.

Following earlier studies (Kamper, 2019; Matusevych et al., 2020b), we first pretrain the model as an autoencoder RNN for 15 epochs without early stopping using the Adam optimization (Kingma and Ba, 2015) with a learning rate of 0.001. We then train the model for 3 epochs on 100k ground truth pairs from either one or two languages as described next. We use 3 hidden layers (400 gated recurrent units each) in both the decoder and the encoder, and an embedding dimensionality of 130.

2.3 Training and test data

The model is trained on isolated words and tested on either phones or words extracted from corpora of natural speech based on existing forced alignments (Matusevych et al., 2020b; Kamper et al., 2020b). All speech data is encoded using a common approach in speech processing: each speech sequence is divided into 25-ms-long frames (sampled every 10 ms), from which 13 Mel-frequency cepstral coefficients (MFCCs) are extracted using Kaldi (Povey et al., 2011).

The subsets of the corpora that we use are listed in Table 1. Within each pair in part A of the table, the subsets are matched on the number of speakers, their gender, and the amount of data per speaker. This ensures that we only compare models trained on the same amount and type of data. In Simulations 1 and 2, we follow the setup from a previous study and use two subsets from different corpora per language. In Simulation 3, we could not obtain two different corpora of Russian speech, and instead train the model five times with different random initializations on the same data.

In case of bilingual models, we train them simultaneously on both languages, using mixed input. We use the relative amount of training data in each language as a simple proxy variable for language proficiency: the higher the model's relative exposure to a language, the higher its proficiency in that language. In bilingual training, we use the same total amount of data as for the corresponding monolingual models—in terms of both the number of tokens (for pretraining the model) and of training pairs. For example, consider a monolingual English model and a monolingual Mandarin model, each trained on 10k tokens and 100k pairs. Then for training a 'balanced' bilingual model we take the 5k most frequent tokens from English and Mandarin each, generate 50k pairs in each language, and use the combined 10k English–Mandarin token data for pretraining and the combined 100k pairs for training the CAE-RNN.

2.4 Simulating discrimination tasks

To test a model's ability to discriminate a particular phonetic or lexical contrast, we use the machine ABX task (Schatz et al., 2013), which is standard in research on zero-resource speech technology for evaluating discriminability of speech units (Versteegh et al., 2015; Dunbar et al., 2017, 2020, etc.) and is commonly used for simulating human speech discrimination tasks (e.g., Martin et al., 2015; Schatz et al., 2019; Millet et al., 2019). The machine ABX task allows us to easily design precise comparisons (e.g., compare words that only differ in 1 phone) and is not sensitive to the absolute distances in the embedding spaces, which may vary across simulations.

In the ABX task, A and X are two instances of the same word type (e.g., *right*), while B is a different word type (e.g., *light*). If A and X are closer to each other in a model's representation space than B and X, the model's prediction is correct, otherwise it is not. Irrespective of the test units (phones, words), an acoustic segment in our model is represented by a single vector. We perform the ABX task directly on the vectors, allowing us to compare segments of different duration (without doing any type of alignment). Following earlier studies, we use angular cosine distance to measure the distance between the stimuli in the embedding space. The model is evaluated by considering the proportion of ABX triplets for which it makes correct predictions: 0% error corresponds to perfect discrimination, and 50% to chance performance.

To test whether the difference between the ABX error rates of several models is significant, we fit mixed-effects regressions to the error rates of these models. Significance for the effect of interest is then determined using two-tailed ANOVA tests (with Satterthwaite degrees of freedom approximation) on the predicted values of the regressions.

3 Simulation 1: Phone discrimination

Previously, the monolingual CAE-RNN was shown to correctly predict the crosslinguistic difference in the discrimination of the Mandarin [ɕ]–[tɕʰ] contrast (Matusevych et al., 2020b), observed in Mandarin-learning vs. English-learning infants (Tsao et al., 2006). Considering this, it may seem trivial to show that a model with some exposure to Mandarin data (bilingual) would also achieve lower error than a model with no such exposure (English monolingual). However, potentially complex interactions between training languages may result in an unpredictable phonetic space. This is why we need to ensure the bilingual model behaves as expected, before we move on to the word-level tasks. To do this, we run a simple sanity check: whether a model trained on two languages behaves in a predictable way on the same Mandarin contrast.

3.1 Setup

We focus on the experiment of Kuhl et al. (2003), who showed that exposing English-learning infants to a small amount of Mandarin Chinese improves their ability to discriminate [ɕ]–[tɕʰ]. Our goal is to test whether the model also correctly predicts the pattern for English-learning infants with vs. without exposure to Mandarin.

It is difficult to estimate how the infants' amount

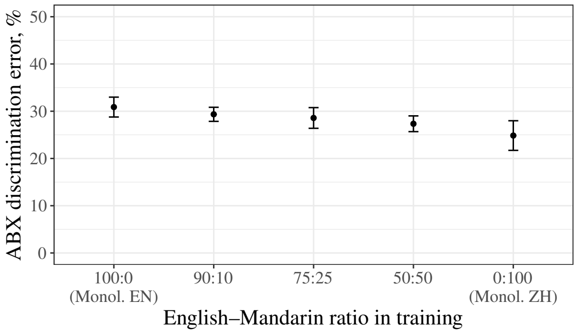

Figure 2: Models' ABX error rates in the Mandarin [ɕ]–[tɕʰ] phone discrimination task. Error bars show standard error of the mean over two training corpus samples × two test samples.

of Mandarin exposure in the experiment maps onto the English–Mandarin ratio of training data in our model. We therefore try the ratios of 90:10 and 75:25 (to simulate an infant with a higher exposure to English than to Mandarin), as well as 50:50 (a control condition, a balanced bilingual). As a baseline to compare our bilingual models to, we train the model on English speech alone (100:0 ratio). For reference, we also train a model on Mandarin speech alone (0:100). Using each model, we embed a set of [ɕ] and [tɕʰ] phones from the test corpus and run a [ɕ]–[tɕʰ] discrimination task. We expect each bilingual model to show lower error than the English monolingual model.

3.2 Results

The ABX error rates of the models (see Figure 2) show the expected pattern: the higher the exposure to Mandarin, the lower the error rates in the target discrimination task. Even having 10% of Mandarin data (90:10 model) on average results in 1.6% reduction in absolute error compared to the monolingual English model. A mixed-effects regression fitted to the models' error rates shows that this difference is not significant, but the other two bilingual models do show significantly lower error rate than the monolingual English model: we observe a 2.2% error reduction in the 75:25 model and 3.5% in the 50:50 model compared to the English baseline. This suggests that even a relatively small amount of training data in a given language (under 25%) can improve the model's ability to discriminate between some contrasts in that language, consistent with the empirical findings of Kuhl et al. (2003) with infants. To summarize, the bilingual CAE-RNN model behaves as we expected: it can correctly predict infant-like behavior in phone discrimination. In the next simulation, we test the model on a word discrimination task.

4 Simulation 2: Word discrimination

Simulation 2 tests whether our bilingual model behaves in predictable ways at the word level. Recall that it represents a sequence of any given duration as a fixed-dimensional vector. The compression of a dynamic speech sequence that unfolds in time into a 'static' vector results in information loss. Since words are normally longer speech sequences than phones, it is not obvious whether the model's behavior in word discrimination and phone discrimination will be consistent. To examine this, we test the model on minimal pairs of words with [ɹ]–[l], a phone contrast on which the monolingual CAE-RNN previously showed an infant-like crosslinguistic discrimination pattern (Matusevych et al., 2020b). As before, we train the model on one or two languages and see if it behaves in a predictable way, this time in a *word* discrimination task.

4.1 Setup

MacKain et al. (1981) tested adult native speakers of American English and native Japanese learners of English on the discrimination of English words *rock–lock* (i.e., [ɹ]–[l] contrast). Learners with low English proficiency scored nearly at chance in this task, while highly proficient learners showed the discrimination scores close to those of native English speakers. This result is also in line with studies showing that native Japanese speakers' discrimination of [ɹ]–[l] can improve after relevant phonetic training in English under certain conditions (e.g., Strange and Dittmann, 1984; Logan et al., 1991; Bradlow et al., 1997; Iverson et al., 2005). Our goal is to test whether our model can correctly predict this word-level discrimination pattern.

Similarly to Simulation 1, we train the model on Japanese (for reference) or English speech alone (as the baseline to compare to), or on a combination of the two in proportion 90:10, 75:25, or 50:50, to simulate native Japanese learners of English with variable proficiency. For each model, we embed a set of acoustic words ([ɹ]–[l] minimal pairs) from the test corpus. As in the original experiment, we compare the bilingual models to the native English model: to make correct predictions, a bilingual model needs to show higher ABX discrimination error than the English model. Also, we expect

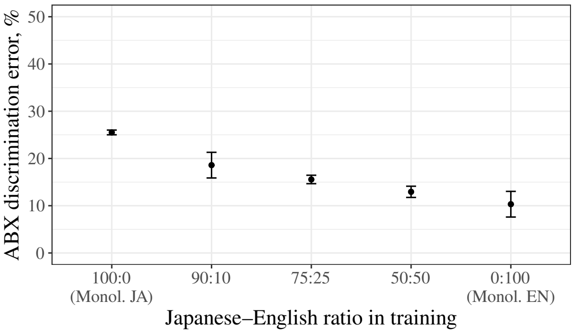

Figure 3: Models' ABX error rates in the word discrimination task with [ɹ]–[l] minimal pairs (e.g., *rock–lock*). Error bars show standard error of the mean over two training × two test corpus samples.

the error rate to decrease with higher exposure to English: 90:10 $>$ 75:25 $>$ 50:50.

4.2 Results

It is clear from Figure 3 that the monolingual Japanese model (100:0) shows higher ABX error rate on the word discrimination task than the monolingual English model (0:100). This extends the previous result for phone-level [ɹ]–[l] discrimination (Matusevych et al., 2020b) to word level.

Comparing all the models, we observe that the error rate decreases as the relative amount of English exposure increases. Even 10% of English in the training data (90:10 model) improves the discrimination by 6.9% in absolute error rate compared to the monolingual Japanese model (25.5% vs. 18.6%), and more so for the models with higher English exposure. A mixed-effects regression fitted to the error rates shows that the pairwise differences between most models are statistically significant, except that the 50:50 model shows error rates too close to both its neighbors: 75:25 and 0:100. Despite that, the expected trend is still present. In other words, our model successfully replicates the direction of the main effect in MacKain et al. (1981): the discrimination error rate decreases with higher English exposure.

The result shows that our bilingual model behaves in a predictable way at the word level, ruling out potentially damaging effect that crosslinguistic interactions can have on its lexical representation space. With this knowledge, in the next simulation we proceed with applying our model to a spoken word processing task.

5 Simulation 3: Spoken word processing

In this section, we present a case study to show how the model can be used to get a better understanding of spoken word processing. Specifically, we are interested to know if some of the effects reported in the literature can be explained in terms of phonetic learning alone. Difficulties with spoken word processing have been attributed to imprecise phonological encoding of non-native lexical representations (Gor and Cook, 2020; Cook et al., 2016; Cook and Gor, 2015; Darcy et al., 2013, 2012), which results in a spurious activation of similarly sounding competitor words. To give an example from Cook et al. (2016), if the word *parent* is encoded as [pɛrə(n)t], with an optional [n], it may often be confused with *parrot* [pɛrət].

We focus on one of the experiments in Cook et al. In a translation judgment task, native Russian speakers (proficient in English) and native English speakers (learning Russian) heard a Russian word (e.g., *moloko* [məɫʌˈko] 'milk') and then saw an English word (e.g., *hammer*, which translates into Russian as 'molotok' [məɫʌˈtok]). The participants had to decide if the English word was a good translation of the Russian one. Cook et al. manipulated the phone edit distance between the true translation and the competitor word: in the example above, the distance between [məɫʌˈko] and [məɫʌˈtok] is 2. They found that non-native speakers made more mistakes than native speakers, and that increasing the phone edit distance between the target words decreased the size of this effect. They explain the effect by ambiguous ('fuzzy') non-native phonolexical representations. It is unclear, however, whether lexical phonology is necessary to explain the observed effect. To answer this question, we test whether our model with no access to phonology can correctly predict the described effect.

Clearly, our model does not know anything about word meanings and cannot be tested on a translation task. Instead, we use a series of ABX discrimination tasks to test whether the lower performance of non-native speakers can be explained in terms of acoustic embeddings of individual word tokens in the model's representation space. Recall that the model has no access to phonology, and its acoustic embeddings result from phonetic learning alone.

Figure 4 shows the error rates of human participants in Cook et al. (2016). The patterns that we focus on are: (1) lower error rate is associated with higher proficiency (exposure to Russian) and higher

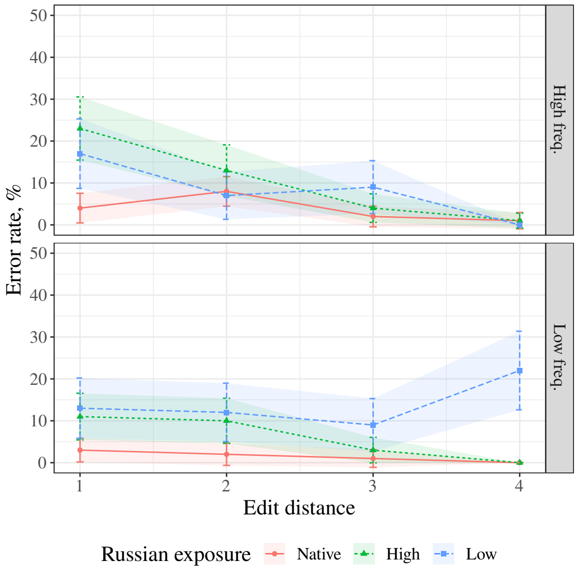

Figure 4: Average error rate of participants in the Russian translation judgment task of Cook et al. (2016) depending on their amount of exposure to Russian and the edit distance between the target and the competitor word. Error bars show mean standard error over participants. Based on Table 3 in Cook et al. (2016).

edit distance; and (2) the difference between the proficiency groups is the highest when the phone edit distance between the target and the competitor word is low. Cook et al. also looked at the effect of competitor word frequency (hence the two panels in Figure 4), but we do not consider this effect here.

5.1 Setup

We train the model on only Russian or only English data (for reference), and also on the combination of the two in proportion 75:25 (to simulate native Russian speakers with some knowledge of English), 50:50, 25:75, or 10:90 (to simulate native English speakers with variable proficiency in Russian). Each model is trained five times with different random initializations.

For testing, we prepare four ABX discrimination tasks: in each task, the words A and X are of the same type, and the words B and X differ in 1, 2, 3 or 4 phones (phone edit distance). We could not obtain the list of the original stimuli from Cook et al. (2016), therefore we sample ABX triplets from our test corpus subset. Following the original experiment, we only consider words containing 4–10 phones. Furthermore, we only consider triplets in which all pairwise ratios of the absolute durations of the words are within the factor of 1.1 (we know from previous work that this model is sensitive to the absolute duration of the test stimuli) and in which B and X are not morphological forms of the same word (such stimuli could not have been used in the original translation judgment task by design). We then sampled 5000 triplets per task, except for edit distance 1 we only had 766 triplets.

As in the original experiment, we first look at the error rates within each model: the error rates are expected to decrease with greater edit distance. Second, we compare the bilingual models to each other: to match the findings from the human study, models with less exposure to Russian (50:50, 25:75, 10:90) must show a higher ABX discrimination error than the model with more exposure (75:25). As a sanity check, we also consider the monolingual Russian (100:0) and English (0:100) models.

5.2 Results

Figure 5 shows the model's ABX error rates across tasks and training conditions. We first observe that all lines have a negative slope: all the six models show lower error in the tasks with greater edit distance between the words, which is the expected pattern. Note that comparing the absolute values to the results of human participants (Figure 4) is not necessarily meaningful because of the task difference: human participants of Cook et al. (2016) had to compare an acoustic word in Russian to a translation of an English word they saw, whereas our model directly compared two Russian acoustic words embedded in its representation space.

Second, we see in Figure 5 that the models with less exposure to Russian have higher error rates. This is especially evident for the data points with edit distance 1, whereas the difference across the models gets smaller with greater edit distances. Again, this is the expected pattern. A mixed-effects regression fitted to the models' error rates suggests that there are significant effects of (1) the amount of Russian language exposure (higher exposure is associated with lower error) and (2) the edit distance (higher edit distance is associated with lower error). A similar pattern is observed when we only consider the bilingual models, for a better analogy with the original experiment: the 75:25 model shows significantly lower error rates than both the 10:90 model and the 25:75 model (but not the 50:50 model), and also the error rates generally get lower as the edit distance increases.

Recall that in each discrimination task, we considered pairs of words with a certain edit distance.

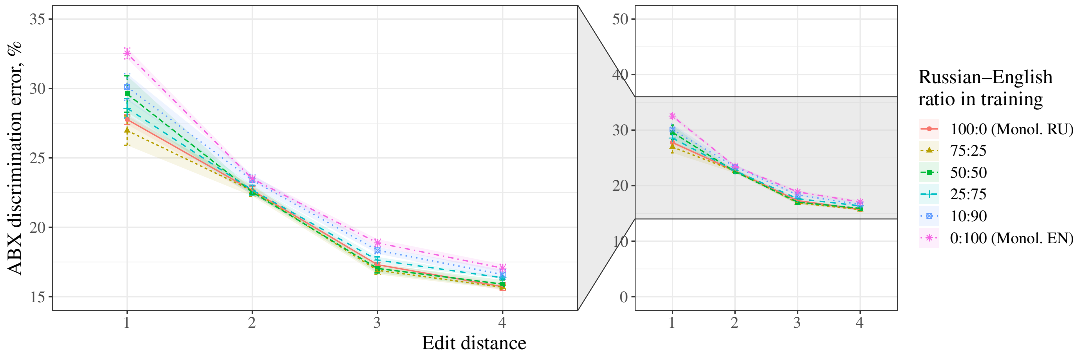

Figure 5: Average ABX discrimination error rate depending on the amount of the model's exposure to Russian and the edit distance between the words in ABX triplets. Error bars show mean standard error over random model initializations.

Most edit operations involve Russian phone contrasts that are also linguistically meaningful in English (e.g., [v]–[s]). However, there is a small number of Russian phone contrasts that are allophones of the same phoneme in English (e.g., [d]–[dʲ]). If our data included a substantial number of contrasts of this type, the model's higher error rates could be attributed to these difficult phone contrasts. To ensure that was not the case, we looked at the contrasts in our pairs with edit distance 1 and found that out of 29 contrasts present in that data, only 1 ([ɫ]–[lʲ]) was not phonemic in English, and excluding the corresponding test pairs from the analysis had only minor impact on the absolute error rates, but not on the reported patterns.

To summarize, our model could correctly predict the direction of the two main effects found in a translation judgment task of Cook et al. (2016). This suggests that their result can at least partially be explained in terms of comparing two acoustic instances: the word a participant hears and the translation of a word that (s)he sees. This presents an alternative explanation of the non-native speakers' difficulties with spoken word processing in terms of phonetic perception, which does not involve phonology.

6 Analyzing the model's representations

Most studies on bilingual lexical access advocate its non-selective nature: that is, speakers activate words in both languages in parallel, including in spoken word processing (e.g., Weber and Cutler, 2004; Lagrou et al., 2011; Shook and Marian, 2012). Ideally, our model should show a similar pattern and not completely separate the two languages in its representation space. To examine this, we run a language classification task, similar to Kamper et al. (2020a). We are interested whether the model can identify the language of a given word based on its acoustic embedding.

	Russian–English ratio			
	75:25	50:50	25:75	10:90
Mean	84.6	86.5	84.3	80.3
SD	1.0	0.9	0.4	1.6

Table 2: Accuracy (in %) of logistic regression classifiers predicting language identity of a given word from its acoustic embedding, averaged over five random initializations of each model.

Using the bilingual models from Simulation 3, we embed 5000 words per language. We then train a logistic regression classifier on 80% of this data to predict the language of a given word from its acoustic embedding, and test the classifier on the remaining 20% of words. The higher the accuracy of the classifier, the more linearly separable the two languages—specifically, their lexicons—in our model's representations. The results (Table 2) show that all models reach accuracy much higher than the 50% chance, although no model reaches 100% accuracy. This means that the lexical representations of words in two languages (acoustic word embeddings) in our bilingual models are not fully linearly separable, indicating a substantial (13.5–19.7%) overlap between the two languages. Because some of the representations from the two languages are close to each other in the embedding space, the model may confuse them, similar to the non-selective lexical access in bilingual speakers.

7 Discussion

We started by asking whether some of the difficulties in non-native spoken word processing can be explained at the level of phonetic perception, without involving phonolexical representations. To address this question, we presented a case study (Simulation 3) with a computational model that learns from unsegmented speech data and does not have access to phonology. Our model showed patterns similar to those found by Cook et al. (2016) in human speakers. This suggests that their results can be at least partly explained by phonetic learning. While we cannot estimate the relative contribution of the two factors—non-native phonetic perception vs. imprecise phonolexical representations—to the behavior of non-native speakers in the experiment of Cook et al., we argue that both factors need to be considered as possible explanations of the spoken word processing difficulties in non-native speakers. Note, however, that this result does not tell us whether the phonetic or the phonolexical explanation is more parsimonious—a question that should be addressed in the future.

One could interpret our main result differently: that our model, in fact, has succeeded in learning phonological systems from speech data and cannot be considered a purely phonetic model. Indeed, we know that deep neural networks can learn to encode various types of linguistic structure without explicit supervision (e.g., Manning et al., 2020; Linzen and Baroni, 2021). In particular, speech models can achieve high accuracy in phone discrimination (Alishahi et al., 2017) and classification (Chung et al., 2019), a finding sometimes interpreted as a successful acquisition of phonetic/phonological *categories*. While our model can discriminate at least some phone contrasts, too (Simulation 1), this does not necessarily mean that it learns phonetic categories (see Schatz et al., 2019, for a relevant discussion). More importantly, what our model does not do is store explicit phonolexical representations in its memory, whereas the (imprecise) storage of word forms is one of the key premises of the phonolexical account explaining non-native speakers' difficulties in spoken word processing (Cook et al., 2016). Therefore, we conclude that our results highlight the effects of phonetic perception on non-native word processing.

In Simulation 1 and 2 we showed that our model trained simultaneously on two languages could correctly predict some phone- and word-level discrimination effects in infants and adults (Kuhl et al., 2003; MacKain et al., 1981). This extends previous results on phone discrimination with monolingual model (Matusevych et al., 2020b) to word discrimination and to bilingual speakers. Also, our analysis of model's representations indicates a substantial overlap between the lexicons of the two languages, mimicking non-selective lexical access in bilingual speakers (e.g., Lagrou et al., 2011). All together, this suggests that the CAE-RNN can be used as a tool to study not only native/non-native phonetic learning, but also native/non-native spoken word processing, including in bilingual speakers.

Our model helps to tease apart the potential impact of phonetic learning from other effects on spoken word processing. At the same time, it is not a cognitive model of the human mental lexicon, for example because it is devoid of semantics. A method to learn acoustic and semantic embeddings in parallel has been proposed in speech engineering (Chen et al., 2018), and future research could shed some light on whether this method can be used for studying human mental lexicon.

Abstract

The advent of neural-networks in NLP brought with it substantial improvements in supervised relation extraction. However, obtaining a sufficient quantity of training data remains a key challenge. In this work we propose a process for bootstrapping training datasets which can be performed quickly by non-NLP-experts. We take advantage of search engines over syntactic-graphs (Such as Shlain et al. (2020)) which expose a friendly by-example syntax. We use these to obtain positive examples by searching for sentences that are syntactically similar to user input examples. We apply this technique to relations from TACRED and DocRED and show that the resulting models are competitive with models trained on manually annotated data and on data obtained from distant supervision. The models also outperform models trained using NLG data augmentation techniques. Extending the search-based approach with the NLG method further improves the results.

1 Introduction

The goal of Relation Extraction (RE) is to find and classify instances of certain relations in raw text. We denote a binary relation instance, *i.e.* a relation instance with two arguments, with a tuple $\boldsymbol{x} = (\boldsymbol{s}, e^1, e^2, r)$, where $\boldsymbol{s} = [w_0 \cdots w_n]$ is a sequence of sentence tokens, e^1, e^2 are entity mentions within $\boldsymbol{s}$ corresponding to the first and second relation argument, respectively, and $r \in R \cup \{\varnothing\}$ is a relation label from a set of predefined relations of interest, or an indication of 'no-relation'. In binary classification our goal is to classify whether, according to $\boldsymbol{s}$, the entity mentions, e^1 and e^2, satisfy r, the relation label. For such classification we require a training dataset X, comprised of X_p, a set of positive examples, representing the relation of interest, and X_n, a set of negatives examples.

The success of recent papers (Soares et al., 2019; Murty et al., 2020) in supervised RE is fueled by advances in deep learning, but also, crucially, by the availability of a large training set such as TACRED (Zhang et al., 2017), containing tens of thousands of training examples. For most relations of interest, such training data is not available.

In this work we examine methods to inexpensively construct X_p and X_n, in cases where a training set is not available. We are especially interested in constructing the positive set, X_p.

In contrast to common NLP tasks like POS tagging, entity extraction and dependency parsing, the task of relation extraction exhibits a much larger degree of label sparsity. For some relations, even when considering only sentences with entities of the relevant types, the ratio between positive and negative examples is highly skewed toward the latter and obtaining a modest amount of positive examples will require a laborious annotation effort (see §3). While manual annotation of large datasets is a viable approach, it typically requires contracting a team of professional annotators (Doddington et al., 2004; Ellis et al., 2015) or crowd workers (Zhang et al., 2017; Yao et al., 2019) and is not well suited for smaller projects or for ad-hoc extraction tasks.

Our main contribution in this paper is a new methodology built on top of Shlain et al. (2020) for cheaply obtaining large datasets (§6). Shlain et al. (2020) proposed a syntactic search engine that given a lightly annotated example sentence, retrieves new sentences with a similar syntactic structure from a pre-annotated dataset. Our syntactic search bootstrapping method requires a small number of manually curated positive example sentences. Then the search engine matches are used as training data for ML models. We evaluate this approach comparing to human annotated data of varying sizes.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1491–1503
April 19 - 23, 2021.

While this method shows promising results with very few user input examples, we also test the impact on performance when more examples are used. One technique for obtaining an abundance of examples uses recent Natural Language Generation (NLG) models (§7.1). It has been shown in recent papers (Wei and Zou, 2019; Anaby-Tavor et al., 2019; Kumar et al., 2020; Amin-Nejad et al., 2020; Russo et al., 2020) that generating abundance of training examples can improve classifier performance. We aim to check whether this can improve our syntactic search method as well.

We evaluate the proposed methodologies by training DL classifiers on the obtained data.

We show that: (1) Syntactic patterns are competitive at bootstrapping training data for ML, even with as little as 3 patterns;
(2) Training DL models over the output of syntactic patterns can significantly improve both recall and F1 over a rule based approach which uses the patterns directly;
(3) Training ML models over the output of syntactic patterns performs better than training models over recently popular NLG data augmentation techniques;
(4) Augmenting the output of syntactic patterns using NLG techniques is often helpful;
(5) Different relations benefit from different strategies.

The code for all our experiments alongside the generation outputs is publicly available[1].

2 Related Work

Distant Supervision. Since its introduction, Distant Supervision (Mintz et al., 2009) has established itself as a viable alternative to manual annotation. Distant Supervision assumes the availability of a knowledge base (KB) of $\langle e^1, r, e^2\rangle$ triplets where e^1, e^2 are entities known to satisfy relation r. To obtain training examples for a relation r, we sample sentences from a large background corpus: sentences which include entity pairs listed in the KB as satisfying r are labeled positive, the remaining sentences are labeled negative (potentially after satisfying additional constraints). While effective in some cases, the reliance on large pre-existing KBs is a significant limitation. Such KBs are not usually available and the cost of constructing them is high.

Bootstrapping from Rules, Snorkel. To eliminate the reliance on external KBs, Angeli et al. (2015) used the predictions of a rule based extractor on a large corpus to train a first iteration of a statistical extractor. They then continued to refine the extractor through self-training.

Another system which can optionally utilize rules instead of external KBs is Snorkel (Ratner et al., 2017). Snorkel is implementing the data-programming paradigm (Ratner et al., 2016) where ML models are trained in three stages: (i) users write labeling functions that weakly label data points using arbitrary heuristics (*e.g.* extraction rules); (ii) the system learns a re-weighted combination of the labeling functions by explicitly modeling the actual distribution of each class. The results are often precise but low-recall; and (iii) The system uses discriminative models to increase recall while preserving precision.

The techniques used by Angeli et al. (2015) and Snorkel can be effective in increasing the accuracy of the initial labeling rules, but coming up with “good enough" initial rules remains a major challenge. In this sense, the search-based methods suggested in this work for bootstrapping RE datasets are complimentary and can be plugged in as a first step in these multi-step solutions.

Only few papers can be directly compared to our paper and use matches as training-data for ML classifiers. One paper similar in that sense is Angeli et al. (2013) which claims that training a classifier using search-based examples works better than traditional bootstrapping methods. See §6.2 for further compression with Angeli et al. (2013).

Augmentation Through Generation. Similarly to our Example Generation approach, recent papers (Anaby-Tavor et al., 2019; Kumar et al., 2020) suggest using pre-trained language models for data augmentation. In both these papers, the authors suggest prepending class labels to generative models in order to augment the number of instances for classes with a small number of examples. In contrast to these papers we use language models in a zero-shot context, and rather than requiring existing labeled examples of the relevant relation, we propose to manually label the generated samples.

3 The data annotation challenge

In contrast to linguistic annotation tasks such as parts-of-speech, syntactic-trees or semantic roles, annotating data for relation-extraction does not require special expertise. Annotation can be easily

---

[1] github.com/mataney/BootstrappingRelationExtractors

performed by a motivated native speaker of the language (in case of "every-day" relations such as those available in TACRED and DocRED) or by a domain expert (in case of "specialized" relations such as in biomedicine or law). Annotating a given sentence for a given relation takes roughly the time it takes to read and understand the sentence. So what stops us from obtaining large amounts of annotated data for ML?

The annotation challenge lies in *relation sparsity* in the wild. In an attempt to get a perspective on this issue, let's consider the *founded-by* relation between a PERSON and an ORG, as attested in the TACRED corpus. Assuming we consider only sentences that contain both a person mention and an organization mention, how many sentences do we have to annotate before we reach, for example, 10 positive examples? The TACRED training set has 124 *founded-by* instances, as well as 6947 "negative" instances with matching entity types ("negative" examples are either other relations, or *no-relation*). This 1-out-of-57 ratio indicates that we will likely sample 56 "negative" sentences before hitting a positive instance.[2] This ratio is overly optimistic, as the annotations in the TACRED corpus are already very skewed in favor of positive examples. Even under this very optimistic scenario, we will need to annotate 570 sentences to recover 10 positive examples. The cost of annotation, then, is not in annotating each individual positive sentence, but in finding the sentences to annotate in the first place. Therefore, we should seek for methods that point towards probable positive instances.

In this paper, we present two methods, the first returns close to 1-out-of-1 positive ratio, although with low syntactic diversity, and a second method with roughly 1-out-of-3 positive ratio.

4 Problem Statement and Setup

We are interested in the problem of obtaining a relation classifier for a binary relation, when no a-priori annotated training data for this relation is available. We seek a methodology that will allow to create an effective extractor, using a minimal amount of data annotation effort.

We compare four approaches – manual annotation, syntactic-search, manual annotation over generated examples, and a combination of the last two – to be described in later sections. Here, we discuss setup which is shared to all experiments.

In order to evaluate the methodology on multiple datasets with similar relations, we chose a set of relations that appear in both the TACRED (Zhang et al., 2017) and DocRED (Yao et al., 2019) datasets with at least 50 development examples[3].

To quantify the performance of our methodology we assess it comparing to varying amounts of manually annotated data. In our settings, large amounts of supervised examples represent upper bound for our bootstrapping methods and are not expected.

While relation extraction is often considered as a multi-class classification problem ("find the occurrences of any of these possible relations"), we instead treat the relations separately, training a binary classifier for each one. We believe this is more representative of a user who wishes to target a low number of relations, who is likely to conduct data collection and evaluation for one relation at a time.

Obtaining Negative Examples When training a binary classifier, it is required to include a set of negative examples alongside the list of positive examples. In all our experiments we obtain negative examples by looking for sentences that contain entity types that are compatible with the relation (i.e, for the *founded-by* relation we sample sentences that include both a PERSON and an ORG). In our syntactic based methods we sample from the same domain as our positive examples (Wikipedia) and then filter this list by removing sentences in which the entities are connected by a syntactic pattern which is attested by the positive examples. For the supervised baselines of various sizes, we obtain negative examples by sampling them from the annotated training set, without replacement.[4]

Datasets We used two datasets to explore our different methods. TACRED (Zhang et al., 2017), a large-scale multi-class relation extraction dataset built over newswire and web text. And DocRED (Yao et al., 2019), a dataset for document level RE, and similarly designed for multi-class prediction. Per our setup above, we changed the setting of both datasets to per relation binary classi-

---

[2] See Appendix A for similar distributions over all relations.

[3] *org:country of headquarters*, *org:founded by*, *per:children*, *per:city of death*, *per:date of death*, *per:origin*, *per:religion*, *per:spouse* for TACRED, and similarly *headquarters location*, *founded by*, *child*, *place of death*, *date of death*, *country of origin*, *religion*, *spouse* for DocRED.

[4] The **positive to negative** ratio in training data has an effect on the resulting model's quality. We experimented with positive-to-negative ratios of 1, 5, 10 and 20, as well as with a "match the dev-set" ratio. We found a ratio of 10 negative examples for each positive sentence to performs well.

fication. As our main goal in this paper is to evaluate different bootstrapping methods, and not novel methods for document-level relation extraction, we chose to include only instances with single supporting sentence in DocRED (*i.e.* sentence level relations). As DocRED's labelled test set is not publicly available, we used the development set as our test set and used 20% of the train set as development set.

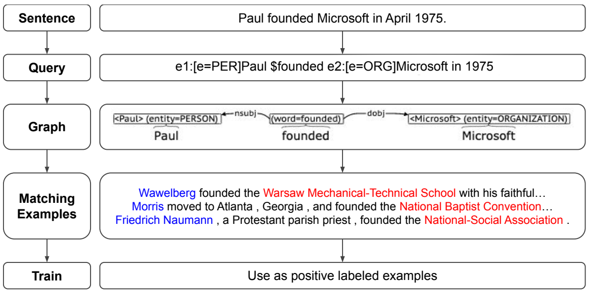
Models Our classifiers throughout the following experiments are based on the Entity Markers architecture (Soares et al., 2019). In the paper, the authors proposed wrapping the relation arguments with marker tokens (*e.g.* $[E1_{start}]$ John $[E1_{end}]$ was born in $[E2_{start}]$ 1948 $[E2_{end}]$). The altered text is then passed as input to a BERT model (Devlin et al., 2018) where the relation between the two entities is represented by the concatenation of the final hidden states corresponding to their respective start tokens. Finally, this representation is fed into a classification head and the model is fine-tuned for relation classification. *cf.* (Soares et al., 2019) for more details. We use a similar model with the exception that we use a more recent pretrained language model, RoBERTa (Liu et al., 2019), and perform binary, rather than multi-class, classification.

In all of the following experiments we trained our model with 3 different random seeds to lower variance introduced to the model with different initializations, and report the average score. At inference time we set the prediction threshold value for the test set to be the cut-off value that maximized F1 over the development set.

5 Manual Annotation Baseline

Setup. Our comparison point throughout the paper is a model trained on traditionally-collected annotated data. We sample increasing-sized annotated sets from TACRED and DocRED, containing 55, 110, 220, 550, and 1100 examples. These correspond to 5, 10, 20, 50, 100 positive examples with 50, 100, 200, 500, 1,000 negatives examples. Additionally, we measure the performance on these datasets when using all available positive examples for each relation.

Results Listed in the top rows of Table 1, averaged over all relations. Unsurprisingly, increasing the number of examples increases performance, with the exception of DocRED on which using all positive labels performs slightly worse than using 100 sampled positive examples for each relation, we attribute this to sampling noise. DocRED scores are generally lower than TACRED scores. This is because of the way we constructed the development and test sets: while in TACRED's development set each sentence includes a single entity pair with a single relation, in DocRED, we pass all possible sentences with entity pairs of the same type as the evaluated relation as possible candidates. This dramatically increases the number of candidates, and by that of possible type I errors. Moreover, as we included only examples with exactly one supporting sentence, the number of positive examples is low for some of the relations. All of this effects DocRED classification scores comparing to TACRED.



Paul founded Microsoft in April 1975.

Use as positive labeled examples

Figure 1: Flow of the Syntactic Search by Example method. For details, see §6.

Importantly, in all these experiments, the number of annotated examples used is significantly higher than the number used in our Syntactic Search experiments (3 examples in total).

6 Syntactic Search by Example

We consider this section to be the main contribution of the work. We show that:
(i) with modern DL modeling, effective relation extractors can be trained using sentences derived from less than a handful of syntactic patterns; and
(ii) through the use of by-example syntactic search engines, one can construct these patterns very quickly, without needing to understand syntax.

To explain the suggested workflow, let's consider a user who wants to train a relation extraction binary classifier for the *founded by* relation, and has a single example sentence, "Paul founded Microsoft in April 1975". Patterns over syntactic structures and entity types are very effective for deriving high-precision extraction templates. For example, searching for sentences containing the word "founded" with an *nsubj* dependency of type PERSON and *dobj* dependency of type ORG, will return many matches for the *founded-by* relations.

Method	**TACRED**	**DocRED**
Annotated 5+50	0.097	0.140
Annotated 10+100	0.136	0.215
Annotated 20+200	0.266	0.271
Annotated 50+500	0.458	0.311
Annotated 100+1000	0.516	0.321
Annotated All	0.569	0.306
Pattern Based RE (3 qrs)	0.128	-
Synt. Search (3 queries)	0.443	0.266
Example Generation	0.439	0.109
Search + Generation	0.491	0.277

Table 1: Average test F1 score over all relations. Pattern Based RE was given 3 positive patterns. Synt. Search is trained on data created from same 3 patterns. The Annotated experiments are denoted by the number of positive examples + negative examples.

There are two issues with this approach (1) while high-precision, the recall of the patterns is low; and (2) syntactic patterns require both linguistic and computational expertise to specify and execute.

The premise of this paper is that the low recall can be offset by machine learning. The sentences resulting from syntactic search over a few patterns are diverse enough that an ML model trained over them manages to generalize from the specific syntactic pattern and identify a broader range of cases, increasing recall substantially. We show this is indeed the case.

To overcome the need for linguistic expertise we propose using a by-example syntactic search engine (Shlain et al., 2020)[5] which allows users to execute syntactic queries based on example sentences: the user enters a sentence satisfying the relation of interest and annotates it with light markup indicating the arguments and the trigger words. The system then automatically translates the markup into a syntactic pattern, matches it against a large pre-annotated corpus (*e.g.* all Wikipedia sentences), and returns results. The user does not need to be familiar with syntactic formalisms or with advanced NLP.

6.1 By-example Patterns for Collecting Training Data

Fig. 1 demonstrates the user process. Starting with the sentence *Paul founded Microsoft in April 1975*, the user marks *Paul* as *e1* (`e1:`) with an entity-type restriction of PERSON (`[e=PER]`), *Microsoft* as *e2* (`e2:`) with an entity-type ORG (`[e=ORG]`), and *founded* as a trigger word (`$founded`). The SPIKE system translates the query into a syntactic graph, which is then matched against Wikipedia, returning 11,345 sentences matching the pattern (note that the word 'founded' is matched lexically, while Paul and Microsoft become place holders for any person and any organization that adhere to the syntactic configuration). A subset of the returned sentences is then used as positive examples for model training.

While 11,345 cases make an impressive training set, these sentences share the same core syntactic configuration, and classifiers, trained on these matches, will not necessarily generalize well. The matches will also share the exact same lexical predicate ("founded"). The lack of lexical diversity of the predicate can be expanded by the user by supplying alternative words, perhaps aided by distributional similarity methods such as word2vec, or by querying a bi-LM such as BERT (Devlin et al., 2018) (§6.2.1). To counter the lack of structural diversity the user can supply additional patterns, derived from example sentences. For example, the user may supply also '[$_{e_2}$Microsoft]'s <u>founder</u> [$_{e_1}$Paul]' (possessive construction) and '[$_{e_2}$Microsoft] was <u>founded</u> by [$_{e_1}$Paul]' (passive) as additional patterns (§6.2).

6.2 Experiments and Results

Setup For each relation, we select 3 representative sentences and annotate them based on the process described above[6]. We do not perform any lexical expansion of trigger words beyond the initial pattern at this point. The queries are processed by SPIKE (Shlain et al., 2020) and the results are used as positive instances in the generated training set. A full list of the SPIKE queries we used can be found in appendix D, Table 5.

We also compare the TACRED classifier to a rule based extractor which uses the syntactic queries directly. Each syntactic query is added as a syntactic pattern to this extractor: any sentence which satisfies one of the syntactic patterns is labeled as a positive instance; sentences which do not satisfy any of the patterns are labeled negative.

Results Listed in the *Synt. Search* and *Pattern*

---

[5] `https://spike.apps.allenai.org`

[6] In this experiment, the selection of representative sentences is based on a heuristic process: we intuitively conceive of basic sentences exemplifying the relation, construct the corresponding Spike queries and briefly validate the number and quality of the returned results. We limit the number of seed examples to 3 since we believe coming up with 3 examples should be simple even for non-experts. In §7.1 we show that using more seed examples can further improve performance.

Dataset	Predicates	100	500	1000
TACRED	One Trig.	0.487	0.459	0.461
	Trig. List	0.517	0.490	0.478
DocRED	One Trig.	0.290	0.336	0.338
	Trig. List	0.316	0.338	0.337

Table 2: F1 scores for *founded by*, *child*, *place of death* and *date of death* and *spouse* when expanding the triggers list for the Syntactic Search "by Example" method.

Based RE rows of Table 1[7], *Pattern Based RE*, using just the 3 patterns per relation, achieves a very low F-score of 12.8%, due to low recall. However, this is already competitive with training a classifier on 5-10 positive examples per relation. Training a classifier on the extracted relations increases the scores significantly, to 44.3F_1 on TACRED and 26.6F_1 on DocRED, approaching supervised training on 50+500 annotations (for TACRED) or 20+200 annotations (for DocRED). This result demonstrates that training an ML model over the output of a rule based model can significantly improve performance, echoing similar conclusions in Angeli et al. (2013). Interestingly, Angeli et al. (2013) used a total of 4,697 patterns across 41 relations, an average of 114 patterns per relation. We demonstrate that by applying syntactic patterns to a large corpus and using modern DL classifiers, results competitive with manual annotation baselines can be reached with as few as 3 syntactic rules.

6.2.1 Syntactic Search with Trigger Expansion

Setup Constructing queries from 3 seed sentences produces retrieved sentences with low lexical diversity. *e.g.* if all the seed sentences for *founded-by* use the word *"founded"* to express the relation, then all retrieved sentences will likewise include the word *"founded"*, and exclude alternatives like "established", "formed", "started", etc.

In this experiment we generalize the seed queries to allow a list of trigger words rather than a single word. We consider only relations which include a lexical trigger in their seed patterns[8]. Alternative triggers are selected by reviewing the closest words to the original triggers in word2vec's embedding space (Mikolov et al., 2013). Appendix C includes the lists of alternative lexical triggers used. We train classifiers on 100+1000, 500+5,000 and 1,000+10,000 examples obtained from these expanded-trigger queries.

Results As illustrated in Table 2, adding alternative triggers improves results across all sample sizes for TACRED and for the 100+1000 size in DocRED.

7 Augmenting Syntactic patterns with Natural Language Generation

We showed how the Syntactic Search by Example method works with only a few human annotated examples. In this section we would like to pursue NLG based methods to expand the number of exemplary patterns. Generative language models, compared to other methods for data augmentation (*e.g.* Iterative bootstrapping and distant supervision) are highly accessible and require low technical expertise (sometimes passing a prompt is enough). Moreover, recent papers (Wei and Zou, 2019; Anaby-Tavor et al., 2019; Kumar et al., 2020; Amin-Nejad et al., 2020; Russo et al., 2020) report high impact of such models for the closely related Data Augmentation task. We therefore present numerous methods that take advantage of such models for RE bootstrapping.

First we show how a user can produce a high number of generated sentences using GPT2 (Radford et al., 2019). Then we demonstrate how the generated sentences can be integrated in the Syntactic Search by Example method (§7.1). Finally, in order to validate the necessity of the syntactic search in this flow we compare it to feeding the raw generations as inputs to a classifier (§7.2).

Generating Examples LM

The user-flow Depicted in Fig. 2: The user enters a relation prompt ("Paul founded Microsoft"), to which the system responds by returning sentences that express the same relation. While not all returned sentences express the relation, many of them do. To filter out out-of-relation sentences the user goes through the list until she identifies a predefined number of positive examples (Here we used 100 sentences). In our experiments we encountered 1 positive example for every 3 examples annotated. This 1-out-of-3 ratio is significantly better than blindly sampling from a corpus (1-out-of-57, see §3), and by that can considerably save annotation time. For each example, the user marks the relevant entities, and optionally also the trig-

---

[7] Results correspond to 100+1,000 (TACRED) and 1,000+10,000 (DocRED) examples, for results and discussions of different dataset sizes, see Appendix B.

[8] *per:children*, *per:date of death*, *org:founded by*, *per:city of death* and *per:spouse*, and DocRED's *child*, *date of death*, *founded by*, *place of death* and *spouse*

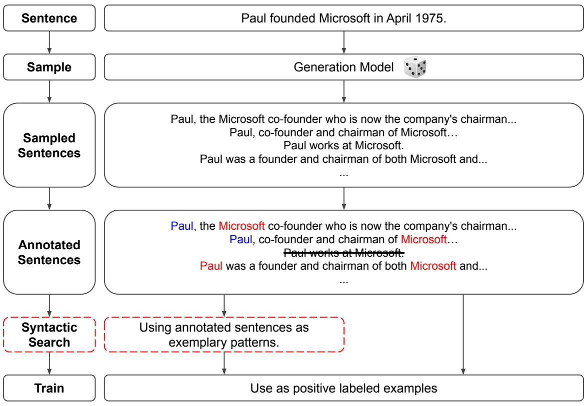

Figure 2: Flow of sampling examples from conditional language model. The "Syntactic Search" step corresponds to §7.1, while skipping this step, corresponds to §7.2.

ger word (the main word indicating the relation). These examples are then used as additional input examples to the syntactic search engine (§7.1) or as train datasets for ML models (§7.2).

Technical details We begin with a large pre-trained LM (we use GPT2-medium (Radford et al., 2019)), and fine-tune it to the generation task. The method assumes the availability of relation-annotated data, though its relations do not need to overlap with the ones we are attempting to extract (in our case, we ensured the groups are distinct). The approach can be considered as an instance of transfer-learning, where we attempt to transfer the example-generation knowledge from the training relations to novel relations. Given the annotated RE dataset, we consider positive examples of the form $(\boldsymbol{s}, e_1, e_2, r)$, where $r \in R$. We transform each instance to a conditioned LM training example, in which the LM sees a prefix (prompt) and should complete it. In our case the prompt is derived from (e_1, e_2, r), followed by a special symbol, and we train the LM to produce the corresponding sentence $\boldsymbol{s}$. To derive the prefix we apply a pre-defined *template* associated with each relation r[9]. The template has two slots to be filled with the entities e_1 and e_2. For example, a template for the *founded-by* relation can take the form $[e_2]$ *founded* $[e_1]$. We then fine-tune GPT2 on these training examples. At inference time, the user provides a *single* prompt based on their desired relation.

Given the user prompt, we generate 1000 sentences with nucleus sampling (Holtzman et al., 2019) of 0.99 and length of up to 50 tokens. We annotate the generated sentences until reaching 100 positive instances (usually requiring 200-300 sentences), this takes up to 1.5 hours per relation. These generated sentences are annotated and used as inputs to the syntactic search method (§7.1) or directly as positive examples to a classifier (§7.2).

7.1 Enhancing Syntactic Search with Example Generation

We integrate the generation outputs in the Syntactic Search by Example method by taking the positive annotated examples (on which we mark the entities as part of the annotation process) and automatically transforming them into SPIKE queries. This step has the potential to add substantial syntactic and lexical diversity to the pattern set, resulting in both larger and more diverse sets of positive examples. This combines the best of both worlds: the generative model is used to provide structural and lexical diversity, while the syntactic search system is used to provide a large selection of naturally occurring corpus sentences adhering to these patterns.

Experiments and Results

Setup To reduce noise, we exclude queries where more than 1 out of 5 sampled results does not express the relation of interest. On average, we increased the number of syntactic patterns to 9.25, ranging from 6 to 14 after filtering.

Results As listed in the *Search + Generation* row of Table 1, this method achieved best performance for both TACRED and DocRED with overall scores corresponding to 550/1100 and 220/550 annotated examples respectively. Using the generation outputs as examples doesn't only help in suggesting more sentences satisfying the relation but also in augmenting the number of predicates used. We looked on the number of predicates used for the TACRED relations which include lexical triggers (similarly to §6.2.1), the generation phase suggested 7.4 predicates on average, more than the 2.8 predicates per relation of our original patterns, and less than the trigger expansion method we suggested in §6.2.1, where we tried to find all the possible predicates, with 18.2 triggers on average. We conclude that while the Syntactic Search by Example method performs well with only a few example patterns, this can be even improved with more input examples. While we report Syntactic Search by Example enjoys such generation-based pattern aug-

---

[9] In our experiments, we use on average 3 different templates for each relation type, so a single annotated relation example will result in 3 (on average) different fine-tuning examples for the LM, each with a different prompt.

mentation, a similar boost with different, non-NLG, methods is of course possible. We leave further probing for other pattern augmentation methods as future work.

7.2 Directly Training Classifiers using Generation Outputs

It is possible that generative models produce diverse enough training examples that will suggest our syntactic search superfluous. We validate the necessity of taking the annotated generations (Annotated similarly to §7.1) through the Syntactic Search by Example method, by comparing it to simply passing the annotated generations as classifier inputs, as depicted in the RHS of Fig. 2.

Experiments and Results

Setup Many of the samples include the entities from the prompt verbatim. Before using them as the model inputs, we replace the entities with a random Wikipedia entity of the same type.

Results As can be seen in the *Example Generation* row in Table 1, on TACRED, this method produces F1 scores on par with Syntactic Search by Example. However, evaluating on DocRED, the method does not produce competitive results[10]. On both datasets it produce worse than *Search + Generation*. We conclude that it is more beneficial to use outputs of generative models as syntactic search queries, and by that find syntactically similar sentences, comparing to simply use generations as the train set. We deduce models are likely to generalize better on “real world" examples.

8 Additional Experiments

8.1 Results across relations

Analyzing the results we highlight some interesting trends (Fig. 3). First, we note that the behavior is not consistent between relations, nor datasets: different relations behave differently, showing different trade-offs between different methods.

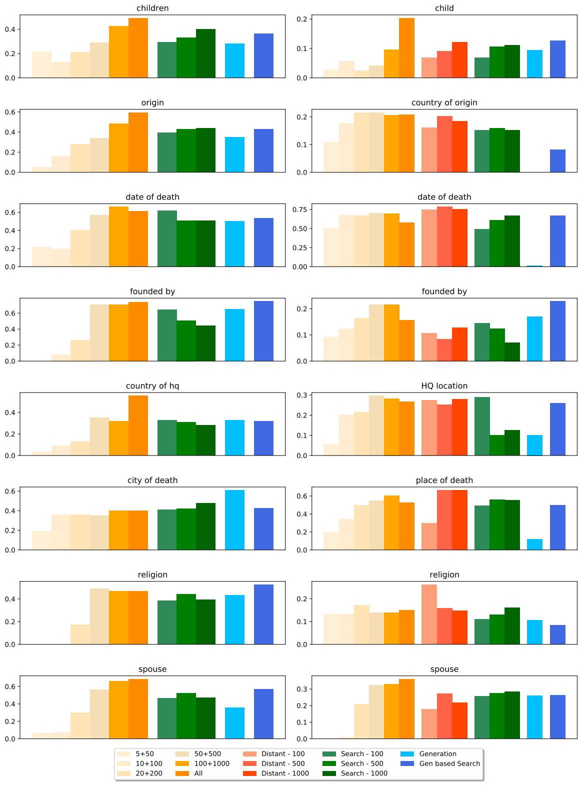

Figure 3: F1 scores of TACRED (right), and DocRED (left) by relation.

Classifiers for relations like *“Religion"*[11], *“City of Death"* and *“Date of Death"* seem to plateau at around 50-100 manually annotated examples. For these relations, annotating more data is not necessarily useful. The syntactic search approach works especially well for these relations: applying syntactic search over 3 seed queries is sufficient to yield results on par or slightly higher than all available manually annotated data. We hypothesize that these findings might be the result of low diversity in the ways these relations are typically expressed.

While the combined *Search + Generation* approach is overall useful, the effect is not consistent across relations: performance improves for some relations and deteriorates for others. In §7.1 we described the techniques we use to reduce the noise coming from additional queries. These techniques however are rather basic and these results indicate that more advanced techniques of the type used in Angeli et al. (2015) and Ratner et al. (2017), are likely to yield more consistent improvements.

8.2 Distant Supervision

Setup Distant supervision (Mintz et al., 2009) suggests a method to construct a training dataset based on a large external KB of relation triplets. Yao et al. (2019) offered a machine annotated version of DocRED constructed by aligning Wikipedia pages

---

[10] The language model used to generate examples was finetuned on a version of TACRED which excludes the relations we evaluate on. Still, for TACRED, the language model is finetuned and evaluated on data from the same domain (newswire). The DocRED data on the other hand, is taken from Wikipedia, so the evaluation is essentially out of domain. We therefore conclude that used independently, this approach is applicable only in cases where a background RE dataset is of the same domain as the target corpus from which we want to extract relations.

[11] TACRED’s “religion" relation plateaus as it has a low number of train instances.

with Wikidata. The authors took great care in creating this resource: a high-quality NER model trained on in-domain manually annotated data was used to automatically annotate possible relation arguments; a named entity linker was used to merge entities with similar KB ID; and finally, Wikidata was queried in order to label pairs of linked entities.

We trained a classifier using the released data, sampling increasing number of examples: (100+1,000, 500+5,000, 1,000+10,000). We report best score of $0.312 F_1$ (500+5,000 split).

Results This Distant Supervision dataset, created by Yao et al. (2019), appears to be of very high quality and the results are on par with the full set of manually annotated data. These results indicate that given a large KB of relation triplets, a high-quality in-domain NER, and a high quality linking solution, distant-supervision is a very promising technique. It should be noted however, that the availability of all these external resources is very rare in practice and is not required by the methods proposed in this work.

9 Applicability to other languages

We explored only English in this work. However, we argue that our main method – example-based syntactic search followed by DL-training – is not strongly tied to English, and we encourage other researchers to experiment with it in their languages of interest. We provide details of what is needed to adapt the system to a different language.

The Syntactic Search by Example method requires (1) An automatically dependency-parsed corpora in the language. These can be readily produced by the many syntactic parsers that are available for many languages (Manning et al., 2014; Honnibal and Montani, 2017; Qi et al., 2020). (2) An indexing engine that supports efficient queries over parse trees. Shlain et al. (2020) uses the open-source Odinson engine (Valenzuela-Escárcega et al., 2015) for this purpose. (3) A component that translates a query in spike's "by example" syntax to the indexing engine's query syntax. This requires finding the minimal (in terms of number of nodes) sub-graph that connects all relation arguments (and predicates if available), then search for sentences with similar sub-graphs in the index. With these three components, a syntactic-search system can be readily implemented. The rest of the components are straightforward application of DL methods. Indeed, we suspect the major obstacle in application to a new language will be the availability of evaluation data.

10 Conclusion

We show that with modern DL classifiers and a dataset bootstrapped using syntactic search with as few as 3 seed patterns can be as effective as a dataset with hundreds of manually annotated samples. Using LMs help to further diversify the dataset and improve results. Overall, our results are positively optimistic for bootstrapping methods. However, this work is only an initial step in exploring methods for bootstrapping relation extractors using minimal user effort, supported by strong pre-trained neural LMs. We hope to encourage further work in this direction.

A Estimated effort for Annotation

Table 3 lists for each relation the ratio of positive to negative examples in the TACRED training set. A negative example for a relation *r*, is any example whose entities share types with a positive example of *r*, but whose label is different from *r*. Note that TACRED significantly under represents negative examples so the reported ratio is an upper bound on the ratio in the wild.

Relation	Pos/Neg Ratio
org:country_of_hq	1/7
org:founded_by	1/56
per:children	1/64
per:city_of_death	1/31
per:date_of_death	1/26
per:origin	1/10
per:religion	1/2
per:spouse	1/52

Table 3: Pos/Neg ratio in TACRED, rounded to the closest fraction.

B Syntactic Search by Example with varying dataset sizes

We experimented with varying the number of sampled examples, using the same 3 seed syntactic patterns. The results are reported in Table 4. While DocRED's F1 scores increase with increasing number of sampled examples, the trend is opposite in TACRED. We believe this is due to different initializations and inductive noise in both the positive and negative samples introduced by sampling from semi-noisy data.

Method	**TACRED**	**DocRED**
Synt. Search - 100	0.443	0.250
Synt. Search - 500	0.434	0.259
Synt. Search - 1000	0.427	0.266

Table 4: Syntactic Search by Example with different training sizes

C Trigger List Expansion

For the majority of patterns used in the Syntactic Search by Example experiments we used a single trigger word (see Appendix D). To experiment with using trigger lists, we modified the patterns in Appendix D in the following way:

We changed the triggers in all *child\children* patterns to include any of the following possibilities:

baby, child, children, daughter, daughters, son, sons, step-daughter, step-son, step-child, step-children, stepchildren, stepdaughter, stepson

For *founded-by* relations we change the "founder" trigger to be any of these triggers:

founder, co-founder, cofounder, creator

and changed "founded" to be any trigger from the following list:

create, creates, created, creating, creation, co-founded, co-found, debut, emerge, emerges, emerged, emerging, establish, established, establishing, establishes, establishment, forge, forges, forged, forging, forms, formed, forming, founds, found, founded, founding, launched, launches, launching, opened, opens, opening, shapes, shaped, shaping, start, started, starting, starts

In *spouse* relations we expanded the "husband\wife" trigger to be any of:

ex-husband, ex-wife, husband, widow, widower, wife, sweetheart, bride

and the "marry" trigger to:

divorce, divorced, married, marry, wed, divorcing

For the *"date of death"* and *"place\city of death"* we changed the "died" trigger to any of:

died, executed, killed, dies, perished, succumbed, passed, murdered, suicide

Abstract

Systems that generate natural language text from abstract meaning representations such as AMR are typically evaluated using automatic surface matching metrics that compare the generated texts to reference texts from which the input meaning representations were constructed. We show that besides well-known issues from which such metrics suffer, an additional problem arises when applying these metrics for AMR-to-text evaluation, since an abstract meaning representation allows for numerous surface realizations. In this work we aim to alleviate these issues by proposing $\mathcal{MF}_\beta$, a decomposable metric that builds on two pillars. The first is the **principle of meaning preservation** $\mathcal{M}$: it measures to what extent a given AMR can be reconstructed from the generated sentence using SOTA AMR parsers and applying (fine-grained) AMR evaluation metrics to measure the distance between the original and the reconstructed AMR. The second pillar builds on a **principle of (grammatical) form** $\mathcal{F}$ that measures the linguistic quality of the generated text, which we implement using SOTA language models. In two extensive pilot studies we show that fulfillment of both principles offers benefits for AMR-to-text evaluation, including explainability of scores. Since $\mathcal{MF}_\beta$ does not necessarily rely on gold AMRs, it may extend to other text generation tasks.

1 Introduction

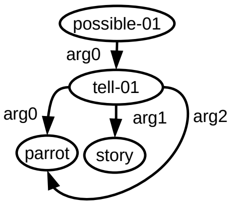

Figure 1: *"Perhaps, the parrot is telling itself a story"*.

Abstract Meaning Representation (AMR, Banarescu et al. (2013)) aims at capturing the meaning of a sentence in a machine-readable graph format. AMR captures, i.a., word senses, semantic roles and coreference. The AMR in Fig. 1 represents the sentence *Perhaps, the parrot is telling itself a story*. In this graph, tell-01 links to a PropBank (Palmer et al., 2005) frame, and arg$_n$ labels indicate participant roles: *parrot* is both *speaker* (arg0) and *hearer* (arg2), *story* is the *utterance* (arg1).

The task of AMR-to-text generation has recently garnered much attention (Song et al., 2017, 2018; Konstas et al., 2017; Cai and Lam, 2020b; Ribeiro et al., 2019). The output of AMR-to-text systems is typically evaluated against the sentence from which the AMR was created, using standard surface string matching metrics such as BLEU (Papineni et al., 2002) or CHRF(++) (Stanojević et al., 2015; Popović, 2015, 2016; Popov, 2017), as is standard in many NLG tasks. These metrics suffer from several issues, for example, they penalize paraphrases, are highly sensitive to outliers (Mathur et al., 2020), and lack interpretability (Sai et al., 2020).

Some of these issues get compounded when evaluating AMR-to-text. The core of the problem is that there are many ways to realize a sentence from a meaning representation. Fig. 2 shows four candidate sentences (**i-iv**) for a given AMR (left). One system generates (**i**): *Maybe the cat is playing.* while another generates (**iii**): *Perhaps, the cat plays the flute*. Clearly, (**i**) captures the meaning of the gold graph better than (**iii**), which contains 'hallucinated' content – a well-known issue in neural generation (Logan et al., 2019; Wang and Sennrich, 2020). Yet, when using a canonical metric such as BLEU to evaluate sentences (**i**) and (**iii**) against the reference, the system that produces hallucinations (**iii**) is greatly rewarded (54 BLEU points) to the disadvantage of systems that yield meaning preserving

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1504–1518
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

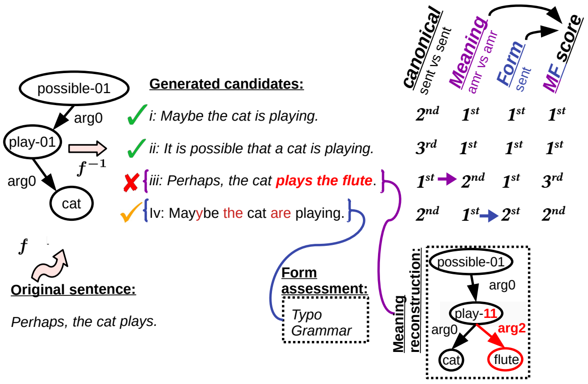

Figure 2: The ***Canonical*** evaluation matches n-grams from the sentences and assigns inappropriate ranks. Our metric $\mathcal{MF}_\beta$ fuses ***Meaning*** and ***Form*** assessment and better reflects the ranking of the generations.

sentences (**i**) (18 points) and (**ii**) (5 points).

This work aims at a (better) metric that **measures meaning preservation** of the generated output towards the MR given as input, by (re-)constructing an AMR from the generated sentence and comparing it to the input AMR. In Fig. 2, Reconstruction is the result of parsing (**iii**). The reconstructed AMR exposes several meaning deviations (marked in red): it contains an alternate sense of *play* and contains an additional semantic role arg2 with filler *flute*. By contrast, when converting sentences (**i**), (**ii**), or (**iv**) to AMRs, we obtain flawless reconstructions. We will measure preservation of ***Meaning*** using well-defined graph matching metrics.

Figure 2 also illustrates that assessing meaning preservation is not sufficient to rate the quality of generations: (**iv**) captures the meaning of the AMR well – but its form is flawed: it suffers from wrong verb inflection, a common issue in low-resource text generation settings (Koponen et al., 2019).

In order to rate both meaning and form of a generated sentence, we combine the score for meaning reconstruction with a score called ***Form*** that **judges the sentence's grammaticality and fluency**. By these moves, we obtain a more suitable and explainable ranking with a combined ***MF*** score.[1] By clearly distinguishing between ***Meaning*** and ***Form***, our ***MF*** score (henceforth denoted by $\mathcal{MF}_\beta$) also aligns well with recent calls to achieve a clearer separation of these aspects in NLU (Bender and Koller, 2020).

Generally, our contributions are as follows:

(1) We propose two linguistically motivated principles that aim at a sound evaluation of AMR-to-text systems: the **principle of meaning preservation** and the **principle of (grammatical) form**.

(2) From these principles we derive and implement a (novel) $\mathcal{MF}_\beta$ **score for AMR-to-text generation**[2] which is composed of individual metrics for meaning and form aspects. $\mathcal{MF}_\beta$ allows users to modulate these two views on generation quality to vary their impact on the final metric score.

(3) We conduct two major pilot studies involving (English) text generations from a range of competitive AMR-to-text systems and human annotations. First we study the potential practical benefits of $\mathcal{MF}_\beta$ when evaluating systems, such as its prospects to offer interpretability of scores and finer-grained system analyses. The second study probes potential weak spots of $\mathcal{MF}_\beta$, e.g., its dependence on a strong AMR parser.

We consider $\mathcal{MF}_\beta$ as it stands as a suitable metric to enhance interpretability of generation scores.

2 Fusing meaning and form into $\mathcal{MF}_\beta$

While current NLG metrics lack *interpretability* and mainly focus on the form of generated text (Sai et al., 2020), in this work we emphasize the *meaning aspect* in NLG evaluation, which is most clearly dissociated from form when generating text from structured inputs such as AMR. At the same time, form and wording of the generated text cannot be ignored, as we want such systems to produce *natural and well-formed sentences*. Equipped with this two-fold objective, we start building our $\mathcal{MF}_\beta$ score which aims at a *balanced combination* of both quality aspects: **meaning and form**.

2.1 From principles to $\mathcal{MF}_\beta$

In a first step we introduce our

Principle of meaning $\mathcal{M}$. *Generated sentences should allow loss-less AMR reconstruction.*

This principle expresses a key expectation for a system that generates NL sentences from abstract meaning representations. Namely, the generated sentence should reflect the meaning of the AMR. So, in order to assess whether a generated sentence $s' = f^{-1}(m)$ is a valid generation for the input AMR m, rather than matching s' against a

---

[1] See Fig. 2: $1^{st}/2^{nd}$ rank: **i**; 3^{rd} rank: **iv**; 4^{th} rank: **iii**.

[2] We make code available at `https://github.com/Heidelberg-NLP/MFscore`.

reference sentence s, we perform this assessment **in the abstract MR domain**, by applying an inverse system f that *parses* the generated text back to an AMR $m' = f(s') = f(f^{-1}(m))$. I.e., we desire a $metric : \mathcal{D} \times \mathcal{D} \rightarrow [0, 1]$ that satisfies: $s \equiv s' \iff m = m' \iff metric(s, s') = 1$. Two texts are equivalent iff their meaning abstractions denote the same meaning. In case $f(s')$ yields an AMR $m' \neq m$, we can still determine the degree to which s' preserves the meaning of AMR m by measuring the distance between m and m' by standard AMR metrics, e.g., $Smatch(m, m')$.

Note that computing $Smatch(m, m')$ does not depend on a reference sentence, because the comparison is conducted purely in the abstract domain. This is mathematically more appealing for the evaluation of AMR-to-text, since it solves the problem that one abstract representation may result in various (valid) surface realizations (cf. Appendix A.1). Finally, we also do not necessarily need to rely on a gold graph m, but can instead set $m = f(s)$, i.e., the parse of the reference sentence. This means that future application of $\mathcal{M}$ to other kinds of text generation tasks is straightforward.

However, the principle $\mathcal{M}$ alone is not sufficient: we also expect the system to generate grammatically well-formed and fluent text. For example, s': *Possibly, it(self) tells parrot a story.* contains relevant content expressed in the AMR of Fig. 1, but it is neither grammatically well-formed, nor a natural and fluent sentence. This leads us to our

Principle of form $\mathcal{F}$. *Generated sentences should be syntactically well-formed, natural and fluent.*

In the style of the well-established F_β score (van Rijsbergen, 1979), we fuse these two principles into the $\mathcal{MF}_\beta$ score:

$$\mathcal{MF}_\beta = (1+\beta^2)\frac{Meaning \times Form}{(\beta^2 \times Meaning) + Form} \quad (1)$$

Here, $Form$ and $Meaning$ are expressed as ratios that will be more closely described in the following subsection. β allows users to gauge the evaluation towards $Form$ or $Meaning$, depending on specific application scenarios. Users may prefer the harmonic mean (β = 1) or may give $Meaning$ double weight compared to $Form$ (e.g., β = .5).[3] In our experiments we consider extreme decompositions into $Meaning\text{-}only$ ($\beta \rightarrow 0$) or $Form\text{-}only$ ($\beta \rightarrow \infty$).

2.2 Parameterizing meaning

We measure $\mathcal{M}$ or $Meaning$ (Meaning Preservation) with a score range in $[0, 1]$ by reconstructing the AMR with a SOTA parser and computing the relative graph overlap of the reconstruction and the source AMR using graph matching. We call this RESMATCH. Given a generated sentence s' and source AMR m, we match $parse(s')$ against m by computing $amrMetric(parse(s'), m)$. This means that we have to decide upon $parse$ and $amrMetric$. We propose two potential settings.

AMR reconstruction To reconstruct the AMR with $parse$, we use the latest state-of-the-art AMR parser by Cai and Lam (2020a). With 80.3 Smatch F1, this parser is almost on-par with human agreement (estimated at 0.71–0.83 Smatch F1 in Banarescu et al. (2013)). We henceforth call it GSII.

Assessing $\mathcal{M}$ with AMR metrics To obtain a score for $\mathcal{M}$ we propose to use S^{2}match (Opitz et al., 2020) – a variant of Smatch (Cai and Knight, 2013) that performs a *graded match for concept nodes*. This offers the potential to compensate for noise in automatically generated text or minor lexical deviations from the original sentence.

Discussion Comparing to references by matching their meaning graphs has the prospect of offering interpretability and explanations, by detecting redundant or missing meaning components in the generations. In our studies, we will see that this assessment can be conducted by computing a *single graph overlap score* (e.g., S^{2}match F1), or along *multiple dimensions of meaning*, such as SRL, coreference or WSD (Damonte et al., 2017). Generally, $\mathcal{MF}_\beta$ gives researchers the flexibility of choosing a $parse$r or $amrMetric$ to their liking. In this work, we choose the best current $parse$r that achieves high IAA with humans. Yet, we would also like to know whether the $parser$ is vulnerable to specific peculiarities of generated sentences, or how using another parser affects the scores. We will investigate these issues more closely in §4.1.

2.3 Parameterizing form with LMs

Assessing sentence grammaticality and fluency is not an easy task (Heilman et al., 2014; Katinskaia and Ivanova, 2019). Recently, Lau et al. (2020); Zhu and Bhat (2020) show that probability estimates based on language models can be used as an indicator for measuring complex notions of form and for measuring acceptability in context. For

---

[3] Generally, $Form$ receives β times as much importance compared with $Meaning$.

our $\mathcal{MF}_\beta$ score we desire an interpretable ratio as input, which we base on LM predictions as follows.

Binary form assessment Given a specific candidate generation s', we use a binary variable to assess whether s' is of satisfactory form. For this, we first calculate the mean token probability:[4]

$$mtp(\cdot) = \frac{1}{n}\sum_{j=1}^{n} P(tok_j|ctx_j), \qquad (2)$$

where ctx_j is different for uni-directional LMs ($ctx_j = tok_{1...j-1}$) and bi-directional LMs ($ctx_j = tok_{1...j-1,j+1...n}$). We compute mtp for the generated sentence s' and the reference s and calculate a preference score $prefScore = \frac{mtp(s')}{mtp(s')+mtp(s)}$. The decision of whether the $Form$ of a generated sentence s' is acceptable is then calculated as

$$accept = \begin{cases} 1, & \text{if } prefScore \geq 0.5 - tol \\ 0, & \text{otherwise,} \end{cases}$$

where tol is a tolerance parameter. Less formally, a sentence is considered to have an acceptable surface form in relation to its reference if its form is estimated to be at least as good as the reference minus a tolerance, which we fix at 0.05. I.e., the corpus-level $Form$ score reflects the ratio of generated sentences that are of acceptable form.[5]

Predictor selection We consider GPT-2 (Radford et al., 2019), distil GPT-2 (Sanh et al., 2019), BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) as a basis for assessing $Form$. We conduct experiments on WebNLG (Gardent et al., 2017; Shimorina et al., 2017), which contains human fluency and grammaticality judgements for machine-generated sentences. We find that GPT-2 performs best: it discriminates sentences of poor and perfect fluency and grammaticality with an F1 score of approximately 0.8, and shows marginally better performance compared to the other LMs (see Appendix A.2 for the experiment details). We thus select GPT-2 as our LM for $Form$ assessment.

Discussion While the reconstruction of meaning does not depend on the reference sentence, we do make use of it, in $prefScore$, for better assessment of $Form$. One reason is that when assessing the form of a sentence s' that contains rare words, the 'raw' $mtp(s')$ may be too pessimistic and may not well relate to the quality of the form. Generally, the mtp (or any LM probability) itself is not well interpretable and hardly allows comparison to the mtp of other sentences (e.g., if they are about a different topic). However, by relating the mtp of the generated sentence to the mtp of a (same-topic) reference, we gain three advantages: first, we do not, a-priori, penalize generations that contain rare words. Second, we obtain an interpretable corpus-level ratio (rate of sentences that are of acceptable form). This is important, since sound $\mathcal{MF}_\beta$ calculation ideally requires two interpretable ratios as input. Third, by avoiding any string matching, we still keep form and meaning aspects clearly distinct.

2.4 Goals of our pilot studies

Our main aim is to establish, with the proposed $\mathcal{MF}_\beta$ score for AMR-to-text generation, **i)** a **balanced** and **interpretable assessment** of generated text according to ***Meaning*** **and** ***Form***. Yet, as detailed in §2.2 and §2.3, both components depend on a number of **ii) hyperparameters**, such as the parser applied for $Meaning$ reconstruction, or the LM used for $Form$ assessment. These parameters may also be subject to change over time. It is thus important to assess the effects of such factors on metric scores and system rankings. We investigate both aspects of $\mathcal{MF}_\beta$ in **two pilot studies**.

In **the first study**, in §3, we aim to assess the prospects of $\mathcal{MF}_\beta$ when ranking SOTA systems. We will see that $\mathcal{MF}_\beta$ can explain system performance differences by disentangling $Form$ and $Meaning$, an asset that no other metric can offer.

The second study, in §4, investigates the impact of $\mathcal{MF}_\beta$'s dependence on a parser and a LM. We i) investigate the effects of using different parsers, ii) assess the potential suitability of $\mathcal{MF}_\beta$ for other text generation tasks, by ablating the human gold graph from the evaluation and using $\mathcal{MF}_\beta$ to evaluate generated text vs. reference text, and iii) validate the LM's binary predictions for $Form$ in a manual annotation study.

3 Study I: Assessing interpretability

Setup: data & metrics for system ranking We obtain test predictions of several state-of-the-art *AMR-to-text generation systems* on LDC2017T10, the main benchmark for this task: (i) densely con-

---

[4] We use the mean (instead of the product) because Bryant and Briscoe (2018) find that basing decisions on the mean works well in practice when assessing possible corrections of grammatical errors.

[5] I.e., the $Form$ score for a single sentence with $accept \geq 0.5 - tol$ equals 1.0. If a precise assessment for a single sentence is needed, we can fall back on $prefScore$ (+/- tol).

Table 1: Main metric results.

nected graph convolutional networks (Guo et al., 2019); (ii) Ribeiro et al. (2019)'s system that uses a dual graph representation; two concurrently published models (iii) based on graph transformers (Cai and Lam, 2020b; Wang et al., 2020a) and (iv) a model based on graph transformers that uses reconstruction information (Wang et al., 2020b) in a multi-task loss; finally, we obtain predictions of two system variants of Mager et al. (2020) that finetune LMs and encode linearized graphs using (v) a large and (vi) a medium-sized LM. We true-case all sentences and parse them with GSII.

To put the results of $\mathcal{MF}_\beta$ into perspective, we display the scores of several metrics that have been previously used for AMR-to-text: BLEU, METEOR, CHRF++. We also calculate BERTscore (Zhang et al., 2020) with RoBERTa-large (Liu et al., 2019).[6] Results are displayed in Table 1, col. 3-6. $\mathcal{MF}_\beta$ scores (col. 7-12) are divided into $Meaning$ (RESMATCH using GSII) and $Form$ scores (based on GPT-2), and composite $\mathcal{MF}_\beta$ scores with $\beta = 1$ (harmonic) and $\beta = 0.5$ (double weight on $\mathcal{M}$).

As an upper-bound approximation for RESMATCH we propose parsing a gold sentence s and comparing the result against the gold AMR m: $apprUB$ = metric(parse(s),m).[7]

3.1 Interpretability of system rankings

Surface matching metrics lack differentiation and interpretability Table 1 shows that the baseline metrics tend to agree with each other on the ranking of systems, but there are also differences, for example, BERTscore and METEOR select M'20 as the best performing system while BLEU and CHRF++ select W'20. While certain differences may be due to individual metric properties, e.g., METEOR allowing inexact word matching of synonyms, the underlying factors are difficult to assess, since the score differences between systems with switched ranks are small, and none of these metrics can provide us with a meaningful interpretation of their score that would extend beyond shallow surface statistics. Hence, these metrics cannot give us much intuition about why and when one system may be preferable over another.

***Meaning* vs. *Form*: How $\mathcal{MF}_\beta$ explains system performance** We have seen that current metrics cannot provide us with convincing explanations as to why, e.g., W'20 should be preferred over M'20 (BLEU), or M'20 over W'20 (BERTscore). $\mathcal{MF}_\beta$ score, however, tells a story about how these systems differ, highlighting their complementary strengths by disentangling $Meaning$ and $Form$ (Bender and Koller, 2020): W'20 displays the highest RESMATCH score, i.e., AMRs constructed from its generations recover a maximum of the meaning contained in the input AMR. M'20, by contrast, outperforms all systems in $Form$ score. Looking at $\mathcal{MF}_1$, the harmonic mean of both, both systems still occupy leading ranks, but W'20 falls back to 3rd rank, due to its weaker $Form$ score.

Hence, given our metric principles, a user who cares about faithfulness to meaning, but less about fluency, should select W'20 (with higher RESMATCH compared to M'20 by Δ=1 point) – a user who desires a system that preserves meaning well but also produces sentences of decent form, should select M(b)'20 (with $\mathcal{MF}_{0.5}$ and $\mathcal{MF}_1$

---

[6] BERTscore computes an F1-score over a *cosim*-based alignment of the contextual embeddings of paired sentences.

[7] This is the score of canonical parser evaluation. I.e., we would not expect the reconstruction m' of s' to score higher than had we applied $parse$ to the original sentence: $metric(m', m) \leq metric(parse(s), m)$ = $apprUB$. This is an idealization, as we can imagine cases where the original sentence s is more complex and thus more difficult to parse to an AMR than a simpler generated paraphrase s'. Since we are interested in a very rough upper bound estimation, we abstract from such cases in our present work.

score differences against W'20 of Δ=3.5 points and Δ=8 points). Overall, $\mathcal{MF}_\beta$ mostly agrees with BERTscore in the rankings of the teams. However, $\mathcal{MF}_\beta$'s larger score differences between the systems, due to $Form$, are striking, prompting us to investigate the $Form$ predictions in closer detail (§4.2). We will see that using a different $Form$ predictor as well as a manual native speaker annotation clearly support our assessment of $Form$.

3.2 On the quest for deeper explanation and interpretation

-------------------------------------------------------------
```

Figure 3: Explainable $Meaning$ score (re-)ranking.

ReSmatch can also provide us with **explanations for single-sentence (re-)rankings**. An example is shown in Figure 3. Here, the gold reference (both sentence and AMR) indicates that a person named Costa *adds* (as a communicative act[8] that some insurgents have been holding large amounts of opium. However, system generation A (which is higher ranked by Bleu) chooses a different sense of *add*, add-02, which represents the action as an operation[9], which results in an incoherent or nonsensical meaning representation where the person Costa *adds* (in the operational sense) the insurgent (as thing being added) to a circumstance to the effect that the insurgents hold a significant amount of opium. By contrast, system generation B preserves more of the gold AMR's meaning and clearly expresses that Costa performs an *act of communication* when he *adds* something. ReSmatch ($\mathcal{MF}_{\beta\to 0}$) is able to detect the meaning differences and assigns candidate B a significantly higher score than A, in fact, an S^2match score of 1.00.

ReSmatch, when parameterized with fine-grained AMR evaluation metrics of Damonte et al. (2017), can also facilitate deeper insight into **how well system generations reflect or violate specific meaning aspects**. E.g., we can investigate a system's capacity to properly reflect negation (NEG); to generate correct surface forms for NEs (NER); assess how well a system captures coreference between entities (Coref); and whether or not the predicate-argument structures (SRL) of generated sentences appropriately reflect the source meaning. We apply these fine-grained AMR metrics to the ReSmatch scores of systems displayed in Table 1 (see Appendix A.3), and observe, e.g., that R'19, which ranks last in the overall ranking, improves upon the best overall system by 3.4 points in NER recall and 1.9 points in F1. The analysis also corroborates that W'20 excels among competitors with best scores for coreference, SRL and negation, i.e., the more global aspects of sentence meaning. Such information can be valuable for researchers for deeper system analysis and for practitioners aiming for specific use cases.

4 Study II: Assess vulnerability of $\mathcal{MF}_\beta$

$\mathcal{MF}_\beta$ has two apparent vulnerabilities: first, it depends on a parser for reconstruction. We have used a SOTA parser that is on par with human IAA. Yet, we cannot exclude the possibility that it introduces unwanted errors in computing $\mathcal{MF}_\beta$ scores.

Second, the $Form$ component is based on a LM and we have seen that it can change system rankings, even when it is discounted.[10] On the one hand, our LM was carefully selected, and other metrics such as BERTscore also heavily depend on LMs.

---

[8] Sense add-01 w/ roles: Arg0: *Speaker*; Arg1: *Utterance*.

[9] Sense add-02 w/role set: Arg0: *adder*; Arg1: *thing being added*; Arg2: *thing being added to*; Arg3: *resulting sum*.

[10] In Table 1, both $\mathcal{MF}_\beta$ with $\beta = 0.5$ and $\beta = 1.0$ slightly disagree with the ranks assigned by $Meaning$ only.

On the other hand, we cannot exclude the possibility that the changed rankings are unjustified.

Our next studies investigate these weak spots more closely. First, in §4.1, we assess the outcome of $\mathcal{MF}_\beta$ when using another parser and assess its potential portability to other text generation tasks by ablating the human gold graph and evaluate generated text against reference *text*. In §4.2 we conduct a human annotation study to assess whether the provided $Form$ rankings are justified.

4.1 The parser: Achilles' heel of $\mathcal{MF}_\beta$?

Using another parser In this experiment we assess the robustness of RESMATCH against using different parsers. This is important, since the metric and rankings could change with the parser. Here, we would hope that the difference of using one competitive parser over another will not be too extreme, especially with regard to system rankings. To investigate this issue, we apply two alternative parsers: i) GPLA (Lyu and Titov, 2018), a neural graph-prediction system that jointly predicts latent alignments, concepts and relations, and ii) TTSA (Groschwitz et al., 2018), a neural transition-based parser that converts dependency trees to AMR graphs using a typed semantic algebra. We select GPLA and TTSA since they constitute technically quite distinct approaches compared to GSII.

The results are shown in Table 2 (columns labelled GPLA, TTSA and GSII). All variants tend to agree in the majority of their rankings[11] (e.g., RESMATCH ^{GPLA} vs. RESMATCH ^{GSII} F1: Spearman's ρ = 0.95, Pearson's ρ = 0.96, p<0.001). When considering $\mathcal{MF}_{\beta=0.5}$, the agreement further increases (e.g., $\mathcal{MF}_{0.5}^{GPLA}$ vs. $\mathcal{MF}_{0.5}^{GSII}$: Spearman's $\rho = 0.95$, Pearson's $\rho = 0.99$, p<0.001).

However, while using TTSA or GPLA instead of GSII has little effect on the ranks, the absolute scores can differ (e.g., W'20 70.5 F1 w/ TTSA, 73.1 F1 w/ GPLA and 75.3 F1 w/ GSII). Yet, we find that none of the generation systems are unfairly treated by our main parser GSII since we observe (mostly uniform) increments from TTSA to GPLA and from GPLA to GSII. An unfair treatment could arise, e.g., if GSII generates bad AMR reconstructions for specific NLG systems but not so for others. However, we do not observe such tendencies.

Hence we assume that GSII's score increments stem from the fact that GSII yields better reconstructions for all systems. In future work, we plan to explore parse quality control (Opitz and Frank, 2019; Opitz, 2020) or ensemble parsing (van Noord and Bos, 2017), to gain more detailed information on the quality of the meaning reconstructions.

Ablating the gold graph? Yes, we can. In lack of a gold standard for the automatic reconstructions, we elicit some indirect answers and insight about the parser's quality, by considering the following question: *What is the effect on system rankings when we replace the input gold graphs with automatic parses of the distant source sentence?* If this effect is large, this will give us reasons to worry, as it would indicate that the parser is less reliable than expected given its high IAA with humans. On the other hand, if we only see a minor effect, this may increase the trust in our parser and indicate that $\mathcal{MF}_\beta$ **could be confidently applied for explainable evaluation in other generation tasks** (such as MT or summarization), where we do not have gold AMRs, and would have to parse both generated *and* reference sentences.

The results of this experiment are displayed in Table 2: our standard setup is displayed in columns labeled GSII and the results of the setup where we replace the gold input graph with an automatic parse is indicated by GSII$^\blacklozenge$. When considering RESMATCH scores, we see only one switched rank between Mb'20 and G'20 (3–4). However, note that the absolute F1 score Δ between these two systems is overall very small (GSII: 0.2; GSII$^\blacklozenge$: 0.5). Overall, the scores do not tend to differ much when the gold graph is ablated, we observe rather small (mostly positive) changes in system scores (GSII $\rightarrow$ GSII$^\blacklozenge$): 0.1 / 1.2 / 0.4 (min/max/avg). In sum, we conclude from this experiment that ablating the gold graph does not have a major effects on the scores and rankings. And when considering the $\mathcal{MF}_{\beta=0.5}$ score, the ranking stays fully stable (the same holds true for $\mathcal{MF}_{\beta=1}$.

Discussion We have shown that metric rankings are fairly robust to using different parsers and that we do not necessarily depend on gold AMR graphs to compute the measure. This offers prospects for **using** $\mathcal{MF}_\beta$ **for an explainable assessment of systems that perform other kinds of text generation**. In order to measure $\mathcal{M}$, a parser could be applied to both the generated and the reference text, to measure their agreement in the domain of ab-

---

[11] We observe one switch of ranks for TTSA-GPLA and GPLA-GSII and 2 rank switches for TTSA–GSII in RESMATCH, and no rank switch for TTSA-GSII and one switch for TTSA-GPLA and GPLA-GSII, for $\mathcal{MF}_{0.5}$.

Table 2: Analysis of our metric using different parsers (GPLA, TTSA GSII) or ablating the gold parse by comparing the parsed generation against the parse (distant) source sentence (GSII$^{\blacklozenge}$).

stract meaning representation. This would in turn offer means for conducting fine-grained meaning analysis of generation tasks where the reference is a natural language sentence (e.g., in MT).

Note, however, that AMR, as of now, does not capture some facets of meaning that may be of interest in some generation tasks. For instance, it does not capture tense or aspect. However, what we have investigated as a *potential weakness* of $\mathcal{MF}_\beta$, namely the necessity to select a meaning parser, can also be viewed as a *potential strength*. E.g., Donatelli et al. (2018) show how tense and aspect can be captured with AMR. This indicates that $\mathcal{MF}_\beta$ can indeed be used for a tense and aspect analysis of generated text – if we parameterize it with a dedicated parser. Finally, if output and reference do not consist of single sentences, it may be apt to use a parser that constructs MRs for discourse (e.g., *DRS* (Kamp, 1981)).

In summary, we conclude that $\mathcal{MF}_\beta$, our proposed metric that aims to assess text generation quality by decomposing it into *form* and *meaning* aspects, is broadly applicable. However, different parser parametrizations may have to be considered in light of the specific nature of a generation task.

4.2 The $Form$ component of $\mathcal{MF}_\beta$

In §3.1, we have seen that the $Form$ aspect of $\mathcal{MF}_\beta$ can change system ranks. Notably, it has promoted M'20 as the best generation system, outranking W'20 (in agreement with BERTscore), whereas W'20 is selected by Bleu or ReSmatch. Now, we aim to investigate whether these impactful decisions of the $Form$ component were justified.

Human annotation We ask a native speaker of English to rate 50 paired generations of M'20 and W'20, considering only grammaticality and fluency.[12] We give more detail and provide examples in Appendix A.6. The annotator agreed in 42 of 50 pairs with the preference predicted by GPT-2 (a significant result: binomial test $p<0.000001$). We find that the M'20 and Mb'20 generations are considerably better on the surface level, compared to generations of all other systems. For instance, the best system according to $Meaning$, W'20, frequently produces inflection mishaps: *Their hopes for entering the heat is already in-sight*, while we find few such violations with M'20 (here: *Their hopes for entering the heat are already in sight*). We also find errors with adverbials, e.g., W'20 writes *They are the most indoor training at home*, while M'20 writes *They are most trained indoors at home*. Arguably both sentences are not perfect but the second is substantially more well-formed.

	R'19	G'20	Wb'20	C'20	Mb'20	M'20	W'20
GPT-2	$51.6_{(4)}$	$47.1_{(6)}$	$49.5_{(5)}$	$51.9_{(4)}$	$74.0_{(1)}$	$69.8_{(2)}$	$55.7_{(3)}$
BERT	$43.4_{(6)}$	$40.6_{(7)}$	$50.4_{(4)}$	$44.7_{(5)}$	$71.4_{(1)}$	$71.0_{(2)}$	$55.9_{(3)}$

Table 3: $Form$ scores when using a different LM.

Using a different LM The human study indicates that GPT-2 is accurate to 84% when favoring one sentence over the other, with respect to fluency and grammaticality. However, when considering that there is a trend to building systems based on fine-tuned LMs, we need to assess whether they may be favored (too) much if $Form$ is parameterized with a same or a highly similar LM to the one used by the NLG model. We find such a case in M'20: while it was not fine-tuned with the same GPT-2 that we used for $Form$ assessment, they fine-tuned their model with its siblings GPT-2-medium and GPT-large, which may share structural similarities. Therefore, we also use BERT for

---

[12] The annotator was explicitly instructed not to consider whether a sentence 'makes sense', by presenting the *Green ideas sleep furiously* example as free from structural error.

$Form$ assessment. The results in Table 3 support the conclusion from the human annotation: by large margins, both M'20 and Mb'20 deliver generations that are of significantly improved form and both agree on the group of the three best systems. Note that this insight can be provided by $\mathcal{MF}_\infty$, but it cannot be carved out by conventional metrics, since these do not disentangle $Form$ and $Meaning$.

5 Related work

Traditionally, the performance of NLG systems has been evaluated with word n-gram matching metrics such as the popular BLEU metric in MT (Papineni et al., 2002) or Rouge (Lin, 2004) in document summarization. Yet, such metrics suffer from several well-known issues (Novikova et al., 2017; Nema and Khapra, 2018; Sai et al., 2020). E.g., due to their symbolic matching strategy they cannot account for paraphrases. Recently, unsupervised (Zhang et al., 2020) or learned metrics (Sellam et al., 2020; Zhou and Xu, 2020) based on contextual language models have been proposed. For example, BERTscore (Zhang et al., 2020) uses BERT (Devlin et al., 2019) to encode candidate and reference and computes a score based on a cross-sentence word-similarity alignment. Compared with BLEU, it is computationally more expensive but tends to show higher agreement with humans. However, *all* of the aforementioned metrics return scores that are hardly interpretable and we cannot tell what exactly they have measured.

These problems carry over to the evaluation of AMR-to-text generation: May and Priyadarshi (2017) find that BLEU does not well correspond to human ratings of generations from AMR, and Manning et al. (2020) show through human analysis that none of the existing automatic metrics can provide nuanced views on generation quality. Our proposal $\mathcal{MF}_\beta$ takes a first step to address these issues by aiming at a clear separation of form and meaning, as called for by Bender and Koller (2020).

First attempts of assessing semantic generation quality have been examined in MT using semantic role labeling (Lo, 2017) or WSD and NLI (Carpuat, 2013; Poliak et al., 2018), in-between lies SPICE that evaluates caption generation via inferred semantic propositions (Anderson et al., 2016). Just like $\mathcal{MF}_\beta$, SPICE relies on automatic parses (a dependency parse of the caption and a scene graph predicted for the image) to evaluate content overlap of image and caption. Thus, SPICE is a direct precursor of an NLG metric in V&L that relies on automatically produced structured representations. Our work extends this previous work by showing ways of probing potentially harmful effects of incorporating automatic parsing components.

6 Conclusion

We propose $\mathcal{MF}_\beta$ score, a new metric for evaluation of text generation from (abstract) meaning representation. The metric is built on two pillars: $Form$ measures grammaticality and fluency of the produced sentences and $Meaning$ assesses to what extent the meaning of the input AMR is reflected in the produced sentence. We show that $\mathcal{MF}_\beta$ has the potential to yield fine-grained performance assessment that go beyond what conventional metrics can provide. Using its β-parameter, $\mathcal{MF}_\beta$ can be decomposed into complementary views – $Meaning$ and $Form$ – paving the way for custom gauging and selection of NLG systems. We have seen that $\mathcal{MF}_\beta$ corresponds well to BERTscore when rankings systems, but overcomes its opaqueness by disentangling $Meaning$- and $Form$-related quality aspects. In sharp contrast to BERTscore, the $Form$ component of $\mathcal{MF}_\beta$ dispenses with string matching against reference sentences, offering an assessment independent of lexical alignment.

An important hyperparameter of our metric is the required AMR parsing component for meaning reconstruction. We investigate the impact of its choice by choosing alternative high-performing parsers. Our study shows that absolute metric scores tend to increment when using a better parser, while system rankings are quite stable. Furthermore, we outline the potential of $\mathcal{MF}_\beta$ to extend to further text generation tasks, by ablating the human gold graph from the evaluation, such that the metric score can be computed from candidate and reference text alone. Since benchmarking of systems needs deeper exploration, we recommend $\mathcal{MF}_\beta$ score to obtain better diagnostics and explainability of text generation systems, including, but not limited to (A)MR-to-text.

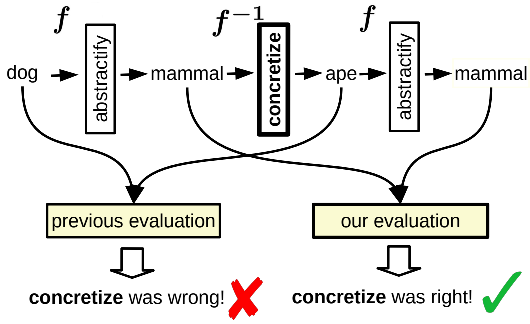

Figure 4: A critical issue and its alleviation.

A Appendices

A.1 On the soundness of comparing generated sentences in the AMR domain

First, we provide a simple example for our argument (it is safer to compare texts generated from AMR in the AMR domain) and then a simple proposition together with its proof. The example is displayed in Fig. 4, where, similar to AMR-to-text, we see a (surjective) function that generates concrete objects from abstract objects (e.g., $mammal \rightarrow \{dog, mouse, cow\}$). Now, imagine we are given $mammal$ and are tasked with generating a single concrete instance. How can we assess whether our output is correct? We cannot safely assess this by testing whether the output (e.g., cow) is the same as another instance of $mammal$ (e.g., dog). Instead, we can re-apply the abstraction f to cow and conduct the comparison safely in the abstract domain.

Proposition. *a) The canoncical AMR-to-text evaluation setup, that matches generated sentence s' to distant source sentence s, is not well defined. b) This issue can be alleviated by grounding the evaluation in the AMR domain by re-appling parse, abstaining from direct use of s (thereby using AMR-to-text generation as a right inverse function).*

Proof. Let X be a set of concrete objects (e.g., sentences) and f a (surjective) function from X to Y (e.g., 'sent-to-AMR'), where Y contains abstract objects (e.g., AMRs), s.t. $|Y| < |X|$. Then, using $f^{-1} : Y \rightarrow X$ (e.g., 'AMR-to-sent')) as right-inverse is well-defined: $f \circ f^{-1} = id_Y$ (Proposition b), but using it solely as left-inverse (as done in previous evaluation) does not guarantee a well-defined result: $f^{-1} \circ f \neq id_X$ (Proposition a). $\square$

A.2 Form predictor selection experiment

To estimate how well they are able to assess $Form$, we make use of human-assigned scores for data from the WebNLG task as provided by Gardent et al. (2017). It contains grammaticality and fluency judgments by humans for more than 2000 machine-generated sentences. We report the F1 score, both for grammaticality and fluency, by converting the human assessment scores to *accept* predictions, and using them as a gold standard to evaluate the LM-based *accept* predictions over (i) all 12k sentence pairs[13] and (ii) only the 5k sentence pairs where both grammaticality and fluency where either rated as 'perfect' (max. score) or 'poor' (min. score) by the human.[14]

	F1 score			
	grammaticality		fluency	
LM	poor/perfect	all	poor/perfect	all
GPT2	**0.80**	**0.74**	**0.80**	0.71
GPT2-distill	0.79	0.73	0.76	0.70
BERT	**0.80**	0.72	**0.80**	**0.72**
RoBERTa	0.66	0.72	0.69	**0.72**

Table 4: Results for assessing the $Form$ score prediction (corpus-level) of different LMs for NLG-generated sentences against humans judgements (separated by grammaticality and fluency); all: all 12k generated sentences vs. 'poor/perfect': the 5k instances of best/worst generations in both grammaticality and fluency.

Table 5: Fine-grained results using $\mathcal{MF}_0$ parameterized with metrics proposed by Damonte et al. (2017).

The results are displayed in Table 4 and show (i) that the LMs lie very close to each other with respect to their capacity to predict fluency and grammatically, and (ii) that both fluency and grammaticality can be predicted fairly well.

A.3 RESMATCH with fine-grained meaning metrics

Using Damonte et al. (2017)'s metric suite for fine grained semantic system analysis, we obtain fine-grained results with respect to various meaning aspects of system performance. The results are shown in Table 5.

In sum, the system of W'20 appears to be the

```

Figure 5: Explained negation confusion.

clear winner in most aspects of meaning. This is intuitive, since the system has been trained with an auxiliary signal that provides information on how well an AMR can be reconstructed from the generated sentence.

A.4 ReSmatch explains negation error

In Figure 5, both systems struggle to fully capture the meaning of the original AMR $f(s)$. However, the system based on GPT medium (Mb'20) erroneously assesses that *we are not responsible* and *we fear*. However, quite the opposite is true: the gold graph and gold sentence states that *there is responsibility* and *there is no fear*. This important facet of meaning is better captured by C'20. The reconstruction shows that it reflects the gold negated concepts much better and does not distort facts that are core to the meaning. In consequence, the negation F1 is zero for the left sentence with the distorted facts and maximum for the sentence that sticks true to the facts.

A.5 ReSmatch explains SRL error

Figure 6 shows an example, were ReSmatch ranks two generated candidate sentences differently compared to Bleu. In this case, gold sentence and gold AMR both express that there is some soldier who tried to defuse a bomb and got injured in the process. Clearly, candidate generation A captures the meaning better, in fact, it captures it almost perfectly. However, since the surface text deviates from the gold sentence, Bleu overly penalizes this generation and assigns a very low score of 10.6 points. In contrast, candidate B matches the surface slightly better (12.2 points), but distorts the meaning: it does not contain any information about the soldier and states that *Disarming was injured*, which is grammatically correct, but semantically wrong, or even non-sense.

We see that the surface matching metric cannot explain its scores (beyond superficial statistics) and delivers a ranking that does not appropriately reflect the performance of the generation systems. However, ReSmatch shows that the gold parse and the parse of candidate A agree with each other in the central *ARG1*-role of the main predicate *injure-01*: *it is the soldier who got injured*. On the other hand, in the reconstruction of the AMR of candidate B, the *ARG1* argument is filled differently: *it is the disarmament that gets injured*.

This assessment allows ReSmatch to increment the score for generation A by a large margin, from 10.6 (Bleu) to 93.3 points (ReSmatch), expressing substantial agreement in meaning with the gold. The score for the candidate generation B also gets incremented – but it gets incremented much less, only to 70.2 points, expressing good to mediocre agreement. Thus, by detecting the SRL confusion, ReSmatch re-ranks the candidate generation such that the resulting ranking is more appropriate.

Abstract

While we live in an increasingly interconnected world, different places still exhibit strikingly different cultures and many events we experience in our every day life pertain only to the specific place we live in. As a result, people often talk about different things in different parts of the world. In this work we study the effect of local context in machine translation and postulate that this causes the domains of the source and target language to greatly mismatch. We first formalize the concept of source-target domain mismatch, propose a metric to quantify it, and provide empirical evidence for its existence. We conclude with an empirical study of how source-target domain mismatch affects training of machine translation systems on low resource languages. While this may severely affect back-translation, the degradation can be alleviated by combining back-translation with self-training and by increasing the amount of target side monolingual data.

1 Introduction

The use of language greatly varies with the geographic location (Firth, 1935; Johnstone, 2010). Even within places where people speak the same language (Britain, 2013), there is a lot of lexical variability due to change of style and topic distribution, particularly when considering content posted on social media, blogs and news outlets. For instance, while a primary topic of discussion between British sport fans is cricket, American sport fans are more likely to discuss other sports such as baseball (Leech and Fallon, 1992).

The effect of local context in the use of language is even more extreme when considering regions where different languages are spoken. Despite the increasingly interconnected world we live in, people in different places tend to talk about different things. There are several reasons for this, from cultural differences due to geographic separation and history, to the local nature of many events we experience in our every day life.

This phenomenon has not only interesting sociolinguistic aspects but it has also strong implications in machine translation (MT) (Bernardini and Zanettin, 2004). In particular, machine translation aims at automatically translating content in two languages that are often spoken in very distant geographic locations by people with rather different cultures.

As of today, most MT research has been based on the often implicit assumption that content in the two languages is *comparable*. Sentences comprising the parallel dataset used for training are assumed to cover the same topic distribution, regardless of the originating language. Even when there exist a mismatch between the source and the target domain, the dataset creator is assumed to have made the effort to equalize the two distributions.

The major contribution of this work is to raise awareness in the MT community that this assumption may not hold in many real world settings of interest, which often involve distant and low-resource language pairs and for content produced every day on the Internet by means of blogs, social platforms and news outlets. The goal of an MT system is to translate source sentences sampled from the source domain to the target language. Training an MT system on a comparable corpus may lead to poor generalization unless the test domain matches the domain of the training data. Likewise, training on an uncurated corpus exhibiting mismatch between the source and the target domain may also work poorly when naïvely applying popular methods like back-translation (Sennrich et al., 2015).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1519–1533
April 19 - 23, 2021.

Notice that there may very well be several factors contributing to such mismatch, such as change of register, different functional use of the text in the two languages, and difference in the quality of the data generation process of the two languages. Regardless of what is contributing to the observed mismatch, it is important to be aware of its existance and effect on MT algorithms.

The source-target domain mismatch (STDM) can be understood as an instance of *multi-domain* MT (see Fig. 1 for an illustration and §3 for a formal definition), whereby part of the parallel dataset and the source monolingual dataset are "in-domain" because they originate from the source domain, and the remaining part of the parallel dataset as well as the target monolingual data are "out-of-domain". There already exist several techniques for domain adaptation, like domain tagging (Caswell et al., 2019) and dataset weighting (Edunov et al., 2018; Wang et al., 2017; van der Wees et al., 2017), which are applicable and which we also employ in this work. However, these may not be enough to improve generalization on low resource languages because STDM effectively decreases the already scarce amount of useful (in-domain) parallel data, hindering good generalization. It is therefore important to quantify STDM (§4) and consider how STDM affects methods that leverage monolingual data (§5).

For instance, STDM may negatively impact the effectiveness of back-translation because, even if the backward model was perfect, the back-translated data is out-of-domain relative to the source domain from which we aim to translate. Empirically we found that this is the case both in a controlled setting (§6.1) as well as in realistic datasets (§6.2). However, this issue can be compensated by adding more target-side monolingual data and by combining back-translation with self-training (Yarowski, 1995).

2 Related Work

The observation that topic distributions and various kinds of lexical variabilities depend on the local context has been known and studied for a long time (Firth, 1935). For instance, Firth (1935) says "*Most of the give-and-take of conversation in our everyday life is stereotyped and very narrowly conditioned by our particular type of culture*". In her seminal work, Johnstone (2010) analyzed the role of place in language, focusing on lexical variations within the same language, a subject further explored by Britain (2013). Some of these works were the basis for later studies that introduced computational models for how language changes with geographic location (Mei et al., 2006; Eisenstein et al., 2010).

In the field of topic modeling, there has been a new sub-field emerging over the past 10 years focusing on modeling multi-lingual corpora (Mimno et al., 2009; Boyd-Graber and Blei, 2009; Gutierrez et al., 2016). However, only recently had researchers dropped assumptions on the use of parallel and comparable corpora (Hao and Paul, 2018; Yang et al., 2019). While some works do investigate issues related to STDM (Gutierrez et al., 2016), like how named entities receive a different distribution over words in different languages (Lin et al., 2018), none of these works have analyzed how the overall topic distribution of data originating in the source and target language differ.

In MT, researchers have often made an explicit assumption on the use of *comparable* corpora (Fung and Yee, 1998; Munteanu et al., 2004; Irvine and Callison-Burch, 2013), i.e. corpora in the two languages that roughly cover the same set of topics. Unfortunately, monolingual corpora are seldom comparable in practice. Leech and Fallon (1992) analyzes two comparable corpora, one in American English and the other in British English, and demonstrate differences that reflect the cultures of origin. Similarly, Bernardini and Zanettin (2004) observes that parallel datasets built for MT exhibit strong biases in the selection of the original documents, making the text collection not quite comparable.

The non-comparable nature of MT datasets is even more striking when considering low resource language pairs, for which differences in local context and cultures are often more pronounced. Recent studies (Søgaard et al., 2018; Neubig and Hu, 2018) have warned that removing the assumption on comparable corpora strongly deteriorates performance of lexicon induction techniques which are at the foundation of MT.

Back-translation (Sennrich et al., 2015) has been the workhorse of modern neural MT, enabling very effective use of target side monolingual data. Back-translation is beneficial because it helps regularizing the model and adapting to new domains (Burlot and Yvon, 2018). However, the typical setting of current MT benchmarks as popularized by re-

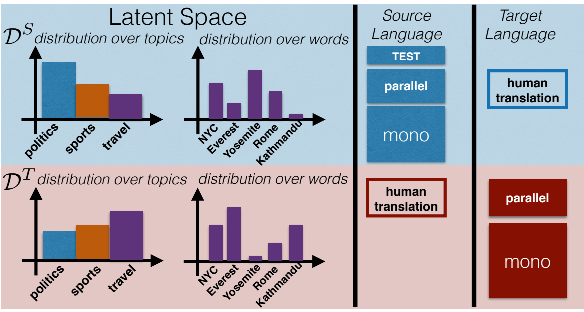

Figure 1: Toy illustration of STDM in MT. There are two domains, the source domain $\mathcal{D}^S$ (top) and the target domain $\mathcal{D}^T$ (bottom). We postulate that in a latent concept space these two domains differ because the topic distributions are different (e.g., in the source domain politics is more popular than travel) and because for the same topic the word distributions are different (e.g., the word "Everest" is more common than "Yosemite" in the travel topic of the target domain). On the right hand side, we show how STDM manifests in machine translation datasets. All data originating in the source language belongs to the source domain, this includes a portion of the parallel dataset, the source side monolingual dataset and the test set we eventually would like to translate. Empty boxes represent human translated data in the parallel training dataset.

cent WMT competitions (Bojar et al., 2019) is a mismatch between *training and test* sets, as opposed to a mismatch between *source and target* domains as in this work. Self-training (Ueffing, 2006; Yarowski, 1995; He et al., 2020) has then been employed to make better use of source side monolingual data as this is in-domain with the text we would like to translate at test time. Finally, there is a vast literature on domain adaptation which has so far mostly focused on domain shift between training and test distribution, and presence of multiple domains. Finetuning (Freitag and Al-Onaizan, 2016), domain tagging (Caswell et al., 2019) and various kinds of dataset weighting (Wang et al., 2017; van der Wees et al., 2017) are among the most popular methods to cope with domain issues, and this is also what we use in this work.

3 The STDM Problem

In this section we formalize the definition of Source-Target Domain Mismatch (STDM); this is an intrinsic property of the data which is independent of the particular MT system under consideration. In practice, there might be several factors contributing to STDM. Here, we are going to consider only the difference in topic distributions, since this is what we can easily quantify.

We assume there exists a latent concept space shared across all languages. The process to generate a sentence follows the standard data generation process used in topic modeling, whereby we first sample a distribution over topics, $\pi_i \sim \Pi$ where i is an index over topics, and then a distribution over words for each topic, $w_{ij} \sim \pi_i$, where j indexes the words in the dictionary. Next, we assume there are two distinct domains, the source domain $\mathcal{D}^S$ and the target domain $\mathcal{D}^T$. These two domains differ in both the distribution over topics Π, and the distribution over words given a certain topic π_i, as depicted in Fig. 1. For the sake of conciseness, we will refer to z^s and z^t as sentences in the concept space generated from domain $\mathcal{D}^S$ and $\mathcal{D}^T$, respectively.

Let's imagine now that we have generated two sets of sentences in each domain. What we observe in practice is their realization in each language, $\text{src}(z^s)$ and $\text{tgt}(z^t)$, where src and tgt map sentences from the concept space to the source and target language, respectively. Finally, let's denote with $h_{s\to t}$ and $h_{t\to s}$ the functions representing human translations of source sentences in the target language and vice versa.

In the simplest setting, a machine translation dataset is composed of parallel and monolingual datasets. Using the notation introduced above, the parallel dataset is denoted by $\mathcal{P} = \{(\text{src}(z^s), h_{s\to t}(\text{src}(z^s))\}_{z^s \sim \mathcal{D}^S} \cup \{(h_{t\to s}(\text{tgt}(z^t)), \text{tgt}(z^t)\}_{z^t \sim \mathcal{D}^T}$. The first set originates in the source language and belongs to the source domain, while the second set originates in the target language and belongs to the target domain. We then have a source side monolingual dataset, $\mathcal{M}^S = \{\text{src}(z^s)\}_{z^s \sim \mathcal{D}^S}$, and a target side monolingual dataset, $\mathcal{M}^T = \{\text{tgt}(z^t)\}_{z^t \sim \mathcal{D}^T}$, belonging to the source and target domains, respectively. Most importantly, the *test set* which we would like to eventually translate contains sentences in the source language, all belonging to the *source* domain. The existence of distinct source and target domains and datasets derived from these two domains as described above define the STDM problem.

While in previous MT studies, there is a mismatch between the training and the test distribution, STDM is a particular case of multi-domain training, with the test set matching one of the training domains. We would like to a) understand the effects of such mismatch and b) understand how to best leverage the out-of-domain data originating from the target language (target monolingual dataset and

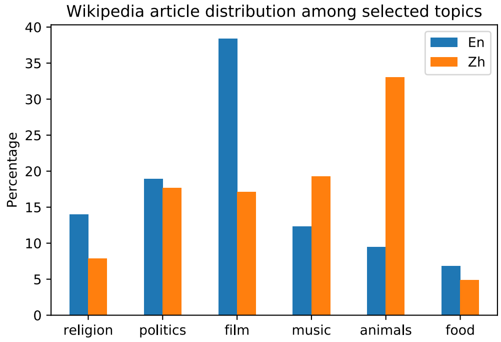

Figure 2: Topic distribution of Wikipedia pages written in English and Chinese.

portion of the parallel dataset originating in the target language).

3.1 Empirical Evidence

In this section we first provide anecdotal evidence that documents originating in different languages possess different distributions over topics. We train two topic classifiers (see Appendix A for details), one for Chinese and the other for English, using the Wikipedia annotated data from Yuan et al. (2018). We apply this classifier to 20,000 documents randomly sampled from English and Chinese Wikipedia. Fig. 2 shows that according to this classifier, English Wikipedia has more pages about entertainment and religion than Chinese Wikipedia, for instance.

Second, we refer the readers to Leech and Fallon (1992)'s study to find evidence that corpora originating in different places may have different word distributions for the same set of topics. In that study, Leech and Fallon (1992) analyzed a British and an American corpus constructed using exactly the same distribution of topics, and yet the word distribution was different, reflecting the different cultural biases of the two countries.

4 Metric: The STDM Score

Given the framework and assumptions introduced in §3, in this section we are going to discuss a practical way to measure STDM. Ideally, we would like to measure a distance between two sample distributions, $z^s \sim \mathcal{D}^S$ and $z^t \sim \mathcal{D}^T$. Unfortunately, we have no access to such latent space. What we observe are realizations in the source and target language. However, it is also an open research question (Hao and Paul, 2018; Yang et al., 2019) how to compare the distribution of $\{\text{src}(z^s)\}$ against $\{\text{tgt}(z^t)\}$, since these are two possibly incomparable corpora in different languages.

In this work, we therefore leverage the existence of a parallel corpus and compare the distribution of $\mathcal{A}^T = \{\text{tgt}(z^t)\}_{z^t \sim \mathcal{D}^T}$ with $\mathcal{A}^S = \{h_{s\to t}(\text{src}(z^s))\}_{z^s \sim \mathcal{D}^S}$. The underlying assumptions are a) we know the originating language of each training example, b) the effect of the change of the word distribution is negligible compared to the shift in topic distribution, and c) the effect of translationese (Baker, 1993; Zhang and Toral, 2019; Toury, 2012) is negligible compared to the actual STDM, and therefore, we can ignore changes to the distribution brought by the mapping $h_{s\to t}$ (we validate this assumption in §C).

Under these assumptions, we define the score as a measure of the topic discrepancy between $\mathcal{A}^S$ and $\mathcal{A}^T$. Let $\mathcal{A} = \mathcal{A}^S \cup \mathcal{A}^T$ be the concatenation of the corpus originating in the source and target language. We first extract topics using LSA. Let $A \in \mathbb{R}^{(n^S+n^T)\times k}$ be the TF-IDF matrix derived from $\mathcal{A}$ where the first n^S rows are representations taken from $\mathcal{A}^S$, the bottom n^T rows are representations of $\mathcal{A}^T$, and k is the number of words in the dictionary. The SVD decomposition of A yields: $A = USV = (U\sqrt{(S)})(\sqrt{(S)}V) = \bar{U}\bar{V}$. Matrix $\bar{U}$ collects topic representations of the original documents; let's denote by $\bar{U}^S$ the first n^S rows corresponding to $\mathcal{A}^S$ and $\bar{U}^T$ the remaining n^T rows corresponding to $\mathcal{A}^T$. Let $C = \bar{U}\bar{U}' = \begin{bmatrix} C^{SS} & C^{ST} \\ C^{ST\prime} & C^{TT} \end{bmatrix}$, where $C^{SS} = \bar{U}^S\bar{U}^{S\prime}$, $C^{ST} = \bar{U}^S\bar{U}^{T\prime}$ and $C^{TT} = \bar{U}^T\bar{U}^{T\prime}$. The STDM score is defined as:

$$\text{score} = \frac{s^{\text{ST}} + s^{\text{TS}}}{s^{\text{SS}} + s^{\text{TT}}}, \text{with } s^{\text{AB}} = \frac{1}{n^A n^B}\sum_{i=1}^{n^A}\sum_{j=1}^{n^B} C_{i,j}^{AB} \quad (1)$$

where s^{AB} measures the average similarity between documents of set A to documents of set B. The score measures the cross-corpus similarity normalized by the within corpus similarity. In the extreme setting where $\mathcal{D}^S$ and $\mathcal{D}^T$ are fully disjoint, then we would have that the off-diagonal block C^{ST} is going to be a zero matrix and therefore the score is equal to 0. When the two domains perfectly match instead, $s^{\text{SS}} = s^{\text{TT}} = s^{\text{ST}} = s^{\text{TS}}$, and therefore, the score is equal to 1. In practice, we expect a score in the range $[0, 1]$. Note that we opted for this metric because of its simplicity, but other methods to extract topics and measure domain mismatch could have been used.

4.1 A Controlled Setting

Similarly to Kilgarriff and Rose (1998), we introduce a *synthetic* benchmark to finely control the

α	0	0.25	0.5	0.75	1.0
STDM score	0.29	0.55	0.78	0.93	0.99

Table 1: STDM score as a function of the parameter α controlling the STDM in the synthetic setting.

domain of the target originating data, and therefore the amount of STDM. The objective is to assess whether the STDM score defined in Eq. 1 captures well the expected amount of mismatch, since we have full control over how the data was generated and its domain.

The key idea of this controlled setting is to use data from two very different domains, assign the source domain to one of them and the target domain to a convex combination of the two. In this work we use EuroParl (Koehn, 2005) as our source originating data, while our target originating data contains a mix of data from EuroParl and OpenSubtitles (Lison and Tiedemann, 2016). Specifically, we consider a French to English translation task with a parallel dataset composed of 10,000 sentences from EuroParl (which "originates" in French) and 10,000 sentences from the target domain (which is "originates" in English)[1]. Let $\alpha \in [0, 1]$, the domain of the target is set to: α EuroParl + $(1 - \alpha)$ OpenSubtitles. α controls how similar the target domain is to the source domain.

For instance, when $\alpha = 0$ then the target domain (OpenSubtitles) is totally out-of-domain with respect to the source domain (EuroParl). When $\alpha = 1$ instead, the target domain matches perfectly the source domain. For intermediate values of α, the match is only partial. Notice that even when $\alpha = 0$, we assume that the parallel dataset is comprised of two halves, one originating from the EuroParl domain (the "French originating" data) and one from OpenSubtitles (the "English originating" data).

Next, we evaluate the STDM score as a function of α. As we can see from Table 1 and as desired, the STDM score increases fairly linearly as we increase the value of α. We refer the reader to Appendix B for experimental details.

4.2 STDM Score of Various Datasets

	De-En	Fi-En	Ru-En	Ne-En	Zh-En	Ja-En
WMT	0.79	0.79	0.76	-	0.65	-
MTNT	-	-	-	-	-	0.69
SMD	0.81	0.71	0.71	0.64	0.71	0.61

Table 2: STDM score on several language pairs using parallel data from WMT, MTNT and from a social media platform (SMD) test sets.

We now evaluate the STDM score on real data. We consider six language pairs, German-English, Finnish-English, Russian-English, Nepali-English, Chinese-English and Japanese-English. We analyze datasets from WMT, MTNT (Michel and Neubig, 2018) and from a social media platform (SMD). For each language, we sample 5000 sentences from WMT newstest sets and MTNT dataset, and 20000 sentences from SMD. We then merge all these datasets and their English translations to compute a common set of topics, making STDM scores comparable across language pairs and datasets.

The results in Table 2 are striking. First, WMT datasets, except for Chinese, show relatively mild signs of STDM and negligible difference across language pairs, suggesting that the data curation process of WMT datasets have made source and target originating corpora rather comparable. The distribution of WMT Chinese originating data instead is rather different because it contains much more local news, while the other languages are mostly about international news which are largely language independent. Interestingly, En-De data derived from social media data has even milder STDM, Fi-En and Ru-En have more substantial STDM. Instead, *MTNT and SMD exhibit strong signs of STDM for distant languages* like Nepali, Chinese and Japanese. This agrees well with our intuition that STDM is more severe for more distant languages associated to more diverse cultures.

5 Machine Translation Baselines

In this section, we turn our attention to how STDM affects training of MT systems. We consider state-of-the-art neural machine translation (NMT) systems based on the transformer architecture (Vaswani et al., 2017) with subword vocabularies learned via byte-pair encoding (BPE) (Sennrich et al., 2015). In order to adapt to the different domains, we employ domain tagging (Zheng et al., 2019) by adding a domain token to the input source sentence, and we cross validate the weights between in-domain and out-domain data[2]. We also

---

[1] Clearly, EuroParl does not originate all in French. However, the chosen domains are so distinct that difference in topic distribution between EuroParl and OpenSubtitles will dominate discrepancies caused by other factors such as the actual origin of the data.

[2] In the controlled setting of §6.1 we found that tagging yields a small but consistent improvement by up to 1 BLEU point, and dataset weighting yields an improvement of up to 0.3 BLEU. ST and BT which are the focus of this study,

use label smoothing (Szegedy et al., 2016) and dropout (Srivastava et al., 2014) to improve generalization, as we focus on low resource language pairs where models tend to severely overfit. Finally, we explore ways to leverage both target and source side monolingual data via back-translation and self-training which we review next.

We simplify our notation and denote with $x^s = \mathrm{src}(z^s)$ and $y^t = \mathrm{tgt}(z^t)$ the source and target originating sentences, $y^s = h_{s\to t}(x^s)$ and $x^t = h_{t\to s}(y^t)$ the corresponding human translations, and $\hat{y}^s$ and $\hat{x}^t$ the corresponding machine translations. The superscript always specifies the domain. We assume access to a parallel dataset $\mathcal{P} = \{(x^s, y^s)\} \cup \{(x^t, y^t)\}$, a source side monolingual dataset $\mathcal{M}^s = \{x^s\}$ and a target side monolingual dataset $\mathcal{M}^t = \{y^t\}$. The test side consists of sentences from the source domain. We study STDM by training with the following algorithms:

Back-translation (BT) (Sennrich et al., 2015) is a very effective data augmentation technique that leverages $\mathcal{M}^t$. The algorithm proceeds in three steps. First, a reverse MT system is trained from target to source using the provided parallel data: $\overleftarrow{\theta} = \arg\max_\theta \mathbb{E}_{(x,y)\sim\mathcal{P}} \log p(x|y;\theta)$. Then, the reverse model is used to translate the target monolingual data: $\hat{x}^t \approx \arg\max_z p(z|y^t; \overleftarrow{\theta})$, for $y^t \sim \mathcal{M}^t$. The maximization is typically approximated by beam search. Finally, the forward model is trained over the concatenation of the original parallel and back-translated data: $\overrightarrow{\theta} = \arg\max_\theta \mathbb{E}_{(x,y)\sim\mathcal{Q}} \log p(y|x;\theta)$ with $\mathcal{Q} = \mathcal{P} \cup \{\hat{x}^t, y^t\}_{y^t\sim\mathcal{M}^t}$. In practice, the parallel data is weighted more in the loss, with a weight selected via hyper-parameter search on the validation set.

Self-Training (ST) (He et al., 2020) is another method for data augmentation that instead leverages $\mathcal{M}^s$; see Alg. 1 in Appendix D.

Also this algorithm proceeds in three steps. First, a forward MT system is trained from source to target using the provided parallel data: $\overrightarrow{\theta} = \arg\max_\theta \mathbb{E}_{(x,y)\sim\mathcal{P}} \log p(y|x;\theta)$. Then, this model is used to translate the source monolingual data: $\hat{y}^s \approx \arg\max_z p(z|x^s; \overrightarrow{\theta})$, for $x^s \sim \mathcal{M}^s$. Finally, the forward model is retrained over the concatenation of the original parallel and forward-translated data: $\overrightarrow{\theta} = \arg\max_\theta \mathbb{E}_{(x,y)\sim\mathcal{Q}} \log p(y|x;\theta)$ with $\mathcal{Q} = \mathcal{P} \cup \{x^s, \hat{y}^s\}_{y^t\sim\mathcal{M}^s}$. As with BT, the parallel data is weighted more in the loss.

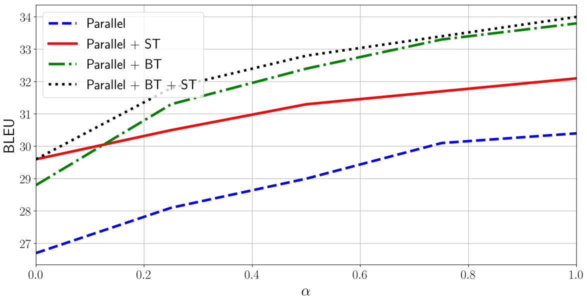

Figure 3: BLEU score in Fr-En as a function of the amount of STDM. The target domain is fully out-of-domain when $\alpha = 0$, and fully in-domain when $\alpha = 1$.

ST + BT also proceeds in three steps. First, we train an initial forward and reverse model using the parallel dataset. Second, we back-translate target side monolingual data using the reverse model and iteratively forward translate source side monolingual data using the forward model. We then retrain the forward model from random initialization using the union of the original parallel dataset, the synthetic back-translated data, and the synthetic forward translated data at the last iteration of the ST algorithm. This combined algorithm aims at leveraging the strengths of both ST and BT: the use of in-domain source monolingual data and the use of synthetic data with correct targets, respectively.

6 Machine Translation Results

In this section, we first study the effect of STDM on NMT using the controlled setting introduced in §4.1 which enables us to assess the influence of various factors, such as the extent to which target originating data is out-of-domain, and the effect of monolingual data size. We then report experiments on genuine low resource language pairs, namely Nepali-English and English-Myanmar. We report SacreBLEU (Post, 2018).

6.1 Controlled Setting

In the default setting, we have a parallel dataset with 20,000 parallel sentences. 10,000 are in-domain source originating data (EuroParl) and the remaining 10,000 are target originating data from a mix of domains, controlled by $\alpha \in [0, 1]$: α EuroParl + $(1-\alpha)$ OpenSubtitles. The source side monolingual dataset has 100,000 French sentences from EuroParl. The target side monolingual dataset has 100,000 English sentences from: α EuroParl + $(1-\alpha)$ OpenSubtitles. Finally, the test set consists of novel French sentences from EuroParl which we wish to translate to English.

---

improve by more than 2 BLEU points instead.

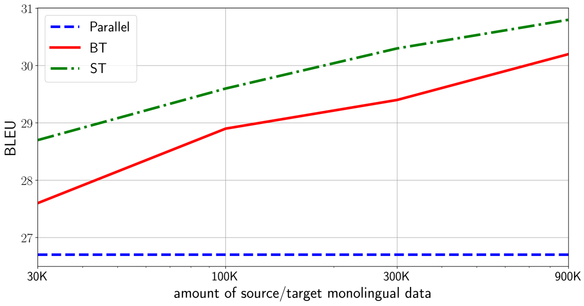

Figure 4: BLEU as a function of the amount of monolingual data when $\alpha = 0$.

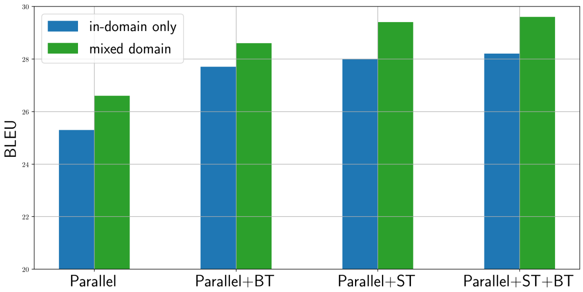

Figure 5: BLEU when using only source originating in-domain data (blue bars) or also out-of-domain target originating data (green bars) for $\alpha = 0$.

We tune model hyper-parameters (e.g., number of layers and hidden state size) and BPE size on the validation set. Based on cross-validation, when training on datasets with less than 300k parallel sentences (including those from ST or BT), we use a 5-layer transformer with 8M parameters. The number of attention heads, embedding dimension and inner-layer dimension are 2, 256, 512, respectively. When training on bigger datasets, we use a bigger transformer with 5 layers, 8 attention heads, 1024 embedding dimension, 2048 inner-layer dimension and a total of 110M parameters. We find that using bigger model can better utilize the monolingual data, but we do not find the bigger model benefits when training with less than 300k parallel sentences. The full list of hyper-parameters can be found in Appendix E.

Varying amount of STDM. In Fig. 3, we benchmark our baseline approaches while varying α (see §4.1 and Tab. 1), which controls the overlap between source and target domain.

First, we observe improved BLEU (Papineni et al., 2002) scores for all methods as we increase α. Second, there is a big gap between the baseline trained on parallel data only and methods which leverage monolingual data. Third, combining ST and BT works better than each individual method, confirming that these approaches are complementary. Finally, BT works better than ST but the gap reduces as the target domain becomes increasingly different from the source domain (small values of α). In the extreme case of STDM ($\alpha = 0$), ST outperforms BT. In fact, we observe that the gain of BT over the baseline decreases as α decreases, despite that the amount of monolingual data and parallel data remains constant across these experiments, thus showing that *BT is less effective in the presence of STDM*.

Varying amount of monolingual data. We next explore how the quantity of monolingual data affects performance and if the relative gain of ST over BT when $\alpha = 0$ disappears as we provide BT with more monolingual data. The experiment in Fig. 4 shows that a) the gain in BLEU tapers off exponentially with the amount of data (notice the log-scale in the x-axis), b) for the same amount of monolingual data ST is always better than BT and by roughly the same amount, and c) BT would require about 3 times more target monolingual data (which is out-of-domain) to yield the performance of ST. Therefore, *increasing the amount of data can compensate for domain mismatch*.

Varying amount of in-domain data. Now we explore whether, in the presence of extreme STDM ($\alpha = 0$), it may be worth restricting the training data to only contain in-domain source originating sentences. In this case, the parallel set is reduced to 10,000 EuroParl sentences, the target side monolingual data is removed and back-translation is performed on the target side of the parallel dataset. Fig. 5 demonstrates that in all cases it is better to include the out-of-domain data originating on the target side (green bars). Particularly in the low resource settings considered here, *neural models benefit from all available examples even if these are out-of-domain*.

Finally, we investigate how to construct a parallel dataset when STDM is significant ($\alpha = 0$), i.e. the target domain is OpenSubtitles. If we have a translation budget of 20,000 sentences, is it best to translate 20,000 sentences from EuroParl or to also include sentences from OpenSubtitles? This is not obvious when training with BT, since the backward model may benefit from in-domain OpenSubtitles data. In order to answer this question, we consider a *parallel* dataset with 20,000 sentences defined as: β EuroParl + $(1-\beta)$ OpenSubtitles, with $\beta \in [0, 1]$.

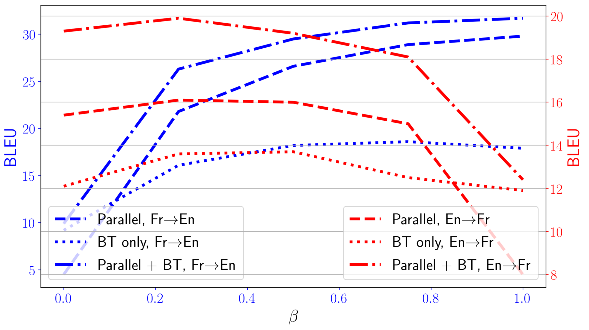

Figure 6: BLEU score as a function of the proportion of parallel data originating in the source and target domain domain. When $\beta = 0$ all parallel data originates from OpenSubtitles, when $\beta = 1$ all parallel data originates from EuroParl. Source and target monolingual corpora have 900,000 sentences from EuroParl and OpenSubtitles, respectively. The blue curves show BLEU in the forward direction (Fr-En translation of EuroParl data). The red curves show BLEU in the reverse direction (En-Fr translation of OpenSubtitles sentences).

When $\beta = 0$, the parallel dataset is out-of-domain; when $\beta = 1$ the parallel data is all in-domain. The target side monolingual dataset is fixed and contains 900,000 sentences from OpenSubtitles.

Fig. 6 shows that taking *all* sentences from EuroParl ($\beta = 1$) is optimal when translating from French (EuroParl) to English (blue curves). At high values of β, we observe a slight decrease in accuracy for models trained only on back-translated data (dotted line), confirming that BT loses its effectiveness when the reverse model is trained on out-of-domain data. However, this is compensated by the gains brought by the additional in-domain parallel sentences (dashed line). In the more natural setting in which the model is trained on both parallel and back-translated data (dash-dotted line), we see monotonic improvement in accuracy with β. A similar trend is observed in the other direction (English to French, red lines). Therefore, if the goal is to maximize translation accuracy in *both* directions, an intermediate value of β (≈ 0.5) is more desirable.

6.2 Low-Resource MT

We now measure STDM on two low-resource language pairs and verify whether in practice BT's performance deteriorates as expected when the STDM score is low, while the combination of ST+BT offers better generalization. We consider two low-resource language pairs, Nepali-English (Ne-En) and English-Myanmar (En-My). Nepali and Myanmar are spoken in regions with unique local context that is very distinct from English-speaking regions, and thus these make good language pairs for studying the STDM setting in real life.

Model	Ne → En	En → My
	STDM score=0.64	STDM score=0.27
baseline	20.4	28.1
BT	22.3	30.0
ST	22.1	31.9
ST + BT	22.9	32.4

Table 3: BLEU scores for the Nepali to English and English to Myanmar translation task.

Data. The Ne-En parallel dataset is composed of 40,000 sentences originating in Nepali and only 7,500 sentences originating in English. There are 5,000 sentences in the validation and test sets all originating in Nepali. We also have 1.8M monolingual sentences in Nepali and English, collected from public posts from a social media platform. This dataset closely resembles our idealized setting of Fig. 1. The STDM score of this dataset is 0.64 (see Tab. 2) and is analogous to our synthetic setting (§6.1) where α is low but β is large.

The En-My parallel data is taken from the Asian Language Treebank (ALT) corpus (Thu et al., 2016; Ding et al., 2018, 2019) with 18,088 training sentences all originating from English news. The validation and test sets have 1,000 sentences each, all originating from English. Following Chen et al. (2019), we use 5M English sentences from NewsCrawl as source side monolingual data and 100K Myanmar sentences from Common Crawl as target side monolingual data. The STDM Score is even lower on this dataset, only 0.27. Comparing to our controlled setting this dataset would have β equal to 1 and presumably a small value of α, an ideal setting for ST.

Models. We run model hyper-parameter sweep on the validation set and pick the best-performing model architecture (e.g., number of layers and hidden layer sizes). On both datasets, the parallel data baseline is a 5-layer transformer with 8 attention heads, 512 embedding dimensions and 2048 inner-layer dimensions, which consists of 42M parameters. When training with BT and ST, we use a 6-layer transformer with 8 attention heads, 1024 embedding dimensions, 2048 inner-layer dimensions, resulting in 186M parameters. The detailed hyper-parameters search range can be found in Appendix §E.

Results. In Table 3, we observe that on the Ne-En task augmenting the parallel dataset with either forward- or back-translated monolingual data achieves almost 2 BLEU points improvement over the supervised baseline. On the En-My task where STDM is more severe (with a value of 0.27 which is similar to $\alpha = 0$ in Tab. 1), BT outperforms the baseline by 1.9 BLEU, while ST improves by twice as much. This is perhaps not surprising since source side monolingual data is in-domain and abundant, while target side monolingual data is scarce and out-of-domain. On both tasks, combining ST and BT outperforms each individual method.

7 Conclusions

While the commonly used WMT datasets exhibit mild STDM, we find that less curated datasets, often in more distant and lower resource language pairs (§4.2), exhibit much stronger STDM. How can these findings inform us on how to better set up a MT system in practice? Our first recommendation is to be aware of possible STDM, and *(i)* check whether origin language information is available. If this is available, then it may be possible to *(ii)* quantitatively measure STDM as described in §4. Next, *(iii)* be aware that when STDM is severe (STDM score is low), BT performance suffers (Fig. 3). However, *(iv)* we may be able to combat this by increasing the amount of target side (out-of-domain) monolingual data (Fig. 4) and *(v)* by combining BT with ST (Fig. 3).

Of course, the relative ratio of monolingual data in the source and target side and the actual degradation brought by STDM depend on the particular language pair. The more distant two languages, the more difficult the learning task and the more data is needed to learn it. And finally, the less parallel data there is, the more monolingual data will be needed to compensate. The intricate dependency between all these factors merits future investigation.

A Topic Classifiers

In this section we provide the experimental details of the findings reported in §3.1.

Dataset We use the WIKISHORT dataset provided by Yuan et al. (2018) [3]. The dataset contains thousands of English and Chinese wikipedia articles, and each article is labeled with one of the six categories, film, music, animals, politics, religion, and food. We use the train split in the dataset for training, validate with test split. The train split includes 7730 and 7095 English and Chinese articles respectively. To make the classifier better differentiate articles that is not one of the six categories, we uniformly sample 1500 wikipedia articles from both English and Chinese wikidump [4] and add them into the training data with 'other' label.

Preprocessing WIKISHORT provides shortened text of Wikipedia articles. To generate the shortened text of articles with 'other' label, we use the text from the first paragraph of the articles and follow similar preprocessing as in Yuan et al. (2018). For English articles, we lowercase the paragraph, tokenize by word, filter out stop words, lemmatize the words and remove all the punctuations. For Chinese articles, we apply Stanford CoreNLP Tokenizer [5] to segment the Chinese text.

Training We train two multi-nomial logistic regression models, one for English and one for Chinese. To extract features from the shortened text, we compute tf-idf weights from the training data. We use the LogisticRegression implementation of SCIKIT-LEARN (Pedregosa et al., 2011) with default setting to train the models. We tune the regularization term C on validation set. However, we do not observe significant accuracy difference between different C values, therefore we use default setting $C = 1.0$. The accuracy on the test set of the English and Chinese classifiers are 92.5% and 77.9%, respectively.

Prediction on Wikipedia articles To estimate the category distribution of English and Chinese Wikipedia articles, we uniformly sampled 8500 articles from wikidump for each language, follow the same preprocessing and feature extraction as how we does for the training data, and we use the classifiers to predict the category of each article. After removing articles labeled "other", we re-normalize the distribution of the prediction of the main six categories and report the values in 2.

B Computing STDM score

In this section we provide the experimental details of the STDM evaluations performed in §4.1 and §4.2.

Dataset In §4.1, we have described the details for constructing datasets from EuroParl and OpenSubtitles with different amount of STDM.

For the experiments in §4.2, we evaluate the STDM score on datasets with known language origins. We use three different data sources, including WMT newstest sets, MTNT (Michel and Neubig, 2018) and a social media platform (SMD). For the WMT newstest sets, we combine datasets from year 2014 to 2019 and sample 5000 sentences for each language. For the analysis on MTNT dataset, we use the train split in the dataset and sample 5000 sentences for each language. For SMD, 20000 sentences are sampled for each language.

Preprocessing We use SentencePiece (Kudo and Richardson, 2018) to learn a BPE vocabulary of size 10000 over the combined English text corpus of all datasets. We preprocess sentences from all datasets with BPE and remove sentences with less than 10 BPE tokens.

Topic Learning and STDM Score Computing For each dataset, we derive the TF-IDF matrix from the preprocessed sentences and perform an SVD decomposition of the matrix. We retain the top 400 eigenvalues and collect the corresponding topic representations of the original sentences. The topic representations of the sentences are used to calculate the STDM score as described in §4.

C The Effect of Translationese

In §3 we have made the assumption that the effect of translationese is negligible when estimating STDM. However, there are previous studies showing clear artifacts in (human) translations (Baker, 1993; Zhang and Toral, 2019; Toury, 2012). In this section we aim at assessing whether our STDM score is affected by translationese.

We consider the WMT'17 De-En dataset from Ott et al. (2018) which contains double translations of source and target originating sentences.

---

[3] https://github.com/forest-snow/mtanchor_demo#data

[4] https://dumps.wikimedia.org/

[5] https://stanfordnlp.github.io/stanza/tokenize.html

From this, we construct paired inputs and labels, $\{(h_{s\to t}(h_{t\to s}(\text{tgt}(z^t))), 1)\} \cup \{(\text{tgt}(z^t), 0)\}$, and train two classifiers to predict whether or not the input is translationese. The first classifier takes as input a TF-IDF representation w of the sentence, while the second classifier takes only the corresponding topic distribution: $\bar{V}w$. On this binary task a linear classifier achieves 58% accuracy on the test set with TF-IDF input representations, and only 52% when given just the topic distribution. If we apply the same binary classifier in the topic space to discriminate between sentences originating in the source and target domain ($\text{tgt}(z^t)$ VS. $h_{s\to t}(\text{src}(z^s))$), the accuracy increases to 64%.

We conclude that once we control for domain effect (by discriminating the same set of sentences in their original form versus their double translationese form), the accuracy is much lower than previously reported (Zhang and Toral, 2019), and working in the topic space further removes translationese artifacts. Therefore, the STDM score computed in the topic space is unlikely affected by such artifacts and captures the desired discrepancy between the source and the target domains.

D Self-Training

```
1 Data: Given a parallel dataset $\mathcal{P}$ and a source
      monolingual dataset $\mathcal{M}^s$ with $N^s$ examples;
2 Noise: Let $n(x)$ be a function that adds noise to the
      input by dropping, swapping and blanking words;
3 Hyper-params: Let $k$ be the number of iterations
      and $A_1 < \cdots < A_k \leq N_S$ be the number of
      samples to add at each iteration;
4 Train a forward model:
      $\overrightarrow{\theta} = \arg\max_\theta \mathbb{E}_{(x,y)\sim\mathcal{P}} \log p(y|x;\theta)$;
5 for $t$ in $[1 \dots k]$ do
6     forward-translate data:
          $(\hat{y}^s, v) \approx \arg\max_z p(z|x^s; \overrightarrow{\theta})$, for $x^s \in \mathcal{M}^s$,
          where $v$ is the model score;
7     Let $\bar{\mathcal{M}}^s \subset \mathcal{M}^s$ containing the top-$A_t$ highest
          scoring examples according to $v$;
8     re-train forward model:
          $\overrightarrow{\theta} = \arg\max_\theta \mathbb{E}_{(x,y)\sim\mathcal{Q}} \log p(y|x;\theta)$ with
          $\mathcal{Q} = \mathcal{P} \cup \{n(x^s), \hat{y}^s\}_{x^s\sim\bar{\mathcal{M}}^s}$.
  end
```

Algorithm 1: Self-Training algorithm.

Alg. 1 describes self-training, a data augmentation method that leverages $\mathcal{M}^s$, using the notation of §5. First, a baseline forward model is trained on the parallel data (line 4). Second, this initial model is applied to the source monolingual data (line 6). Finally, the forward model is re-trained from random initialization by augmenting the original parallel dataset with the forward-translated data. As with BT, the parallel dataset receives more weight in the loss. In order to increase robustness to prediction mistakes, we make the algorithm iterative and add only the examples for which the model was most confident (line 3, loop in line 5 and line 7). In our experiments we iterate three times. We also inject noise to the input sentences, in the form of word swap and drop (Lample et al., 2018), to further improve generalization (line 8).

E Hyper-parameters Used in MT Experiments

In this section, we report the hyper-parameters used in Sec. 6.

In all our experiments we use the standard machine learning methodology of model cross-validation to select hyper-parameters. We train models with several random combination of hyper-parameters and select the best configuration based on the performance on the validation set. We finally report results on the test set.

Data The full list of datasets we have considered in this work with some basic statistics is reported in Tab. 4

We jointly learn BPEs on both source and target languages. First, we train an MT system on the parallel data for each BPE setting, with values in the set {3000, 5000, 10000, 20000}. Then, we select the number of BPE tokens by selecting the setting that yields the best performance on the validation set. We report below the value that worked best in each experiment.

Loss and Optimizer All models are trained using cross-entropy loss with label smoothing (Szegedy et al., 2016) equal to 0.2. The optimizer is Adam (Kingma and Ba, 2015) with beta1 = 0.9, beta2 = 0.98 and warm-up steps 4000. We share embeddings across encoder and decoder, and input and output lookup tables. We use fixed batch size with 4000 tokens per GPU, and we train with 4 GPUs in fp16. Other optimization hyper-parameters are reported below.

Model Architecture and Training To decide the model architecture hyper-parameters for different amount of parallel and monolingual data, we use random search to find the setting that yields the best performance on validation set. The range of values that we used in our random hyper-parameter search are:

MT Experiments	Language Pair	BPE size	Origin	Parallel data		Monolingual data	
				Domain	# sents (train/valid/test)	Domain	# sents
Controlled Setting	Fr->En	5000	source	Europarl	10K / 10K / 10K	Europarl	900K
			target	OpenSubtitle	10K / 10K / 10K	OpenSubtitle	900K
Low-Resource MT	Ne->En	5000	source	Social Media	40K / 5K / 5K	Social Media	1.8M
			target	Social Media	7.5K / 5K / 5K	Social Media	1.8M
	En-My	10000	source	ALT(News)	18K / 1K / 1K	NewsCrawl	5M
			target	-	-	CommonCrawl	100K

Table 4: Datasets used for the machine translation experiments of Sec. 6

- Layers: {4, 5, 6}
- Embedding dimension: {256, 512, 1024}
- Inner-layer dimension: {512, 1024, 2048, 4096}
- Attention Heads: {2, 4, 8, 16}

We report the model architecture of each experiment in §E.1.

For each data point which corresponds to a particular combination of $(\mathcal{P}, \mathcal{M}^s, \mathcal{S}^t, \alpha, \beta, \text{training procedure})$, we use random search to sweep over hyper-parameters. The hyper-parameters are dropout rate, learning rate, source side noise level for ST experiments and upsample ratio between parallel data, back-translated data and self-translated data. For all experiments, the dropout rates are {0.1, 0.2, 0.3, 0.4, 0.5}, and the learning rate takes values in {0.0007, 0.001, 0.003, 0.005}.

E.1 Hyper-parameter for Controlled Setting Experiments

We use the same BPEs for all the experiments in the controlled setting of §6.1. The BPE size is 5000 and it is shared between English and French.

Varying amount of STDM. We use embedding dimension 256, inner-layer dimension 512, 2 attention heads. We sweep the upsampling ratio of parallel data, back-translated data and self-training data in a range between 1 and 8.

We train the ST system with 2 iterations ($k = 2$), where $A_1 = 30K$ and $A_2 = 100K$. In each iteration, we use random search to sweep over different source side noise, and we report the model with the best performance based on validation set. The values of input noise are as follows: Word shuffling {0, 2, 3}, word dropout {0.0, 0.1, 0.2}, word blank {0.0, 0.1, 0.2}.

Varying amount of monolingual data. When the monolingual data has less than 300k sentences, we use embedding dimension 256, inner-layer dimension 512 and 2 attention heads. For bigger monolingual datasets, we use embedding dimension 1024, inner-layer dimension 2048 and 8 attention heads. We sweep the upsampling ratio of parallel data, back-translated data and self-training data in a range between 1 and 8.

We train the ST system with 5 iterations ($k = 5$), where $A_1 = 10K$, $A_2 = 30K$, $A_3 = 100K$, $A_4 = 300K$ and $A_5 = 900K$. The values of input noise are as follows: Word shuffling {0, 2, 3}, word dropout {0.0, 0.1, 0.2}, word blank {0.0, 0.1, 0.2}.

Varying amount of in-domain data. When training only with parallel data, we use embedding dimension 256, inner-layer dimension 512, and 2 attention heads. For models trained with BT-only and parallel + BT instead, we use embedding dimension 1024, inner-layer dimension 2048 and 8 attention heads. We sweep the parallel data upsampling ratio in a range between 1 and 16.

E.2 Hyper-parameter for Low-Resource MT Experiments

We use a joint BPE tokenization with 5000 tokens for En $\rightarrow$ Ne and 10000 tokens for En $\rightarrow$ My.

On both datasets (Ne $\rightarrow$ En and En $\rightarrow$ My), the baseline trained only on the parallel dataset is a 5-layer transformer model with 512 embedding dimensions, 2048 inner-layer dimensions and 8 attention heads. For models trained with BT and ST, we use a 6-layer transformer with 1024 embedding dimensions, 2048 inner-layer dimensions and 8 attention heads. We sweep the parallel data and ST data ratio between 1 and 32.

For both language pairs, we train the ST systems with 3 iterations ($k = 3$). For Ne $\rightarrow$ En, we use A_1 = 600K, A_2 = 1M, A_3 = 1.8M. For En $\rightarrow$ My, we use A_1 = 1M, A_2 = 3M and A_3 = 5M. The values of input noise are as follows: Word shuffling {0, 2, 3}, word dropout {0.0, 0.1, 0.2}, word blank {0.0, 0.1, 0.2}.

Cross-Topic Rumor Detection using Topic-Mixtures

Abstract

There has been much interest in rumor detection using deep learning models in recent years. A well-known limitation of deep learning models is that they tend to learn superficial patterns, which restricts their generalization ability. We find that this is also true for cross-topic rumor detection. In this paper, we propose a method inspired by the "mixture of experts" paradigm. We assume that the prediction of the rumor class label given an instance is dependent on the topic distribution of the instance. After deriving a vector representation for each topic, given an instance, we derive a "topic mixture" vector for the instance based on its topic distribution. This topic mixture is combined with the vector representation of the instance itself to make rumor predictions. Our experiments show that our proposed method can outperform two baseline debiasing methods in a cross-topic setting. In a synthetic setting when we removed topic-specific words, our method also works better than the baselines, showing that our method does not rely on superficial features.

1 Introduction

Recently, there has been much interest in detecting online false information such as rumors and fake news. Existing work has explored different features including network structures (Ma et al., 2019a), propagation paths (Liu and Wu, 2018), user credibility (Castillo et al., 2011) and the fusion of heterogeneous data such as image and text (Wang et al., 2018). However, these proposed algorithms still cannot be easily deployed for real-world applications, and one of the key reasons is that, just like many other NLP problems, rumor or fake news detection models may easily overfit the training data and thus cannot perform well on new data. The problem can be more serious with deep learning solutions, because deep neural networks tend to learn superficial patterns that are specific to the training data but do not always generalize well (Wang et al., 2018).

In this work, we study the task of rumor detection and focus on the problem of adapting a rumor detection model trained on a set of *source* topics to a *target* topic, which we refer to as *cross-topic rumor detection*. In a recent study by Khoo et al. (2020), the authors compared the performance of rumor detection in an in-topic setting and an out-of-topic setting. They found that their model could achieve 77.4% macro F-score on the in-topic testing data but the performance of the same classifier dropped to 39.5% when applied to out-of-topic testing data, which describe events different from the training events.

In this paper, we propose a method inspired by the "mixture of experts" paradigm, abbreviated as "MOE". Understanding that the rumor prediction model may work differently for different topics, we assume that the prediction result on an instance is dependent on the topic distribution of that instance. While a standard method is to train topic-specific classifiers and then use the topic distribution to combine these topic-specific classifiers, we propose a different approach where the topic distribution is used to linearly combine a set of vectors representing different topics. This gives us a "topic-mixture" given an example. This topic-mixture vector of the example is concatenated with the vector representation of the example itself and used as the input to a neural network model for rumor label prediction.

We implement our method on top of a state-of-the-art StA-HiTPLAN model and conduct experiments using the PHEME dataset. Compared with two baseline methods that also perform debiasing, we find that our method can achieve clearly better cross-topic performance. We also experiment with

modified within-topic data where we intentionally remove topic-specific words. This creates a setting where it is hard for models to rely on topic-specific words to make rumor predictions. We find that our method can also outperform the baselines substantially.

2 Performance Degradation in Cross-Topic Rumur Detection

In this section, we present a case study on the PHEME dataset to quantify the degree of overfitting of an existing model by analyzing the influence of topic-specific words.

Concretely, we use the PHEME dataset, which has five topics. We use four topics during training and the remaining one for out-of-domain testing. After obtaining a trained hierarchical transformer model (Vaswani et al., 2017), we perform post-hoc testing by applying it to different topics, with K topic-specific words masked to examine the performance drop. Here the topic-specific words are identified based on log-odds ratio with Dirichlet prior (Monroe et al., 2008), and we regard these topic-specific words as possible spurious patterns. It is a common way to identify words that are statistically over-represented in a particular population compared to others. For the in-domain testing, we split the data as 7:2:1 for training, testing and validation. Experiments are performed using $K \in \{20, 50, 100, 200\}$.

Results: The partial results are shown in Table 1. It is noteworthy that the accuracy drops from 67.69% to 36.7% when we only mask the top-20 frequent event-aware words in in-domain set - the model is highly sensitive to event sensitive patterns. Besides, the little dropping in accuracy with the out-of-domain setting when we mask top-20 out-of-domain words may indicate that we mask some training unseen words compared with non-mask setting. These experiments confirm our hypothesis that the baseline classifier is primarily learning topical correlations, and motivate the need for a debiased classification approach which we will describe next.

3 Method

3.1 Notation

Let x be an input, which is a thread represented as a sequence of tokens. We assume that x consists of a sequence of posts $x = x_1, x_2, \ldots, x_T$ chronologically ordered, in which x_1 represents a source post and x_i $(i > 1)$ represents a reply post. Let y be the rumor label (e.g., true rumor, false rumor, etc.) we want to predict. We assume that the training data come from a set of M different topics, and we use $\{\mathcal{S}_i\}_{i=1}^{M}$ to denote the data, where $\mathcal{S}_i \triangleq \{(x_n^i, y_n^i)\}_{n=1}^{|\mathcal{S}_i|}$. Our goal is to train a rumor detection classifier using the labeled data from the M topics such that the classifier can work well on a target example.

tA-HiTPLAN	**in-domain**	**out-of-domain**
`{non-mask}`	0.6769	0.3441
`{+MASK TOP 20}`	0.3670	0.3425
`{+MASK TOP 50}`	0.3526	0.3255
`{+MASK TOP 100}`	0.3413	0.3122
`{+MASK TOP 200}`	0.3202	0.2903

Table 1: Accuracy on PHEME event-5 datset.

3.2 Mixture Of Experts

Our idea is inspired by Mixture of Experts models (Jacobs et al., 1991). Specifically, we assume that each example $\mathbf{x}$ has a distribution over the M training topics. Let t be a variable denoting topic. We model $p(y|x)$ as follows:

$$p(y|x) \quad = \quad \sum_{i=1}^{M} p(t=i|x) p(y|x, t=i). \quad (1)$$

Normally, to model $p(t|x)$ and $p(y|x,t)$, we can train parameterized models $p(t|x;\theta_1)$ and $p(y|x,t;\theta_2)$ using our training data, because our examples have clear topic labels. However, if the number of topics is large, or the number of training instances for each topic is small, training such topic-specific models may not work well. Moreover, if we train independent models for each training topic and combine their out-of-domain testing result as a whole, the result may be unsatisfactory because each model may be overfitting a specific topic. Our initial experimental observation also verifies that independent training method works well on in-topic setting but does not perform well on out-of-topic setting. Here we explore an alternative approach as described below.

We assume that x and t are both represented as vectors (which we will explain later). We can then use the following neural network model to model $p(y|x,t)$:

$$\begin{aligned} p(y|x,t) &= p(y|\mathbf{x} \oplus \mathbf{t}; \theta) \\ &= \frac{\exp(\theta_y \cdot (\mathbf{x} \oplus \mathbf{t}))}{\sum_{y'} \exp(\theta_{y'} \cdot (\mathbf{x} \oplus \mathbf{t}))}, \end{aligned}$$

where θ_y are vectors to be learned and $\oplus$ means vector concatenation.

Now we can make an approximation of Eqn. (1) as follows:

$$\begin{aligned} p(y|x) &= \sum_{i=1}^{M} p(y|x,t)p(t|x) \\ &= p(y|\mathbf{x} \oplus \sum_{i=1}^{M} p(t=i|x)\mathbf{t}_i;\theta), \quad (2) \end{aligned}$$

where $\mathbf{t}_i$ is a vector representation of topic i. We can see that instead of computing $p(y|x, t = i)$ for each i, and then use $p(t = i|x)$ to obtain a weighted sum of these $p(y|x, t = i)$, we first get a sum of the vector representations of different topics weighted by $p(t|x)$, and then use this weighted sum to compute $p(y|x)$.

To obtain a vector representation of x, we can use BERT to process the sequence of tokens in x and then use the vector representing the `[CLS]` token at the top layer as $\mathbf{x}$. For each topic t, since we have instances of x belonging to each topic, here we explore two ways of deriving $\mathbf{t}_i$ for topic i: (1) We use the average of the vectors $\mathbf{x}$ belonging to topic i to form $\mathbf{t}_i$. We refer to this as **Avg**. (2) We use the parameters at the top layer of the topic classification model $p(t|x)$ as vector representations for the different topics. We refer to this as **Param**. During test time, since our instance x does not have a t associated with it, we use a topic classification model trained on the training data where each example has its correct topic labeled to estimate $p(t|x)$.

4 Experiments

4.1 Implementation Details

We follow the model architecture StA-PLAN in (Khoo et al., 2020) as our backbone. StA-PLAN is a hierarchical transformer which contains 12 post-level multi-head attention layer (MHA) and 2 token-level MHA layers. As claimed in (Khoo et al., 2020) that BERT (Devlin et al., 2018) did not improve results and was time-consuming, we apply GLOVE-300d (Pennington et al., 2014) to embed each token in a post. The initial learning rate was set as 0.01 with 0.3 dropout and we used the ADAM optimizer with 6000 warm start-up steps. Batch size is set as 256 for all cross-validation tasks.

4.2 Dataset

We use the public PHEME dataset (Zubiaga et al., 2016) for our evaluation. PHEME was collected based on 9 breaking news stories and can be categorised into four classes: true rumor, false rumour, unverified rumour and non-rumour. Following the setting in (Kumar and Carley, 2019), we select five breaking events from PHEME and split them into two sets. Four events are chosen for training and in-domain testing, and the remaining one is used as out-of-domain testing set.

4.3 Baselines and Our Methods

We consider a state-of-the-art model and some baselines that are also addressing cross-domain issues.

StA-HiTPLAN: Replicating (Khoo et al., 2020), we train a hierarchical transformer model which is a state-of-the art model and can be viewed as a feature extractor in the following experiments.

Ensemble-based model (EM): Following (He et al., 2019; Clark et al., 2019), we take topical words as bias features and introduce an auxiliary bias_only model f_b taking bias priori features as input. Then using this bias_only model to train a robust model through an ensemble model. We firstly obtain the class distribution $p_b(y|x)$ using this biased model. Then we train an ensemble model that combines the former biased model with a robust model through this function: $p(\hat{y}|x) = T(p(y|x) + p_b(y|x))$. In the testing stage, only the robust model $p(y|x)$ is used for prediction.

Adversary-based model (AM): This is a common way to learn domain-invariant features. We implement a recent work (Wang et al., 2018; Ma et al., 2019b) and replace their Bi-LSTM with (Khoo et al., 2020) as backbones for fair comparison. The parameter of the gradient reversal layer is set as 1.

MOE-Avg and **MOE-Param:** These are our proposed models, where MOE-Avg and MOE-Param are according to our descriptions given in Section 3.2.

4.4 Cross-Topic and In-Topic Settings

We use two settings to evaluate the effectiveness of our method for cross-topic rumor detection. The first setting is the standard setting where we train on a set of source topics and test the performance of the model on a different target topic. For PHEME dataset, we use 4 topics as training topics and the remaining topic as the test topic. We repeat this 5

Method	Orig.		Mask-20		Mask-50		Mask-100	
	Accuracy	Macro F	Accuracy	Macro F	Accuracy	Macro F	Accuracy	Macro F
StA-HiTPLAN	67.69	62.69	36.70	34.12	35.26	30.86	34.13	29.78
EM	72.31	72.77	38.46	32.28	37.65	31.92	37.58	31.62
AM	66.81	60.65	47.47	38.54	43.35	34.99	42.15	33.93
MOE-Avg	76.48	73.72	50.01	39.56	47.42	37.11	44.54	33.02
MOE-Param	76.54	73.85	50.23	39.74	47.51	37.46	44.82	33.17

Table 2: Average accuracy and macro-F scores (%) of the in-topic setting on PHEME. Orig. refers to the original data. Mask-k refers to the setting where we artificially mask k topic-specific words.

times with different split of training/test topics, and report the average performance. We refer to this as the "cross-topic" setting. We also experiment with a second in-topic setting, where we train and test on the same topic, but we artificially remove topic-specific words. We refer to this as our "in-topic" setting. In Table 2, these are labeled as Mask-20, Mask-30 and Mask-50, depending on how many topic-specific words we mask (i.e., remove).

4.5 Results and Analysis

We present our experiments on the PHEME dataset in Table 2 and Table 3. Several observations can be made from the experiment results:

1) From Table 3, we can see that MOE-Avg and MOE-Param are both effective strategies that mitigate the topic overfitting problem. The accuracy improves from 34.41% to 41.24% and 41.33%, respectively, when we only intervene feature without modify the backbone network. 2) Adversarial training model AM works better than ensemble methods EM in the early stage but deteriorates after we mask more than 50 event sensitive words. One reason is ensemble-based model depends on the bias only model : the model is sensitive to the choice of bias, and seems more robust when we mask more irrelevant words. 3) Instead of unstable adversarial training method, we show that MOE-Avg and MOE-Param can make the model robust to topic bias and increase generalization ability. 4) Instead of using the average of the vector representation of x for those x belonging to the same topic, we also aggregate the final layer parameters of topic classifier. MOE-Param works slightly better than MOE-Avg method. More attention can be given to how to better represent a topic embedding in future work.

Method	NON-MASK	
	Accuracy	Macro F
StA-HiTPLAN	34.41	32.69
EM	39.96	34.79
AM	38.03	34.32
MOE-Avg	41.24	36.84
MOE-Param	41.33	36.95

Table 3: Average accuracy and macro-F score (%) on PHEME data for the cross-topic setting.

5 Conclusion and Future work

In this work, we propose a new cross-topic rumor detection task base on mixture of experts, which can reinforce the generalization capacity of a model when adapting to new topics. we suggest that: 1) instead of training an unstable adversarial component or removing bias directly from semantic contents, the mixture of experts provides us with another way to increase generalization ability. 2) in this work, we use feature concatenation and train one classifier rather than several expert classifiers, and utilize a fixed confidence score. In the future, we can learn adaptive weights to make the model more flexible. For example, we could use variational inference methods to dynamically learn the best mixture of topics for a given held-out topic.

Understanding Pre-Editing for Black-Box Neural Machine Translation

Rei Miyata[†] **Atsushi Fujita**[‡]
[†]Nagoya University, Nagoya, Japan
[‡]National Institute of Information and Communications Technology, Kyoto, Japan
`miyata@nuee.nagoya-u.ac.jp`, `atsushi.fujita@nict.go.jp`

Abstract

Pre-editing is the process of modifying the source text (ST) so that it can be translated by machine translation (MT) in a better quality. Despite the unpredictability of black-box neural MT (NMT), pre-editing has been deployed in various practical MT use cases. Although many studies have demonstrated the effectiveness of pre-editing methods for particular settings, thus far, a deep understanding of what pre-editing is and how it works for black-box NMT is lacking. To elicit such understanding, we extensively investigated human pre-editing practices. We first implemented a protocol to incrementally record the minimum edits for each ST and collected 6,652 instances of pre-editing across three translation directions, two MT systems, and four text domains. We then analysed the instances from three perspectives: the characteristics of the pre-edited ST, the diversity of pre-editing operations, and the impact of the pre-editing operations on NMT outputs. Our findings include the following: (1) enhancing the explicitness of the meaning of an ST and its syntactic structure is more important for obtaining better translations than making the ST shorter and simpler, and (2) although the impact of pre-editing on NMT is generally unpredictable, there are some tendencies of changes in the NMT outputs depending on the editing operation types.

1 Introduction

Recent advances in machine translation (MT) have greatly facilitated its practical use in various settings from business documentation to personal communication. In many practical cases, MT systems are used as black-box and one well-tested approach to make use of a black-box MT is pre-editing, i.e., modifying the source text (ST) to make it suitable for the intended MT system.

The effectiveness of pre-editing has so far been demonstrated in many studies (Pym, 1990; O'Brien and Roturier, 2007; Seretan et al., 2014). A study focusing on statistical MT (SMT) has also shown that more than 90% of an ST can be rewritten into a text that can be machine-translated with sufficient quality (Miyata and Fujita, 2017), exhibiting the potential of the pre-editing approach.

However, the feasibility and possibility of pre-editing for neural MT (NMT) has not been examined extensively. While efforts have recently been invested in the implementation of pre-editing strategies for black-box NMT settings, achieving improved MT quality (e.g., Hiraoka and Yamada, 2019; Mehta et al., 2020), the potential gains of pre-editing remain unexplored. Notably, the impact of pre-editing on black-box MT is unpredictable in nature. In particular, NMT models trained in an end-to-end manner can be sensitive to minor modifications of the ST (Cheng et al., 2019), which may affect the feasibility of pre-editing.

In short, while pre-editing has been implemented in practical MT use cases, what pre-editing is and how it works with black-box NMT systems remain open questions. To explore the possibility of pre-editing and its automation, in this study, we provide fine-grained analyses of human pre-editing practices and their impact on NMT. We systematically collected pre-editing instances in various conditions, i.e., translation directions, NMT systems, and text domains (§3). We then conducted in-depth analyses of the collected instances from the following three perspectives: the characteristics of the pre-edited ST (§4), the diversity of pre-editing operations (§5), and the impact of pre-editing operations on the NMT outputs (§6). The findings of these analyses provide useful insights into the effective and efficient implementation of pre-editing for the better use of black-box NMT systems in the future, as well as the robustness of current NMT systems when STs are manually perturbed.

2 Related Work

Pre-editing is the process of rewriting the source text (ST) to be translated in order to obtain better translations by MT. Though the scope of effective pre-editing operations depends on the downstream MT system and there is no deterministic relation between pre-editing operations and the quality of MT output, its effectiveness has been demonstrated for various translation directions, MT architectures, and text domains.

Manual pre-editing has long been implemented in combination with controlled languages (Pym, 1990; Reuther, 2003; Nyberg et al., 2003; Kuhn, 2014). In the period of rule-based MT (RBMT), pre-editing was considered as a promising approach since the behaviour of RBMT is more predictable and controllable. For example, O'Brien and Roturier (2007) examined the impact of English controlled language rules on two different MT engines, revealing the rules of high effectiveness. The pre-editing approach with controlled languages has also been tested for statistical MT (SMT) (Aikawa et al., 2007; Hartley et al., 2012; Seretan et al., 2014). These studies developed or utilised a set of controlled language rules for rewriting ST. While these rule sets are optimised for particular MT systems and differ from each other, we can observe some shared characteristics among them. In particular, rules that prohibit long sentences (e.g., of more than 25 words) are widely adopted in the existing rule sets (O'Brien, 2003).

Automation of pre-editing is also an important research field in natural language processing. Semi-automatic tools such as controlled language checkers (Bernth and Gdaniec, 2001; Mitamura et al., 2003) and interactive rewriting assistants (Mirkin et al., 2013; Gulati et al., 2015) were developed to facilitate manual pre-editing activities. Fully automatic pre-editing has long been explored (e.g., Shirai et al., 1998; Mitamura and Nyberg, 2001; Yoshimi, 2001; Sun et al., 2010). In particular, many researchers have examined methods of *reordering* the source-side word order as a pre-translation processing (Xia and McCord, 2004; Li et al., 2007; Hoshino et al., 2015). While the reordering approach has generally proven effective for SMT, its effectiveness for NMT is not obvious; negative effects have even be reported (Zhu, 2015; Du and Way, 2017). In recent years, techniques of automatic text simplification have been applied to improve NMT outputs (Štajner and Popović, 2018; Mehta et al., 2020). The underlying assumption of these studies is that simpler sentences are more machine translatable.

Previous studies have investigated various pre-editing methods from different perspectives, focusing on different linguistic phenomena. Indeed, individual research has led to improved MT results. However, what is crucially needed is a broad understanding of what pre-editing is and how it works. For example, Miyata and Fujita (2017) addressed this issue by collecting instances of *bilingual pre-editing*, i.e., pre-editing ST while referring to its MT output, done by human editors and analysing them in detail. They demonstrated the maximum gain of pre-editing for an SMT and provided a comprehensive typology of editing operations. Nevertheless, their study has two major limitations: (1) recent NMT was not examined, and (2) practical insights for better practices of pre-editing were not sufficiently presented.

NMT models trained in an end-to-end manner behave very differently from SMT and RBMT, which, in turn, affects pre-editing practices. As reported in several studies, despite their rapid improvement, NMT models are still vulnerable to input noise (Belinkov and Bisk, 2018; Ebrahimi et al., 2018; Cheng et al., 2019; Niu et al., 2020). The pre-editing operations identified in previous studies are not necessarily effective for current black-box NMT systems.[1] For example, Marzouk and Hansen-Schirra (2019) adopted nine controlled language rules[2] and evaluated their impact on the MT output for German-to-English translation in the technical domain. The human evaluation results revealed that these rules improved the performance of the RBMT, SMT, and hybrid systems, but did not have positive effects on the NMT system. Hiraoka and Yamada (2019) demonstrated the effectiveness of the following three pre-editing rules in improving Japanese-to-English TED Talk subtitle

---

[1] The ideal goal of the pre-editing approach is to adapt the STs to what the intended NMT system can properly translate, and in the end, what it has been trained on, i.e., training data. For a black-box MT system, because we cannot directly refer to its training data, we should grasp its statistical characteristics indirectly through MT output.

[2] The rules are as follows: (1) using straight quotes for interface texts, (2) avoiding light-verb construction, (3) formulating conditions as if sentences, (4) using unambiguous pronominal references, (5) avoiding participial constructions, (6) avoiding passives, (7) avoiding constructions with "sein" + "zu" + infinitive, (8) avoiding superfluous prefixes, and (9) avoiding omitting parts of the words (Marzouk and Hansen-Schirra, 2019, p.184).

5. Perfect	Information in the original text has been completely translated. There are no grammatical errors in the translation. The word choice and phrasing are natural even from a native speaker's point of view.
4. Good	The word choice and phrasing are slightly unnatural, but the information in the original text has been completely translated, and there are no grammatical errors in the translation.
3. Fair	There are some minor errors in the translation of less important information in the original text, but the meaning of the original text can be easily understood.
2. Acceptable	Important parts of the original text are omitted or incorrectly translated, but the core meaning of the original text can still be understood with some effort.
1. Incorrect/nonsense	The meaning of the original text is incomprehensible.

Table 1: MT evaluation criterion adopted in Miyata and Fujita (2017): The "Perfect" and "Good" ratings are regarded as satisfactory quality.

reuters	English-origin news article from Reuters	written	25	36.8 (15.3)

Table 2: Statistics for the Org-ST datasets for pre-editing.

translation using a black-box NMT system: (1) inserting punctuation, (2) making implied subjects and objects explicit, and (3) writing proper nouns in the target language (English).

As these studies cover a limited range of linguistic phenomena, translation directions, and text domains, we are not in the position to draw decisive conclusions; we still do not know what types of pre-editing operations are possible and how NMT is affected when these operations are performed. To elicit the best pre-editing practices for NMT, as a starting point, we need to understand what is happening and what can be obtained in the process of pre-editing, while also re-examining the previous findings and conventional methods.

3 Collection of Pre-Editing Instances

3.1 Protocol

To collect fine-grained manual pre-editing instances, we adopted the protocol formalised by Miyata and Fujita (2017), in which a human editor incrementally and minimally rewrites an ST on a trial-and-error basis with the aim of obtaining better MT output. An original ST (Org-ST) and its pre-edited versions are collectively called a *unit*. Using an online editing platform we developed, editors implement the protocol in the following steps:

Step 1. Evaluate the MT output of the current ST based on a 5-point scale criterion shown in Table 1. If the quality of the MT output is satisfactory (i.e., "Perfect" or "Good"), go to Step 4; otherwise, go to Step 2.

Step 2. Select one of the versions of the ST in the unit to be rewritten and go to Step 3. If none of the versions are likely to become satisfactory through further edits, go to Step 4.

Step 3. Minimally edit the ST[3] while maintaining its meaning, referring to the corresponding MT output. The MT output for the edited ST is automatically generated and registered in the unit. Return to Step 1.

Step 4. Select one version of the ST that achieves the best MT quality (Best-ST) from among all the versions in the unit, and terminate the process for the unit.

The pre-editing instances in a unit collected through this protocol form a tree structure as shown in Figure 1. We refer to the shortest path between the Org-ST and the Best-ST as *Best path*. An important extension to the work in Miyata and Fujita (2017) is that our platform provides editors with a visualisation of the tree representation of the pre-editing history. This can facilitate the selection of ST versions in Step 2.

3.2 Implementation

To extensively investigate pre-editing phenomena, we prepared the following conditions:

Translation directions: We targeted Japanese-to-English (Ja-En), Japanese-to-Chinese (Ja-Zh), and Japanese-to-Korean (Ja-Ko) translations.

---

[3] We operationally defined "to minimally edit" as "to modify an ST with a small edit that is difficult to be further decomposed into more than one independent edit, without inducing ungrammaticality in the edited sentence."

Lang.	**System**	**Domain**	**Num. of pre-editing instances**				**Num. of units**

Table 3: Statistics for the collected pre-editing instances and the MT quality achievement.

MT systems: As black-box MT systems, we adopted Google Translate[4] and TexTra.[5] Both are general-purpose NMT systems that are prevalently used for translating Japanese texts into other languages.

Text domains: We selected four text domains, whose linguistic characteristics, such as mode and sentence length, are different from each other (see Table 2 for details).

We randomly selected 25 Japanese sentences for each of the four text domains, and used the resulting ST set consisting of 100 sentences for all of the six combinations of translation direction and MT system. We assigned one editor to each translation direction. Each editor was asked to work with both MT systems, without being informed of the type of MT system used in the task. All editors were professional translators with sufficient writing skills in Japanese and experience for evaluating MT outputs. Before the commencement of the formal tasks, we trained the editors using example sentences so that they could become accustomed to the task and platform.

The Ja-En task was implemented from November to December 2019; the Ja-Zh and Ja-Ko tasks were implemented from December 2019 to February 2020.

3.3 Statistics

Table 3 shows statistics for the pre-editing instances collected through the protocol described above. In general, the numbers of collected instances for the **hospital** and **municipal** domains were smaller than those for the **bccwj** and **reuters** domains, reflecting the influence of sentence length of the Org-ST. In other words, the shorter the sentence is, the fewer parts there are to be edited.

A notable finding is that while only about 11% (69/600) of the MT output for the Org-ST was of satisfactory quality, 95% (571/600) of the MT output of the Best-ST was satisfactory. This means that almost all the ST can be pre-edited into a form that can lead to satisfactory MT output, demonstrating the potential of both pre-editing and NMT.

The number of collected instances can be interpreted as the editing efforts required to obtain the Best-ST from the Org-ST. In most of the settings, the median number of collected instances for a unit falls in the range of 5 to 10. It is thus necessary to optimise the pre-editing process for an intended MT system. The length of the Best path approximates the minimum editing efforts needed to obtain the Best-ST. The total number of pre-editing instances in the Best path was 2,443, while the total of all instances is 6,652. This implies that there is substantial opportunity for reduction of the pre-editing efforts.

Table 4: Linguistic characteristics of the Org-ST and Best-ST.

4 Characteristics of Pre-Edited Sentences

To understand the differences between the original and pre-edited STs, in this section, we describe their general linguistic characteristics. Here, we compare the Org-ST and the Best-ST that achieved a satisfactory MT result in order to elicit the features of machine translatable ST.

4.1 Structural Characteristics

To quantify structural complexity, we used the following three indices:

(1) sentence length: the number of words per sentence[6]
(2) attachment distance: the averaged distance of all attachment pairs of the Japanese base phrases in a sentence
(3) dependency depth: the maximum distance from the root word in the dependency tree

We used the Japanese tokeniser MeCab[7] to calculate (1) and the Japanese dependency parser JUMAN/KNP[8] to calculate (2) and (3).

The first three blocks in Table 4 show the results for these indices. It is evident on all indices, the Org-ST exhibits the lowest scores. In other words, the length and surface complexity of the sentences generally increased through the pre-editing operations. This is a counter-intuitive finding in that most previous pre-editing practices have axiomatically assumed that shorter and less complex sentences are better for MT. We further delve into this in §5.

4.2 Lexical Characteristics

The remaining two blocks in Table 4 present statistics for the lexical characteristics of the STs. The results for lexical diversity indicate that both the total number of word types and the Token/Type ratio increased from the Org-ST to the Best-ST for all the conditions. This suggests that though the diversity of words increased slightly, the word distribution became peakier through pre-editing.

We also calculated the word frequency rank with Wikipedia as the reference.[9] To assess the status of word frequency in relation to MT, it would be ideal to use the training data for each MT system, but such data are unavailable in black-box MT settings. Therefore, we decided to use Wikipedia as a convenient way to observe general word frequency. Lower numbers indicate higher word frequencies in Wikipedia. The 50th and 75th percentile values in the datasets imply that pre-editing induced the avoidance of low-frequency words.

To further inspect the differences between the Org-ST and the Best-ST, we extracted the word types (a) that appeared only in the Org-ST and (b) that appeared only in the Best-ST. Figure 2 illustrates the rank distributions of (a) and (b) for each condition. It is clear that low-frequency words with a frequency rank of around 10,000 decreased in the Best-ST, while words with a frequency rank of around 2,000–4,000 increased in the Best-ST. As Koehn and Knowles (2017) demonstrated, low-frequency words still pose major obstacles for NMT systems. Our results endorse this claim from a different perspective and can provide general strategies for word choice in the pre-editing task.

---

[6] If ST instance includes multiple sentences, we averaged the scores.

5 Diversity of Pre-Editing Operations

5.1 Typology of Edit Operations

To understand the diversity of edit operations for pre-editing, we manually annotated the collected pre-editing instances in terms of linguistic operations. Given that the Best path contains effective editing operations for improved MT quality, we focused on the pairs of ST versions in the Best path (e.g., the pairs {1→3, 3→7, 7→8} in Figure 1). We randomly selected 10 units for each of the 24 combinations of translation direction, MT system, and text domain, resulting in a total of 961 pre-editing instances. We then excluded 26 instances that could be decomposed into multiple smaller edits[10] and classified the remaining 935 instances, each of which consists of a minimum edit of ST, based on the typology proposed by Miyata and Fujita (2017). Through the classification, we refined the existing typology to consistently accommodate all the instances.

Table 5 presents our typology of editing operations with the number of instances in the different conditions. The typology consists of 39 operation types under 6 major categories, which enables us to grasp the diversity and trends of pre-editing operations. Compared to structural editing, local modifications of words and phrases were frequently used in the Best path. The dominant type is **C01 (Use of synonymous words)**: content words are replaced by another synonymous word. This operation is important for achieving appropriate word choice in the MT output. **C07 (Change of content)**, the second dominant type, includes the addition of information that is inferred by human editors based on the intra-sentential context or even external knowledge. For example, a named entity '*Nemuro-sho*' (Nemuro office) was changed into '*Nemuro-keisatsu-sho*' (Nemuro police office) by using the knowledge of the entity. It might be challenging to automate such *creative* operations.

It is also notable that **S01 (Sentence splitting)** only amounts to 1.5% of all instances, which supports the observation in §4.1 that in general, sentence length was not reduced, and even increased by pre-editing. Among the 14 cases of this type, nine of the split sentences were 60–67 words in length. These results support the empirical observation by Koehn and Knowles (2017) that NMT systems still have difficulty in translating sentences longer than 60 words, and suggest that sentence splitting may only be promising for such very long sentences.

5.2 Strategies for Effective Pre-Editing

Towards the effective exercise of pre-editing, we further analysed the pre-editing instances in terms of *informational strategies* based on the notion of explicitation/implicitation acknowledged in translation studies (Vinay and Darbelnet, 1958; Chesterman, 1997; Murtisari, 2016). Following these studies, we broadly defined explicitation as an act of indicating what is implied in the text to clarify its meaning and implicitation as the inverse act of explicitation. We classified all the instances analysed above except for the **E01** and **E02** types into three general strategies, namely, explicitation, implicitation, and (information) preservation. The right side of Table 5 shows the classification result. The total numbers of instances classified into each strategy were 329, 88, and 480, respectively. Not surprisingly, this indicates that explicitation is an essential

---

[10] Only 2.7% of the edits were not regarded as minimum, which demonstrated satisfactory adherence to our instructions, compared with the implementation by Miyata and Fujita (2017), in which 568 pre-editing instances were finally decomposed into 979 instances.

ID	Editing operation type	Ja-En		Ja-Zh		Ja-Ko		Total	Expl.	Impl.	Pres.

Table 5: Constructed typology of editing operations (G: Google, T: TexTra). The first letter of ID indicates the six major categories (S: Structure, P: Phrase, C: Content word, F: Functional word, O: Orthography, E: Errors casually introduced in the ST). The right three columns provide the frequencies for general informational strategies (Expl.: Explicitation, Impl.: Implicitation, Pres.: Preservation).

strategy for effective pre-editing.

We also grouped all the 329 instances of explicitation into the following four subcategories.[11]

Information addition is the strategy of adding supplementary information, such as subjects, modality, and explanation, to clarify the content of the ST. For example, subjects were sometimes inserted as they tend to be omitted in Japanese sentences. This strategy generally corresponds to operation **C07 (Change of content)** described earlier.

Use of clear relation includes structural changes and the use of explicit connective markers to make the relation between words, phrases, and clauses more intelligible. For example, the relation between the subject and object can be clarified by using the nominative case marker '*ga*' in Japanese.

Use of narrower sense is the strategy of replacing general words with more specific ones. For example, the verb '*dasu*,' which has multiple meanings such as 'put,' 'take,' and 'send,' was replaced with the verb '*teishutsusuru*,' which has a narrower range of meaning and was correctly translated as 'submit.'

Normalisation includes the use of authorised or standardised expressions, style, and notation. For example, elliptic sentence-ending was completed to construct a normal structure.

---

[11] See Appendix A for details.

		Ja-En		Ja-Zh		Ja-Ko

	Spearman's ρ	0.210	0.221	0.219	0.226	0.449	0.245

Table 6: Correlation of the TER and the number of edits between ST and MT.

These strategies can be used as concise pre-editing principles for human editors and can guide researchers in devising effective tools for pre-editing. We also emphasise that these general informational strategies are not specific to the Japanese language and could be applied to other languages.

6 Impact of Pre-Editing on Neural Machine Translation

This section investigates how pre-editing operations affect the NMT output. As indicated in §2, NMT systems still lack robustness, and minor modifications of the input would drastically change the output. From the practical viewpoint of deploying pre-editing, predictability is an important object to pursue. Here, we examine the impacts of minimum edits of the ST on the NMT output. To measure the amount of text editing, hereafter, we use the Translation Edit Rate (TER), which is calculated by dividing the number of edits (insertion, deletion, substitution, and shift) required to change a string into the reference string by the average number of reference words (Snover et al., 2006). For any consecutive pair of STs or their corresponding MT outputs, we used the chronologically later version as the reference. For word-level tokenisation, we used MeCab for Japanese, NLTK[12] for English, jieba[13] for Chinese, and KoNLPy[14] for Korean.

6.1 Correlation of the Amount of Edits between the ST and MT

To grasp the general tendency, using all the collected pre-editing instances (see Table 3), we first calculated the correlation coefficients (Pearson's r and Spearman's ρ) between the amount of edits (the TER and the number of edits) in the ST and in the MT. More formally, let $\mathtt{ST}'$ be the pre-edited versions of $\mathtt{ST}$. For TER, the correlation is between $\mathtt{TER}(\mathtt{ST}, \mathtt{ST}')$ and $\mathtt{TER}(\mathtt{MT}(\mathtt{ST}), \mathtt{MT}(\mathtt{ST}'))$. For the number of edits, the correlation is between $\mathtt{EditCount}(\mathtt{ST}, \mathtt{ST}')$ and $\mathtt{EditCount}(\mathtt{MT}(\mathtt{ST}), \mathtt{MT}(\mathtt{ST}'))$.

As shown in Table 6, most coefficients are in the range of 0.15–0.25, suggesting a very weak correlation. This means that the change in NMT output is hardly predictable based on the amount of edits in the ST. For example, the replacement of a single particle in the ST sometimes caused drastic changes of lexical choices in the MT output.

The Japanese-to-Korean translation is an exception; in particular, the correlation coefficients of the TER for the Google NMT system, i.e., 0.580 for Pearson's r and 0.574 for Spearman's ρ, indicate a moderate positive relationship between the changes in the ST and those in the MT. This is partly attributable to the fact that the syntactic structures of Japanese and Korean, including the word order and usage of particles, are substantially close. Thus, it is relatively easy to build sufficiently accurate MT systems.

6.2 Impact of Editing Operations on NMT

Finally, using the pre-editing instances in the Best path analysed in §5, we further investigated to what extent each type of minimum editing operation affects the MT output. At this stage, we focused on the 28 editing types that have at least 10 instances, considering that it is difficult to derive reliable insights from fewer data.

Figure 3 presents the distribution of the degree of changes in the MT output when an ST is pre-edited, measured by $\mathtt{TER}(\mathtt{MT}(\mathtt{ST}), \mathtt{MT}(\mathtt{ST}'))$. Most of the structural edits (**S01–S04**) resulted in sizeable changes in the MT. This is reasonable since structural modifications in the ST tended to cause major changes in the MT as well, leading to high TER. In contrast, many of the editing types that include local modifications of functional words and orthographic notations (**F01–F03, F05, F06, O01, O02**) did not have major impacts on the MT results.

It is worth noticing that **P03 (Phrase reordering)** did not drastically affect the MT output. In other words, recent NMT systems in practical use manage to retain the phrase-level equivalence even

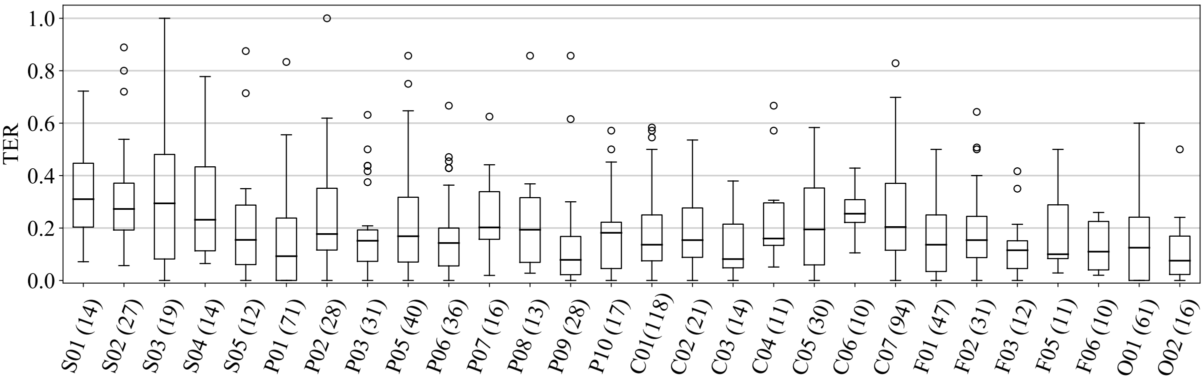

Figure 3: Distribution of the TER for changes in the MT for each operation type with at least 10 instances. The numbers in parentheses indicate the number of instances.

when the position of a phrase is shifted. The influence of **P02 (Use/disuse of chunking marker(s))** is fairly significant. For human readers, the use of chunking markers, such as double quotes and square brackets, does not greatly affect the sentence parsing, but for NMT, it might seriously impinge on the tokenisation result, eventually leading to a large change in the final output.

7 Conclusion and Outlook

Towards a better understanding of pre-editing for black-box NMT settings, in this study, we collected instances of manual pre-editing in various conditions and conducted in-depth analyses of the instances. We implemented a human-in-the-loop protocol to incrementally record minimum edits of ST for all combinations of three translation directions, two NMT systems, and four text domains, and obtained a total of 6,652 instances of manual pre-editing. Since more than 95% of the STs were successfully pre-edited into one that led to a satisfactory MT quality, our collected instances contain empirical, tacit human knowledge on the effective use of black-box NMT systems. We also investigated the collected data from three perspectives: the characteristics of the pre-edited STs, the diversity of pre-editing operations, and the impact of pre-editing operations on the NMT output. The remarkable findings can be summarised as follows:

- Contrary to the acknowledged practices of pre-editing, the operation of making source sentences shorter and simpler was not frequently observed. Rather, it is more important to make the content, syntactic relations, and word senses clearer and more explicit, even if the ST becomes longer.
- As indicated by recent studies, the NMT systems are still sensitive to minor edits in the ST, and are unpredictable in general. However, there are recognisable tendencies in the MT output according to the types of editing operations, such as the relatively small impact of phrase reordering on NMT.

In future work, we plan to explore the effective implementation of pre-editing. The findings of this study provide a broad overview of the range of pre-editing operations and their expected benefits, which enables us to find feasible pre-editing solutions in practical use cases of black-box NMT systems. To develop automatic pre-editing tools using a collection of pre-editing instances, we need to handle the data insufficiency issue in machine learning, filling the gap between the training data and targeted black-box MT systems.

Moreover, as our pre-editing instances contain a wide variety of perturbations in the ST, they can also be used to evaluate the robustness of MT systems, which can lead to advances in MT research. We aim to jointly improve the two wheels of translation technology: pre-editing and MT.

Table 7: The number of instances and an example of each explicitation strategy for pre-editing ST with MT outputs.

A Details of Explicitation Strategy

Table 7 shows the statistics and examples of each subcategory of the explicitation strategy. A total of 329 pre-editing instances of the explicitation strategy can be further classified into four subcategories: information addition, use of clear relation, use of narrower sense, and normalisation.

The example of the information addition illustrates the insertion of a subject '*kabushiki shijo wa*' ('stock market'), which is implicit in the preceding ST. The example of the use of clear relation shows that the relation between the subject and object can be clarified by using the nominative case marker '*ga*' instead of the accusative one '*o*' and accordingly changing the voice of the main clause. As a result, the inappropriate imperative construction 'Withdraw from ...' in the MT output is changed to the correct passive construction 'will be debited.' In the example of the use of narrower sense, the verb '*dashite*,' which has multiple meanings such as 'put,' 'take,' and 'send,' was replaced with the verb '*teishutsushite*,' which has a narrower range of meaning and was correctly translated as 'submit.' In the example of normalisation, the elliptic sentence-ending was completed with a normal structure '... desu.' This operation led to not only the improvement of the sentence construction, but also the semantic correctness in the MT output ('billions'→'100 million').

RelWalk – A Latent Variable Model Approach to Knowledge Graph Embedding

Abstract

Embedding entities and relations of a knowledge graph in a low-dimensional space has shown impressive performance in predicting missing links between entities. Although progresses have been achieved, existing methods are heuristically motivated and theoretical understanding of such embeddings is comparatively underdeveloped. This paper extends the random walk model (Arora et al., 2016a) of word embeddings to Knowledge Graph Embeddings (KGEs) to derive a scoring function that evaluates the strength of a relation R between two entities h (head) and t (tail). Moreover, we show that marginal loss minimisation, a popular objective used in much prior work in KGE, follows naturally from the log-likelihood ratio maximisation under the probabilities estimated from the KGEs according to our theoretical relationship. We propose a learning objective motivated by the theoretical analysis to learn KGEs from a given knowledge graph. Using the derived objective, accurate KGEs are learnt from FB15K237 and WN18RR benchmark datasets, providing empirical evidence in support of the theory.

1 Introduction

Knowedge graphs (KGs) such as Freebase (Bollacker et al., 2008) organise information in the form of graphs, where entities are represented by the vertices and the relations between two entities are represented by the edges that connect the corresponding vertices. Despite the best efforts to create complete and large-scale KGs, most KGs remain incomplete and do not represent all the relations that exist between entities (Min et al., 2013). In particular, new entities are constantly being generated, and new relations are formed between new as well as existing entities. Therefore, it is unrealistic to assume that a real-world KG would be complete at any given time point. Developing approaches for KG completion is an important research field associated with KGs.

KG components can be embedded into numerical formats by learning representations (a.k.a embeddings) for the entities and relations in a given KG. The learnt KGEs can be used for *link prediction*, which is the task of predicting whether a particular relation exists between two given entities in the KG. Specifically, given KGEs for entities and relations, in link prediction, we predict R that is most likely to exist between h and t according to some scoring formula. Thus, by embedding entities and relations that exist in a KG in some (possibly lower-dimensional and latent) space, we can infer previously unseen relations between entities, thereby expanding a given KG.

KGE can be seen as a two-step process. Given a KG represented by a set of relational triples (h, R, t), where a semantic relation R holds between a head entity h and a tail entity t, first a scoring function is defined that measures the *relational strength* of a triple (h, R, t). Second,the entity and relation embeddings that optimise the defined scoring function are learnt using some optimisation method. Despite the wide applications of entity and relation embeddings created via KGE methods, the existing scoring functions are heuristically motivated to capture some geometric requirements of the embedding space. For example, TransE (Bordes et al., 2011) assumes that the entity and relation embeddings co-exist in the same (possibly lower dimensional) vector space and translating (shifting) the head entity embedding by the relation embedding must make it closer to the tail entity embedding, whereas ComplEx (Trouillon et al., 2016) models the asymmetry in relations using the component-wise multi-linear inner-product among

entity and relation embeddings.

Theoretical understanding of KGE methods is under developed. For example, it is not clear how the heuristically defined KGE objectives relate to the generative process of a KG. Providing such a theoretical understanding of the KGE process will enable us to develop KGE methods that address the weaknesses in the existing KGE methods. For this purpose, we propose Relational Walk (**RelWalk**), a theoretically motivated generative approach for learning KGEs. We are particularly interested in the semantic relationships that exist between entities such as the is-CEO-of relation between a person such as **Jeff Bezos** and a company such as **Amazon Inc.**

We model KGE as a random walk over the KG. Specifically, a random walker at the vertex corresponding to the (head) entity h will uniformly at random select one of the outgoing edges corresponding to the semantic relation R, which will lead it to the vertex corresponding to the (tail) entity t. Continuing this random walk will result in a traversal over a path in the KG. Based on this random walk model we derive a relationship between the probability of R holding between h and t, $p(h, t \mid R)$, and their KGEs $\mathbf{R}$, $\boldsymbol{h}$ and $\boldsymbol{t}$. Interestingly, the derived relationship is not covered by any of the previously proposed heuristically-motivated scoring functions, providing the first-ever KGE method with a provable generative explanation.

We show that the *margin loss*, a popular training objective in prior work on KGE, naturally emerges as the log-likelihood ratio computed from the derived $p(h, t \mid R)$. Based on this result, we derive a training objective that is optimised for learning KGEs that satisfy our theoretical relationship. This enables us to empirically verify the theoretical relationships that we derived from the proposed random walk process.

Using FB15K237 and WN18RR benchmarks, we evaluate the learnt KGEs on link prediction and triple classification. Although we do not obtain state-of-the-art (SoTA) performance on these benchmark datasets, KGEs learnt using RelWalk perform consistently well on both tasks, providing empirical support to the theoretical analysis conducted in this paper. We re-emphasise that our main objective in this paper is to study KGEs from an interpretable theoretical perspective and not necessarily improving SoTA. To this end, we study the relationship between the concentration of the partition function as predicted by our theoretical analysis and the performance of the learnt KGEs. We observe that when the partition function is narrowly distributed, we are able to learn accurate KGEs. Moreover, we empirically verify that the learnt relation embedding matrices satisfy the orthogonality property as expected by the theoretical analysis.

2 Related Work

At a high-level of abstraction, KGE methods can be seen as differing in their design choices for the following two main problems: (a) how to represent entities and relations, and (b) how to model the interaction between two entities and a relation that holds between them. Next, we briefly discuss prior proposals to those two problems (refer to Wang et al. (2017); Nguyen (2017); Nickel et al. (2015) for an extended survey on KGE).

A popular choice for representing entities is to use vectors (Bordes et al., 2013; Ji et al., 2015; Yang et al., 2015), whereas relations have been represented by vectors, matrices (Bordes et al., 2011; Nguyen et al., 2016; Nickel et al., 2011) or tensors (Socher et al., 2013). ComplEx (Trouillon et al., 2016) introduced complex vectors for KGEs to capture the asymmetry in semantic relations. Ding et al. (2018) further improved ComplEx by imposing non-negativity and entailment constraints to ComplEx.

Given entity and relation embeddings, a scoring function evaluates the strength of a triple (h, R, t). Scoring functions that encode various intuitions have been proposed such as the ℓ_1 or ℓ_2 norms of the vector formed by a translation of the head entity embedding by the relation embedding over the target embedding, or by first performing a projection from the entity embedding space to the relation embedding space (Yoon et al., 2016). As an alternative to using vector norms as scoring functions, DistMult (Yang et al., 2015) and ComplEx (Trouillon et al., 2016) use the component-wise multi-linear dot product. Lacroix et al. (2018) proposed the use of nuclear 3-norm regularisers instead of the popular Frobenius norm for canonical tensor decomposition. Table 1 shows the scoring functions along with algebraic structures for entities and relations proposed in selected prior work in KGE learning. Given a scoring function, KGEs are learnt that assign higher scores to relational triples in existing KGs over triples where the relation does not hold (negative triples) by minimising a loss function such as the logistic loss (RESCAL, DistMult, ComplEx) or marginal loss (TransE).

Alternatively to directly learning embeddings from a graph, several methods (Grover and Leskovec, 2016; Perozzi et al., 2014; Ristoski et al., 2018) have considered the vertices visited during truncated random walks over the graph as *pseudo sentences*, and have applied popular word embedding learning algorithms such as continuous bag-of-words model (Mikolov et al., 2013) to learn vertex embeddings. However, pseudo sentences generated in this manner are syntactically very different from sentences in natural languages.

On the other hand, our work extends the random walk analysis by Arora et al. (2016a) that derives a useful connection between the joint co-occurrence probability of two words and the ℓ_2 norm of the sum of the corresponding word embeddings. Specifically, they proposed a latent variable model where the words in a corpus are generated by a probabilistic model parametrised by a time-dependent discourse vector that performs a random walk. In contrast to Arora's model that uses co-occurrences as a generic relation, in our work we include relations as labels for the edges in the graph. Bollegala et al. (2018) extended the model proposed by Arora et al. (2016a) to capture co-occurrences involving more than two words. Specifically, they defined the co-occurrence of k unique words in a given context as a k-way co-occurrence, where Arora et al. (2016a) result could be seen as a special case corresponding to $k = 2$. Moreover, it has been shown that it is possible to learn word embeddings that capture some types of semantic relations such as antonymy and collocation using 3-way co-occurrences more accurately than using 2-way co-occurrences. However, that model does not explicitly consider the relations between words/entities and uses only a corpus for learning the word embeddings.

3 Relational Walk

Let us consider a KG, $\mathcal{D}$, where the *knowledge* is represented by relational triples $(h, R, t) \in \mathcal{D}$. Here, R is a relational predicate with two arguments, where h (*head*) and t (*tail*) entities respectively filling the first and second arguments. In this work, we assume relations to be asymmetric in general (if $(h, R, t) \in \mathcal{D}$ then it does not necessarily follow that $(t, R, h) \in \mathcal{D}$). The goal of KGE is to learn embeddings for the relations and entities in the KG such that the entities that participate in similar relations are embedded closely to each other in the entity embedding space, while at the same time relations that hold between similar entities are embedded closely to each other in the relational embedding space. We call the learnt entity and relation embeddings collectively as KGEs. We assume that entities and relations are embedded in the same vector space, allowing us to perform linear algebraic operations using the embeddings in the same vector space.

KGE method	Score function $f(h, R, t)$	Relation parameters
Unstructured (Bordes et al., 2012)	$\|\|\boldsymbol{h} - \boldsymbol{t}\|\|_{\ell_{1/2}}$	none
Structured (Bordes et al., 2011)	$\|\|\mathbf{R}_1\boldsymbol{h} - \mathbf{R}_2\boldsymbol{t}\|\|_{\ell_{1,2}}$	$\mathbf{R}_1, \mathbf{R}_2 \in \mathbb{R}^{d \times d}$
TransE (Bordes et al., 2013)	$\|\|\boldsymbol{h} + \boldsymbol{r} - \boldsymbol{t}\|\|_{\ell_{1/2}}$	$\boldsymbol{r} \in \mathbb{R}^d$
DistMult (Yang et al., 2015)	$\langle \boldsymbol{h}, \boldsymbol{r}, \boldsymbol{t} \rangle$	$\boldsymbol{r} \in \mathbb{R}^d$
RESCAL (Nickel et al., 2011)	$\boldsymbol{h}^\top \mathbf{R} \boldsymbol{t}$	$\mathbf{R} \in \mathbb{R}^{d \times d}$
ComplEx (Trouillon et al., 2016)	$\langle \boldsymbol{h}, \boldsymbol{r}, \bar{\boldsymbol{t}} \rangle$	$\boldsymbol{r} \in \mathbb{C}^d$

Table 1: Score functions proposed in selected prior work on KGEs. Entity embeddings $\boldsymbol{h}, \boldsymbol{t} \in \mathbb{R}^d$ are vectors in all models, except in ComplEx where $\boldsymbol{h}, \boldsymbol{t} \in \mathbb{C}^d$. Here, $\ell_{1/2}$ denotes either ℓ_1 or ℓ_2 norm of a vector. In ComplEx, $\bar{\boldsymbol{t}}$ is the element-wise complex conjugate.

Following our aforementioned modelling of a knowledge base as a graph, let us consider a random walker who is at a vertex corresponding to some entity h. This entity will have one or more semantic relations with other entities in the KG. The random walker will uniformly at random pick one of the outgoing edges corresponding to a particular semantic relation R, and follow it to land on the entity t. This one-step of the random walk thus *generates* a tuple (h, R, t) in the KG. The random walker proceeds by using t as the new starting point. Multiple steps of this random walk trace a single *path* in the KG.

To illustrate a random walk over a KG, let us assume that we are currently at the vertex corresponding to the company entity **Amazon Inc.** Possible outgoing edges at **Amazon Inc.** would correspond to semantic relations such as has-ceo, is-headquarted-at, founded-in etc., where **Amazon Inc.** is the head entity. If there are only three such outgoing relations at **Amazon Inc.**, then the random walker will pick any one of those relations with a probability $1/3$. For example, by selecting has-ceo, is-headquarted-at or founded-in the random walker would arrive at entities respectively **Jeff Bezos**, **Seattle** or **1994**. Let us assume that the random walker selected the has-ceo relation and landed at **Jeff Bezos**. The random walker might subsequently continue its random walk from **Jeff Bezos** following the relation born-in and transiting to **New Mexico, US**. Prior work studying inferences in KGs have successfully used random walk models similar to what we describe here (Gardner et al., 2013; Lao et al., 2012, 2011; Lao and Cohen, 2010).

Let us consider a random walk characterised by a time-dependent *knowledge vector* $\boldsymbol{c}_k$, where k is the current time step. The knowledge vector represents the knowledge we have about a particular group of entities and relations that express some facts about the world. For example, when we are talking about **Amazon Inc.**, we will use the knowledge associated with **Amazon Inc.** such as its CEO, location of the headquarters, when it was founded etc. Therefore, it is intuitive to assume that the entities associated with **Amazon Inc.** with some set of semantic relations can be generated from this knowledge vector. Each entity and relation has time-independent latent representations that capture their correlations with $\boldsymbol{c}_k$. For entities h and t, we denote their representations by d-dimensional vectors respectively $\boldsymbol{h}, \boldsymbol{t} \in \mathbb{R}^d$.

We assume the task of generating a relational triple (h, R, t) in a given KG to be a two-step process as described next. First, given the current knowledge vector at time k, $\boldsymbol{c} = \boldsymbol{c}_k$ and the relation R, we assume that the probability of an entity h satisfying the first argument of R to be given by the loglinear entity production model in (1).

$$p(h \mid R, \boldsymbol{c}) = \frac{1}{Z_c} \exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right). \tag{1}$$

Here, $\mathbf{R}_1 \in \mathbb{R}^{d \times d}$ is a relation-specific orthogonal matrix that evaluates the appropriateness of h for the first argument of R. For example, if R is the is-ceo-of relation, we would require a person as the first argument and a company as the second argument of R. However, note that the role of $\mathbf{R}_1$ extends beyond simply checking the types of the entities that can fill the first argument of a relation. For our example above, not all people are CEOs and $\mathbf{R}_1$ evaluates the likelihood of a person to be selected as the first argument of the ceo-of relation. Z_c is a normalisation coefficient such that $\sum_{h \in \mathcal{V}} p(h \mid R, \boldsymbol{c}) = 1$, where the vocabulary $\mathcal{V}$ is the set of all entities in the KG.

After generating h, the state of our random walker changes to $\boldsymbol{c}' = \boldsymbol{c}_{k+1}$, and we next generate the second argument of R with the probability given by (2).

$$p(t \mid R, \boldsymbol{c}') = \frac{1}{Z_{c'}} \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}'\right). \tag{2}$$

Here, $\mathbf{R}_2 \in \mathbb{R}^{d \times d}$ is a relation-specific orthogonal matrix that evaluates the appropriateness of t as the second argument of R. $Z_{c'}$ is a normalisation coefficient such that $\sum_{t \in \mathcal{V}} p(t \mid R, \boldsymbol{c}') = 1$. Following our previous example of is-ceo-of relation, $\mathbf{R}_2$ evaluates the likelihood of an organisation to be a company with a CEO position. Importantly, $\mathbf{R}_1$ and $\mathbf{R}_2$ are representations of the relation R and independent of the entities. Therefore, we consider ($\mathbf{R}_1$ and $\mathbf{R}_2$) to collectively represent the embedding of R. Orthogonality of $\mathbf{R}_1, \mathbf{R}_2$ is a requirement for the mathematical proof and also acts as a regularisation constraint to prevent overfitting by restricting the relational embedding space (Tang et al., 2020). Intuitively, orthogonality of the relation embedding matrices ensures that the length of the head and tail entity embeddings are not altered during the generation of the tuple. Orthogonal transformation has been shown to improve the performance of relation representation in prior work. For example, Tang et al. (2020) apply orthogonal transformation that extends RotatE (Sun et al., 2019) to model complex relations (e.g., N-to-N). For relationships in word embedding space, Ethayarajh (2019) use orthogonal transformation for analogical reasoning between words. The performance of hypernymy prediction through orthogonal projections has been improved as shown in Wang et al. (2019).

The knowledge vector $\boldsymbol{c}_k$ performs a *slow* random walk (meaning $\boldsymbol{c}_{k+1}$ is obtained from $\boldsymbol{c}_k$ by adding a small random displacement vector) such that the head and tail entities of a relation are generated under similar knowledge vectors. More specifically, we assume that $||\boldsymbol{c}_k - \boldsymbol{c}_{k+1}|| \leq \epsilon_2$ for some small $\epsilon_2 > 0$. This is a realistic assumption for generating the two entity arguments in the same relational triple because, if the knowledge vectors were significantly different in the two generation steps, then it is likely that the corresponding relations are also different, which would not be coherent with the above-described generative process. Moreover, we assume that the knowledge vectors are distributed uniformly in the unit sphere and denote the distribution of knowledge vectors by $\mathcal{C}$.

To relate KGEs with the connections in the graph, we must estimate the probability that h and t satisfy the relation R, $p(h, t \mid R)$, which can be obtained by taking the expectation of $p(h, t \mid R, \boldsymbol{c}, \boldsymbol{c}')$ w.r.t. $\boldsymbol{c}, \boldsymbol{c}' \sim \mathcal{C}$ given by (3).

$$p(h, t \mid R) = \mathbb{E}_{\boldsymbol{c},\boldsymbol{c}'}\left[p(h, t \mid R, \boldsymbol{c}, \boldsymbol{c}')\right] \tag{3}$$

$$= \mathbb{E}_{\boldsymbol{c},\boldsymbol{c}'}\left[p(h \mid R, \boldsymbol{c})p(t \mid R, \boldsymbol{c}')\right] \tag{4}$$

$$= \mathbb{E}_{\boldsymbol{c},\boldsymbol{c}'}\left[\frac{\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)}{Z_c}\frac{\exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}'\right)}{Z_{c'}}\right]. \tag{5}$$

Here, partition functions are given by

$$Z_c = \sum_{h \in \mathcal{V}} \exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) \tag{6}$$

$$Z_{c'} = \sum_{t \in \mathcal{V}} \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}'\right) \tag{7}$$

(4) follows from our two-step generative process where the generation of h and t in each step is independent given the relation and the corresponding knowledge vectors.

Computing the expectation in (5) is generally difficult because of the two partition functions Z_c and $Z_{c'}$. However, Lemma 1 shows that the partition functions are narrowly distributed around a constant value for all c (or c') values with high probability.

Lemma 1 (Concentration Lemma). *If the entity embedding vectors satisfy the Bayesian prior* $\boldsymbol{v} = s\hat{\boldsymbol{v}}$, *where* $\hat{\boldsymbol{v}}$ *is from the spherical Gaussian distribution, and* s *is a scalar random variable, which is always bounded by a constant* κ, *then the entire ensemble of entity embeddings satisfies that:*

$$\Pr_{c \sim \mathcal{C}}[(1 - \epsilon_z)Z \leq Z_c \leq (1 + \epsilon_z)Z] \geq 1 - \delta, \tag{8}$$

for $\epsilon_z = O(1/\sqrt{n})$, *and* $\delta = \exp(-\Omega(\log^2 n))$, *where* $n \geq d$ *is the number of entities in a given KG and* Z_c *is the partition function for* c *given by* $\sum_{h \in \mathcal{V}} \exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)$.

Refer to Appendix A for the proof of the concentration lemma. We empirically investigate the relationship between the performance of the KGEs and the degree to which Lemma 1 is satisfied in subsection 5.1. Under the conditions required to satisfy Lemma 1, the following main theorem of this paper holds:

Theorem 1. *Suppose that the entity embeddings satisfy* (1). *Then, we have*

$$\log p(h, t \mid R) = \frac{\left|\left|{\mathbf{R}_1}^\top \boldsymbol{h} + {\mathbf{R}_2}^\top \boldsymbol{t}\right|\right|_2^2}{2d} - 2\log Z \pm \epsilon. \tag{9}$$

for $\epsilon = O(1/\sqrt{n}) + \widetilde{O}(1/d)$, *where*

$$Z = Z_c = Z_{c'}. \tag{10}$$

Proof sketch: Let F be the event that both c and c' are within $(1 \pm \epsilon_z)Z$. Then, from Lemma 1 and the union bound, event F happens with probability at least $1 - 2\exp(-\Omega(\log^2 n))$. The R.H.S. of (5) can be split into two parts T_1 and T_2 according to whether F happens or not.

$$p(h, t \mid R) = \underbrace{\mathbb{E}_{c,c'}\left[\frac{\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)}{Z_c}\frac{\exp\left(\boldsymbol{h}^\top \mathbf{R}_2 \boldsymbol{c}'\right)}{Z_{c'}}\mathbf{1}_F\right]}_{=T_1} + \underbrace{\mathbb{E}_{c,c'}\left[\frac{\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)}{Z_c}\frac{\exp\left(\boldsymbol{h}^\top \mathbf{R}_2 \boldsymbol{c}'\right)}{Z_{c'}}\mathbf{1}_{\bar{F}}\right]}_{=T_2}. \tag{11}$$

T_1 can be approximated as given by (12).

$$T_1 = \frac{1 \pm \mathcal{O}(\epsilon_z)}{Z^2}\mathbb{E}_{c,c'}\left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)\exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}'\right)\right] \tag{12}$$

On the other hand, T_2 can be shown to be a constant, independent of d, given by (13).

$$|T_2| = \exp(-\Omega(\log^{1.8} n)) \tag{13}$$

The vocabulary size n of real-world KGs is typically over 10^5, for which T_2 becomes negligibly small. Therefore, it suffices to consider only T_1. Because of the slowness of the random walk we have $\boldsymbol{c} \approx \boldsymbol{c}'$.

Using the law of total expectation we can write T_1 as follows:

$$T_1 = \frac{1 \pm \mathcal{O}(\epsilon_z)}{Z^2}\mathbb{E}_c\left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)\mathbb{E}_{c'|c}\left[\exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}'\right)\right]\right]$$

$$= \frac{1 \pm \mathcal{O}(\epsilon_z)}{Z^2}\mathbb{E}_c\left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)A(c)\right] \tag{14}$$

where $A(c) := \mathbb{E}_{c'|c}\left[\exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}'\right)\right]$. Doing some further evaluations we show that

$$A(c) = (1 \pm \epsilon_2)\exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}\right) \tag{15}$$

Plugging (51) back in (14) provides the claim of the theorem. Detailed proof is shown in Appendix B. □

The relationship given by (9) indicates that head and tail entity embeddings are first transformed respectively by ${\mathbf{R}_1}^\top$ and ${\mathbf{R}_2}^\top$, and the squared ℓ_2 norm of the sum of the transformed vectors is proportional to the probability $p(h, t \mid R)$.

4 Learning KG Embeddings

In this section, we derive a training objective from Theorem 1 that we can then optimise to learn KGEs. The goal is to empirically validate the theoretical result by evaluating the learnt KGEs. KGs represent information about relations between two entities in the form of *relational triples*. The joint probability $p(h, R, t)$ given by Theorem 1 is useful for determining whether a relation R exists between two given entities h and t. For example, if we know that with a high probability that R holds between h and t, then we can append (h, R, t) to the KG. The task of expanding KGs by predicting missing links between entities or relations is known as the *link prediction* problem (Trouillon et al., 2016). In particular, if we can automatically append such previously unknown knowledge to the KG, we can expand the KG and address the knowledge acquisition bottleneck.

To derive a criteria for determining whether a link must be predicted among entities and relations, let us consider a relational triple $(h, R, t) \in \mathcal{D}$ that exists in a given KG $\mathcal{D}$. We call such relational triples as *positive* triples because from the assumption it is known that R holds between h and t. On the other hand, consider a *negative* relational triple $(h', R, t') \in \mathcal{D}$ formed by, for example, randomly perturbing a positive triple. A popular technique for generating such (pseudo) negative triples is to replace h or t with a randomly selected different instance of the same entity type. As an alternative for random perturbation, Cai and Wang (2018) proposed a method for generating negative instances using adversarial learning. Here, we are not concerned about the actual method used for generating the negative triples but assume a set of negative triples, $\bar{\mathcal{D}}$, generated using some method, to be given.

Given a positive triple $(h, R, t) \in \mathcal{D}$ and a negative triple $(h', R, t') \in \bar{\mathcal{D}}$, we would like to learn KGEs such that a higher probability is assigned to (h, R, t) than that assigned to (h', R, t'). We can formalise this requirement using the likelihood ratio given by (16).

$$\frac{p(h, R, t)}{p(h', R, t')} \geq \eta \tag{16}$$

Here, $\eta > 1$ is a threshold that determines how higher we would like to set the probabilities for the positive triples compares to that of the negative triples.

By taking the logarithm of both sides in (16) we obtain

$$\log p(h, R, t) - \log p(h', R, t') \geq \log \eta$$
$$\log \eta + \log p(h', R, t') - \log p(h, R, t) \leq 0 \tag{17}$$

If a positive triple (h, R, t) is correctly assigned a higher probability than a negative triple $p(h', R, t')$, then the left hand side of (17) will be negative, indicating that there is no *loss* incurred during this classification task. Therefore, we can re-write (17) to obtain the *marginal loss* (Bordes et al., 2013, 2011), $L(\mathcal{D}, \bar{\mathcal{D}})$, a popular choice as a learning objective in prior work in KGE, as shown in (18).

$$\begin{aligned} L(\mathcal{D}, \bar{\mathcal{D}}) = & \\ & \sum_{\substack{(h,R,t)\in\mathcal{D} \\ (h',R,t')\in\bar{\mathcal{D}}}} \max\left(0, \log \eta + \log p(h', R, t') - \log p(h, R, t)\right) \\ = & \max\Big(0, 2d \log \eta + \left|\left|\mathbf{R}_1{}^\top \boldsymbol{h}' + \mathbf{R}_2{}^\top \boldsymbol{t}'\right|\right|_2^2 \\ & - \left|\left|\mathbf{R}_1{}^\top \boldsymbol{h} + \mathbf{R}_2{}^\top \boldsymbol{t}\right|\right|_2^2\Big) \end{aligned} \tag{18}$$

We can assume $2d \log \eta$ to be the *margin* for the constraint violation.

Theorem 1 requires $\mathbf{R}_1$ and $\mathbf{R}_2$ to be orthogonal. To reflect this requirement, we add two ℓ_2 regularisation terms $\left|\left|\mathbf{R}_1{}^\top \mathbf{R}_1 - \mathbf{I}\right|\right|_2^2$ and $\left|\left|\mathbf{R}_2{}^\top \mathbf{R}_2 - \mathbf{I}\right|\right|_2^2$ respectively with regularisation coefficients λ_1 and λ_2 to the objective function given by (18). In our experiments, we compute the gradients (18) w.r.t. each of the parameters $\boldsymbol{h}$, $\boldsymbol{t}$, $\boldsymbol{R}_1$ and $\boldsymbol{R}_2$ and use stochastic gradient descent (SGD) for optimisation. Considering that negative triples are generated via random perturbation, it is important to consider multiple negative triples during training to better estimate the classification boundary. This approach can be easily extended to learn from multiple negative triples as shown in Appendix C.

5 Empirical validation

To empirically evaluate the theoretical result stated in Theorem 1, we learn KGEs (denoted by **RelWalk**) by minimising the marginal loss objective derived in section 4. We use the FB15k237, FB13 (subsets of *Freebase*) and WN18RR (a subset of *WordNet*) datasets, which are standard benchmarks for KGE. We use the standard training, validation and test splits. Statistics about the datasets and training details are in Appendix D. **RelWalk** is implemented in the open-source toolkit OpenKE (Han et al., 2018) and the code and learnt KGEs will are publicly available[1].

We conduct two evaluation tasks: *link prediction* (predict the missing head or tail entity in a given triple $(h, R, ?)$ or $(?, R, t)$) (Bordes et al., 2011) and *triple classification* (predict whether a relation R holds between h and t in a given triple

(h, R, t)) (Socher et al., 2013). We evaluate the performance in the link prediction task using mean reciprocal rank (**MRR**), mean rank (**MR**) (the average of the rank assigned to the original head or tail entity in a corrupted triple) and hits at ranks 1, 3 and 10 (**H@1, 3, 10**), whereas in the triple classification task we use **accuracy** (percentage of the correctly classified test triples). We only report scores under the *filtered* setting (Bordes et al., 2013), which removes all triples appeared in training, validating and testing sets from candidate triples before obtaining the rank of the ground truth triple. In link prediction, we consider all entities that appear in the corresponding argument in the entire knowledge graph as candidates.

In Table 2 we compare the KGEs learnt by **RelWalk** against prior work using the published results. For triple classification, **RelWalk** reports the best performance on FB13, outperforming all methods compared. For the link prediction results as shown in Table 2, we see that **RelWalk** obtains competitive performance on both WN18RR and FB15K237 under all evaluation measures. In particular, it is outperformed by the KGE method proposed by Lacroix et al. (2018) (**CP-N3**), which uses nuclear 3-norm regularisers with canonical tensor decomposition. Interestingly, the improvement against structured embeddings (SE) is consistent and interesting because the scoring function of SE closely resembles that of RelWalk as we can redefine $\mathbf{R}_2$ with the negative sign. However, SE learns KGEs that *minimise* the $\ell_{1,2}$ norm whereas according to (9) we must *maximise* the probability for relational triples in a knowledge graph. WN18RR excludes triples from WN18 that are simply inverted between train and test partitions (Toutanova and Chen, 2015; Dettmers et al., 2017b), making it a difficult dataset for link prediction using simple memorisation heuristics. **RelWalk**'s consistent good performance on both versions of this dataset shows that it is considering the global structure in the KG when learning KGEs.

We note that our goal in this paper is *not* to claim SoTA for KGE but to provide a theoretical understanding with empirical validation. To this end, the experimental results support our theoretical claim and emphasise the importance of theoretically motivating the KGE scoring function design process.

5.1 Orthogonality and Concentration

Our theoretical analysis depends on two main assumptions: (a) concentration of the partition function Z_c (Lemma 1), and (b) the orthogonality of the relation embedding matrices $\mathbf{R}_1, \mathbf{R}_2$. In this section, we empirically study the relationship between these assumptions and the performance of RelWalk.

Given $\mathbf{R}_1$ and $\mathbf{R}_2$ learnt by RelWalk for a particular R, we can measure the degree to which the orthogonality, ν_R, is satisfied by the sum of the non-diagonal elements (19).

$$\nu_R = \sum_{i \neq j} |{\mathbf{R}_1}^\top \mathbf{R}_1|_{ij} + |{\mathbf{R}_2}^\top \mathbf{R}_2|_{ij} \tag{19}$$

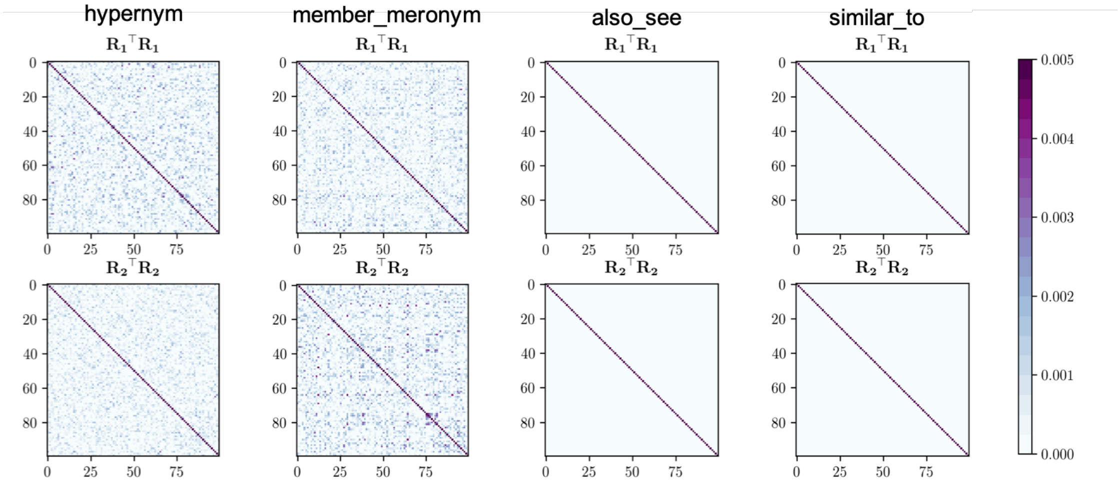

Figure 1: Heatmap visualisation of the orthogonality in different relation embeddings from the WN18RR.

If a matrix $\mathbf{A}$ is orthogonal, then the non-diagonal elements of the inner-product $\mathbf{A}^\top\mathbf{A}$ will contain zeros. Therefore, the smaller the ν_R values, more orthogonal the relation embeddings will be. We measure ν_R values for the 11 relation types in the WN18RR dataset as shown in Table 3. From Table 3 we see that ν_R values are indeed small for different relation types indicating that the orthogonality requirement is satisfied as expected. Interestingly, a moderately high (-0.515) negative Pearson correlation between H@10 and ν_R shows that orthogonality correlates with the better the performance.

To visualise how the orthogonality affects different relation types, we plot the elements in $\mathbf{R}_1{}^\top\mathbf{R}_1$ and $\mathbf{R}_2{}^\top\mathbf{R}_2$ for four relations in the WN18RR dataset in Figure 1 for 100×100 dimensional relational embeddings. For the two relations also_see and similar_to we see that the corresponding inner-products are sparse except in the main diagonal, compared to that in hypernym and member_meronym relations. On the other hand, according to Table 3 the H@10 values for also_see and similar_to are higher than that for hypernym and member_meronym as implied by the negative correlation.

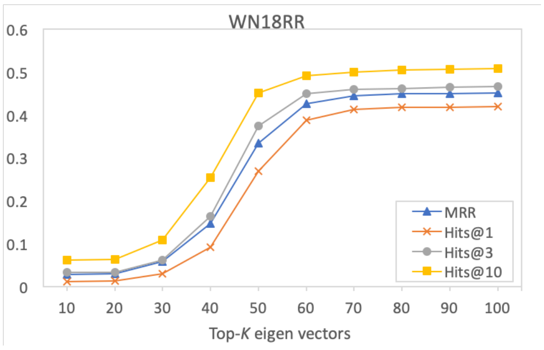

Figure 2: Results for the approximated relation embeddings for link prediction on WN18RR.

To test for the concentration of the partition function, for a relation R we compute Z_c and $Z_{c'}$ values using respectively (6) and (7) over a set of randomly sampled 10000 head or tail entities. We compute the standard deviations σ_c and $\sigma_{c'}$ respectively for the distributions of Z_c and $Z_{c'}$ and their geometric means as shown in Table 3. We observed a Gaussian-like distributions for the partition functions for different relations for which smaller standard deviations indicate stronger concentration around the mean. Interestingly, from Table 3 we see a negative correlation between H@10 and the standard deviations indicating that the performance of RelWalk depends on the validity of the concentration assumption.

5.2 Compression of Embeddings

To reduce the amount of memory required for KGEs, especially with a large KG, compressing KGEs has been studied recently (Sachan, 2020). **RelWalk** uses (orthogonal) matrices to represent relations, which require more parameters compared to a vector representation of the same dimensionality of a relation. Prior work studying lower-rank decomposition of KGEs have shown that, although linear embeddings of graphs can require prohibitively large dimensionality to model certain types of relations (Nickel et al., 2014) (e.g. sameAs), nonlinear embeddings can mitigate this problem (Bouchard et al., 2015). In this section, we propose memory-efficient low-rank approximations to the **RelWalk** embeddings.

From the definition of orthogonality it follows that the relation embeddings $\mathbf{R}_1, \mathbf{R}_2 \in \mathbb{R}^{d \times d}$ learnt by **RelWalk** for a particular relation R means that $\mathbf{R}_1, \mathbf{R}_2$ are both full-rank and cannot be factorised as the product of two lower rank matrices. This prevents us from directly applying matrix decomposition methods such as non-negative matrix factorisation on the learnt relation embeddings to obtain low-rank approximations. Therefore, we subtract the identity matrix $\mathbf{I} \in \mathbb{R}^{n \times n}$ from the relation embedding $\mathbf{R}(\in \{\mathbf{R}_1, \mathbf{R}_2\})$ and factorise the remainder $\mathbf{R}' \in \mathbb{R}^{n \times n}$ as the product of two low-rank matrices using the eigendecomposition of $\mathbf{R}'$ as given by (20).

$$\begin{aligned}\mathbf{R} &= \mathbf{I} + \mathbf{R}' \\ &= \mathbf{I} + \mathbf{U}_R \mathbf{D} \mathbf{U}_R{}^\top \\ &\approx \mathbf{I} + \sum_{k=1}^{K} \mathbf{D}_{(k,k)} \mathbf{U}_{R(k,:)} \mathbf{U}_{R(:,k)} \end{aligned} \quad (20)$$

Here, $\mathbf{U}$ is the matrix formed by arranging the eigenvectors of $\mathbf{R}'$ as columns, and $\mathbf{D}$ is a diagonal matrix containing the eigenvalues of $\mathbf{R}'$ in the descending order. We can then use the largest $K \leq d$ eigenvalues and corresponding eigenvectors to obtain a rank-K approximation in the sense of minimum Frobenius distance between $\mathbf{R}'$ and its rank-K approximation. In the case we use K factors in the approximation, we must store dK real numbers corresponding to the d-dimensional eigen vectors per each of the K components as opposed to d^2 real numbers in $\mathbf{R}$. The compression ratio in this case becomes $dK/d^2 = K/d$. When $K \ll d$, this results in a significant compression.

To empirically evaluate the trade-off between the number of singular vectors used in the compression and the accuracy of the learnt relation embeddings, we use the approximated relation embeddings for link prediction on WN18RR as shown in Figure 2 (similar trend was observed for FB15K237). We use $d = 100$ dimensional relation embeddings learnt by **RelWalk** and approximate using top-K eigenvectors. From Figure 2 we see for $K > 60$ components the performance saturates in both datasets. On the other hand, we need at least $K = 30$ components to get any meaningful accuracy for link prediction on these two datasets. With $K = 60$ and $d = 100$ this approximation results in an 60% compression ratio.

6 Conclusion

We proposed **RelWalk**, a generative model of KGE and derived a theoretical relationship between the probability of a triple consisting of head, tail entities and the relation that exists between those two entities, and the embedding vectors for the two entities and embeddings matrices for the relation. In RelWalk, we represented entities by vectors and relations by matrices. We then proposed a learning objective based on the theoretical relationship we derived to learn entity and relation embeddings from a given knowledge graph. Experimental results on a link prediction and a triple classification tasks show that **RelWalk** outperforms several previously proposed KGE learning methods. The key assumptions of **RelWalk** are validated by empirically analysing the relationship between such assumptions and the performance of the learnt embeddings from a KG. Moreover, we studied the compressibility of the learnt relation embeddings and discovered that using only 60% of the components, we can approximate the relation embeddings without any significant loss in performance.

A Proof of the Concentration Lemma

To prove the concentration lemma, we show that the mean $\mathbb{E}_{\boldsymbol{h}}[Z_c]$ of Z_c is concentrated around a constant for all knowledge vectors $\boldsymbol{c}$ and its variance is bounded. If $\mathbf{P}$ is an orthogonal matrix and $\boldsymbol{x}$ is a vector, then $||\mathbf{P}^\top \boldsymbol{x}||_2^2 = (\mathbf{P}^\top \boldsymbol{x})^\top (\mathbf{P}^\top \boldsymbol{x}) = \boldsymbol{x}^\top \mathbf{P}\mathbf{P}^\top \boldsymbol{x} = ||\boldsymbol{x}||_2^2$, because $\mathbf{P}^\top \mathbf{P} = \mathbf{I}$. Therefore, from (6) and the orthogonality of the relational embeddings, we see that $\mathbf{R}_1 \boldsymbol{c}$ is a simple rotation of $\boldsymbol{c}$ and does not alter the length of $\boldsymbol{c}$. We represent $\boldsymbol{h} = s_h \hat{\boldsymbol{h}}$, where $s_h = ||\boldsymbol{h}||$ and $\hat{\boldsymbol{h}}$ is a unit vector (i.e. $\left|\left|\hat{\boldsymbol{h}}\right|\right|_2 = 1$) distributed on the spherical Gaussian with zero mean and unit covariance matrix $\mathbf{I}_d \in \mathbb{R}^{d \times d}$. Let s be a random variable that has the same distribution as s_h. Moreover, let us assume that s is upper bounded by a constant κ such that $s \leq \kappa$. From the assumption of the knowledge vector $\boldsymbol{c}$, it is on the unit sphere as well, which is then rotated by $\mathbf{R}_1$.

We can write the partition function using the inner-product between two vectors $\boldsymbol{h}$ and $\mathbf{R}_1 \boldsymbol{c}$, $Z_c = \sum_{h \in \mathcal{V}} \exp\left(\boldsymbol{h}^\top (\mathbf{R}_1 \boldsymbol{c})\right)$. Arora et al.(Arora et al., 2016a) showed that (Lemma 2.1 in their paper) the expectation of a partition function of this form can be approximated as follows:

$$\mathbb{E}_{\boldsymbol{h}}[Z_c] = n\mathbb{E}_{\boldsymbol{h}}[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)] \tag{21}$$

$$\geq n\mathbb{E}_{\boldsymbol{h}}[1 + \boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}] = n. \tag{22}$$

where $n = |\mathcal{V}|$ is the number of entities in the vocabulary. (21) follows from the expectation of a sum and the independence of $\boldsymbol{h}$ and $\mathbf{R}_1$ from $\boldsymbol{c}$. The inequality of (22) is obtained by applying the Taylor expansion of the exponential series and the final equality is due to the symmetry of the spherical Gaussian. From the law of total expectation, we can write

$$\begin{aligned}\mathbb{E}_{\boldsymbol{h}}[Z_c] &= n\mathbb{E}_{\boldsymbol{h}}[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)] \\ &= n\mathbb{E}_{s_h}\left[\mathbb{E}_{x|s_h}\left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) \mid s_h\right]\right].\end{aligned} \tag{23}$$

where, $x = \boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}$. Note that conditioned on s_h, $\boldsymbol{h}$ is a Gaussian random variable with variance $\sigma^2 = s_h^2$. Therefore, conditioned on s_h, x is a random variable with variance $\sigma^2 = \sigma_h^2$. Using this distribution, we can evaluate $\mathbb{E}_{x|s_h}\left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)\right]$ as follows:

$$\begin{aligned}&\mathbb{E}_{x|s_h}\left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) \mid s_h\right] \\ &= \int_x \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{x^2}{2\sigma^2}\right) \exp(x) dx \\ &= \int_x \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(x-\sigma^2)^2}{2\sigma^2} + \sigma^2/2\right) dx \\ &= \exp(\sigma^2/2).\end{aligned} \tag{24}$$

Therefore, it follows that

$$\begin{aligned}\mathbb{E}_{\boldsymbol{h}}[Z_c] &= n\mathbb{E}_{s_h}[\exp(\sigma^2/2)] \\ &= n\mathbb{E}_{s_h}[\exp(s_h^2/2)] = n\exp(s^2/2),\end{aligned} \tag{25}$$

where s is the variance of the ℓ_2 norms of the entity embeddings. Because the set of entities is given and fixed, both n and σ are constants, proving that $\mathbb{E}_{\boldsymbol{h}}[Z_c]$ does not depend on c.

Next, we calculate the variance $\mathbb{V}_{\boldsymbol{h}}[Z_c]$ as follows:

$$\begin{aligned}\mathbb{V}_{\boldsymbol{h}}[Z_c] &= \sum_h \mathbb{V}_{\boldsymbol{h}}[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)] \\ &\le n\mathbb{E}_{\boldsymbol{h}}\left[\exp\left(2\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)\right] \\ &= n\mathbb{E}_{s_h}\left[\mathbb{E}_{x|s_h}\left[\exp\left(2\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) \mid s_h\right]\right].\end{aligned} \tag{26}$$

Because $2\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}$ is a Gaussian random variable with variance $4\sigma^2 = 4s_h^2$ from a similar calculation as in (24) we obtain,

$$\mathbb{E}_{x|s_h}\left[\exp\left(2\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) \mid s_h\right] = \exp(2\sigma^2). \tag{27}$$

By substituting (27) in (26) we have that

$$\mathbb{V}_{\boldsymbol{h}}[Z_c] \le n\mathbb{E}_{s_h}\left[\exp\left(2\sigma^2\right)\right] = n\mathbb{E}_{s_h}\left[\exp(2s^2)\right] \le \Lambda n \tag{28}$$

for $\Lambda = \exp(8\kappa^2)$ a constant bounding $s \le \kappa$ as stated. From above, we have bounded both the mean and variance of the partition function by constants that are independent of the knowledge vector. Note that neither $\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)$ nor $\exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right)$ are sub-Gaussian nor sub-exponential. Therefore, standard concentration bounds derived for sub-Gaussian or sub-exponential random variables cannot be used in our analysis. However, the argument given in Appendix A.1 in (Arora et al., 2016b) for a partition function with bounded mean and variance can be directly applied to Z_c in our case, which completes the proof of the concentration lemma. From the symmetry between h and t, the concentration Lemma is also applies for the partition function $Z_{c'} = \sum_{t \in \mathcal{V}} \left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right)$.

B Proof of RelWalk Theorem

Let us consider the probabilistic event that $(1-\epsilon_z)Z \le Z_c \le (1+\epsilon_z)Z$ to be F_c and $(1-\epsilon_z)Z \le Z_{c'} \le (1+\epsilon_z)Z$ to be $F_{c'}$. From Lemma 1 we have $\Pr[F_c] \ge 1-\delta$. Then from the union bound we have,

$$\begin{aligned}\Pr[\bar{F}_c \cup \bar{F}_{c'}] &\le \Pr[\bar{F}_c] + \Pr[\bar{F}_{c'}] \\ &= 1 - \Pr[F_c] + 1 - \Pr[F_{c'}] \\ &= 2\delta.\end{aligned} \tag{29}$$

where $\bar{F}$ is the complement of event F. Moreover, let F be the probabilistic event that both F_c and $F_{c'}$ being True. Then from $\Pr[F] = 1 - \Pr[\bar{F}_c \cup \bar{F}_{c'}]$ we have, $\Pr[F] \ge 1 - 2\exp\left(-\Omega\left(\log^2 n\right)\right)$. The R.H.S. of (5) can be split into two parts T_1 and T_2 according to whether F happens or not.

$$\begin{aligned}p(h,t \mid R) = &\underbrace{\mathbb{E}_{\boldsymbol{c},\boldsymbol{c'}}\left[\frac{\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)}{Z_c}\frac{\exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right)}{Z_{c'}}\mathbf{1}_F\right]}_{T_1} \\ &+ \underbrace{\mathbb{E}_{\boldsymbol{c},\boldsymbol{c'}}\left[\frac{\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)}{Z_c}\frac{\exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right)}{Z_{c'}}\mathbf{1}_{\bar{F}}\right]}_{T_2}.\end{aligned} \tag{30}$$

Here, $\mathbf{1}_F$ and $\mathbf{1}_{\bar{F}}$ are indicator functions of the events F and $\bar{F}$ given as follows:

$$\mathbf{1}_F = \begin{cases} 1 & \text{if } F \text{ is True,} \\ 0 & \text{otherwise,} \end{cases} \tag{31}$$

$$\mathbf{1}_{\bar{F}} = \begin{cases} 0 & \text{if } F \text{ is True,} \\ 1 & \text{otherwise.} \end{cases} \tag{32}$$

Let us first show that T_2 is negligibly small.

For two real integrable functions $\psi_1(x)$ and $\psi_2(x)$ in $[a, b]$, the Cauchy-Schwarz's inequality states that

$$\left[\int_a^b \psi_1(x)\psi_2(x)dx\right]^2 \leq \int_a^b [\psi_1(x)]^2 dx \int_a^b [\psi_2(x)]^2 dx. \tag{33}$$

Applying (33) to T_2 in (30) we have:

$$\begin{aligned}
&\left(\mathbb{E}_{c,c'}\left[\frac{1}{Z_c Z_{c'}} \exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right) \mathbf{1}_{\bar{F}}\right]\right)^2 \\
&\leq \left(\mathbb{E}_{c,c'}\left[\frac{1}{Z_c^2} \exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)^2 \mathbf{1}_{\bar{F}}\right]\right) \times \\
&\quad \left(\mathbb{E}_{c,c'}\left[\frac{1}{Z_{c'}^2} \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right)^2 \mathbf{1}_{\bar{F}}\right]\right) \\
&= \left(\mathbb{E}_{c}\left[\frac{1}{Z_c^2} \exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)^2 \mathbb{E}_{c'|c}\left[\mathbf{1}_{\bar{F}}\right]\right]\right) \times \\
&\quad \left(\mathbb{E}_{c'}\left[\frac{1}{Z_{c'}^2} \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right)^2 \mathbb{E}_{c|c'}\left[\mathbf{1}_{\bar{F}}\right]\right]\right)
\end{aligned} \tag{34}$$

Note that $Z_c \geq 1$ because Z_c is the sum of positive numbers and if $\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c} > 0$ for at least one of the $h \in \mathcal{V}$, then the total sum will be greater than 1. Therefore, by dropping Z_c term from the denominator we can further increase the first term in (34) as given by (35).

$$\begin{aligned}
&\mathbb{E}_c\left[\frac{1}{Z_c^2} \exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)^2 \mathbb{E}_{c'|c}\left[\mathbf{1}_{\bar{F}}\right]\right] \\
&\leq \mathbb{E}_c\left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)^2 \mathbb{E}_{c'|c}\left[\mathbf{1}_{\bar{F}}\right]\right]
\end{aligned} \tag{35}$$

Let us split the expectation on the R.H.S. of (35) into two cases depending on whether $\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c} > 0$ or otherwise, indicated respectively by $\mathbf{1}_{(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c} > 0)}$ and $\mathbf{1}_{(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c} \leq 0)}$.

$$\begin{aligned}
&\mathbb{E}_c\left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)^2 \mathbb{E}_{c'|c}\left[\mathbf{1}_{\bar{F}}\right]\right] \\
&= \mathbb{E}_c\left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)^2 \mathbf{1}_{(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c} > 0)} \mathbb{E}_{c'|c}\left[\mathbf{1}_{\bar{F}}\right]\right] \\
&+ \mathbb{E}_c\left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)^2 \mathbf{1}_{(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c} \leq 0)} \mathbb{E}_{c'|c}\left[\mathbf{1}_{\bar{F}}\right]\right]
\end{aligned} \tag{36}$$

The second term of (36) is upper bounded by

$$\mathbb{E}_{c,c'}\left[\mathbf{1}_{\bar{F}}\right] \leq \exp\left(-\Omega(\log^2 n)\right) \tag{37}$$

The first term of (36) can be bounded as follows:

$$\begin{aligned}
&\mathbb{E}_c\left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)^2 \mathbf{1}_{(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c} > 0)} \mathbb{E}_{c'|c}\left[\mathbf{1}_{\bar{F}}\right]\right] \\
&\leq \mathbb{E}_c\left[\exp(\alpha \boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c})^2 \mathbf{1}_{(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c} > 0)} \mathbb{E}_{c'|c}\left[\mathbf{1}_{\bar{F}}\right]\right] \\
&\leq \mathbb{E}_c\left[\exp(\alpha \boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c})^2 \mathbb{E}_{c'|c}\left[\mathbf{1}_{\bar{F}}\right]\right]
\end{aligned} \tag{38}$$

where $\alpha > 1$. Therefore, it is sufficient to bound $\mathbb{E}_c\left[\exp(\alpha \boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c})^2 \mathbb{E}_{c'|c}\left[\mathbf{1}_{\bar{F}}\right]\right]$ when $||\boldsymbol{h}|| = \Omega(\sqrt{d})$.

Let us denote by z the random variable $2\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}$. Moreover, let $r(z) = \mathbb{E}_{c'|z}[\mathbf{1}_{\bar{F}}]$, which is a function of z between $[0, 1]$. We wish to upper bound $\mathbb{E}_c[\exp(z) r(z)]$. The worst-case $r(z)$ can be quantified using a continuous version of Abel's inequality (proved as Lemma A.4 in (Arora et al., 2015)), we can upper bound $\mathbb{E}_c\left[\exp(z) r(z)\right]$ as follows:

$$\mathbb{E}_c\left[\exp(z) r(z)\right] \leq \mathbb{E}\left[\exp(z) \mathbf{1}_{[t,+\infty]}(z)\right] \tag{39}$$

where t satisfies that $\mathbb{E}_c[\mathbf{1}_{[t,+\infty]}(z)] = \Pr[z \geq t] = \mathbb{E}_c[r(z)] \leq \exp(-\Omega(\log^2 n))$. Here, $\mathbf{1}_{[t,+\infty]}(z)$ is a function that takes the value 1 when $z \geq t$ and zero elsewhere. Then, we claim $\Pr_c[z \geq t] \leq \exp(-\Omega(\log^2 n))$ implies that $t \geq \Omega(\log^{.9} n)$.

If c was distributed as $\mathcal{N}(0, \frac{1}{d}\mathbf{I})$, this would be a simple tail bound. However, as c is distributed uniformly on the sphere, this requires special care, and the claim follows by applying the tail bound for the spherical distribution given by Lemma A.1 in (Arora et al., 2015) instead. Finally, applying Corollary A.3 in (Arora et al., 2015), we have:

$$\begin{aligned}
\mathbb{E}[\exp(z) r(z)] &\leq \mathbb{E}[\exp(z) \mathbf{1}_{[t,+\infty]}(z)] \\
&= \exp(-\Omega(\log^{1.8} n))
\end{aligned} \tag{40}$$

From a similar argument as above we can obtain the same bound for c' as well. Therefore, T_2 in (30) can be upper bounded as follows:

$$\begin{aligned}
&\mathbb{E}_{c,c'}\left[\frac{1}{Z_c Z_{c'}} \exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right) \mathbf{1}_{\bar{F}}\right] \\
&\leq \left(\mathbb{E}_c\left[\frac{1}{Z_c^2} \exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right)^2 \mathbb{E}_{c'|c}\left[\mathbf{1}_{\bar{F}}\right]\right]\right)^{1/2} \times \\
&\left(\mathbb{E}_{c'}\left[\frac{1}{Z_{c'}^2} \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right)^2 \mathbb{E}_{c|c'}\left[\mathbf{1}_{\bar{F}}\right]\right]\right)^{1/2} \\
&\leq \exp(-\Omega(\log^{1.8} n))
\end{aligned} \tag{41}$$

Because $n = |\mathcal{V}|$, the size of the entity vocabulary, is large (ca. $n > 10^5$) in most knowledge graphs, we can ignore the T_2 term in (30).

Combining the above analysis of T_2 term with (30) we obtain an upper bound for $p(h, t \mid r)$ given by (42).

$$\begin{aligned}
p(h, t \mid R) \leq\ & (1 + \epsilon_z)^2 \frac{1}{Z^2} \mathbb{E}_{c,c'}\left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right) \mathbf{1}_F\right] \\
& + |\mathcal{D}| \exp(-\Omega(\log^{1.8} n)) \\
=\ & (1 + \epsilon_z)^2 \frac{1}{Z^2} \mathbb{E}_{c,c'}\left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right)\right] + \delta_0
\end{aligned} \tag{42}$$

where $|\mathcal{D}|$ is the number of relational tuples (h, r, t) in the KB and $\delta_0 = |\mathcal{D}| \exp(-\Omega(\log^{1.8} n)) \leq \exp(-\Omega(\log^{1.8} n))$ by the fact that $Z \leq \exp(2\kappa)n = O(n)$, where κ is the upper bound on $\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}$ and $\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}$, which is regarded as a constant.

On the other hand, we can lower bound $p(h, t \mid r)$ as given by (43).

$$
\begin{aligned}
p(h, t \mid R) &\geq (1 - \epsilon_z)^2 \frac{1}{Z^2} \mathbb{E}_{c,c'} \left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right) 1_{\mathcal{F}} \right] \\
&\geq (1 - \epsilon_z)^2 \frac{1}{Z^2} \mathbb{E}_{c,c'} \left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right) \right] \\
&\quad - |\mathcal{D}| \exp(-\Omega(\log^{1.8} n)) \\
&\geq (1 - \epsilon_z)^2 \frac{1}{Z^2} \mathbb{E}_{c,c'} \left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right) \right] - \delta_0
\end{aligned} \tag{43}
$$

Taking the logarithm of both sides, from (42) and (43), the multiplicative error translates to an additive error given by (44).

$$
\begin{aligned}
\log p(h, t \mid R) &= \log \left(\mathbb{E}_{c,c'} \left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right) \right] \pm \delta_0 \right) \\
&\quad - 2 \log Z + 2 \log(1 \pm \epsilon_z) \\
&= \log \left(\mathbb{E}_{c} \left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) \mathbb{E}_{c'|c} \left[\exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right) \right] \right] \pm \delta_0 \right) \\
&\quad - 2 \log Z + 2 \log(1 \pm \epsilon_z) \\
&= \log \left(\mathbb{E}_{c} \left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) A(c) \right] \pm \delta_0 \right) \\
&\quad - 2 \log Z + 2 \log(1 \pm \epsilon_z)
\end{aligned} \tag{44}
$$

where $A(c) := \mathbb{E}_{c'|c} \left[\exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right) \right]$.

We assumed that $\boldsymbol{c}$ and $\boldsymbol{c'}$ are on the unit sphere and $\mathbf{R}_1$ and $\mathbf{R}_2$ to be orthogonal matrices. Therefore, $\mathbf{R}_1 \boldsymbol{c}$ and $\mathbf{R}_2 \boldsymbol{c'}$ are also on the unit sphere. Moreover, if we let the upper bound of the ℓ_2 norm of the entity embeddings to be $\kappa' \sqrt{d}$, then we have $||\boldsymbol{h}|| \leq \kappa' \sqrt{d}$ and $||\boldsymbol{t}|| \leq \kappa' \sqrt{d}$. Therefore, we have

$$
\langle \mathbf{R}_1 \boldsymbol{h}, \boldsymbol{c'} - \boldsymbol{c} \rangle \leq ||\boldsymbol{h}|| \, ||\boldsymbol{c} - \boldsymbol{c'}|| \leq \kappa' \sqrt{d} \, ||\boldsymbol{c} - \boldsymbol{c'}|| \tag{45}
$$

Then, we can upper bound $A(c)$ as follows:

$$
\begin{aligned}
A(c) &= \mathbb{E}_{c'|c} \left[\exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c'}\right) \right] \\
&= \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}\right) \mathbb{E}_{c'|c} \left[\exp\left(\boldsymbol{t}^\top \mathbf{R}_2 (\boldsymbol{c'} - \boldsymbol{c})\right) \right] \\
&\leq \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}\right) \mathbb{E}_{c'|c} \left[\exp\left(\kappa' \sqrt{d} \, ||\boldsymbol{c'} - \boldsymbol{c}||\right) \right] \\
&\leq (1 + \epsilon_2) \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}\right)
\end{aligned} \tag{46}
$$

For some $\epsilon_2 > 0$. The last inequality holds because

$$
\begin{aligned}
&\mathbb{E}_{c|c'} \left[\exp\left(\kappa' \sqrt{d} \, ||\boldsymbol{c'} - \boldsymbol{c}||\right) \right] \\
&= \int \exp\left(\kappa' \sqrt{d} \, ||\boldsymbol{c'} - \boldsymbol{c}||\right) p(c'|c) dc' \\
&= \underbrace{\exp(\kappa' \sqrt{d})}_{\geq 1} \underbrace{\int \exp(||\boldsymbol{c} - \boldsymbol{c'}||) p(c'|c) dc'}_{\geq 1} \\
&= 1 + \epsilon_2
\end{aligned} \tag{47}
$$

To obtain a lower bound on $A(c)$ from the first-order Taylor approximation of $\exp(x) \geq 1 + x$ we observe that:

$$
\begin{aligned}
&\mathbb{E}_{c|c'} \left[\exp\left(\kappa' \sqrt{d} \, ||\boldsymbol{c'} - \boldsymbol{c}||\right) \right] \\
&+ \mathbb{E}_{c|c'} \left[\exp\left(-\kappa' \sqrt{d} \, ||\boldsymbol{c'} - \boldsymbol{c}||\right) \right] \geq 2.
\end{aligned} \tag{48}
$$

Therefore, from our model assumptions we have

$$
\mathbb{E}_{c|c'} \left[\exp\left(-\kappa' \sqrt{d} \, ||\boldsymbol{c'} - \boldsymbol{c}||\right) \right] \geq 1 - \epsilon_2 \tag{49}
$$

Hence,

$$
\begin{aligned}
A(c) &= \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}\right) \mathbb{E}_{c'|c} \left[\exp\left(\boldsymbol{t}^\top \mathbf{R}_2 (\boldsymbol{c'} - \boldsymbol{c})\right) \right] \\
&\geq \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}\right) \mathbb{E}_{c'|c} \left[\exp\left(-\kappa' \sqrt{d} \, ||\boldsymbol{c'} - \boldsymbol{c}||\right) \right] \\
&\geq (1 - \epsilon_2) \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}\right)
\end{aligned} \tag{50}
$$

Therefore, from (47) and (50) we have

$$
A(c) = (1 \pm \epsilon_2) \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}\right) \tag{51}
$$

Plugging $A(c)$ back in (44) results in $\log p(h, t \mid r)$ equal to:

$$
\begin{aligned}
&\log \left(\mathbb{E}_{c} \left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) A(c) \right] \pm \delta_0 \right) - 2 \log Z + 2 \log(1 \pm \epsilon_z) \\
&= \log \left(\mathbb{E}_{c} \left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) (1 \pm \epsilon_2) \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}\right) \right] \pm \delta_0 \right) \\
&\quad - 2 \log Z + 2 \log(1 \pm \epsilon_z) \\
&= \log \left(\mathbb{E}_{c} \left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c}\right) \exp\left(\boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}\right) \right] \pm \delta_0 \right) \\
&\quad - 2 \log Z + 2 \log(1 \pm \epsilon_z) + \log(1 \pm \epsilon_2) \\
&= \log \left(\mathbb{E}_{c} \left[\exp\left(\boldsymbol{h}^\top \mathbf{R}_1 \boldsymbol{c} + \boldsymbol{t}^\top \mathbf{R}_2 \boldsymbol{c}\right) \right] \pm \delta_0 \right) \\
&\quad - 2 \log Z + 2 \log(1 \pm \epsilon_z) + \log(1 \pm \epsilon_2) \\
&= \log \left(\mathbb{E}_{c} \left[\exp\left(\left(\mathbf{R}_1{}^\top \boldsymbol{h} + \mathbf{R}_2{}^\top \boldsymbol{t}\right)^\top \boldsymbol{c}\right) \right] \pm \delta_0 \right) \\
&\quad - 2 \log Z + 2 \log(1 \pm \epsilon_z) + \log(1 \pm \epsilon_2)
\end{aligned} \tag{52}
$$

Note that $\boldsymbol{c}$ has a uniform distribution over the unit sphere. In this case, from Lemma A.5 in (Arora et al., 2015), (53) holds approximately.

$$
\begin{aligned}
&\mathbb{E}_{c} \left[\exp\left(\left(\mathbf{R}_1{}^\top \boldsymbol{h} + \mathbf{R}_2{}^\top \boldsymbol{t}\right)^\top \boldsymbol{c}\right) \right] \\
&= (1 \pm \epsilon_3) \exp\left(\frac{||\mathbf{R}_1{}^\top \boldsymbol{h} + \mathbf{R}_2{}^\top \boldsymbol{t}||_2^2}{2d} \right)
\end{aligned} \tag{53}
$$

where $\epsilon_3 = \tilde{O}(1/d)$. Plugging (53) in (52) we have that

$$\log p(h, t \mid R) = \frac{\left|\left|\mathbf{R}_1{}^\top \boldsymbol{h} + \mathbf{R}_2{}^\top \boldsymbol{t}\right|\right|_2^2}{2d} + O(\epsilon_z) + O(\epsilon_2) + O(\epsilon_3) + O(\delta_0') - 2\log Z \tag{54}$$

where $\delta_0' = \delta_0$. $\left(\mathbb{E}_c\left[\exp\left((\mathbf{R}_1{}^\top \boldsymbol{h} + \mathbf{R}_2{}^\top \boldsymbol{t})^\top \boldsymbol{c}\right)\right]\right)^{-1} = \exp(-\Omega(\log^{1.8} n))$. Therefore, δ_0' can be ignored. Note that $\epsilon_3 = \tilde{O}(1/d)$ and $\epsilon_z = \tilde{O}(1/\sqrt{n})$ by assumption. Therefore, we obtain that

$$\log p(h, t \mid R) = \frac{\left|\left|\mathbf{R}_1{}^\top \boldsymbol{h} + \mathbf{R}_2{}^\top \boldsymbol{t}\right|\right|_2^2}{2d} + O(\epsilon_z) + O(\epsilon_2) + \tilde{O}(1/d) - 2\log Z \tag{55}$$

C Learning with Multiple Negative Triples

This approach can be easily extended to learn from multiple negative triples as follows. Let us consider that we are given a positive triple, (h, R, t) and a set of K negative triples $\{(h_k', R, t_k')\}_{k=1}^K$. We would like our model to assign a probability, $p(h, t \mid R)$, to the positive triple that is higher than that assigned to any of the negative triples. This requirement can be written as (56).

$$p(h, t|R) \geq \max_{k=1,\ldots,K} p(h_k', t_k' \mid R) \tag{56}$$

We could further require the ratio between the probability of the positive triple and maximum probability over all negative triples to be greater than a threshold $\eta \geq 1$ to make the requirement of (56) to be tighter.

$$\frac{p(h, t \mid R)}{\max_{k=1,\ldots,K} p(h_k', t_k' \mid R)} \geq \eta \tag{57}$$

By taking the logarithm of (57) we obtain

$$\log p\left(h, t \mid R\right) - \log\left(\max_{k=1,\ldots,K} p\left(h_k', t_k' \mid R\right)\right) \geq \log(\eta) \tag{58}$$

Therefore, we can define the marginal loss for a misclassification as follows:

$$L\left(\left(h, R, t\right), \{(h_k', R, t_k')\}_{k=1}^K\right) = \max\left(0, \log\left(\max_{k=1,\ldots,K} p(h_k', t_k' \mid R)\right) + {} + \log\left(\eta\right) - \log p\left(h, t \mid R\right)\right) \tag{59}$$

However, from the monotonicity of the logarithm we have $\forall x_1, x_2 > 0$, if $\log(x_1) \geq \log(x_2)$ then $x_1 \geq x_2$. Therefore, the logarithm of the maximum can be replaced by the maximum of the logarithms in (59) as shown in (60).

Dataset	#R	#E	Train	Test	Val.
FB15K237	237	14,541	272,115	17,535	20,466
WN18RR	11	40,943	86,835	3,134	3,034
FB13	13	75,043	316,232	23,733	5,908

Table 4: Statistics of the datasets

$$L\left(\left(h, R, t\right), \{(h_k', R, t_k')\}_{k=1}^K\right) = \max\left(0, \max_{k=1,\ldots,K} \log\left(p\left(h_k', t_k' \mid R\right)\right) + \log\left(\eta\right) - \log p\left(h, t \mid R\right)\right) \tag{60}$$

By substituting (9) for the probabilities in (60) we obtain the rank-based loss given by (61).

$$L\left((h, R, t), \{(h_k', R, t_k')\}_{k=1}^K\right) = \max\left(0, 2d\log(\eta) + \max_{k=1,\ldots,K} \left|\left|\mathbf{R}_1{}^\top \boldsymbol{h}_k' + \mathbf{R}_2{}^\top \boldsymbol{t}_k'\right|\right|_2^2 - \left|\left|\mathbf{R}_1{}^\top \boldsymbol{h} + \mathbf{R}_2{}^\top \boldsymbol{t}\right|\right|_2^2\right) \tag{61}$$

In practice, we can use $p(h_k', t_k' \mid R)$ to select the negative triple with the highest probability for training with the positive triple.

D Training Details

The statistics of the benchmark datasets are shown in Table 4. We selected the initial learning rate (α) for SGD in $\{0.01, 0.001\}$, the regularisation coefficients (λ_1, λ_2) for the orthogonality constraints of relation matrices in $\{0, 1, 10, 100\}$. The number of randomly generated negative triples n_{neg} for each positive example is varied in $\{1, 10, 20, 50, 100\}$ and $d \in \{50, 100\}$. Optimal hyperparameter settings were: $\lambda_1 = \lambda_2 = 10$, $n_{\text{neg}} = 100$ for all the datasets, $\alpha = 0.001$ for FB15K237 and FB13, $\alpha = 0.01$ for WN18RR. For FB15K237 and WN18RR $d = 100$ was the best, whereas for FB13 $d = 50$ performed best. Negative triples are generated by replacing a head or a tail entity in a positive triple by a randomly selected entity and learn KGEs. We train the model until convergence or at most 1000 epochs over the training data where each epoch is divided into 100 mini-batches. The best model is selected by early stopping based on the performance of the learnt embeddings on the validation set (evaluated after each 20 epochs).

Few-shot Learning for Slot Tagging with Attentive Relational Network

Abstract

Metric-based learning is a well-known family of methods for few-shot learning, especially in computer vision. Recently, they have been used in many natural language processing applications but not for slot tagging. In this paper, we explore metric-based learning methods in the slot tagging task and propose a novel metric-based learning architecture - Attentive Relational Network. Our proposed method extends relation networks, making them more suitable for natural language processing applications in general, by leveraging pretrained contextual embeddings such as ELMO and BERT and by using attention mechanism. The results on SNIPS data show that our proposed method outperforms other state of the art metric-based learning methods.

1 Introduction

Neural networks have been successfully utilized in natural language processing (NLP) applications with a large amount of hand-labeled data whereas they suffer a persistent challenge of low-resource. The approach of learning with few samples, known as few-shot learning - a branch of meta-learning (*learn to learn*) - has recently been popularized (Fei-Fei et al., 2006; Ravi and Larochelle, 2016; Vinyals et al., 2016; Snell et al., 2017; Sung et al., 2018) in computer vision. Recently, few-shot learning has also been applied to NLP tasks, e.g. natural language understanding (Dou et al., 2019), text classification (Jiang et al., 2018; Rios and Kavuluru, 2018; Gao et al., 2019; Geng et al., 2019), machine translation (Gu et al., 2018) and relation classification (Obamuyide and Vlachos, 2019).

In the slot tagging task, we aim at predicting task-specific values (e.g. artist, time) for slots (placeholders) in user utterances. Oguz and Vu (2020) propose a two-stage modeling approach to exploit domain-agnostic features to tackle low-resource domain challenges. Besides, the other state of the art techniques e.g. based on external memory (Peng and Yao, 2015), ranking loss (Vu et al., 2016), encoder (Kurata et al., 2016), and attention (Zhu and Yu, 2017) have achieved promising results with a wide range of neural networks methods.

However as many other NLP applications, the low-resource issue is a tremendous challenge for slot tagging in new domains, although labeled samples exist in related domains. Many studies have recently proposed to overcome this low-resource challenge using different techniques, e.g. multi-task modeling (Jaech et al., 2016), adversarial training (Kim et al., 2017), and pointer networks (Zhai et al., 2017). In addition, studies like zero-shot learning has influenced the studies of the domain scaling problem for slots prediction (Bapna et al., 2017), eliminating the need of labeled examples for transferring reusable concepts (Zhu and Yu, 2018; Lee and Jha, 2019), and conveying the domain-agnostic concepts between the intents (Shah et al., 2019) by exploiting label names and descriptions. Likewise, (Hou et al., 2020) use label semantics within a few-shot classification method TapNet (Yoon et al., 2019).

We suggest using a small amount of annotated samples from different domains as training input instead of slot descriptions and slot names as in previos zero-shot (Bapna et al., 2017; Lee and Jha, 2019; Shah et al., 2019) and few-shot (Hou et al., 2020) slot tagging studies for two reasons: (1) The creation of slot descriptions needs qualified linguistic expertise and is thus expensive. (2) The relationship between slot names and the corresponding tokens is not constant. To give an example, the relationship between the '*genre*' slot name and '*drama*' token is hypernymic whereas the relationship between the '*artist*' slot name and '*Tarkan*' token is instance based. Hence, it may not be valid to learn only one function to represent the different

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1566–1572
April 19 - 23, 2021.

relationships between names and tokens.

In this paper, we provide a new experimental design where the slot tagging task needs to be solved for unseen slot labels. The experimental design mimics previous few-shot learning studies (Vinyals et al., 2016; Snell et al., 2017; Sung et al., 2018). Thus, the existing data sources from different domains are used to learn meta-knowledge, whereas unseen labels from low-resource domains are used to evaluate the models. Furthermore, we propose a novel modeling approach - *Attentive Relational Network*, inspired by (Sung et al., 2018; Jiang et al., 2018; Jetley et al., 2018), that leverages contextual embeddings such as ELMO and BERT and extends the previous relation networks (Sung et al., 2018) by learning to attend local and global features (Jetley et al., 2018). Experimental results on SNIPS data show that the proposed model outperforms other few-shot learning networks.

2 Methods

2.1 Input

FastText (Mikolov et al., 2018) is an approach to enrich the word vectors with a bag of character n-gram vectors.

ELMo (Peters et al., 2018) is a contextualized word representation methods. It concatenates the output of two LSTM independently trained on the bidirectional language modeling task and return the hidden states for the given input sequence.

BERT (Devlin et al., 2019) uses a bidirectional transformer model that is trained on a masked language modeling task. Because of WordPiece embeddings (Wu et al., 2016), there are different choices of presenting words. We use the first subtoken for representing the word as proposed in (Devlin et al., 2019). Additionally, due to the structure of multiple successive layers, i.e., 24 layers and as suggested in (Oguz and Vu, 2020), we select *10th*, *11th*, *12th*, and *13th* as the focused layers on local context (Clark et al., 2019; Tenney et al., 2018) for slot tagging.

2.2 Meta-learning strategy

Despite the fact that the proposed methods differ in their learning strategies, episode-based training is the same in meta-training and meta-testing phases for proposed meta models as mentioned in (Chen et al., 2018). For the purpose of applying episodic training in a robust way, we follow the proposed procedures in Vinyals et al. (2016); Snell et al. (2017). In the episodic training, each step - episode - is formed to compute gradients and update the model parameters. An episode consists of two components: support and query sets. To construct an episode, C unique classes are randomly sampled, and for each selected C unique classes K labeled examples randomly drawn for support $S = \{(x_i, y_i)\}_{i=1}^{m}$ and query $Q = \{(x_i, y_i)\}_{i=1}^{m}$ set, where $K > 1$ and $m = K * C$. The same episode composition strategy is applied in the meta-testing stage to evaluate the performance of the trained model over unseen classes.

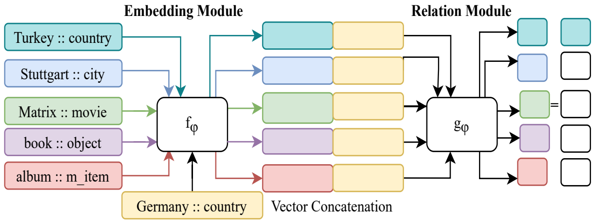

Figure 1: One-shot training example of slot tagging with Relation Network: Embedding Module extracts the feature vectors of each slot value whereas Relation Module calculates the relation scores between support samples and query. Then, the label of most relational value is assigned as a label of query.

Meta-training. The aim of this phase is to learn a meta learner that maps from a few labeled samples to a classifier. In each episode, meta-training employs a two-stage process: (1) the first stage implies producing the feature maps from the given input S and Q, called embedding function $f_\phi(x)$ (2) the second stage is to make prediction conditioned on few labeled examples, S. More formally, we define an episode E_{train} includes S and Q selected from train data,D_{train} . Then, the model is trained to minimize the label prediction error in the Q conditioned on S, i.e., $P_\theta(y_j|x_j, S)$, by utilizing the distance or relation metrics like $distance/relation(f_\phi(x_j), f_\phi(x_i))$, as also shown with an example in Figure 1.

Meta-testing. In this phase, we test the performance of trained meta-learner on unseen labels by following the same steps in meta-training phase. An episode E_{test} with S and Q is formed by randomly selecting from test data, D_{test}. The over all accuracy is computed by averaging the test episodes, $acc = \frac{1}{||E_{test}||} \sum_i E_{test}$.

We define $C = 5$ in meta-training and meta-testing stages except the meta-testing stage of *SearchCreativeW.* domain with $C = 3$ because *SearchCreativeW.* domain has only three slots. We

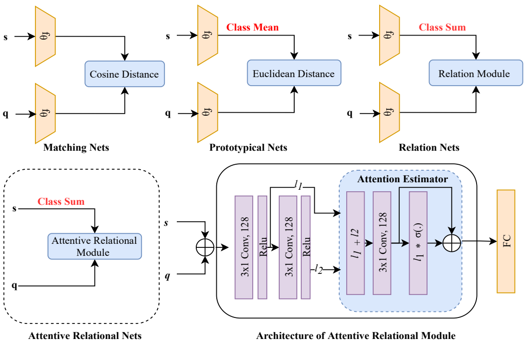

Figure 2: Few-shot learning models: Matching Nets compare each support sample with query in order to calculate the distance metric, Prototypical Nets rely on class mean of support set, and Relation Nets are based on class sum of support samples. f_θ represent the embedding module of each network and Attentive Relational Nets eject embedding module. Support sets are represented with s whereas q denotes the query.

train all the model within 10,000 episodes, and evaluate with 1000 test episode after every 500 steps of total train episodes.

2.3 Models

We focus on three *metric-based learning* few-shot learning methods such as Matching Networks (Vinyals et al., 2016), Prototypical Network (Snell et al., 2017), and Relation Network (Sung et al., 2018). Each network consists of two consecutive modules. The first module, called embedding function, focuses on the learning of the transferable embeddings for support and query samples. The second module is the classifier which identify the corresponding classes over the defined metric scores, e.g., distance and relation.

Matching Networks (MatchingNets) compare the cosine distance between the query feature and each support feature, and computes average cosine distance for each class.

Prototypical Networks (PrototypicalNets) compare the Euclidean distance between query features and the class mean of support features.

Relation Networks (RelationNets) propose a learnable non-linear relation module to output the relation scores over element-wise sum of each support and query features.

In one-shot scenario, MatchingNets and PrototypicalNets could be interpreted as identical, RelationNets differs with the relation module in order to calculate the relation score.

2.3.1 Attentive Relational Networks

We propose a novel metric-learning approach - Attentive Relational Networks (AttentiveRelationalNets) that highlight the relevant, and suppress the misleading between support and query samples. AttentiveRelationalNets address the few-shot classification problem by utilizing *learn to compare based on attention* insight. This can be seen as extending the strategy of Sung et al. (2018) to include a learnable attention module. A trainable attention module, inspired from Jetley et al. (2018), is added to incorporate the relation module of RelationNets. Besides, we make use of pretrained (contextual) embeddings since they have the proven strength on feature extraction for linguistics items instead of using embedding module, Figure 2.

For AttentiveRelationalNets, as shown in Figure 2, we implement two convolution blocks as it is in RelationNets with residual connection, as proposed in He et al. (2016).Then, the convolution blocks produce local descriptors, i.e., l_1 and l_2, as the output of activation function and pass them to the attention estimator in order to find the global g feature vector.

In order to compute the compatibility function, we define a convolution function with the input of two local features to an addition operation, $c = \langle u, l_1 + l_2 \rangle$. Here, u represents the universal set of features relevant to the s and q pairs in the object categories. We normalize the compatibility scores by using sigmoid operation, $a = \sigma(c)$. Then, the global feature vector is assessed by element-wise weighted average, i.e, $g = l_1 * a$. Afterwards, we concatenate the global features g with learned compatibility scores c as the input of the linear classifier which eventually produces a scalar in range of 0 to 1 representing the similarity between s and q , which is called relation score r. We define *mean square error*, as proposed in RelationNets, as the objective function of our model.

2.4 Evaluation

As we use the same implementation details for meta-training and meta-testing stages, we also evaluate the performance by few-shot classification accuracy following previous studies few-shot learning (Vinyals et al., 2016; Snell et al., 2017; Sung et al., 2018) with a small change: since the meta-learning approaches are fast learning methods, we present the average accuracies of training epochs instead of presenting the best accuracy.

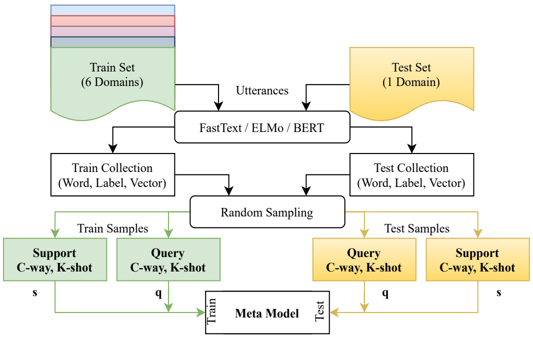

Figure 3: The schema of few-shot data construction for train and test episodes. 6 different domains are used for training phase whereas one different domain is used for test. Green path indicates the training support and query samples while yellow path represents the samples of test episodes. Train and test collections include N number of values of each slot. Random sampling function draws K samples for each of C slots.

3 Settings

3.1 Resources

In our study we address the few-shot learning approaches to recognize novel slot categories with very few examples from a new domain. In order to provide a deep experimental analysis of proposed networks and language models and to compare our model among each other, we set various experimental scenarios with different data and different K-shot sizes. Hence, we utilize the SNIPS dataset (Coucke et al., 2018) as a base dataset in our experiment. SNIPS is a SLU dataset of crowd-sourced user utterances with 39 slots and 7 intents. Thus, it is a well-categorized dataset which include tasks in domains, which makes the setup more realistic; learn to learn on a bunch of domains and test on new domains. We split SNIPS with the purpose of creating a single-domain dataset. We combine the originally divided training, testing, and development sets and separate them into domain sets in order to create new train and test data.

3.2 Few-shot Data Construction

Meta-learning models aim to learn from the training tasks, i.e. the train label space is disjoint with test label space and the trained model evaluated on unseen classes. Therefore, we utilize other domain data as the training set whereas the models are evaluated by using the current domain. Thus, we created 7 different sets contain a train which consists of 6 different domains as well as a test set which includes only one test domain.

As can be seen from Figure 3, we aggregate the six different domain data for the training set, whereas the remain one domain is used for testing, aiming at evaluating the performance of models on unseen classes per domain. Then, we convert the train and test sets to *train* and *test* collection that contain triplets in order to mimic the same data organization in the previous meta-learning studies. The triplet consists of three items: token, label, vector. The vector of the corresponding token is produced by using different (contextual) embeddings from randomly selected sentences for each label from the train and test set separately. Thus, the train collection is formed with the triplets from the different domain slots, whereas the test collection includes only the triplets of labels from the corresponding domain.

To investigate the efficiency of different models according to data availability in the few-shot setting, we experiment with three data collections sizes of slot values: 50, 100, and 200. Note that the collection size controls the total number of values that can be seen for each slot during training. In the meta-testing stage, we only use the test collection with size of 200 to be able to keep the comparative analyses under control. Furthermore, we examine different numbers of K shot, namely 5-shot, 10-shot, and 15-shot.

4 Results and Analysis

4.1 Different Network Architectures

Table 1 shows the performance in comparison with state of the art metric-based learning models on slot tagging task with different (contextual) embeddings. As can be seen from the scores, RelationNets with ELMo embeddings constantly give the best results, whereas MatchingNets present the lowest scores for each embedding variance. We assume that learning from the distance or relation scores with individual support and query samples instead of the class sum, i.e., as it is in PrototypicalNets, or class mean, i.e., as it is in RelationNets, decrease the learning performance.

Furthermore, Table 2 presents the results from AttentiveRelationalNets with different embeddings methods and demonstrates that our proposed model with ELMo and BERT outperforms the previous models consistently. Additionally, AttentiveRelationalNets significantly improve the results with BERT from the previous experiments in Table 1. When the success of AttentiveRelationalNets is

examined extensively, it seems that our proposed model gives better results on slot labels that categorize common nouns, while provides relative competitive results for proper nouns. Note that proper nouns, in general, seem to be challenging for all setups. In addition, RelationalNets outperform AttentiveRelationalNets with FastText along with the explanation that embedding function is still effective with average embeddings. However, as opposed to RelationNets, Attentive Relational Networks do better classification overall because of trainable attention. Since trainable attention highlights the relevant features between the slot values labeled with the same slot, whereas it suppresses the misleading them. In an other word, slot local features are able to be more informative for the model while the global features are suppressed.

4.2 Different Contextual Embeedings

Table 2 shows that ELMo and BERT have comparable performance, with BERT slightly better on most tasks: ELMo, however, scores higher on *FindScreeningE.* consistently with AttentiveRelationalNets and all different Ks. Although embedding modules are presented as a feature extraction method for inputs according to distance or relational score, the significant performance gap between FastText and contextualized embeddings shows that the contextualized features outperform the embedding module of few-shot classification models. On the other hand, when we compare FastText embeddings with contextualized word vectors in Table 2, the lower results can be seen. Additionally, when FastText features are compared between the results of RelationNets and AttentiveRelationalNets, we observe that RelationNets outperform AttentiveRelationalNets.

We further look at the wrong predictions in order to understand the reason for the success of ELMo on *FindScreeningE.* and observe that ELMo shows high performance on the labels of proper nouns such as city and location and the labels like *object_type* and *movie_type*. However, BERT demonstrates high performance on proper nouns such as artist, album, hence it outperforms ELMo on *AddToPlaylist* and *PlayMusic* domains. In addition, the improvement of BERT with AttentiveRelationalNets mostly relies on the increase of the accuracy of overall labels, but especially the slot labels that contain common nouns.

4.3 Different Collection and Shot Sizes

AttentiveRelationalNets demonstrate a linear correlation between the increase of performance and the increase of collection size. In addition, the increase of shot size mostly shows improvement in overall results, apart from PrototypicalNets which show their highest result with 10-shot.

5 Conclusion

We presented a deep analysis with a wide variety of few-shot learning methods and pretrained (contextual) embeddings for slot tagging. Furthermore, we proposed a novel architecture that leverages attention mechanism attending both, local and global features of given support samples. Experimental results on SNIPS dataset show that a) pretrained contextual embeddings contributed to high performance and b) our proposed approach consistently outperformed other methods in all setups.

SpanEmo: Casting Multi-label Emotion Classification as Span-prediction

Hassan Alhuzali **Sophia Ananiadou**
National Centre for Text Mining
Department of Computer Science, The University of Manchester, United Kingdom
{hassan.alhuzali@postgrad.,sophia.ananiadou@}manchester.ac.uk

Abstract

Emotion recognition (ER) is an important task in Natural Language Processing (NLP), due to its high impact in real-world applications from health and well-being to author profiling, consumer analysis and security. Current approaches to ER, mainly classify emotions independently without considering that emotions can co-exist. Such approaches overlook potential ambiguities, in which multiple emotions overlap. We propose a new model "SpanEmo" casting multi-label emotion classification as span-prediction, which can aid ER models to learn associations between labels and words in a sentence. Furthermore, we introduce a loss function focused on modelling multiple co-existing emotions in the input sentence. Experiments performed on the SemEval2018 multi-label emotion data over three language sets (i.e., English, Arabic and Spanish) demonstrate our method's effectiveness. Finally, we present different analyses that illustrate the benefits of our method in terms of improving the model performance and learning meaningful associations between emotion classes and words in the sentence[1].

1 Introduction

Emotion is essential to human communication, thus emotion recognition (ER) models have a host of applications from health and well-being (Alhuzali and Ananiadou, 2019; Aragón et al., 2019; Chen et al., 2018) to consumer analysis (Alaluf and Illouz, 2019; Herzig et al., 2016) and user profiling (Volkova and Bachrach, 2016; Mohammad and Kiritchenko, 2013), among others. Interest in this area has given rise to new NLP approaches aimed at emotion classification, including single-label and multi-label emotion classification. Most existing approaches for multi-label emotion classification (Ying et al., 2019; Baziotis et al., 2018; Yu et al., 2018; Badaro et al., 2018; Mulki et al., 2018; Mohammad et al., 2018; Yang et al., 2018) do not effectively capture emotion-specific associations, which can be useful for prediction, as well as learning of association between emotion labels and words in a sentence. In addition, standard approaches in emotion classification treat individual emotion independently. However, emotions are not independent; a specific emotive expression can be associated with multiple emotions. The existence of association/correlation among emotions has been well-studied in psychological theories of emotions, such as Plutchik's wheels of emotion (Plutchik, 1984) that introduces the notion of mixed and contrastive emotions. For example, "joy" is close to "love" and "optimism", instead of "anger" and "sadness".

#	Sentence	GT
S1	well my day started off great the mocha machine wasn't working @ mcdonalds.	anger, disgust, joy, sadness
S2	I'm doing all this to make sure you smiling down on me bro.	joy, love, optimism

Table 1: Example Tweets from SemEval-18 Task 1. GT represents the ground truth labels.

Consider S1 in Table 1, which contains a mix of positive and negative emotions, although it is more negative oriented. This can be observed clearly via the ground truth labels assigned to this example, where the first part of this sentence only expresses a positive emotion (i.e., joy), while the other part expresses negative emotions. For example, clue words like "great" are more likely to be associated with "joy", whereas "wasn't working" are more likely to be associated with negative emotions. Learning such associations between emotion labels and

---

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1573–1584
April 19 - 23, 2021.

words in a sentence can help ER models to predict the correct labels. S2 further highlights that certain emotions are more likely to be associated with each other. Mohammad and Bravo-Marquez (2017) also observed that negative emotions are highly associated with each other, while less associated with positive emotions. Based on these observations, we seek to answer the following research questions: i) how to enable ER models to learn emotion-specific associations by taking into account label information and ii) how to benefit from the multiple co-existing emotions in a multi-label emotion data set with the intention of learning label correlations. Our contributions are summarised as follows:

I. a novel framework casting the task of multi-label emotion classification as a span-prediction problem. We introduce "SpanEmo" to train the model to take into consideration both the input sentence and a label set (i.e., emotion classes) for selecting a span of emotion classes in the label set as the output. The objective of SpanEmo is to predict emotion classes directly from the label set and capture associations corresponding to each emotion.

II. a loss function, modelling multiple co-existing emotions for each input sentence. We make use of the label-correlation aware loss (LCA) (Yeh et al., 2017), originally introduced by Zhang and Zhou (2006). The objective of this loss function is to maximise the distance between positive and negative labels, which is learned directly from the multi-label emotion data set.

III. a large number of experiments and analyses both at the word- and sentence-level, demonstrating the strength of SpanEmo for multi-label emotion classification across three languages (i.e. English, Arabic and Spanish).

The rest of the paper is organised as follows: section 2 describes our methodology, while section 3 discusses experimental details. We evaluate the proposed method and compare it to related methods in section 4. Section 5 reports on the analysis of results, while section 6 reviews related work. We conclude in section 7.

2 Methodology

2.1 Framework

Figure 1 presents our framework (SpanEmo). Given an input sentence and a set of classes, a base encoder was employed to learn contextualised word representations. Next, a feed forward network (FFN) was used to project the learned representations into a single score for each token. We then used the scores for the label tokens as predictions for the corresponding emotion label. The green boxes at the top of the FFN illustrate the positive label set, while the red ones illustrate the negative label set for multi-label emotion classification. We now turn to describing our framework in detail.

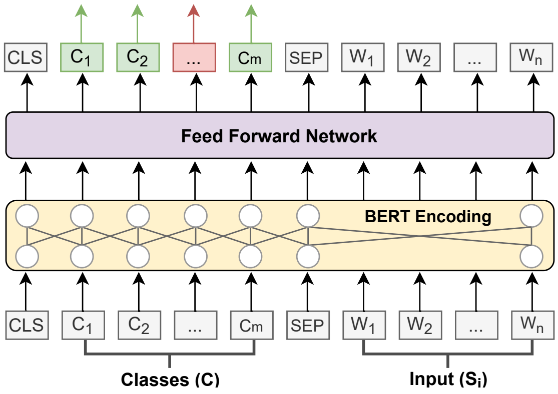

Figure 1: Illustration of our proposed framework (SpanEmo).

2.2 Our Method (SpanEmo)

Let $\{(s_i, y_i)\}_{i=1}^{N}$ be a set of N examples with the corresponding emotion labels of C classes, where s_i denotes the input sentence and $y_i \in \{0,1\}^m$ represents the label set for s_i. As shown in Figure 1, both the label set and the input sentence were passed into the encoder BERT (Devlin et al., 2019). The encoder received two segments: the first corresponds to the set of emotion classes, while the second refers to the input sentence. The hidden representations ($H_i \in R^{T \times D}$)[2] for each input sentence and the label set were obtained as follows:

$$\mathrm{H}_i = \mathrm{Encoder}([\mathrm{CLS}] + |\mathrm{C}| + [\mathrm{SEP}] + \mathrm{s}_i), \quad (1)$$

where {[CLS], [SEP]} are special tokens and |C| denotes the size of emotion classes. Feeding both segments to the encoder has a few advantages. First, the encoder can interpolate between emotion classes and all words in the input sentence. Second, a hidden representation is generated both for words and emotion classes, which can be further used to understand whether the encoder can learn association between the emotion classes and words in the input sentence. Third, SpanEmo is flexible because its predictions are directly produced from the first segment corresponding to the emotion classes.

---

[2] T and D denote the input length and dimensional size, respectively.

We further introduced a feed-forward network (FFN) consisting of a non-linear hidden layer with a Tanh activation ($f_i(\text{H}_i)$) as well as a position vector $p_i \in R^D$, which was used to compute a dot product between the output of f_i and p_i. As our task involved a multi-label emotion classification, we added a sigmoid activation to determine whether class$_i$ was the correct emotion label or not. It should be mentioned that the use of the position vector is quite similar to how start and end vectors are defined in transformer-based models for question-answering. Finally, the span-prediction tokens were obtained from the label segment and then compared with the ground truth labels since there was a 1-to-1 correspondence between the label tokens and the original emotion labels.

$$\hat{\mathbf{y}} = \text{sigmoid}(\text{FFN}(\mathbf{H}_i)), \tag{2}$$

2.3 Label-Correlation Aware (LCA) Loss

Following Yeh et al. (2017), we employed the label-correlation aware loss, which takes a vector of true-binary labels (y), as well as a vector of probabilities ($\hat{y}$), as input:

$$\mathcal{L}_{\text{LCA}}(\mathbf{y}, \hat{\mathbf{y}}) = \frac{1}{|\mathbf{y}^0||\mathbf{y}^1|} \sum_{(p,q)\in \mathbf{y}^0 \times \mathbf{y}^1} \exp(\hat{\mathbf{y}}_p - \hat{\mathbf{y}}_q), \tag{3}$$

where y^0 denotes the set of negative labels, while y^1 denotes the set of positive labels. $\hat{y}_p$ represents the p^{th} element of vector $\hat{y}$. The objective of this loss function is to maximise the distance between positive and negative labels by implicitly retaining the label-dependency information. In other words, the model should be penalised when it predicts a pair of labels that should not co-exist for a given example.

2.4 Training Objective

To model label-correlation, we combined LCA loss with binary cross-entropy (BCE) and trained them jointly. This aimed to help the LCA loss to focus on maximising the distance between positive and negative label sets, while at the same time taking advantage of the BCE loss through maximising the probability of the correct labels. We experimentally observed that training our approach jointly with those two loss functions produced the best results. The overall training objective was computed as follows:

$$\mathcal{L} = (1-\alpha)\mathcal{L}_{\text{BCE}} + \alpha \sum_{i=1}^{M} \mathcal{L}_{\text{LCA}}, \tag{4}$$

where $\alpha \in [0, 1]$ denotes the weight used to control the contribution of each part to the overall loss.

3 Experiments

3.1 Implementation Details

We used PyTorch (Paszke et al., 2017) for implementation and ran all experiments on an Nvidia GeForce GTX 1080 with 11 GB memory. We also trained BERT$_{\text{BASE}}$ utilising the open-source Hugging-Face implementation (Wolf et al., 2019). For experiments related to Arabic, we chose "bert-base-arabic" developed by Safaya et al. (2020), while selecting "bert-base-spanish-uncased" developed by Cañete et al. (2020) for Spanish. All three models were trained on the same hyper-parameters with a fixed initialisation seed, including a feature dimension of 786, a batch size of 32, a dropout rate of 0.1, an early stop patience of 10 and 20 epochs. Adam was selected for optimisation (Kingma and Ba, 2014) with a learning rate of $2e$-5 for the BERT encoder, and a learning rate of $1e$-3 for the FFN. It should be mentioned that we tuned our method only on the validation set and further report on the analysis of the effect of parameter α in section 5.4. Table 2 summarises the hyper-parameters used in our experiments.

Parameter	**Value**
Feature dimension	768
Batch size	32
Dropout	0.1
Early stop patience	10
Number of epochs	20
lr-BERT	$2e$-5
lr-FFN	$1e$-3
Optimiser	Adam
Alpha (α)	0.2

Table 2: Hyper-parameter values. lr: refers to the Learning rate.

3.2 Data Set and Task Settings

In this work, we chose semEval2018 (Mohammad et al., 2018) for our multi-label emotion classification, which is based on labelled data from tweets in English, Arabic and Spanish. The data was originally partitioned into three sets: training set (Train), validation set (Valid) and test (Test) set. Following the metrics in Mohammad et al. (2018), we run our experiments on micro F1-score, macro F1-score and Jaccard index score[3]. Table 3 presents the summary of all three sets for each language, including the number of instances in the train, valid and test sets. In addition, the number of emotion classes and the percentage of instances with varying numbers of classes (co-existing) are included. It is worth noting that these percentages do not include the neutral instances.

Info./Lang.	**English**	**Arabic**	**Spanish**
Train (#)	6,838	2,278	3,561
Valid (#)	886	585	679
Test (#)	3,259	1,518	2,854
Total (#)	10,983	4,381	7,094
Classes (#)	11	11	11
1 co.emo (%)	14.36	21.38	39.11
2 co.emo (%)	40.55	39.03	42.15
3 co.emo (%)	30.92	29.85	12.76

Table 3: Data Statistics. co.emo: refers to the percentage of co-existing emotions.

To pre-process the data, we utilised a tool designed for the specific characteristics of Twitter, i.e., misspellings and abbreviations (Baziotis et al., 2017). The tool offers different functionalities, such as tokenisation, normalisation, spelling correction, and segmentation. We used the tool to tokenise the text, convert words to lower case, normalise user mentions, urls and repeated-characters.

3.3 Multi-label Emotion Classification

We compared the performance of SpanEmo to some baseline as well as state-of-the-art models on all three languages. For experiments related to English, we selected seven models, while we chose three models for both Arabic and Spanish. We also include the results of $\text{BERT}_{\text{BASE}}$.

3.3.1 English

English models include JBNN (He and Xia, 2018), DATN (Yu et al., 2018), NTUA (Baziotis et al., 2018), RERc (Zhou et al., 2018), $\text{BERT}_{\text{BASE}}$+DK (Ying et al., 2019), $\text{BERT}_{\text{BASE}}$-GCN (Xu et al., 2020) and LEM (Fei et al., 2020). JBNN introduces a joint binary neural network, which focuses on learning the relations between emotions based on the theory of Plutchik's wheel of emotions (Plutchik, 1980), and then performing multi-label emotion classification via integrating these label relations into the loss function. DATN proposes a dual attention transfer network to improve multi-label emotion classification with the help of sentiment classification, while NTUA is ranked the top-1 model of the SemEval2018 competition as it relies on different pre-training and fine-tuning strategies. RERc defines a ranking emotion relevant loss focused on incorporating emotion relations into the loss function to improve both emotion prediction and rankings of relevant emotions. Both $\text{BERT}_{\text{BASE}}$+DK and $\text{BERT}_{\text{BASE}}$-GCN utilise the same encoder as our own with the former considering additional domain knowledge (DK) and the latter capturing emotion relations through Graph Convolutional Network (GCN), respectively. LEM introduces a latent emotion memory network, in which the latent emotion module learns emotion distribution via a variational autoencoder, while the memory module captures features corresponding to each emotion.

3.3.2 Arabic

Arabic models consist of EMA (Badaro et al., 2018), Tw-StAR (Mulki et al., 2018) and HEF (Alswaidan and Menai, 2020). EMA is the best performing model from the SemEval2018 competition on this set. It utilises various pre-processing steps (e.g. diacritics removal, normalisation, emojis transcription and stemming), as well as different classification algorithms. The Tw-StAR model applies some pre-processing steps and then uses TF-IDF to learn features of a Support Vector Machine. HEF is based on a hybrid neural network, including different word embeddings (e.g. Word2Vec, Glove, FastText) plus variations of RNN neural networks, such as Long Short-Term Memory and Gated Recurrent Unit.

3.3.3 Spanish

Spanish models comprise Tw-StAR (Mulki et al., 2018), ELiRF (González et al., 2018) and MILAB (Mohammad et al., 2018). The ELiRF model applies some pre-processing steps while also adapting the tweet tokeniser for Spanish tweets. MILAB is the best performing model from the SemEval2018 shared-task on this set.

4 Results

Table 4 presents the performance of our proposed approach (SpanEmo) on all three languages, in terms of micro F1-score (miF1), macro F1-score (maF1) and Jaccard index score (jacS), and compares it to the baseline and state-of-the-art models

---

[3] jacS is defined as the size of the intersection divided by the size of the union of the true label set and predicted label set.

discussed in section 3.3.

Table 4: The results of multi-label emotion classification on SemEval-2018 test set.

As shown in Table 4, our method outperformed all models on all languages, as well as on almost all metrics, with a marginal improvement of up to 1-1.3% for English, 1.9-3.6% for Arabic and 6.3-9.2% for Spanish. This demonstrates the utility and advantages of SpanEmo, as well as the label-correlation aware loss for improving the performance of multi-label emotion classification in English, Arabic and Spanish.

Based on the empirical results reported in Table 4, the following observations can be made. First, incorporating the relations between emotions into the models tends to lead to higher performance, especially for macro F1-score. For example, both DATN and LEM learn emotion-related features and achieve better performance than NTUA and $\text{BERT}_{\text{BASE}}$+DK. Additionally, ELiRF makes use of various sentiment/emotion features (i.e., learned from lexica) and it yielded the best performance among the three compared models. This corroborates our earlier hypothesis that learning emotion-specific associations is crucial for improving the performance. Although $\text{BERT}_{\text{BASE}}$+DK adopts the same encoder as our own and adds domain knowledge, our method still performs strongly, especially for both macro F1- and jaccard score with a marginal improvement of up to 2.9% and 1%, respectively. In short, capturing emotion-specific associations as well as integrating the relations between emotions into the loss function, helped SpanEmo to achieve the best results compared with all models on almost all metrics.

4.1 Ablation Study

To understand the effect of our framework, we undertook an ablation study of the model performance under three settings: firstly, the model was trained only with BCE loss; secondly, it was trained only with LCA loss; and thirdly it was trained without the label segment. The third setting is equivalent to training the model as a simple multi-label classification task, by only considering the input sentence.

Language	**English**		
Model/Metric	**miF1**	**maF1**	**jacS**
SpanEmo (joint)	**0.713**	0.578	**0.601**

$\text{BERT}_{\text{base}}$	BCE	0.603	0.476	0.526	0.567	0.461	0.441	0.518	0.432	0.364
SpanEmo	BCE	0.653	0.528	0.561	0.646	0.528	0.519	**0.663**	0.566	**0.508**
SpanEmo	Joint	**0.662**	**0.565**	**0.581**	**0.655**	**0.568**	**0.530**	0.644	**0.570**	0.490

Table 6: Presenting the number of co-existing emotion classes. The best results in each language group are marked in bold.

by 1-2% for macro F1- and jaccard score. In addition, the results of SpanEmo dropped by 1-2% for two metrics apart from the macro F1-score when trained without the BCE loss. However, the removal of the label segment led to a much higher drop of 3-6%. The same patterns were also observed in the Arabic and Spanish experiments. This supports our earlier hypothesis that casting the task of multi-label emotion classification as span-prediction is beneficial for improving both the representation and performance of multi-label emotion classification.

5 Analysis

5.1 Prediction of Multiple Emotions

We additionally validated the effectiveness of our method for learning the multiple co-existing emotions on English, Arabic and Spanish sets. Table 6 presents the results, including $\text{BERT}_{\text{BASE}}$. SpanEmo demonstrated a strong ability to handle multi-label emotion classification much better than $\text{BERT}_{\text{BASE}}$. Since $\text{BERT}_{\text{BASE}}$ is trained only with binary cross-entropy (BCE) loss, here we include the results of our method trained only with this loss function. SpanEmo still achieved consistent improvement as the number of co-existing emotions increases, showing the usefulness of our method in learning multiple emotions. Improvement can clearly be observed for English and Arabic experiments, but not as much for Spanish. This may be attributed to the high percentage of single-label data, which is around (40%) for Spanish, while it is lower than that for both English and Arabic. Obviously, SpanEmo can be used without LCA loss, and still obtain descent performance. Nevertheless, training our method jointly with the LCA loss leads to better results.

5.2 Learning Emotion-specific Associations

5.2.1 Word-Level

In this section, we present the top 10 words learned by SpanEmo for each emotion class by extracting the learned representations for each emotion class and all words in every input sentence, and then computing the similarity between them via cosine similarity. Finally, we performed this operation on all inputs in the SemEval2018 English validation set and then sorted all words for each emotion class in ascending order.

Table 7 presents the top-10 words per emotion class. As shown in Table 7, the words discovered by our framework are indicative of the corresponding emotion. This helps to show that SpanEmo learns meaningful associations between emotion classes and words automatically, which can be beneficial for feature extraction and learning. Additionally, SpanEmo demonstrated that it can learn diverse words as well as shareable words across some emotions. For example, the words $\{pissed, wrath, smashed\}$ are associated with both anger and disgust, demonstrating the ability of SpanEmo to learn the relations between emotions.

Emotion	Top 10 Words
anger	anger pissed wrath idiots dammit kicking irritated thrown smashed complain
anticipation	prediction planning mailsport assumptions upcoming waiting route waited frown ideas
disgust	disgusting smashed gross hate pissed wrath dirty awful vile dumb
fear	nervous fear terror frightening afraid frown panic terrifying scary dreading
joy	happy excitement joyful congratulations glad delightful excited adorable amusing smiling
love	love sweetness loved hug mate lucky carefree shine care gracious
optimism	optimism integrity salvation persevere perspective bright effort faith glad lord
pessimism	hopeless frown disappointed weary dread despair depressing chronic suicide pain
sadness	sadness frown depressing saddened hurt disappointed weary upset sorrow hate
surprise	stunned awestruck shocking awe mailsport buster genuinely curious hardly believing
trust	integrity shine respect courage sign effort confident faith easy kindness

Table 7: Top 10 words associated with each corresponding emotion.

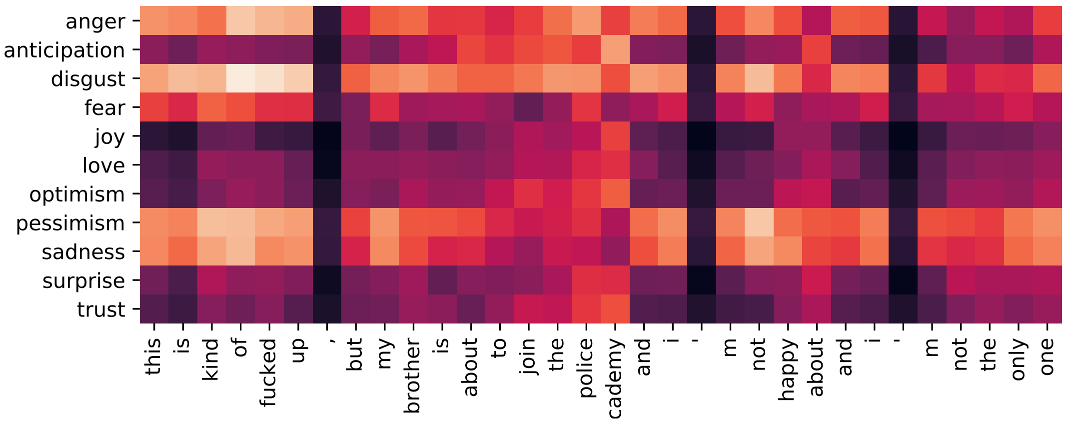

Figure 2: Visualisation on an example. The left presents the emotion labels, and the bottom presents the example. Each cell shows the cosine similarity value computed via using the hidden representation of each word and label. Lighter colour indicates higher similarity.

5.2.2 Sentence-Level

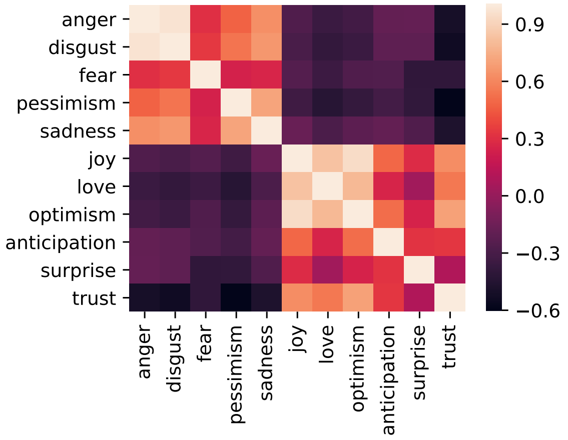
We visualised an example from the English validation set annotated with four emotions, which were anger, disgust, pessimism and sadness. Our goal was to determine whether by adding emotion classes to the example, SpanEmo could learn their associations to each other (i.e., associations between emotion classes and words in the example). To compute the similarity between emotion classes and words in the example, we also followed the same process discussed in section 5.2.1.

Figure 2 presents the results, where lighter cells indicate higher similarity, while darker cells indicate lower similarity. As shown in Figure 2, the learned representations capture the association between the correct emotion label set and every token in the example. Interestingly, we can also observe that the word "happy" is usually expressed as a positive emotion, but, in this context, this word becomes negative and the model learns this contextual information. Moreover, the phrase "about to join the police academy" is associated with "anticipation", which makes sense although this class is not part of the correct label set. This demonstrates the utility and advantages of our approach not only in deriving associations reported in the annotations, but also providing us with a mechanism to explore additional information beyond them.

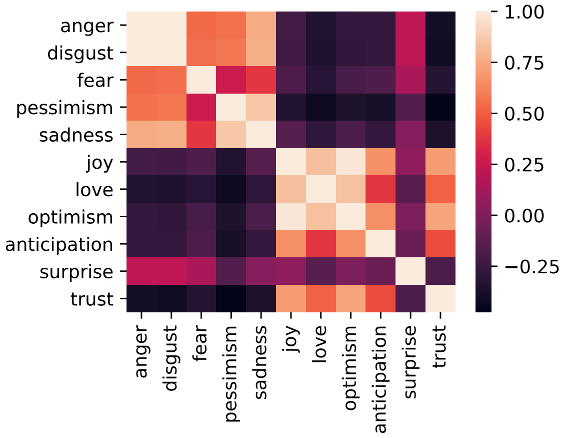
5.3 Label Correlations

Since one of the research questions in this paper was to learn the multiple co-existing emotions from a multi-label emotion data set, we analysed the learned emotion correlations from SpanEmo and compared them to those adopted from the ground truth labels in the SemEval2018 validation set. Figure 3 presents the two emotion correlations as obtained from the ground truth labels and from the predicted labels, respectively.

It can be observed that Figure 3(b) is almost identical to 3(a), demonstrating that our method in capturing the emotion correlations is in line with



(a) Emotion correlations: GT



(b) Emotion correlations: Prediction

Figure 3: The top plot presents emotion correlations obtained from the ground truth (GT) labels, whereas the bottom plot presents emotion correlations obtained from the predicted labels.

what the emotion annotations have revealed. 3(b), which was learned by SpanEmo, also highlights that negative emotions are positively correlated with each other, and negatively correlated with positive emotions. For example, “anger and disgust” share almost the same patterns, which is consistent with the studies of Mohammad and Bravo-Marquez (2017) and Agrawal et al. (2018), both of which report the same issue with negative emotions of “anger” and “disgust”, as they are easily confused with each other. This is not surprising as their manifestation in language is quite similar in terms of the use of similar words/expression. We also noted this finding when analysing the top-10 key words learned by SpanEmo in section 5.2.1. In short, taking into account emotion correlations is crucial for multi-label emotion classification in addressing the ambiguity characteristic of the task, especially for emotions that are highly correlated.

5.4 Influence of Parameter (α)

SpanEmo was trained with BCE loss and with LCA loss via a weight (α), whose impact on the results is presented in Figure 4. It should be mentioned that this analysis was performed on the validation set of SemEval2018 data set. The lower bound (i.e., 0.0) indicates that the model was trained only with the BCE loss, whereas the upper bound (i.e., 1.0) indicates that it was trained only with the LCA loss. When the value of α increased from 0.0 to 0.5, the results first improved considerably and then gradually deteriorated apart from the results of the macro F1-score. The results of BCE loss favoured the micro F1- and jaccard score, whereas the results of LCA loss favoured the macro F1-score. However, integrating LCA with BCE can balance the results across all three metrics, resulting in strong performance. The best results were achieved on almost all metrics when the value of α was set to 0.2. Thus, we set the value of parameter α to 0.2 for all experiments reported in this paper.

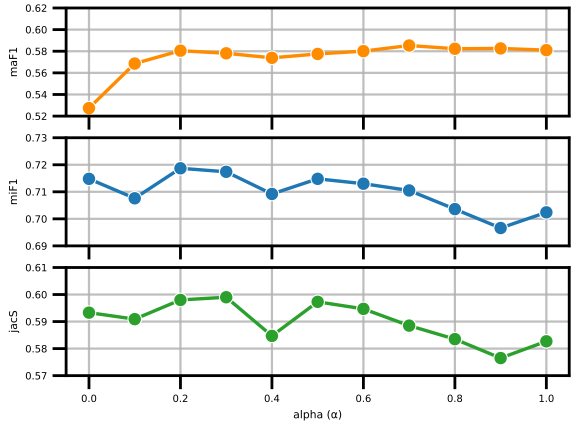


Figure 4: Sensitivity analysis of parameter (α). Note that $\alpha = 0.0$ means that only BCE loss is used in training SpanEmo, whereas $\alpha = 1.0$ means that only LCA loss is utilised in training it.

6 Related Work

There is a large body of NLP literature on emotion recognition (Mohammad and Alm, 2015). Earlier studies focused on lexicon-based approaches, which make use of some words and their corresponding labels to identify emotions in text, e.g. NRC[4] (Mohammad and Turney, 2013) and

---

[4] Bravo-Marquez et al. (2016) proposes an approach for expanding it for the language used in Twitter.

EmoSenticNet (Poria et al., 2014). Other methods treat the emotion recognition task as a supervised learning task, in which a learner (e.g. linear classifier based methods) is trained on the features of labelled data to classify inputs into one label (Bostan and Klinger, 2018; Liew et al., 2016; Mohammad et al., 2015; Tang et al., 2013; Wang et al., 2012; Aman and Szpakowicz, 2007).

More recently, several neural network models have been developed for this task, obtaining competitive results on different emotion data sets. Some of these models generally focus on a single-label emotion classification, in which only a single label is assigned to each input (Islam et al., 2019; Xia and Ding, 2019; Alhuzali et al., 2018b,a; Agrawal et al., 2018; Saravia et al., 2018; Felbo et al., 2017; Abdul-Mageed and Ungar, 2017). Other models have also been proposed for multi-label emotion classification, in which one or more labels are assigned to each input (see detailed description in section 3.3).

Our work is motivated by research focused on learning features corresponding to each emotion as well as incorporating the relations between emotions into a loss function (Fei et al., 2020; He and Xia, 2018). Our work differs from these two works in the following ways: i) our method learns features related to each corresponding emotion without relying on any external resources (e.g. lexicons). ii) We further integrated the relations between emotions into the loss function by taking advantage of the label co-occurrences in a multi-label emotion data set. In this respect, our approach does not rely on any theory of emotion. iii) We empirically evaluated our method for three languages, demonstrating its effectiveness as being language agnostic. In contrast to previous research, we focus on both learning emotion-specific associations and integrating the relations between emotions into the loss function.

7 Conclusion

We have proposed a novel framework "SpanEmo" aimed at casting multi-label emotion classification as a span-prediction problem. We demonstrated that our proposed method outperforms prior approaches reported in the literature on three languages (i.e., English, Arabic and Spanish). Our empirical evaluation and analyses also demonstrated the utility and advantages of our method for multi-label emotion classification, specifically the addition of emotion classes to the input sentence, which helped the model learn emotion-specific associations and increase its performance. Finally, training our method with LCA loss jointly led to better results, showing the benefits of integrating the relations between emotions into the loss function.

The standard approach in a multi-label emotion classification problem often focuses on modelling individual emotion independently. In this respect, most existing methods do not take into account label dependencies while learning emotion-specific associations. However, we demonstrated the effectiveness of including label information to the input sentence when training SpanEmo, helping it achieve better performance and capture emotion correlations. We hope that this study will inspire the community to investigate further the vital role of learning label dependencies and associations corresponding to each emotion.

Abstract

Keyphrases associated with research papers provide an effective way to find useful information in the large and growing scholarly digital collections. In this paper, we present KPRank, an unsupervised graph-based algorithm for keyphrase extraction that exploits both positional information and contextual word embeddings into a biased PageRank. Our experimental results on five benchmark datasets show that KPRank that uses contextual word embeddings with additional position signal outperforms previous approaches and strong baselines for this task.

1 Introduction

Keyphrase extraction is the task of automatically extracting a small set of descriptive words or phrases that can accurately summarize the topics discussed in a document (Hasan and Ng, 2010, 2014). Keyphrases are useful in many applications such as document indexing and summarization (Abu-Jbara and Radev, 2011; Qazvinian et al., 2010; Turney, 2003), topic tracking (Augenstein et al., 2017), contextual advertising (Yih et al., 2006), and opinion mining (Berend, 2011).

Most of the previous approaches to keyphrase extraction are either supervised or unsupervised. While supervised approaches perform generally better (Kim et al., 2013), the unsupervised ones have the advantage that they do not require large human-annotated corpora for training reliable models. Unsupervised keyphrase extraction methods usually use graph-based ranking algorithms such as PageRank that work on the word graph constructed from the target document (Mihalcea and Tarau, 2004). Various PageRank extensions have been proposed that incorporate different types of information (Wan and Xiao, 2008; Gollapalli and Caragea, 2014). For example, Wan and Xiao (2008) proposed to incorporate a local neighborhood of the target document into the graph construction, with the neighborhood being determined based on the textual similarity between documents. Liu et al. (2010) exploited topical information to select keyphrases from all major topics. More recently, Mahata et al. (2018) proposed a theme-weighted biased PageRank, called Key2Vec, for keyphrase extraction. In Key2Vec, a theme-vector is computed by averaging the embeddings of words and phrases from the title of a scientific document to capture its theme and the PageRank is biased based on the similarity of candidate words or phrases to the computed theme vector. However, this model is oblivious to the position of words in a scientific document, in which more important words appear not only frequently, but also close to the beginning of the document (Florescu and Caragea, 2017).

Inspired by the Transformer models (Vaswani et al., 2017) that infuse positional information into the word embeddings to produce embeddings with time signal, we propose an extension of Key2Vec that incorporates words' positions into a biased PageRank. Moreover, different from Mahata et al. (2018), who used non-contextual FastText embeddings (Mikolov et al., 2018), we propose to integrate SciBERT contextual embeddings (Beltagy et al., 2019) into our biased PageRank extension. Our contributions are as follows: (1) We propose KPRank, an unsupervised graph-based algorithm that exploits both the position of words in a document and the contextual word embeddings for computing a biased PageRank score for ranking candidate phrases; (2) We show empirically that infusing position information into our biased KPRank model yields better performance compared with its counterpart that does not use the position information. In addition, KPRank with contextual SciBERT embeddings performs better than FastText-based KPRank; (3) Finally, we show that KPRank outperforms many previous unsupervised models.

April 19 - 23, 2021.

2 Proposed Approach

In this section, we describe our unsupervised graph-based algorithm called KPRank, that exploits both position information of the words in a document along with contextual word embeddings for computing a biased PageRank score for each candidate word. Our approach consists of three steps: (1) candidate word selection and word graph construction; (2) word scoring by biased PageRank; and (3) candidate phrase formation.

2.1 Candidate Word Selection and Graph Construction

For a target doucment D, we first apply a part-of-speech filter[1] and select only nouns and adjectives as candidate words, consistent with previous works (Gollapalli and Caragea, 2014; Mihalcea and Tarau, 2004; Wan and Xiao, 2008). We build a word graph $G = (N, E)$ for D using the candidate words as nodes in G. N and E are the sets of nodes and edges, respectively. We consider an edge $(n_i, n_j) \in E$ between two nodes n_i and n_j in N if the words corresponding to these nodes appear within a window of k consecutive words in the content of D. We experimented with values of k from 1 to 10 and obtained best results with $k = 10$, which is consistent with (Wan and Xiao, 2008). The weight of an edge (n_i, n_j), denoted as w_{ij}, is computed based on the co-occurrence count of the two words within k consecutive words in D ($k = 10$). Here, we build undirected graphs because prior work (Mihalcea and Tarau, 2004; Liu et al., 2010) observed that the type of graph (directed or undirected) used to represent the text does not significantly influence the performance of the keyphrase extraction task.

2.2 Biased PageRank

Preliminaries. PageRank (Page et al., 1998) is a graph-based ranking algorithm that iteratively calculates the importance of each node in a graph through endorsements from its neighbors. For document D, we construct an undirected graph G as explained above. Initially, the score of each node in G is set to $\frac{1}{|N|}$. This score is then iteratively updated using PageRank. That is, the score s for node n_i is obtained by applying the equation:

$$s(n_i) = (1 - \alpha)\widetilde{p_i} + \alpha \sum_{n_j \in Adj(n_i)} \frac{w_{ji}}{O(n_j)} s(n_j) \quad (1)$$

where $O(n_j) = \sum_{n_k \in Adj(n_j)} w_{jk}$ and $Adj(n_j)$ is the set of all adjacent nodes of node $n_j \in N$. $\widetilde{p_i}$ is defined below.

In order to prevent the PageRank from getting stuck in cycles or dead ends, a dumping factor α was added to Eq. (1) to allow the PageRank to randomly jump to any node in the graph ($\alpha = 0.85$). Let $\widetilde{p} = [\widetilde{p}_1, \cdots, \widetilde{p}_i, \cdots, \widetilde{p}_{|N|}]$ be the probability distribution of randomly jumping to any node in the graph. For an unbiased PageRank, this is a uniform distribution, with $\widetilde{p_i} = \frac{1}{|N|}$, for all i from 1 to $|N|$. For a biased PageRank, this probability distribution is not uniform, but rather the nodes in the graph are visited preferentially, with some nodes being visited more often than others, depending on the $\widetilde{p_i}$ value for node n_i (Haveliwala, 2003). Key2Vec is an example of (topic) biased PageRank for keyphrase extraction that computes $\widetilde{p_i}$ for node n_i using the cosine similarity between the embedding of word/phrase corresponding to node n_i and a theme vector for the entire document, which corresponds to the aggregated word/phrase embeddings from the document's title (Mahata et al., 2018). That is, $\widetilde{p_i}$ is higher for words/phrases that are topically (semantically) more similar to the overall theme vector for the document. Next, we describe our extension KPRank of Key2Vec.

KPRank. In our proposed approach, we calculate $\widetilde{p_i}$ for node n_i using two types of scores: *theme (or topic) score* and *positional score*. We multiply both scores to assign a final weight to node n_i before running the biased PageRank algorithm. Both scores and their calculation are explained below.

To calculate the *theme score* (ts_i) for node $n_i \in N$, we first calculate a theme vector (T_D) for document D. A *theme vector* is obtained by averaging SciBERT (Beltagy et al., 2019) word embeddings of adjectives and nouns from D's title. The *theme score* for node n_i is calculated using the cosine similarity of the SciBERT word embedding corresponding to node n_i and T_D. The idea is to assign a higher score to a word if that word is closer to the theme (topic) of a given document. For obtaining word embeddings, for all the words with similar stemmed version (obtained with Porter stemmer), we averaged the contextualized word embeddings of a word obtained by using SciBERT. We used the title and abstract of a document as input to the SciBERT model. We also experimented with pretrained BERT (Devlin et al., 2018), and found that the performance of BERT-based KPRank and SciBERT-based KPRank are very similar.

---

[1] We used Python's NLTK toolkit for POS tagging.

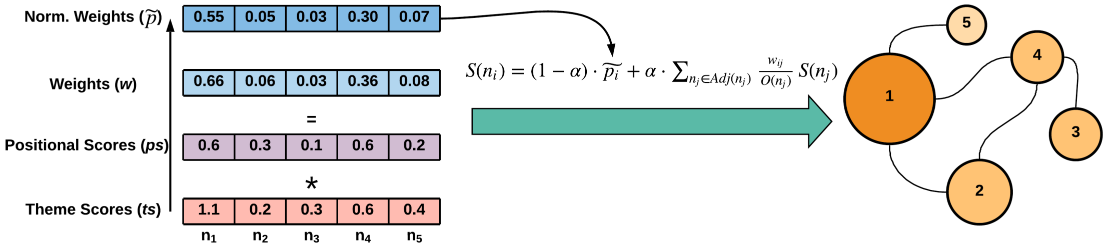

Figure 1: Illustration of our approach.

To calculate the *positional score* (ps_i) for node n_i, we consider the set P_i that contains all the positions of occurrence in the text of the word corresponding to node n_i. Then, ps_i is calculated as $ps_i = \sum_{j\in P_i}\frac{1}{j}$. For example, for a word occurring on positions 1 and 10 in the text, its ps_i score is $\frac{1}{1}+\frac{1}{10}$, whereas for a word occurring on position 100, its ps_i score is $\frac{1}{100}$. The intuition behind this weighting scheme is to give higher weight to words appearing in the beginning of a document since in scientific writing, authors tend to use keyphrases very early in the document (even from the title) (Florescu and Caragea, 2017). Based on these considerations, the first position of a phrase/word and its relative position are also used in many supervised approaches as powerful features (Patel and Caragea, 2019; Hulth, 2003; Wu et al., 2005)

To calculate the weight w_i for n_i, we perform multiplication of both the *theme score* (ts_i) and the *positional score* (ps_i). The intuition is that we give preference to words that appear near the beginning of the document and are more frequent as compared with less frequent words appearing later in document even though both words may be equally close to the theme of the document or may have similar theme score. The vector $\widetilde{p}$ is last set to the normalized weights for each node as follows:

$$\widetilde{p} = \left[\frac{w_1}{\sum_{i=1}^{|N|} w_i}, \frac{w_2}{\sum_{i=1}^{|N|} w_i}, \ldots, \frac{w_{|N|}}{\sum_{i=1}^{|N|} w_i}\right] \qquad (2)$$

The biased PageRank scores for each node n_i are finally calculated by iteratively applying Eq. (1) with $\widetilde{p}$ as in Eq. (2). Figure 1 shows the illustration of our approach. As can be seen, even though both n_1 and n_4 have similar *theme score*, final weights are different based on different *positional scores*.

In our experiments, the PageRank scores are updated until the difference between two consecutive iterations is ≤ 0.001 or for 100 iterations.

2.3 Candidate Phrases Formation

Candidate words appearing continuously in the document are concatenated to generate candidate phrases. We consider phrases with the regular expression (adjective)*(noun)+, of length up to four words, to generate candidate phrases. We used stemmed version of each word using Porter stemmer. We use POS tagger from Python's NLTK toolkit. The score for each candidate phrase is calculated by summing up the scores of its individual words (Wan and Xiao, 2008). The top-scoring phrases are output as predicted keyphrases for a given document.

Dataset	# Test Papers	Avg. # KP per doc.
SemEval	100	6.87
Inspec	500	8.82
Krapivin	400	3.48
NUS	211	5.49
ACM	20,000	2.67

Table 1: The summary of the datasets along with their gold-standard keyphrases (KP).

3 Data

For evaluation, we use five datasets, which we describe below. We use the combination of controlled (author assigned) and uncontrolled (reader assigned) keyphrases as gold-standard phrases. We used uncontrolled keyphrases when available. Table 1 shows the summary of the datasets.

SemEval (Kim et al., 2010) contains 288 research papers with a train and test split consisting of 188 and 100 papers, respectively.

Inspec (Hulth, 2003) contains 2,000 research papers. It has a train-validation-test split of 1,000, 500 and 500 papers, respectively.

Krapivin (Krapivin et al., 2009) contains 2,304 ACM research papers with full text and author-assigned keyphrases. Similar to (Meng et al., 2017), since the dataset does not have a train-test split, we sampled 400 papers as the test set.

NUS (Nguyen and Kan, 2007) contains 211 research papers. This dataset does not have a train and test split and it is relatively small. Hence, consistent with (Meng et al., 2017) we used entire dataset as the test set.

ACM (Patel and Caragea, 2019) This dataset

Table 2: The comparison of SciBERT (SB) based KPRank, and previous works.

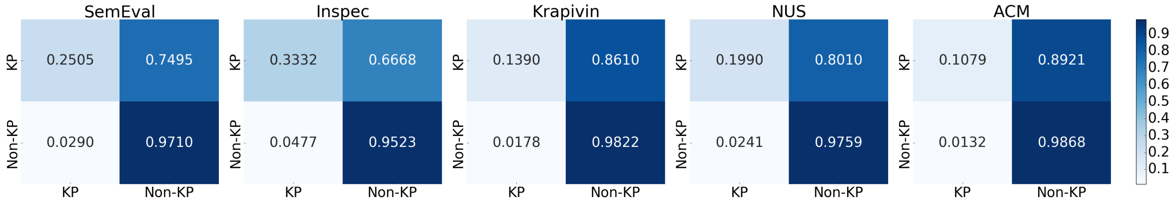

Figure 2: Keyphrase extraction confusion matrices of KPRank(SB) using @5 predictions on all the datasets. The darker the blue on the main diagonal, the more accurate the model is.

contains 30,000 papers published in ACM conferences with a train and test split consisting of 10,000 and 20,000 papers, respectively.

For each dataset we use its test set for evaluation.

4 Experimental Setup and Results

Evaluation metrics. To evaluate the performance of different methods, we use micro avg. F1-score. We report the performance for the top 5 and 10 candidate phrases returned by different methods as in (Meng et al., 2017). To create a word graph for a given document, we use its title and abstract. To match the predicted keyphrases with gold-standard keyphrases, we do exact match between the stemmed version of each.

The effect of position, contextual embeddings, and the comparison with previous works. To see the effect of positional information, we compare the performance of KPRank that uses contextual SciBERT (SB) embeddings along with positional information (denoted as KPRank(SB)) with that of its counterpart that does not use positional information (denoted as KPRank(SB−POS)). Moreover, to see the effect of contextual embeddings, we compare the performance of SciBERT-based KPRank (KPRank(SB)) with that of KPRank that uses FastText non-contextual word embeddings (Mikolov et al., 2018) (denoted as KPRank(FastText)). For FastText, we used pre-trained 300 dimensional embeddings trained on subword information on Common Crawl. Note that KPRank(SciBERT) and KPRank(FastText) use positional information along with the theme score. Last, we compare the performance of KPRank with Tf-Idf and six PageRank based unsupervised methods as baselines: PositionRank (Florescu and Caragea, 2017), Key2Vec (Mahata et al., 2018), TextRank (Mihalcea and Tarau, 2004), SingleRank (Wan and Xiao, 2008), ExpandRank (Wan and Xiao, 2008), TopicRank (Bougouin et al., 2013).

Tables 2 shows these comparisons on SemEval, Inspec, Krapivin, NUS, and ACM. It can be seen from the table that adding position information shows much higher improvement in the performance of KPRank, i.e. KPRank(SB) substantially outperforms KPRank(SB−POS). Moreover, KPRank(SB) outperforms KPRank(FastText) on all the datasets except for Krapivin. Importantly, KPRank(SB) outperforms most baseline methods, including Key2Vec (by a large margin) e.g., on SemEval, KPRank(SB) achieves an F1@5 of 22.51% as compared with 17.54% achieved by Key2Vec. We can also notice from Table 2 that KPRank(SB) achieves comparable performance whenever any baseline method achieves the best performance.

Figure 2 shows the confusion matrices of KPRank(SB) using @5 predictions on all five datasets. Each matrix is represented as a heat map, i.e., the darker the blue color the higher the value at that position and the darker the blue on the main diagonal, the more accurate the model is.

Organization design: The continuing influence of *information technology*

Drawing from an *information processing perspective*, this paper examines how *information technology* (IT) has been a catalyst in the development of new forms of *organizational structures*. [...] to the present *environmental instability* that now characterizes many industries. Specifically, the authors suggest that advances in IT have enabled managers to adapt existing forms and create new models for *organizational design* that better fit requirements of an unstable environment. [...]. IT has gone from a support mechanism to a substitute for *organizational structures* in the form of the shadow structure. [...]

Gold-standard keyphrases: *Organization design, Information processing perspective, Organizational structures, Environmental instability, Information technology*

Predicted keyphrases: ***Organization design***, ***Information technology***, ***Information processing perspective***, ***Organizational structures***, *Organizational design, Organization, Information processing, Shadow structure, New forms, Bureaucratic structure*

Figure 3: The title, abstract, gold-standard keyphrases and predicted keyphrases of a paper. The phrases marked with cyan in the title and abstract shown on the top of the figure are gold-standard keyphrases.

Comparison with a supervised approach. Usually, the performance of the supervised keyphrase extraction models is better than the unsupervised models (Kim et al., 2013). We compare the performance of KPRank(SB) with the CRF based sequence classification model for the keyphrase extraction (Patel and Caragea, 2019) that uses word embeddings as features along with document specific features. The CRF model outperforms KPRank(SB) on all five datasets, e.g., CRF model achieves an F1 of 45.73% as compared with 25.76% achieved by KPRank(SB) on SemEval.

Anecdotal example. To see the quality of predicted phrases by the KPRank(SB), we randomly selected a paper from the Inspec dataset and evaluated the KPRank(SB) on it. We manually inspected the top-10 predictions by the KPRank(SB) and contrasted them with the gold-standard keyphrases. The title, abstract, gold-standard keyphrases and top-10 predicted keyphrases for this paper are shown in Figure 3. Precisely, in the figure, the cyan italic phrases shown in the text on the top of the figure represent gold-standard keyphrases, whereas the bottom of the figure shows gold-standard keyphrases and the top-10 predicted keyphrases by KPRank(SB) (shown in the order of their prediction). It can be seen from the figure that four out of five gold-standard keyphrases are present in the top-5 predicted keyphrases.

We can also see that KPRank(SB) did not predict gold-standard phrase "environmental instabily." A closer inspection of the document and both types of scores (*theme score* and *positional score*) assigned by KPRank(SB) to both constituent words of the gold-standard phrase that was not ranked in top-10 predictions revealed that these constituent words have lower values of *theme score* and they both appear only once in the document. Hence, the Pagerank algorithm will not boost these words. Inspecting other errors, we found that KPRank can fail to predict phrases that contain words that are less frequent in the document and their word embeddings are far from the *theme vector*.

5 Conclusion and Future Work

In this paper, we proposed a novel unsupervised graph-based algorithm, named KPRank, which incorporates both positional appearances of the words along with contextual word embeddings for computing a biased PageRank score for each candidate word. Our experimental results on five datasets show that incorporating position information into our biased KPRank model yields better performance compared with a KPRank that does not use the position information, and SciBERT-based KPRank usually outperforms FastText-based KPRank on this task. Moreover, KPRank outperforms strong baseline methods. In the future, it would be interesting to explore KPRank on other domains, such as Biology, and Social Science.

Abstract

Machine reading comprehension (MRC) has received considerable attention as a benchmark for natural language understanding. However, the conventional task design of MRC lacks explainability beyond the model interpretation, i.e., reading comprehension by a model cannot be explained in human terms. To this end, this position paper provides a theoretical basis for the design of MRC datasets based on psychology as well as psychometrics, and summarizes it in terms of the prerequisites for benchmarking MRC. We conclude that future datasets should (i) evaluate the capability of the model for constructing a coherent and grounded representation to understand context-dependent situations and (ii) ensure substantive validity by shortcut-proof questions and explanation as a part of the task design.

1 Introduction

Evaluation of natural language understanding (NLU) is a long-standing goal in the field of artificial intelligence. Machine reading comprehension (MRC) is a task that tests the ability of a machine to read and understand unstructured text and could be the most suitable task for evaluating NLU because of its generic formulation (Chen, 2018). Recently, many large-scale datasets have been proposed, and deep learning systems have achieved human-level performance for some of these datasets.

However, analytical studies have shown that MRC models do not necessarily achieve human-level understanding. For example, Jia and Liang (2017) use manually crafted adversarial examples to show that successful systems are easily distracted. Sugawara et al. (2020) show that a significant part of already solved questions is solvable even after shuffling the words in a sentence or dropping content words. These studies demonstrate that we cannot explain what type of understanding is required by the datasets and is actually acquired by models. Although benchmarking MRC is related to the intent behind questions and is critical to test hypotheses from a top-down viewpoint (Bender and Koller, 2020), its theoretical foundation is poorly investigated in the literature.

In this position paper, we examine the prerequisites for benchmarking MRC based on the following two questions: (i) *What* does reading comprehension involve? (ii) *How* can we evaluate it? Our motivation is to provide a theoretical basis for the creation of MRC datasets. As Gilpin et al. (2018) indicate, interpreting the internals of a system is closely related to only the system's architecture and is insufficient for explaining how the task is accomplished. This is because even if the internals of models can be interpreted, we cannot explain what is *measured* by the datasets. Therefore, our study focuses on the explainability of the task rather than the interpretability of models.

We first overview MRC and review the analytical literature that indicates that existing datasets might fail to correctly evaluate their intended behavior (Section 2). Subsequently, we present a psychological study of human reading comprehension in Section 3 for answering the *what* question. We argue that the concept of *representation levels* can serve as a conceptual hierarchy for organizing the technologies in MRC. Section 4 focuses on answering the *how* question. Here, we implement psychometrics to analyze the prerequisites for the task design of MRC. Furthermore, we introduce the concept of *construct validity*, which emphasizes validating the interpretation of the task's outcome. Finally, in Section 5, we explain the application of the proposed concepts into practical approaches, highlighting potential future directions toward the advancement of MRC. Regarding the *what* question, we indicate that datasets should evaluate the capability of the *situation model*, which refers to the construction

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1592–1612
April 19 - 23, 2021.

Question	Foundation	Requirements	Future direction
What is reading comprehension?	Representation levels in human reading comprehension: (A) surface structure, (B) textbase, and (C) situation model.	(A) Linguistic-level sentence understanding, (B) comprehensiveness of skills for inter-sentence understanding, and (C) evaluation of coherent representation grounded to non-textual information.	(C) Dependence of context on defeasibility and novelty, and grounding to non-textual information with a long passage.
How can we evaluate reading comprehension?	Construct validity in psychometrics: (1) content, (2) substantive, (3) structural, (4) generalizability, (5) external, and (6) consequential aspects.	(1) Wide coverage of skills, (2) evaluation of the internal process, (3) structured metrics, (4) reliability of metrics, (5) comparison with external variables, and (6) robustness to adversarial attacks and social biases.	(2) Creating shortcut-proof questions by filtering and ablation, and designing a task for validating the internal process.

Table 1: Overview of theoretical foundations, requirements, and future directions of MRC discussed in this paper.

of a coherent and grounded representation of text based on human understanding. Regarding the *how* question, we argue that among the important aspects of the construct validity, *substantive validity* must be ensured, which requires the verification of the internal mechanism of comprehension.

Table 1 provides an overview of the perspectives taken in this paper. Our answers and suggestions to the *what* and *how* questions are summarized as follows: (1) Reading comprehension is the process of creating a situation model that best explains given texts and the reader's background knowledge. The situation model should be the next focal point in future datasets for benchmarking the human-level reading comprehension. (2) To evaluate reading comprehension correctly, the task needs to provide a rubric (scoring guide) for sufficiently covering the aspects of the construct validity. In particular, the substantive validity should be ensured by creating shortcut-proof questions and by designing a task formulation that is explanatory itself.

2 Task Overview

2.1 Task Variations and Existing Datasets

MRC is a task in which a machine is given a document (*context*) and it answers the questions based on the context. Burges (2013) provides a general definition of MRC, i.e., *a machine comprehends a passage of text if, for any question regarding that text that can be answered correctly by a majority of native speakers, that machine can provide a string which those speakers would agree both answers that question*. We overview various aspects of the task along with representative datasets as follows. Existing datasets are listed in Appendix A.

Context Styles A context can be given in various forms with different lengths such as a single passage (MCTest (Richardson et al., 2013)), a set of passages (HotpotQA (Yang et al., 2018)), a longer document (CBT (Hill et al., 2016)), or open domain (Chen et al., 2017). In some datasets, a context includes non-textual information such as images (RecipeQA (Yagcioglu et al., 2018)).

Question Styles A question can be an interrogative sentence (in most datasets), a fill-in-the-blank sentence (cloze) (CLOTH (Xie et al., 2018)), knowledge base entries (QAngaroo (Welbl et al., 2018)) and search engine queries (MSMARCO (Nguyen et al., 2016)).

Answering Styles An answer can be (i) chosen from a text span of the given document (*answer extraction*) (NewsQA (Trischler et al., 2017)), (ii) chosen from a candidate set of answers (*multiple choice*) (MCTest (Richardson et al., 2013)), or (iii) generated as a free-form text (*description*) (NarrativeQA (Kočiský et al., 2018)). Some datasets optionally allow answering by a *yes*/*no* reply (BoolQ (Clark et al., 2019)).

Sourcing Methods Initially, questions in small-scale datasets are created by experts (QA4MRE (Sutcliffe et al., 2013)). Later, fueling the development of neural models, most published datasets have more than a hundred thousand questions that are automatically created (CNN/Daily Mail (Hermann et al., 2015)), crowdsourced (SQuAD v1.1 (Rajpurkar et al., 2016)), and collected from examinations (RACE (Lai et al., 2017)).

Domains The most popular domain is Wikipedia articles (Natural Questions (Kwiatkowski et al., 2019)), but news articles are also used (Who-did-What (Onishi et al., 2016)). CliCR (Suster and Daelemans, 2018) and emrQA (Pampari et al., 2018) are datasets in the clinical domain. DuoRC

(Saha et al., 2018) uses movie scripts.

Specific Skills Several recently proposed datasets require specific skills including unanswerable questions (SQuAD v2.0 (Rajpurkar et al., 2018)), dialogues (CoQA (Reddy et al., 2019), DREAM (Sun et al., 2019)), multiple-sentence reasoning (MultiRC (Khashabi et al., 2018)), multi-hop reasoning (HotpotQA (Yang et al., 2018)), mathematical and set reasoning (DROP (Dua et al., 2019)), commonsense reasoning (CosmosQA (Huang et al., 2019)), coreference resolution (QuoRef (Dasigi et al., 2019)), and logical reasoning (ReClor (Yu et al., 2020)).

2.2 Benchmarking Issues

In some datasets, the performance of machines has already reached human-level performance. However, Jia and Liang (2017) indicate that models can easily be fooled by manual injection of distracting sentences. Their study revealed that questions simply gathered by crowdsourcing without careful guidelines or constraints are insufficient to evaluate precise language understanding.

This argument is supported by further studies across a variety of datasets. For example, Min et al. (2018) find that more than 90% of the questions in SQuAD (Rajpurkar et al., 2016) require obtaining an answer from a single sentence despite being provided with a passage. Sugawara et al. (2018) show that large parts of twelve datasets are easily solved only by looking at a few first question tokens and attending the similarity between the given questions and the context. Similarly, Feng et al. (2018) and Mudrakarta et al. (2018) demonstrate that models trained on SQuAD do not change their predictions even when the question tokens are partly dropped. Kaushik and Lipton (2018) also observe that question- and passage-only models perform well for some popular datasets. Min et al. (2019) and Chen and Durrett (2019) concurrently indicate that for multi-hop reasoning datasets, the questions are solvable only with a single paragraph and thus do not require multi-hop reasoning over multiple paragraphs. Zellers et al. (2019b) report that their dataset unintentionally contains stylistic biases in the answer options which are embedded by a language-based model.

Overall, these investigations highlight a grave issue of the task design, i.e., even if the models achieve human-level accuracies, we cannot prove that they successfully perform reading comprehension. This issue may be attributed to the low interpretability of black-box neural network models. However, a problem is that we cannot explain what is measured by the datasets even if we can interpret the internals of models. We speculate that this benchmarking issue in MRC can be attributed to the following two points: (i) we do not have a comprehensive theoretical basis of reading comprehension for specifying what we should ask (Section 3) and (ii) we do not have a well-established methodology for creating a dataset and for analyzing a model based on it (Section 4).[1] In the remainder of this paper, we argue that these issues can be addressed by using insights from the psychological study of reading comprehension and by implementing psychometric means of validation.

3 Reading Comprehension from Psychology to MRC

3.1 Computational Model in Psychology

Human text comprehension has been studied in psychology for a long time (Kintsch and Rawson, 2005; Graesser et al., 1994; Kintsch, 1988). Connectionist and computational architectures have been proposed for such comprehension including a mechanism pertinent to knowledge activation and memory storing. Among the computational models, the construction–integration (CI) model is the most influential and provides a strong foundation of the field (McNamara and Magliano, 2009).

The CI model assumes three different representation levels as follows:

- *Surface structure* is the linguistic information of particular words, phrases, and syntax obtained by decoding the raw textual input.
- *Textbase* is a set of propositions in the text, where the propositions are locally connected by inferences (*microstructure*).
- *Situation model* is a situational and coherent mental representation in which the propositions are globally connected (*macrostructure*), and it is often grounded to not only texts but also to sounds, images, and background information.

The CI model first decodes textual information (i.e., the surface structure) from the raw textual

---

[1] These two issues loosely correspond to the plausibility and faithfulness of explanation (Jacovi and Goldberg, 2020). The plausibility is linked to what we expect as an explanation, whereas the faithfulness refers to how accurately we explain models' reasoning process.

input, then creates the propositions (i.e., textbase) and their local connections occasionally using the reader's knowledge (*construction*), and finally constructs a coherent representation (i.e., situation model) that is organized according to five dimensions including time, space, causation, intentionality, and objects (Zwaan and Radvansky, 1998), which provides a global description of the events (*integration*). These steps are not exclusive, i.e., propositions are iteratively updated in accordance with the surrounding ones with which they are linked. Although the definition of successful text comprehension can vary, Hernández-Orallo (2017) indicates that comprehension implies the process of creating (or searching for) a situation model that best explains the given text and the reader's background knowledge (Zwaan and Radvansky, 1998). We use this definition to highlight that the creation of a situation model plays a vital role in human reading comprehension.

Our aim in this section is to provide a basis for explaining what reading comprehension is, which requires terms for explanation. In the computational model above, the representation levels appear to be useful for organizing such terms. We ground existing NLP technologies and tasks to different representation levels in the next section.

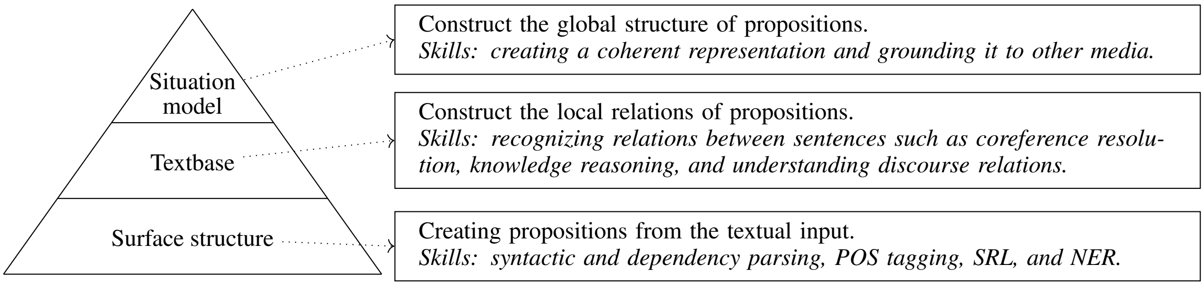
3.2 Skill Hierarchy for MRC

Here, we associate the existing NLP tasks with the three representation levels introduced above. The biggest advantage of MRC is its general formulation, which makes it the most general task for evaluating NLU. This emphasizes the importance of the requirement of various *skills* in MRC, which can serve as the units for the explanation of reading comprehension. Therefore, our motivation is to provide an overview of the skills as a hierarchical taxonomy and to highlight the missing aspects in existing MRC datasets that are required for comprehensively covering the representation levels.

Existing Taxonomies We first provide a brief overview of the existing taxonomies of skills in NLU tasks. For recognizing textual entailment (Dagan et al., 2006), several studies present a classification of reasoning and commonsense knowledge (Bentivogli et al., 2010; Sammons et al., 2010; LoBue and Yates, 2011). For scientific question answering, Jansen et al. (2016) categorize knowledge and inference for an elementary-level dataset. Similarly, Boratko et al. (2018) propose types of knowledge and reasoning for scientific questions in MRC (Clark et al., 2018). A limitation of both these studies is that the proposed sets of knowledge and inference are limited to the domain of elementary-level science. Although some existing datasets for MRC have their own classifications of skills, they are coarse and only cover a limited extent of typical NLP tasks (e.g., word matching and paraphrasing). In contrast, for a more generalizable definition, Sugawara et al. (2017) propose a set of 13 skills for MRC. Rogers et al. (2020) pursue this direction by proposing a set of questions with eight question types. In addition, Schlegel et al. (2020) propose an annotation schema to investigate requisite knowledge and reasoning. Dunietz et al. (2020) propose a template of understanding that consists of spatial, temporal, causal, and motivational questions to evaluate precise understanding of narratives with reference to human text comprehension.

In what follows, we describe the three representation levels that basically follow the three representations of the CI model but are modified for MRC. The three levels are shown in Figure 1. We emphasize that we do not intend to create exhaustive and rigid definitions of skills. Rather, we aim to place them in a hierarchical organization, which can serve as a foundation to highlight the missing aspects in the current MRC.

Surface Structure This level broadly covers the linguistic information and its semantic meaning, which can be based on the raw textual input. Although these features form a proposition according to psychology, it should be viewed as sentence-level semantic representation in computational linguistics. This level includes part-of-speech tagging, syntactic parsing, dependency parsing, punctuation recognition, named entity recognition (NER), and semantic role labeling (SRL). Although these basic tasks can be accomplished by some recent pretraining-based neural language models (Liu et al., 2019), they are hardly required in NLU tasks including MRC. In the natural language inference task, McCoy et al. (2019) indicate that existing datasets (e.g., Bowman et al. (2015)) may fail to elucidate the syntactic understanding of given sentences. Although it is not obvious that these basic tasks should be included in MRC and it is not easy to circumscribe linguistic knowledge from concrete and abstract knowledge (Zaenen et al., 2005; Manning, 2006), we should always care about the capabilities of basic tasks (e.g., use of checklists



Construct the global structure of propositions.
Skills: creating a coherent representation and grounding it to other media.

Construct the local relations of propositions.
Skills: recognizing relations between sentences such as coreference resolution, knowledge reasoning, and understanding discourse relations.

Creating propositions from the textual input.
Skills: syntactic and dependency parsing, POS tagging, SRL, and NER.

Figure 1: Representation levels and corresponding natural language understanding skills.

(Ribeiro et al., 2020)) when the performance of a model is being assessed.

Textbase This level covers local relations of propositions in the computational model of reading comprehension. In the context of NLP, it refers to various types of relations linked between sentences. These relations not only include the typical relations between sentences (discourse relations) but also the links between entities. Consequently, this level includes coreference resolution, causality, temporal relations, spatial relations, text structuring relations, logical reasoning, knowledge reasoning, commonsense reasoning, and mathematical reasoning. We also include multi-hop reasoning (Welbl et al., 2018) at this level because it does not necessarily require a coherent global representation over a given context. For studying the generalizability of MRC, Fisch et al. (2019) propose a shared task featuring training and testing on multiple domains. Talmor and Berant (2019) and Khashabi et al. (2020) also find that training on multiple datasets leads to robust generalization. However, unless we make sure that datasets require various skills with sufficient coverage, it might remain unclear whether we evaluate a model's transferability of the reading comprehension ability.

Situation Model This level targets the global structure of propositions in human reading comprehension. It includes a coherent and situational representation of a given context and its grounding to the non-textual information. A coherent representation has well-organized sentence-to-sentence transitions (Barzilay and Lapata, 2008), which are vital for using procedural and script knowledge (Schank and Abelson, 1977). This level also includes characters' goals and plans, meta perspective including author's intent and attitude, thematic understanding, and grounding to other media. Most existing MRC datasets seem to struggle to target the situation model. We discuss further in Section 5.1.

Passage: *The princess climbed out the window of the high tower and climbed down the south wall when her mother was sleeping. She wandered out a good way. Finally, she went into the forest where there are no electric poles.*

Q1: *Who climbed out of the castle?* A: *Princess*
Q2: *Where did the princess wander after escaping?*
A: *Forest*
Q3: *What would happen if her mother was not sleeping?*
A: *the princess would be caught soon (multiple choice)*

Figure 2: Example questions of the different representation levels. The passage is taken from MCTest.

Example The representation levels in the example shown in Figure 2 are described as follows. Q1 is at the surface-structure level where a reader only needs to understand the subject of the first event. We expect that Q2 requires understanding of relations among described entities and events at the textbase level; the reader may need to understand who *she* means using coreference resolution. *Escaping* in Q2 also requires the reader's commonsense to associate it with the first event. However, the reader might be able to answer this question only by looking for a place (specified by *where*) described in the passage, thereby necessitating the validity of the question to correctly evaluate the understanding of the described events. Q3 is an example that requires imagining a different situation at the situation-model level, which could be further associated with a grounding question such as *which figure best depicts the given passage?*

In summary, we indicate that the following features might be missing in existing datasets:

- Considering the capability to acquire basic understanding of the linguistic-level information.
- Ensuring that the questions comprehensively specify and evaluate textbase-level skills.
- Evaluating the capability of the situation model in which propositions are coherently organized

and are grounded to non-textual information.

Should MRC models mimic human text comprehension? In this paper, we do not argue that MRC models should mimic human text comprehension. However, when we design an NLU task and create datasets for testing human-like linguistic generalization, we can refer to the aforementioned features to frame the intended behavior to evaluate in the task. As Linzen (2020) discusses, the task design is orthogonal to how the intended behavior is realized at the implementation level (Marr, 1982).

4 MRC on Psychometrics

In this section, we provide a theoretical foundation for the evaluation of MRC models. When MRC measures the capability of reading comprehension, validation of the measurement is crucial to obtain a reliable and useful explanation. Therefore, we focus on psychometrics—a field of study concerned with the assessment of the quality of psychological measurement (Furr, 2018). We expect that the insights obtained from psychometrics can facilitate a better task design. In Section 4.1, we first review the concept of validity in psychometrics. Subsequently, in Section 4.2, we examine the aspects that correspond to construct validity in MRC and then indicate the prerequisites for verifying the intended explanation of MRC in its task design.

4.1 Construct Validity in Psychometrics

According to psychometrics, *construct validity* is necessary to validate the interpretation of outcomes of psychological experiments.[2] Messick (1995) report that construct validity consists of the six aspects shown in Table 2.

In the design of educational and psychological measurement, these aspects collectively provide verification questions that need to be answered for justifying the interpretation and use of test scores. In this sense, the construct validation can be viewed as an empirical evaluation of the meaning and consequence of measurement. Given that MRC is intended to capture the reading comprehension ability, the task designers need to be aware of these validity aspects. Otherwise, users of the task cannot justify the score interpretation, i.e., it cannot be confirmed that successful systems actually perform intended reading comprehension.

4.2 Construct Validity in MRC

Table 2 also raises MRC features corresponding to the six aspects of construct validity. In what follows, we elaborate on these correspondings and discuss the missing aspects that are needed to achieve the construct validity of the current MRC.

Content Aspect As discussed in Section 3, sufficiently covering the skills across all the representation levels is an important requirement of MRC. It may be desirable that an MRC model is simultaneously evaluated on various skill-oriented examples.

Substantive Aspect This aspect appraises the evidence for the consistency of model behavior. We consider that this is the most important aspect for explaining reading comprehension, a process that subsumes various implicit and complex steps. To obtain a consistent response from an MRC system, it is necessary to ensure that the questions correctly assess the internal steps in the process of reading comprehension. However, as stated in Section 2.2, most existing datasets fail to verify that a question is solved by using an intended skill, which implies that it cannot be proved that a successful system can actually perform intended comprehension.

Structural Aspect Another issue in the current MRC is that they only provide simple accuracy as a metric. Given that the substantive aspect necessitates the evaluation of the internal process of reading comprehension, the structure of metrics needs to reflect it. However, a few studies have attempted to provide a dataset with multiple metrics. For example, Yang et al. (2018) not only ask for the answers to questions but also provide sentence-level supporting facts. This metric can also evaluate the process of multi-hop reasoning whenever the supporting sentences need to be understood for answering a question. Therefore, we need to consider both substantive and structural aspects.

Generalizability Aspect The generalizability of MRC can be understood from the reliability of metrics and the reproducibility of findings. For the reliability of metrics, we need to take care of the reliability of gold answers and model predictions. Regarding the accuracy of answers, the performance of the model becomes unreliable when the answers are unintentionally ambiguous or impractical. Because the gold answers in most datasets are only decided by the majority vote of crowd workers, the ambiguity of the answers is not considered. It

---

[2] In psychology, a construct is an abstract concept, which facilitates the understanding of human behavior such as vocabulary, skills, and comprehension.

Validity aspects	Definition in psychometrics	Correspondence in MRC
1. Content	Evidence of content relevance, representativeness, and technical quality.	Questions require reading comprehension skills with sufficient coverage and representativeness over the representation levels.
2. Substantive	Theoretical rationales for the observed consistencies in the test responses including task performance of models.	Questions correctly evaluate the intended intermediate process of reading comprehension and provide rationales to the interpreters.
3. Structural	Fidelity of the scoring structure to the structure of the construct domain at issue.	Correspondence between the task structure and the score structure.
4. Generalizability	Extent to which score properties and interpretations can be generalized to and across population groups, settings, and tasks.	Reliability of test scores in correct answers and model predictions, and applicability to other datasets and models.
5. External	Extent to which the assessment scores' relationship with other measures and non-assessment behaviors reflect the expected relations.	Comparison of the performance of MRC with that of other NLU tasks and measurements.
6. Consequential	Value implications of score interpretation as a basis for the consequences of test use, especially regarding the sources of invalidity related to issues of bias, fairness, and distributive justice.	Considering the model vulnerabilities to adversarial attacks and social biases of models and datasets to ensure the fairness of model outputs.

Table 2: Aspects of the construct validity in psychometrics and corresponding features in MRC.

may be useful if such ambiguity can be reflected in the evaluation (e.g., using the item response theory (Lalor et al., 2016)). As for model predictions, an issue may be the reproducibility of results (Bouthillier et al., 2019), which implies that the reimplementation of a system generates statistically similar predictions. For the reproducibility of models, Dror et al. (2018) emphasize statistical testing methods to evaluate models. For the reproducibility of findings, Bouthillier et al. (2019) stress it as the transferability of findings in a dataset/task to another dataset/task. In open-domain question answering, Lewis et al. (2021) point out that successful models might only memorize dataset-specific knowledge. To facilitate this transferability, we need to have units of explanation that can be used in different datasets (Doshi-Velez and Kim, 2018).

External Aspect This aspect refers to the relationship between a model's scores on different tasks. Yogatama et al. (2019) point out that current models struggle to transfer their ability from a task originally trained on (e.g., MRC) to different unseen tasks (e.g., SRL). To develop a general NLU model, one would expect that a successful MRC model should show sufficient performance on other NLU tasks as well. To this end, Wang et al. (2019) propose an evaluation framework with ten different NLU tasks in the same format.

Consequential Aspect This aspect refers to the actual and potential consequences of test use. In MRC, this refers to the use of a successful model in practical situations other than tasks, where we need to ensure the robustness of a model to adversarial attacks and the accountability for unintended model behaviors. Wallace et al. (2019) highlight this aspect by showing that existing NLP models are vulnerable to adversarial examples, thereby generating egregious outputs.

Summary: Design of Rubric Given the validity aspects, our suggestion is to design a *rubric* (scoring guide used in education) of what reading comprehension we expect is evaluated in a dataset; this helps to inspect detailed strengths and weaknesses of models that cannot be obtained only by simple accuracy. The rubric should not only cover various linguistic phenomena (the *content* aspect) but also involve different levels of intermediate evaluation in the reading comprehension process (the *substantive* and *structural* aspects) as well as stress testing of adversarial attacks (the *consequential* aspect). The rubric is in a similar motivation with dataset statements (Bender and Friedman, 2018; Gebru et al., 2018); however, taking the validity aspects into account would improve its substance.

5 Future Directions

This section discusses future potential directions toward answering the *what* and *how* questions in Sections 3 and 4. In particular, we infer that the *situation model* and *substantive validity* are critical for benchmarking human-level MRC.

5.1 *What* Question: Situation Model

As mentioned in Section 3, existing datasets fail to fully assess the ability of creating the situation model. As a future direction, we suggest that the task should deal with two features of the situation model: context dependency and grounding.

5.1.1 Context-dependent Situations

A vital feature of the situation model is that it is conditioned on a given text, i.e., a representation is constructed distinctively depending on the given context. We elaborate it by discussing the two key features: defeasibility and novelty.

Defeasibility The defeasibility of a constructed representation implies that a reader can modify and revise it according to the newly acquired information (Davis and Marcus, 2015; Schubert, 2015). The defeasibility of NLU has been tackled in the task of if-then reasoning (Sap et al., 2019a), abductive reasoning (Bhagavatula et al., 2020), counterfactual reasoning (Qin et al., 2019), or contrast sets (Gardner et al., 2020). A possible approach in MRC is that we ask questions against a set of modified passages that describe slightly different situations, where the same question can lead to different conclusions.

Novelty An example showing the importance of contextual novelty is *Could a crocodile run a steeplechase?* by Levesque (2014). This question poses a novel situation where the solver needs to combine multiple commonsense knowledge to derive the correct answer. If non-fiction documents, such as newspaper and Wikipedia articles, are only used, some questions require only the reasoning of facts already known in web-based corpus. Fictional narratives may be a better source for creating questions on novel situations.

5.1.2 Grounding to Other Media

In MRC, grounding texts to non-textual information is not fully explored yet. Kembhavi et al. (2017) propose a dataset based on science textbooks, which contain questions with passages, diagrams, and images. Kahou et al. (2018) propose a figure-based question answering dataset that requires the understanding of figures including line plots and bar charts. Although another approach could be vision-based question answering tasks (Antol et al., 2015; Zellers et al., 2019a), we cannot directly use them for evaluating NLU because they focus on understanding of images rather than texts. Similarly to the textbook questions (Kembhavi et al., 2017), a possible approach would be to create questions for understanding of texts through showing figures. We might also need to account for the *scope* of grounding (Bisk et al., 2020), i.e., ultimately understanding human language in a social context beyond simply associating texts with perceptual information.

5.2 *How* Question: Substantive Validity

Substantive validity requires us to ensure that the questions correctly assess the internal steps of reading comprehension. We discuss two approaches for this challenge: creating shortcut-proof questions and ensuring the explanation by design.

5.2.1 Shortcut-proof Questions

Gururangan et al. (2018) reveal that NLU datasets can contain unintended dataset biases embedded by annotators. If machine learning models exploit such biases for answering questions, we cannot evaluate the precise NLU of models. Following Geirhos et al. (2020), we define *shortcut-proof* questions as ones that prevent models from exploiting dataset biases and learning decision rules (*shortcuts*) that perform well only on i.i.d. test examples with regard to its training examples. Gardner et al. (2019) also point out the importance of mitigating shortcuts in MRC. In this section, we view two different approaches for this challenge.

Removing Unintended Biases by Filtering Zellers et al. (2018) propose a model-based adversarial filtering method that iteratively trains an ensemble of stylistic classifiers and uses them to filter out the questions. Sakaguchi et al. (2020) also propose filtering methods based on both machines and humans to alleviate *dataset-specific* and *word-association* biases. However, a major issue is the inability to discern knowledge from bias in a closed domain. When the domain is equal to a dataset, patterns that are valid only in the domain are called *dataset-specific* biases (or annotation artifacts in the labeled data). When the domain covers larger corpora, the patterns (e.g., frequency) are called *word-association* biases. When the domain includes everyday experience, patterns are called *commonsense*. However, as mentioned in Section 5.1, commonsense knowledge can be *defeasible*, which implies that the knowledge can be false in unusual situations. In contrast, when the domain is our real world, indefeasible patterns are called *factual knowledge*. Therefore, the distinction of bias and knowledge depends on where the pattern is recognized. This means that a dataset should be created so that it can evaluate reasoning on the intended knowledge. For example, to test defeasible reasoning, we must filter out questions that are solvable by usual commonsense only. If we want to investigate the reading comprehension ability without depending on factual knowledge, we can consider counterfactual or fictional situations.

Identifying Requisite Skills by Ablating Input Features Another approach is to verify shortcut-proof questions by analyzing the human answerability of questions regarding their key features. We speculate that if a question is still answerable by humans even after removing the intended features, the question does not require understanding of the ablated features (e.g., checking the necessity of resolving pronoun coreference after replacing pronouns with dummy nouns). Even if we cannot accurately identify such necessary features, by identifying partial features of them in a sufficient number of questions, we could expect that the questions evaluate the corresponding intended skill. In a similar vein, Geirhos et al. (2020) argue that a dataset is useful only if it is a good proxy for the underlying ability one is actually interested in.

5.2.2 Explanation by Design

Another approach for ensuring the substantive validity is to include explicit explanation in the task formulation. Although gathering human explanations is costly, the following approaches can facilitate the explicit verification of a model's understanding using a few test examples.

Generating Introspective Explanation Inoue et al. (2020) classify two types of explanation in text comprehension: *justification explanation* and *introspective explanation*. The justification explanation only provides a collection of supporting facts for making a certain decision, whereas the introspective explanation provides the derivation of the answer for making the decision, which can cover linguistic phenomena and commonsense knowledge not explicitly mentioned in the text. They annotate multi-hop reasoning questions with introspective explanation and propose a task that requires the derivation of the correct answer of a given question to improve the explainability. Rajani et al. (2019) collect human explanations for commonsense reasoning and improve the system's performance by modeling the generation of the explanation. Although we must take into account the faithfulness of explanation, asking for introspective explanations could be useful in inspecting the internal reasoning process, e.g., by extending the task formulation so that it includes auxiliary questions that consider the intermediate facts in a reasoning process. For example, before answering Q2 in Figure 2, a reader should be able to answer *who escaped?* and *where did she escape from?* at the surface-structure level.

Creating Dependency Between Questions Another approach for improving the substantive validity is to create dependency between questions by which answering them correctly involves answering some other questions correctly. For example, Dalvi et al. (2018) propose a dataset that requires a procedural understanding of scientific facts. In their dataset, a set of questions corresponds to the steps of the entire process of a scientific phenomenon. Therefore, this set can be viewed as a single question that requires a complete understanding of the scientific phenomenon. In CoQA (Reddy et al., 2019), it is noted that questions often have pronouns that refer back to nouns appearing in previous questions. These mutually-dependent questions can probably facilitate the explicit validation of the models' understanding of given texts.

6 Conclusion

In this paper, we outlined current issues and future directions for benchmarking machine reading comprehension. We visited the psychology study to analyze *what* we should ask of reading comprehension and the construct validity in psychometrics to analyze *how* we should correctly evaluate it. We deduced that future datasets should evaluate the capability of the situation model for understanding context-dependent situations and for grounding to non-textual information and ensure the substantive validity by creating shortcut-proof questions and designing an explanatory task formulation.

Acknowledgments

The authors would like to thank Xanh Ho for helping create the dataset list and the anonymous reviewers for their insightful comments. This work was supported by JSPS KAKENHI Grant Number 18H03297, JST ACT-X Grant Number JPMJAX190G, and JST PRESTO Grant Number JPMJPR20C4.

A Machine Reading Comprehension Datasets

Tables 3, 4, 5, and 6 list machine reading comprehension and related datasets along with their answer styles, dataset size, type of corpus, sourcing methods, and focuses.

Dataset	Answer style	Size	Corpus	Question source	Focus
QA4MRE (Sutcliffe et al., 2013)	multiple-choice	240	technical document	expert	exam-level questions
MCTest (Richardson et al., 2013)	multiple-choice	2.6K	written story	crowd	children-level narrative
bAbI (Weston et al., 2015)	descript	10K * 20	generated text	automated	toy tasks for prerequisite skills
CNN/ DailyMail (Hermann et al., 2015)	extract	1.4M	news article	automated	entity cloze
Children's Book Test (Hill et al., 2016)	extract	688K	narrative	automated	large-scale automated
SQuAD 1.1 (Rajpurkar et al., 2016)	extract	100K	Wikipedia	crowd	large-scale crowdsourced
LAMBADA (Paperno et al., 2016)	descript	10K	narrative	crowd	hard language modeling
WikiReading (Hewlett et al., 2016)	descript	18m	Wikipedia	automated	Wikidata articles
Who did What (Onishi et al., 2016)	multiple-choice	200K	news article	automated	cloze of person names
MS MARCO (Nguyen et al., 2016)	descript	100K	web snippet	query	description on web snippets
NewsQA (Trischler et al., 2017)	extract	120K	news article	crowd	blindly created questions
SearchQA (Dunn et al., 2017)	extract	140K	web snippet	trivia	49.6 snippets on average
RACE (Lai et al., 2017)	multiple-choice	100K	language exam	expert	middle and high school English exam in China
Story Cloze Test (Mostafazadeh et al., 2017)	multiple-choice	3.7K	written story	crowd	98,159 stories for training
TriviaQA (Joshi et al., 2017)	extract	650K	web snippet	trivia	trivia questions
Quasar (Dhingra et al., 2017)	extract	80K	web snippet	query	search queries
TextbookQA (Kembhavi et al., 2017)	multiple-choice	26K	textbook	expert	figures included
AddSent SQuAD (Jia and Liang, 2017)	extract	3.6K	Wikipedia	crowd	distracting sentences injected

Table 3: Machine reading comprehension datasets published until 2017. In the *answer style* column, *descript* represents description (free-form answering) and *extract* denotes answer extraction by selecting a span in given texts. *Size* indicates the size of the whole dataset including training, development, and test sets. In the *question source* column, *crowd* indicates questions written by crowdworkers and *query* indicates questions collected from search-engine queries.

Dataset	Answer style	Size	Corpus	Question source	Focus
ARCT (Habernal et al., 2018)	multiple-choice	2.0K	debate article	crowd expert	reasoning on argument
QAngaroo (Welbl et al., 2018)	multiple-choice	50K	Wikipedia, MEDLINE	automated	multi-hop reasoning
CLOTH (Xie et al., 2018)	multiple-choice	99K	various	expert	cloze in exam texts
NarrativeQA (Kočiský et al., 2018)	descript	45K	movie script	crowd	summary and full story tasks
MCScript (Ostermann et al., 2018)	multiple-choice	30K	written story	crowd	commonsense reasoning, script knowledge
CliCR (Suster and Daelemans, 2018)	extract	100K	clinical case text	automated	cloze style queries
ARC (Clark et al., 2018)	multiple-choice	8K	science exam	expert	retrieved documents from textbooks
DuoRC (Saha et al., 2018)	extract	186K	movie script	crowd	commonsense reasoning, multi-sentence reasoning
ProPara (Dalvi et al., 2018)	extract	2K	science exam	automated	procedural understanding
DuReader (He et al., 2018)	descript	200K	web snippet	query crowd	Chinese, Baidu Search/Knows
MultiRC (Khashabi et al., 2018)	multiple-choice	6K	various documents	crowd	multi-sentence reasoning
Multi-party Dialog (Ma et al., 2018)	extract	13K	TV show transcript	automated	1.7k crowd dialogues, cloze query
SQuAD 2.0 (Rajpurkar et al., 2018)	extract no answer	100K	Wikipedia	crowd	unanswerable questions
ShARC (Saeidi et al., 2018)	yes/no/ irrelevant	32K	web snippet	crowd	reasoning on rules from government documents
QuAC (Choi et al., 2018)	extract yes/no	100K	Wikipedia	crowd	dialogue-based, 14k dialogues
Textworlds QA (Labutov et al., 2018)	extract	1.2M	generated text	automated	simulated worlds, logical reasoning
SWAG (Zellers et al., 2018)	multiple-choice	113K	video captions	language-model	commonsense reasoning
emrQA (Pampari et al., 2018)	extract	400K	clinical documents	automated	using annotated logical forms on i2b2 dataset
HotpotQA (Yang et al., 2018)	extract yes/no	113K	Wikipedia	crowd	multi-hop reasoning
OpenbookQA (Mihaylov et al., 2018)	multiple-choice	6.0K	textbook	crowd	commonsense reasoning
RecipeQA (Yagcioglu et al., 2018)	multiple-choice	36K	recipe script	automated	multimodal questions
ReCoRD (Zhang et al., 2018)	extract	120K	news article	crowd	commonsense reasoning, cloze query

Table 4: Machine reading comprehension datasets published in 2018. In the *answer style* column, *descript* represents description (free-form answering) and *extract* denotes answer extraction by selecting a span in given texts. *Size* indicates the size of the whole dataset including training, development, and test sets. In the *question source* column, *crowd* indicates questions written by crowdworkers and *query* indicates questions collected from search-engine queries.

Dataset	Answer style	Size	Corpus	Question source	Focus
CoQA (Reddy et al., 2019)	extract yes/no	127K	Wikipedia	crowd	dialogue-based, 8k dialogues
Commonsense QA (Talmor et al., 2019)	multiple-choice	12K	ConceptNet	crowd	commonsense reasoning
Natural Questions (Kwiatkowski et al., 2019)	extract yes/no	323K	Wikipedia	query crowd	short or long answer styles
DREAM (Sun et al., 2019)	multiple-choice	10K	language exam	expert	dialogue-based, 6.4k multi-party dialogues
DROP (Dua et al., 2019)	descript	96K	Wikipedia	crowd	discrete reasoning
SocialIQA (Sap et al., 2019b)	multiple-choice	38K	crowd	crowd	commonsense reasoning about social situation
BoolQ (Clark et al., 2019)	yes/no	16K	Wikipedia	query crowd	boolean questions, subset of Natural Questions
MSCript 2.0 (Ostermann et al., 2019)	multiple-choice	20K	narrative	crowd	commonsense reasoning, script knowledge
HellaSWAG (Zellers et al., 2019b)	multiple-choice	70K	web snippet	language-model	commonsense reasoning, WikiHow and ActivityNet
CODAH (Chen et al., 2019)	multiple-choice	2.8K	written prompt	expert	adversarial collection
Quoref (Dasigi et al., 2019)	extract	24K	Wikipedia	crowd	coreference resolution
CosmosQA (Huang et al., 2019)	multiple-choice	36K	narrative	crowd	commonsense reasoning
PubMedQA (Jin et al., 2019)	yes/no	273.5K	PubMed	expert automated	biomedical domain, 1k expert questions
ROPES (Lin et al., 2019)	extract	14K	textbook Wikipedia	crowd	paragraph effects in situations

Table 5: Machine reading comprehension datasets published in 2019. In the *answer style* column, *descript* represents description (free-form answering) and *extract* denotes answer extraction by selecting a span in given texts. *Size* indicates the size of the whole dataset including training, development, and test sets. In the *question source* column, *crowd* indicates questions written by crowdworkers and *query* indicates questions collected from search-engine queries.

Dataset	Answer style	Size	Corpus	Question source	Focus
QuAIL (Rogers et al., 2020)	multiple-choice	15K	various	crowd	prerequisite real tasks
QASC (Khot et al., 2020)	multiple-choice	10K	textbook	crowd	knowledge composition
AdversarialQA (Bartolo et al., 2020)	extract	36K	Wikipedia	crowd	adversarial collection
ReClor (Yu et al., 2020)	multiple-choice	6.1K	exam	expert	logical reasoning
R^{4}C (Inoue et al., 2020)	extract descript	5K	Wikipedia	crowd	multi-hop reasoning
TechQA (Castelli et al., 2020)	descript	1.4K	tech documents	crowd	tech forum questions
LogiQA (Liu et al., 2020)	multiple-choice	8.7K	exam	expert	logical reasoning
ProtoQA (Boratko et al., 2020)	descript	9.8K	web snippet	crowd	commonsense reasoning over prototypical situtations
IIRC (Ferguson et al., 2020)	descript	13K	Wikipedia	crowd	incomplete information
HybridQA (Chen et al., 2020)	extract	70K	Wikipedia	crowd	understanding tabular data
TORQUE (Ning et al., 2020)	extract	21K	TempEval-3	crowd	temporal ordering
2WikiMultiHopQA (Ho et al., 2020)	extract yes/no descript	200K	Wikipedia	automated	multi-hop reasoning

Table 6: Machine reading comprehension datasets published in 2020. In the *answer style* column, *descript* represents description (free-form answering) and *extract* denotes answer extraction by selecting a span in given texts. *Size* indicates the size of the whole dataset including training, development, and test sets. In the *question source* column, *crowd* indicates questions written by crowdworkers and *query* indicates questions collected from search-engine queries.

Multilingual Neural Machine Translation with Deep Encoder and Multiple Shallow Decoders

Abstract

Recent work in multilingual translation advances translation quality surpassing bilingual baselines using deep transformer models with increased capacity. However, the extra latency and memory costs introduced by this approach may make it unacceptable for efficiency-constrained applications. It has recently been shown for bilingual translation that using a deep encoder and shallow decoder (DESD) can reduce inference latency while maintaining translation quality, so we study similar speed-accuracy trade-offs for multilingual translation. We find that for many-to-one translation we can indeed increase decoder speed without sacrificing quality using this approach, but for one-to-many translation, shallow decoders cause a clear quality drop. To ameliorate this drop, we propose a deep encoder with *multiple* shallow decoders (DEMSD) where each shallow decoder is responsible for a disjoint subset of target languages. Specifically, the DEMSD model with 2-layer decoders is able to obtain a **1.8x speedup** on average compared to a standard transformer model with no drop in translation quality.

1 Introduction

Encoder-decoder based neural machine translation (NMT) systems have achieved great success on bilingual translation tasks (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2014; Gehring et al., 2017; Vaswani et al., 2017). Recently, multilingual neural machine translation (MNMT) has also attracted much attention because of its ease of deployment, knowledge transfer among languages and the potential to enable zero-shot translation (Dong et al., 2015; Firat et al., 2016; Ha et al., 2016; Johnson et al., 2017; Arivazhagan et al., 2019; Zhang et al., 2020). While MNMT can support translations in several directions, not all of them have better performance when compared to their corresponding bilingual models. Suspecting that poor performance in some directions is due to the limited model capacity, many prior works adopt deeper encoder and decoder (Zhang et al., 2019; Wang et al., 2019; Zhang et al., 2020). However, increasing the number of layers, especially in the decoder, deteriorates the latency of translation and memory costs. Recently, Kasai et al. (2020) show that given a fixed capacity budget, as measured by the number of layers, models with a deep encoder and a shallow decoder (DESD) are faster at inference time when compared to standard models with an equal number of encoder and decoder layers while maintaining translation quality.

Inspired by findings from Kasai et al. (2020), in this work, we explore the speed-accuracy trade-off in multilingual machine translation systems. Given the same model capacity budget, we experiment various layer allocation strategies. We analyze multilingual models in the one-to-many (O2M) setting and many-to-one (M2O) setting. In the one-to-many setting, there are numerous target languages from a single source language (limited to English in this study); and in the many-to-one setting, several possible source languages are translated into a single target language (again, English in this study).

In the many-to-one scenario, we find that allocating more capacity to the encoder reduces the latency while achieving comparable performance. We hypothesize that a deeper encoder helps the model accommodate multiple source languages, while a shallow decoder is sufficient to support a single target language.

However, in the one-to-many translation setting, speed-accuracy trade-off is complicated. We observe a performance drop as the decoder depth is reduced. We hypothesize that the shallow decoder

---

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1613–1624
April 19 - 23, 2021.

can no longer model several different target languages adequately. With the goal of obtaining low latency while maintaining translation quality, we propose using *multiple* shallow decoders where each decoder is responsible for a subset of the target languages. Clearly, the introduction of multiple shallow decoders increases the size of our model. However, at inference time only one shallow decoder will be used, thus not adding latency or memory costs. With multiple target languages and decoders, one natural question is how to assign each target language to one of these decoders. We investigate several methods to assign each target language to one of these shallow decoders. More details are in the Section 3. Experimental results on three multilingual translation corpora show the effectiveness of our method to improve translation accuracy with lower latency at the same time.

Our main contributions are summarized as follows:

- We extend the speed-accuracy trade-off study of DESD models from bilingual to multilingual machine translation tasks with various layer allocations.
- We show that on many-to-one translation, multilingual DESD models enable 1.8x speedup on average without sacrificing performance comparing to the baseline (equal model capacity).
- We further proposed shared encoder and *multiple* shallow decoders (DEMSD) for one-to-many setting again achieving 1.8x speed-up in decoding while preserving high-quality translations at the same time.

2 Deep encoder and shallow decoder (DESD) for multilingual NMT

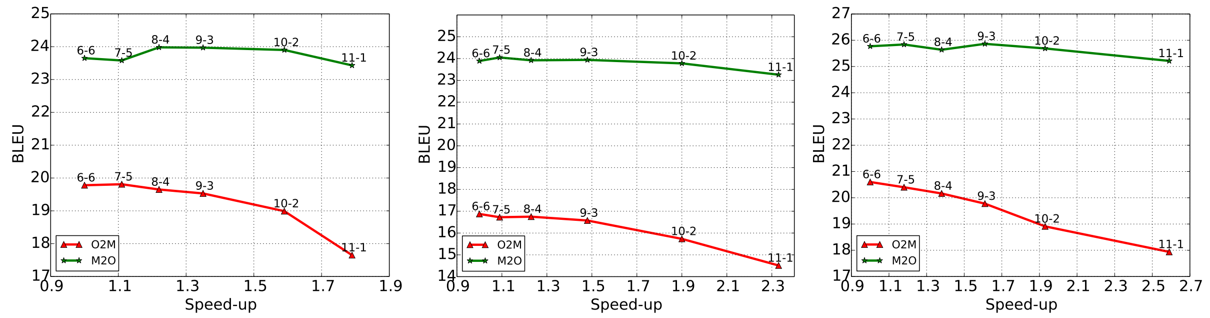
Background The transformer-based NMT model (Vaswani et al., 2017) achieves state-of-the-art performance on many translation tasks. It consists of an encoder and a decoder, each of which contains several stacked layers. Since the transformer relies entirely on the attention mechanism, it allows more parallelization compared to recurrent neural networks. Specifically, at training time, the computation can be parallelized both in the encoder and decoder. At inference time, due to the auto-regressive property, the decoder needs to generate tokens one by one. However, the computation in the encoder is still parallelized given the source sentence. Therefore, the main latency of the transformer at inference time happens in the decoder, especially translating long sentences. Recently, Kasai et al. (2020) find that on bilingual machine translation tasks, putting more capacity of the transformer model to the encoder substantially reduces the decoding time and maintain the performance at the same time.

Because this deep encoder and shallow decoder model achieves a superior speed-accuracy trade-off on bilingual translation tasks, in this section, we try to understand the layer allocations of transformer on the multilingual neural machine translation task given the same capacity budget which is measured by the number of layers in the encoder and decoder. We first experiment with three multilingual translation corpora.

- ML50 (Tang et al., 2020): a large-scale multilingual translation dataset which contains 49 languages↔English and more than 200 million training sentence pairs in total. All data are collected from open-resource data such as WMT, IWSLT, WAT, TED, etc.
- TED8-Related (Wang et al., 2020): 4 low resource languages (Azerbaijani: az, Belarusian: be, Glacian: gl, Slovak: sk) and 4 relevant high resource languages (Turkish: tr, Russian: ru, Portuguese: pt, Czech: cs)
- TED8-Diverse (Wang et al., 2020): 8 languages without consideration for relatedness (Bosnian: bs, Marathi: hr, Hindi: hi, Macedonian: mk, Greek: el, Bulgarian: bg, French: fr, Korean: ko)

Instead of just trying the shallowest possible decoder (1-layer), we train models with various configurations on each of these three corpora. Other than the layer allocation, all the other hyper-parameters and model configurations are the same among these models and the same training procedure is applied to these models (odel and training details are listed in Appendix A.). To understand the speed and accuracy trade-off of the layer allocation, two metrics are reported:

- BLEU: the average tokenized BLEU score (Papineni et al., 2002) over all directions.
- DS: the decoding speed. It is measured by the number of tokens per second the system



(a) ML50 (b) TED8-Related (c) TED8-Diverse

Figure 1: Speed and accuracy trade-off of various layer allocations for O2M and M2O translations on ML50, TED8-Related and TED8-Diverse corpora. X-Y denotes X and Y layers in the encoder and decoder respectively. Best viewed in color.

translates given one sentence at a time on a single GPU.

The results are shown in Figure 1. Models with fewer decoder layers obtain higher decoding speed.

2.1 Many-to-one translation

In the M2O translation, there is no significant performance difference among these layer allocations. We hypothesize that this is because the deeper encoder learns better representations from a large number of source languages while on the decoder side only one language needs to be modeled. Therefore, given a more robust representation of source languages, the shallow decoder is able to generate high-quality translations. For example, the model with 10 encoder layers and 2 decoder layers obtain slightly better performance and a 1.8**x** speedup at the same time.

2.2 One-to-many translation

However, in the O2M translation setting, although models with the shallower decoder have lower latency compared to the standard transformer (6-6), there is a clear performance drop in terms of translation accuracy, especially for models with just 1 or 2 decoder layers. We attribute this to the shallow decoder not having enough capacity to model a large number of target languages.

3 Deep Encoder and Multiple Shallow Decoders (DEMSD)

We have seen that in one-to-many translation, DESD models have a performance drop compared to the standard transformer. In order to preserve translation quality and low latency at the same time, we propose a model with a shared encoder and *multiple* shallow decoders (DEMSD), each of which is used to decode a subset of target languages. Although this will introduce more parameters, at inference time only one shallow decoder is needed for a given translation (since the output language is fixed) thus the model incurs no extra latency or memory costs. One natural question that arises when using this multiple-decoder approach is how to assign output languages to each of the decoders. In this section, we explore several language assignment methods to assign each target language (or language group) to one of these multiple decoders. As a result, each decoder only needs to handle a disjoint subset of target languages.

3.1 One language per decoder (EACH)

The simplest way is to use a separate decoder for each output language. As a result, we will have as many decoders as the number of target languages and each decoder only needs to model one language.

3.2 Random language set per decoder (RAND)

In this method, we assign a random set of languages to a single decoder. As the performance of the model will vary significantly based on the random assignment, we repeat this scheme with three different random assignments and report the average results. Instead of completely random grouping languages, we let each decoder handle a same number of languages but languages in one decoder are randomly grouped.

Language Family	Languages
TURKIC	az, tr
SLAVIC	be, ru
ROMANCE	gl, pt
CZECH–SLOVAK	sk, cs

Table 1: Language families in the TED8-Related corpus.

3.3 One language family per decoder (FAM)

Another intuitive way for language assignment is to use linguistic features (Comrie, 1989; Lewis, 2009; Dryer and Haspelmath, 2013), such as language family, typology, etc. In this method, we are guided by the intuition that languages from the same linguistic family share similar features which might be captured by a single decoder resulting in better performance. Thus, we group languages into several sets based on their linguistic families, and assign a family of languages to each decoder. As a result, we will have as many decoders as the number of language families in the target languages. We expect that in the same decoder, a better knowledge transfer will happen among languages in the same language family. For example, in the TED8-Related corpus, 8 target languages are split into 4 languages families which are TURKIC, SLAVIC, ROMANCE and CZECH–SLOVAK. The details are shown in Table 1. The language family-based assignment results on other corpora are shown in Appendix B.

3.4 Pre-trained language embedding based assignment (EMB)

From Johnson et al. (2017), a common way to indicate the target language is prepending a target language token to the source sentence. With the goal of capturing the information of languages they represent, their embeddings are trained end-to-end with source-target sentence pairs. We call these embeddings as the language embeddings here. According to Johnson et al. (2017), these language embeddings are able to capture target language features in their training data. Therefore, we first extract them from a well-trained model and group target languages according to them. Finally, each group are assigned to one of these decoders.

3.5 Self-taught assignment (ST)

One disadvantage of the pre-trained language embedding based grouping method is the need of a pre-trained machine translation model. It would be better if the model assign each target languages to one of these multiple shallow decoders during the training automatically. We expect that given a fixed number of decoders and target languages, the model is capable of choosing the most appropriate decoders for each language.

Specifically, our model consists of a shared encoder, E, and N multiple decoders, $D = [D_1, D_2, ..., D_N]$. Given a language L, the model will choose a decoder, D_i for training and translation so that the log probability of output sequence y given the input sequence x is $\log p(y|x, E, D_i)$ where i=$\arg\max_j p(j|L_e)$ and $p(\cdot|L_e)$ is the probability of each decoder being chosen given the language L and its language embedding vector L_e. Intuitively, our model will learn the distribution of each decoder being chosen given a language and choose the one with the highest probability. However, the $\arg\max$ operation here is non-differenetiable thus during trainiing we consider the Gumbel-Softmax (Jang et al., 2016), a differentiable approximation of the $\arg\max$ operation.

In Gumbel-Softmax, it models the $p(j|L_e)$ as:

$$p(j|L_e) = \frac{\exp(l_j + g_j)/\tau}{\sum_{k=1}^{N} \exp(l_k + g_k)/\tau} \quad (1)$$

where l is the logit and g=$-\log(-\log(u))$ and $u \sim \mathcal{U}(0, 1)$. In the forward pass, the differentiable approximation of the $\arg\max$ operation is used to choose the decoder for the input language and during the backward, the true gradient of the Straight-Through Gumbel-Softmax outputs is used. In our experiments, the temperature τ is linearly reduced from 5 to 0.5. Finally, during training, the probability of the target sequence y given the source sentence x and multiple decoders D is:

$$p(y|x) = \sum_{n=1}^{N} p(n|L_e) p_n(y|x) \quad (2)$$

where $p_n(y|x)$ is the probability of y given x in the n-th decoder and $p(n|L_e)$ is the probability of the n-th decoder being sampled given the embedding of the language L. During inference, only the decoder with the highest probability will be used to decode the input sentences.

corpora. ML50 (Tang et al., 2020) is an English-central translation benchmark of 50 languages with publicly available training and evaluation sets, including high, mid, and extremely low resource directions. Following Tang et al. (2020), we adopt the 250k SentencePiece model (Kudo and Richardson, 2018) used in XLM-R (Conneau et al., 2019) to tokenize the dataset so that all languages share the same vocabulary. For TED8-Related, TED8-Diverse corpora, we follow the preprocessing steps in Wang et al. (2020).

Hyperparameters On ML50, we follow most of the standard hyperparameters in the transformer-base (Vaswani et al., 2017): 8 attention heads per layer, 512 model dimensions, 2048 hidden dimensions and 0.1 dropout. We train batches of 64k tokens using Adam (Kingma and Ba, 2014) with $\beta = (0.9, 0.98)$ and $\epsilon = 10^{-6}$ and 0.1 label smoothing. The learning rate goes to $1e{-}3$ within 4,000 steps, and then decays with the inverse square-root schedule. All models are trained for 100,000 steps. Furthermore, to mitigate the training data imbalance issue, the temperature sampling method is adopted (Arivazhagan et al., 2019) which is set as 5 in all experiments.

On TED8 corpora, a smaller transformer model with 512 model dimensions, 1024 hidden dimensions and 0.3 dropout is adopted. All models are trained for 40k steps with batches of 16k tokens with a smaller learning rate $2e{-}4$. The other training procedure is the same as the ML50.

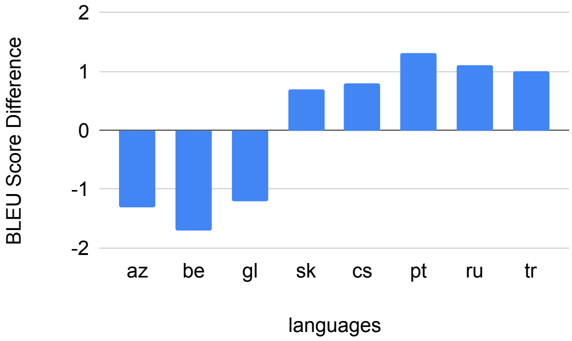

Figure 2: The BLEU score difference between models 10-2-EACH and 10-2 on TED8-Related ($\text{BLEU}_{\text{10-2-EACH}} - \text{BLEU}_{\text{10-2}}$). (Left four languages are low-resourced and the right four are high-resourced.)

Evaluation metrics For all models, we evaluate on the checkpoint with the best validation loss and use beam size 5 and length penalty 1.0 in decoding. Besides reporting the average BLEU score over all languages, on ML50, we predefine high ($>$ 1M), mid (100K, 1M]) and low ($<$ 100K) resource languages according to their data sizes and average BLEU scores on each of them are also computed. For the evaluation speed, **DS**, it is measured by the number of tokens the system translates per second given one sentence at a time on a single GPU.

4.2 Results

From Figure 1, we find that for O2M translation, models with 1- or 2-layer decoders have a clear performance drop compared to the standard transformer (6-6). Therefore, our main experiments adopt multiple shallow decoders with 1 and 2 decoder layers. Results on ML50 and TED8 corpora are shown in Table 3 and 4 respectively. For simplicity, we introduce the abbreviation of each language assignment method and evaluating metrics in Table 2.

One language per decoder (EACH) With this assignment method, models obtain superior performance on high and mid resource languages but poor results on low resource languages. On ML50, if each language has its own decoder, we find that it achieves great results on high resource languages (BLEU_H in rows 2 vs. 3 and 8 vs. 9 in Table 3). We think that given enough training data, the shallow decoder has enough ability to model one language. However, it performs worse on the low resource languages compared with the baseline (BLEU_L between rows 2 vs. 3 and 8 vs. 9 in Table 3). To further understand this assignment method, we also

Table 4: Translation speed and accuracy trade-off on TED8-Related and TED8-Diverse corpora. Notation information can be found in Table 2.

show the BLEU score differences between models 10-2 and 10-2-EACH on TED8-Related in Figure 2. The left three languages are relatively low resourced and their performance is lower than the baseline model in which all languages share one decoder[1]. This also demonstrates that their decoders are not able to learn robust representations given a limited amount of training data. And decoders trained with high resource languages generate higher quality translations and we attribute this to the enough training data and no negative transfer effect when trained without other languages (Arivazhagan et al., 2019).

Random language set assignment (RAND) We find that random language set assignment slightly improve the performance over the baseline due to the sub-optimal knowledge transfer among languages in the same decoder. If each decoder handles a similar number of languages, it also slightly improve the performance compared to the model with one shared decoder (BLEU scores between rows 2 vs. 4 and 8 vs. 10 in Tables 3 and 4). We attribute this to that the shallow decoder performs better given fewer languages. This also demonstrates that one shallow decoder does not have enough capacity to model a large number of languages. However, compared to language family and embedding assignment methods, the random

---

[1] Note that although sk is defined as a low resourced language in this dataset, the reason why language sk still have slightly better result is that sk has 61.5k training data but the other three low resource languages (az, be, gl) have less than 10k training sentence pairs.

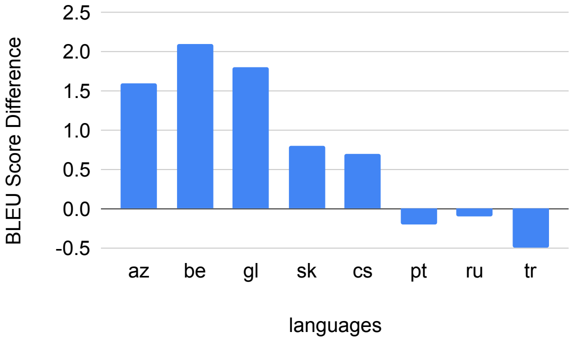

Figure 3: The BLEU score difference between models 10-2-FAM and 10-2-EACH on TED8-Related ($\text{BLEU}_{\text{10-2-FAM}} - \text{BLEU}_{\text{10-2-EACH}}$). (Left four languages are low-resourced and the right four are high-resourced.)

language set method has lower translation quality, showing that how to assign target languages into these decoders is also crucial.

One language family per decoder (FAM) We group all languages into several groups according to their language families and assign each family to one shallow decoder. As a result, we have 15, 4, 5 language families in ML50, TED8-Related and TED8-Diverse corpora respectively. From the comparison between rows 2 vs. 5 and 8 vs 11 in Tables 3 and 4. It is clear to find that language family-based decoders achieves better accuracy and maintain the low latency at the same time. Furthermore, for models with multiple 2-layer decoders, they achieve comparable performance with the model 6-6 and obtain around a 1.8 times speedup at inference time. We think the improvement is mainly coming from the better knowledge transfer among similar languages (in one language family). In order to understand this further, we plot the BLEU score difference between models 10-2-EACH and 10-2-FAM on TED8-Related in Figure 3.

We find that the major improvement of model 10-2-FAM over 10-2-EACH is from the low resource languages which means the high resource languages help their relevant low resource languages effectively.

Language embedding-based assignment (EMB) For the fair comparison, languages are also grouped into the same number of language families according to language embeddings from the well-trained baseline model 6-6. Grouping results are listed in the Appendix C. We first find that language embedding-based grouping method is able to group similar languages together, showing the ability of language embeddings to effectively capture language characteristics during training. For example, on TED8-Related, the language embedding achieve the same grouping result as the language family-based one shown in Table 1. The language embedding-based assignment method achieves similar results compared to the language family-based one and effectively improve the performance of the baseline model.

Self-taught language assignment (ST) In this method, the model tries to assign target languages to multiple decoders automatically and there is no need having any prior knowledge (linguistic families) or well-trained models (language embeddings). From the rows 7 vs. 2 and 13 vs. 8 in Tables 3 and 4, our self-taught method improves around 1 BLEU score over the baseline. It also achieves similar results compared with the language family (embedding)-based language assignment methods, demonstrating the effectiveness of this method.

5 Analysis and Discussion

5.1 Multiple decoders for various layer allocations

In our main experiments, we use multiple very shallow decoders (i.e., 1 and 2-layer decoders) because there is a clear performance drop when using a single decoder with this configuration for one-to-many translation compared with the standard transformer (6-6), and compared to deeper decoders, employing multiple 1- or 2-layer decoders keeps the number of parameters manageable at training time. Nevertheless, it will be meaningful to explore the effect of multiple decoders on various layer allocations. Considering the model size and tractable training time, we only conduct experiments on TED8 corpora and the results are shown in Figure 4. On each line (the same language assignment method), the deeper decoders achieve better performance and the shallower decoder has lower latency. Moreover, if we compare language family-based assignment and the baseline models, given the same decoding speed at inference time, the former one consistently improve the performance with the same decoding speed at inference time. And with the similar performance, e.g., 10-2-FAM and 6-6, our best multiple shallow decoder models have much

(b) TED8-Diverse

Figure 4: Multiple decoders with various layer allocations of Transformer on ML50, TED8-Related and TED8-Diverse corpora. X-Y denotes X and Y layers in the encoder and decoder respectively. 'BASE' denotes the shared decoder model.

lower latency.

5.2 Speed-accuracy trade-off in multilingual machine translation

From the above experiments and findings, in the one-to-many translation, the DESD framework obtains superior speed-accuracy trade-off. For example, the model with 10 encoder layers and 2 decoder layers obtain slightly better accuracy and a 1.8**x** speedup.

Under the one-to-many setting, multiple shallow decoders are needed to mitigate the performance drop of the DESD model. And the crucial part is to group languages with similar features to one decoder to obtain the better knowledge transfer among languages (our FAM, EMB and ST methods). With this, our DEMSD model with multiple 2-layer decoder is capable of achieving similar performance and a 1.8**x** speedup compared to the standard transformer.

6 Related Work

Speed and accuracy are two important metrics to evaluate a machine translation system. In this work, we mainly discuss the transformer architecture (Vaswani et al., 2017). A number of works have explored various ways to improve its inference speed. Kim et al. (2019) adopt shallow decoder and layer trying to speed up the inference on CPUs. Shi and Knight (2017) and Senellart et al. (2018) employee vocabulary reduction to speed up the softmax layer. Li et al. (2020) employ a latent depth transformer model which prune layers during inference time to reduce the inference cost. There are also some works optimizing attention computations to speed up the inference speed (Zhang et al., 2018; Kitaev et al., 2020; Katharopoulos et al., 2020; Chelba et al., 2020). Recently, Kasai et al. (2020) places more capacity to the encoder side and keep an extremely shallow (one-layer) decoder to achieve a superior speed-accuracy trade-off.

Multilingual neural machine translation (MNMT) is an attractive field recently (Firat et al., 2016; Ha et al., 2016; Johnson et al., 2017) because MNMT tries to employ one model to translate more than one language pair, even including ones unseen during training (zero-shot translation). Knowledge transfer among languages boosts the performance of low-resource languages. However, many works (Arivazhagan et al., 2019; Zhang et al., 2020; Aharoni et al., 2019) have shown the capacity bottleneck of translation when modeling many languages. Therefore, before simply stacking more layers in the encoder and decoder, it is crucial to first understand how to balance the speed and accuracy given a fixed capacity budget. Therefore, in this work, we try to understand various capacity allocations to achieve the best speed-accuracy trade-off.

7 Conclusion

In this work, we study speed-accuracy trade-offs using various layer configurations for multilingual neural machine translation. We find that for many-to-one translation, deep encoder and shallow decoder (DESD) models improve decoding speed while maintaining translation quality with the same model capacity. However, for one-to-many translation we do observe a drop in quality when the decoder depth is reduced. To mitigate the performance drop of DESD models in one-to-many translation, we proposed using a shared encoder and *multiple* shallow decoders (DEMSD). Our best DEMSD models with 2-layer decoders are capable of speeding up decoding by 1.8 times while achieving the same quality compared to a standard transformer.

Our work can be combined with techniques mentioned in Section 6 such as optimized attention computation, vocabulary reduction, knowledge distillation, etc. We expect that these combinations will further improve the decoding speed and obtain a better speed-accuracy trade-off. This work can also be extended to other encoder-decoder applications beyond translation, such as question answering, dialogues, and so on. We will explore these directions in the future work.

A Training details of DESD model

In order to explore how DESD models work on multilingual machine translation, we train transformer-based models with various layer allocations on three multilingual machine translation corpora, ML50, TED8-Related and TED8-Diverse. For the fair comparison, the training process is the same across all models.

On ML50, we employ the standard transformer-base model: 8 attention heads per layer, 512 model dimensions, 2048 hidden dimensions and 0.1 dropout. All models are trained for 100,000 with batches of 64k tokens using Adam and 0.1 label smoothing. The learning rate goes to $1e{-3}$ within 4,000 steps,and then decays with the inverse square-root schedule.

On TED8 corpora, following (Wang et al., 2020), a smaller transformer model is adopted, i.e., 4 attention heads per layer, 512 model dimensions, 1024 hidden dimensions and 0.3 dropout. All models are trained for 40,000 with batches of 16k tokens using Adam and 0.1 label smoothing. The learning rate goes to $2e{-4}$ within 4,000 steps, and then decays with the inverse square-root schedule.

B Language family assignment results

In Table 5, we show the language family-based assignment result on TED8-Diverse. Since this corpus is collected without considering relatedness, some groups just have one language. But its multiple decoders model improves the accuracy, showing the effectiveness of this method.

The language families in ML50 is shown in Table 6.

Abstract

Sentence Compression is the task of generating a shorter, yet grammatical version of a given sentence, preserving the essence of the original sentence. This paper proposes a Black-Box Optimizer for Compression (`B-BOC`): given a black-box compression algorithm and assuming not all sentences need be compressed – find the best candidates for compression in order to maximize both compression rate and quality. Given a required compression ratio, we consider two scenarios: (i) single-sentence compression, and (ii) sentences-sequence compression. In the first scenario, our optimizer is trained to predict how well each sentence could be compressed while meeting the specified ratio requirement. In the latter, the desired compression ratio is applied to a sequence of sentences (e.g., a paragraph) as a whole, rather than on each individual sentence. To achieve that, we use `B-BOC` to assign an optimal compression ratio to each sentence, then cast it as a Knapsack problem, which we solve using bounded dynamic programming. We evaluate `B-BOC` on both scenarios on three datasets, demonstrating that our optimizer improves both accuracy and Rouge-F1-score compared to direct application of other compression algorithms.

1 Introduction

Sentence Compression is the task of generating a short, accurate, and fluent sentence that preserves the essence of a given original sentence by removing nonessential words and/or rephrasing it in a compact form. Compression can take many forms, ranging from Extractive and Abstractive Summarization (Jing, 2000; Madnani et al., 2007; Cohn and Lapata, 2008, 2009; Galanis and Androutsopoulos, 2010; Rush et al., 2015; Chopra et al., 2016) to Text Simplification and Paraphrasing (Bannard and Callison-Burch, 2005; Xu et al., 2012; Klerke et al., 2016; Narayan et al., 2017; Aharoni and Goldberg, 2018; Botha et al., 2018), among others.

On the sentential level, compression is often viewed as a *word deletion* task (Knight and Marcu, 2000, 2002; Filippova and Strube, 2008; Filippova et al., 2015; Wang et al., 2016, 2017; Zhou and Rush, 2019). However, not all sentences could, or should be compressed as part of compressing a longer text they reside in. Consider the familiar scenario in which a full paragraph needs to be compressed in order to have an EACL paper meet the page restriction specified in the submission guidelines. A common approach by LaTeX users is to first identify paragraphs ending with a short line, (e.g., this very paragraph), then choose one or more sentences that could be compressed with a minimal loss of information – shaving the extra line. We propose a Black-Box Optimizer for Compression (`B-BOC`) that mitigates this problem. Given a compression algorithm A, a desired compression ratio, and a document D, `B-BOC` chooses the best sentences to compress using A in order to produce a shorter version of D, while keeping the other sentences of D untouched. `B-BOC` achieves that without explicit knowledge of the inner-workings of the given compression algorithm, hence we call it a *black-box* optimizer. Selected sentences are expected to be the best candidates for compression – balancing compression rate with compression quality.

This paper addresses two main research questions: (1) How to predict the compression performance (preserving meaning and grammar) of an algorithm on a given sentence? (2) Given a document

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1625–1634
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

and a required compression ratio, how to choose the optimal *subset* of sentences to compress, along with the appropriate compression ratio per each of the sentences, so that the *total* compression meets the required compression requirement?

Given a gold set of pairs of sentences and their compressions, we represent each sentence as a vector of shallow and syntactic features, and train a regression model to predict its expected compression rate. `B-BOC` ranks all sentences by the predicted compression potential while considering a required compression ratio.

The document-level task could be modeled as a Knapsack optimization problem, considering the subset of sentences to be compressed in order to satisfy the overall compression requirement (capacity), with a minimal loss of information (value). The solution space covers the trade-off between aggressively compressing only a few sentences and applying minimal compression on a larger number of sentences. While the general Knapsack is NP-complete, the 0-1 variation can be approximated efficiently by using Dynamic Programming (Hristakeva and Shrestha, 2005).

We evaluate `B-BOC` on three benchmarks commonly used for the sentence compression task. We show that applying `B-BOC` on top of state-of-the-art sentence compression models improves the performance for any desired compression rate. In addition, optimizing the `B-BOC`-Knapsack achieves top performance on the document-level task.

2 Related Work

Early sentence compression works employ the noisy channel model, learning the words and clauses to be pruned (Knight and Marcu, 2000, 2002; Filippova and Strube, 2008; Clarke and Lapata, 2008; Cohn and Lapata, 2009).

The top-performing sentence compression models use a Policy Network coupled with a Syntactic Language Model (bi-LSTM) evaluator (Zhou and Rush, 2019), and a stacked LSTM with dropout layers (Filippova et al., 2015). An extension of Filippova et al., adding syntactic features and using Integer Linear Programming (ILP), yields improved results in a cross-domain setting (Wang et al., 2017).

Sentence selection is used for document extractive summarization – a task conceptually close to ours, in which full sentences are extracted from a long document, see (Nenkova et al., 2011) for an overview. State-of-the-art selection is achieved by combining sentence and document encoders (CNN and LSTM) with a sentence extraction model (LSTM) and a reinforcement layer (Narayan et al., 2018).

Sentence rephrasing is an abstractive approach to rewrite a sentence into a shorter form using some words that may not appear in the original sentence. A data-driven approach to abstractive sentence summarization is suggested in (Rush et al., 2015; Chopra et al., 2016), using about four million title-article pairs from the Gigaword corpus for training, and uses a convolutional neural network model to encode the source and produce a single representation for the entire input sentence. Tree-to-tree grammar extraction method for the rewriting task is used in (Cohn and Lapata, 2008, 2009). State-of-the-art performance on the abstractive summarization task is obtained using Hierarchical Attentional Seq2Seq Recurrent Neural Network (Nallapati et al., 2016; See et al., 2017).

3 Task Definitions and Methodology

In this section we formally define the sentence-level and the document-level tasks (§3.1) and provide a detailed description of the application of `B-BOC` in both settings (§3.2).

3.1 Problem Definitions

Sentence-Level Compression Given a set of sentences $S = \{s_i\}_{i=1}^{n}$; a desired compression rate γ; the number of sentences to compress $k \leq n$; a compression algorithm A; and an oracle $\mathbb{R} : (A, S) \rightarrow [0, 1]$, returning a score reflecting the compression quality (grammaticality and minimal loss of information) A would achieve on $s \in S$ – we would like to choose a set $S^{k,\gamma} \subseteq S$ of k sentences:

$$S^{k,\gamma} = \{s_j | \frac{|A(s_j)|}{|s_j|} \leq \gamma \wedge \underset{s_j}{\operatorname{argmax}}\, \mathbb{R}(A, s_j)\}_{j=1}^{k}.$$

We call this *sentence-level* compression since each sentence should meet the γ constraint independently. It is important to note that $\gamma' \leq \gamma \not\Rightarrow S^{k,\gamma} \subseteq S^{k,\gamma'}$, since different sentences may be better compressed to different γ values. Consider the following two sentences used to illustrate the importance of the Oxford comma: $S =${*"I had a yummy dinner with my parents, Batman and Catwoman", "I had a yummy dinner with my parents, Batman, and Catwoman"*}[1], and $k = 1$. The first

---

[1] The first sentence, without the Oxford comma, implies that Batman and Catwoman are the speaker's parents, the

sentence could be compressed to "I had a yummy dinner with my parents" with a minimal loss of information, while it does not make sense to compress the second sentence this way and it should be compressed to "I had a yummy dinner", thus specifying $k = 1$, the sentence to be compressed with minimal loss of meaning depends on the desired γ value.

Document-Level Compression In this setting, we are given a sequence of sentences $D = \{s_i\}_{i=1}^{n}$ (a paragraph or a full document), and a desired compression rate γ that should be applied to D as a *whole*. That is, we wish to find an optimal subset of S^γ that satisfies:

$$\underset{S^\gamma \subseteq D}{\operatorname{argmax}} \sum_{s_i \in S^\gamma} \mathbb{R}(A, s_i) \tag{1}$$
$$\text{s.t.} \quad \frac{\sum_{s_i \in S^\gamma} |A(s_i)| + \sum_{s_i \in D \setminus S^\gamma} |s_i|}{|D|} \leq \gamma$$

Since γ refers to D rather than to individual sentences, the overall quality can be maximized by choosing a varying number of sentences expected to achieve different optimal compressions. Unlike the sentence-level setting, here, an optimal S^γ may contain a combination of sentences, for some of which $\frac{|A(s)|}{|s|} \leq \gamma$, and for others $\frac{|A(s)|}{|s|} > \gamma$.

3.2 Computational Approach

Scoring Function Given a corpus $C = \{\langle s_i, \hat{s}_i \rangle\}_i^m$ of sentence pairs, each pair contains an original sentence s and its gold compression $\hat{s}$, we define the golden ratio $\hat{\gamma}_i = \frac{|\hat{s}_i|}{|s_i|}$, and posit $\mathbb{R}(A, s) \approx 1 - |\hat{\gamma}_i - \frac{|A(s_i)|}{|s_i|}|$.

We justify the use of $\hat{\gamma}_i$ as a proxy to the optimal compression quality, as compression ratios are found to correlate with compression quality measured against gold compressions (Napoles et al., 2011). The use of $\hat{\gamma}_i$ as a proxy is validated through manual evaluation, see Sections 4.2 and 5.1.

Syntactic features were successfully used for sentence compression (Clarke and Lapata, 2008; Wang et al., 2017; Liu et al., 2017; Futrell and Levy, 2017). Assuming that sentence complexity correlates with the ease of compression, we follow (Brunato et al., 2018) and represent each sentence as a vector of shallow features (sentence length, average word length, punctuation counts, etc.) and syntactic features (depth of constituent parse tree as well as the number of internal nodes, word's depth in a dependency parse tree, mean dependency distance, etc.).

We now train a regression model and learn the scoring function $R(A, s)$ by minimizing the loss:

$$L(C, A) = \Sigma_{s_i \in C} \left[R(A, s_i) - \mathbb{R}(A, s_i)\right]^2$$

We note that we do not train a compression algorithm, but an oracle – a scoring function that predicts the *quality* of the compression algorithm A will achieve on a given sentence. This oracle will be used to rank candidate sentences in order to optimize the choice of sentences in the two tasks defined in Section 3.1.

We train a Gradient Boosted Tree regression model using XGBoost. The model's hyperparameters (e.g., subsample ratio, learning rate, max depth) were tuned on a separated development set.

Sentence level compression: Given a set of sentences S, B-BOC operates on two steps: (i) It applies R on every $s \in S$, producing an ordered set $\hat{S}$ for which $\forall_{i<j} R(A, s_i) \geq R(A, s_j)$. (ii) It constructs $S^{k,\gamma}$ by iterating over $\hat{S}$, choosing the first k sentences that satisfy the γ requirement.

Document level compression: Using the task definition in Section 3.1, it is straight forward to cast the task as a combinatorial 0-1 Knapsack problem in the following way: Given a set of items (sentences) $S = \{s_1, ..., s_n\}$, each weighs $w_i = |A(s_i)|$ if compressed, or $|s_i|$ if kept in the original form, and each holds a value $v_i = R(A, s_i)$ (predicted compression quality), if compressed and $v_i = 1$ if kept in the original form; and given a weight limit $W = \gamma \cdot \sum_1^n |s_i|$ – we wish to find $S^\gamma = \{s_i | x_i = 1\}$ that maximizes:

$$\sum_i (v_i x_i - [1 - x_i]^{-1}) \qquad \text{s.t.}$$
$$\sum_i (w_i x_i - |s_i| \, [1 - x_i]^{-1}) \leq W \quad , x_i \in \{0, 1\}$$

were $x_i = 1$ denotes we choose to compress s_i and $x_i = 0$ denotes that s_i remains in its original long form (hence the 0-1 Knapsack setting). Note that the value we maximize and the weight constraints include a term for the unchanged sentences, in case they are not chosen for compression. This term is introduced since the γ constraint in the task definition applies to the document as a whole.

---

second sentence implies that the speaker had dinner with four people – her parents *and* Batman *and* Catwoman.

B-BOC-knapsack returns S^{γ} by solving the 0-1 knapsack problem using the dynamic programming approach proposed by (Hristakeva and Shrestha, 2005) to reduce the computation complexity to a pseudo-polynomial time. Knapsack's solution ensures an optimal set of sentences, satisfying the required compression limitations, while achieving the maximum quality score.

4 Experimental Setting

4.1 Datasets

Training Data: We train B-BOC on a dataset of 200,000 sentence-compression pairs[2] used by Filippova and Altun (2013). Each pair is composed of a long sentence (usually the teaser, caption, extract or the first sentence that bears the most salient information) from a news story and the story's headline, which is a compressed version of the long sentence.

Out of these 200,000 sentences, we set aside 9,000 to be used as a development set, and 1,000 as one of our three test sets.

Evaluation datasets: Three datasets are used for evaluation:

1. Google (GGL) – the first 1000 sentences of the training corpus (described above) were used for testing.
2. British National Corpus (BNC) – a manually crafted dataset of $\sim$ 1500 sentence-compression pairs. Given a long sentence, annotators were asked to produce a short version by deleting extraneous words from the source without changing the order of words [3].
3. Gigaword (GIGA)- headline-generation corpus of articles[4] consists $\sim$ 4 million sentence-compression pairs. We note that this dataset contains abstractive pairs, nevertheless, it can be used to measure accuracy.

4.2 Evaluation Procedures

Evaluation metrics: We used four evaluation metrics that complement each other, providing a comprehensive evaluation of the different factors that contribute to quality summarization as suggested by (Filippova et al., 2015): (1) Accuracy – how many compressed sentences are fully reproduced, (i.e., the generated compression is identical to the golden one). (2) F-score – given the golden and predicted compressions, recall and precision are based on the ROUGE metric. (3) Readability score – the grammaticality of the compression. (4) Informativeness – the level in which the compression covers the most salient information.

The two latter metrics are based on a manual evaluation by three annotators, scoring Readability and Informativeness on a 5-Point Likert scale. The annotators were guided to give a top Readability score (score 5) if the predicted compressed sentence is clear and grammatically correct, regardless of the original context, and a top Informativeness score (score 5) if the essence of the original is preserved completely. The Informativeness measurement bears some degree of subjectivity as annotators may not agree on what should be considered "the essence" of a sentence, see examples in Table 1. We used Cohen's Kappa (Cohen, 1960) to measure inter-annotator agreements. Low agreements are expected due to the subjectivity and the five-point scale, i.e., when two raters agree on the grammaticality of a sentence, but do not give the same exact Informativeness score. To account for slight variations in assessment, we measure agreement using the off-by-one procedure proposed by (Tsur and Rappoport, 2009) and supported by (Toutanova et al., 2016). Linear and Quadratic weighting were added as additional statistical methods. Nevertheless, we kept the 5-point scale to be aligned with Filippova's evaluations. The Kappa values for the strict and the off-by-one agreement for a sample of 200 sentences of the GGL dataset are reported in Table 2. These scores are comparable with the scores reported by (Filippova et al., 2015). Agreement of 0.86 and 0.78 for Readability and Informativeness reflect an almost perfect agreement on Readability and substantial agreement on Informativeness, according to the interpretation protocol suggested by McHugh (2012).

4.2.1 Black-Box Compression Models

As described in Section 3.2, B-BOC accommodates any compression model used to compress the sentences. To show this independence, B-BOC is evaluated with three competitive compression models: (1) `Filippova`: An LSTM model trained on two million sentence-compression pairs (Filippova et al., 2015), (2) `Zhou`: An unsupervised model for sentence summarization (Zhou and Rush, 2019), and (3) `Klerke`: A three-layer bi-LSTM model (Klerke et al., 2016).

4.3 Experimental Procedure

Given the two settings presented in Section 3.1, we aim to evaluate the performance of `B-BOC` in optimizing compression quality, on top of a number of black-box compression algorithms. We evaluate the way different values of k affect the performance, and explore the contribution of various feature types to the trained optimizer.

4.3.1 Sentence level compression:

We evaluate the effectiveness of `B-BOC` for varied compression rates. The tested sentences were divided into buckets of different compression rates 0.1-0.9. For each bucket we set k to be 50% of the sentence in a bucket and compare `B-BOC` selections to: (1) A random selection of k sentences from the bucket (RANDOM). (2) The average of all sentences in the compression rate bucket (ALL). We report results of this comparison for each of the black-box algorithms listed in Section 4.2.1). Note that the F-score is based on the actual results of each of the black-box models, and that both `B-BOC` and RANDOM choose from the same pool of candidates for each compression rate bucket.

4.3.2 Document level compression

Having a document or a paragraph comprised of several sentences that are needed to be compressed, the target is to find the sentences that would gain the highest performance score subject to the overall compression ratio constraint.

To simulate a document, we synthesized one hundred documents by randomly sampling sentences from the test set. Every document contains 100 different sentences of varying lengths. We then use `B-BOC`-Knapsack as described in 3.2. `B-BOC`-Knapsack is compared with: (1) an oracle Knapsack solution where the golden scores are provided, rather than estimated by `B-BOC` (ORACLE). (2) We iteratively sample sentences to compress until the compression ratio is reached (RANDOM). (3) A sorted selection- choosing sentences by their lengths in an ascending sort (SHORTER FIRST). The latter baseline was added followed by our experiments, showing that compression quality tends to be higher for shorter sentences.

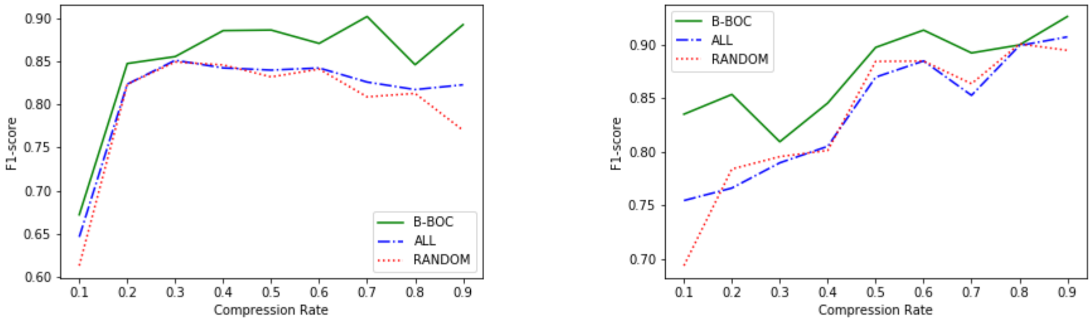
5 Results and Discussion

5.1 Results

Detailed results for both sentence level and document level compression are presented below.

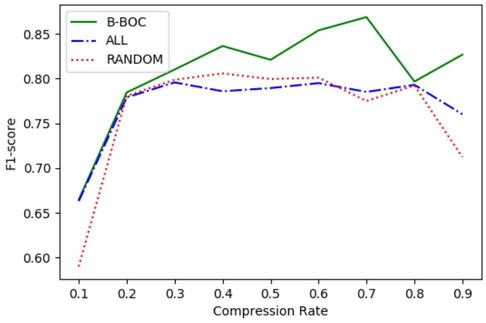
Sentence level compression: Figure 1 presents the F1 performance of sentence selection methods over varied γ-buckets on the GGL dataset, while training with the compression models of Filippova and Zhou respectively. `B-BOC` is compared with all sentences and a random selection of sentences, as described in Section 4.3.1. It can be seen that `B-BOC` achieves the highest F1-score for every γ. The evaluated metrics' averages for all compression buckets are presented in Table 3, evaluating the GGL dataset using three different compression models. Best results are in bold. `B-BOC` achieves the best performance overall measures – automatic and manual (F1-score, Accuracy, Readability and Informativeness).

The results confirm that by utilizing `B-BOC`, the top sentences which yield the best overall compression results will be chosen, no matter which black-box compression model is applied, for every given compression ratio. Table 4 describes the average F1-scores and variances for the manual evaluations



(a) Filippova's compression model

(b) Zhou's compression model



(c) Klerke's compression model

Figure 1: Average F1-score (y-axis) applied on the GGL dataset for different compression rate buckets (x-axis) while training `B−BOC` with Filippova (a), Zhou's (b) and Klerke (c) compression models.

		F1-score	F2-score	Accuracy	Readability	Info.
Filippova	ALL	0.837	0.77	0.31	4.562	3.78
	RANDOM	0.835	0.76	0.306	4.559	3.79
	`B−BOC`	**0.86 ***	**0.795**	**0.332**	**4.65**	**4.08**
Zhou	ALL	0.82	0.7	0.24	**3.92**	3.41
	RANDOM	0.815	0.69	0.226	3.91	3.41
	`B−BOC`	**0.87 ***	**0.77**	**0.30**	**3.92**	**3.60**
Klerke	ALL	0.787	0.685	0.187	4.12	3.73
	RANDOM	0.783	0.677	0.156	4.00	3.65
	`B−BOC`	**0.815 ***	**0.72**	**0.214**	**4.23**	**3.97**

Table 3: GGL dataset: Evaluation metrics' average results over all compression rate buckets. Statistical significance using a paired T-test is indicated by *.

Likert score	Info. F1	Read. F1	Info. Var	Read. Var
1	0.59	0.67	0.13	0.10
2	0.66	0.66	0.07	0.04
3	0.70	0.69	0.05	0.05
4	0.77	0.74	0.04	0.05
5	0.77	0.75	0.03	0.04

Table 4: Readability and Informativeness average F1-scores and variance.

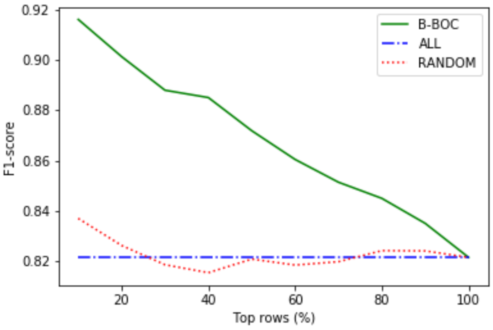


Figure 2: F1-score (y-axis) per top X% of sentences (x-axis) that are ranked by `B−BOC`.

of the GGL dataset using Filippova's compression model. It can be seen that both Readability and Informativeness are correlated with F1-scores. A compression that gets a higher Readability or Informativeness on the 5-point Likert score, will most probably get a higher F1-score as well, with a lower variance. This manual evaluation of Readability and Informativeness supports our choice of $\mathbb{R}$ (see Section 3.2).

As described in Section 4.3.1, the top 50% of the test dataset are chosen for our evaluations. We repeated the same experiment varying the number (percentage) of sentences ranked by `B-BOC`. Figure 2 presents the impact of the number of sentences we consider, and demonstrates the deterministic trend of `B-BOC` ranking method. It can be seen that when considering only the higher ranked sentences, their compression will produce a higher F1-score. It suggests that the lower number of sentences we consider – the higher the benefit of `B-BOC` is, compared with a random selection of the same number of selected sentences.

Document level compression: Given a document or a paragraph and a specified compression rate requirement, `B-BOC`-Knapsack aims to find a subset of sentences, that together will satisfy the compression rate constraints if being compressed, and while guaranteeing a top F1-score. Our results below depict an experiment for compressing a document with a certain compression ratio constraint. A document is constructed using 100 sentences with variate lengths, randomly selected from a given dataset. `B-BOC`-Knapsack sentence selection is being compared with a random selection and a sorted selection of the sentences, as described in Section 4.3.2. Each experiment was repeated 100 times, sampling different sentences for each of the datasets. The average scores reported below were achieved with the same compression model used by Filippova (see Section 4.2.1) for all sentences.

Figure 3 presents the experiments for GGL and BNC datasets respectively. An overall compression requirement is added, ranging from 0.1 to 0.5 (e.g., 0.1 means that the document should be compressed in 10 percent). `B-BOC`-Knapsack has a higher F1-score for almost every compression ratio, especially at the lower ratios.

Knapsack's oracle solution can be created when considering the actual F1 and compression rates for all sentences. A histogram of the sentences that the oracle Knapsack chose to compress, grouped by their lengths is presented in Figure 4. The Figure provides a number of insights: (1) The F1-score decreases as the number of compressed sentences grow, due to the increased uncertainty when compressing more sentences. A similar pattern is observed in Figure 3. (2) The Knapsack prefers to choose shorter sentences, as these perform better than longer sentences. We attribute this to the fact that shorter sentences may be easier to optimize, as compression alternatives are limited, compared to longer sentences.

		F1-score	Readability	Informativeness
GGL	ORACLE	0.89	4.64	4.05
	RANDOM	0.837	4.59	3.76
	SHORTER FIRST	0.850	4.6	3.97
	`B-BOC`	**0.854**	**4.62**	**4.01**
BNC	ORACLE	0.68	3.77	3.26
	RANDOM	0.55	3.53	3.13
	SHORTER FIRST	0.62	3.69	3.24
	`B-BOC`	**0.63**	**3.79**	**3.28**
GIGA	ORACLE	0.47	-	-
	RANDOM	0.256	-	-
	SHORTER FIRST	0.297	-	-
	`B-BOC`	**0.303**	-	-

Table 5: Average results- Document level compression.

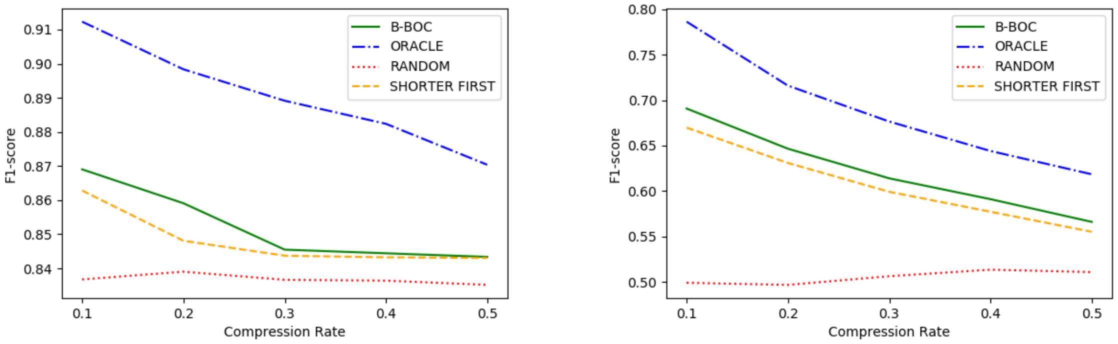
The average results for the three datasets are presented in Table 5. Best results are in bold. Informativeness and Readability average scores are aligned with the F1-scores (note that the GIGA dataset was not manually annotated for Readability and Informativeness, since we are focused on extractive summarization rather than abstractive, and the Readability and Informativeness of the two types cannot be compared directly). We observe that `B-BOC` chooses the best sentences and provides a better compression performance for any compression ratio.

Feature Importance: Sentence complexity is correlated with the parse tree structure (Oya, 2011). Analyzing the contribution of each feature type, we find the tree depth features and especially Mean Dependency Distance (MDD) to do the heavy lifting. The MDD is the sum of the depth of words in the dependency tree, divided by the total number of dependencies. For example, the MDD scores for two sentences of the same character length "Sarah read the book quickly and understood it correctly" (Figure 5 top) and "US President Donald Trump tests positive for coronavirus" (Figure 5 bottom) is $19/8 = 2.735$ and $11/7 = 1.57$, respectively. This observation validates the relation between sentence complexity and compression.

Table 6 presents the importance of the syntactic features to the `B-BOC` model in terms of weight, which means the relative number of times a feature occurs in the boosted trees of the trained model. Shallow properties such as the number of verbs and number of nodes are located at the bottom.

5.2 Discussion

Limitation of the F1-score Our main target is maximizing the F1-score, which happens to be a common approach for the sentence compression task, e.g., (Filippova et al., 2015; Zhao et al., 2018).



(a) GGL dataset

(b) BNC dataset

Figure 3: 0-1 Knapsack's F-score results for GGL dataset (a) and BNC dataset (b). x-axis is the total desired compression rate of the document (i.e., 0.1 means compressing the whole document by 10 percent). y-axis is the average F1-score of the subset of sentences being compressed.

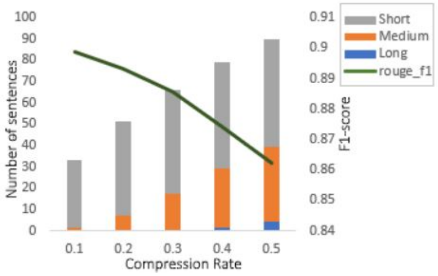


Figure 4: GGL dataset: Oracle Knapsack subset's histogram. Two y-axis are average F1-score of the subset (right axis, describes the line) and the number of selected sentences to be compressed (left axis, describes the bars' height). x-axis is the total desired compression rate of the document.

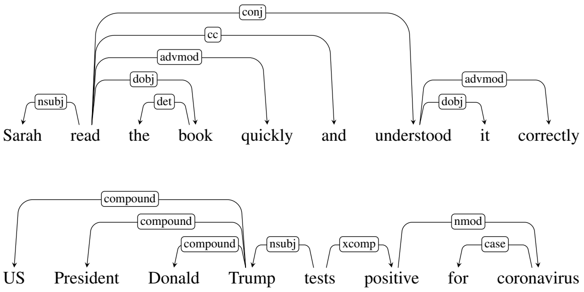

Figure 5: Dependency trees of sentences of the same length (chars), but different depth and MDD score.

Feature name	Weight
Word Length Average	0.140630
MDD-score	0.121428
Tree Depth Average	0.116776
Character count	0.093331
Count Relations	0.079562
Count PoS	0.072715
Parse-Tree Height	0.069478
Count Nodes	0.066835
Parse-Tree sub trees	0.061700
Count words	0.051541
Dependency tree depth	0.045512
Verb count	0.042461
Parse-Tree count POS types	0.038032

Table 6: Feature Importance of B-BOC. The percentages representing the relative number of times a particular feature occurs in the trees of the model.

Automatic evaluation metrics like the F1-score serve complementary purposes for linguistic quality evaluation rather than replacement because it is unclear whether the improvement in F1-score necessarily indicates the improvement of linguistic quality. Nevertheless, it was shown that the F1-score correlates with human judgment (Napoles et al., 2011). We manually performed additional evaluation for Readability and Informativeness to complement the evaluation based on the F1-score. For example, when applied on the document-level on the BNC dataset, B-BOC does not achieve the best F-score but does achieve best Readability and Informativeness scores (see Table 5).

Fairness Compression algorithms should be compared for similar levels of compression (Napoles et al., 2011). Partitioning S to different compression rate buckets, as explained in 4.3.1 and demonstrated in Figure 1, ensures a fair comparison between the different compression models.

Manual evaluations. Exploring the cases in which annotators did not agree on either Readability or Informativeness, we noticed a higher likelihood for disagreement in the lower scale of both measurements, especially in case the original sentence was convoluted or grammatically flawed.

6 Conclusions

In this paper we presented `B-BOC`- Black-Box Optimizer for Compression, a new complexity optimization method designated to the sentence compression problem. We defined the correlation between the complexity of a sentence and the chance that a black-box compression model could successfully compress it. Our optimization model is independent of the compression model used to compress the sentences and can be combined with any sentence compression model. Our evaluation on three benchmarks revealed promising results when applied to three different types of sentence compression models. We achieve top performance for a document compression problem using the `B-BOC`-Knapsack optimization implemented with a bounded Dynamic Programming technique. Our method could assist in compressing any kind of text while applying their desired compression model. Utilizing our method provides a proper guideline for which of the sentences are the most beneficial to focus on, in order to compress a given text, while yielding the best overall compression results.

For future work, we plan to construct Model-Dependant Optimization that accounts for the features of each compression model. This will facilitate a choice of the compression model that is the most suitable for a given sentence.

Acknowledgments

We would like to thank Katja Filippova and Alexander Rush for providing us with the outputs of their compression models.

Abstract

We present WiC-TSV, a new multi-domain evaluation benchmark for Word Sense Disambiguation. More specifically, we introduce a framework for *Target Sense Verification of Words in Context* which grounds its uniqueness in the formulation as binary classification task thus being independent of external sense inventories, and the coverage of various domains. This makes the dataset highly flexible for the evaluation of a diverse set of models and systems in and across domains. WiC-TSV provides three different evaluation settings, depending on the input signals provided to the model. We set baseline performance on the dataset using state-of-the-art language models. Experimental results show that even though these models can perform decently on the task, there remains a gap between machine and human performance, especially in out-of-domain settings. WiC-TSV data is available at `https://competitions.codalab.org/competitions/23683`

1 Introduction

Word Sense Disambiguation (WSD) is a long-standing task in Natural Language Processing and Artificial Intelligence. While progress has been made in recent years, mainly thanks to the surge of transformer-based language models such as BERT (Loureiro and Jorge, 2019; Vial et al., 2019; Huang et al., 2019), the evaluation of WSD models has been limited to a set of (mostly SemEval-based) standard WSD datasets (Raganato et al., 2017). These datasets usually come in one of the two forms: *lexical sample*, in which a target word is placed in various contexts, triggering different senses, and *all-words*, in which all the content words in a given text are to be disambiguated. Both settings, however, come with a major restriction: word senses in the datasets are linked to external sense inventories such as WordNet (Fellbaum, 1998). Therefore, existing benchmarks are limited to only those WSD systems in which sense distinctions are defined according to an underlying sense inventory. This not only gives restrictions to the model's flexibility, but also enforces the assumption of the availability of complete data. However, as general sense inventories are complex to maintain they often lag behind in being up-to-date[1], yielding to the absence of novel terms and term usages. Furthermore, the coverage of domain-specific terms and named entities in general sense inventories is quite limited, while domain-specific sense inventories are rare and in most cases incomplete.

As a motivating example, let us assume *Technology* as the target domain and the collection of information on the current technology landscape as a goal. Therefore, the following context needs to be disambiguated in order to evaluate its relevance:

> *From 1970 to 2007,* ***Apple's*** *chief executive was former Beatles road manager Neil Aspinall.*

Even when incorporating a general sense inventory (which would include senses for the fruit and the tree) and a technology-specific sense inventory (which would include the sense for Apple Inc. the technology company), the actual target sense of this context (i.e., Apple Corps Limited, a multimedia corporation founded by the Beatles) may still be missing, which makes the annotation of the correct sense impossible. For these reasons, the current WSD task formulation and existing benchmarks are not fully able to evaluate the suitability of disambiguation systems in realistic domain-specific and/or enterprise settings.

In this paper, we try to fill this gap by proposing a re-formulation of the existing WSD task as well as a new benchmark for evaluating WSD systems under this paradigm.

---

[1] The last update in WordNet dates back to June 2011.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1635–1645
April 19 - 23, 2021.

Target Sense Verification (TSV) formulates the disambiguation of a word as a binary classification task where the equivalence of the intended sense of a word in context and a single given sense is evaluated. For instance, in the example above, the system would need to decide whether the sentence refers to *Apple Inc.* the technology company or not, by being provided with a sense indicator for solely Apple Inc. (e.g., the hypernym *technology company* or the definition).

A system able to efficiently solve the TSV task could be effectively used in the scenario of collecting and tagging large amounts of textual data; e.g., from social media, news agencies, blogs and for downstream tasks such as information retrieval, sentiment analysis or relation extraction. Furthermore, such a system could be a good candidate for entity linking (EL) as the task statement of TSV resembles the usage of enterprise knowledge graphs (Galkin et al., 2017) for EL: typically, small domain-specific enterprise knowledge graphs only contain entities from the domain of interest, partially or completely missing the general purpose senses of the contained labels.

In order to train and evaluate models for TSV we constructed **WiC-TSV (Word in Context - Target Sense Verification)** a multi-domain dataset and evaluated standard unsupervised and supervised approaches (including language models). While WiC-TSV's training and development set consist of general purpose instances, the test set contains domain-specific instances from three different domains. Therefore, this dataset aims at evaluating the ability of a model to (1) disambiguate the word in context without an external sense inventory, (2) deal with unseen instances and incomplete data, and (3) transfer the intrinsic knowledge (gained on general domain data) into a specific domain.

2 Related Work

Word Sense Disambiguation. The task of WSD consists of associating a word in context with its most appropriate entry in a given sense inventory (Navigli, 2009), e.g., WordNet. For WSD there are many associated datasets (Raganato et al., 2017; Vial et al., 2018; Röder et al., 2018; Ling et al., 2015), including domain-specific ones (Agirre et al., 2009; Faralli and Navigli, 2012). The main difference between WSD and its re-formulation TSV is that for TSV the availability of a sense inventory is not required. Instead of associating a word in context with its most appropriate sense, the usage of a single given sense in the provided context is to be verified. Systems that aim to solve the proposed task are therefore not required to model all senses of the target word, but only a single sense instead.

This facilitates the development of systems for specific domains or settings, as no general-domain knowledge resource is required to perform this task. For instance, an Indonesian company may want to retrieve all sentences referring to the *Java* island and not other unrelated senses. This framing of the task is frequent in business and data mining settings where domain-specific knowledge resources or inventories may be available, without the need for modeling instances from other domains.

WiC. The task closest to the proposed WiC-TSV is probably Word-in-Context (Pilehvar and Camacho-Collados, 2019, WiC), which our dataset is based on. WiC is a binary classification dataset where a target word is presented within two different contexts. The task consists of deciding whether the word is associated with the same sense in the two contexts or not. WiC is also one of the tasks included in the general language understanding framework SuperGLUE (Wang et al., 2019).

WiC-TSV inherits some of the desirable properties of WiC, such as independence from external sense inventories and the binary classification nature of the task. However, though our benchmark draws ideas from the Word-in-Context benchmark, it provides a different evaluation setting with additional flavors. The main difference with respect to our dataset lies in the presence of relevant information such as hypernyms and definitions, which makes our dataset more realistic and a direct proxy for downstream evaluation: in WiC-TSV the ambiguous target word in a single context is compared against a specific target sense (indicated by provided hypernyms and definitions), in contrast to the comparison of the intended senses of the target word in two different contexts. Also, the task is more targeted at word-level representation, as in one of the tasks (i.e. *hypernymy* task) the model is not provided with any contextual information and, therefore, needs to have a clear understanding of the word to be able to make correct judgements. Moreover, WiC-TSV includes instances from three domains (cocktails, medicine, and computer science) in its test set, which makes the benchmark more challenging and comparable to a real setting.

3 WiC-TSV: The Benchmark

A goal of this benchmark is to evaluate the ability of a model to verify the target sense of a word in a context without the usage of an external sense inventory, i.e., without knowing all possible senses of the target word. Another model quality that is aimed at with the presented benchmark is the ability to transfer the intrinsic knowledge into a specific domain. As for most areas, domain-specific training data is hard to obtain, being able to learn on general purpose data and still perform well on domain-specific data is a huge advantage in a real world setting.

To this end, we constructed a benchmark satisfying following requirements:

1. Knowledge of only a **single sense** of the target word;
2. Knowledge of the **definition and/or hypernyms** of the target sense;
3. Ability to test the models capability to disambiguate both **general purpose and domain-specific** senses;
4. Ability to test the models capability to classify usages of previously **unseen words**;

Formally, each instance in the dataset consists of a target word w, a context c containing the target word w, and its corresponding target sense s represented by either its definition (Task 1), its hypernym/s (Task 2), or both definition and hypenyms (Task 3). The task aims to determine whether the intended sense of the word w used in the context c matches the target sense s.

Table 1 contains examples of instances from the WiC-TSV test set. Furthermore, a small sample of 10 instances is available online in the form of a survey[2], where the achieved score is shown to the user after the submission.

3.1 Dataset Construction

In this section we detail the construction of the dataset. First, we describe the construction of the training and development set (Section 3.1.1) and then the test set (Section 3.1.2), with a special focus on the creation of the domain-specific subsets.

3.1.1 Training and Development Set

Instances in the training and development set do not focus on a specific domain. As basis served the Word-in-Context (WiC) dataset (Pilehvar and Camacho-Collados, 2019), which contains a target word w and two contexts c_1 and c_2 for each instance. The contexts from WiC for noun instances come from two resources: WordNet and Wiktionary. To maintain the desirable characteristics of the WiC dataset (e.g., balanced data, not having repeated contexts across instances), the splits of the original training and development sets were treated separately in the following way: starting from a noun-only sub-sample, for each context c_i, the sense of the target word w was mapped to the corresponding synset of WordNet, adding a sense identifier. Each WiC instance was then split into two instances, one for each context. For initial negative instances (i.e. w has different intended senses in c_1 and c_2), the sense identifiers of these two instances were switched. To avoid information leakage, only one of the two instances were kept for the WiC-TSV dataset[3]. Finally, for each sense, the definition and hypernyms were derived from WordNet using the sense identifiers.[4]

3.1.2 Test Sets

To make the dataset more challenging and realistic, the test set incorporates both general purpose and domain-specific instances.

General Purpose (WNT/WKT). The general purpose instances were generated analogously to 3.1.1. Hence, this test set is composed of both WordNet and Wiktionary examples, with definitions and hypernyms extracted from WordNet.

In the following we describe the construction of the domain-specific subsets. The main difference between domain-specific and WNT/WKT test sets is that in the former the target sense remains the same. That means, that even though "fork" might have different senses within the computer science domain, we are only interested in one of these senses.

Cocktails (CTL). For the cocktails instances the target words were taken from the "All about cocktails" thesaurus[5]. The thesaurus contains 300 en-

---

[2] https://www.surveymonkey.com/r/LHYWXPV

[3] If both instances were kept, the label could have been predicted with a high accuracy by counting the appearance of the target sense (even=True, odd=False).

[4] WordNet sense identifiers are omitted in the final dataset.

Table 1: Sample instances from WiC-TSV. Target words are marked in bold. Tags: T (True) and F (False).

tries describing not only cocktails, but also beverages, garnishes and glassware, among others. For instances obtained from this resource, the hypernym "cocktail" is used in the WiC-TSV dataset, while the definition is derived from the thesaurus.

Medical Subjects (MSH). For medical subject instances we use terms, definitions and hypernyms from the MeSH thesaurus[6]. This thesaurus is used for indexing medical articles and therefore contains a wide variety of terms in this domain. We considered various types, such as diseases, symptoms and body parts as target words.

Computer Science (CPS). Target words in the computer science domain were gathered manually, without a readily available thesaurus. The definitions were derived from the lead section of the corresponding Wikipedia page, while hypernyms were created by the consensus of two domain experts.

In order to create the domain-specific instances, first a list of ambiguous words and their domain-specific target senses was fixed for each domain. Then, we used the Wikilinks dataset (Singh et al., 2012) as a basis for collecting different contexts containing the target words. This dataset contains documents – blog posts scraped from the web – and the links from these documents to the Wikipedia pages, which were used to assign the intended sense (i.e., target sense or other sense) to the target word. Where needed, additional contexts were collected manually by incorporating a search engine to find contexts for the target word. The intended senses for these instances were assigned manually.

Postprocessing. After creating the initial domain-specific instances, the subsets were checked manually to remove non-suitable and unsolvable instances. To maintain a rather realistic evaluation setup, data was not completely cleaned, meaning that contexts can contain *noisy* elements such as headings or meta-info derived from the websites (e.g., "posted by").

3.2 Data Cleaning

While the quality of the domain-specific instances is assured due to their manual creation process,

---

[6] `www.nlm.nih.gov/mesh/`

an additional data cleaning step was introduced in which general purpose instances were manually curated. The instances from the test set were split into four sets with an overlap of 20%. Each set was evaluated by an annotator regarding correctness and solvability of the instances. For example, when the hypernym of an instance was too generic to help in the disambiguation process, or the context itself was too ambiguous, the instance was marked as "to filter out". Each marked instance was reviewed by a second annotator, who could either confirm, or reject the request of removal. Instances marked by both annotators were removed.

An example of such a removed instance would be the context *"The* ***zero*** *sign in American Sign Language is considered rude in some cultures ."* for the target word "zero" with the target definition '*a mathematical element that when added to another number yields the same number*'. In American Sign Language (ASL), "zero sign" is a ring-shaped hand sign using the thumb and pointing finger, similar to the OK-gesture. The provided instance mixes two senses of "zero sign". On the one hand, it refers to the hand gesture itself (synonymous to OK-gesture) which does not fully match the target sense. On the other hand, it also refers to the sign of the digit zero in ASL, which does match the target sense.

Other examples of filtered instances involve sentences where the target word may have been used metaphorically.

This procedure resulted in 106 instances which were removed. About 8% of these instances were part of evaluation sets created to measure the human performance (see 3.4)[7]: the annotators achieved a mean accuracy of only 56% on these instances. This shows that the data cleaning step was necessary in order to ensure the data quality of the test set.

3.3 Statistics

A statistical overview of the dataset and their splits is shown in Table 2. The totality of 3832 available instances were split into train, development and test sets with a ratio of 56:10:34 which allows a sophisticated analysis of the generalisation capabilities of tested systems, while still providing an appropriately sized training set.

The test set contains around 55% general purpose instances and 45% from specific domains. For each domain, the number of unique target words is relatively low compared to the general domain subset, which results in a higher number of instances per target word. However, for domain specific words, a great variety of senses is used in the contexts, yielding a big diversity among the instances. For all three splits, positive and negative instances are approximately balanced.

		Total	N_w	R_+
Train	**WNT/WKT**	2137	864	0.56
Dev	**WNT/WKT**	389	377	0.51
Test	**General-domain (WNT/WKT)**	717	664	0.54
	Domain-specific (MSH+CTL+CPS)	589	25	0.47
	MSH	205	8	0.52
	CTL	216	9	0.43
	CPS	168	8	0.46
	All	1306	689	0.51

Table 2: Statistics of training, development and testing splits of WiC-TSV, including total number of instances (Total), unique number of target words (N_w) and percentage of positive instances (R_+).

3.4 Human Performance

To estimate the human performance upper bound, a sub-sample of the test set was manually annotated. The performance was evaluated on the setting of Task 3, meaning that both the definition and the hypernyms were provided to disambiguate. A random selection of 250 instances were split into two evaluation sets of the size of 150, resulting in a 20% overlap. Each evaluation set was assigned to a non-expert annotator with English as native language. No additional information - especially not from the respective ontology or about other senses of the target - was provided to the annotators and they were instructed not to use external knowledge sources (e.g. if they are not familiar with the domain-specific sense of a word).

Results of the human performance evaluation can be found in Table 3. The mean accuracy for the evaluated datasets was 85%, with individual scores of 81% and 89%. To estimate the inter-annotator reliability, the agreement of the two annotators on the overlapping instances was calculated: for 42 instances (84%) the annotators agreed on the label.

When evaluating the instances per domain, it can be seen that the general purpose instances were

---

[7] Annotations for these instances were removed before calculating the metrics presented in 3.4

	Human Perf.
WNT/WKT	82.1
MSH	89.1
CTL	92.0
CPS	86.5
All	85.3

Table 3: Average human accuracy for native English annotators, on different subsets of the dataset: general purpose, i.e., WNT/WKT, and the domain specific, i.e., MSH, CTL, and CPS.

more difficult than the domain-specific ones, as annotators achieved an average accuracy of 82% (individual scores of 77% and 87%) on the general purpose instances, while the mean accuracy on the domains were 89% (83% and 96%), 92% (88% and 96%), and 86.5% (89% and 84%) for MSH, CTL, and CPS, respectively. This performance difference is even more evident when comparing to the performance of non-native speakers: an additional experiment showed, that evaluators whose mother language is not English only achieved an average accuracy of about 77% on the WNT/WKT instances, while performances on the domain specific subsets were comparable to native speakers.

4 Experimental Results

In this section we evaluate the performance of different baseline models on our WiC-TSV benchmark. For our experiments we considered two main systems, namely BERT (Devlin et al., 2019) and FastText (Joulin et al., 2017), as well as unsupervised baselines adapted to the corresponding tasks in WiC-TSV.

4.1 Evaluation Tasks

The benchmark provides three different tasks depending on the input information available: definition-based (Section 4.1.1), hypernym-based (Section 4.1.2), and both (Section 4.1.3).

4.1.1 Task 1: Definition Information

In this task, the goal is to identify if the intended sense of the target word in the *context* matches the target sense described by the *definition*.

In other words, the model has to check if the sense represented by the *definition* can fit within the given *context*. For this task, the system is provided with a *context* (in which the target word is marked) along with a *definition* (which describes one of the possible senses of the word).

Baselines. The first baseline is based on the pre-trained transformer-based language model **BERT**[8]. It consists of a simple classification layer on top of the BERT model which is responsible for encoding the input. For this task, we concatenate the context and the definition and feed the whole sequence to BERT. Then, the classification layer takes as input the concatenation of three different vectors, all provided by BERT: the `[CLS]` token representation, the representation of the target word in the context and the average representation of the words in the definition. This is similar to the baseline BERT model employed in SuperGLUE (Wang et al., 2019). It is worth mentioning that BERT is originally trained using WordPiece tokenization (Wu et al., 2016), which means that each word can be broken down into more than one sub-word. Therefore, in order to have a fixed length representation for each word, we take the average of its sub-word representations. Finally, the whole model is fine-tuned on the training set.

For the **FastText**-based baseline, we first extract the corresponding embeddings for each word in the context and definition, respectively. Then, the representation is simply computed as the average of the corresponding embeddings it contains. Next, these two representations are concatenated together to form a fixed length vector which we then feed to a fully connected layer. Finally, we put a simple classification layer on top of this fully connected layer and train the model on the training set.

We also evaluated **GlossBERT** (Huang et al., 2019) on our dataset. The authors describe a weak supervision algorithm that consists in surrounding the target word with special symbols – quotation marks are used in the available implementation[9]. We provide results both with (GBERT$_{ws}$) and without (GBERT) weak supervision. We chose the hyper-parameters as suggested by the authors, trained for 6 epochs and achieved the highest scores on the 4th epoch.

Unsupervised baselines **U-BERT** and **U-dBERT**, which do not make use of the training set, are simple threshold-based classifier which take the cosine distance of a target word representation and

---

[8] We used the implementation of BERT available at `https://github.com/CyberZHG/keras-bert` for the *base* (BERT-B) and *large* (BERT-L) pre-trained models.

[9] `https://github.com/HSLCY/GlossBERT`

a definition representation into account. As source for these vectors serve BERT and DistilBERT, respectively.

Similar to before, we derive the target word vector by taking the embedding of the target word in the context and the definition vector by averaging over all embeddings of the definition. The threshold is tuned on the development set with a step size of 0.02.

4.1.2 Task 2: Hypernym Information

For this task, the system is provided with a target word (in a *context*) and a set of *hypernyms* for the target sense. The task is to identify if the intended sense given through the context is the hyponym of the provided hypernyms. Note that, unlike Task 1, no *definition* is involved in this setting and the task is directed only by hypernymy information.

Baselines. We used baseline models similar to those used in the previous task. The only difference lies in how we shape the inputs fed to these models.

For the supervised and unsupervised BERT-based models, we put together the context with the hypernyms to form the input. Similarly, for the FastText-based model, the hypernyms' embeddings are concatenated with the context's representation and fed to the classifier.

4.1.3 Task 3: Both Sources of Information

In the third task systems are provided with both definition and hypernymy information.

Baselines. For this task, we concatenate the definition and the hypernyms, and feed the generated sequence together with the context to BERT. Then, the concatenation of the [CLS] token representation, the representation of the target word in the context and the average representation of the words in the definition/hypernyms sequence is fed to the classification layer.

For the unsupervised model we use the same BERT input and take the representation of the target in context and the average over the definition and hypernyms as input vectors. For the FastText-based baseline, the hypernyms' embeddings are concatenated with both the context's representation and the definition representation and the combination is fed to the classifier.

Human		*85.3*	*80.2*	*96.2*	*87.4*

Table 4: Test set performance of the baseline models on WiC-TSV, in terms of accuracy, precision, recall, and F1, on the three different tasks. Baseline$_{\text{True}}$ is a naive baseline that always returns *True* and the human performance is computed as described in Section 3.4.

4.2 Results

Table 4 shows the overall results for the three tasks. As can be observed, GlossBERT performs best in terms of accuracy and F$_1$. BERT-L is a little worse, but achieves the best recall. The worst supervised baseline – FastText – does not perform better than a naive baseline that retrieves all instances as true. This also reinforces the challenging nature of the benchmark, as even BERT-based models are far from the human annotator performance (estimated on 85.3% for accuracy). Clearly, the definition information is more helpful than the hypernyms for BERT, while the combination of both attains the best overall results. Yet GlossBERT reaches a better performance with definition only[10].

The unsupervised models only perform well with hypernyms. Though U-dBERT reaches the best precision in Task 1, the recall remains very low and therefore the overall performance.

Another point to highlight is the high recall of BERT-based models, in contrast to its precision. This is mainly attributed to the domain-specific subsets as it will be analysed below. As for the comparison between BERT-based models, the larger model (BERT-L) performs as expected better than

---

[10] We did not evaluate GlossBERT with hypernyms as such-configuration was not considered by the authors in the original system and its integration would not be straightforward.

Table 5: Performance for the baseline models for the three tasks (i.e., T1: definition-based, T2: hypernymy-based, and T3: both sources of information) split by domain: General (WNT/WKT), Cocktails (CTL), Medical Subjects (MSH), and Computer Science (CPS). Baseline$_{\text{True}}$ is a naive baseline that always returns "True". Human performance in terms of accuracy is estimated to be 82.1% (WNT/WKT), 92.0% (CTL), 89.1% (MSH) and 86.5% (CPS) as described in Section 3.4.

the base model (BERT-B) overall.

4.3 Analysis

In order to better understand the results, in this section we perform a focused analysis on the performance split by domain.

4.3.1 Domain-based Analysis

Table 5 presents the results split by domain. FastText faces a massive challenge in adapting to new domains and generalising from WNT/WKT to the other domains. However, BERT-based models show to be much more robust to domain changes. In fact, the results on the domain-specific instances are in the same ballpark as the WNT/WKT test set. This can be attributed to the fact that specific domains highly constrain the set of possible senses for a word, resulting in an easier WSD classification task (Magnini et al., 2002). On the other hand, WordNet is known to be quite fine-grained (e.g., the noun *run* has 16 different senses in WordNet).

Surprisingly, unsupervised DistilBERT achieves the best accuracy over all tasks and classifiers on MSH. However, both unsupervised models do not perform well on WNT/WKT and CTL. We can observe that supervised models are significantly more reliable and produce similar scores on different tasks and datasets than unsupervised models.

In general, for BERT-based models, recall is substantially higher than precision on the domain-specific subsets. This is desirable in a retrieval setting where a high-coverage retrieval of relevant cases is of more importance. Interestingly, among the two BERT alternatives, the smaller model performs better on the domain-specific subsets, suggesting that it is more robust to domain changes. This is an important observation which needs further careful investigation in future work, given that most evaluation benchmarks (on which the larger model consistently outperforms the smaller one) comprise in-domain test sets, which cannot reveal robustness across domains.

4.3.2 In-domain Few-shot Analysis

Although the availability of big annotated domain-specific training sets is quite rare, the presence of a small training set forms a realistic scenario. Incorporating these domain-specific instances in the model training could potentially increase its prediction performance. To investigate this theory, we performed an additional analysis focusing on the usage of in-domain examples in the learning process, where for each domain 100 instances from the test sets were used as a training set. To enforce the assumption that not all target senses would be seen during the training process, we put aside all instances of 3 target words for each domain test set.[11] Two additional domain-based strategies were considered: (1) *few-shot learning:* only using the domain-specific instances, and (2) *continued learning:* extending the existing general-purpose training set with the domain-specific instances.

For this analysis we focused on Task-3 and BERT-large, which performed better overall. Table 6 shows the F1 results. In general, few-shot learning works surprisingly well overall (achieving the best overall performance in the CTL and MSH domains). On CTL pairs unseen during training, it even performs considerably better than the same BERT model trained in the continued learning setting. In the CPS domain, for both few-shot in-domain learning and continued learning the performance on seen target words is quite high, while the prediction of unseen target words produces relatively low F1 scores, which indicates a low ability to generalise to new senses. As for the model trained on the general-domain dataset, it performs best in the CPS domain, but performs considerably lower than the domain-tuned alternatives in the CTL domain. Indeed, the domain-tuned BERT systems clearly outperform the same model trained on the general domain on seen pairs, proving the importance of obtaining word-specific examples to boost performance. However, this may not be realistic in practice, and therefore further research should be devoted in improving the generalization capabilities of disambiguation systems, and language models in particular. These findings are consistent with the results of an experiment conducted with GlossBERT in the few-shot learning setting on Task-1: the overall accuracy increase ranged from 0.1% (CPS) to 13.6% (CTL) compared to the model trained solely on general domain instances.

Train	**CTL**			**MSH**			**CPS**		
	All	**See**	**Uns**	**All**	**See**	**Uns**	**All**	**See**	**Uns**
WNT	76.5	74.7	75.5	77.4	82.9	76.0	**74.9**	77.8	**74.8**
WNT+D	80.2	**89.5**	75.5	78.5	86.2	**76.6**	73.6	88.9	72.9
Dom	**84.2**	88.8	**82.6**	**78.7**	**88.6**	75.5	70.7	**93.3**	69.1
Base$_{\text{True}}$	58.5	54.8	59.1	68.2	70.9	67.5	62.6	58.3	62.8

Table 6: F1 score for the in-domain few-shot analysis (Task-3) using BERT-L trained on general domain (WNT), domain-specific (Dom) and general domain fine-tuned on the target domain (WNT+D). In addition to the full test set (All), results are split on seen (See) and unseen (Uns), as per the presence or absence of the target word in the domain-specific training set.

5 Conclusions and Future Work

In this paper we have introduced the Target Sense Verification task, a re-formulation of WSD where the equivalence of the intended sense of a word in context and a single given sense is evaluated. Furthermore, we presented WiC-TSV, a multi-domain benchmark which differs from existing WSD datasets in three main ways: (1) it is based on TSV and therefore framed as a binary classification task where only one target sense needs to be verified, (2) it is independent from external sense inventories, and (3) its test set contains instances from three specific and heterogeneous domains are included: cocktails, medical subjects and computer science. Our benchmark therefore opens the floor for different disambiguation algorithms that do not require modeling the entirety of a sense inventory. This characteristic also provides a crucial advantage in enterprise and domain-specific settings as it facilitates the development of systems which are only aimed at modelling the domain at hand. Moreover, having these out-of-domain test instances makes our benchmark more robust and generalisable, preventing (or making it harder) for statistical models to learn spurious correlations from the training set, which has been proven to be an issue in standard NLP tasks (Poliak et al., 2018; Gururangan et al., 2018; Linzen, 2020).

In our initial experiments we found that current state-of-the-art disambiguation techniques based on pre-trained language models such as BERT are very accurate at handling ambiguity, even in specialised domains. However, there is still room for improvement as highlighted by the gap with the human performance. This benchmark therefore opens up avenues for future research on domain-transfer and on developing general-purpose solutions which can perform well on a variety of domains without the need for large amounts of training data.

As future work, we are planning to further investigate and analyse the robustness of pre-trained models with respect to domain changes. Also, it would be interesting to develop hybrid models which take both definition and hypernymy information into account – in this paper we combined both sources in BERT in a simple manner, but more complex models should lead to further improvements.

---

[11] To add robustness to the results, three different random samples were considered for this experiment, with the results being averaged after the three different runs.

Abstract

We address the problem of unsupervised abstractive summarization of collections of user generated reviews through self-supervision and control. We propose a self-supervised setup that considers an individual document as a target summary for a set of similar documents. This setting makes training simpler than previous approaches by relying only on standard log-likelihood loss and mainstream models. We address the problem of hallucinations through the use of control codes, to steer the generation towards more coherent and relevant summaries. Our benchmarks on two English datasets against graph-based and recent neural abstractive unsupervised models show that our proposed method generates summaries with a superior quality and relevance, as well as a high sentiment and topic alignment with the input reviews. This is confirmed in our human evaluation which focuses explicitly on the faithfulness of generated summaries. We also provide an ablation study showing the importance of the control setup in controlling hallucinations.

1 Introduction

Recent progress in unsupervised methods has created breakthroughs in natural language processing applications, such as machine translation (Artetxe et al., 2018; Lample et al., 2018). Those have been mostly based on a bootstrapping approach, which consists in iteratively alternating between two representations, and optimizing a reconstruction loss. Beyond machine translation, other applications include Question-Answering (Lewis et al., 2019) and parsing (Drozdov et al., 2019). While similar ideas have been applied as well for video summarization (Yuan et al., 2019), such a bootstrapping approach seems less suited for summarization, because of the inherent information loss when going from the full text to the summarized one. Existing unsupervised approaches for summarization therefore relied mostly on extractive graph-based systems (Mihalcea and Tarau, 2004). Only recently have there been proposals for unsupervised abstractive summarization, using auto-encoders (Chu and Liu, 2019; Bražinskas et al., 2020). However, these set-ups are complex and require a combination of loss functions (Chu and Liu, 2019) or hierarchical latent variables (Bražinskas et al., 2020) to ensure that the generated summaries remain on-topic.

In this paper, we investigate a self-supervised approach for multi-document opinion summarization. In this setting, there are multiple opinions (reviews), one entity (products, venues, movies, etc) and the goal is to extract a short summary of those opinions. Our approach is based on self-supervision and does not require any gold summaries. We train a supervised model on examples artificially created by selecting (i) one review that will act as a target summary and (ii) a subset of reviews of the same entity that acts as a document collection.

Neural models have a known problem of hallucination (Rohrbach et al., 2018), which can be misleading in natural language generation tasks as the fluency of those models often distract from the wrong facts stated in the generated text. To reduce this effect, we propose to use control tokens (Fan et al., 2018; Keskar et al., 2019; Krause et al., 2020). Control tokens are discrete variables that are used to condition the generation. Different from previous work, our goal is not to allow users to control the generated text, but instead to steer the generated text to produce an output which is consistent with the input documents to be summarized.

Our main contributions are therefore three-fold:

- performing multi-document summarization by modelling it as a self-supervised problem where one document acts as the summary of a subset. We carefully select those two, and

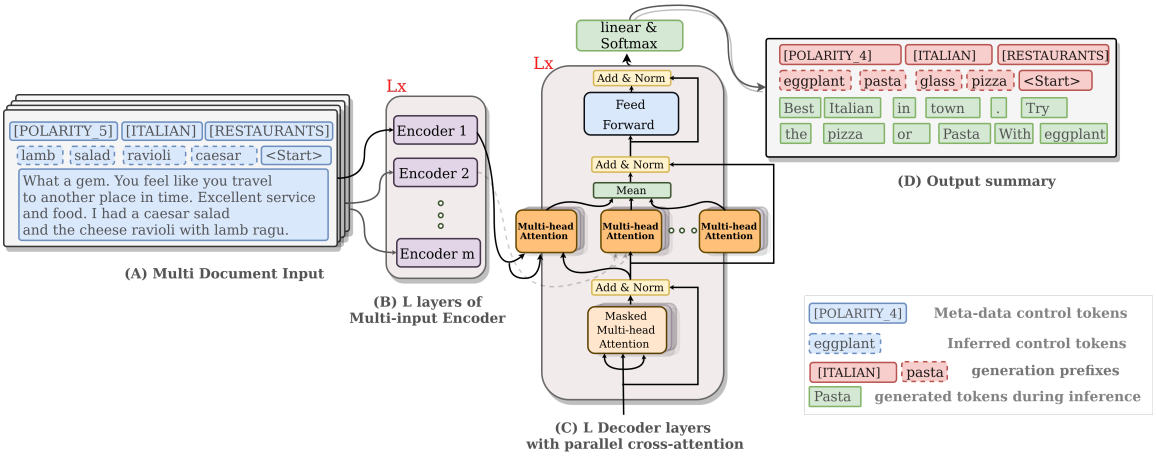

Figure 1: Description of our proposed model: (A) is the set of input reviews, augmented with control tokens (from meta-data in uppercase, inferred in lowercase). (B) is the encoder, which is run separately on each input review. The standard Transformer decoder is modified in (C) to allow for Parallel cross-attention on different inputs separately. Finally, (D) is the generated output. During inference the control tokens are fed as prompts to the decoder and generation starts afterwards.

link the resulting formulation to a recent theoretical framework (Peyrard, 2019) (Sect. 3);

- using control tokens to steer the model towards consistency, increasing relevance of the generated summary (Sect. 4);
- an application of multi-input transformer model (Libovický et al., 2018) to summarization. This model encodes each input independently, and at decoding time applies parallel attention to each encoded input (Sect. 5).

Our experimental results (Sect. 6 and 7) show that our approach outperforms existing models on two datasets: Yelp reviews on venues (Chu and Liu, 2019) and Rotten Tomatoes movie reviews (Wang and Ling, 2016). We focus the human evaluation on the faithfulness of the summaries, confirming they are more factually correct than baselines.

2 Related Work

Unsupervised Opinion Summarization Extractive summarization consists in selecting a few sentences from the input documents to form the output summary. The centroid method (Radev et al., 2004; Rossiello et al., 2017; Gholipour Ghalandari, 2017) consists in ranking sentences according to their relevance to the whole input. Graph-based methods, such as LexRank (Erkan and Radev, 2004) or TextRank (Mihalcea and Tarau, 2004; Zheng and Lapata, 2019), use the PageRank algorithm to find the most central sentences in a graph of input sentences, where edge weights indicate word overlap. In contrast to these methods, we focus on abstractive summarization methods.

Non-neural abstractive methods (Ganesan et al., 2010; Nayeem et al., 2018) are also graph-based, but work on word-type graphs. West et al. (2019) introduced a self-supervised model for sentence compression: they use an unsupervised extractive system to generate training data for a supervised sentence compressor. Their system works on single sentences whereas our end-to-end approach summarizes multiple reviews.

Recently, a few approaches for *neural* unsupervised abstractive summarization have been proposed. Chu and Liu (2019, MeanSum) introduced a summarization system based on a review autoencoder. At inference time, MeanSum encodes every review for a product to a vector, computes the centroid of reviews and uses this centroid to seed the decoder and generate a summary. However, averaging representations of statements that are sometimes contradictory tends to confuse the decoder, and might lead it to ignore the input signal. To deal with this limitation, Coavoux et al. (2019) add a clustering step to group similar reviews and to generate one sentence per such found cluster. Bražinskas et al. (2020) proposed to solve the problem of unsupervised opinion summarization with an auto-encoder with latent variables. They use latent variable for products and reviews to address the hallucination issue, while at the same time allowing it to capture information from the set of reviews on the same entity. In contrast, we argue that our self-supervised setting is simpler as it relies on training with standard models. In addition, the use of Transformer (as opposed to GRU in their case) makes it possible to apply separate attentions to each input. Probably most similar to our self-supervised proposal is the recent work of Amplayo and Lapata (2020), in particular their document noising sub-strategy. Compared to it, our simple selection criteria of the dataset avoids any use of (domain-specific) noise generator. In addition, our use of control tokens allows to easily include existing (or inferred) meta-information. A similar approach is also used by Shapira and Levy (2020), which trains a seq2seq model by clustering reviews and using the medoid as target summary.

Another work that has recently shown the promise of self-supervision for summarization is Zhang et al. (2020a), in which masked-out sentences are predicted from the surrounding text. Our self-supervision training mechanism can be seen as a multi-document version of that.

Controlled Generation Controllable text generation has been previously investigated to apply global constraints on text generation, by directly optimizing evaluation metrics through policy gradient methods (Ranzato et al., 2016; Wu et al., 2018; Liu et al., 2017; Li et al., 2016b; Yi et al., 2018) or continuous approximation methods (Chu and Liu, 2019; Yang et al., 2018).

Other methods applied control only at inference time. Weighted decoding (Holtzman et al., 2018) was shown to be challenging, and often detrimental to fluency and coherence (See et al., 2019). Constrained beam search (Anderson et al., 2017; Hokamp and Liu, 2017; Post and Vilar, 2018) is slower, requires very large beam sizes, and does not enable soft constraints. Finally, updating the decoder hidden states (Chen et al., 2018; Dathathri et al., 2020) requires an extra training step.

Control codes have been introduced in generation as an early form of copy mechanism (Luong et al., 2015; ElSahar et al., 2018) to address the problem of rare words. They were widely adopted to steer language models towards specific features, such as aspects (Keskar et al., 2019) or structured outputs (Zellers et al., 2019).

In prior work, controlled language models rely on a predefined set of control tokens, collected manually (Keskar et al., 2019) or from dictionaries (Dathathri et al., 2020), which can lead to low domain coverage. Nabil et al. (2014) and ElSahar and El-Beltagy (2015) construct lexicons by exploiting the feature selection ability of sentiment classifiers, an approach that produces more relevant lexicons than classical topic models (e.g. LDA, Blei et al., 2003). In our work, we also rely on classifiers using the categories of reviews provided as meta-data. Without meta-data, we could have relied instead on unsupervised or weakly supervised aspect extractors (He et al., 2017; Angelidis and Lapata, 2018).

Hierarchical encoding. In order to allow a neural summarizer to read several sections, Cohan et al. (2018) proposes a hierarchical LSTM that works at two level. Similar to our proposal, Liu and Lapata (2019) extends a Transformer network to read several ranked paragraphs as input, avoiding a retrieve-then-read pipeline. In multi-document summarization, the paragraphs are not ranked but independent. This entails a significant change model-wise. We propose to encode each review independently (avoiding inter-paragraph self-attention) and only adapt the decoder-encoder attention.

3 Self-Supervision

In order to create our training dataset we assume that a review s_i for an entity (venue or product) can serve as a summary for a set of other similar reviews D_i. This simple intuition allows us to create training points (D_i, s_i) in a very similar way to what the model will experience at inference time. However, there are two issues with this approach. First, the potential set of training points is too large to be explored exhaustively. Given the set of all reviews $\mathcal{D}$ the total number of possible input-output pairs is $2^{|\mathcal{D}|-1} \times |\mathcal{D}|$. Second, the assumption that any review is fit to serve as a summary for any set of other reviews is obviously not true, and might yield a very noisy training dataset.

To solve the combinatorial explosion, we limit the size of D_i to k, and from a given s_i, we look for a set of k *good* reviews D_i, for which s_i serves as a good summary. Fixing k also simplifies training, and enables comparison with previous work where the number of input reviews is fixed (Chu and Liu, 2019; Bražinskas et al., 2020). Both s_i and all members of D_i are reviews of the same entity.

Having s_i fixed, we now search for reviews $d_1, \dots, d_k$ for which s_i is a relevant review:

$$\begin{aligned} \mathit{rel}(s_i) &= \{d_1, d_2, ..., d_k\}, \\ &= \underset{D_i \subset \mathcal{D} \setminus \{s_i\}, |D_i| = k}{\arg\max} \sum_{d_j \in D_i} \text{sim}(s_i, d_j) \end{aligned} \tag{1}$$

where *sim* is an arbitrary similarity function (that we define at the end of this section).

Fixing first the target summaries turns traditional approaches upside down. In particular, a recently proposed theoretical model of importance in summarization (Peyrard, 2019) defines the importance of a summary based on three aspects: (i) minimum redundancy, (ii) maximum relevance with the input document, and (iii) maximum informativeness. In that line of work D_i is considered fixed: redundancy and informativeness are not dependent on D_i and can therefore be ignored when s_i is fixed. In this setting Peyrard (2019) reduces then to Eq. 1

Then, we sort the data-points $(d_i, \mathit{rel}(d_i))$ according to the value of the relevance $(\sum_{d_j \in \mathrm{rel}(d_i)} \mathrm{sim}(d_i, d_j))$. Depending on the desired size of the target dataset, we keep the top-T pairs for training. Limiting T inherently increases informativeness, since it limits the creation of training examples where input and outputs are repetitive similar reviews that might be very prominent on corpora level (e.g. "Great restaurant."). This method is simple and fast, thanks to nearest neighbour search libraries (Pedregosa et al., 2011b). For all our experiments we defined *sim* to be the cosine similarity over a tf-idf bag-of-word representation (Ramos et al., 2003).

4 Controlling Hallucinations

Hallucinations are pieces of generated text that bear no relationship to the text they were conditioned on. They are likely to happen in our self-supervised setting, due to the noise from the construction of training instances. This might happen if the synthetically created training data contains contradictory signals, or because certain types of review are overly present (e.g. "great movie"). The model might default to those frequent patterns if it finds itself in a unfrequent state during decoding. To alleviate the problem of hallucinations, we propose to use *control tokens* that represent desired traits of the output text to steer the generated text towards more input-coherent summaries. These control tokens are inferred from each review, and used as prompts at inference time. We use two types of codes as follows:

1) Metadata control tokens. Those are special tokens that are associated with each input review, and are the capitalized control tokens in Fig. 1. We use two types of metadata that represent (i) the review **polarity**, a numerical value denoting the average sentiment score of the input reviews; (ii) **categorical tokens** representing the type of the entity of the review (e.g. Deli, Beauty&Spa, Furniture Stores). When meta-data labels are unavailable for all reviews (as in the Rotten-Tomatoes dataset), we infer control tokens with the same process, but using categories predicted by a classifier trained on labeled examples from the same domain.

2) Inferred control tokens. We follow recent work (Keskar et al., 2019; Dathathri et al., 2020) that shows that it is preferable to condition NLG models on control tokens that naturally co-occur in text. On one side, this allows for better control, and at the same it seems to be more robust when new (previously unseen) control codes are used. Here, we propose to use control codes that represent informative aspects (e.g. wine, service, ingredients) that occur in the input reviews text. However, instead of relying on manually created bag of control tokens for each desired attribute – which comes with obvious domain coverage limitations – we propose to infer those control codes from the text corpus.

To do so, we rely on the intrinsic feature selection capabilities of regularized linear classification models. For each category ℓ in the meta-data associated with each review we train a linear support vector machine (SVM) classifier (Vapnik and Lerner, 1963)[1] that learns to classify between reviews from this category and negative examples sampled randomly from the rest of the corpus. The features of the SVMs are parameterized by the weight vector $\theta_\ell \in \mathcal{R}^d$, where d is the number of features (in our experiments: all unigrams and bigrams present in the corpus). We used a squared hinge loss with $L1$ regularization over θ_ℓ – the latter to increase sparsity and force feature selection (Tibshirani, 1996; Ng, 2004). Finally, we trim the feature list into those who correspond to positive weights and renormalize the weights. The output of this step is a ranked list of n-grams that represent the distinctive aspects of each category.

When creating training data for summarization, we enrich each review with the top weighted n-grams of their corresponding categories as follows. For a given review d about entity p, we consider all m labels of p and use the weights of the corresponding classifiers $\theta_{\ell_i^{(p)}}$ (for each label $\ell_i^{(p)}$ of p). We only consider those n-grams actually occurring in d, and keep the top 8 such features. Note that these features could come from different classifiers, as we consider all m labels.

During training, we enrich each review with its tailored control codes. In particular, the reviews acting as summary also contain them, and by con-

---

[1] We use `liblinear` (Fan et al., 2008).

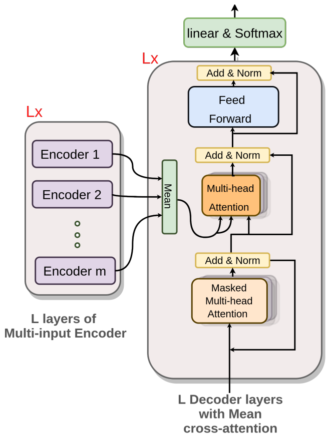

Figure 2: Our adaptation of the Transformer cross-attention to allow *Mean* combination of multi-sources.

struction those are n-grams present in the text. At inference time – when the target side and its control codes are not available – we select the most repeated control tokens from the input side and feed them as a prefix to the decoder. There is clearly a risk that the model just learns to copy the control codes it has seen somewhere in the text. We check whether this is the case in Sect. 7.

5 Multi-source Transformer Model

Previous work for multi-document summarization (Chu and Liu, 2019) built multi-source input representations through a simple mean over the last hidden states of the encoder. An intrinsic limitation of this method is that the full set of reviews is represented as a single vector. This aggregation might cause information distortion especially when some input reviews are expected to have conflicted opinions in between. Standard transformer models (Vaswani et al., 2017) consider only a single input to the decoder part of the model. Aggregating all input reviews into a single input (Junczys-Dowmunt, 2019) with special tokens to represent document boundaries might be slow and impractical due the $O(n^2)$ complexity of the self-attention mechanism. We therefore experiment with several input combination strategies of the transformer cross-attention (Libovický et al., 2018).

Parallel. At each cross-attention head, the decoder set of queries Q attend to each of the encoded inputs separately from which the set of keys ($K_i \in K_{1:m}$) and values ($V_i \in V_{1:m}$) are generated and then the yielded context is averaged and followed by a residual connection from the previous decoder layer (box C in Fig. 1).

$$A^h_{\text{parallel}}(Q, K_{1:m}, V_{1:m}) = \frac{1}{m} \sum_{i=1}^{m} A^h(Q, K_i, V_i).$$

Mean. We also propose a simpler and less computationally demanding input combination strategy. It does not apply the cross-attention with each encoder separately. Instead, the set of keys and values coming from each input encoder are aggregated using the average at each absolute position. Afterwards the decoder set of queries attend to this aggregated set of keys and values. This combination can be seen as a more efficient variation of the flat combination strategy (Libovický et al., 2018) with mean instead of concatenation. Fig. 2 depicts this strategy, which replaces box (C) in Fig. 1.

$$A^h_{\text{mean}}(Q, K_{1:m}, V_{1:m}) = A^h\left(Q, \frac{1}{|m|}\sum_{i=1}^{m} K_i, \frac{1}{|m|}\sum_{i=1}^{m} V_i\right)$$

In practice, we share the parameters across all encoders, this can be also seen as a single encoder used to encode each input document independently. We believe that this is an appropriate design choice as the order of the input document doesn't matter. Furthermore, this is necessary to allow variable number of input documents during different training batches or during inference. In Sect. 7, we compare both approaches through an ablation study, focusing on summary quality as well as empirical training times.

6 Experimental Setup

Experimental Details All our models are implemented with PyTorch (Paszke et al., 2019) and Fairseq (Ott et al., 2019) libraries, as well as scikit-learn (Pedregosa et al., 2011a) for the classifiers used either for inferring control tokens or for evaluation. For all our models we use sentence piece (Kudo and Richardson, 2018) as a tokenizer with a vocabulary size of 32 000. We use the same hyperparameters as the Transformer Big model described by Vaswani et al. (2017) ($d_{\text{model}} = 1024$, $n_{\text{heads}} = 16$, $n_{\text{layer}} = 6$, dropout $= 0.1$). We optimize them with a Nesterov accelerated SGD optimizer with a learning rate of 0.01. We train all models for a total of 80 000 steps across 25 epochs, with linear warm-up for the first 8 000 steps. We select the best model checkpoint based on perplexity on the validation set. All models were trained on one machine with 4 NVIDIA V100 GPUs, the

Table 2: Referenceless evaluation results on Yelp dataset.

longest model took 50 hours to train. For inference, we use a beam size of 35. We discard hypotheses that contain twice the same trigram. We limit generation of each summary to a maximum budget of 150 tokens for each summary for Yelp, as was done by Chu and Liu (2019), and a budget of 50 tokens for Rotten Tomatoes. We set a similar budget for all other extractive baselines in the experiments. Finally, we use length normalization (Wu et al., 2016) with length penalty 1.2 to account for the model's bias towards shorter sequences.

Datasets We evaluate our proposal on two English datasets: Yelp[2] (Chu and Liu, 2019) and Rotten Tomatoes (Wang and Ling, 2016). The Yelp dataset contains reviews of businesses (around 1M reviews for 40k venues). As described in Sect. 3, for each venue, we select the best reviews to use as target summaries: either the top-p (with $p = 15\%$) or the top-T (with $T = 100$) reviews, whichever is smaller. For each selected target summary, we take its $k = 8$ most similar reviews (cosine) to form its input. We obtain around 340k training examples, representing 22.5k venues. The Rotten Tomatoes dataset was constructed by (Wang and Ling, 2016) from the movie review website `rottentomatoes.com`. We use the same process as for Yelp, but use $p = 1\%$ and $T = 150$. We construct around 170k training examples, representing 3.7k movies. We provide more details in the supplementary material.

Evaluation Metrics We evaluate summary systems with the classical ROUGE-F-{1,2,L} metrics (Lin, 2004).[3] We also report BERT-score (Zhang et al., 2020b), a metric that uses pre-trained BERT (Devlin et al., 2019) to compute the semantic similarity between a candidate summary and the gold summary. Dist-n and Dist_c-n ($n = 1, 2, 3$) scores (Li et al., 2016a) are the percentage of distinct n-grams in the generated text on the summary level or the corpora level respectively. Dist-n is an indicator of repetitiveness within a single summary while Dist_c-n indicates the diversity of different generations. Finally, as done by Chu and Liu (2019), we use a classifier to check whether the sentiment of the summary is consistent with that of input reviews (Sentiment Acc., Tab. 1).[4] We extend this method to check whether the correct product category can also be inferred from the summary, we report $\mathbf{F}_{\text{category}}$ the micro F-score of the multi-label category classifier.

Baselines and Other Systems We compare our system to three unsupervised baselines. TextRank (Mihalcea and Tarau, 2004) and LexRank (Radev et al., 2004) are extractive systems. Opinosis (Ganesan et al., 2010) is an abstractive graph-based system. We use openly available Python implementations for TextRank[5] (Barrios et al., 2015)

---

[2] `https://www.yelp.com/dataset/challenge`

[3] For Yelp we use Chu and Liu (2019)'s implementation to keep results comparable. For RottenTomatoes we use *py-rouge* package `pypi.python.org/pypi/pyrouge/0.1.3`

[4] We use 3 classes: negative (1, 2 star), neutral (3), positive (4, 5). Numbers are not comparable with Chu and Liu (2019).

$\text{Ours}_{\text{Parallel}}$ − cntrl.	25.3	3.7	15.5	85.2	76.9	43.9	7609
$\text{Ours}_{\text{Mean}}$ − cntrl.	27.5	5.3	17.1	87.3	80.0	52.1	**8714**

Table 3: Ablation study showing the effectiveness of parallel-cross attention and control tokens on Yelp dataset. "−cntrl." denotes models trained without the control step. "Train. (wps)" denotes the word per second rate at training time.

OURS:
This was my *first visit* to *Capriotti's* and I really enjoyed it . I had the *Capastrami* and my husband had *the Bobbie* . We both enjoyed our *sandwiches* as well . The *quality* of the *ingredients*, however, was not what we expected . We also enjoyed the *cheese steak* as well as the *turkey*, which was not bad at all . This place is a bit on the expensive side for what you get, but you get what you pay for . The *seating* is limited, so it's a good place to visit if you're in a hurry.

MeanSum:
Drove by here for the *first time*. I just went to the *deli* with a friend and it's a quick fix that is just about as good as it gets. But it's not an actual *sandwich*, but it's not as good as I remembered it, but they were great!! *Sandwich* was also very good, just a hint of cinnamon. I will be back for the other locations.

TextRank (Extractive):
Will not return This place is always good, I think the owner actually made my sandwich last time I was there , owner or manager, anyway it was superb! Ordered a sandwich, watched the guy write it down and 25 minutes later the same person asked what I wanted when I reminded him of my sandwich, he only said he can't remember where the order went. I watched 4 people come in after me order, one person the same sandwich just a different size then me get their food, pay and leave. At that point I gave up because as much as I like their sandwiches I am never going back.

Figure 3: Examples of different model generations to the same input set of documents. Green (italics) denotes substrings with exact match with the input, red (underlined) denotes statements without support in the input. TextRank is shown as a reference: all substrings are present in the input, but note the lack of cohesion.

and LexRank,[6] with their default parameters. For Opinosis, we use the official Java implementation, with default hyperparameters.[7] We also compare our systems with recent neural unsupervised summarization systems (Chu and Liu, 2019; Bražinskas et al., 2020). In addition, in our ablation study (next section) we also compare against a vanilla Transformer system, to capture the relative gains obtained on top of that model.

7 Evaluation Results

Automatic Evaluation Table 1 contains the automatic evaluation metrics with respect to reference summaries. The proposed multi-input self-supervised model with control codes perform consistently better in the Yelp dataset across the benchmarked models, including the recent neural unsupervised models of MeanSum and H-VAE. For the recent H-VAE model we report the numbers from their paper.[8] For MeanSum we re-run their provided checkpoint and run evaluation through the same pipeline. The BERTScore (Zhang et al., 2020b) differences are closer and seem to favour neural models.

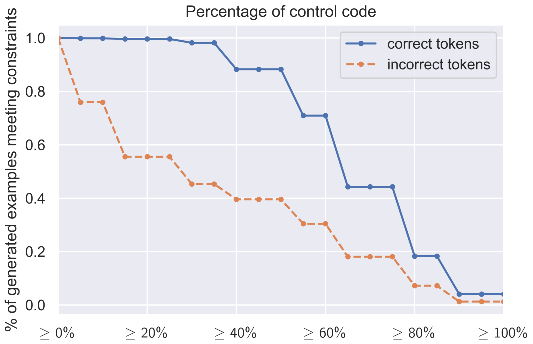

Figure 4: Proportion of control tokens fed as prompts that occur in the generated summary. When the model is fed control tokens that occur in the input reviews (*correct*) it tends to generate them in the output. Contrary to this, *incorrect* control tokens are mostly ignored.

With the RottenTomatoes dataset we only benchmarked the graph-based unsupervised methods, since the released pretrained MeanSum model does not cover the domain of movie reviews. We attribute the lower score in sentiment accuracy to the fact that the "summaries" in RottenTomatoes are critical reviews, written in a very different style than the original reviews.

Table 2 contains reference-less evaluation, analyzing the number of distinct n-grams (an indicator of repetitiveness) on the summary level and corpora level. On the summary level our model outperforms all the baselines: our model is capable of generating richer and less repetitive summaries. On the level of all generations our model generates

---

[6] `https://github.com/crabcamp/lexrank`

[7] Except for the redundancy parameter set to one, since the default led to many empty outputs. `https://github.com/kavgan/opinosis-summarization`

[8] While the ROUGE implementation might be different, the numbers of the common baselines are very close.

text with more diversity than MeanSum. In general however extractive models tend to have more diversity on the corpus level as they directly copy from each input separately, while abstractive models tend to learn repetitive patterns present in the training set.

Fig. 3 shows summaries generated by different models from the same input. We notice that our model learned to copy aspects of the input documents such as restaurant names "Capricotti's" and menu items "the Bobbie", possibly due to the cross-attention mechanism. We provide more examples as supplementary material.

Human Evaluation Existing natural language generation systems are known to generate very fluent language, that looks very natural to native speakers. On the other side, current neural models are known to generate factually incorrect data, something which was less of a concern in pre-neural methods but also much harder to detect. As mentioned by Kryscinski et al. (2019): "Neither of the methods explicitly examines the factual consistency of summaries, leaving this important dimension unchecked." Inspired by Falke et al. (2019) we decided to focus the human evaluation on those aspects of the summarization evaluation in which existing models risk failing the most, the one of *faithfulness*.

We annotated 94 summaries through a crowdsourcing platform, comparing 3 systems (Gold, MeanSum and ours). Workers were asked if "the summary contains correct information given the original reviews". In total we had 282 tasks (94×3) and each task was labeled by 3 annotators and paid $0.50 (defined by a pilot study to aim for $15 / hour) and restricted to experienced, English-speaking workers. A full description of the campaign, including the filtering of the annotations, is detailed in the supplementary material.

Faithfulness	**Gold**	**Ours**	**MeanSum**
Correct	67	47	43
Incorrect	3	7	16
%Correct	95.71	87.04	72.88

Table 4: Results of the human evaluation focused on faithfulness of generated reviews.

The results in Table 4 show that 87.0% of the generated summaries of our system are considered factually correct (compare with 95.7% for the gold summaries), as opposed to 72.9% of MeanSum.

Ablation We analyzed the impact of our proposed variations of the basic self-supervised setting in Table 3. Removing control codes degrades significantly sentiment and category classification of the produced summary F_1. It also impacts greatly the ROUGE score. Changing the decoder-encoder attention from parallel to mean (Sect. 5) also degrades ROUGE. The difference of this attention change without control codes is smaller but – surprisingly – in the different direction.

Control Codes The previous ablation study shows the importance of the control codes in the quality of the final summaries. In order to see how rigidly the model follows those control codes we devise the following experiment to see if the tokens used as control codes are forced to appear in the output text, independent of the input text.

For this, we sample 500 reviews (for 279 venues from the Yelp validation set). For each input example, we randomly sample 8 inferred control tokens (see Sect 4) from the tokens occurring in the review, referring to these as *correct control tokens*. We run the decoder using these control tokens as prompt and count the proportion of them that also occurs in the generated summary. For comparison, we repeat the same experiment but sampling instead 8 control tokens that do *not* occur in the input text, referring to these as *incorrect*.

To minimize the possibility of conditioning on control tokens that might show up naturally in the generated text, for both settings, we repeat the process 5 times per input example (resulting in 2500 with *correct control tokens* as prefix and 2500 using *incorrect*). We report in Fig. 4 the proportion of fed control codes that are generated by the model in both cases. We observe that the model tends to comply with the correct control tokens that occur in the input documents (eg: 89% of the summaries contain more than 50% of the control tokens), but tends to ignore the control tokens when they do not occur in the input. We illustrate this behaviour with a set of examples generated from the same input but different control tokens in the supplementary material.

8 Conclusion

The promise of unsupervised multi-document abstractive summarization is been hampered by the complexity of those models and the problem of hallucinations. Our proposed model has the advantage of being very simple to train compared to previous proposals. In addition, the combined use of control-codes to steer the generation and of multi-input transformers results in summaries that are better (as measured by automatic measures), and produce more faithful summaries (as measured by human evaluation).

While the generated reviews are more factual than those generated by other models, we want to stress that inaccuracies can still appear. Generated summaries are often conjugated in first person, which could lend to believe that an actual human wrote those. We recommend strongly that any use of such algorithms to be accompanied by a clear disclaimer on its true nature.

A Generated Examples

Figures 6, and 7 include a set of samples generated from our model and baselines, full generations our model can be downloaded from `https://www.dropbox.com/s/w6eqviy5fnda11f/hypos_and_refs.zip?dl=0`

B Control Codes Analysis

Figure 5 illustrates the behaviour of the model on the same input when it is fed either ‘correct’ or ‘incorrect’ control codes. The correct control codes occur in the output, but this is not the case for incorrect control codes: the model does not simply learn to copy control codes, it ignores them when they are inconsistent with the input reviews.

Correct Control Tokens: *eat*, *lentil*, *eggplant*, *new*, remember, *flavourful*, *friendly*
Seriously best we’ve had in Toronto. We were looking for a *new* place to *eat* and stumbled upon this place. The atmosphere is very authentic, the food is authentic, and the service is very *friendly* and attentive. We started with the *lentil* soup, which was very *flavourful* and full of flavor. For dinner, I had the lamb shank and my husband had the *eggplant* dish. Both were very good. We also had the baklava for dessert and it was amazing. We can’t wait to come back and try more of the menu

Correct Control Tokens: *yogurt*, *remember*, *service*, *shawarma*, *dishes*, *eat*, *restaurant*, *flavourful*
Seriously best I’ve had in Toronto. We were looking for a place to *eat* and this was the first *restaurant* we went to. The *service* was great and the *dishes* were authentic, *flavourful* and authentic. We had the *shawarma* sampler and the *yogurt* sampler. Both dishes were amazing. We also had the baklava, which was also very good. I can’t *remember* the name of the dish, but it was very authentic

Incorrect Control Tokens: open, tortellini, filter, details, rabbit, signature, craving, double
Seriously best I’ve had in Toronto. We were looking for a new place to try and stumbled upon Syrianian food. We came across this place on yelp and decided to give it a try. The food, the service, the atmosphere, the quality of the food, and the service were all amazing. We ordered the sampler platter for two and it was enough for two people to share. We also ordered the Brabianianian appetizer, which was one of the best we’ve ever had. For our main course, we ordered the Crabian Frabian Bianianca and the Bianca. Both were so authentic, and full of flavour. For dessert, we had the Turkish coffee which was also very good. The only thing I didn’t like was the bread they give you .

Incorrect Control Tokens: beer, balls, skip, mains, croissant, replacement, wish
Seriously best I’ve had in Toronto. We came here with a friend and we were looking for a place to eat. We found Syrianian food, which was very authentic. We were very impressed with the quality of the food, the service, and the atmosphere. We had the sampler platter, which came with two mains and two mains for dinner. We also had the bread pudding for dessert and it was to die for. I’m not a huge fan of sweets, but this was one of the best we’ve ever had. I wish we lived in Toronto so we could come here all the time. We’ll be back to try more of the menu .

Figure 5: Summaries generated **from the same input** when different ‘correct’ and ‘incorrect’ control tokens are fed as prefixes at inference time. Control tokens that occur in the summary are highlighted (green/italics for the first rows, red/underlined for the other two).

C Inferred Control Tokens

Fig. 8 shows examples of the top inferred tokens for some categories in the Yelp dataset, those tokens have been inferred using our proposed method in this work.

D Human Evaluation Campaign

We used Amazon Mechanical Turk to ask 3 “workers” to assess if 282 summaries produced by 3 systems (94 from each: ours, gold from human experts and MeanSum) aligned correctly with sets of 8 reviews. Workers had to read the reviews, the summary and answer the question: “does the summary contain correct information given in the original reviews?” Instructions specified to “assess the faithfulness of the summary with respect to the set of reviews,” specifically to “verify that the summary did not contain factually incorrect or self-contradicting statements that could not be inferred from what was provided in the original reviews.” Using Mechanical Turk qualification criteria, we asked for the workers: (1) to be located in the United States, Canada or United Kingdom; (2) to have a HIT approval rate higher than 98; (3) to have more than 1000 HITs approved.

Note that in an initial pilot, we asked evaluators to pick the best and worst summaries for fluency, coherency and alignment, as well as overall. We decided to simplify the task because it turned out to be a quite difficult one as workers struggled on many summaries to decide of the best and worst. We decided to focus the human evaluation on the aspect that is currently very difficult to automate, faithfulness to the original text. We see this evaluation as complementary to the automatic evaluation, focusing on different aspects.

We did an internal run to estimate the time needed per individual assignment – each Human Intelligence Task, or HIT, an annotation in our case, was assigned to 3 workers. We followed it by a short pilot to validate the average 2 minutes we had estimated. This is important to establish the rate to pay: 2 minutes translate into 30 potential assignments per hour, we picked $0.50 to target an average $15 hourly wage. Beyond the timing, the pilot was also used as a dry run for the full campaign. The average time to answer and the theoretical hourly wage are provided in Table 6

By using shuffled gold summaries, hence written for another set of reviews, we included 21 badly aligned “negatives.” Workers who answered *yes* for these obvious *no* were filtered out as “dubious” from the results: all their answers were dis-

Dataset	Reviews		Businesses / Movies
	Train	Valid	
Yelp — Ours	349,839	48,677	22,522
Yelp — Ours + Control	404,811	47,938	22,522
Rotten Tomatoes — Ours	167,168	18,731	3,732

Table 5: Sizes of Training and validation splits of different datasets.

carded. After filtering out the "negatives" HITs and the ones from "dubious" answers, we were left with 446 annotations, from the 782 we received. We further discarded all annotations made in less than a minute to keep 377 realistic answers —one minute may seem harsh but we estimated it was the minimum time needed to first read the reviews, then the summary, and to assess the latter, given the question: proceeding backward by first reading the summary would still require the worker to read all summaries, to make sure a factual error according to one review is not extracted from another one.

Finally we looked for full agreement at the HIT level and kept only the ones with either 0 *yes* or 0 *no*, with varying numbers, from 1 to 3, of the alternatives after the filtering of the "dubious" and "unrealistic" answers. Not surprisingly, as we focused on alignment, Gold summaries scored best but ours scored nicely, with a very low number of misaligned summaries.

Assessing the alignment of summaries to a set of reviews is not an easy task. We decided to discard all answers from the "dubious" workers who erred on our "negatives" summaries to be on the safe side. Mechanical Turk reports the time taken for an assignment, their averages is an interesting metric to look at, especially the way it evolves along our filterings — we translated it to the associated theoretical hourly wages, alas all under the $15 we initially targeted.

We also looked at the results with no full agreement: instead of doing it per HIT, or summary, it had to be done at the lower level of the evaluation. For the 276 evaluations with full agreement, the numbers are: Gold 108/4 (96.43% correct), Ours 69/7 (90.79%), MeanSum 63/25 (71.59%).
When including the disagreements (377 evaluations), they are: Gold 116/13 (89.92%), Ours 89/27 (76.72%), MeanSum 85/47 (64.39%).
The numbers are similar, however given the difficulty of the assessment for the workers, we decided to focus on the summaries they agreed on.

Inputs:

1. Best Philly Ever!!! Thank You Sam!!! Sometimes it is the little things in life that can Make You Happy- All it took was a Perfect Cheese Steak to Cheer Me Up, not to mention seeing a Friend Again - Thanks again Sam,, It wouldn't be the same without You

2. Wow after all the hype about what a great place I was really disappointed. If this is a franchised operation than the quality control is really lacking. Our first visit to Capriotti's and with so many other quality places I doubt if they will get us as repeat customers. Well, here it is. We ordered the Bobbie and the Capastrami shared it. Both had cold bread in fact we got the impression that both sandwiches had been pre made and put in a refrigerator because the insides were also cold. No taste at all in either. For a company that supposedly cooks overnight you would think the turkey ingredients would look like turkey but apparently they shred it into little tiny bits. Will not return

3. This place is always good, I think the owner actually made my sandwich last time I was there , owner or manager, anyway it was superb! quite flavorful, even the next day it tasted just as good. Grab a Capistrami you can't go wrong, until next time Cappie's , be well.

4. one New Year's resolution is to write more Yelp reviews, so here goes... In Vegas for NYE and gave this place a shot per other Yelp reviews. I had the Capistrami and the girlfriend had the Cheese Steak, which I had few bites of. Both were absolutely delicious in an awesome-deli-sandwich-sort-of-way. The shop is no-frills with only some bar seating, but the sandwiches are really reasonably priced. So if all you're after is a fantastic deli sandwich, definitely go.

5. number 1 in Vegas for a reason. Everyone has their favs.... the capistrami, the cheese steak with mush... Mine is definitely the Bobby. In case you haven't viewed their menu yet, the bobby is thanksgiving leftovers in a huge sandwich... yeah, exactly.

6. Worst service I have seen at a capriotti's. Ordered a sandwich, watched the guy write it down and 25 minutes later the same person asked what I wanted when I reminded him of my sandwich, he only said he can't remember where the order went. I watched 4 people come in after me order, one person the same sandwich just a different size then me get their food, pay and leave. I will not be coming back to the location ever again. Looks like I will be going to firehouse for now on!

7. Stopped in for a sandwich on the way to the park. Next day I notice the charge has had a $2 tip added to it that I did not authorize. (I left a cash tip in the beer money jar) I called Corporate and got nowhere because this is a franchise store. At that point I gave up because as much as I like their sandwiches I am never going back.

8. Don't bother calling in an order. If they tell you a time it will be off by at least thirty minutes. Terrible service. Great food tho.

Summary OURS:

This was my *first visit* to *Capriotti's* and I really enjoyed it . I had the *Capastrami* and my husband had *the Bobbie* . We both enjoyed our *sandwiches* as well . The *quality* of the *ingredients*, however, was not what we expected . We also enjoyed the *cheese steak* as well as the *turkey*, which was not bad at all . This place is a bit on the expensive side for what you get, but you get what you pay for . The *seating* is limited, so it's a good place to visit if you're in a hurry.

Summary MeanSum:

Drove by here for the *first time*. I just went to the *deli* with a friend and it's a quick fix that is just about as good as it gets. But it's not an actual *sandwich*, but it's not as good as I remembered it, but they were great!! *Sandwich* was also very good, just a hint of cinnamon. I will be back for the other locations.

Summary TextRank (Extractive):

Will not return This place is always good, I think the owner actually made my sandwich last time I was there , owner or manager, anyway it was superb! Ordered a sandwich, watched the guy write it down and 25 minutes later the same person asked what I wanted when I reminded him of my sandwich, he only said he can't remember where the order went. I watched 4 people come in after me order, one person the same sandwich just a different size then me get their food, pay and leave. At that point I gave up because as much as I like their sandwiches I am never going back.

Figure 6: Examples of output summaries for different models.

Set	**Unfiltered**	**Negatives discarded**	**Dubious discarded**	**less than 1min discarded**	**Agreement**
Average time to Answer	2min16s	2min17	2min9	2min26	2min26
Theoretical hourly wage	13.22	13.16	13.96	12.36	12.35

Table 6: Average time to Answer and the theoritical hourly wage of turkers (in USD) for the crowdsourcing experiments of human evaluation.

Inputs:
1. Great service and a super clean nice location here. Considering this is in a busy airport, I was impressed. The pricing here, which is about double to triple regular prices, was what knocks off a star for me.
2. If you’re by the D gates at Sky Harbor, this is your coffee stop. Much better than the Starsucks at the high C gates.
3. Spotted in due to flight delay. The big comfy brown lawyer seats is what attracted me in. I figured I could get some work done. I ordered a non fat vanilla iced tea. It was pretty good. I noticed the prices were a lil bit more expensive.
4. $9 for a sandwich. I guess you can charge whatever you want when the airport doesn’t have any other options in concourse C
5. The line is quick, the people are friendly and the drinks are tasty. Also for skyharbor employees, they actually give an airport discount, unlike Starbucks.
6. Try gingerbread latte yum. This is the best looking, most comfortable airport coffee shop I’ve ever been in !!! Big comfy chairs with little tables. A big water container with cups in the restaurant away from the congestion of the order counter. Friendly , happy workers equals happy customers. I know you can’t please everyone, but at 5am a room full of happy airline travelers is a hard thing to come by. If your in need of coffee in Phoenix Sky Harbor , terminal 3 be sure to stop by and take a load off !!
7. The lid fell off my cup, burned my hand, and spilled half of my coffee. Employees never asked if I was okay, or offered to replace my coffee. Will not be back to this location.
8. Delicious cup of coffee. Very impressed Mr. Peets. Will be returning whenever I can.

OURS:
Try the *gingerbread* cups. The coffee and ginger cups are *delicious* and the *chairs are comfortable* . I’ve been working in the *terminal* for a long time . This is a must stop if you’re in the *airport* . The staff is *friendly* .

MeanSum:
5.50 for a 2.5” breakfast sandwich. I’m a big fan of the concept but this place is way better than *Starbucks*. The staff is *friendly*, and fast. I’m not a big fan of sweets but I’d be happy to come back.

TextRank (Extractive):

NewsMTSC: A Dataset for (Multi-)Target-dependent Sentiment Classification in Political News Articles

Felix Hamborg[1,2] **Karsten Donnay**[3,2]

Abstract

Previous research on target-dependent sentiment classification (TSC) has mostly focused on reviews, social media, and other domains where authors tend to express sentiment explicitly. In this paper, we investigate TSC in news articles, a much less researched TSC domain despite the importance of news as an essential information source in individual and societal decision making. We introduce NewsMTSC, a high-quality dataset for TSC on news articles with key differences compared to established TSC datasets, including, for example, different means to express sentiment, longer texts, and a second test-set to measure the influence of multi-target sentences. We also propose a model that uses a BiGRU to interact with multiple embeddings, e.g., from a language model and external knowledge sources. The proposed model improves the performance of the prior state-of-the-art from $F1_m = 81.7$ to 83.1 (real-world sentiment distribution) and from $F1_m = 81.2$ to 82.5 (multi-target sentences).

1 Introduction

Previous research on target-dependent sentiment classification (TSC, also called aspect-term sentiment classification) and related tasks, e.g., aspect-based sentiment classification (ABSC, or aspect-category sentiment classification) and stance detection, has focused mostly on domains in which authors tend to express their opinions explicitly, such as reviews and social media (Pontiki et al., 2015; Nakov et al., 2016; Rosenthal et al., 2017; Zhang et al., 2020; Hosseinia et al., 2020; AlDayel and Magdy, 2020; Liu, 2012; Zhang et al., 2018).

We investigate TSC in news articles – a much less researched domain despite its critical relevance, especially in times of "fake news," echo chambers, and news ownership centralization (Hamborg et al., 2019). How persons are portrayed in news on political topics is very relevant, e.g., for individual and societal opinion formation (Bernhardt et al., 2008).

We define our problem statement as follows: we seek to detect polar judgments towards target persons (Steinberger et al., 2017). Following the TSC literature, we include only in-text, specifically in-sentence, means to express sentiment. In news texts such means are, e.g., word choice and generally framing[1] (Kahneman and Tversky, 1984; Entman, 2007), e.g., "freedom fighters" vs. "terrorists," or describing actions performed by the target, and indirect sentiment through quoting another person (Steinberger et al., 2017). Other means may also alter the perception of persons and topics in the news, but are not in the scope of the task (Balahur et al., 2010), e.g., because they are not on sentence-level. For example, story selection, source selection, article's placement and size (Hamborg et al., 2019), and epistemological bias (Recasens et al., 2013).

The main contributions of this paper are: (1) We introduce *NewsMTSC*, a large, manually annotated dataset for TSC in political news articles. We analyze the quality and characteristics of the dataset using an on-site, expert annotation. Because of its fundamentally different characteristics compared to previous TSC datasets, e.g., as to sentiment expressions and text lengths, NewsMTSC represents a challenging novel dataset for the TSC task. (2) We propose a neural model that improves TSC performance compared to prior state-of-the-art models. Additionally, our model yields competitive performance on established TSC datasets. (3) We perform an extensive evaluation and ablation study of the proposed model. Among others, we investigate the recently claimed "degeneration" of TSC to sequence-level classification (Jiang et al., 2019)

---

[1] Political frames determine what a causal agent does with which benefit and cost (Entman, 2007). They are defined on a higher level than semantic frames (Fillmore and Baker, 2001).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1663–1675

finding a performance drop in all models when comparing single- and multi-target sentences.

In a previous short-paper, we explored the characteristics of how sentiment is expressed in news articles by creating and analyzing a small-scale TSC dataset (Hamborg et al., 2021). The paper at hand addresses our former exploratory work's critical findings, including essential improvements to the dataset. Key differences and improvements are as follows. We significantly increase the dataset's size and the number of annotators per example and address its class imbalance. Further, we devise annotation instructions specifically created to capture a broad spectrum of sentiment expressions specific to news articles. In contrast, the early dataset misses the more implicit sentiment expressions commonly used by news authors (Hamborg et al., 2021; Steinberger et al., 2017). Also, we comprehensively test various consolidation strategies and conduct an expert annotation to validate the dataset.

We provide the dataset and code to reproduce our experiments at:
`https://github.com/fhamborg/NewsMTSC`

2 Related Work

Analogously to other NLP tasks, the TSC task has recently seen a significant performance leap due to the rise of language models (Devlin et al., 2019). Pre-BERT approaches yield up to $F1_m = 63.3$ on the SemEval 2014 Twitter set (Kiritchenko et al., 2014). They employ traditional machine learning combining hand-crafted sentiment dictionaries, such as SentiWordNet (Baccianella et al., 2010), and other linguistic features (Biber and Finegan, 1989). On the same dataset, vanilla BERT (also called BERT-SPC) yields 73.6 (Devlin et al., 2019; Zeng et al., 2019). Specialized downstream architectures improve performance further, e.g., LCF-BERT yields 75.8 (Zeng et al., 2019).

The vast majority of recently proposed TSC approaches employ BERT and focus on devising specialized down-stream architectures (Sun et al., 2019a; Zeng et al., 2019; Song et al., 2019). More recently, to improve performance further, additional measures have been proposed. For example, domain adaption of BERT, i.e., domain-specific language model finetuning prior to the TSC finetuning (Rietzler et al., 2019; Du et al., 2020); use of external knowledge, such as sentiment or emotion dictionaries (Hosseinia et al., 2020; Zhang et al., 2020), rule-based sentiment systems (Hosseinia et al., 2020), and knowledge graphs (Ghosal et al., 2020); use of all mentions of a target and/or related targets in a document (Chen et al., 2020); and explicit encoding of syntactic information (Phan and Ogunbona, 2020; Yin et al., 2020).

To train and evaluate recent TSC approaches, three datasets are commonly used: Twitter (Nakov et al., 2013, 2016; Rosenthal et al., 2017), Laptop and Restaurant (Pontiki et al., 2014, 2015). These and other TSC datasets (Pang and Lee, 2005) suffer from at least one of the following shortcomings. First, implicitly or indirectly expressed sentiment is rare in them. In their domains, e.g., social media and reviews, typically authors explicitly express their sentiment regarding a target (Zhang et al., 2018). Second, they largely neglect that a text may contain coreferential mentions of the target or mentions of different concepts (with potentially different polarities), respectively (Jiang et al., 2019).

Texts in news articles differ from reviews and social media in that news authors typically do not express sentiment toward a target explicitly (exceptions include opinion pieces and columns). Instead, journalists implicitly or indirectly express sentiment (Section 1) because language in news is typically expected to be neutral and journalists to be objective (Balahur et al., 2010; Godbole et al., 2007; Hamborg et al., 2019).

Our problem statement (Section 1) is largely identical to prior news TSC literature (Steinberger et al., 2017; Balahur et al., 2010) with key differences: we do not generally discard the "author-" and "reader-level." Doing so would neglect large parts of sentiment expressions. Thus, it would degrade real-world performance of the resulting dataset and models trained on it. For example, word choice (listed as "author-level" and discarded from their problem statement) is in our view an in-text means that may in fact strongly influence how readers perceive a target, e.g., "freedom fighters" or "terrorists." While we do not exclude their "reader-level," we do seek to exclude polarizing or contentious cases, where no uniform answer can be found in a set of randomly selected readers (Sections 3.3 and 3.4). As a consequence, we generally do not distinguish between the three levels of sentiment ("author," "reader," and "text") in this paper.

Previous news TSC approaches mostly employ sentiment dictionaries, e.g., created manually (Balahur et al., 2010; Steinberger et al., 2017) or extended semi-automatically (Godbole et al., 2007), but yield poor or even “useless” (Steinberger et al., 2017) performances. To our knowledge, there exist two datasets for evaluation of news TSC methods (Steinberger et al., 2017), which – perhaps due to its small size ($N = 1274$) – has not been used or tested in recent TSC literature. Recently, Hamborg et al. (2021) proposed a dataset ($N = 3002$) used to explore target-dependent sentiment in news articles. The dataset suffers from various shortcomings, particularly its small size, class imbalance, and lacking the more ambiguous and implicit types of sentiment expressions described above. Another dataset contains quotes extracted from news articles, since quotes more likely contain explicit sentiment ($N = 1592$) (Balahur et al., 2010).

3 NewsMTSC: Dataset Creation

In creating the dataset, we rely on best practices reported in literature on the creation of datasets for NLP (Pustejovsky and Stubbs, 2012), especially for the TSC task (Rosenthal et al., 2017). Compared to previous TSC datasets though, the nature of sentiment in news articles requires key changes, especially in the annotation instructions and consolidation of answers (Steinberger et al., 2017).

3.1 Data sources

We use two datasets as sources: POLUSA (Gebhard and Hamborg, 2020) and Bias Flipper 2018 (BF18) (Chen et al., 2018). Both satisfy five criteria that are important to our problem. First, they contain news articles reporting on political topics. Second, they approximately match the online media landscape as perceived by an average US news consumer.[2] Third, they have a high diversity in topics due to the number of articles contained and time frames covered (POLUSA: 0.9M articles published between Jan. 2017 and Aug. 2019, BF18: 6447 articles associated to 2781 events). Fourth, they feature high diversity in writing styles because they contain articles from across the political spectrum, including left- and right-wing outlets. Fifth, we find that they contain only few minor content errors albeit being created through scraping or crawling.

3.2 Creation of examples

To create a batch of examples for annotation, we devise a three tasks process: first, we extract example candidates from randomly selected articles. Second, we discard non-optimal candidates. Only for the train set, third, we filter candidates to address class imbalance. We repeatedly execute these tasks so that each batch yields 500 examples for annotation, contributed equally by both sources.

First, we randomly select articles from the two sources. Since both are at least very approximately uniformly distributed over time (Gebhard and Hamborg, 2020; Chen et al., 2018), randomly drawing articles will yield sufficiently high diversity in both writings styles and reported topics (Section 3.1). To extract from an article examples that contain meaningful target mentions, we employ coreference resolution (CR).[3] We iterate all resulting coreference clusters of the given article and create a single example for each mention and its enclosing sentence.

Extraction of mentions of named entities (NEs) is the commonly employed method to create examples in previous TSC datasets (Rosenthal et al., 2017; Nakov et al., 2016, 2013; Steinberger et al., 2017). We do not use it since we find it would miss $\gtrapprox 30\%$ mentions of relevant target candidates, e.g., pronominal or near-identity mentions.

Second, we perform a two level filtering to improve quality and “substance” of candidates. On coreference cluster level, we discard a cluster c in a document d if $|M_c| \leq 0.2|S_d|$, where $|...|$ is the number of mentions of a cluster (M_c) and sentences in a document (S_d). Also, we discard non-persons clusters, i.e., if $\exists m \in M_c : t(m) \notin \{-, P\}$, where $t(m)$ yields the NE type[4] of m, and $-$ and P represent the unknown and person type, respectively. On example level, we discard short and similar examples e, i.e., if $|s_e| < 50$ or if $\exists \hat{e} : sim(s_e, s_{\hat{e}}) > 0.6 \land m_e = m_{\hat{e}} \land t_e = t_{\hat{e}}$ where s_e, m_e, and t_e are the sentence of e, its mention, and the target's cluster, respectively, and $sim(...)$ the cosine similarity. Lastly, if a cluster has multiple mentions in a sentence, we try to select the most meaningful example. In short, we prefer the cluster's representative mention[5] over nominal mentions, and those over all other instances.

Third, for only the train set, we filter candidates to address class imbalance. Specifically, we discard examples e that are likely the majority class ($p(\text{neutral}|s_e) > 0.95$) as determined by a simple binary classifier (Sanh et al., 2019). Whenever annotated and consolidated examples are added to the

---

[2] POLUSA by design (Gebhard and Hamborg, 2020) and BF18 was crawled from a news aggregator on a daily basis.

[3] We employ spaCy 2.1 and neuralcoref 4.0.

[4] Determined by spaCy.

[5] Determined by neuralcoref.

train set of NewsMTSC, we retrain the classifier on them and all previous examples in the train set.

3.3 Annotation

Instructions used in popular TSC datasets plainly ask annotators to rate the sentiment of a text toward a target (Rosenthal et al., 2017; Pontiki et al., 2015). For news texts, we find that doing so yields two issues (Balahur et al., 2010): low inter-annotator reliability (IAR) and low suitability. Low suitability refers to examples where annotators' answers can be consolidated but the resulting majority answer is incorrect as to the task. For example, instructions from prior TSC datasets often yield low suitability for polarizing targets, independently of the sentence they are mentioned in. Figure 2 (Appendix) depicts our final annotation instructions.

In an interactive process with multiple test annotations (six on-site and eight on Amazon Mechanical Turk, MTurk), we test various measures to address the two issues. We find that asking annotators to think from the perspective of the sentence's author strongly facilitates that annotators overcome their personal attitude. Further, we find that we can effectively draw annotators' attention not only at the event and other "facts" described in sentence (the "what") but also at word choice ("how" it is described) by exemplarily mentioning both factors and abstracting these factors as the author's holistic "attitude." [6] We further improve IAR and suitability, e.g., by explicitly instructing annotators to rate sentiment only regarding the target but not other aspects, such as the reported event.

While most TSC dataset creation procedures use 3- or 5-point Likert scales (Nakov et al., 2013, 2016; Rosenthal et al., 2017; Pontiki et al., 2014, 2015; Balahur et al., 2010; Steinberger et al., 2017), we use a 7-point scale to encourage rating also only slightly positive or negative examples as such.

Technically, we closely follow previous literature on TSC datasets (Pontiki et al., 2015; Rosenthal et al., 2017). We conduct the annotation of our examples on MTurk. Each example is shown to five randomly selected crowdworkers. To participate in our annotation, crowdworkers must have the "Master" qualification, i.e., have a record of successfully completed, high quality work on MTurk. To ensure quality, we implement a set of objective measures and tests (Kim et al., 2012). While we pay all crowdworkers always (USD 0.07 per assignment), we discard all of a crowdworker's answers if at least one of the following conditions is met. A crowdworker (a) was not shown any test question or answered at least one incorrectly[7], (b) provided answers to invisible fields in the HTML form (0.3% of crowdworkers did so, supposedly bots), or (c) the average duration of time spent on the assignments was extremely low ($< 4s$).

The IAR is sufficiently high ($\kappa_C = 0.74$) when considering only examples in NewsMTSC. The expected mixed quality of crowdsourced work becomes apparent when considering all examples, including those that could not be consolidated and answers of those crowdworkers who did not pass our quality checks ($\kappa_C = 0.50$).

3.4 Consolidation

We consolidate the answers of each example to a majority answer by employing a restrictive strategy. Specifically, we consolidate the set of five answers A to the single-label 3-class polarity $p \in \{\text{pos.}, \text{neu.}, \text{neg.}\}$ if $\exists C \subseteq A : |C| \geq 4 \wedge \forall c \in C : s(c) = p$, where $s(c)$ yields the 3-class polarity of an individual 7-class answer c, i.e., neutral ⇒ neutral, any positive (from slightly to strongly) ⇒ positive, and respectively for negative. If there is no such consolidation set C, A cannot be consolidated and the example is discarded. Consolidating to 3-class polarity allows for direct comparison to established TSC dataset.

While the strategy is restrictive (only 50.6% of all examples are consolidated this way), we find it yields the highest quality. We quantify the dataset's quality by comparing the dataset to an expert annotation (Section 3.6) and by training and testing models on dataset variants with different consolidations. Compared to consolidations employed for previous TSC datasets, quality is improved significantly on our examples, e.g., our strategy yields $F1_m = 86.4$ when comparing to experts' annotations and models trained on the resulting set yield up to $F1_m = 83.1$ whereas the two-step majority strategy employed for the Twitter 2016 set (Nakov et al., 2016) yields 50.6 and 53.4 respectively.

3.5 Splits and multi-target examples

NewsMTSC consists of three sets as depicted in Table 1. For the *train* set, we employ class balanc-

---

[6] To think from the author's perspective is not to be confused with the "author-level" defined by Balahur et al. (2010).

[7] Prior to submitting a batch of examples to MTurk, we add 6% test examples with unambiguous sentiment, e.g., "Mr. Smith is a bad guy."

Set	Total	Pos.	Neu.	Neg.	MT-a	MT-d	+Corefs	Pos.	Neu.	Neg.
Train	8739	2395	3028	3316	972	341	11880	3434	3744	4702
Test-mt	1476	246	748	482	721	294	1883	333	910	640
Test-rw	1146	361	587	624	73	30	1572	361	587	624

Table 1: Statistics of NewsMTSC. Columns (f.l.t.r.): name; count of targets with any, positive, neutral, and negative sentiment, respectively; count of examples with multiple targets of any and different polarity, respectively; count of targets and their coreferential mentions with any, pos., neu. and neg. sentiment, respectively.

ing prior to annotation (Section 3.2). To minimize dataset shift, which might yield a skewed sentiment distribution in the dataset compared to the real-world (Quionero-Candela et al., 2009), we do not use class balancing for either of the two test sets. Sentences can have multiple targets (MT) with potentially different polarities. We call this *MT property*. To investigate the effect on TSC performance of considering or neglecting the MT property (Jiang et al., 2019), we devise a test set named *test-mt*, which consists only of examples that have at least two semantically different targets, i.e., each belonging to a separate coreference cluster (Section 3.2). Since the additional filtering required for *test-mt* naturally yields dataset shift, we create a second test set named *test-rw*, which omits the MT filtering and is thus designed to be as close as possible to the real-world distribution of sentiment. We seek to provide a sentiment score for each person in each sentence in *train* and *test-rw* but mentions may be missing, e.g., because of erroneous coreference resolution or crowdworkers' answers could not be consolidated.

3.6 Quality and characteristics

We conduct an expert annotation of a random subset of 360 examples used during the creation of NewsMTSC with five international graduate students (studying Political or Communication Science at the University of Zurich, Switzerland, 3 female, 2 male, aged between 23 and 29). Key differences compared to the MTurk annotation are: first, extensive training until high IAR is reached (considering all examples: $\kappa_C = 0.72$, only consolidated: $\kappa_C = 0.93$). We conduct five iterations, each consisting of individual annotations by the students, quantitative and qualitative review, adaption of instructions, and individual and group discussions. Second, comprehensive instructions (4 pages). Third, no time pressure, since the students are paid per hour (crowdworkers per assignment).

When comparing the expert annotation with our dataset, we find that NewsMTSC is of high quality ($F1_m = 86.4$). The quality of unfiltered answers from MTurk is, as expected, much lower (50.1).

What is contained in NewsMTSC? In a random set of 50 consolidated examples from MTurk, we find that most frequent, non-mutually exclusive means to express a polar statement (62% of the 50) are usage of quotes (in total, direct, and indirect 42%, 28%, and 14%, respectively), target being subject to action (24%), evaluative expression by the author or an opinion holder mentioned outside of the sentence (18%), target performing an action (16%), and loaded language or connotated terms (14%). Direct quotes often contain evaluative expressions or connotated terms, indirect quotes less. Neutral examples (38% of the 50) contain mostly objective storytelling about neutral events (16%) or variants of "[target] said that ..." (8%).

What is not contained in NewsMTSC? We qualitatively review all examples where individual answers could not be consolidated to identify potential causes why annotators do not agree. The predominant reason is technical, i.e., the restrictiveness of the consolidation (MTurk compared to experts: $26\% \approx 30\%$). Other examples lack apparent causes ($24\% \gg 8\%$). Further potential causes are (not mutually exclusive): ambiguous sentence ($16\% \approx 18\%$), sentence contains positive and negative parts ($8\% \approx 6\%$), opinion holder is target ($6\% \approx 8\%$), e.g., "[...] Bauman asked supporters to 'push back' against what he called a targeted campaign to spread false rumors about him online."

What are qualitative differences in the annotations by crowdworkers and experts? We review all 63 cases (18%) where answers from MTurk could be consolidated but differ to experts' answers. The major reason for disagreement is the restrictiveness of the consolidation (53 cases have no consolidation among the experts). In 10 cases the consolidated answers differ. We find that in few examples (2-3%) crowdsourced annotations are superficial and fail to interpret the full sentence correctly.

Texts in NewsMTSC are much longer than in prior TSC datasets (mean over all examples): 152 characters compared to 100, 96, and 90 in Twitter, Restaurant, and Laptops, respectively.

4 Methodology

The goal of TSC is to find a target's polarity $y \in \{\text{pos.}, \text{neu.}, \text{neg.}\}$ in a sentence. Our model consists of four key components (Figure 1): a pre-trained language model (LM), a representation of external knowledge sources (EKS), a target mention mask, and a bidirectional GRU (BiGRU) (Cho et al., 2014). We adapt our model from Hosseinia et al. (2020) and change the design as follows: we employ a target mask (which they did not) and use multiple EKS simultaneously (instead of one). Further, we use a different set of EKS (Section 5) and do not exclude the LM's parameters from fine-tuning.

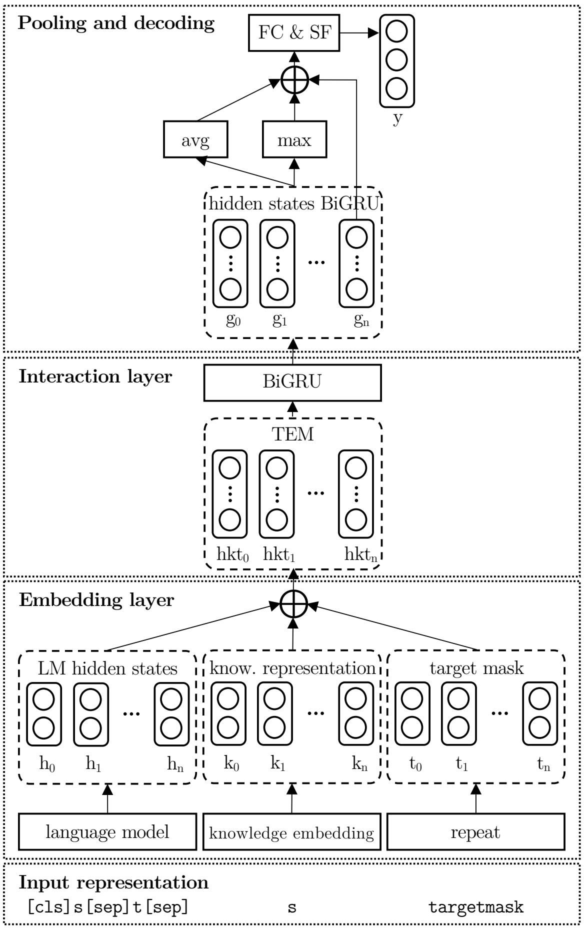

Figure 1: Overall architecture of the proposed model.

4.1 Input representation

We construct three model inputs. The first is a text input T constructed as suggested by Devlin et al. (2019) for question-answering (QA) tasks. Specifically, we concatenate the sentence and target mention and tokenize the two segments using the LM's tokenizer and vocabulary, e.g., WordPiece for BERT (Wu et al., 2016).[8] This step results in a text input sequence $T = [\text{CLS}, s_0, s_1, ..., s_p, \text{SEP}, t_0, t_1, ..., t_q, \text{SEP}] \in \mathbb{N}^n$ consisting of n word pieces, where n is the manually defined maximum sequence length.

The second input is a feature representation of the sentence, which we create using one or more EKS, such as dictionaries (Hosseinia et al., 2020; Zhang et al., 2020). Given an EKS with d dimensions, we construct an EKS representation $E \in \mathbb{R}^{n \times d}$ of S, where each vector $e_{i \in \{0,1,...,p\}}$ is a feature representation of the word piece i in the sentence. To facilitate learning associations between the token-based EKS representation and the WordPiece-based sequence T, we create E so that it contains k repeated vectors for each token where k is the token's number of word pieces. Thereby, we also consider special characters, such as CLS. If multiple EKS with a total number of dimensions $\hat{d} = \sum d$ are used, their representations of the sentence are stacked resulting in $E \in \mathbb{R}^{n \times \hat{d}}$.

The third input is a target mask $M \in \mathbb{R}^n$, i.e., for each word piece i in the sentence that belongs to the target, $m_i = 1$, else 0 (Gao et al., 2019).

4.2 Embedding layer

We feed T into the LM to yield a contextualized word embedding of shape $\mathbb{R}^{n \times h}$, where h is the number of hidden states in the language model. We feed E into a randomly initialized matrix $W_E \in \mathbb{R}^{\hat{d} \times h}$ to yield an EKS embedding. We repeat M to be of shape $\mathbb{R}^{n \times h}$. By creating all embeddings in the same shape, we facilitate a balanced influence of each input to the model's downstream components. We stack all embeddings to form a matrix $TEM \in \mathbb{R}^{n \times 3h}$.

4.3 Interaction layer

We allow the three embeddings to interact using a single-layer BiGRU (Hosseinia et al., 2020), which yields hidden states $H \in \mathbb{R}^{n \times 6h} = \text{BiGRU}(TEM)$. RNNs, such as LSTMs and GRUs, are commonly used to learn a higher-level representation of a word embedding, especially in state-of-the-art TSC prior to BERT-based models but also recently (Liu et al., 2015; Li et al., 2019; Hosseinia et al., 2020; Zhang et al., 2020). We

---

[8] For readability, we showcase inputs as used for BERT.

choose an BiGRU over an LSTM because of the smaller number of parameters in BiGRUs, which may in some cases result in better performance (Chung et al., 2014; Jiang et al., 2019; Hosseinia et al., 2020; Gruber and Jockisch, 2020).

4.4 Pooling and decoding

We employ three common pooling techniques to turn the interacted, sequenced representation H into a single vector (Hosseinia et al., 2020). We calculate element-wise (1) mean and (2) maximum over all hidden states H and retrieve the (3) last hidden state h_{n-1}. Then, we stack the three vectors to P, feed P into a fully connected layer FC so that $z = FC(P)$ and calculate $y = \sigma(z)$.

5 Experiments

5.1 Experimental data

In addition to NewsMTSC, we use the three established TSC sets: Twitter, Laptop, and Restaurant.

5.2 Evaluation metrics

We use metrics established in the TSC literature: macro F1 on all ($F1_m$) and only the positive and negative classes ($F1_{pn}$), accuracy (a), and average recall (r_a). If not otherwise noted performances are reported for our primary metric, $F1_m$.

5.3 Baselines

We compare our model with TSC methods that yield state-of-the-art results on at least one of the established datasets: SPC-BERT (Devlin et al., 2019): input is identical to our text input. FC and softmax is calculated on CLS token. TD-BERT (Gao et al., 2019): masks hidden states depending on whether they belong to the target mention. LCF-BERT (Zeng et al., 2019): similar to TD but additionally weights hidden states depending on their token-based distance to the target mention. We use the improved implementation (Yang, 2020) and enable the dual-LM option, which yields slightly better performance than using only one LM instance (Zeng et al., 2019). We also planned to test LCFS-BERT (Phan and Ogunbona, 2020) but due to technical issues we were not able to reproduce the authors' results and thus exclude LCFS from our experiments.

5.4 Implementation details

To find for each model the best parameter configuration, we perform an exhaustive grid search. Any number we report is the mean of five experiments that we run per configuration. We randomly split each test set into a dev-set (30%) and the actual test-set (70%). We test the base version of three LMs: BERT, RoBERTa, and XLNET. For all methods, we test parameters suggested by their respective authors.[9] We test all 15 combinations of the following 4 EKS: (1) *SENT* (Hu and Liu, 2004): a sentiment dictionary (number of non-mutually exclusive dimensions: 2, domain: customer reviews). (2) *LIWC* (Tausczik and Pennebaker, 2010): a psychometric dictionary (73, multiple). (3) *MPQA* (Wilson et al., 2005): a subjectivity dictionary (3, multiple). (4) *NRC* (Mohammad and Turney, 2010): dictionary of sentiment and emotion (10, multiple).

5.5 Overall performance

Table 2 reports the performances of the models using different LMs and evaluated on both test sets. We find that the best performance is achieved by our model ($F1_m = 83.1$ on *test-rw* compared to 81.8 by prior state-of-the-art). For all models, performances are (strongly) improved when using RoBERTa, which is pre-trained on news texts, or XLNET, likely because of its large pre-training corpus. Because of limited space, XLNET is not reported in Table 2, but results are generally similar to RoBERTa except for the TD model, where XLNET degrades performance by 5-9pp. Looking at BERT, we find no significant improvement of GRU-TSC over prior state-of-the-art. Even if we domain-adapt BERT (Rietzler et al., 2019) for 3 epochs on a random sample of 10M English sentences (Gebhard and Hamborg, 2020), BERT's performance ($F1_m = 81.8$) is lower than RoBERTa. We notice a performance drop for all models when comparing *test-rw* and *test-mt*. It seems that RoBERTa is better able to resolve in-sentence relations between multiple targets (performance degeneration of only up to -0.6pp) than BERT (-2.9pp). We suggest to use RoBERTa for TSC on news, since fine-tuning it is faster than fine-tuning XLNET, and RoBERTa achieves similar or better performance than other LMs.

While GRU-TSC yields competitive results on

---

[9] Epochs $\in \{2, 3, 4\}$; batch size $\in \{8, 16\}$ (due to constrained resources not 32); learning rate $\in \{2e{-}5, 3e{-}5, 5e{-}5\}$; label smoothing regularization (LSR) (Szegedy et al., 2016): $\epsilon \in \{0, .2\}$; dropout rate: .1; $\mathcal{L}_2$ regularization: $\lambda = 1e{-}5$; SRD for LCF $\in \{3, 4, 5\}$. We use Adam optimization (Kingma and Ba, 2014), Xavier uniform initialization (Glorot and Bengio, 2010), and cross-entropy loss.

best combination	**81.0**	83.3

Table 4: Results of exemplary EKS combinations.

previous TSC datasets (Table 3), LCF is the top performing model.[10] When comparing the performances across all four datasets, the importance of the consolidation becomes apparent, e.g., performance is lowest on Twitter, which employs a simplistic consolidation (Section 3.4). The performance differences of individual models when contrasting their use on prior datasets and NewsMTSC highlight the need LCF performs consistently best on prior datasets but worse than GRU-TSC on NewsMTSC. One reason might be that LCF's weighting approach relies on a static distance parameter, which seems to degrade performance when used on longer texts as in NewsMTSC (Section 3.6). When increasing LCF's window width SRD, we notice a slight improvement of 1pp (SRD=5) but degradation for larger SRD.

5.6 Ablation study

We perform an ablation study to test the impact of four key factors: target mask, EKS, coreferential mentions, and fine-tuning the LM's parameters. We test all LMs and if not noted otherwise report results for RoBERTa since it generally performs best (Section 5.5). We report results for *test-mt* (performance influence is similar on either test set, with performances generally being $\approx$ 3-5pp higher on *test-rw*). Overall, we find that our changes to the initial design (Hosseinia et al., 2020) contribute to an improvement of approximately 1.9pp. The most influential changes are the selected EKS and in part use of coreferential mentions. Using the target mask input channel without coreferences and LM fine-tuning yield insignificant improvements of up to 0.3 each. We do not test the VADER-based sentence classification proposed by Hosseinia et al. (2020) since we expect no improvement by using it for various reasons. For example, VADER uses a dictionary created for a domain other than news and classifies the sentence's overall sentiment and thus is target-independent.

Table 4 details the results of exemplary EKS, showing that the best combination (SENT, MPQA, and NRC) yields an improvement of 2.6pp compared to not using an EKS (zeros). The single best EKS (LIWC or SENT) each yield an improvement of 2.4pp. The two EKS "no EKS" and "zeros" represent a model lacking the EKS input channel and an EKS that only yields 0's, respectively.

The use of coreferences has a mixed influence on performance (Table 5). While using coreferences has no or even negative effect in our model for large LMs (RoBERTa and XLNET), it can be beneficial

---

[10] For previous models, Table 3 lists results reported by their authors. In our experiments, we find 0.4-1.8pp lower performance compared to the reported results.

Name	BERT	RoBERTa
none	73.1	**78.1**
target mask	73.3	**78.2**
add coref. to mask	**75.6**	**78.1**
add coref. as example	73.0	73.4

Table 5: Influence of target mask and coreferences.

for smaller LMs (BERT) or batch sizes (8). When using the mode "ignore," "add coref. to mask," and "add coref. as example" we ignore coreferences, add them to the target mask, and create an additional example for each, respectively. Mode "none" represents a model that lacks the target mask input channel.

6 Error Analysis

To understand the limitations of GRU-TSC, we carry out a manual error analysis by investigating a random sample of 50 incorrectly predicted examples for each of the test sets. For *test-rw*, we find the following potential causes (not mutually exclusive): edge cases with very weak, indirect, or in part subjective sentiment (22%) or where both the predicted and true sentiment can actually be considered correct (10%); sentiment of given target confused with different target (14%). Further, sentence's sentiment is unclear due to missing context (10%) and consolidated answer in NewsMTSC is wrong (10%). In 16% we find no apparent reason. For *test-mt*, potential causes occur approximately similarly often except that targets are confused more often (20%).

7 Future Work

We identify three main areas for future work. The first area is related to the dataset. Instead of consolidating multiple annotators' answers during the dataset creation, we propose to test to integrate the label selection into the model (Raykar et al., 2010). Integrating the label selection into the machine learning part could improve the classification performance. It could also allow us to include more sentences in the dataset, especially the edge cases that our restrictive consolidation currently discards.

To improve the model design, we propose to design the model specifically for sentences with multiple targets, for example, by classifying multiple targets in a sentence simultaneously. While we early tested various such designs, we did not report them in the paper due to their comparably poor performances. Further work in this direction should perhaps also focus on devising specialized loss functions that set multiple targets and their polarity into relation. Lastly, one can improve various technical details of GRU-TSC, e.g., by testing other interaction layers, such as LSTMs, or using layer-specific learning rates in the overall model, which can increase performance (Sun et al., 2019b).

8 Conclusion

We present NewsMTSC, a dataset for target-dependent sentiment classification (TSC) on news articles consisting of 11.3k manually annotated examples. Compared to prior TSC datasets, it is different in key factors, such as its texts are on average 50% longer, sentiment is expressed explicitly only rarely, and there is a separate test set for multi-target sentences. As a consequence, state-of-the-art TSC models yield non-optimal performances. We propose GRU-TSC, which uses a bidirectional GRU on top of a language model (LM) and other embeddings, instead of masking or weighting mechanisms as employed by prior state-of-the-art. We find that GRU-TSC achieves superior performances on NewsMTSC and is competitive on prior TSC datasets. RoBERTa yields best results compared to using BERT, because RoBERTa is pre-trained on news and we find it can better resolve in-sentence relations of multiple targets.

Acknowledgments

The work described in this paper is partially funded by the WIN program of the Heidelberg Academy of Sciences and Humanities, financed by the Ministry of Science, Research and the Arts of the State of Baden-Wurttemberg, Germany. We are grateful to the crowdworkers who participated in our online annotation and the UZH students who participated in the expert annotation: F. Jedelhauser, Y. Kipfer, J. Roberts, L. Sopa, and F. Wallin. We thank the anonymous reviewers for their valuable comments that helped to improve this paper.

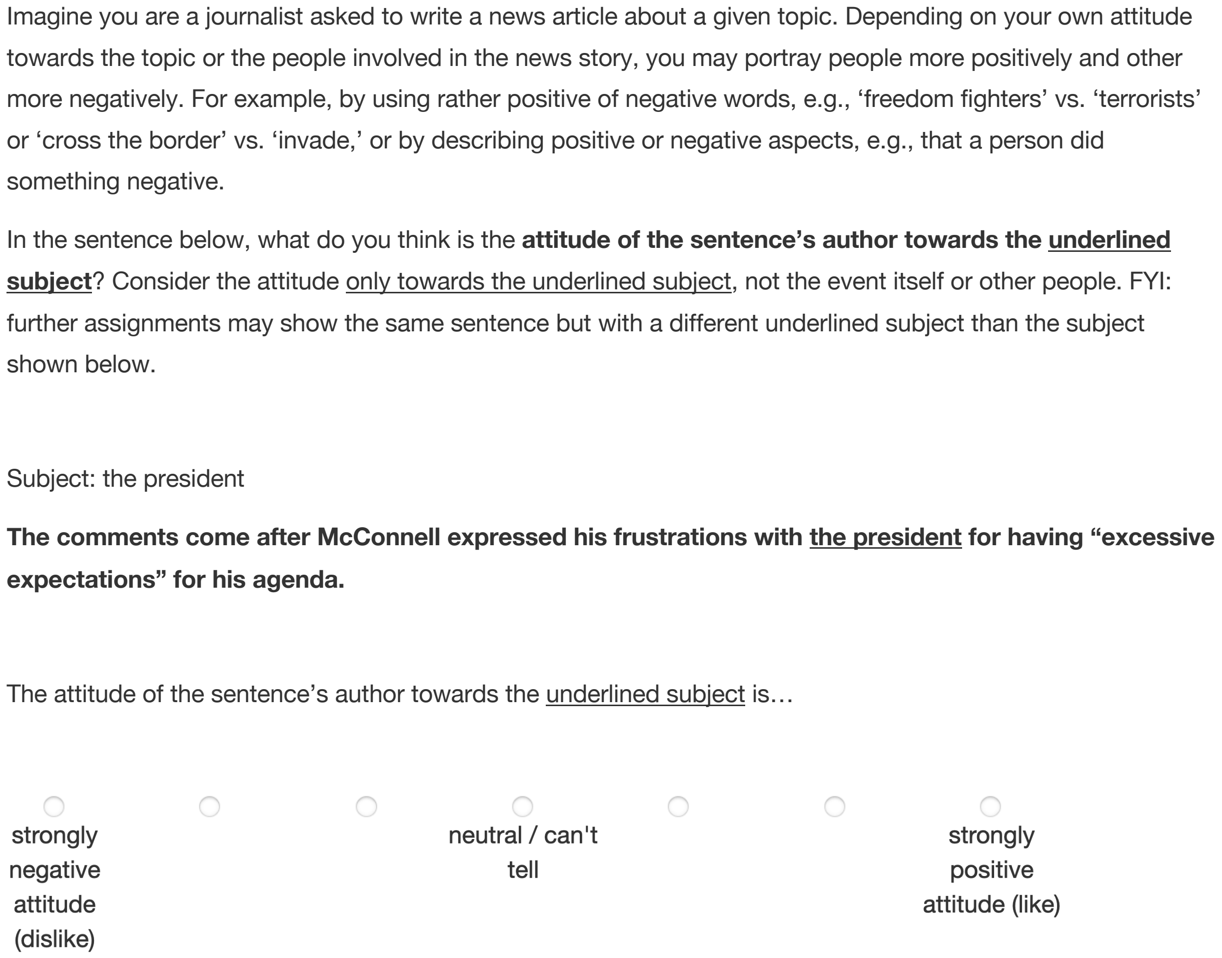
A Appendices



Imagine you are a journalist asked to write a news article about a given topic. Depending on your own attitude towards the topic or the people involved in the news story, you may portray people more positively and other more negatively. For example, by using rather positive of negative words, e.g., ‘freedom fighters’ vs. ‘terrorists’ or ‘cross the border’ vs. ‘invade,’ or by describing positive or negative aspects, e.g., that a person did something negative.

In the sentence below, what do you think is the **attitude of the sentence’s author towards the underlined subject**? Consider the attitude only towards the underlined subject, not the event itself or other people. FYI: further assignments may show the same sentence but with a different underlined subject than the subject shown below.

Subject: the president

The comments come after McConnell expressed his frustrations with the president for having “excessive expectations” for his agenda.

The attitude of the sentence’s author towards the underlined subject is…

○	○	○	○	○	○	○
strongly negative attitude (dislike)			neutral / can't tell			strongly positive attitude (like)

Abstract

Many data sets (e.g., reviews, forums, news, etc.) exist parallelly in multiple languages. They all cover the same content, but the linguistic differences make it impossible to use traditional, bag-of-word-based topic models. Models have to be either single-language or suffer from a huge, but extremely sparse vocabulary. Both issues can be addressed by transfer learning. In this paper, we introduce a zero-shot cross-lingual topic model. Our model learns topics on one language (here, English), and predicts them for unseen documents in different languages (here, Italian, French, German, and Portuguese). We evaluate the quality of the topic predictions for the same document in different languages. Our results show that the transferred topics are coherent and stable across languages, which suggests exciting future research directions.

1 Introduction

Topic models (Blei et al., 2003; Blei, 2012) allow us to find the main themes and overarching tropes in textual data. However, traditional methods are language-specific and cannot be used in a *transferable manner*. They rely on a fixed vocabulary specific to the training language.

Therefore, currently available topic models suffer from two limitations: (i) they cannot handle unknown words by default, and (ii) they cannot easily be applied to other languages - except the one in the training data - since the vocabulary would not match. Training on several languages together, though, results in a vocabulary so vast that it creates problems with parameter size, search, and overfitting (Boyd-Graber et al., 2014). Traditional topic modeling provides methods to extract meaningful word distributions from "unstructured" text but requires language-specific bag-of-words (BoW) representations (Boyd-Graber and Blei, 2009; Jagarlamudi and Daumé, 2010).

A cross-lingual setup proves ideal for *transfer learning*: provided that the gist of topics is the same across languages, we can learn this gist on texts in one language and then apply it to others. This setup is *zero-shot learning*: we train a model on one language and test it on several other languages to which the model had no access during training.

To this end, we need to leverage external information to support the topic modeling task. Indeed, topic models have often gained significant advantages from introducing external knowledge, e.g., document relationships (Yang et al., 2015; Wang et al., 2020; Terragni et al., 2020a,b) and word embeddings (Nozza et al., 2016; Li et al., 2016; Zhao et al., 2017; Dieng et al., 2020). Recently, pre-trained contextualized embeddings, e.g., BERT (Devlin et al., 2019) embeddings, have enabled exciting new results in several NLP tasks (Rogers et al., 2020; Nozza et al., 2020). More importantly, there do exist contextualized embeddings that are also multilingual.

This paper introduces a novel neural topic modeling architecture in which we *replace* the input BoW document representations with multilingual *contextualized* embeddings. Neural topic models take in input the document BoW representations, which provide valuable symbolic information; however, this information's structure is lost after the first hidden layer in any neural architecture. We, therefore, hypothesize that contextual information can replace the BoW representation.

We use a neural encoding layer for the pre-trained document representations from a contextu-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1676–1683
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

alized embedding model input (e.g., BERT) before the neural topic model's sampling process. This change allows us to address the two limitations mentioned above jointly: (i) our approach solves the problem of dealing with unseen words at test time since we do not need them to have a BoW representation; moreover, (ii) the model infers topics on unseen documents in languages other than the one in the training data. The inferred topics consist of tokens from the training language and can be applied to any supported test language. We show the high quality of the resulting topics for four test languages both quantitatively and qualitatively.

To the best of our knowledge, there is no prior work on zero-shot cross-lingual topic modeling. Our model can be applied to new languages after training is complete and does not require external resources, alignment, or other conditions. Nonetheless, the flexibility of the input means our model will benefit from any future improvement of language modeling techniques.

Contributions We release a novel neural topic model that relies on language-independent representations to generate topic distributions. We show that this input can replace the standard input BoW without loss of quality. We show that its multilingual representations enable zero-shot cross-lingual tasks. The solution we propose is straightforward and does not require high computational resources since it can efficiently run on common laptops (see Appendix). We have implemented the tool as a documented python package available at `https://github.com/MilaNLProc/contextualized-topic-models`.

2 Contextualized Neural Topic Models

We extend Neural-ProdLDA (Srivastava and Sutton, 2017), one of the most recent and promising approaches of neural topic modeling, based on the Variational AutoEncoder (VAE) (Kingma and Welling, 2014). The neural variational framework trains an inference network, i.e., a neural network that directly maps the BoW representation of a document onto a continuous latent representation. A decoder network then reconstructs the BoW by generating its words from the latent document representation. This latent representation is sampled from a Gaussian distribution parameterized by μ and σ^2 that are part of the variational inference framework (Kingma and Welling, 2014) — see (Srivastava and Sutton, 2017) for more details.

We replace the input BoW in Neural-ProdLDA with pre-trained multilingual representations from SBERT (Reimers and Gurevych, 2019), a recent and effective model for contextualized representations. In Figure 1, we sketch the architecture of our contextualized neural topic model. The final *reconstructed BoW* layer is still a component of our model: the BoW representation is necessary for the model's training to obtain the topic indicators (i.e., the most likely words representing a topic), but it becomes useless during testing.

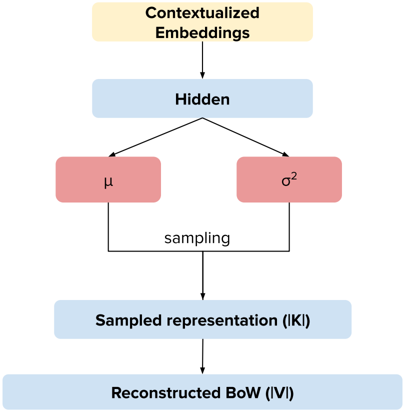

Figure 1: High-level schema of the architecture for the proposed contextualized neural topic model.

Our proposed model, **Zero-Shot Topic Model** (ZeroShotTM), is trained with input document representations that account for word-order and contextual information, overcoming one of the central limitations of BoW models. Moreover, the use of language-independent document representations allows us to do zero-shot topic modeling for unseen languages. This property is essential in low-resource settings in which there is little data available for the new languages. Because multilingual contextualized representations exist for multiple languages, it allows zero-shot modeling in a *cross-lingual* scenario. Indeed, ZeroShotTM is language-independent: given a contextualized representation of a new language as input,[1] it can predict the topic distribution of the document. The predicted topic descriptors, though, will be from the training language. Let us also notice that our method is agnostic about the choice of the neural topic model architecture (here, Neural-ProdLDA), as long as it extends a Variational Autoencoder.

---

[1] As long as a multilingual model - like multilingual BERT - covers it.

3 Experiments

Our experiments evaluate two main hypotheses: (i) *we can define a topic model that does not rely on the BoW input but instead uses contextual information;* (ii) *the model can tackle zero-shot cross-lingual topic modeling*. The Appendix contains more details about the experiments (e.g., code, data, runtime, replication details).

Datasets We use datasets collected from English Wikipedia abstracts from DBpedia.[2] The first dataset (W1) contains 20,000 randomly sampled abstracts. The second dataset (W2) contains 100,000 English documents. We use 99,700 documents as training and consider the remaining 300 documents as the test set. We collect the 300 respective instances in Portuguese, Italian, French, and German. This collection creates a test set of comparable documents, i.e., documents that refer to the same entity in Wikipedia, but in different languages.

We extract only the first 200 tokens of each abstract to reduce the length limit's effects in the tokenization process. In particular, we use the efficient and effective SBERT (Reimers and Gurevych, 2019),[3] using the multilingual model,[4] on this unpreprocessed text. We then remove stopwords and use the most frequent remaining 2,000 words to create the English vocabulary for BoW model comparisons.

3.1 To Contextualize or Not To Contextualize

First, we want to check if **ZeroShotTM** maintains comparable performance to other topic models; if this is true, we can then explore its performance in a cross-lingual setting. Since we use only English text, in this setting we use English representations.[5]

Model	τ (50)	τ (100)
ZeroShotTM	0.1632	0.1381
Combined TM	0.1644	**0.1409***
Neural-ProdLDA	**0.1658**	0.1285
LDA	-0.0246	-0.0757

Table 1: NPMI Coherences on W1 data set. * denotes the statistically significant results (t-test).

We compare **ZeroShotTM** on W1 with: (i) Combined TM (Bianchi et al., 2020), an extension of Neural-ProdLDA that concatenates *both* BoWs and SBERT representations (transformed to the same dimension of the BoWs) as inputs to the model, (ii) Neural-ProdLDA (Srivastava and Sutton, 2017), and (iii) LDA (Blei et al., 2003).

We compute the topic coherence (Lau et al., 2014) via NPMI (τ) for 50 and 100 topics averaging models' results over 30 runs. We report the results in Table 1. ZeroShotTM obtains comparable results to Combined TM and Neural-ProdLDA in this setting. Contextualized embeddings *can* replace BoW input representations without loss of coherence.

3.2 Zero-shot Cross-Lingual Topic Modeling

ZeroShotTM can be used for zero-shot cross-lingual topic modeling. We evaluate multilingual topic predictions on the multilingual abstracts in W2. We use SBERT [6] to generate multilingual embeddings as the input of the model.

3.2.1 Quantitative Evaluation

Since the predicted document-topic distribution is subject to a stochastic sampling process, we average it over 100 samples to obtain a better estimate.

Metrics We expect the topic distributions over a set of comparable documents (e.g., in English and Portuguese) to be similar to each other. We compare the topic distributions of each abstract in a test language with the topic distribution of the respective abstract in English, which is the training language. Note that the English test document is also unseen, i.e., the training data does not include it. We evaluate our model on three different metrics. The first metric is **matches**, i.e., the percentage of times the predicted topic for the non-English test document is the same as for the respective test document in English. The higher the scores, the better.

To also account for similar but not exactly equal topic predictions, we compute the **centroid embeddings** of the five words describing the predicted topic for both English and non-English documents. Then we compute the cosine similarity between those two centroids (CD).

Finally, to capture the **distributional similarity**, we also compute the KL divergence between the

Table 2: Match, KL, and centroid similarity for 25 and 50 topics on various languages on W2.

predicted topic distribution on the test document and the same test document in English. Here, lower scores are better, indicating that the distributions do not differ by much.

Automatic Evaluation We use two baselines: the first one (Ori) consists of performing topic modeling on documents translated into English via DeepL.[7] While this is an easily accessible baseline, automatic translation is costly and may introduce bias in the representations (as shown by Hovy et al. (2020)). We compare the predicted topics of each translated document to the ones predicted for the original English document (as done above). The second baseline is a uniform distribution (Uni): we compute all the metrics over a uniform distribution (this baseline gives a lower bound).

Table 2 shows the evaluation results of our model in the zero-shot context. Note that because we trained on English data, the topic descriptors are in English. Topic predictions are significantly better than the uniform baselines: more than 70% of the times, the predicted topic on the test set matches the topic of the same document in English. The CD similarity suggests that even when there is no match, the predicted topic on the unseen language is at least similar to the one on the English testing data. Simultaneously, the predictions for the contextualized model are in line with the ones obtained using the translations (Ori Avg), showing that our model is capable of finding good topics for documents in unseen languages without the need for translation.

Manual Evaluation We rated the predicted topics for 300 test documents in five languages (thus, 1500 docs including English) on an ordinal scale from 0-3. A 0 rate means that the predicted topic is wrong, a 1 rate means the topic is somewhat related, a 2 rate means the topic is good, and a 3 rate means the topic is entirely associated with the considered document. Table 3 shows the results per language. We evaluate the inter-rater reliability using Gwet AC1 with ordinal weighting (Gwet, 2014). The resulting value of 0.88 indicates consistent scoring.

Language	Average Topic Quality
English	2.35
Italian	2.29
French	2.22
Portuguese	2.26
German	2.19
Average	2.26

Table 3: Average topic quality (out of 3).

3.2.2 Qualitative Evaluation

In Table 4, we show some examples of topic predictions on test languages. Our model predicts the main topic for all languages, even though they were unseen during training.

The predicted topic is generally consistent with the text. I.e., the topics are easily interpretable and give the user a coherent impression. In some circumstances, noise biases the results: dates in the abstract tend to make the model predict a topic about time. Another interesting case is the abstract of the artist Joan Brossa, who was both a poet and a graphic designer. In the English and Italian abstract, the model has discovered a topic related to writing. In constrast, in the Portuguese abstract, the model has found a topic related to art, which is still meaningful.

4 Related Work

While not in a zero-shot fashion, several researchers have studied multilingual and cross-lingual topic modeling (Ma and Nasukawa, 2017; Gutiérrez et al., 2016; Hao and Paul, 2018; Heyman et al., 2016; Liu et al., 2015; Krstovski et al., 2016).

The first model proposed to process multilingual corpora with LDA is the Polylingual Topic Model by Mimno et al. (2009). It uses LDA to extract language-consistent topics from parallel multilingual corpora, assuming that translations share the same topic distributions. Models that transfer knowledge on the document level have many variants, including (Hao and Paul, 2018; Heyman et al., 2016; Liu et al., 2015; Krstovski et al., 2016). However, existing models require to be trained on multilingual corpora and are always language-dependent: they cannot predict the main topics of a document in an unseen language.

Other models use multilingual dictionaries (Boyd-Graber and Blei, 2009; Jagarlamudi and Daumé, 2010), requiring some predefined mapping. Embeddings, both for words and documents, have been shown to capture a wide range of semantic, syntactic, and social aspects of language (Hovy and Purschke, 2018; Rogers et al., 2020). Our work adds language-independent topics to that list.

5 Conclusions

We propose a novel neural architecture for cross-lingual topic modeling using contextualized document embeddings as input. Our results show that (i) contextualized embeddings can replace the input BoW representations and (ii) using contextualized representations allows us to tackle zero-shot cross-lingual topic modeling. The resulting model can be trained on any one language and applied to any other language for which embeddings are available.

A Datasets

We used the English DBpedia 2016-10 abstract dump[8] to create our datasets.

W1 We randomly sampled 20,000 documents from the English DBpedia abstract dump to create our first set of documents. We created W1 to provide a quick collection of documents to test if our Contextual TM performance does not decrease significantly.

W2 We collected 100,000 abstracts sampling randomly from those that had at least 200 chars. Given this set, we extracted 300 random English abstracts. Given the random abstracts, we retrieved the respective version in other languages using the DBpedia SPARQL endpoint.[9] We manually evaluated the quality of the 300 abstracts since we looked at each of those during our manual evaluation, finding no mismatch between the abstract and no corrupted text.

A.1 Preprocessing

We followed a standard pre-processing pipeline to generate the preprocessed set of documents. We removed punctuation, digits, and nltk's English stop-words.[10] Following other researchers, we selected 2,000 as the maximum number of words for the BoW, and thus we kept in the abstracts only the 2,000 most frequent words.

B Models and Baselines

B.1 Neural-ProdLDA

We use the implementation made available by Carrow (2018) since it is the most recent and with the most updated packages (e.g., one of the latest versions of PyTorch). The model is trained for 100 epochs. We use ADAM optimizer (with a learning rate equal to 2e-3). The inference network is composed of a single hidden layer and 100-dimension of softplus units. The priors over the topic and document distributions are learnable parameters. Momentum is set to 0.99, the learning rate is set to 0.002, and we apply 20% of drop-out to the hidden document representation. The batch size is equal to 200. More details related to the architecture can be found in the original work (Srivastava and Sutton, 2017).

B.2 ZeroShot TM

The model and the hyper-parameters are the same for Neural-ProdLDA, with the difference that we replace the BoW with SBERT features. The model is trained for 100 epochs. We use ADAM optimizer.

B.3 Combined TM

The model (Bianchi et al., 2020)[11] and the hyper-parameters are the same used for Neural-ProdLDA with the difference that we also use SBERT features in combination with the BoW: we take the SBERT embeddings, apply a (learnable) function/dense layer $R^{512} \rightarrow R^{|V|}$ and concatenate the representation to the BoW. The model is trained for 100 epochs. We use ADAM optimizer.

B.4 LDA

We use Gensim's[12] implementation of this model. The hyper-parameters $alpha$ and $beta$, controlling the document-topic and word-topic distribution respectively, are estimated from the data during training.

C Computing Infrastructure

We ran experiments on two common laptops, equipped with a GeForce GTX 1050 (running CUDA 10). As our experiments show, the models can be easily run with basic hardware (having a GPU is better than just using CPU, but the experiments can also be replicated on CPU). Both laptops have 16GB of RAM.

C.1 Runtime

Our implementation is written in PyTorch and runs on both GPU and CPU. Table 5 shows the runtime for one epoch of both our Combined TM and Neural-ProdLDA for 25 and 50 topics on the GeForce GTX 1050. Neural-ProdLDA is slightly faster than our ZeroShotTM. This is due to the additional representation that cannot be encoded as a sparse matrix. However, we believe that these numbers are comparable and make our model easy to use even with common hardware.

Model	W1 (25)	W1 (50)
ZeroShot TM	1.2s	1.2s
Neural-ProdLDA	0.8s	0.9s

Table 5: Time to complete one epoch on the **W1** dataset with 25 and 50 topics.

Dependency parsing with structure preserving embeddings

Ákos Kádár[*] [†] **Lan Xiao**[*] **Mete Kemertas**[‡] **Federico Fancellu**

Abstract

Modern neural approaches to dependency parsing are trained to predict a tree structure by jointly learning a contextual representation for tokens in a sentence, as well as a head–dependent scoring function. Whereas this strategy results in high performance, it is difficult to interpret these representations in relation to the geometry of the underlying tree structure. Our work seeks instead to learn interpretable representations by training a parser to explicitly preserve structural properties of a tree. We do so by casting dependency parsing as a tree embedding problem where we incorporate geometric properties of dependency trees in the form of training losses within a graph-based parser. We provide a thorough evaluation of these geometric losses, showing that the majority of them yield strong tree distance preservation as well as parsing performance on par with a competitive graph-based parser (Qi et al., 2018). Finally, we show where parsing errors lie in terms of tree relationship in order to guide future work.

1 Introduction

Dependency grammars are syntactic formalisms that represent the syntactic structure of a sentence as asymmetric binary grammatical relations among words (Tesnière, 1959; Hudson, 1984; Melcuk, 2003). An example dependency structure is given in Figure 1. Formally, a dependency structure is defined as a directed graph where words are vertices and relations are labelled directed edges (the *arcs*) between a child (the *dependent*) and its parent (the *head*). In practice, dependency structures considered for syntactic analysis are trees. Dependency trees have long been used to improve the performance of many NLP applications, including machine translation (Ding and Palmer, 2004; Menezes et al., 2010; Bastings et al., 2017), relation extraction (Kambhatla, 2004; Bunescu and Mooney, 2005; Miwa and Bansal, 2016; Zhang et al., 2018), and semantic role labeling (Hacioglu, 2004; Marcheggiani and Titov, 2017; He et al., 2018).

In order to assign the correct dependency tree to a sentence, dependency parsers are trained to correctly identify head–dependent relations between pairs of words. Modern neural approaches do so by jointly learning contextual feature representations for the tokens in a sentence, as well as a parsing decision function. This is the case for recent graph-based parsers (Zhang et al., 2017; Dozat et al., 2017; Mohammadshahi and Henderson, 2020, *inter alia*) where an encoder feature extractor is complemented by a score function predicting the likelihood of a word to be the head of another. However, whereas this joint learning strategy results in state-of-the-art performance, the representations learned by these parsers are opaque.

As a first step towards learning interpretable parser representations, here we take a different approach: in addition to learning-to-parse, we seek to learn representations from which tree distances between words in dependency trees can be recovered. This stems from one simple observation: previous approaches do not take into account the *geometry* of the tree they try to model. That is, parsers are unaware of the structural properties of the tree (e.g., distance between nodes, depth from root), and as such are not trained to *explicitly* preserve these properties. In this respect, our approach is aligned with recent work looking at these geometric properties in the context of *probing* the BERT (Devlin et al., 2019) embedding space for syntactic structure (Hewitt and Manning, 2019; Reif et al., 2019). In particular, Hewitt and Manning (2019)

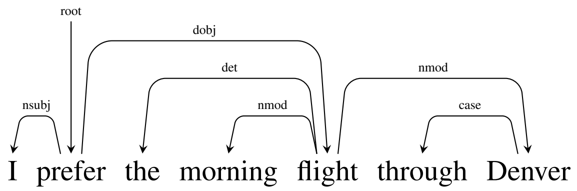

Figure 1: Example dependency tree.

have shown that it is possible to recover approximate syntactic trees from BERT embeddings by a linear transformation trained to minimize the difference between predicted and ground-truth tree distances. Given these results we then ask: is it possible to extend this idea to directly train tree-aware dependency parsers? We argue that using the geometric tree structure to embed the dependency trees enhances the interpretability of the learned representations

In this paper, we show that this is indeed possible by casting dependency parsing as a tree embedding problem. Specifically, we view a dependency tree as a finite metric space, and compute head–dependent scores for all word pairs within a sentence as follows: Given a sentence $s = (w_0, \ldots, w_{n_s})$, where w_0 is a special ROOT token, we compute a geometric tree embedding $\phi : \{w_0, \ldots, w_{n_s}\} \to \mathbb{R}^m$ that maps tokens w_i to m-dimensional vectors. Geometric properties of an ideal isometric tree embedding are used to define the functional form of head–dependent (edge) scores $\psi(w_i, w_j)$. Concretely, our approach predict dependency trees only from pairwise embedded node distances, which completely specify the score function. We consider this as a step in the direction of interpretable end-to-end dependency parsing. We start with a straight-forward application of Hewitt and Manning (2019) and consider a mean absolute error (MAE) loss that encourages the embedding ϕ to approximate an isometric embedding of the ground-truth tree T_s into $(\mathbb{R}^m, d_R)$. In this paper, we use the squared Euclidean distance semi-metric (d_2^2) as in Hewitt and Manning (2019) and also consider the distance obtained from the ℓ_1-norm (d_1)[1]. We show formally that any isometric d_2^2 embedding can be simply rotated to form an isometric d_1 embedding.

We learn the tree embedding ϕ and the edge score function ψ through end-to-end training, by incorporating geometric properties of dependency trees (in terms of distance and depth) in the form of geometric losses within a graph-based parser. As our base parser, we use a simplified version of the biaffine parser of Qi et al. (2018). This setup allows us to directly compare the performance of our losses and score functions to the biaffine score function used in several state-of-the-art graph parsers. We propose three additional losses for training a dependency parser expressed explicitly through tree distances: a maximum likelihood estimation function, a margin-based loss function, and one based on cross-entropy.

Finally, we explore whether adding a soft global constraint on the isometry of the learned trees helps with parsing performance; to this end, we combine our novel loss functions with the MAE loss.

We evaluate our approach on 16 languages from different families. We complement unlabeled accuracy of head–dependent attachement scores (UAS) with a Spearman's ρ correlation between predicted and true distances (DSpr) to directly assess geometric properties of the output trees. We also provide labeled attachment scores (LAS) for completeness. Through extensive experimentation, we make the following observations:

- All of our novel tree distance based losses outperform the MAE loss of Hewitt and Manning (2019)
- All losses using the d_1 metric provide better distance preservation properties and dependency parsing performance than using the d_2^2 semi-metric.
- Five of the six loss combinations (using d_1) show both strong distance preservation properties and parsing performance, indicating that distance preservation can be obtained without trading off parsing performance. Only the maximum likelihood estimation loss (on its own) has poor distance preservation; however, we find that the combination of this loss with the MAE loss greatly improves distance preservation, while achieving similar or better parsing performance.
- We show that the majority of parsing errors are local in tree distance, with by far the most frequent incorrect head assignments being either true sisters or grandparents.

---

[1] The squared Euclidean distance is a semi-metric, not a metric, as it does not respect the triangle inequality. Here $d_1(\mathbf{u}, \mathbf{v}) := ||\mathbf{u} - \mathbf{v}||_1$. Other distance functions could also be considered for d_R but that is beyond the scope of current work.

Our results in the direction of accurate dependency parser that closely preserve tree distances are encouraging.

2 Background: Metric Tree Embeddings

A tree $T = (V, E)$ along with the distance $d_T(u, v)$ is a finite metric space,[2] where $d_T(u, v)$ is the length of the shortest path between any $u, v \in V$. In this paper we consider tree embeddings, $\phi : V \to \mathbb{R}^m$, which map nodes $v \in V$ to points $\phi(v) \in \mathbb{R}^m$ such that the mapping ϕ approximately preserves tree distance. That is, for all pairs $u, v \in V$, the tree distance $d_T(u, v)$ is roughly the corresponding distance $d_R(\phi(u), \phi(v))$ in the embedding space $\mathbb{R}^m$, where we select the metric or semi-metric $d_R(x, y)$ in $\mathbb{R}^m$.

In this section, we discuss the choice of d_R and illustrate distortion free (i.e., isometric) embeddings $\phi : V \to \mathbb{R}^m$. These distortion free embeddings motivate the formulation of losses that we use for training suitable embeddings, as discussed in § 3.

To choose the distance measure d_R in the embedding space, we note that for a sufficiently large dimension m: i) any tree can be embedded isometrically into ℓ_1; ii) any metric space (including trees) can be embedded into ℓ_∞; and iii) for ℓ_p spaces, with $1 < p < \infty$, trees can only be embedded with distortion (Linial et al., 1995). The power transform of the Euclidean distance $d_2(\mathbf{x}, \mathbf{y})^c$, with $c \geq 2$, allows for isometric embedding of trees (Reif et al., 2019). However, the squared Euclidean distance $d_2(\mathbf{x}, \mathbf{y})^2$ does not satisfy the triangle inequality[3] and therefore is only a semi-metric. Nevertheless, both $(\mathbb{R}^m, d_1)$ and $(\mathbb{R}^m, d_2^2)$ are natural choices for embedding spaces for trees and, in this paper, we restrict our attention to these.

We follow Reif et al. (2019) to explicitly construct squared Euclidean embeddings. Specifically, all distortion free embeddings into $(\mathbb{R}^m, d_2^2)$ can be simply expressed in terms of the edge displacement vectors $\{\mathbf{z}_i\}_{i=1}^{|E|}$, where $\mathbf{z}_i \in \mathbb{R}^m$ is the displacement between the embedded endpoints of edge $e_i \in E$ (i.e., $\mathbf{z} := \phi(c) - \phi(p)$, where $c, p \in V$ are a pair of child and parent nodes). For an isometric embedding, it turns out we require these $\mathbf{z}_i$'s to be orthonormal, that is

$$\mathbf{Z}^T \mathbf{Z} = \mathbb{1}, \tag{1}$$

where $\mathbf{Z} \in \mathbb{R}^{m \times |E|}$ is the matrix having $\mathbf{z}_i$ as the i^{th} column and $\mathbb{1}$ denotes the $|E| \times |E|$ identity matrix. In addition, it is useful to define $\rho(u, v)$ to denote the shortest path between two vertices $u, v \in V$. And, finally, define the indicator vector $\mathbf{b}(u, v) \in \mathbb{Z}^{|E|}$ such that $b_i(u, v) = 1$ when edge e_i is on the shortest path between u and v, and $b_i(u, v) = 0$ otherwise. With this notation we have the following theorem:

Theorem 2.1. Pythagorean Embeddings. Given a rooted tree (V, E, r), where $r \in V$ denotes the root, then for any $m \geq |E|$ there exists an embedding $\phi : V \to \mathbb{R}^m$ such that,

$$\forall_{u,v \in V}\ d_T(u, v) = ||\phi(u) - \phi(v)||_2^2. \tag{2}$$

Moreover, ϕ satisfies (2) if and only if

$$\phi(v) = \phi(r) + \mathbf{Z}\,\mathbf{b}(r, v) \tag{3}$$

for some matrix $\mathbf{Z} \in \mathbb{R}^{m \times |E|}$ with orthonormal columns (i.e., Eqn. (1) is satisfied).

See Appendix B-D for an example that demonstrates this construction along with proofs.

The edge-on-path indicator vectors $\mathbf{b}(r, v)$ provide some additional intuition about these squared Euclidean embeddings. Specifically, for $v, w \in V$ we have

$$\begin{aligned}
g(v) := \mathbf{Z}^T \phi(v) &= \mathbf{Z}^T \phi(r) + \mathbf{b}(r, v), & (4)\\
g(v) - g(w) &= \mathbf{Z}^T \mathbf{Z}(\mathbf{b}(r, v) - \mathbf{b}(r, w)), &\\
&= \mathbf{b}(r, v) - \mathbf{b}(r, w) & (5)\\
||g(v) - g(w)||_1 &= ||\mathbf{b}(r, v) - \mathbf{b}(r, w)||_1 &\\
&= d_T(v, w) & (6)
\end{aligned}$$

Here (5) follows from (1), (3) and (4). Therefore g is an isometric ℓ_1 embedding which expresses tree distance in terms of the ℓ_1 norm of the difference between two path vectors $\mathbf{b}$. One interesting consequence of Theorem 2.1, along with Eqn.'s (4) and (6), is:

Corollary 2.1. ℓ_1 Embeddings. Given any isometric embedding $\phi : V \to \mathbb{R}^m$ using the squared Euclidean distance, the embedding $g(v) = \mathbf{Z}^T \phi(v)$ is an isometric embedding of the same tree (V, E, r) into $(\mathbb{R}^{|E|}, d_1)$. Here $\mathbf{Z}$ is as described in (3).

---

[2] Metric spaces are 2-tuples (X, d_X) consisting of a set of elements X and a metric $d_X : X \times X \mapsto [0, \infty)$ quantifying notion of distance between any pair of elements of X.

[3] Consider three points on a line with successive pairs separated by a d_2^2 distance of 1. Then the outer two are separated by an d_2^2 of $2^2 = 4$, which is larger than the sum of the distances between the successive pairs.

That is, any distance preserving tree embedding using the squared Euclidean norm can simply be rotated to an isometric ℓ_1 tree embedding.[4] Note the converse of Cor. 2.1 is not true. For example, three equally spaced points on a line form an ℓ_1 embedding that cannot be linearly transformed to a d_2^2 embedding. Indeed, it is shown in (Aksoy et al., 2020) that a finite metric tree can be embedded into $(\mathbb{R}^m, d_1)$ if and only if it has at most $2m$ leaves. Thus, for a fixed dimensional embedding space $\mathbb{R}^m$, the metric d_1 allows for more trees to be isometrically embedded than d_2^2.

In this paper we use an embedding dimension m that is larger than the number of edges and thus isometric tree embeddings are feasible using both d_2^2 and d_1. The learning problem considered in this paper is, given a sentence s, we seek to embed each of the sentence's tokens into $(\mathbb{R}^m, d_R)$ such that the embedded tree is nearly isometric to the dependency parse tree for s. Here we evaluate using both d_1 and d_2^2 for d_R.

3 Geometric Losses for Tree Embeddings

Given a sentence $s = (w_0, \dots, w_{n_s})$, where w_0 is a special ROOT token inserted at the beginning of every sentence, dependency parsing seeks to recover the correct dependency tree $T_s = (V_s, E_s)$. For simplicity, we label the tree nodes in V_s with the tokens themselves, so $V_s = \{w_0, \dots, w_{n_s}\}$. A geometric tree embedding maps tokens w_i within a sentence s to embedded points $\mathbf{v}_i = \phi(i, s) \in \mathbb{R}^m$ (for brevity, we drop the dependence on the whole sentence s and simply write $\phi(w_i)$). In § 2, we describe the exact geometry of the isometric embeddings using the d_2^2 semi-metric. For d_1 isometric embeddings we show one sub-class are simply rotations of isometric d_2^2 embeddings, but there are other forms. This section examines the use of auxiliary losses on the embedding ϕ that encourage approximately isometric embeddings. We expect an approximation of this geometry holds in d_2^2 when the losses are sufficiently small. Since we do not have a similar proof of necessity as in Appendix D for d_1 embeddings, the local geometry is more open.

Given such an embedding, we then follow first-order graph-based dependency parsers (McDonald et al., 2005) which compute a pairwise score $\psi(\mathbf{v}_i, \mathbf{v}_j)$ that indicates how likely it is for w_j to be the head of w_i. These scores provide edge weights on a fully connected embedded graph on $\phi(V_s) \times \phi(V_s)$. Having trained a network to compute suitable embeddings $\mathbf{v}_i = \phi(w_i)$ and edge weights $\psi(\mathbf{v}_i, \mathbf{v}_j)$, parsing then amounts to finding the maximum spanning tree in this weighted graph that is rooted at $\mathbf{v}_0$; a detailed description of the parser architecture is provided in § 4.

Given this general approach, a natural choice for an auxiliary loss on ϕ is to consider the mean absolute error (MAE) in the distances between the embeddings of any two nodes:

$$\mathcal{L}_{MAE}(\phi, T) = \frac{1}{|V|(|V|-1)} \sum_{\substack{w_i, w_j \in V, \\ i \neq j}} |\, d_R(\mathbf{v}_i, \mathbf{v}_j) - d_{T_s}(w_i, w_j)|, \quad (7)$$

where $\mathbf{v}_i = \phi(w_i)$ (we drop the subscripts s for brevity). This MAE loss treats the distance errors for all pair of nodes as equally important, and we therefore refer to it as a *global* loss. Note the loss in (7) is zero only when the embedding ϕ is an isometric tree embedding with respect to d_R.

We next consider the edge scoring function ψ, whose role is to assign costs to proposed head–dependent pairs (w_i, w_j). We denote this ground-truth head–dependent relation by $\varrho(w_i, w_j)$ (which is true when w_j is the head of w_i in T) and note it can be defined **only** in terms of the distance $d_T(w_i, w_j)$ and depth difference $\Delta_s(w_i, w_j) = d_T(w_0, w_i) - d_T(w_0, w_j)$ as follows:

$$\forall_{w_i, w_j \in V}\, \varrho(w_i, w_j) \iff d_T(w_i, w_j) = 1 \land \Delta(w_i, w_j) = 1. \quad (8)$$

Each node w_i then has a unique head w_j defined by (8), except for the `ROOT` w_0 which has none. Given the embedding ϕ is providing a near-isometric tree, we define an edge scoring function in the embedding space, namely $\psi(\mathbf{v}_i, \mathbf{v}_j)$, by rewriting (8) in the following probabilistic form:

$$\mathbf{v}_i := \phi(w_i), \quad (9)$$

$$\Delta_{ij}^{\phi} := d_R(\mathbf{v}_i, \mathbf{v}_0) - d_R(\mathbf{v}_j, \mathbf{v}_0), \quad (10)$$

$$\ell_{ij}^{\phi} := |d_R(\mathbf{v}_i, \mathbf{v}_j) - 1| + |\Delta_{ij}^{\phi} - 1|, \quad (11)$$

$$\psi(\mathbf{v}_i, \mathbf{v}_j) := -\ell_{ij}^{\phi}, \quad (12)$$

$$p_\phi(w_j | w_i) := \frac{e^{\psi(\mathbf{v}_i, \mathbf{v}_j)/\tau}}{\sum_{\substack{0 \le k \le n \\ k \neq i}} e^{\psi(\mathbf{v}_i, \mathbf{v}_k)/\tau}}. \quad (13)$$

where τ is a temperature parameter. Here we refer to ℓ_{ij}^{ϕ} as the "head–dependent cost" for the pair w_i and w_j.

---

[4] This rotation aligns the edge directions $\mathbf{z}_i$ with the standard bases vectors $\pm e_i$ of $\mathbb{R}^m$.

A natural loss on both the embedding $\phi : V \to \mathbb{R}^m$ and the edge-cost $\psi(\mathbf{v}_i, \mathbf{v}_j)$ is the maximum likelihood loss

$$\mathcal{L}_{MLE}(\phi, T) = \sum_{\substack{w_i, w_j \in V, \\ i \neq j}} \varrho(w_i, w_j) \left[-\log(p_\phi(w_j \mid w_i))\right] \tag{14}$$

where $p_\phi(w_j|w_i)$ is defined in (13).

As an alternative to the MLE loss we consider a margin based approach where the task is to minimize ℓ_{ij}^ϕ for the true head j, subject to $\ell_{ik}^\phi \geq \ell_{ij}^\phi + \alpha$ for all $k \in \{0, \ldots, n\} \backslash \{i, j\}$, where $\alpha > 0$ is a margin.[5] We explore such a margin-based approach using the soft triplet loss (Sohn, 2016)

$$\mathcal{L}_\alpha(\phi, T) = \tag{15}$$
$$\sum_{\substack{w_i, w_j \in V, \\ i \neq j}} \varrho(w_i, w_j) \log \left[1 + \sum_{w_k \in V \backslash \{w_j, w_i\}} e^{\alpha - \ell_{ik}^\phi + \ell_{ij}^\phi}\right].$$

As a third alternative for the head–dependent loss we consider the cross-entropy between the probability distribution $p_\phi(w_j|w_i)$ and the corresponding distribution $p_T(w_i|w_j)$ formed by using an isometric embedding ϕ_T in Eqns. (9 - 13). Note that for an isometric embedding ϕ_T we have $d_R(\mathbf{v}_i, \mathbf{v}_j) = d_T(w_i, w_j)$, and this can be used to simplify the resulting expression. Specifically, we find $p_T(w_j|w_i)$ depends only on the true tree distance d_T and not on the details of ϕ_T. The cross-entropy loss is then

$$\mathcal{L}_{CE}(\phi, T) = \sum_{\substack{w_i \in V \backslash \{w_0\}, \\ w_j \in V \backslash \{w_i\}}} p_T(w_j|w_i) \left[-\log(p_\phi(w_j|w_i))\right]. \tag{16}$$

In summary, we investigate the choice between several different head–dependent losses (i.e., Eqn.'s (14), (15), or (16), and optionally combine each of these with the explicit global MAE loss (7).

4 Evaluation

4.1 Model

We use a simplified version of the Biaffine dependency parser of Qi et al. (2018).[6] First, we give an overview of the Biaffine parser, and then describe our modifications. Biaffine is composed of a highway-BiLSTM encoder (Srivastava et al., 2015) that takes as input a sequence of $n_s + 1$ embeddings $\mathbf{x}_0, \ldots, \mathbf{x}_{n_s}$, where each $\mathbf{x}_i$ is a concatenation of word-level, character-level, part-of-speech and morphological feature embeddings. We use pre-trained word2vec (Mikolov et al., 2013) when available, and fastText embedding (Bojanowski et al., 2017) otherwise. We train the rest of the embeddings from scratch.

Given such an input sequence, the Biaffine parser predicts the most likely head for each word (referred to as unlabelled attachment prediction), along with the grammatical relation between each pair of head and dependent words (labelled attachment prediction). Biaffine first calculates contextual embeddings $\mathbf{h}_i$ (through the encoder), and then projects these into separate head and dependent representations for each word (through two separate MLP networks):

$$\mathbf{h}_i = \text{BiLSTM}_i(\mathbf{x}_0, \ldots, \mathbf{x}_{n_s}), \tag{17}$$
$$\mathbf{h}_i^{\text{head}}, \mathbf{h}_j^{\text{dep}} = \text{MLP}^{\text{head}}(\mathbf{h}_i), \text{MLP}^{\text{dep}}(\mathbf{h}_j), \tag{18}$$

where $\mathbf{h}_i^{\text{head}}$ and $\mathbf{h}_i^{\text{dep}}$ are the *head* and *dependent* representations. Next, for each pair of words w_i and w_j, a head–dependent score s_{ij} and a corresponding probability $p(w_j|w_i)$ are calculated with a learnable biaffine weight $\mathbf{U}$:

$$\begin{aligned} s_{ij} &= \mathbf{h}_i^{\text{head}} \mathbf{U} \mathbf{h}_j^{\text{dep}}, \\ &:= \text{Biaffine}(\mathbf{h}_i, \mathbf{h}_j), \end{aligned} \tag{19}$$
$$p(w_j|w_i) = \frac{e^{s_{ij}}}{\sum_{w_k \in V_s \backslash \{w_i\}} e^{s_{ik}}}. \tag{20}$$

Our geometric tree embedding ϕ computes a single representation for each node, as such we replace the separate head and dependent MLP networks with a single MLP network[7]:

$$\mathbf{v}_i := \phi(w_i), \tag{21}$$
$$= \text{MLP}(\mathbf{h}_i). \tag{22}$$

Given $\mathbf{v}_0, \ldots, \mathbf{v}_n$, head–dependent scores s_{ij} are defined as in:

$$s_{ij} = \psi(\mathbf{v}_i, \mathbf{v}_j), \tag{23}$$

where ψ is calculated as in Eqn. (12). We obtain asymmetry in our score function $\psi(\mathbf{v}_i, \mathbf{v}_j)$ from the depth difference term $|\Delta_{ij}^\phi - 1|$ in Eqn. (11).

---

[5] Note that an isometric embedding ϕ provides one solution for which $\ell_{ij}^\phi = 0$ for all head–dependent pairs, and $\ell_{ij}^\phi \geq 2$ otherwise.

[6] We use the codebase provided at `https://github.com/stanfordnlp/stanfordnlp`.

[7] To focus on learning unlabeled tree structures, we also remove the auxiliary losses that penalize rightward attachments or long dependencies, since the model behaves differently from the unlabeled prediction.

During inference, we use the Chu-Liu-Edmonds algorithm (Chi, 1999; Edmonds, 1967) to find the highest-scoring dependency tree. While our main focus is embedding unlabeled trees for dependency relation prediction, for completeness we also report results on labeled dependency tree prediction. We use the same classifier as Biaffine — with the same setting as described in Qi et al. (2018) — to estimate the probabilities of dependency labels $\mathbf{l}_{ij}$ for a given head–dependent pair w_i and w_j:

$$p(l_{k,ij}|w_j, w_i) = \frac{e^{s^{\text{rel}}_{k,ij}}}{\sum_n e^{s^{\text{rel}}_{n,ij}}} \tag{24}$$

$$\mathbf{s}^{\text{rel}}_{ij} = \text{Biaffine}^{\text{rel}}(\mathbf{h}_i, \mathbf{h}_j) \tag{25}$$

where $\mathbf{s}^{\text{rel}}_{ij} \in \mathbb{R}^K$ is a K-dimensional vector containing the dependency relation scores for each of the K dependency labels.

4.2 Experimental Setup

Data. We perform experiments on Universal Dependencies (UD; Nivre et al. 2020). Relying on criteria proposed by Kulmizev et al. (2019), we select 16 languages from different families, with different scrips and training sizes, all with good annotation quality. We use the following treebanks from UD v2.2: Arabic-PADT, Basque-BDT, Bulgarian-BTB, Chinese-GSD, Czech-PDT, Danish-DDT, English-EWT, Finnish-TDT, Hebrew-HTB, Hindi-HDTB, Italian-ISDT, Japanese-GSD, Korean-GSD, Russian-SynTagRus, Swedish-Talbanken, Turkish-IMST.

Performance Measures. We report the overall accuracy of head and relation predictions for all tokens in the test portion of the data sets. Given our model prediction and a reference parse for a given input, accuracy is calculated using two standard measures: Unlabelled Attachment Score (UAS), that is the percentage of tokens that are assigned the correct head; and Labelled Attachment Score (LAS) that is the percentage of tokens that are assigned the correct head and the correct grammatical relation. We use UAS for model selection.

To assess how well the learned tree embeddings preserve distances, we follow Hewitt and Manning (2019) and Hall Maudslay et al. (2020), and measure the correlation between the learned and ground-truth tree distances. Specifically, for all words in all sentences, we compute Spearman's ρ between predicted and true distances. We first average the correlation coefficients for sentences of the same length. We report the macro-average over these averages for sentences of length 5–50, referred to as DSpr.

	d_2^2	d_1	d_1 [+ $\mathcal{L}_{MAE}$]
$\mathcal{L}_{MAE}$	90.28 (0.89)	90.53 (0.89)	N/A
$\mathcal{L}_{MLE}$	91.47 (0.60)	91.51 (0.71)	91.77 (0.85)
$\mathcal{L}_{\alpha}$	91.43 (0.83)	91.57 (0.88)	91.41 (0.89)
$\mathcal{L}_{CE}$	86.82 (0.38)	91.79 (0.81)	91.85 (0.88)

Table 1: UAS (DSpr) of d_2^2 and d_1 embeddings, plus effects of adding the auxiliary MAE loss; reported on the development portion of English-EWT.

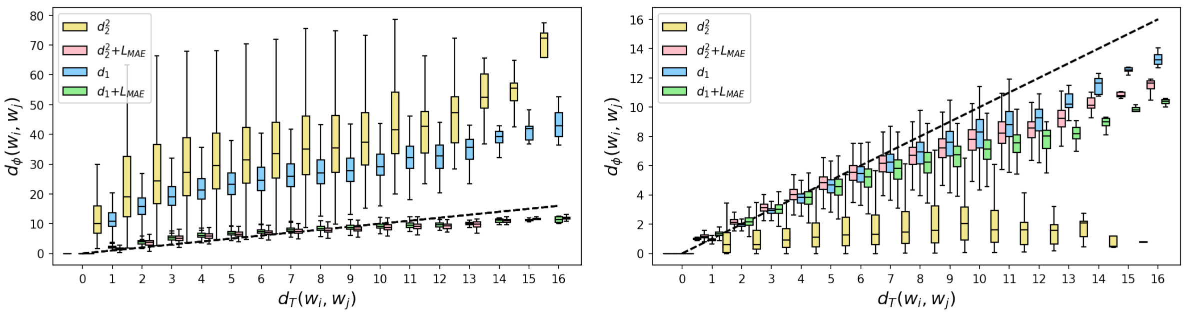
Hyperparameters. We adopt the same hyperparameter configuration as in the original Biaffine model (Qi et al., 2018) up to the BiLSTM layer for the head–dependent classifier, and the same configuration for the entire dependency label classifier. We perform grid search on the remaining hyperparameters and select best hyperparameter configurations based on UAS on the development portion of the English-EWT data. Based on the results, we set the margin $\alpha = 3$ for $\mathcal{L}_\alpha$, and the temperature $\tau = 1$ for $\mathcal{L}_{MLE}$ and $\tau = 0.2$ for $\mathcal{L}_{CE}$. In our evaluation, we run experiments that involve the combination of any of $\mathcal{L}_\alpha$, $\mathcal{L}_{CE}$, and $\mathcal{L}_{MLE}$ with $\mathcal{L}_{MAE}$ as an auxiliary loss, with a coefficient λ_1. We find the best values for λ_1 to be 0.2 for $\mathcal{L}_\alpha$, and 0.1 for both $\mathcal{L}_{CE}$ and $\mathcal{L}_{MLE}$. We refer the reader to Appendix A for the full list of hyperparameters and training details.

5 Results

5.1 Metric Spaces and Geometric Losses

We first verify whether the choice of metric space impacts performance. Table 1 reports UAS (and DSpr) on the development portion of the English-EWT corpus, for tree embeddings in both $(\mathbb{R}^m, d_1)$ and $(\mathbb{R}^m, d_2^2)$ metric spaces (referred to as d_1 and d_2^2 for brevity, respectively).

The first row shows results when trained with $\mathcal{L}_{MAE}$ only. It learns an embedding that provides good approximation of global tree distances using d_2^2 (DSpr: 0.89), which is similar to the findings reported by Hewitt and Manning (2019), but is suboptimal in terms of parsing (UAS: 90.28). On the other hand we can see that all head–dependent losses achieve stronger parsing performances in both spaces, with the proper metric d_1 leading to higher UAS and DSpr scores across the board (including $\mathcal{L}_{MAE}$) when compared to d_2^2. We will then report results in the rest of this section only



(a) (b)

Figure 2: Distance distributions for (a) $\mathcal{L}_{MLE}$ and (b) $\mathcal{L}_{CE}$, for different metric spaces (d_2^2/d_1) and trained with or without the auxiliary loss $\mathcal{L}_{MAE}$. The four box plots at each x-tick summarize the distribution of predicted distances for a particular ground-truth distance. Each box covers data distribution between 25 to 75 percentile, with median showing by the black line. The dashed line represents perfect correlation.

with the d_1 metric, unless otherwise stated.

Table 1 also shows a comparison between the different head–dependent losses, with and without the auxiliary loss $\mathcal{L}_{MAE}$ that further constrains ϕ to be globally isometric. In isolation, $\mathcal{L}_{CE}$ yields the best UAS while $\mathcal{L}_{\alpha}$ the best DSpr; interpolating the losses with $\mathcal{L}_{MAE}$ improves results for $\mathcal{L}_{MLE}$ and $\mathcal{L}_{CE}$, especially in terms of DSpr. This is in line with our expectations that the auxiliary loss encourages the parser to learn an embedding that more faithfully preserves global tree distances.

$\mathcal{L}_{MLE}$ seeks to correctly identify all head–dependent relations by maximizing the probability $p_\phi(w_j|w_i)$ of true head–dependent pairs with no explicit constraints on global isometry; see Eqn. (14). We thus hypothesize that $\mathcal{L}_{MLE}$ can learn an embedding that produces good UAS, but is far from being isometric to the ground-truth tree. We verify this empirically: Figure 2(a) shows that the addition of $\mathcal{L}_{MAE}$ greatly regulates the embedding distances of the trees produced by $\mathcal{L}_{MLE}$, hence improving the DSpr score for this loss.[8] $\mathcal{L}_{CE}$ on the other hand seeks to match $p_\phi(w_j|w_i)$ with $p_T(w_j|w_i)$, which encourages all embedding distances to be correlated with tree distances; see Eqn. (16). However, the $p_T(w_j|w_i)$ term in this loss gives higher weights to word pairs that are closer in terms of ground-truth tree distance and therefore the model is trained to focus more on preserving short distances.[9] Figure 2(b) confirms that the embedding obtained using $\mathcal{L}_{CE}$ underestimates the ground-truth tree distances, and adding the auxiliary MAE loss helps regulate this distortion of tree distances.

§ 2 describes the exact geometry of the embeddings that out model learns using the d_2^2 semi-metric in the special case that $\mathcal{L}_{MAE}$ is reduced to zero. In Figure 2(b), we observe small losses up to tree distance five when d_2^2 is used with $\mathcal{L}_{CE}$ and $\mathcal{L}_{MAE}$. Therefore we expect the local geometry of d_2^2 trees to approximately follow Eqn. (3).

Overall, for both losses we observe that, on average, d_2^2 embeddings lead to predicted tree distances that have large variances, as well as medians further away from the ground-truth, whereas the d_1 embeddings are more stable and accurate. This agrees with the observations in Table 1 that embeddings in d_1 have better DSpr than embeddings in d_2^2 for all losses we considered. The same comparison between d_ϕ and d_T for $\mathcal{L}_\alpha$ is provided in Appendix E.

5.2 Comparison with Qi et al. (2018)

We compare the parsing results for the six geometric loss combinations against the biaffine parser of Qi et al. (2018) for all treebanks in Table 2. For a fair comparison, we re-run all experiments and report our results for the biaffine parser. We report UAS for models trained without the dependency label prediction loss in order to focus on unlabeled tree structure and LAS for completeness. In general, the parsing performance is stable across

---

[8] We observe that the optimized $\mathcal{L}_{MLE}$ (without MAE) is lower than that produced by an isometric embedding on the development portion of English-EWT, indicating that the observed distortion of tree distances is an overfitting issue.

[9] The local emphasis is stronger with lower temperature. We chose temperature $\tau = 0.2$ based on UAS on the development portion of English-EWT. However, we find a temperature of 1 to provide better approximation of global distances, especially for tree distances less than five (see Appendix E and Figure 6).

$\mathcal{L}_{MLE}$	0.72 ± 0.03	0.85 ± 0.02
$\mathcal{L}_{CE}$	0.89 ± 0.03	0.86 ± 0.05
$\mathcal{L}_{\alpha}$	0.87 ± 0.03	0.89 ± 0.03

Table 3: Average DSpr over all (test) treebanks.

different languages for all geometric losses. Overall, $\mathcal{L}_{CE+MAE}$ is our best performing model and the average UAS/LAS across languages are on par with the Biaffine parser in spite of only having a single representation for each token. Moreover, it achieves top performance on Czech, Hindi and Turkish. All other geometric losses also achieve competitive results that are within 1% of the Biaffine parser for both UAS and LAS.

We also report the mean DSpr along with standard deviation across the 16 treebanks in Table 3. Unlike the UAS and LAS we find a substantial difference in the DSpr score for the loss $\mathcal{L}_{MLE}$. When combined with the auxiliary loss $\mathcal{L}_{MAE}$ we find a pronounced increase in DSpr, this agrees with the findings in § 5.1.

5.3 Parsing Errors w.r.t. Tree Relationships

Inspired by the geometric structure of tree embeddings, we investigate the sources of errors in terms of ground-truth dependency trees. Given a sentence s and a dependency tree T_s, we define the type of relation between a pair of token (w_i, w_j) by a 2-tuple consisting the distance $d_{T_s}(w_i, w_j)$ and depth difference $\Delta_s(w_i, w_j) = d_{T_s}(w_0, w_i) - d_{T_s}(w_0, w_j)$. This definition follows naturally from the geometric interpretation of trees: for a node w_i, (1, -1) defines its children, (2, 0) defines its sisters, and (2, 2) defines its grandparents.

To visualize the distribution of errors, for each trained model, we plot the percentage of wrong edges for each relation type on the development set of English-EWT. We show an example plot in Figure 3 for our best $\mathcal{L}_{CE+MAE}$, with results for other losses provided in Appendix F.

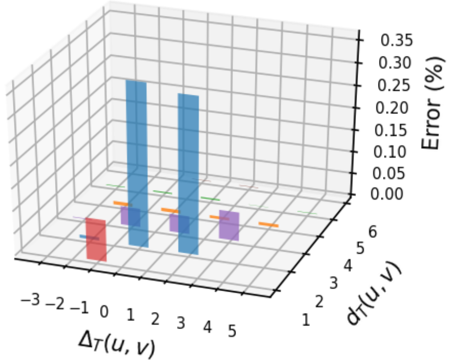

Figure 3: Distribution of edge errors on the development portion of English-EWT, optimized with $\mathcal{L}_{CE+MAE}$; the two axes are $(d_T(i, v), \Delta_T(u, v))$.

Surprisingly, we do not identify long distance ambiguities as a major source of errors (i.e., 99.8% of UAS errors have incorrectly assigned a head node that is within a tree distance of 5 from the dependent). Moreover, we find that sisters and grandparents account for 36.2% and 34.8% of all the UAS errors, respectively. To put these results into context, we construct a synthetic random error distribution: for each tree in the English-EWT development set we generate all trees with a single attachment error. We observe 81.6% of the errors to be local (up to distance 5) and sisters account for 22.5% and grandparents only account for 5.4% of the errors. We further compare with the biaffine parser and find 99.5% of UAS errors are local with 40.2% for sister and 32.7% for grandparent errors. Therefore parsing errors for a trained parser are dominated by errors that are more local in terms of tree distance than expected from a uniform error distribution. One immediate question that may arise is how can we reduce these specific high-frequency errors. One intuitive extension of the current work is to modify the formulation of edge scores in Eqn. (12) to push the decision boundary away from sisters or grandparents during inference. By training to explicitly model the geometry of the tree, our approach is one step closer towards addressing specific high-frequency errors.

6 Conclusions

In this work, we propose to use the geometry of (dependency) tree structures to construct a neural dependency parser that improves the interpretability of the learned representations without compromising parsing performance. We propose several geometric loss functions, and show that for a majority of them, our simple network learns distance-preserving embeddings through end-to-end training. In doing so, we also compare squared Euclidean distance (d_2^2) with the distance obtained from ℓ_1-norm (d_1), as the (semi-)metric in the embedding space $\mathbb{R}_m$, and provide empirical evidence for using the proper d_1 metric. We compare our results with a competitive and widely-used graph-parser proposed by Qi et al. (2018) on 16 languages from different families, and show overall parser performances that are on par with it. Our experiments also suggest a new way of looking at the sources of parsing errors in terms of tree distances, and show that the majority of errors are local (e.g., sisters or grandparents).

For future work, we suggest looking at potential ways to correct such high-frequency head prediction errors, defined by their relationship within a tree. Another interesting direction that's worth exploring is to use the continuous tree distances predicted by our methods as features for downstream tasks instead of the discrete tree structures produced by conventional parsers. As recent work has been exploring, this differentiable representation of tree structure is potentially useful within the iterative-refinement framework (Mohammadshahi and Henderson, 2020), or as additional tree-specific positional features in a transformer (Omote et al., 2019).

A Hyperparameters

We use 2 layers of MLP with leaky-relu as activation to map the biLSTM outputs into a 800-dimensional embedding space[10]. The layer weights are initialized with the values from uniform distribution $\mathcal{U}(-0.05, 0.05)$, and biases are initialized to zero.

We train the models with Adam (Kingma and Ba, 2015) with an initial learning rate of 0.001, $\beta_1 = 0.9$, $\beta_2 = 0.95$, and $\epsilon = 1e-8$ for up to $50,000$ iterations, where each iteration is a batch of up to 5000 tokens or the maximum number of tokens we can fit in the GPU memory. We evaluate the models every 100 steps and save them only if we see improvement in UAS on development data. We switch to AMSGrad (Reddi et al., 2018) after 3000 iterations with no observed improvement on development set UAS, at which point we terminate training when another 3000 iterations pass without improving development set UAS.

B Example d_2^2 and d_1 Tree Embeddings

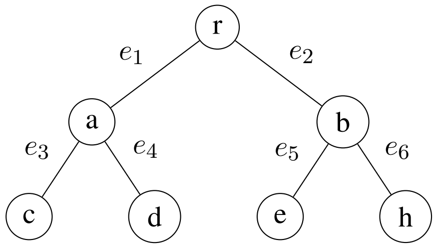

Figure 4: Simple binary tree example.

Let us take as a working example the binary tree on Figure 4. The embedding of node v is the embedding of the root r plus the sum of all direction vectors on the path $\rho(r, v)$, from r to v. If can take $f(r)$ to be **0** or any random vector then embedding of all nodes in the tree are by definition:

$$f(a) = f(r) + \mathbf{u}_1$$
$$f(c) = f(r) + \mathbf{u}_1 + \mathbf{u}_3$$
$$f(d) = f(r) + \mathbf{u}_1 + \mathbf{u}_4$$
$$f(b) = f(r) + \mathbf{u}_2$$
$$f(e) = f(r) + \mathbf{u}_2 + \mathbf{u}_5$$
$$f(h) = f(r) + \mathbf{u}_2 + \mathbf{u}_6$$

We took an arbitrary root embedding $f(r)$ and $n-1$ orthogonal unit-length vectors $\mathbf{u}_i$. If the $\mathbf{u}_i$-s are the standard unit basis vectors, for example, then the tree is embedded on the edges of the unit cube and it is an isometric embedding for both d_2^2 and d_1.

C Proof of Thm. 2.1, Sufficiency

Proof. **Eqn. (3) sufficient.** We first show that an embedding of the form given in Eqn. (3) necessarily satisfies (2). This is Thm. 1 in Reif et al. (2019) and here we find it useful to expand on their proof to introduce notation and assist the reader.

Let $T = (V, E, r)$, **Z** and $b(r, u)$ be as described in § 2. Then Eqn. (3) is simply

$$f(v) = f(r) + \sum_{\{i \in \rho(r,v)\}} \mathbf{z}_i, \tag{26}$$

where the notation $\{i \in \rho(r, v)\}$ is short for $\{i \mid e_i \in \rho(r, v)\}$, which is the set of i's for which $b_i(r, v) = 1$. Consider any two vertices v and w. Notice the two paths $\rho(r, v)$ and $\rho(r, w)$ must share a common prefix, namely $\rho(r, a)$, the sub-path from r to the lowest common ancestor a of v and w, with the remaining paths $\rho(a, v)$ and $\rho(a, w)$ being edge disjoint. Therefore

$$\begin{aligned} &||f(v) - f(w)||_2^2 \\ &= || \sum_{\{i \in \rho(r,v)\}} \mathbf{z}_i - \sum_{\{j \in \rho(r,v))\}} \mathbf{z}_j ||_2^2 && (27) \\ &= || \sum_{\{i \in \rho(a,v)\}} \mathbf{z}_i - \sum_{\{j \in \rho(a,w)\}} \mathbf{z}_j ||_2^2 && (28) \\ &= |\rho(a, v)| + |\rho(a, w)| && (29) \\ &= |\rho(v, w)| \equiv d_T(v, w). && (30) \end{aligned}$$

Here we canceled the common term $f(r)$ and common prefix edges to derive Eqn. (27) and (28). Eqn. (29) follows from the fact that paths $\rho(a, v)$ and $\rho(a, w)$ are edge disjoint and the orthonormality of the $\mathbf{z}_i$'s. Here $|\rho(a, v)|$ denotes the number of edges on the a to v path. Finally, (30) follows since a is the least common ancestor of v and w.

□

D Proof of Thm. 2.1, Necessity

We provide a proofs that any isometric d_2^2 embedding must have the form defined in (3) that relies only on linear algebra and may provide the reader with additional intuition about the construction of d_2^2 embeddings.

---

[10] The maximum length of any sentence in the dataset is smaller than 800 and thus an isometric tree embeddings are feasible using both d_2^2 and d_1

Proof. First, for the case $|V| \leq m+1$, we use induction to show that any isometric d_2^2 embedding f must have the form described in Eqn. (3). Then we show that for $|V| > m+1$, such an f cannot exist.

We use the notation $V = \{v_j \mid 0 \leq j < k\}$, where $v_0 = r$, $|V| = k$ and $|E| = k-1$. For $2 \leq k \leq m+1$ define the the $|E| \times |E|$ path matrix B to be

$$\mathbf{B} = (\mathbf{b}(r, v_1), \ldots, \mathbf{b}(r, v_{k-1})), \tag{31}$$

where $\mathbf{b}(r,v)$ are defined to be the binary path vectors used in (3).

We use induction to prove that if $f : V \to \mathbb{R}^m$ is an isometric embedding for any $k \leq m+1$ then (3) must hold and $\mathbf{B}$ must be full rank. Note this statement is trivially true for $k = 1$ and 2.

Let $k \geq 2$ and $k \leq m$. Let $T = (V, E, r)$ be a tree of size $|V| = k$. Consider the induction hypothesis that any isometric embedding (using d_2^2) of T must have the form in (3) and, moreover, the matrix $\mathbf{B}$ in (31) has full rank. We next show that it follows the same is true for any tree of size $k+1$.

Suppose $T' = (V', E', r)$ is a rooted tree with $|V'| = k+1 \leq m+1$. Suppose $f : V' \to \mathbb{R}^m$ is an isometric embedding using d_2^2. Let $c \neq r$ be a leaf and p be its parent in T'[11], and consider the subtree $T = (V, E, r)$ formed by removing the vertex c and the edge (c, p) from the tree. So $|V| = k$, and the restriction of f to V must provide an isometric embedding of this subtree T. By the induction hypothesis this embedding f, when restricted to V, must satisfy (3) and have the form in (3). Moreover the path matrix $\mathbf{B}$ in (31) for T must be full rank.

Since the full embedding f of T' (including the new vertex c) is isometric it follows that

$$\begin{aligned} ||f(c) - f(v)||_2^2 &= d_T(c, v), \\ &= d_T(p, v) + 1, \ \forall v \in V. \end{aligned} \tag{32}$$

Specifically, when $v = p$ this constrains the embedded displacement for the (p, c) edge, namely $\mathbf{z} := f(c) - f(p)$, to be length 1. Moreover, for any $v \in V' \setminus \{p, c\}$, consider the triangle with vertices $f(c)$, $f(p)$, and $f(v)$. Then (32) states that the squared Euclidean distances of the triangle edges $(f(c), f(p))$, $(f(p), f(v))$ and $(f(c), f(v))$, must be 1, $d_T(p, v)$, and $d_T(p, v) + 1$, respectively. By the Pythagorean Theorem, this must be a right triangle with

$$\mathbf{z}^T (f(p) - f(v)) = 0, \forall v \in V' \backslash \{p, c\}.$$

By using Eqn. (3) on the subtree T this can be rewritten as

$$\mathbf{z}^T \mathbf{Z} (\mathbf{b}(r, p) - \mathbf{b}(r, v)) = 0, \forall v \in V' \backslash \{p, c\}. \tag{33}$$

By setting $v = r$ in (33) and using $\mathbf{b}(r, r) = \mathbf{0}$ (i.e., null vector in $\mathbb{Z}^{|E|}$) we find $\mathbf{z}^T \mathbf{Z} \mathbf{b}(r, p) = 0$. So (33) is equivalent to

$$\mathbf{z}^T \mathbf{Z} \mathbf{b}(r, v) = 0, \forall v \in V' \backslash \{c\}. \tag{34}$$

That is $z^T \mathbf{Z} B = 0$. However, by the induction hypothesis, the $(k-1) \times (k-1)$ matrix $\mathbf{B}$ (for T) is full rank, and so we must have $\mathbf{z}^T \mathbf{Z} = \mathbf{0}$. That is, the direction of the edge (p, c) in the embedding space, $\mathbf{z} = f(c) - f(p)$, must be perpendicular to all the other edges in the tree T' and have unit length, so

$$\begin{aligned} \mathbf{z}^T \mathbf{Z} &= \mathbf{0}, \\ ||\mathbf{z}||_2 &= 1. \end{aligned} \tag{35}$$

Since $\mathbf{Z}$ is a $m \times (k-1)$ matrix with $k \leq m$ it follows that such $\mathbf{z}$ must exist.

Note the path vector $\mathbf{b}(r, c)$, in the tree T', is just the path vector for the parent, $\mathbf{b}(r, p)$, modified to have a 1 in the k^{th} row, while all other path vectors $\mathbf{b}(r, v_j)$ must have zero in this k^{th} row (since c is a leaf). The path matrix $\mathbf{B}'$ for T' therefore has the form

$$\mathbf{B}' = \begin{pmatrix} \mathbf{B} & \mathbf{b}(r, p) \\ \mathbf{0} & \mathbf{1} \end{pmatrix}. \tag{36}$$

Since the induction hypothesis ensures that $\mathbf{B}$ has full rank, it follows that $\mathbf{B}'$ has full rank. Finally, defining $\mathbf{Z}' = (\mathbf{Z}\mathbf{z}) \in \mathbb{R}^{m \times k}$, it follows from (35) that $(\mathbf{Z}')^T \mathbf{Z}' = \mathbb{1}$ and therefore we have shown that f must have the form in (3) with this $\mathbf{Z}'$ and these path vectors $\mathbf{b}(r, v)$. This completes the proof of the induction step, the desired result follows by induction.

To show that there is no embedding for $|V'| \geq m+2$ it is sufficient to show that there is no embedding for $|V'| = m+2$. We use contradiction. Suppose $f : V' \to \mathbb{R}^m$ is such an embedding. We can proceed as above, with c a leaf node of $T' = (V', E', r)$, and p its parent. Then, by using the previous result, any isometric embedding of the subtree $T = (V, E, r)$ that is formed by removing

---

[11] Note $c \neq r$ is possible since $k \geq 2$

this child (so $|V| = m + 1$) must have the form described in (3) with a full rank $m \times m$ path matrix $\mathbf{B}$ and orthonormal $m \times m$ matrix $\mathbf{Z}$. The same line of reasoning then shows that $z := f(c) - f(p)$ must satisfy (35). But here $\mathbf{Z}$ is full rank and so $z = 0$, which contradicts the constraint that the (c, p) edge in the embedding must have length 1. $\square$

Abstract

Annotating training data for sequence tagging of texts is usually very time-consuming. Recent advances in transfer learning for natural language processing in conjunction with active learning open the possibility to significantly reduce the necessary annotation budget. We are the first to thoroughly investigate this powerful combination for the sequence tagging task. We conduct an extensive empirical study of various Bayesian uncertainty estimation methods and Monte Carlo dropout options for deep pre-trained models in the active learning framework and find the best combinations for different types of models. Besides, we also demonstrate that to acquire instances during active learning, a full-size Transformer can be substituted with a distilled version, which yields better computational performance and reduces obstacles for applying deep active learning in practice.

1 Introduction

In many natural language processing (NLP) tasks, such as named entity recognition (NER), obtaining gold standard labels for constructing the training dataset can be very time and labor-consuming. It makes the annotation process expensive and limits the application of supervised machine learning models. This is especially the case in such domains as biomedical or scientific text processing, where crowdsourcing is either difficult or prohibitively expensive. In these domains, highly-qualified experts are needed to annotate data correctly, which dramatically increases the annotation cost.

Active Learning (AL) is a technique that can help to reduce the amount of annotation required to train a good model by multiple times (Settles and Craven, 2008; Settles, 2009). Opposite to exhaustive and redundant manual annotation of the entire corpus, AL drives the annotation process to focus the expensive human expert time only on the most informative objects, which contributes to a substantial increase in the model quality.

AL is an iterative process that starts from a small number of labeled seeding instances. In each iteration, an *acquisition* model is trained on the currently annotated dataset and is applied to the large pool of unannotated objects. The model predictions are used by the AL query strategy to sample the informative objects, which are then further demonstrated to the expert annotators. When the annotators provide labels for these objects, the next iteration begins. The collected data can be used for training a final *successor* model that is used in a target application.

During AL, acquisition models have to be trained on very small amounts of the labeled data, especially during the early iterations. Recently, this problem has been tackled by transfer learning with deep pre-trained models: ELMo (Peters et al., 2018), BERT (Devlin et al., 2019), ELECTRA (Clark et al., 2020), and others. Pre-trained on a large amount of unlabeled data, they are capable of demonstrating remarkable performance when only hundreds or even dozens of labeled training instances are available. This trait suits the AL framework but poses the question about the usefulness of the biased sampling provided by the AL query strategies.

In this work, we investigate AL with the aforementioned deep pre-trained models and compare the results of this combination to the outcome of

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1698–1712
April 19 - 23, 2021.

the models that do not take advantage of deep pretraining. The main contributions of this paper are the following:

- We are the first to thoroughly investigate deep pre-trained models in the AL setting for sequence tagging of natural language texts on the widely-used benchmarks in this area.
- We conduct an extensive empirical study of various AL query strategies, including Bayesian uncertainty estimation methods with multiple Monte Carlo (MC) dropout variants (Gal and Ghahramani, 2016a; Gal et al., 2017). We find the best combinations of uncertainty estimates and dropout options for different types of deep pre-trained models.
- We show that to acquire instances during AL, a full-size Transformer can be substituted with a distilled version, which yields better computational performance and reduces obstacles for applying deep AL in practice.

The remainder paper is structured as follows. Section 2 covers relevant works on AL for sequence tagging. In Section 3, we describe the sequence tagging models. Section 4 describes the AL strategies used in the experiments. In Section 5, we discuss the experimental setup and present the evaluation results. Finally, Section 6 concludes the paper.

2 Related Work

AL for sequence tagging with classical machine learning algorithms and a feature-engineering approach has a long research history, e.g. (Settles and Craven, 2008; Settles, 2009; Marcheggiani and Artières, 2014). More recently, AL in conjunction with deep learning has received much attention.

In one of the first works on this topic, Shen et al. (2018) note that practical deep learning models that can be used in AL should be computational efficient both for training and inference to reduce the delays in the annotators' work. They propose a CNN-CNN-LSTM architecture with convolutional character and word encoders and an LSTM tag decoder, which is a faster alternative to the widely adopted LSTM-CRF architecture (Lample et al., 2016) with comparable quality. They also reveal disadvantages of the standard query strategy – least confident (LC), and propose a modification, namely Maximum Normalized Log-Probability (MNLP). Siddhant and Lipton (2018) experiment with Bayesian uncertainty estimates. They use CNN-CNN-LSTM and CNN-BiLSTM-CRF (Ma and Hovy, 2016) networks and two methods for calculating the uncertainty estimates: Bayes-by-Backprop (Blundell et al., 2015) and the MC dropout (Gal and Ghahramani, 2016a). The experiments show that the variation ratio (Freeman, 1965) has substantial improvements over MNLP. In contrast to them, we additionally experiment with the Bayesian active learning by disagreement (BALD) query strategy proposed by Houlsby et al. (2011) and perform a comparison with variation ratio.

There is a series of works that tackle AL with a trainable policy model that serves as a query strategy. For this purpose, imitation learning is used in Liu et al. (2018); Vu et al. (2019); Brantley et al. (2020), while in (Fang et al., 2017), the authors use deep reinforcement learning. Although the proposed solutions are shown to outperform other heuristic algorithms with comparably weak models (basic CRF or BERT without fine-tuning) in experiments with a small number of AL iterations, they can be not very practical due to the high computational costs of collecting training data for policy models. Other notable works on deep active learning include (Erdmann et al., 2019), which proposes an AL algorithm based on a bootstrapping approach (Jones et al., 1999) and (Lowell et al., 2019), which concerns the problem of the mismatch between a model used to construct a training dataset via AL (acquisition model) and a final model that is trained on it (successor model).

Deep pre-trained models are evaluated in the AL setting for NER by Shelmanov et al. (2019). However, they perform the evaluation only on the specific biomedical datasets and do not consider the Bayesian query strategies. Ein-Dor et al. (2020) conduct an empirical study of AL with pre-trained BERT but only on the text classification task. Brantley et al. (2020) use pre-trained BERT in experiments with NER, but they do not fine-tune it, which results in suboptimal performance. In this work, we try to fill the gap by evaluating deep pre-trained models: ELMo and various Transformers, in the AL setting with practical query strategies, including Bayesian, and on the widely-used benchmarks in this area.

3 Sequence Tagging Models

We use a tagger based on the Conditional Random Field model (Lafferty et al., 2001), two BiLSTM-

CRF taggers (Lample et al., 2016) with different word representation models, and taggers based on state-of-the-art Transformer models.

3.1 Conditional Random Field

As a baseline for comparison, we use a feature-based linear-chain Conditional Random Field (CRF) model (Lafferty et al., 2001). It is trained to maximize the conditional log-likelihood of entire tag sequences. The inference is performed using the Viterbi decoding algorithm, which maximizes the joint probability of tags of all tokens in a sequence. The features used for the CRF model are presented in Appendix B.

3.2 BiLSTM-CRF

This model encodes embedded input tokens via a bidirectional long short term memory neural network (LSTM) (Hochreiter and Schmidhuber, 1997). BiLSTM processes sequences in two passes: from left-to-right and from right-to-left producing a contextualized token vector in each pass. These vectors are concatenated and are used as features in a CRF layer that performs the final scoring of tags.

We experiment with two versions of the BiLSTM-CRF model. The first one uses GloVe (Pennington et al., 2014) word embeddings pre-trained on English Wikipedia and the 5-th edition of the Gigaword corpus, and a convolutional character encoder (Ma and Hovy, 2016), which helps to deal with out-of-vocabulary words. As in (Chiu and Nichols, 2016), the model additionally leverages the basic capitalization features, which has been shown to be useful for achieving good performance with this model. We will refer to it as CNN-BiLSTM-CRF. We consider this model as another baseline that does not exploit deep pre-training. The second version of the BiLSTM-CRF model uses pre-trained medium-size ELMo (Peters et al., 2018) to produce contextualized word representations. ELMo is a BiLSTM language model enhanced with a CNN character encoder. This model does not rely on feature-engineering at all. We will refer to it as ELMo-BiLSTM-CRF.

3.3 Transformer-based Taggers

We perform AL experiments with state-of-the-art pre-trained Transformers: BERT (Devlin et al., 2019), DistilBERT (Sanh et al., 2019), and ELECTRA (Clark et al., 2020). The sequence tagger, in this case, consists of a Transformer "body" and a decoding classifier with one linear layer. Unlike BiLSTM that encodes text sequentially, these Transformers are designed to process the whole token sequence in parallel with the help of the self-attention mechanism (Vaswani et al., 2017). This mechanism is bi-directional since it encodes each token on multiple neural network layers taking into account all other token representations in a sequence. These models are usually faster than the recurrent counterparts and show remarkable performance on many downstream tasks (Li et al., 2020).

BERT is a masked language model (MLM). Its main learning objective is to restore randomly masked tokens, so it can be considered as a variant of a denoising autoencoder. Although this objective makes the model to learn many aspects of natural languages (Tenney et al., 2019; Rogers et al., 2020), it has multiple drawbacks, including the fact that training is performed only using a small subset of masked tokens. ELECTRA has almost the same architecture as BERT but utilizes a novel pre-training objective, called replaced token detection (RTD), which is inspired by generative adversarial networks. In this task, the model has to determine what tokens in the input are corrupted by a separate generative model, in particular, a smaller version of BERT. Therefore, the model has to classify all tokens in the sequence, which increases training efficiency compared to BERT, and the RTD task is usually harder than MLM, which makes the model learn a better understanding of a language (Clark et al., 2020).

DistilBERT is a widely-used compact version of BERT obtained via a distillation procedure (Hinton et al., 2015). The main advantages of this model are the smaller memory consumption and the higher fine-tuning and inference speed achieved by sacrificing the quality. We note that good computational performance is a must for the practical applicability of AL. Delays in the interactions between a human annotator and an AL system can be expensive. Therefore, although DistilBERT is inferior compared to other Transformers in terms of quality, it is a computationally cheaper alternative for acquiring training instances during AL that could be used for fine-tuning bigger counterparts. Lowell et al. (2019) showed that a mismatch between an acquisition model and a successor model (the model that is trained on the annotated data for the final application) could eliminate the benefits of AL. The similarity in the architectures and the shared knowledge between the smaller distilled Transformer and its ancestor potentially can help to alleviate this problem and deliver an AL solution that is both effective and practical.

4 Active Learning Query Strategies

We experiment with four query strategies for the selection of training instances during AL.

Random sampling is the simplest query strategy possible: we just randomly select instances from the unlabeled pool for annotation. In this case, there is no active learning at all.

Uncertainty sampling (Lewis and Gale, 1994) methods select instances according to some probabilistic criteria, which indicates how uncertain the model is about the label that was given to the instance. The baseline method is Least Confident (LC): the instances are sorted in the ascending order of probabilities of the most likely tag sequence. Let y_i be a tag of a token i that can take one class c out of C values, let x_j be a representation of a token j in an input sequence of length n. Then the LC score can be formulated as follows:

$$LC = 1 - \max_{y_1,\dots,y_n} \mathbb{P}\left[y_1,\dots,y_n \middle| \{\mathbf{x}_j\}\right]$$

This score favors longer sentences since long sentences usually have a lower probability. Maximization of probability is equivalent to maximizing the sum of log-probabilities:

$$\max_{y_1,\dots,y_n} \mathbb{P}\left[y_1,\dots,y_n|\{\mathbf{x}_j\}\right] \Leftrightarrow$$
$$\Leftrightarrow \max_{y_1,\dots,y_n} \sum_i^n \log \mathbb{P}\left[y_i|\{y_j\} \setminus y_i, \{\mathbf{x}_j\}\right]$$

To make LC less biased towards longer sentences, Shen et al. (2018) propose a normalization of the log-probability sum. They call the method ***Maximum Normalized Log-Probability (MNLP)***. The MNLP score can be expressed as follows:

$$MNLP = -\max_{y_1,\dots,y_n} \frac{1}{n} \sum_i^n \log \mathbb{P}\left[y_i|\{y_j\} \setminus y_i, \{\mathbf{x}_j\}\right]$$

In our experiments, we use this normalized version of the uncertainty estimate since it has been shown to be slightly better than the classical LC (Shen et al., 2018), and it is commonly applied in other works on active learning for NER.

Following Siddhant and Lipton (2018), we implement extensions for the Transformer-based and BiLSTM-based sequence taggers applying the MC dropout technique. Gal and Ghahramani (2016a) showed that applying a dropout at the prediction time allows us to consider the model as a Bayesian neural network and calculate theoretically-grounded approximations of uncertainty estimates by analyzing its multiple stochastic predictions. Like Shen et al. (2018) and Siddhant and Lipton (2018) we experiment with ***variation ratio (VR)*** (Freeman, 1965): a fraction of models, which predictions differ from the majority:

$$VR_i = 1 - \frac{\text{count}\left(\text{mode}\left(\{y_i^m\}_m^M\right), \{y_i^m\}_m^M\right)}{M}$$
$$VR = \frac{1}{n}\sum_i^n VR_i,$$

where M is a number of stochastic predictions.

Siddhant and Lipton (2018) and Shen et al. (2018) refer to this method as BALD. However, the ***Bayesian active learning by disagreement (BALD)*** proposed by Houlsby et al. (2011) leverage mutual information between outputs y_i and model parameters θ trained on a dataset $\mathcal{D}$:

$$BALD_i = H(y_i|x_i, \mathcal{D}) - E_{\theta \sim p(\theta|\mathcal{D})}\left[H(y_i|x_i, \theta)\right]$$

Let p_i^{cm} be a probability of a tag c for a token i that is predicted by a m-th stochastic pass of a model with the MC dropout. Then the BALD score can be approximated according to the following expression (Gal et al., 2017):

$$BALD_i \approx$$
$$-\sum_c^C \left(\frac{1}{M}\sum_m^M p_i^{cm}\right) \log\left(\frac{1}{M}\sum_m^M p_i^{cm}\right)$$
$$+\frac{1}{M}\sum_{c,m}^{C,M} p_i^{cm} \log p_i^{cm}$$
$$BALD \approx \frac{1}{n}\sum_i^n BALD_i$$

Although BALD can be considered similar to VR, it potentially can give better uncertainty estimates than VR since it leverages the whole probability distributions produced by the model. However, this method has not been tested in the previous works on active learning for sequence tagging.

For Transformer models, we have two variants of the Monte Carlo dropout: the MC dropout on the last layer before the classification layer (MC last), and on all layers (MC all). We note that calculating uncertainty estimates in the case of MC all requires multiple stochastic passes, and in each of them, we have to perform inference of the whole Transformer model. However, if we replace the dropout only in the classifier, multiple recalculations are needed only for the classifier, while it is enough to perform the inference of the massive Transformer "body" only once. Therefore, in this case, the overhead of calculating the Bayesian uncertainty estimates can be less than 1% (in the case of 10 stochastic passes for ELECTRA according to the number of parameters) compared to deterministic strategies like MNLP.

The BiLSTM-CRF model has two types of dropout: the word dropout that randomly drops entire words after the embedding layer and the locked dropout (Gal and Ghahramani, 2016b) that drops the same neurons in the embedding space of a recurrent layer for a whole sequence. Therefore, for the BiLSTM-CRF taggers, we have three options: replacing the locked dropout (MC locked), replacing the word dropout (MC word), and replacing both of them (MC all). We should note that obtaining Bayesian uncertainty estimates does not require the recalculation of word embeddings (in our case, ELMo).

5 Experiments and Results

5.1 Experimental Setup

We experiment with two widely-used datasets for evaluation of sequence tagging models and AL query strategies: English CoNLL-2003 (Sang and Meulder, 2003) and English OntoNotes 5.0 (Pradhan et al., 2013). The corpora statistics are presented in Appendix A. In the experiments, we use the "native" tag schemes: IOB1 for CoNLL-2003 and IOB2 for OntoNotes 5.0.

Each experiment is an *emulation* of the AL cycle: selected instances are not presented to experts for annotation but are labeled automatically according to the gold standard. Each experiment is performed for each AL query strategy and is repeated five times for CoNLL-2003 and three times for OntoNotes to report the standard deviation. A random 2% subset in tokens of the whole training set is chosen for seeding, and instances with 2% of tokens in total are selected for annotation on each iteration. Overall, 24 AL iterations are made, so in the final iteration, half of the training dataset (in tokens) is labeled. We do not use validation sets provided in the corpora but keep 25% of the labeled corpus as the development set and train models from scratch on the rest. For OntoNotes, the AL query strategy is applied to only the 50% subsample of the unlabeled dataset. This helps to reduce the duration of the inference phase. In preliminary experiments, we note that it does not seriously affect the AL performance, but the further reduction of the subsample size has a significant negative impact.

MODEL	CONLL-2003	ONTONOTES
CRF	78.2 ± NA	79.8 ± NA
CNN-BILSTM-CRF	88.3 ± 0.2	82.9 ± 0.3
ELMO-BILSTM-CRF	91.2 ± 0.2	87.2 ± 0.2
DISTILBERT	89.8 ± 0.2	87.3 ± 0.1
BERT	91.1 ± 0.2	88.2 ± 0.2
ELECTRA	91.5 ± 0.2	87.6 ± 0.2

Table 1: Performance of models built on the entire training datasets without active learning

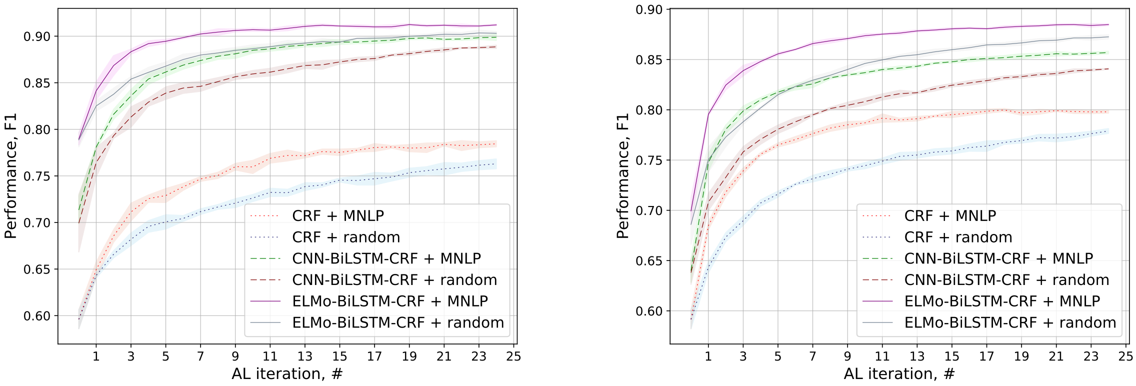
Details of models and training procedures are presented in Appendix C. We conduct AL experiments with the pre-selected model and training hyperparameters. Tuning hyperparameters of acquisition models during AL would drastically increase the duration of an AL iteration, which makes AL impractical. The hyperparameter optimization is reasonable for successor models. However, in preliminary AL experiments, tuning hyperparameters of successor models on the development set appeared to demonstrate an insignificant difference in the performance compared to using pre-selected hyperparameters that are fixed for all AL iterations. Therefore, since tuning hyperparameters for training a successor model on each AL iteration drastically increases the amount of computation, we fix them to the values pre-selected for experiments without AL.

The evaluation is performed using the span-based F1-score (Sang and Meulder, 2003). For query strategies based on the MC dropout, we make ten stochastic predictions.

5.2 Results and Discussion

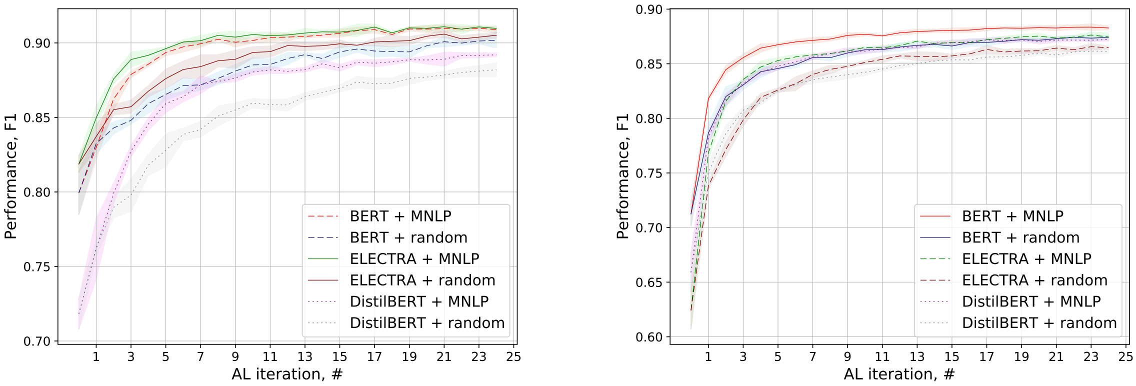
5.2.1 Training on Entire Datasets

We evaluate the performance of models trained on 75% of the available training corpus while keeping the rest 25% as the development set similarly to the experiments with AL. From Table 1, we can find that for both OntoNotes and CoNLL-2003, the model performance pattern is almost the same.



a) CoNLL-2003 b) OntoNotes

The comparison of MNLP and random query strategies for CRF and BiLSTM-based models.



c) CoNLL-2003 d) OntoNotes

The comparison of MNLP and random sampling query strategies for Transformers.

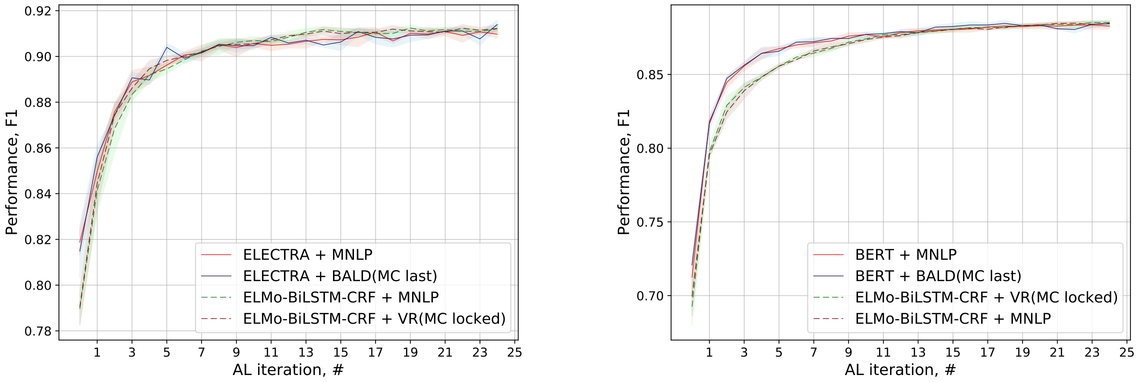
Figure 1: The comparison of MNLP and random query strategies

CRF, as the baseline model, has the lowest F1 score. Sequence taggers based on deep pre-trained models achieve substantially higher results compared to the classical CNN-BiLSTM-CRF model and CRF. BERT and ELECTRA significantly outperform ELMo-BiLSTM-CRF on OntoNotes, while on CoNLL-2003, all models have comparable scores. DistilBERT is behind larger Transformers. It also has a lower performance than ELMo-BiLSTM-CRF on CoNLL-2003 but similar scores on the OntoNotes dataset. We should note that our goal was not to show the state-of-the-art performance on each dataset but to determine reasonable hyperparameters and reference scores for experiments with AL.

5.2.2 Active Learning

The main results of experiments with AL are presented in Figures 1–3. AL shows significant improvements over the random sampling baseline for all models and on both datasets. Performance gains are bigger for simpler models like CRF or CNN-BiLSTM-CRF without deep pre-training and for the more complex OntoNotes dataset. However, we see that both ELMo-BiLSTM-CRF and Transformers benefit from a biased sampling of AL query strategies, which magnifies their ability to be trained on extremely small amount of labeled data. For example, to get 99% of the score achieved with training on the entire CoNLL-2003 dataset, only 20% of the annotated data is required for the ELECTRA tagger accompanied with the best AL strategy. For OntoNotes and BERT, only 16% of the corpus is required. Random sampling requires more than 44% and 46% of annotated data for CoNLL-2003 and OntoNotes correspondingly.

MNLP strategy. For the CoNLL-2003 corpus, the best performance in AL with the MNLP query strategy is achieved by the ELECTRA model. It



a) CoNLL

b) OntoNotes

Figure 2: The comparison of the best query strategies and models overall

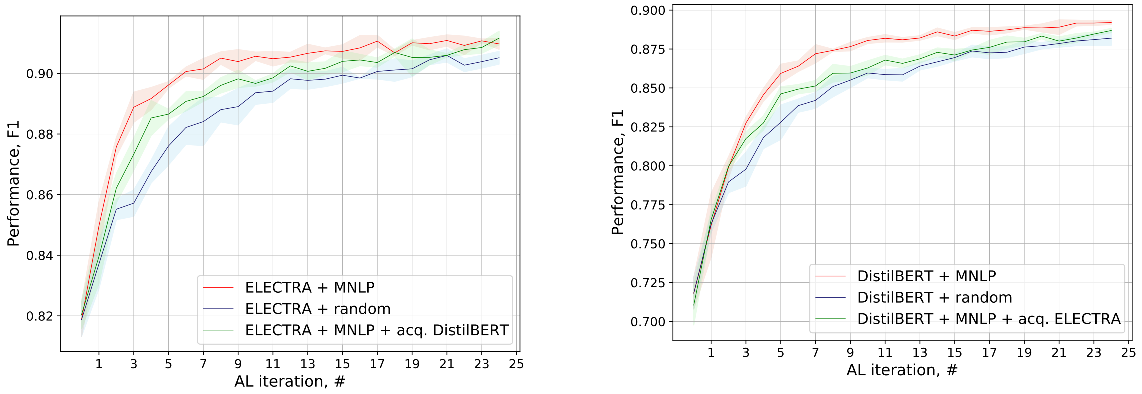
shows significantly better results in the beginning compared to BERT (see Figure 1c). ELECTRA also slightly outperforms the ELMo-BiLSTM-CRF tagger in the beginning and is on par with it on the rest of the AL curve (see Figure 2a). The CNN-BilSTM-CRF model is always better than the baseline CRF but worse than the models that take advantage of deep pre-training (see Figure 1a). DistilBERT appeared to be the weakest model in the experiments on the CoNLL-2003 dataset. With random sampling, it is on par with the baseline CNN-BiLSTM-CRF model on most iterations, but with the MNLP strategy, DistilBERT significantly falls behind CNN-BiLSTM-CRF.

Although BERT is slightly worse than the ELECTRA and ELMo-BiLSTM-CRF taggers in the experiments on the CoNLL-2003 corpus, for OntoNotes, BERT has a significant advantage over them up to 2.3 % of the F1 score in the AL setting on early iterations. The ELMo-BiLSTM-CRF tagger falls behind the main Transformers on the OntoNotes corpus. This might be because the BiLSTM-based tagger is underfitted to the bigger corpus with only 30 training epochs. Likewise, the baseline CNN-BiLSTM-CRF model without deep pre-training significantly falls behind DistilBERT on this corpus for MNLP and random query strategies.

Bayesian active learning. Bayesian uncertainty estimates based on the MC dropout perform comparably with the deterministic MNLP strategy for Transformer-based and BiLSTM-CRF-based taggers (see Figure 2 and Tables 5, 6 in Appendix D). We consider that Bayesian uncertainty estimates do not outperform the deterministic uncertainty estimates because the performance of the latter is very close to the maximum that can be achieved with the given amount of data.

We compare the performance of Bayesian AL strategies, when different dropout layers are replaced with the MC dropout. For ELMo-BiLSTM-CRF, we compare three options: replacing the dropout that follows word embeddings (embeddings acquired from ELMo), locked dropout in the recurrent layer, and both. Replacing the dropout that follows the embedding layer degrades the performance of AL significantly, especially for BALD. Replacing both yields the same performance as replacing only the locked dropout. We consider that the latter option is the best for AL since it requires fewer changes to the architecture. Overall, for both datasets, variation ratio has a slight advantage over the BALD strategy for the ELMo-BiLSTM-CRF model for all MC dropout options.

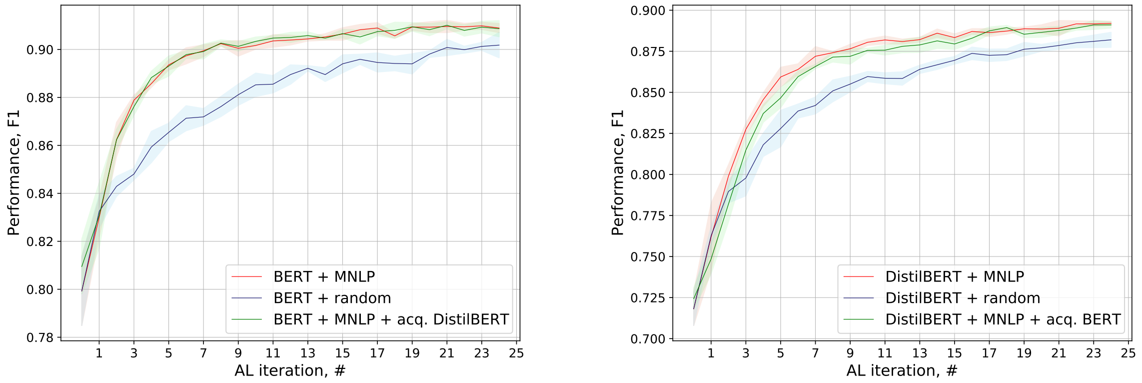
For Transformers, we compare two options: replacing the dropout only on the last classification layer and all dropouts in the model. When the variation ratio strategy is used, replacing only the last dropout layer with the MC dropout degrades the performance compared to MNLP, while replacing all dropout layers shows comparable results with it. However, for the BALD strategy, we see the inverse situation: replacing the last dropout layer leads to the significantly better performance than replacing all layers. This pattern can be noted for both ELECTRA and DistilBERT on the CoNLL-2003 corpus and for both BERT and DistilBERT on the OntoNontes corpus. Therefore, for Transformers, BALD with the MC dropout on the last layer is the best Bayesian query strategy since it



a) DistilBERT is an acquisition model

b) ELECTRA is an acquisition model

DistilBERT/ELECTRA as acquisition/successor models.



c) DistilBERT is an acquisition model

d) BERT is an acquisition model

DistilBERT/BERT as acquisition/successor models.

Figure 3: AL experiments on the CoNLL-2003 dataset, in which a successor model does not match an acquisition model.

Table 2: Duration of active learning iteration phases (seconds). The presented values correspond to the 5-th iteration of AL on the CoNLL-2003 dataset with the MNLP query strategy. The duration is averaged over three runs.

MODEL	ACQ. MODEL TRAINING	QUERYING INST.	TOTAL
CNN-BILSTM-CRF	1052	68	1120
ELMO-BILSTM-CRF	339	100	439
ELECTRA	100	50	150
DISTILBERT	61	27	88

provides both good quality and low computational overhead.

Duration of AL iterations. The valuable benefit of deep pre-trained models is also their high inference and training speed, which helps to significantly reduce the duration of an AL iteration and makes it feasible to implement text annotation tools empowered with interactive deep active learning. We measure the duration of the acquisition model training phase and the duration of the instance querying phase, which includes model inference on the whole unlabeled dataset (see Table 2). The experiments were conducted using the Nvidia V100 GPU and Xeon E5-2698 CPU.

According to obtained results, the large ELECTRA model can be trained more than ten times faster than the basic CNN-BiLSTM-CRF model because of a hardware-optimized architecture, a smaller number of the necessary training epochs, and the absence of the validation on the development set. ELECTRA also helps to reduce the duration of the query selection by more than 26%. The lightweight DistilBERT model is expectedly even faster. We also should note that using BiLSTM-

CRF with the pre-trained contextualized word representation model ELMo also helps to make the duration of AL iterations shorter compared to CNN-BiLSTM-CRF due to no need for training of the CNN word representation subnetwork (ELMo usually is not fine-tuned) and caching of the forward passes of ELMo during training across different epochs.

Mismatch between a successor model and an acquisition model. Since AL creates substantial computational overhead caused by training and inference of an acquisition model, for practical usage, it is reasonable to keep an acquisition model as lightweight as possible, while retaining the successor model complex and full-fledged. However, Lowell et al. (2019) demonstrate that the mismatch between an acquisition model and a successor model can diminish the benefits of applying the AL. They show that using AL can even harm the performance of the successor model compared to random sampling. We investigate the situation when an acquisition model does not match a successor model. Figure 3 shows the results of BERT, DistilBERT, and ELECTRA in this setting.

From Figures 3a and 3b, we can find that, when DistilBERT is used as an acquisition model for ELECTRA and vice versa, improvements achieved due to AL over the random sampling baseline are substantially lower compared to the "native" acquisition model. The same negative effect can be seen due to a mismatch between ELECTRA and BERT models in Figure 4 in Appendix E. These results support the findings presented in (Lowell et al., 2019). However, in our case, AL still gives notable improvements over the random sampling baseline. From Figure 3d, we can see that using BERT as an acquisition model for DistilBERT results only in a slight reduction of performance compared to using the "native" acquisition model. Moreover, in a reversed experiment, when DistilBERT is used as an acquisition model (see Figure 3c), there is no performance drop in AL at all. Such results for BERT-DistilBERT can be explained by the relationship between the distilled model and its ancestor resulting in similar uncertainty estimates for unlabeled instances in the annotation pool. This finding reveals the possibility of replacing a big acquisition model such as BERT with a distilled version that is faster and requires much less amount of memory. This can help to alleviate practical obstacles of deploying AL in real-world scenarios.

6 Conclusion

In this work, we investigated the combination of AL with sequence taggers that take advantage of deep pre-trained models. In the AL setting, these sequence taggers substantially outperform the models that do not use deep pre-training. We show that AL and transfer learning is a very powerful combination that can help to produce remarkably performing models with just a small fraction of the annotated data. For the CoNLL-2003 corpus, the combination of the best performing pre-trained model and AL strategy achieves 99% of the score that can be obtained with training on the full corpus, while using only 20% of the annotated data. For the OntoNotes corpus, one needs just 16%.

We performed a large empirical study of AL query strategies based on the Monte Carlo dropout in conjunction with deep pre-trained models and are the first to apply Bayesian active learning by disagreement to sequence tagging tasks. Bayesian active learning by disagreement achieves better results than the variation ratio for Transformers. However, we find that the variation ratio is slightly better for the ELMo-BiLSTM-CRF model. It is reasonable to use both MC dropout-based query strategies when only the last dropout layer works in a stochastic mode during the inference. This makes this type of query strategies suitable for practical usage due to little computational overhead. Finally, we demonstrate that it is possible to reduce the computational overhead of AL with deep pre-trained models by using a smaller distilled version of a Transformer model for acquiring instances.

In the future work, we are seeking to extend the empirical investigation of deep pre-trained models in active learning to query strategies that aim at better handling the batch selection of instances for annotation.

Acknowledgments

We thank the reviewers for their valuable feedback. This work was done in the framework of the joint MTS-Skoltech lab. The development of the experimental setup for the study of active learning methods and its application to sequence tagging tasks (Section 4) was supported by the Russian Science Foundation grant 20-71-10135. The Zhores supercomputer (Zacharov et al., 2019) was used for computations. We are very grateful to Sergey Ustyantsev for help with the implementation and the execution of the experiments.

B Features Used by the CRF Model

1. A lowercased word form.
2. Trigram and bigram suffixes of words.
3. Capitalization features.
4. An indicator that shows whether a word is a digit.
5. A part-of-speech tag of a word with specific info (plurality, verb tense, etc.)
6. A generalized part-of-speech.
7. An indicator whether a word is at the beginning or ending of a sentence.
8. The aforementioned characteristics for the next word and previous word except suffixes.

C Model and Training Details

C.1 CRF

We set CRF L1 and L2 regularization terms equal to 0.1, and limit the number of iterations by 100.

C.2 BiLSTM-CRF Taggers

We implement the BiLSTM-CRF sequence tagger on the basis of the `Flair` package[1] (Akbik et al., 2018). We use the same parameters for both types of BiLSTM-CRF models. The recurrent network has one layer with 128 neurons. During training, we anneal the learning rate by half, when the performance of the model stops improving on the development set for 3 epochs. After annealing, we restore the model from the epoch with the best validation score. The starting learning rate is 0.1. The maximal number of epochs is 30, and the batch size is 32. For optimization, we use the standard SGD algorithm.

C.3 Transformer-based Taggers

The implementation of Trasnformer-based taggers is based on the `Hugging Face Transformers` (Wolf et al., 2019)[2] library. We use the following pre-trained versions of BERT, ELECTRA, and DistilBERT accordingly: *'bert-base-cased'*, *'google/electra-base-discriminator'*, and *'distilbert-base-cased'*. The corrected version of Adam (AdamW from the `Transformers` library) is used for optimization with the base learning rate of 5e-5. The linear decay of the learning rate is applied following the (Devlin et al., 2019). The number of epochs is 4 and the batch size is 16. As in (Shen et al., 2018), we see that it is critical to adjust the batch size on early AL iterations, when only small amount of labeled data is available. We reduce the batch size to keep the number of iterations per epoch over 50, but limit the minimal batch size to 4.

Abstract

When responding to a disaster, humanitarian experts must rapidly process large amounts of secondary data sources to derive situational awareness and guide decision-making. While these documents contain valuable information, manually processing them is extremely time-consuming when an expedient response is necessary. To improve this process, effective summarization models are a valuable tool for humanitarian response experts as they provide digestible overviews of essential information in secondary data. This paper focuses on extractive summarization for the humanitarian response domain and describes and makes public a new multilingual data collection for this purpose. The collection – called MultiHumES – provides multilingual documents coupled with informative snippets that have been annotated by humanitarian analysts over the past four years. We report the performance results of a recent neural networks-based summarization model together with other baselines. We hope that the released data collection can further grow the research on multilingual extractive summarization in the humanitarian response domain.

1 Introduction

The disaster risk management cycle consists of four stages: mitigation, preparedness, response, and recovery (Alexander, 2002). The review of secondary data sources (i.e., reports, news, and other forms of text data) is embedded in all these stages, with varying levels of importance from stage to stage. The work of secondary data review is characterized by a high and ever-increasing amount of information to be analyzed. At the same time, typically, only a small workforce is available to analyze such information. Early in the response phase, namely in the first 72 hours after a disaster strikes, secondary data review to gain situational awareness is essential, as it brings to light which type of relief activities to undertake. After this stage, primary data collection (such as surveys) begins while still supported by the secondary data review processes.

The disaster information cycle by its part consists of the collection, collation, analysis, dissemination, decision-making, and reporting stages. An effective summarization tool can provide meaningful support for the collection stage when analysts prioritize what documents to read first (i.e., offering an overview of a document). In the collation stage, when analysts need to take and merge the most important findings from several documents, and even in the reporting stage, analysts are asked to bring in a few sentences containing the key findings of what they have written. An auto summarization system aims to provide analysts with a starting point from which they can continue their work rather than replace it. Such a system can significantly save time in the overall disaster information cycle.

In this work, we take the initial steps of creating such an extractive summarization system for humanitarian responders by curating and releasing the novel publicly available Multilingual Humanitarian Response Dataset for Extractive Summarization (MultiHumES)[1]. This collection is annotated by humanitarian experts and consists of the data related to various disasters around the globe that occurred in the last four years. Our contribution in this work occurs in two ways: the collection and consultation process for the possible release of the dataset and the dataset curation for performing extractive summarization tasks.

The dataset consists of approximately 50K documents in three languages: English, French, and Spanish. Among these documents, approximately 35K are annotated with informative snippets and can be used for the training and evaluation of ex-

April 19 - 23, 2021.

tractive summarization models. We evaluate the performance of LEAD4, TextRank (Mihalcea and Tarau, 2004) – an unsupervised graph-based model –, and NeuSum (Qingyu et al., 2018) – a recently created supervised neural model in the dataset.

To the best of our knowledge, this is the first multilingual dataset released for summarization in the humanitarian domain. The most similar initiatives are done by (Alam et al., 2020), which released a social-media based dataset for classification in the humanitarian domain, and by Appen, which released a set of short messages from social media and news articles for classification in the humanitarian domain [2].

This article is structured as follows: Section 2 describes the background, annotation process, curation process, and main statistics of the MultiHumES collection. Section 3 explains the experiment design of the summarization models on the dataset, and Section 4 presents and discusses the results.

2 MultiHumES Collection

This section first provides the background on the humanitarian response domain and the ecosystem from which the collection originated. Then it explains the annotation process, the curation process and finalizes presenting key statistics from the collection.

2.1 Collection Background

The collection originated from a multi-organizational platform called DEEP[3]. The DEEP platform was created due to a direct need for effective secondary data management during the Nepal 2015 earthquake response. The platform facilitates classifying primarily qualitative information with respect to analysis frameworks and allows for collaborative classification and annotation of secondary data. To date, the platform has processed almost 250k manually annotated snippets across 1.7k humanitarian projects across the globe.

This research dataset contains the documents analyzed from 2016 to 2019 related to projects that occurred within 159 countries. Approximately 46% of the documents came from media sources, 29% from international organizations, and the rest from various organizations such as United Nations agencies, governments, academic and research institutions, NGOs, donors, and Red Cross/Red Crescent Movement.

Although 82% of the uploaded documents were from publicly available sources, and more than 96% are labeled as non-confidential, we made an additional consultation process with the involved organizations to ensure that the released collection preserves the privacy and dignity of any affected populations discussed in the reports.

2.2 Collection Annotation Process

Taggers (or humanitarian annotators) are trained in analytical standards and thinking. While undertaking secondary data review, information is selected if it fits within a given project's scope and can lead to more appropriate decision-making in a given humanitarian crisis. Key information relevant to understanding unmet needs and their underlying factors is captured and categorized into a commonly agreed analysis framework (or taxonomy), enabling a comprehensive and holistic understanding of humanitarian needs. Detailed categories and sub-categories in line with global standards and taxonomies (geographical area assessed, sectors and sub-sectors, demographic and specific needs groups, etc.) are also labeled. These selected snippets of text fill critical analysis information needs that are essential for strategic and programmatic decision-making in humanitarian response.

One of the major features of the collection is that the data has gone through a rigorous quality control process to ensure standardization, accuracy, and comprehensiveness. Designated quality control experts undertake this process in addition to peer-review and continuous training. The efficacy of the quality control efforts is seen in an external quality assessment, which shows an inter indexer consistency metric of 0.97[4].

2.3 Collection Curation

The original dataset consists of the plain text of 66,412 documents, the snippets extracted from each document by humanitarian analysts, and in some cases, the humanitarian classification label related to each snippet. We parsed the documents provided in HTML format to extract their text content. We also filtered out documents with 50 tokens

---

[2] `https://appen.com/datasets/combined-disaster-response-data/`

[3] `https://thedeep.io/`

[4] `https://github.com/IFRCGo/Tagging-QAQC`

or less. As verified manually, these documents were either title of web pages or small descriptions of attached documents.

The remaining documents are in a variety of languages, but mainly in English, French or Spanish. For automatically identifying the languages, we used the `langdetect` library. We kept documents in the three mentioned languages, resulting in 50,380 documents.

Note that a highlight or relevant text snippet is a sentence or a set of sentences that a humanitarian analyst deems as providing relevant information on a specific category embedded in a conceptual framework. We follow the assumption that these text snippets are not only relevant for a specific analyst and for a specific topic but also for the general summary of the document. Therefore, we combine all text snippets of a document into one document summary, which is used as the ground truth for the extractive summarization task.

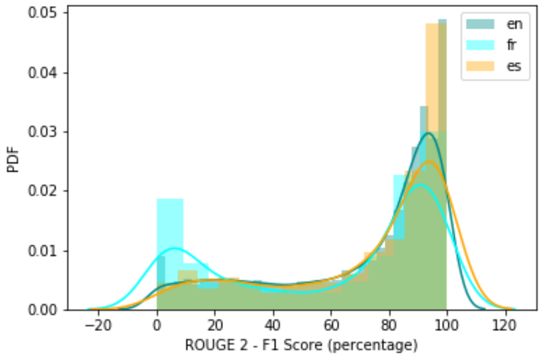

Figure 1: Oracle performance across languages.

Following Qingyu et al. (2018), we constructed an Oracle version of those summaries. Figure 1 shows the ROUGE 2 F1 Score behavior of the Oracle summaries across languages. The x-axis shows the ROUGE 2 F1 Score in a percentage format, and the y-axis shows the probability density function for the kernel density estimation. Based on these results, we see that even with an average score of 70

We evaluated some of the documents in which that score was 0 and found that some were summaries in a language different from the source document. Some had extra characters within the text caused by problems reading the texts from PDF files and implied differences between the document and summary sentences.

After conducting these preprocessing steps, 35,567 documents remained used to create the extractive summarization collection.

2.4 Collection Statistics

	English	**French**	**Spanish**
# of documents	29351	4311	1904
# of tokens	222918	58921	49609
Median number of sent in doc	30	16	23
Median number of sent in sum	5	4	5

Table 1: Dataset Statistics

Table 1 reports the total number of documents, unique tokens, and the median values of the number of sentences per document and summary. The distributions of the number of sentences per document and summary are highly skewed, such that 80% of the documents have less than 191 sentences, and 80% of the summaries have less than 11 sentences.

3 Experiment Design

This section explains the baseline extractive summarization models and their corresponding parameter settings.

3.1 Baseline Models

LEAD4 LEAD-n is an algorithm that selects the first n sentences from a document as its summary. It is a simple but strong baseline for extractive summarization models, created based on the assumption that the first sentences in a document are the most informative ones. In our experiments, we use $n = 4$ as it shows the best performance on the validation set.

Text Rank Text Rank is a graph-based model that ranks text units from most relevant to least relevant by using text units as vertices and the similarity between text units as edges. Given this ranking and a fixed length of the desired output summary, the model produces a summary in an unsupervised manner (Mihalcea and Tarau, 2004).

NeuSum NeuSum is a neural extractive summarization method that employs a hierarchical document encoder to produce sentence representations. It also uses a sentence extractor to iteratively extract sentences from sentence representation extracts according to their overall contribution to the

	ROUGE-1 F1			ROUGE-2 F1		
Model	**en**	**es**	**fr**	**en**	**es**	**fr**
Oracle	0.713	0.761	0.668	0.706	0.733	0.619
LEAD4	0.389	0.454	0.438	0.318	0.378	0.344
TextRank	0.419	0.456	0.418	0.289	0.320	0.277
NeuSum	**0.474**	**0.531**	**0.470**	**0.380**	**0.424**	**0.358**

Table 2: Models' ROUGE scores by language.

performance of the current summary (Qingyu et al., 2018).

The hierarchical document encoder is composed of two Recurrent Neural Networks (RNNs). The first network encodes each word in a sentence (sentence encoder), while the second network encodes each sentence given its context in the document (document encoder). Bidirectional Gated Recurrent Units (BiGRU) (Cho et al., 2014) are used for both RNNs.

3.2 Training and Evaluation

We partition the data into training, validation, and test sets for each language with portions of 70%, 10%, and 20%, respectively.

To evaluate the models, we used ROUGE-1 F1 and ROUGE-2 F1 as standard metrics to evaluate extractive summarization tasks. For each one of the models in each language, the 95% confidence interval of the measures' average values was calculated. The results are reported as significantly different if there is no intersection between the intervals.

For the ROUGE-1 F1 metric, we found that NeuSum performed statistically better for all languages. For the English corpus, TextRank performed statistically better than the LEAD4 baseline. For the ROUGE-2 F1 metric, we found that all results per language were significantly different.

3.3 Parameter Setting

We used the TextRank model implemented by the gensim library (Řehůřek and Sojka, 2010). This implementation uses the Okapi Best Matching 25 similarity measure (BM25+) to measure the similarity between sentences (Barrios et al., 2016). We modified the preprocessing steps and fixed the summaries' length to 100 words to have coherent results with the TextRank model.

For the NeuSum model, we used the word2vec SkipGram model (Mikolov et al., 2013) created on a corpus of Wikipedia provided by the gensim library (Řehůřek and Sojka, 2010). This provided embeddings trained in a similar corpus with a similar dimensionality for the three languages considered. We used 100 as the embedding dimension and 100,000 as the vocabulary size. The pre-trained embeddings covered 51.85% of the English vocabulary, 60.54% of the French vocabulary, and 70.88% of the Spanish vocabulary.

We set 200 sentences as the maximum number of sentences per document and 80 tokens as the maximum length of a sentence. The length of the output summary was set to 4. We ran the model for 40 epochs with a batch size of 64. The rest of the parameters were set as proposed in the original paper.

4 Results and Discussion

Table 2 reports the performance on the test sets. It can be seen that the best performing model was NeuSum, which improved by up to 10 points compared to the TextRank and LEAD4 performance.

The French corpus had the lowest performance, but the fact that the Oracle presents a low performance indicates that this result may be more related to the corpus's nature or the preprocessing of the data rather than the model.

LEAD4 bases its success on the position of the relevant sentences. TextRank bases its success on the content of the relevant sentences. NeuSum higher performance may be explained by the joint encoding of the position information and the content information of a sentence.

It is also key to remember that we truncated each document to a maximum length of 200 sentences because of our GPU capacity. This meant that reports such as the *Humanitarian Needs Overview* with around 60 pages (900 sentences) were reduced to 200 sentences and were therefore not well summarized. Our neural approach for the summarization task of humanitarian documents was useful for setting a precedent of how good these models are in the domain. However, until higher computational resources are more readily available, it would be necessary to have a simpler model to treat longer documents.

5 Conclusions and Future Work

Automatic summarization in the humanitarian domain is crucial for supporting fast and effective responses to crises. To facilitate this process, we provide MultiHumES, a novel multilingual collection for extractive summarization in the humanitarian response domain. The collection enables the training and evaluation of machine/deep learning-based models, revealing new horizons for research in this domain. The collection consists of approximately 50k documents, from which 35K have related annotated snippets by experts. We test and evaluate the performance of three strong baselines on the collection.

We consider the following points as potential future directions. First, a key aspect of automatic summarization for the humanitarian response domain is the human evaluation of the output. It is indeed important to understand whether the reported performance results correlate with the evaluation of domain experts. The second direction is learning multilingual models, trained over all the data, and investigating whether this approach can improve performance, especially in languages with a smaller amount of available training data.

Learning From Revisions:
Quality Assessment of Claims in Argumentation at Scale

Abstract

Assessing the quality of arguments and of the claims the arguments are composed of has become a key task in computational argumentation. However, even if different claims share the same stance on the same topic, their assessment depends on the prior perception and weighting of the different aspects of the topic being discussed. This renders it difficult to learn topic-independent quality indicators. In this paper, we study claim quality assessment irrespective of discussed aspects by comparing different *revisions of the same claim*. We compile a large-scale corpus with over 377k claim revision pairs of various types from *kialo.com*, covering diverse topics from politics, ethics, entertainment, and others. We then propose two tasks: (a) assessing which claim of a revision pair is better, and (b) ranking all versions of a claim by quality. Our first experiments with embedding-based logistic regression and transformer-based neural networks show promising results, suggesting that learned indicators generalize well across topics. In a detailed error analysis, we give insights into what quality dimensions of claims can be assessed reliably. We provide the data and scripts needed to reproduce all results.[1]

1 Introduction

Assessing argument quality is as important as it is questionable in nature. On the one hand, identifying the good and the bad claims and reasons for arguing on a given topic is key to convincingly support or attack a stance in debating technologies (Rinott et al., 2015), argument search (Ajjour et al., 2019), and similar. On the other hand, argument quality can be considered on different granularity levels and from diverse perspectives, many of which are inherently subjective (Wachsmuth et al., 2017a); they depend on the prior beliefs and stance on a topic as well as on the personal weighting of different aspects of the topic (Kock, 2007).

Existing research largely ignores this limitation, by focusing on learning to predict argument quality based on subjective assessments of human annotators (see Section 2 for examples). In contrast, Habernal and Gurevych (2016) control for topic and stance to compare the convincingness of arguments. Wachsmuth et al. (2017b) abstract from an argument's text, assessing its relevance only structurally. Lukin et al. (2017) and El Baff et al. (2020) focus on personality-specific and ideology-specific quality perception, respectively, whereas Toledo et al. (2019a) asked annotators to disregard their own stance in judging length-restricted arguments. However, none of these approaches controls for the concrete aspects of a topic that the arguments claim and reason about. This renders it difficult to learn what makes an argument and its building blocks good or bad in general.

In this paper, we study quality in argumentation irrespective of the discussed topics, aspects, and stances by assessing different revisions of the basic building blocks of arguments, i.e., claims. Such revisions are found in large quantities on online debate platforms such as *kialo.com*, where users post claims, other users suggest revisions to improve claim quality (in terms of clarity, grammaticality, grounding, etc.), and moderators approve or disapprove them. By comparing the quality of different revisions of the same instance, we argue that we can learn general quality characteristics of argumentative text and, to a wide extent, abstract from prior perceptions and weightings.

To address the proposed problem, we present a new large-scale corpus, consisting of 124k unique claims from kialo.com spanning a diverse range of topics related to politics, ethics, and several others (Section 3). Using distant supervision, we derive a total number of 377k claim revision pairs from the

Table 1: Four examples of claims from Kialo before and after revision, along with the type of revision performed.

platform, each reflecting a quality improvement, often, with a specified revision type. Four examples are shown in Table 1. To the best of our knowledge, this is the first corpus to target quality assessment based on claim revisions. In a manual annotation study, we provide support for our underlying hypothesis that a revision improves a claim in most cases, and we test how much the revision types correlate with known argument quality dimensions.

Given the corpus, we study two tasks: (a) how to compare revisions of a claim by quality and (b) how to rank a set of claim revisions. As initial approaches to the first task, we select in Section 4 a "traditional" logistic regression model based on word embeddings as well as transformer-based neural networks (Vaswani et al., 2017), such as BERT (Devlin et al., 2019) and SBERT (Reimers and Gurevych, 2019). For the ranking task, we consider the Bradley-Terry-Luce model (Bradley and Terry, 1952; Luce, 2012) and SVMRank (Joachims, 2006). They achieve promising results, indicating that the compiled corpus allows learning topic-independent characteristics associated with the quality of claims (Section 5). To understand what claim quality improvements can be assessed reliably, we then carry out a detailed error analysis for different revision types and numbers of revisions.

The main contributions of our work are: (1) A new corpus for topic-independent claim quality assessment, with distantly supervised quality improvement labels of claim revision pairs, (2) initial promising approaches to the tasks of claim quality classification and ranking, and (3) insights into what works well in claim quality assessment and what remains to be solved.

2 Related Work

In the recent years, there has been an increase of research on the quality of arguments and the claims and reasoning they are composed of. Wachsmuth et al. (2017a) describe argumentation quality as a multidimensional concept that can be considered from a logical, rhetorical, and dialectical perspectives. To achieve a common understanding, the authors suggest a unified framework with 15 quality dimensions, which together give a holistic quality evaluation at a certain abstraction level. They point out, that several dimensions may be perceived differently depending on the target audience. In recent follow-up work, Wachsmuth and Werner (2020) examined how well each dimension can be assessed only based on plain text only.

Most existing quality assessment approaches target a single dimension. On mixed-topic student essays, Persing and Ng (2013) learn to score the clarity of an argument's thesis, Persing and Ng (2015) do the same for argument strength, and Stab and Gurevych (2017) classify whether an argument's premises sufficiently support its conclusion. All these are trained on pointwise quality annotations in the form of scores or binary judgments. Gretz et al. (2019) provide a corpus with crowdsourced quality annotations for 30,497 arguments, the largest to date for pointwise argument quality. The authors studied how their annotations correlate with the 15 dimensions from the framework of Wachsmuth et al. (2017a), finding that only *global relevance* and *effectiveness* are captured. Similarly, Lauscher et al. (2020) built a new corpus based on the framework to then exploit interactions between the dimensions in a neural approach. We present a small related annotation study for our dataset below. However, we follow Habernal and Gurevych (2016) in that we cast argument quality assessment as a relation classification problem, where the goal is to identify the better among a pair of instances.

In particular, Habernal and Gurevych (2016) created a dataset with argument convincingness pairs on 32 topics. To mitigate annotator bias, the arguments in a pair always have the same stance on the same topic. The more convincing argument is then predicted using a feature-rich SVM and a simple bidirectional LSTM. Other approaches to the same task map passage representations to real-valued scores using Gaussian Process Preference Learning (Simpson and Gurevych, 2018) or represent arguments by the sum of their token embeddings (Potash et al., 2017), later extended by a Feed Forward Neural Network (Potash et al., 2019). Recently, Gleize et al. (2019) employed a Siamese neural network to rank arguments by the convincingness of evidence. In our experiments below, we take on some of these ideas, but also explore the impact of transformer-based methods such as BERT (Devlin et al., 2019), which have been shown to predict argument quality well (Gretz et al., 2019).

Potash et al. (2017) observed that longer arguments tend to be judged better in existing corpora, a phenomenon we will also check for below. Toledo et al. (2019b) prevent such bias in their corpora for both pointwise and pairwise quality, by restricting the length of arguments to 8–36 words. The authors define quality as the level of preference for an argument over other arguments with the same stance, asking annotators to disregard their own stance. For a more objective assessment of argument relevance, Wachsmuth et al. (2017b) abstract from content, ranking arguments only based on structural relations, but they employ majority human assessments for evaluation. Lukin et al. (2017) take a different approach, including knowledge about the personality of the reader into the assessment, and El Baff et al. (2020) study the impact of argumentative texts on people depending on their political ideology.

As can be seen, several approaches aim to control for length, stance, audience, or similar. However, all of them still compare argumentative texts with different content and meaning in terms of the aspects of topics being discussed. In this work, we assess quality based on different revisions of the same text. In this setting, the quality is primarily focused on how a text is formulated, which will help to better understand what influences argument quality in general, irrespective of the topic. To be able to do so, we refer to online debate portals.

Debate portals give users the opportunity to discuss their views on a wide range of topics. Existing research has used the rich argumentative content and structure of different portals for argument mining, including *createdebate.com* (Habernal and Gurevych, 2015), *idebate.org* (Al-Khatib et al., 2016), and others. Also, large-scale debate portal datasets form the basis of applications such as argument search engines (Ajjour et al., 2019). Unlike these works, we exploit debate portals for studying *quality*. Tan et al. (2016) predicted argument persuasiveness in the discussion forum *ChangeMyView* from ground-truth labels given by opinion posters, and Wei et al. (2016) used user upvotes and downvotes for the same purpose. Here, we resort to *kialo.com*, where users cannot only state argumentative claims and vote on the impact of claims submitted by others, but they can also help improve claims by suggesting revisions, which are approved or disapproved by moderators. While Durmus et al. (2019) assessed quality based on the impact value of claims from kialo.com, we derive information on quality from the revision history of claims.

The only work we are aware of that analyzes revision quality of argumentative texts is the study of Afrin and Litman (2018). From the corpus of Zhang et al. (2017) containing 60 student essays with three draft versions each, 940 sentence writing revision pairs were annotated for whether the revision improves essay quality or not. The authors then trained a random forest classifier for automatic revision quality classification. In contrast, instead of sentences, we shift our focus to claims. Moreover, our dataset is orders of magnitude larger and includes notably longer revision chains, which enables deeper analyses and more reliable prediction of revision quality using data-intensive methods.

3 Data

Here, we present our corpus created based on claim revision histories collected from *kialo.com*.

3.1 A New Corpus based on Kialo

Kialo is a typical example of an online debate portal for collaborative argumentative discussions, where participants jointly develop complex pro/con debates on a variety of topics. The scope ranges from general topics (religion, fair trade, etc.) to very specific ones, for instance, on particular policy-making (e.g., whether wealthy countries should provide citizens with a universal basic income). Each debate consists of a set of claims and is associated with a list of related pre-defined generic categories, such as politics, ethics, education, and entertainment.

What differentiates Kialo from other portals is

Corpus	Type of Instances	Instances
ClaimRev$_{\text{BASE}}$	**Total claim pairs**	**210 222**
	Claim Clarification	63 729
	Typo/Grammar Correction	59 690
	Corrected/Added Links	17 882
	Changed Meaning of Claim	1 178
	Misc	10 464
	None	57 279
ClaimRev$_{\text{EXT}}$	**Total claim pairs**	**377 659**
	Revision distance 1	77 217
	Revision distance 2	27 819
	Revision distance 3	10 753
	Revision distance 4	4 460
	Revision distance 5	2 055
	Revision distance 6+	2 008
Both Corpora	**Claim revision chains**	**124 312**

Table 2: Statistics of the two provided corpus versions. ClaimRev$_{\text{BASE}}$: Number of claim pairs in total and of each revision type. ClaimRev$_{\text{EXT}}$: Number of claim pairs in total and of each revision distance. The bottom line shows the number of unique revision chains in the corpora.

that it allows editing claims and tracking changes made in a discussion. All users can help improve existing claims by suggesting edits, which are then accepted or rejected by the moderator team of the debate. As every suggested change is discussed by the community, this collaborative process should lead to a continuous improvement of claim quality and a diverse set of claims for each topic.

As a result of the editing process, claims in a debate have a version history in the format of claim pairs, forming a chain where one claim is the successor of another and is considered to be of higher quality (examples found in Table 1). In addition, claim pairs may have a revision type label assigned to them via a non-mandatory free form text field, where moderators explain the reason of revision.

Base Corpus To compile the corpus, we scraped all 1628 debates found on Kialo until June 26th, 2020, related to over 1120 categories. They contain 124,312 unique claims along with their revision histories, which comprise of 210,222 pairwise relations. The average number of revisions per claim is 1.7 and the maximum length of a revision chain is 36. 74% of all pairs have a revision type. Overall, there are 8105 unique revision type labels in the corpus. 92% of labeled claim pairs refer to three types only: *Claim Clarification*, *Typo/Grammar Correction*, and *Corrected/Added Links*. An overview of the distribution of revision labels is given in Table 2. We refer to the resulting corpus as *ClaimRev*$_{\mathit{BASE}}$.

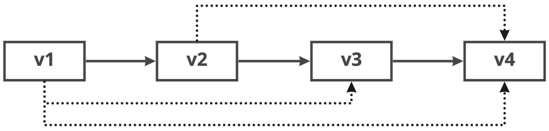

Figure 1: Visual representation of relations between revisions. Solid and dashed lines denote original and inferred non-consecutive relations respectively.

Data pre-processing included removing all claim pairs from debates carried out in languages other than English. Also, we considered claims with less than four characters as uninformative and left them out. As we seek to compare different versions of the *same* claim, claim version pairs with a general change of meaning do not satisfy this description. Thus, we removed such pairs from the corpus, too (inspecting the data revealed that such pairs were mostly generated due to debate restructuring). For this, we assessed the cosine similarity of a given claim pair using *spacy.io* and remove a pair if the score is lower than the threshold of 0.8.

Extended Corpus To increase the diversity of data available for training models, without actually collecting new data, we applied data augmentation. ClaimRev$_{\text{BASE}}$ consists of consecutive claim version pairs, i.e., if a claim v has four versions, it will be represented by three three pairs: (v_1, v_2), (v_2, v_3), and (v_3, v_4), where v_1 is the original claim and v_4 is the latest version. We extend this data by adding all pairs between non-consecutive versions that are inferrable transitively. Considering the previous example, this means we add (v_1, v_3), (v_1, v_4), and $(v2, v4)$. This is based on our hypothesis that every argument version is of higher quality than its predecessors, which we come back to below. Figure 1 illustrates the data augmentation. We call the augmented corpus *ClaimRev*$_{\mathit{EXT}}$.

For this corpus, we introduce the concept of *revision distance*, by which we mean the number of revisions between two versions. For example, the distance between v_1 and v_2 would be 1, whereas the distance between v_1 and v_3 would be 2. The distribution of the revision distances across ClaimRev$_{\text{EXT}}$ is summarized in Table 2.

The number of claim pairs of the 20 most frequent categories in both corpus versions are presented in Figure 2. We will restrict our view to the topics in these categories in our experiments.

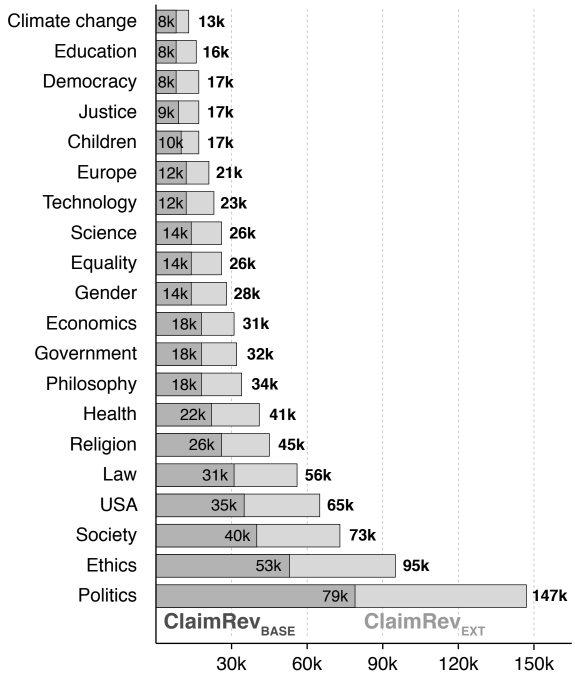

Figure 2: Number of claim revision pairs in each debate category of the two provided versions of our corpus (ClaimRev$_{\text{BASE}}$, ClaimRev$_{\text{EXT}}$).

3.2 Data Consistency on Kialo

While collaborative content creation enables leveraging the wisdom of large groups of individuals toward solving problems, it also poses challenges in terms of quality control, because it relies on varying perceptions of quality, backgrounds, expertise, and personal objectives of the moderators. To assess the consistency of the distantly-supervised corpus annotations, we carried out two annotation studies on samples of our corpus.

Consistency of Relative Quality In this study, we aimed to capture the general perception of claim quality on a meta-level, by deriving a data-driven quality assessment based on the revision histories. This was based on our hypothesis that every claim version is better than its predecessor. To test the validity of this hypothesis, two authors of this paper annotated whether a revision increases, decreases, or does not affect the overall claim quality. For this purpose, we randomly sampled 315 claim revision pairs, found in the supplementary material.

The results clearly support our hypothesis, showing an increase in quality in 292 (93%) of the annotated cases at a Cohen's κ agreement of 0.75, while 8 (3%) of the revisions had no effect on quality and only 6 (2%) led to a decrease. On the remaining 2%, the annotators did not reach an agreement.

Consistency of Revision Type Labels Our second annotation study focused on the reliability of the revision type labels. We restricted our view to the top three revision labels, which cover 96% of all revisions. We randomly sampled 140–150 claim pairs per each revision type, 440 in total. For each claim pair, the same annotators as above provided a label for the revision type from the following set: *Claim Clarification*, *Typo/Grammar Correction*, *Corrected/Added Links*, and *Other*.

Comparing the results to the original labels in the corpus revealed that the annotators strongly agreed with the labels, namely, with Cohen's κ of 0.82 and 0.76 respectively. The level of agreement between the annotators was even higher ($\kappa = 0.84$). In further analysis, we observed that most confusion happened between the revision types *Typo/Grammar correction* and *Claim Clarification*. This may be due to the non-strict nature of the revision type labels, which leaves space for different interpretations on a case-to-case basis. Still, we conclude that the revision type labels seem reliable in general.

3.3 Quality Dimensions on Kialo

To explore the relationship between the revision types on Kialo and argument quality in general, we conducted a third annotation study. In particular, for each of the 315 claim pairs from Section 3.2, one of the authors of this paper provided a label indicating whether the revision improved for each of the 15 quality dimensions defined by Wachsmuth et al. (2017a) or not. It should be noted that the annotators reached an agreement on the revision type for all these pairs.

Table 3 shows Pearson's r rank correlation for each quality dimension for the three main revision types. We observe a strong correlation between the revision type *Corrected/Added Links* and the logical quality dimensions *Cogency* (0.65) and *Local Sufficiency* (0.62), which matches the main purpose of such revisions: to add supporting information to a claim. The high negative correlation of this revision type with *Global Acceptability* (-0.82) indicates that improvements regarding the dimension in question are more prominent in other types. Complementarily, *Claim Clarification* mainly improves the other logical dimensions (*Local Acceptability* 0.38, *Local Relevance* 0.44), matching the intuition that a clarification helps to ensure a correct understanding of the meaning. *Typo/Grammar corrections*, finally, rather seem to support an accept-

	Clarification	Grammar	Links
Cogency	**-0.31**	**-0.31**	**0.65**
Local Acceptability	**0.38**	-0.20	-0.19
Local Relevance	**0.44**	-0.25	-0.22
Local Sufficiency	-0.28	**-0.33**	**0.62**
Effectiveness	0.02	**-0.35**	**0.34**
Credibility	0.06	-0.16	0.10

Clarity	-0.16	**0.35**	-0.18
Appropriateness	0.01	0.02	-0.04
Arrangement	0.00	0.00	0.00
Reasonableness	0.07	-0.04	-0.04
Global Acceptability	**0.37**	**0.42**	**-0.82**
Global Relevance	0.02	**-0.43**	**0.42**
Global Sufficiency	0.00	0.00	0.00
Overall	-0.05	0.00	0.05
Pairs with revision type	120	100	95

Table 3: Pearson's r correlation in our annotation study between increases in the 15 quality dimensions of Wachsmuth et al. (2017a) and the main revision types: Claim *Clarification*, Typo/*Grammar* Correction, Corrected/Added *Links*. Moderate and high correlations are shown in bold ($r \geq 0.3$).

able linguistic shape, improving *Clarity* (0.35) and *Global Acceptability* (0.42).

Finding only low correlations for many rhetorical dimensions (credibility, emotional appeal, etc.) as well as for overall quality, we conclude that the revisions on Kialo seem to target primarily the general form a well-phrased claim should have.

4 Approaches

To study the two proposed tasks, claim quality classification and claim quality ranking, on the given corpus, we consider the following approaches.

4.1 Claim Quality Classification

We cast this task as a pairwise classification task, where the objective is to compare two versions of the same claim and determine which one is better. To solve this task, we compare four methods:

Length To check whether there is a bias towards longer claims in the data, we use a trivial method which assumes that claims with more characters are better.

S-BOW As a "traditional" method, we employ the siamese bag-of-words embedding (S-BOW) as described by Potash et al. (2017). We concatenate two bag-of-words matrices, each representing a claim version from a pair, and input the concatenated matrix to a logistic regression. We also test whether information on length improves S-BOW.

	v_1	v_2	v_3
v_1	0	0.018	0.002
v_2	0.982	0	0.428
v_3	0.998	0.572	0

Table 4: Example of a pairwise score matrix for ranking of three claim revisions, v_1–v_3, given the following pairwise scores: $(v_1, v_2) = (0.018, 0.982)$, $(v_2, v_3) = (0.428, 0.572)$, and $(v_1, v_3) = (0.002, 0.998)$.

BERT We select the BERT model, as it has become the standard neural baseline. BERT is a pre-trained deep bidirectional transformer language model (Devlin et al., 2019). For our experiments we use the pre-trained version *bert-base-cased*, as implemented in the *huggingface* library.[2] We fine-tune the model for two epochs using the Adam optimizer with learning rate 1e-5. [3]

SBERT We also use Sentence-BERT (SBERT) to learn to represent each claim version as a sentence embedding (Reimers and Gurevych, 2019), opposed to the token-level embeddings of standard BERT models. We fine-tune SBERT based on *bert-base-cased* using a siamese network structure, as implemented in the *sentence-transformers* library.[4] We set the numbers of epochs to one which is recommended by the authors (Reimers and Gurevych, 2019), and we use a batch-size of 16, Adam optimizer with learning rate 1e-5, and a linear learning rate warm-up over 10% of the training data. Our default pooling strategy is MEAN.

4.2 Claim Quality Ranking

In contrast to the previous task, we cast this problem as a sequence-pair regression task. After obtaining all pairwise scores using S-BOW, BERT, and SBERT respectively, we map the pairwise labels to real-valued scores and rank them using the following models, once for each method.

BTL For mapping, we use the well-established Bradley-Terry-Luce (BTL) model (Bradley and Terry, 1952; Luce, 2012), in which items are ranked according to the probability that a given item beats an item chosen randomly. We feed the BTL model a pairwise-comparison matrix for all revisions related to a claim, generated as follows: Each row

Table 5: Claim quality classification results: Accuracy and Matthew Correlation Coefficient (MCC) for all tested approaches in the random-split and the cross-category setting on the two corpus versions. The first value in each value pair is obtained by a model trained on ClaimRev$_{\text{BASE}}$, the second by a model trained on ClaimRev$_{\text{EXT}}$. All improvements from one row to the next are significant at $p < 0.001$ according to a two-sided Student's t-test.

represents the probability of the revision being better than other revisions. All diagonal values are set to zero. Table 4 illustrates an example for a set of three argument revisions.

SVMRank Additionally, we employ SVMRank (Joachims, 2006), which views the ranking problem as a pairwise classification task. First, we change the input data, provided as a ranked list, into a set of ordered pairs, where the (binary) class label for every pair is the order in which the elements of the pair should be ranked. Then, SVMRank learns by minimizing the error of the order relation when comparing all possible combinations of candidate pairs. Given the nature of the algorithm we cannot work with token embeddings obtained from BERT directly. Thus, we utilize one of most commonly used approaches to transform token embeddings to a sentence embedding: extracting the special [CLS] token vector (Reimers and Gurevych, 2019; May et al., 2019). In our experiments we select a linear kernel for the SVM and use PySVMRank,[5] a python API to the SVM^{rank} library written in C.[6]

5 Experiments and Discussion

We now present empirical experiments with the approaches from Section 4. The goal is to evaluate how hard it is to compare and rank the claim revisions in our corpus from Section 3 by quality.

5.1 Experimental Setup

We carry out experiments in two settings. The first considers creating *random splits* over revision histories, ensuring that all versions of the same claim are in a single split in order to avoid data leakage. We assign 80% of the revision histories to the training set and the remaining 20% to the test set. A drawback of this setup is that it is not clear how well models generalize to unseen debate categories. In the second setting, we therefore evaluate the methods also in a *cross-category* setup using a leave-one-category-out paradigm, which ensures that all claims from the same debate category are confined to a single split. We split the data in this way to evaluate if our models learn independent features that are applicable across the diverse set of categories. To assess the effect of adding augmented data, we evaluate all models on both ClaimRev$_{\text{BASE}}$ and ClaimRev$_{\text{EXT}}$.

For quality *classification*, we report accuracy and the Matthews correlation coefficient (Matthews, 1975). We report the mean results over five runs in the random setting and the mean results across all test categories in the cross-category setting. To ensure balanced class labels, we create one false claim pair for each true claim pair by shuffling the order of the claims: $(v_1, v_2, true) \rightarrow (v_2, v_1, false)$, where the label denotes whether the second claim in the pair is of higher quality. We report results obtained by models trained on ClaimRev$_{\text{BASE}}$ and ClaimRev$_{\text{EXT}}$ as score pairs in Table 5.

To measure *ranking* performance, we calculate Pearson's r and Spearman's ρ correlation, as well as NDCG and MRR. We also compute the Top-1 accuracy, i.e. the proportion of claim sets, where the latest version has been ranked best. We average the results on each claim set across the test set for each metric. Afterwards we average the results across five runs or across all categories, depending on the chosen setting.

---

	Random-Split					**Cross-Category**				
Model	r	ρ	**Top-1**	NDCG	MRR	r	ρ	**Top-1**	NDCG	MRR
BTL + SBOW+L	0.38	0.37	0.62	0.94	0.79	0.36	0.35	0.60	0.94	0.78
BTL + BERT	0.60	0.59	0.74	0.96	0.86	0.58	0.57	0.72	0.96	0.85
BTL + SBERT	0.63	0.62	0.77	**0.97**	0.87	0.62	0.61	0.75	0.97	0.86
SVMRank + SBOW+L	0.18	0.18	0.50	0.93	0.73	0.24	0.23	0.52	0.93	0.75
SVMRank + BERT CLS	0.50	0.49	0.67	0.95	0.84	0.51	0.51	0.67	0.96	0.84
SVMRank + SBERT	**0.70**	**0.70**	**0.79**	**0.97**	**0.90**	**0.73**	**0.72**	**0.80**	**0.98**	**0.91**
Random baseline	0.00	0.00	0.42	0.91	0.68	0.00	0.00	0.42	0.91	0.67

Table 6: Claim quality ranking results: Pearson's r and Spearman's ρ correlation as well as top-1 accuracy for all tested approaches in the random-split and the cross-category setting on ClaimRev$_{\text{EXT}}$.In all cases, SVMRank + SBERT is significantly better than all others at $p < 0.001$ according to a two-sided Student's t-test.

5.2 Claim Quality Classification

The results in Table 5 show that a claim's *length* is a weak indicator of quality (up to 61.3 accuracy). An intuitive explanation is that, even though claims with more information may be better, it is also important to keep them readable and concise.

Despite *SBOW*'s good performance on predicting convincingness (Potash et al., 2017), the claim quality in our corpus cannot be captured by a model of such simplicity (maximum accuracy of 65.4). We point out that adding other linguistic features (for example, part-of-speech tags or sentiment scores) may further improve SBOW. Exemplarily, we equip SBOW with length features and observe a significant improvement (up to 67.5).

As for the transformer-based methods, we see that *BERT* and *SBERT* consistently outperform SBOW in all settings on both corpus versions, with SBERT's accuracy of up to 77.7 being best.[7]

A comparison of the performance of the methods depending on the corpus used for training in Table 5 shows the effect of augmenting the original Kialo data. In most cases, the results obtained by models trained on ClaimRev$_{\text{EXT}}$ are comparable (slightly higher/lower) than results obtained by models trained on ClaimRev$_{\text{BASE}}$. This means that adding relations between non-consecutive claim versions does not improve the reliability of methods. Given that the performance scores obtained on the ClaimRev$_{\text{EXT}}$ test set are evidently higher than on the ClaimRev$_{\text{BASE}}$ test set, we can conclude that the augmented cases are easier to classify and the cumulative difference in quality is more evident.

We can also see in Table 5 that the trained models are able to generalize across categories; the accuracy and MCC scores in the random split and cross-category settings for each method are very similar, with only a slight drop in the cross-category setting. This indicates that the nature of the revisions is relatively consistent among all categories, yet reveals the existence of some category-dependent features.

To find out whether BERT really captures the relative revision quality and not only lexical features present in the original claim, we introduced a *Single claim* baseline, analogous to the *hypothesis-only* baseline in natural language inference(Poliak et al., 2018). It can be seen that the accuracy and MCC scores are low across all settings (maximum accuracy of 59.8), which indicates that BERT indeed captures relative revision quality mostly.

5.3 Claim Quality Ranking

Table 6 lists the results of our ranking experiments, which show patterns similar to the results achieved in the classification task.

We can observe similar patterns in both of the selected ranking approaches: SBERT consistently outperforms all other considered approaches across all settings (up to 0.73 and 0.72 in Pearson's r and Spearman's ρ accordingly). BERT and SBERT outperform SBOW, indicating that transformer-based methods are more capable of capturing the relative quality of revisions. While BTL + BERT obtains results comparable to BTL + SBERT, we find that using the CLS-vector as a sentence embedding representation leads to lower results. We point out, though, that using other sentence embeddings and/or pooling strategies (for example, averaged BERT embeddings) may further improve results.

Similar to the results of the classification task, we observe only a slight performance drop in the

---

[7] Additionally, we have experimented with an adversarial training algorithm, ELECTRA (Clark et al., 2020), and obtained results slightly better than BERT, yet inferior to SBERT. We omit to report these results here, since they did not provide any further notable insights.

Task	Label	Accuracy	Instances
Type	Claim Clarification	69.7	12 856
	Typo/Grammar Correction	83.6	12 125
	Corrected/Added Links	89.3	3 660
	Changed Meaning of Claim	57.3	232
	Misc	67.2	2 130
	None	78.3	45 842
Distance	Revision distance 1	76.2	42 341
	Revision distance 2	79.6	17 478
	Revision distance 3	80.6	8 023
	Revision distance 4	81.0	3 979
	Revision distance 5	79.5	2 103
	Revision distance 6+	74.9	2 921
	All	**77.7**	**76 845**

cross-category setting when using BTL for ranking, yet an increase when using SVMRank, again emphasizing the topic-independent nature of claim quality in our corpus.

5.4 Error Analysis

To further explore the capabilities and limitations of the best model, SBERT, we analyzed its performance on each revision type and distance.

As the upper part of Table 7 shows, SBERT is highly capable of assessing revisions related to the correction and addition of links and supporting information. This revision type also obtained the highest correlations between quality dimensions and type of revision (see Table 3), which indicates that the patterns of changes performed within this type are more consistent. In contrast, we observe that the model fails to address revisions related to the changed meaning of a claim. On the one hand, this may be due to the fact that such examples are underrepresented in the data. On the other hand, the consideration of such examples in the selected tasks is questionable, since changing the meaning of claim is usually considered as the creation of a *new claim* and not a *new version* of a claim.

An insight from the lower part of Table 7 is that the accuracy of predictions increases from revision distance 1 to 4. We obtain better results when comparing non-consecutive claims than when comparing claim pairs with distance of 1. An intuitive explanation is that, since each single revision should ideally improve the quality of a claim, the more revisions a claim undergoes, the more evident the quality improvement should be. For distances > 5, the accuracy starts to decrease again, but this may be due to the limited number of cases given.

6 Conclusion and Future Work

In this paper, we have proposed a new way of assessing quality in argumentation by considering different revisions of the same claim. This allows us to focus on characteristics of quality regardless of the discussed topics, aspects, and stances in argumentation. We provide a new corpus of web claims, which is the first large-scale corpus to target quality assessment and revision processes on a claim level. We have carried out initial experiments on this corpus using traditional and transformer-based models, yielding promising results but also pointing to limitations. In a detailed analysis we have studied different kinds of claim revisions and provided insights into the aspects of a claim that influence the users' perception of quality. Such insights could help improve writing support in educational settings, or identify the best claims for debating technologies and argument search.

We seek to encourage further research on how to help online debate platforms automate the process of quality control and design automatic quality assessment systems. Such systems can be used to indicate if the suggested revisions increase the quality of an argument or recommend the type of revision needed. We leave it for future work to investigate whether the learned concepts of quality are transferable to content from other collaborative online platforms (such as idebate.org or Wikipedia), or to data from other domains, such as student essays and forum discussions.

Acknowledgments

We thank Andreas Breiter for feedback on early drafts, and the anonymous reviewers for their helpful comments. This work was partially funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under project number 374666841, SFB 1342.

Abstract

Dialogue State Tracking (DST) forms a core component of automated chatbot based systems designed for specific goals like hotel, taxi reservation, tourist information etc. With the increasing need to deploy such systems in new domains, solving the problem of zero/few-shot DST has become necessary. There has been a rising trend for learning to transfer knowledge from resource-rich domains to unknown domains with minimal need for additional data. In this work, we explore the merits of meta-learning algorithms for this transfer and hence, propose a meta-learner D-REPTILE specific to the DST problem. With extensive experimentation, we provide clear evidence of benefits over conventional approaches across different domains, methods, base models and datasets with significant (5-25%) improvement over the baseline in low-data setting. Our proposed meta-learner is agnostic of the underlying model and hence any existing state-of-the-art DST system can improve its performance on unknown domains using our training strategy.

1 Introduction

Task-Oriented Dialogue (TOD) systems are automated conversational agents built for a specific goal (for example hotel reservation). Many businesses from wide-variety of *domains* (like hotel, restaurant, car-rental, payments etc) have adopted these systems to cut down their cost on customer support services. Almost all such systems have a Dialogue State Tracking (DST) module which keeps track of values for some predefined domain-specific slots (example hotel-name, restaurant-rating etc) after every turn of utterances from user and system. These values are then used by Natural Language Generator (NLG) to generate system responses and fulfill the user goals.

Many of the recent works (Wu et al., 2019; Zhang et al., 2019; Goel et al., 2019; Heck et al., 2020) have proposed various neural models that achieve good performance for the task but are data hungry in general. Therefore, adapting to a new unknown domain (*target* domain) requires large amounts of domain-specific annotations limiting their use. However, given a wide range of practical applications, there has been a recent interest in data-efficient approaches. Lee et al. (2019), Gao et al. (2020) used transformer (Vaswani et al., 2017) based models which significantly reduce data dependence. Further, Gao et al. (2020) model the problem as machine reading comprehension task and benefit from its readily available external datasets and methods. Wu et al. (2019) were first to propose transferring knowledge from one domain to another. Since, many domains like restaurant and hotel share a lot of common slots like name, area, rating, etc and hence such a transfer proved to be effective for a low-resource domain. More recently, Campagna et al. (2020) aimed at zero-shot DST using synthetic data generation for the *target* domain imitating data from other domains.

Recent meta-learning methods like MAML (Finn et al., 2017), REPTILE (Nichol et al., 2018) have proven to be very successful in efficient and fast adaptations to new tasks with very few labelled samples. These methods specifically aim at the setting where there are many similar tasks but very small amount of data for each task. Agnostic of the underlying model, these meta-learning algorithms spit out initialization for its parameters which when fine-tuned using low-resource *target* task achieves good performance. Following their widespread success in few-shot image classification, there has been a lot of recent work on their merit in natural language processing tasks. Huang et al. (2018); Gu et al. (2018); Sennrich and Zhang (2019); Bansal et al. (2019); Dou et al. (2019); Yan et al. (2020)

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1730–1739
April 19 - 23, 2021.

attempt at using meta-learning for efficient transfer of knowledge from high-resource tasks to a low-resource task. Further, some of the more recent works (Dai et al., 2020; Qian and Yu, 2019) have shown meta-learners can be used for system response generation in TOD systems which is generally downstream task for our DST task.

To the best of our knowledge, ours is the first work exploring meta-learning algorithms for the DST problem. While prior work focused on training their models with a mixture of data from other available domains (*train* domains) followed by fine-tuning with data from *target* domain, we identify that this method of transferring knowledge between domains is inefficient, particularly in very low-data setting with just $0, 1, 2, 4$ annotated examples from *target* domain. We, on the other hand, use *train* domains to meta-learn the parameters of the model used to initialize the fine-tuning process. We hypothesize that though different domains share many common slots, they can have different complexities. For some of the domains, it might be easier to train the model using very few examples while others may require large number of gradient steps (based on their different data complexity and training curves with 1%, 5%, 10% data in Gao et al. (2020)). Meta-learning takes into account that this gradient information and share it across domains. Rather than looking for an initialization that try to simultaneously minimizes joint loss over all the domains, it looks for a point from which the optimum parameters of individual domains are reachable in few (< 5) gradient steps (and hence very few training examples for these steps). Then the hope is that the *target* domain is similar to at least one of the *train* domains (for example hotel & restaurant or taxi & train) and hence the learned initialization will achieve efficient fine-tuning with very few examples for the *target* domain as well. This direction of limited data is motivated by practical applicability, where it might be possible for any developer to manually annotate 4-8 examples before deploying the chatbot for a new domain.

We highlight the main contributions of our work below (i) We are the first to explore and reason about the benefits of meta-learning algorithms for DST problem (ii) We propose a meta-learner D-REPTILE that is agnostic to underlying model and hence has the ability to improve the state of the art performance in zero/few-shot DST for new domains. (iii) With extensive experimentation, we provide evidence of the benefit of our approach over conventional methods. We achieve a significant 5-25% improvement over the baseline in few-shot DST that is consistent across different *target* domains, methods, base models and datasets.

2 Background

2.1 Dialogue State Tracking

DST refers to keeping track of the *state* of the dialogue at every turn. *State* of dialogue can be defined as $\langle slot\_name, slot\_value \rangle$ pairs that represents, given a domain-specific slot, the value that the user provides or system-provided value that the user accepts. Further, many domains have a pre-defined *ontology* that specify the set of values each slot can take. Note that the number of values in ontology varies a lot with slots. Some slots like hotel-stars might have just five different values (called *categorical* slots), while those like hotel-name have hundreds of possible values (called *extractive* slots). It might be possible that a slot has never been discussed in the dialogue sequence and in that case, model has to predict a *None* value for that particular slot.

Various models have been proposed for the above task, but particularly relevant to this work is transformer-based model *STARC* by Gao et al. (2020). For each slot, they form a question (like what is the name of the hotel for hotel-name slot) and then at each turn append the tokens from dialogue utterance and the question separated by [SEP] token. They then pass these sequence of tokens through a transformer to form *token embeddings*. For the *extractive* slots, they use *token embeddings* to mark the span (start and end position) of the answer value in the dialogue itself (called *extractive-model*). For the *categorical* slots with less number of possible values, *categorical-model* append embeddings of each possible value to the *token embeddings* and then use a classifier with softmax layer to predict the correct option.

2.2 Meta-Learning

With advances in model-agnostic meta-learning framework by Finn et al. (2017); Nichol et al. (2018), the few-shot problems have been revolutionized. These frameworks define a underlying task-distribution from which both train (τ) and target tasks ($\tau^{'}$) are sampled. For each task τ, we are given very few labelled datapoints $\mathcal{D}_{\tau}^{train}$ and a loss function $\mathcal{L}_{\tau}$. Now, given a new data point $\mathcal{D}_{\tau'}^{test}$ from target task τ', the goal is to learn parameters $\theta_{\mathcal{M}}$ of any model $\mathcal{M}$ such that $\mathcal{L}_{\tau'}(\mathcal{D}_{\tau'}^{test};\theta_{\mathcal{M}})$ is minimized. This is achieved by k-steps of gradient descent using $\mathcal{D}_{\tau'}^{train}$ with learning rate α. More formally, $\theta_{\mathcal{M}} = SGD(\mathcal{D}_{\tau'}^{train}, \mathcal{L}_{\tau'}, \theta_{\mathcal{M}}^{INIT}; k, \alpha)$ where $SGD(\mathcal{D}, \mathcal{L}, \theta^{INIT}; k, \alpha)$ gives $\theta^{(k)}$ such that

$$\theta^{(t)} = \theta^{(t-1)} - \alpha\nabla_{\theta}(\mathcal{L}(\mathcal{D};\theta)), \theta^{(0)} = \theta^{INIT} \quad (1)$$

Therefore, the goal now is to find a good initialization $\theta_{\mathcal{M}}^{INIT}$ for the gradient descent using the data from train tasks τ. This is achieved by minimizing the empirical loss as

$$\theta^{(k)} = SGD(\mathcal{D}_{\tau}^{train}, \mathcal{L}_{\tau}, \theta; k, \alpha) \quad (2)$$

$$\theta_{\mathcal{M}}^{INIT} = arg\ \min_{\theta} \sum_{\tau} \mathcal{L}_{\tau}(\mathcal{D}_{\tau}^{train}; \theta^{(k)}) \quad (3)$$

Note that the above optimization is complex and involve second-order derivatives. For computational benefits, Nichol et al. (2018) proposed REPTILE and showed that these terms can be ignored without effecting the performance of the meta-learning algorithm. We refer the reader to their work for more details.

3 Methodology

In this work, we propose D-REPTILE, a meta-learning algorithm specific to DST task. Following what Qian and Yu (2019) did for dialogue generation problem, we treat different domains as tasks for the meta-learning algorithm. Let D $= \{d_1, d_2, \dots d_n\}$ (eg. $\{restaurant, taxi, payment, \dots\}$) be the set of *train* domains for which we have annotated data available. Let $p_D(.)$ define a probability distribution over these domains. Let $\mathcal{D}_{d_1}, \mathcal{D}_{d_2} \dots \mathcal{D}_{d_n}$ be the training data from each of these domains. Let $\mathcal{M}$ be any DST model with parameters $\theta_{\mathcal{M}}$. Let m be the task-batch size (number of domains in a batch in our case), α, β be the inner and outer learning rate respectively, k be the number of gradient steps. Let $SGD(.)$ be the function as defined in equation 1. Borrowing the meta-learning theory regarding optimizing the objective equation 3 from Nichol et al. (2018), we define the algorithm D-REPTILE in Algorithm 1. The update rule for initialization (as defined in step 8) is same as that of REPTILE. We chose REPTILE over other meta-learning algorithms because of its simplicity and computational advantages. Nonetheless, its straight-forward to switch any other initialization based meta-learner by changing meta-update step. The novelty of our learner lies in its definition of the meta-learning tasks that represent different domains of DST problem. This algorithm aims to find $\theta_{\mathcal{M}}^{INIT}$, which we use to initialize the model for the fine-tuning stage with the *target* domain.

Algorithm 1: D-REPTILE: Meta Learner for DST

```
Input: $\mathcal{D}_{d_1}, \mathcal{D}_{d_2} \dots \mathcal{D}_{d_n}$
Parameters: $\mathcal{M}$, $\mathcal{L}$, $p_D(.)$, $\alpha$, $\beta$, $k$, m
Result: $\theta_{\mathcal{M}}^{INIT}$
1  Initialize $\theta_{\mathcal{M}}$ randomly
2  for iteration $i = 1, 2, \dots$ do
3      sample m domains D_i using $p_D(.)$
4      for domain $d_j \in$ D_i do
5          sample data points $\mathcal{D}_{ij}$ from $\mathcal{D}_{d_j}$
6          $\theta_{\mathcal{M}}^{d_j} \leftarrow SGD(\mathcal{D}_{ij}, \mathcal{L}, \theta_{\mathcal{M}}; k, \alpha)$
7      end
8      $\theta_{\mathcal{M}} \leftarrow \theta_{\mathcal{M}} + \beta\frac{1}{m}\sum_{j=1}^{m}(\theta_{\mathcal{M}}^{d_j} - \theta_{\mathcal{M}})$
9  end
10 return $\theta_{\mathcal{M}}$;
```

We argue that the meta-learned initialization are better suited for fine-tuning than conventional methods. In the hope that joint optimal parameters for *train* domains lie close to individual domains, Wu et al. (2019) initialize the fine-tuning stage of the *target* domain from the joint minimum of the loss from data from all the *train* domains (called Naive pre-training before Fine-Tuning or NFT here). More formally, they chose the following initialization

$$\theta_{\mathcal{M}}^{INIT} = arg \min_{\theta} \sum_{j=1}^{n} \mathcal{L}(\mathcal{D}_{d_j}; \theta) \quad (4)$$

Such an initialization tries to simultaneously minimize the loss for all the domains which might be useful if the goal was to perform well on test data coming from mixture of these domains. However, here our goal is to perform well on a single unknown *target* domain and no direct relation between this initialization and the optimal parameters for the *target* domain can be seen. Further, as the number of *train* domains increases or training data for each domain decreases, the joint optimum can be very far-off from the individual domain-optimum parameters. Therefore, these methods perform particularly bad. We show empirical evidence for this hypothesis in Section 4. On the other hand, if we optimize equation 3, we will reach a point in the parameter space from where all the domain-optimum parameters are reachable in k-gradient descent steps. Therefore, we can hope to reach the optimum parameters for the *target* domain as well efficiently. This hope is much larger for DST problem specifically because of similarities in different related domains (specifically related slots as shown in Section 5).

Let us consider the following example, let restaurant and taxi be two of the *train* domains. Optimizing equation 3, we might reach a point which is closer to optimum parameters of restaurant domain than taxi domain if we have have smaller gradient values for restaurant data but large for taxi. However notably, both the optimum-parameters are reachable in k-gradient steps. Now if *target* domain is hotel (similar to restaurant domain with common slots like rating, name, etc), we will already be close to its optimum parameters. Also if the *target* domain is bus (similar to taxi domain with common slots like time, place, etc), we will have larger gradients in fine-tuning stage and thus will reach the optimum parameters for bus as well. This might not have been possible with equation 4 as the optimum parameters for joint of restaurant and taxi data might be very far from both the individual *train* domains and will also have no specific gradient properties for faster adaptation for any of hotel or bus *target* domains.

4 Experiments

4.1 Datasets

We used two different DST datasets for our experiments. (i) MultiWoz 2.0 (Budzianowski et al., 2018), 2.1 (Eric et al., 2019) (ii) DSTC8 (Rastogi et al., 2019). The former is manually annotated complex dataset with mostly 5 different domains, 8438 dialogues while the latter is relatively simple synthetically generated dataset with 26 domains and 16142 dialogues. Both the datasets contains dialogues spanning multiple domains. Following the setting from Wu et al. (2019), for extracting data of a particular domain from the dataset, we consider all the dialogues in which that domain is present and ignore slots from other domains both in train and test set. Further, as shown by Gao et al. (2020), we use external datasets from Machine Reading for Question Answering (MRQA) 2019 shared task (Fisch et al., 2019), DREAM (Sun et al., 2019), RACE (Lai et al., 2017) to pre-train our transformer in our experiments and label it with suffix '-RC' to distinguish it from '-base' model.

4.2 Evaluation Metric

Based on the objective in DST, there is a well established metric Joint Goal Accuracy (JGA). JGA is the fraction of total turns across all dialogues for which the predicted and ground truth dialogue state matches for all slots. Following Wu et al. (2019), for testing for a single *target* domain in a multi-domain dialogue, we only consider slots from that domain in metric computation. Note that in some of our experiments (where explicitly mentioned), we further restrict the slots to only extractive or only categorical slots. Also, as it happens most of the times, whenever a slot is not mentioned in any turn, the ground truth value for that slot is *None*. For analysis, we further use the metric Active Slot Accuracy which is the fraction of predicted values of a particular slot that were correct whenever the ground truth value was not *none*.

4.3 Experimental Setting

For all our experiments, both D-REPTILE and baseline (NFT (Sec. 3)) uses STARC (Sec. 2) as base model $\mathcal{M}$. This ensures that all the gains achieved in our experiments are only due to meta-learning. In our implementation [1], we use pre-trained word embeddings Roberta-Large (Liu et al., 2019), Adam optimizer (Kingma and Ba, 2014) for gradient updates in both inner and outer loop, $\alpha = 5e^{-5}$, $\beta = 1$, $m = 4$, $k = 5$, $p_D(i) \propto |\mathcal{D}_{d_i}|$ (chosen using dev-set experiments as explained in Section 5). As shown recently (Mosbach et al., 2020), the fine-tuning of transformer based model is unstable, therefore, we run fine-tuning multiple times and report the mean and the standard deviation of the performance. Also, the performance varies with the choice of training data from *target* domain used for fine-tuning. However, for our experiments, we chose these dialogues based on number of active slots (not *None*) and use the same dialogue for both D-REPTILE and baseline. Since, we use very little data (0, 1, or 2 examples) from *target* domain, we obviously would like to have dialogues that at-least have all the slots being discussed in the utterances. In practical scenarios, where a developer might be creating 1 or 2 examples for a new domain, it is always possible to include all the slots in the dialogue utterances.

---

[1] https://github.com/saketdingliwal/Few-Shot-DST

4.4 Results

In our experiments, we are able to achieve significant improvement over the baseline method under low-data setting (< 32 dialogues). Note that the choice of low-data setting is guided by the practical applications of the method. It also validates our hypothesis that the initialization chosen by meta-learning is closer to optimal parameters of the *target* domain in terms of gradient steps and therefore perform better when there is very less data. However, as fine-tuning data is increased to 1000s of dialogues, any random initialization is also able to reach the optimal parameters for *target* domain. We observe the benefits of D-REPTILE in limited data consistently across different domains, datasets and models as explained one-by-one below

Across domains - We used all different domains of MultiWoz 2.0 data as *target* domain in 5 plots in Figure 1. We pre-train D-REPTILE (solid) and NFT (dashed) versions of different models (represented by different colors). For the models represented by red and blue colors, we used all domains other than *target* domain as our *train* domains. For example, for the first plot, hotel domain is our *target* domain, while restaurant, train, attraction and taxi are our *train* domains. The red corresponds to starting with Roberta-Base embeddings, while the blue represent Roberta-RC which is pre-trained Roberta-Base with reading comprehension datasets (Gao et al., 2020). The green dotted line represent model without any pretraining. It is clearly very bad and unstable. This shows importance of using other domains for few-shot experiments. We fine-tune all our models using different amount of training data of *target* domain (x-axis). In each one of our models, the solid lines (D-REPTILE) lies strictly above the dashed lines (NFT) in JGA metric. The gains obtained are as high as 47.8% (D-REPTILE) vs 22.3% (NFT) for restaurant domain with 1 dialogue which is more than 100% improvement at no annotation cost at all.

Across models - Not only the results are consistent across different base models for transformer as shown in Figure 1 but also across different DST methods. As done in Gao et al. (2020), we train separate categorical and extractive models for hotel domain (using categorical and extractive data respectively from *train* domains) (which we have combined to plot Figure 1). If we consider these two fairly different models separately, we achieve similar trends in each individually as plotted in Figure 2. Note that JGA metric is computed here with restricted slots based on the type of the model. The gains are larger for the extractive model possibly because marking span in original dialogue can be considered slightly harder task than choosing among limited number of choices.

Joint Goal Accuracy	Hotel	Restaurant	Taxi	Attraction	Train
TRADE (Wu et al., 2019)	13.7	11.52	60.58	19.87	22.37
STARC (Gao et al., 2020)	28.6	28.2	65	36.9	26.1
STARC + D-REPTILE	**32.4**	**47.8**	**67.2**	**45.9**	**46.1**

Table 1: Zero-shot performance on MultiWoz 2.0 dataset. Domains like restaurant and train witness a significant boost in performance over baselines

Across datasets - To show that the merits of D-REPTILE are not limited to MultiWoz data, we tested with domains from DSTC8 dataset as both *train* and *target* domain. In Figure 1, the orange lines represent model pre-trained using all the domains in DSTC8 as *train* domains while *target* domain is from MultiWoz. As expected, the performance of these models fall below red and blue lines (models pre-trained with MultiWoz *train* domains) but above green (no pre-training) as training and testing datasets are different. However, the solid orange line (D-REPTILE) lies above dashed line (NFT). In another set of experiments, we used *target* domain from DSTC8 and compiled the results in Figure 3. Except for Hotels_1, Hotels_2 and Hotels_3, all other domains from DSTC8 are used as *train* domains while Hotels_2 is kept as *target* domain. We see that the benefits of meta-learning are much larger for DSTC8 dataset than MultiWoz. For example, with 8 dialogues for fine-tuning, D-REPTILE achieves JGA of 43.9% while NFT is only able to get 14.1%. This can be attributed to increase in number of different training tasks (23 domains were used as *train* domains for DSTC8 as opposed to 4 for MultiWoz experiments).

Surprisingly, the meta-learned initializations not only adapt faster but are also better to start with. We see an improvement in zero-shot performance as well. In addition to comparison with the NFT baseline, we also show improvement over existing models on MultiWoz 2.0 dataset in Table 1. Also note that D-REPTILE is model-agnostic and therefore has the capability to improve the JGA for any underlying model for a new unknown domain.

5 Ablation Studies

To validate our various theoretical hypothesis, search for hyper-parameters, clearly identify and

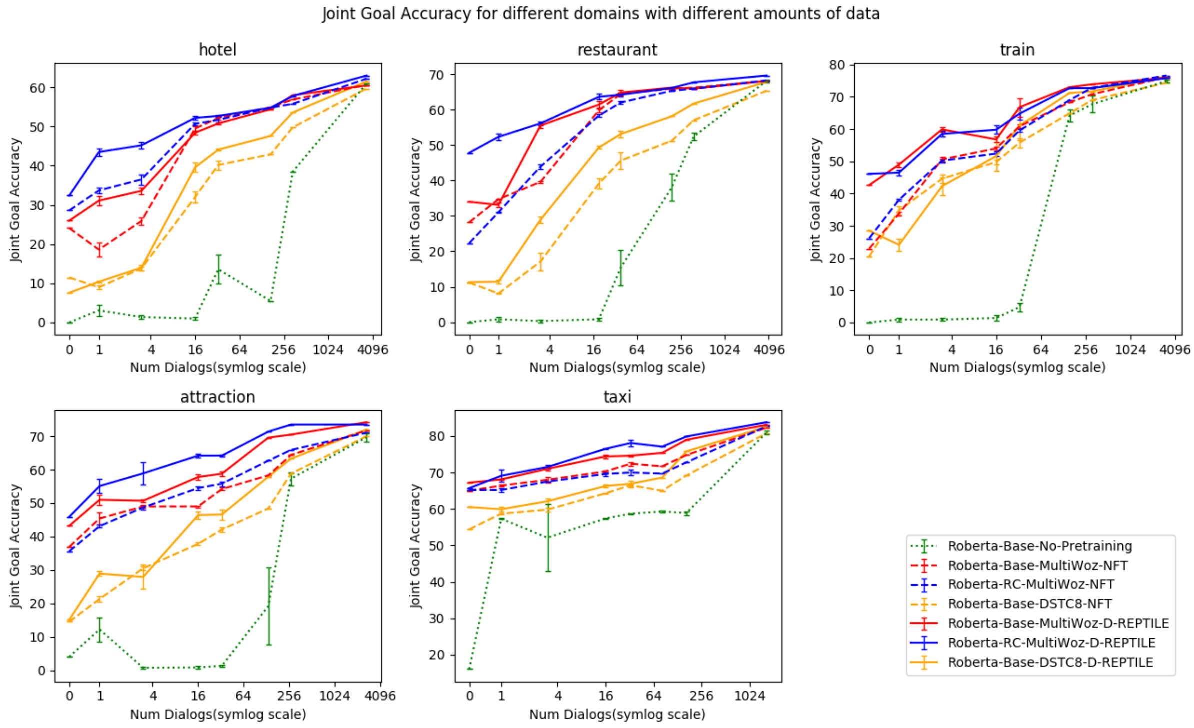

Figure 1: Performance of D-REPTILE vs NFT for different MultiWoz domains with three different models.

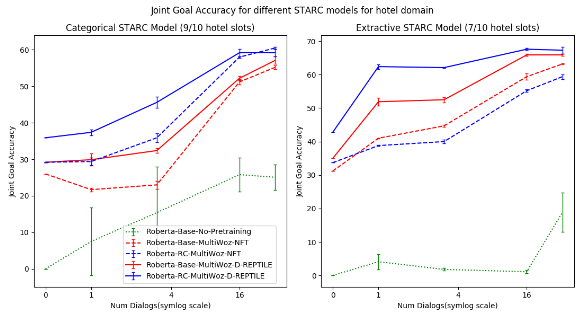

Figure 2: Performance of D-REPTILE vs NFT for different DST models for different slots in hotel domain.

Figure 3: Performance of D-REPTILE vs NFT for Hotels_2 domain in DSTC8 data as *target* domain.

reason about the situations where using meta-learning helps DST, we perform additional analysis as written in subsections below.

5.1 Slot-wise Analysis

To exactly pin-point the advantage of D-REPTILE, we do a slot-wise analysis of our models in Figure 4 and 5. Note that slots are defined as *domain_name.slot_name*. For example, *hotel.day* represents performance of the models in predicting the values for *day* slot where the *target* domain was *hotel*. Overall performance or JGA in plot 1 of Figure 1 is combination of all the *hotel* slots like *day, people, area, etc*. Figure 4 shows the slots which are common among different domains while Figure 5 compare the performance for slots that are unique to a *target* domain. We can see that for the common slots, the solid lines (D-REPTILE) mostly lie higher than the dashed (NFT) counterparts. However, nothing can be said in particular about slots in Figure 5. This behaviour is expected as unique slots particular to a *target* domain have little to gain from the different slots present in *train* domains (which were used for pre-training). This is evident from the fact that slots like *hotel.internet*, *hotel.parking* have zero-shot active accuracy close to zero for all kinds of pretraining strategies (Figure 5). However, wherever slots between different do-

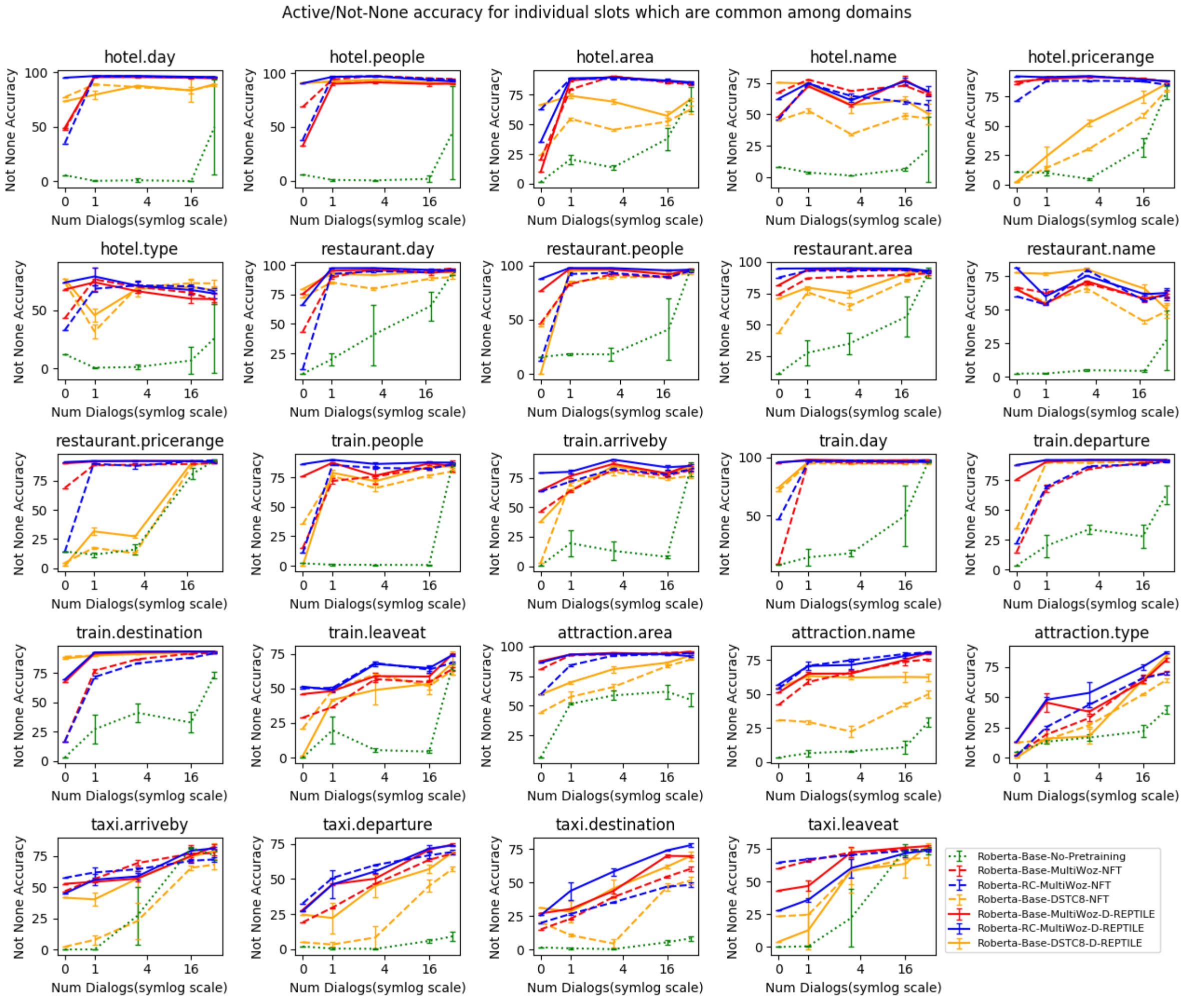

Figure 4: Active Slot accuracy for slots common between different domains

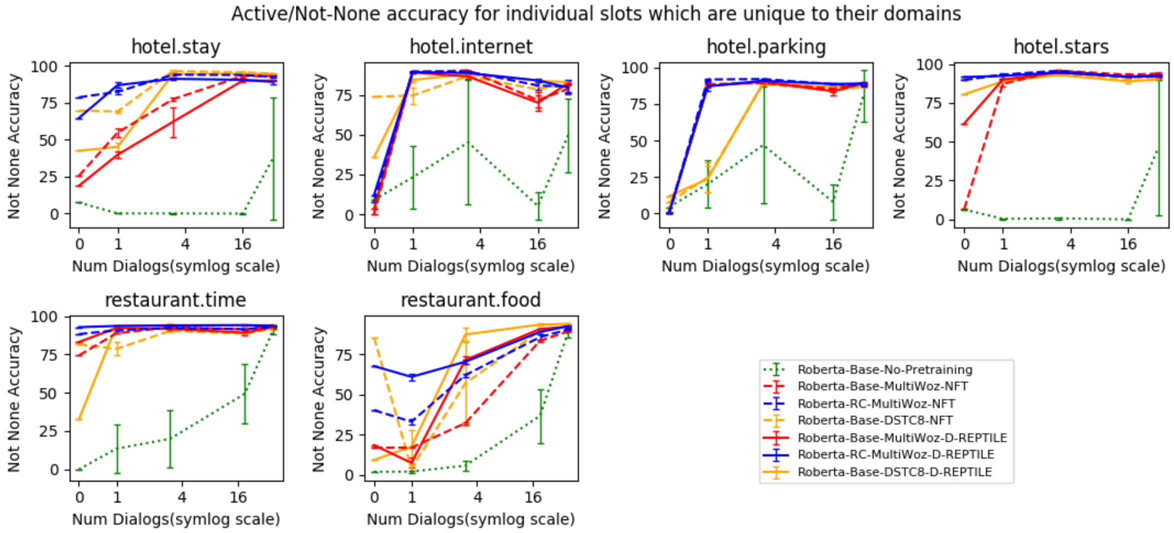

Figure 5: Active Slot accuracy for slots unique to specific *target* domain

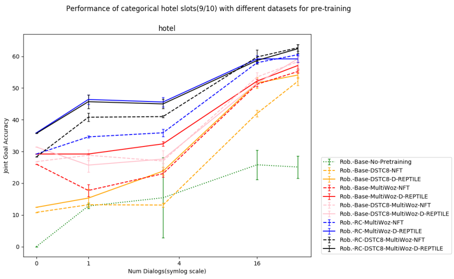

Figure 6: JGA for categorical model for hotel domain with different datasets

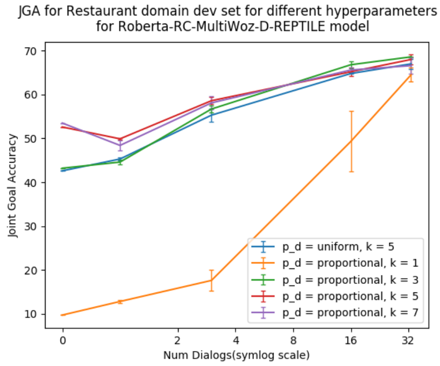

Figure 7: JGA for restaurant domain dev set with different hyper-parameters for the best D-REPTILE model

mains are similar, the pretraining have much larger influence. In that case, the merit of learning generalizable initialization from D-REPTILE than NFT is much more clearly evident (Figure 4).

5.2 Hyper-parameter Search

We briefly discuss the choice of various hyperparameters here. We use dev set from restaurant domain for searching for optimum values for different parameters introduced by meta-learning, while the rest are kept same as STARC model (Gao et al., 2020). In Figure 7, we plot the variation in performance with k and $p_D(.)$. Like any meta-learning algorithm, setting k too small or too large hurts the performance in our case as well (specially $k = 1$ where it becomes theoretically similar to NFT (Nichol et al., 2018)). Hence, optimum value $k = 5$ is used for all our experiments. Also, similar to the conclusion in Dou et al. (2019), we find choosing $p_D(.)$ of any domain as proportional to the size of the training dataset of that domain helpful (blue vs red line). This is attributed to the fact that in case of imbalance in data among different *train* domains, the algorithm gets to see all the data from the resource-rich domain as it is chosen more often and hence generalizes better.

5.3 Adding more *train* domains

As mentioned in previous section, we observe that benefits of D-REPTILE are much more profound when *target* domain is from DSTC8 dataset than when it is from MultiWoz (Figure 3). Given that DSTC8 has 23 *train* domains as compared to 4 in MultiWoz, it is not difficult to see the reason for this boost in performance. In this subsection, we try to answer the question whether MultiWoz *target* can also gain from additional domains of DSTC8. Here, for ease of computation, we only experiment with categorical model with *hotel* domain as *target* . We use both DSTC8 domains and MultiWoz domains (of course excluding hotel domain data during pre-training) and test it on *hotel* data from MultiWoz. These are represented by additional pink and black lines in Figure 6. We observe that although D-REPTILE helps to improve performance over baseline NFT but adding additional domains does not help the model much overall(solid black line is similar to solid blue line). This shows that in addition to the number of different training tasks, the relatedness of those tasks is also very crucial for meta-learning. The DSTC8 domains which are out-of-sample for MultiWoz *target* domain did not prove to be effective. (the small difference between JGA values for 1-dialogue fine-tuning in Figure 6 and categorical model in Figure 2 is due to difference in the choice of the single dialogue from hotel domain used for fine-tuning)

6 Conclusion

We conclude our analysis on the merits of meta-learning as compared to naive pre-training for DST problem on a very positive note. Given the practical applicability of very-low data analysis, we provide enough evidence to a developer of an automated conversational system for an unknown domain that irrespective of his/her model and *target* domain, D-REPTILE can achieve significant improvement (sometimes almost double) over conventional fine-tuning methods with no additional cost. With detailed ablations, we further provide insights on which slots and domains will particularly benefit from pre-traning strategies and which of those will require additional data. Being agnostic to underlying model, our proposed algorithm has capability to push state-of-the-art in zero/few-shot DST problem, giving hope for expanding the scope of similar chatbot based systems in new businesses.

Abstract

Pretrained transformer-based models, such as BERT and its variants, have become a common choice to obtain state-of-the-art performances in NLP tasks. In the identification of Adverse Drug Events (ADE) from social media texts, for example, BERT architectures rank first in the leaderboard. However, a systematic comparison between these models has not yet been done. In this paper, we aim at shedding light on the differences between their performance analyzing the results of 12 models, tested on two standard benchmarks.

SpanBERT and PubMedBERT emerged as the best models in our evaluation: this result clearly shows that span-based pretraining gives a decisive advantage in the precise recognition of ADEs, and that in-domain language pretraining is particularly useful when the transformer model is trained just on biomedical text from scratch.

1 Introduction

The identification of Adverse Drug Events (ADEs) from text recently attracted a lot of attention in the NLP community. On the one hand, it represents a challenge even for the most advanced NLP technologies, since mentions of ADEs can be found in different varieties of online text and present unconventional linguistic features (they may involve specialized language, or consist of discontinuous spans of tokens etc.) (Dai, 2018). On the other hand, the task has an industrial application of primary importance in the field of digital pharmacovigilance (Sarker et al., 2015; Karimi et al., 2015b).

This raising interest is attested, for example, by the ACL workshop series on Social Media Health Mining (SMM4H), in which shared tasks on ADE detection have been regularly organized since 2016 (Paul et al., 2016; Sarker and Gonzalez-Hernandez, 2017; Weissenbacher et al., 2018, 2019). With the recent introduction of Transformers architectures and their impressive achievements in NLP (Vaswani et al., 2017; Devlin et al., 2019), it is not surprising that these tools have become a common choice for the researchers working in the area.

The contribution of this paper is a comparison between different Transformers on ADE detection, in order to understand which one is the most appropriate for tackling the task. Shared tasks are not the best scenario for addressing this question, since the wide range of differences in the architectures (which could include, for example, ensembles of Transformers and other types of networks) does not allow a comparison on the same grounds. In our view, two key questions deserve a particular attention in this evaluation. First, whether there is an advantage in using a model with some form of *in-domain language pretraining*, given the wide availability of Transformers for the biomedical domain (Lee et al., 2020; Gu et al., 2020). Second, whether a model trained *to predict coherent spans of text* instead of single words can achieve a better performance (Joshi et al., 2019), since our goal is to identify the groups of tokens corresponding to ADEs as precisely as possible.

Two models that we introduce for the first time in this task, SpanBERT and PubMedBERT, achieved the top performance. The former takes advantage of a span-based pretraining objective, while the latter shows that in-domain language data are better used for training the model from scratch, without any general-domain pretraining.

2 Related Work

2.1 ADE Detection

Automatic extraction of ADE in social media started receiving more attention in the last few

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1740–1747
April 19 - 23, 2021.

years, given the increasing number of users that discuss their drug-related experiences on Twitter and similar platforms. Studies like Sarker and Gonzalez (2015); Nikfarjam et al. (2015); Daniulaityte et al. (2016) were among the first to propose machine learning systems for the detection of ADE in social media texts, using traditional feature engineering and word embeddings-based approaches.

With the introduction of the SMM4H shared task, methods based on neural networks became a more and more common choice for tackling the task (Wu et al., 2018; Nikhil and Mundra, 2018), and finally, it was the turn of Transformer-based models such as BERT (Devlin et al., 2019) and BioBERT (Lee et al., 2020), which are the building blocks of most of the top performing systems in the recent competitions (Chen et al., 2019; Mahata et al., 2019; Miftahutdinov et al., 2019).

At the same time, the task has been independently tackled also by researchers in Named Entity Recognition, since ADE detection represents a classical case of a challenging task where the entities can be composed by discontinuous spans of text (Stanovsky et al., 2017; Dai et al., 2020; Wunnava et al., 2020).

2.2 Transformers Architectures in NLP

There is little doubt that Transformers (Vaswani et al., 2017) have been the dominant class of NLP systems in the last few years. The "golden child" of this revolution is BERT (Devlin et al., 2019), which was the first system to apply the bidirectional training of a Transformer to a language modeling task. More specifically, BERT is trained with a Masked Language Modeling objective: random words in the input sentences are replaced by a [MASK] token and the model attempts to predict the masked token based on the surrounding context.

Following BERT's success, several similar architectures have been introduced in biomedical NLP, proposing different forms of in-domain training or using different corpora (Beltagy et al., 2019; Alsentzer et al., 2019; Lee et al., 2020; Gu et al., 2020). Some of them already proved to be efficient for ADE detection: for example, the top system of the SMM4H shared task 2019 is based on an ensemble of BioBERTs (Weissenbacher et al., 2019).

Another potentially interesting addition to the library of BERTs for ADE detection is SpanBERT (Joshi et al., 2019). During the training of SpanBERT, random contiguous spans of tokens are masked, rather than individual words, forcing the model to predict the full span from the tokens at its boundaries. We decided to introduce SpanBERT in our experiments because longer spans and relations between multiple spans of text are a key factor in ADE detection, and thus encoding such information is potentially an advantage.

3 Experimental Settings

3.1 Datasets

The datasets chosen for the experiments are two widely used benchmarks. They are annotated for the presence of ADEs at character level: each document is accompanied by list of start and end indices for the ADEs contained in it. We convert these annotations using the IOB annotation scheme for the tokens: B marks the start of a mention, I and O the tokens inside and outside a mention respectively.

CADEC (Karimi et al., 2015a) contains 1250 posts from the health-related forum "AskaPatient", annotated for the presence of ADEs. We use the splits made publicly available by Dai et al. (2020).

SMM4H is the training dataset for Task 2 of the SMM4H shared task 2019 (Weissenbacher et al., 2019). It contains 2276 tweets which mention at least one drug name, 1300 of which are positive for the presence of ADEs while the other 976 are negative samples. The competition includes a blind test set, but in order to perform a deeper analysis on the results, we use the training set only. As far as we know there is no official split for the training set alone, so we partitioned it into training, validation and test sets (60:20:20), maintaining the proportions of positive and negative samples. This split and the code for all the experiments are available at `https://github.com/AilabUdineGit/ADE`.

The datasets correspond to different text genres: the tweets of SMM4H are mostly short messages, containing informal language, while the texts of CADEC are longer and structured descriptions. To verify this point, we used the TEXTSTAT Python package to extract some statistics from the texts of the two datasets (see Appendix A).

3.2 Metrics

As evaluation metrics we use the Strict F1 score, which is commonly adopted for this task (Segura-Bedmar et al., 2013). It is computed at the entity level, and assigns a hit only in case of perfect match between the labels assigned by the model and the labels in the gold annotation.

In CADEC around 10% of mentions are discontinuous (Dai et al., 2020) and it is possible to have overlaps and intersections of discontinuous spans. We performed data tidying by merging overlapping ADE mentions, keeping only the longer span (as it is customary in the literature) and splitting discontinuous spans in multiple continuous spans.

3.3 Overview of the Models

3.3.1 Pretrained BERT Variants

Apart from the original BERT, we experimented with SpanBERT, for its peculiar pretraining procedure which focuses on predicting and encoding spans instead of single words, and with four BERT variants with in-domain knowledge, which differ from each other both for the corpus they were trained on and for the kind of pretraining.

BERT Standard model, pretrained on general purpose texts (Wikipedia and BookCorpus).

SpanBERT This model is pretrained using the same corpus as the original BERT, so it comes with no in-domain knowledge. But the pretraining procedure makes its embeddings more appropriate for NER-like tasks. as it introduces an additional loss called Span Boundary Objective (SBO), alongside the traditional Masked Language Modelling (MLM) used for BERT.
Let us consider a sentence $S = [w_1, w_2, \dots, w_k]$ and its substring $S_{m:n} = [w_m, \dots, w_n]$. w_{m-1} and w_{n+1} are the boundaries of $S_{m:n}$ (the words immediately preceding and following it). We *mask* S by replacing all the words in $S_{m:n}$ with the `[MASK]` token. SpanBERT reads the masked version of S and returns an embedding for each word. The MLM loss measures if it is possible to reconstruct each original word $w_i \in S_{m:n}$ from the corresponding embedding. The SBO loss measures if it is possible to reconstruct each $w_i \in S_{m:n}$ using the embeddings of the boundary words w_{m-1} and w_{n+1}.

BioBERT (Lee et al., 2020), pretrained from a BERT checkpoint, on PubMed abstracts.
The authors of BioBERT provide different versions of the model, pretrained on different corpora. We selected the version which seemed to have the greatest advantage on this task, according to the results by Lee et al. (2020). We chose BioBERT v1.1 (+PubMed), which outperformed other BioBERT v1.0 versions (including the ones trained on full texts) in NER tasks involving Diseases and Drugs. Preliminary experiments against BioBERT v.1.0 (+PubMed+PMC) confirmed this behaviour (see Appendix D).

BioClinicalBERT (Alsentzer et al., 2019), pretrained from a BioBERT checkpoint, on clinical texts from the MIMIC-III database.

SciBERT (Beltagy et al., 2019), pretrained *from scratch*, on papers retrieved from Semantic Scholar (82% of medical domain).

PubMedBERT (Gu et al., 2020), pretrained *from scratch*, on PubMed abstracts and full text articles from PubMed Central. This model was created to prove that pretraining from scratch on a *single domain* produces substantial gains on in-domain downstream tasks. Gu et al. (2020) compared it with various other models pretrained on either general texts, mixed-domain texts or in-domain texts starting from a general-purpose checkpoint (e.g. BioBERT), showing that PubMedBERT outperforms them on several tasks based on medical language. The vocabulary of PubMedBERT contains more in-domain medical words than any other model under consideration. However, it should be kept in mind that ADE detection requires an understanding of *both* medical terms and colloquial language, as both can occur in social media text.

Notice that two in-domain architectures were pretrained from scratch (SciBERT and PubMedBERT), meaning that they have a unique vocabulary tailored on their pretraining corpus, and include specific embeddings for in-domain words. BioBERT and BioClinicalBERT were instead pretrained starting from a BERT and BioBERT checkpoint, respectively. This means that the vocabularies are built from general-domain texts (similarly to BERT) and the embeddings are initialized likewise.

3.3.2 Simple and CRF Architecture

For all of the BERT variants, we take into account two versions. The first one simply uses the model to generate a sequence of embeddings (one for each sub-word token), which are then passed to a Linear Layer + Softmax to project them to the output space (one value for each output label) and turn them into a probability distribution over the labels.

The second version combines the Transformer-based model with a Conditional Random Field (CRF) classifier (Lafferty et al., 2001; Papay et al., 2020). The outputs generated by the first version become the input of a CRF module, producing another sequence of subword-level IOB labels. This step aims at denoising the output labels produced by the previous components.

The output labels are calculated for sub-word tokens, then we aggregate each set of sub-word labels $\{\ell_i\}$ into a word label $\mathcal{L}$ using the first rule that applies: (i) if ℓ_i = O for all i, then $\mathcal{L}$ = O; (ii) if ℓ_i = B for any i, then $\mathcal{L}$ = B; (iii) if ℓ_i = I for any i, then $\mathcal{L}$ = I. The aggregated output is a sequence of word-level IOB labels.

3.3.3 Baseline

As a strong baseline, we used the **TMRLeiden** architecture (Dirkson and Verberne, 2019), which achieved the 2nd best Strict F1-Score in the latest SMM4H shared task (Weissenbacher et al., 2019) and is composed of a BiLSTM taking as input a concatenation of BERT and Flair embeddings (Akbik et al., 2019). We chose this baseline since the TMRLeiden code is publicly available.

3.4 Implementation details

TMRLeiden was re-implemented starting from its the original code[1] and trained according to the details in the paper. As for the Transformers, all experiments were performed using the TRANSFORMERS library (Wolf et al., 2019) (see Appendix C). Parameter-tuning was done via grid-search, using different learning rates ($[5e{-}4, 5e{-}5, 5e{-}6]$) and dropout rates (from 0.15 to 0.30, increments of 0.05). All the architectures were trained for 50 epochs on the training set. Learning rate, dropout rate and maximum epoch were chosen evaluating the models on the validation set.

During evaluation all the models were then trained using the best hyperparameters on the concatenation of the training set and the validation set, and tested on the test set. This procedure was repeated five times with different random seeds, and finally we averaged the results over the five runs.

4 Evaluation

The results for the two datasets are shown in Table 1 (we focus on the F1-score, but Precision and Recall are reported in Appendix D). For reference, we reported the scores of the best architecture by Dai et al. (2020), which is the state-of-the-art system on CADEC. At a glance, all systems perform better on CADEC, whose texts belong to a more standardized variety of language. SpanBERT and PubMedBERT emerge as the top performing models, with close F1-scores, and in particular, the SpanBERT models achieve the top score on both datasets, proving that modeling spans gives an important advantage for the identification of ADEs.

	SMM4H		**CADEC**	
Architecture	**F1**	**std**	**F1**	**std**
Dai et al. (2020)	–	–	**68.90**	–
TMRLeiden	60.70	2.08	65.03	1.14
BERT	54.74	1.40	65.20	0.47
BERT+CRF	59.35	1.23	64.36	0.83
SpanBERT	**62.15**	2.17	67.18	0.78
SpanBERT+CRF	59.89	2.16	**67.59**	0.60
PubMedBERT	61.88	0.79	67.16	0.52
PubMedBERT+CRF	59.53	2.07	67.28	0.82
BioBERT	57.83	2.59	65.59	1.10
BioBERT+CRF	58.05	1.45	66.00	0.67
SciBERT	57.75	1.55	65.61	0.54
SciBERT+CRF	58.86	1.55	67.09	0.74
BioClinicalBert	58.03	0.89	64.64	0.53
BioClinicalBert+CRF	59.11	1.99	65.97	0.60

Table 1: F1 scores with standard deviations for all models (our best performing model is in bold).

For both models, the addition of CRF generally determines a slight improvement on CADEC, while it is detrimental on SMM4H. On SMM4H, the F1-scores of BioBERT, SciBERT and BioClinicalBERT consistently improve over the standard BERT, but they are outperformed by its CRF-augmented version, while on CADEC they perform closely to the standard model. The results suggest that in-domain knowledge is consistently useful only when *training is done on in-domain text from scratch*, instead of using general domain text first. SciBERT is also trained from scratch, but on a corpus that is less specific for the biomedical domain than the PubMedBERT one (Gu et al., 2020).

The models are also being compared with TMRLeiden: we can notice that both versions of SpanBERT and PubMedBERT outperform it on CADEC (the differences are also statistically significant for the McNemar test at $p < 0.001$), while only the basic versions of the same models retain an advantage on it on SMM4H (also in this case, the difference is significant at $p < 0.001$).

4.1 Error Analysis

We analyzed the differences between the ADE entities correctly identified by the models and those that were missed, using the text statistics that we previously extracted with TEXTSTAT. As it was

Table 2: Examples of ADEs extracted by PubMedBERT (overlined in blue) and SpanBERT (underlined in red). Actual ADEs in bold with gray background. The Samples belong to SMM4H (1–3, 6) and CADEC (4–5).

predictable, it turns out that longer ADE spans are more difficult to identify: for all models, we extracted the average word length of correct and missed spans and we compared them with a two-tailed Mann-Whitney U test, finding that the latter are significantly longer (Z = -6.176, $p < 0.001$). We also extracted the average number of difficult words in the correct and in the missed spans, defined as words with more than two syllables that are not included in the TEXTSTAT list of words of common usage in standard English. We took this as an approximation of the number of "technical" terms in the dataset instances. However, the average values for correct and missed instances do not differ (Z = 0.109, $p > 0.1$), suggesting that the presence of difficult or technical words in a given instance does not represent an inherent factor of difficulty or facilitation. Still, for some of the models – including SpanBERT, PubMedBERT and TMRLeiden – this difference reaches a marginal significance ($p < 0.05$) exclusively on the SMM4H dataset, where correctly identified spans have more difficult words. A possible interpretation is that, as the tweets' language is more informal, such words represent a stronger ADE cue, compared to the more technical language of the CADEC dataset.

Finally, we performed a qualitative analysis, comparing the predictions of SpanBERT and PubMedBERT. We selected the samples on which one of the architectures performed significantly better than the other one in terms of F1-Score, and analyzed them manually. Some significant samples can be found in Table 2. We observed that most of the samples in which PubMedBERT performed better than SpanBERT contained medical terms, which SpanBERT had completely ignored (e.g. Sample 1). The samples in which SpanBERT outperformed the in-domain model contained instead long ADE mentions, often associated with informal descriptions (e.g. Samples 2, 3). As regards false positives, both models make similar errors, which fit into two broad categories: (1) extracting diseases or symptoms of a disease (e.g. Samples 4, 6); (2) not being able to handle general mentions, hypothetical language, negations and similar linguistic constructs (e.g. Sample 5). While the second kind of error requires a deeper reflection, the first one might be addressed by training the model to extract multiple kinds of entities (e.g. both ADEs and Diseases).

5 Conclusions

We presented a comparison between 12 transformers-based models, with the goal of "prescribing" the best option to the researchers working in the field. We also wanted to test whether the span-based objective of SpanBERT and in-domain language pretraining were useful for the task. We can positively answer to the first question, since SpanBERT turned out to be the best performing model on both datasets. As for the in-domain models, PubMedBERT came as a close second after SpanBERT, suggesting that pretraining from scratch with no general domain data is the best strategy, at least for this task.

We have been the first, to our knowledge, to test these two models in a systematic comparison on ADE detection, and they delivered promising results for future research. For the next step, a possible direction would be to combine the strengths of their respective representations: the accurate modeling of text spans on the one side, and deep biomedical knowledge on the other one.

A Text statistics for datasets

Some statistics for the texts of the two datasets have been extracted with the TEXTSTAT Python package and reported reported in Table A: we extracted the counts of syllables, lexicon (how many different word types are being used), sentences and characters. Difficult words refers to the number of polysyllabic words with Syllable Count > 2 that are not included in the list of words of common usage in English.

Metric	**CADEC**	**SMM4H**
Syllable Count	116 ± 2.7	26 ± 0.2
Lexicon Count	83 ± 1.9	18 ± 0.1
Sentence Count	5 ± 0.1	1 ± 0.0
Character Count	461 ± 10.5	104 ± 0.7
Difficult Words	14 ± 0.3	4 ± 0.1

Table 3: Average metrics per dataset, computed by the TEXTSTAT Python library.

B Best hyperparameters on the two datasets

Table 4 reports the best hyperparameters for all architectures on SMM4H and CADEC, respectively.

Table 4: Best hyperparameters for all Transformer-based architectures on SMM4H and CADEC.

C General information on the models

Table 5 is a summary of the information about the version of all Transformer-based models used and their pretraining methods.

D Detailed metrics of all the models

Table 6 and 7 report as Strict and Partial metrics the F1-score, Precision and Recall calculated for all architectures on SMM4H and CADEC respectively. Results are the average over five runs.

The Partial scores are standard metrics for this task (Weissenbacher et al., 2019) and take into account "partial"matches, in which it is sufficient for a system prediction to partially overlap with the gold annotation to be considered as a true match.

Semantic Parsing of Disfluent Speech

Abstract

Speech disfluencies are prevalent in spontaneous speech. The rising popularity of voice assistants presents a growing need to handle naturally occurring disfluencies. Semantic parsing is a key component for understanding user utterances in voice assistants, yet most semantic parsing research to date focuses on written text. In this paper, we investigate semantic parsing of disfluent speech with the ATIS dataset. We find that a state-of-the-art semantic parser does not seamlessly handle disfluencies. We experiment with adding real and synthetic disfluencies at training time and find that adding synthetic disfluencies not only improves model performance by up to 39% but can also outperform adding real disfluencies in the ATIS dataset.

1 Introduction

Spoken language differs from written language. Unlike written texts, spontaneous speech frequently contains disfluencies such as filled pauses, repetitions, repairs, and false starts. These affect around 6% of words (Kasl and Mahl, 1965; Tree, 1995; Bortfeld et al., 2001) and occur in both human-human and human-computer interactions (Oviatt, 1995). While considerable research has been done on speech disfluencies in syntactic parsing (Johnson and Charniak, 2004; Wang et al., 2018; Jamshid Lou et al., 2019), semantic parsing of disfluent speech has received less attention.

Semantic parsing is the task of mapping written text to a representation of its meaning. In voice assistants, such as Amazon Alexa, Google Assistant, or Siri, an automated speech recognition (ASR) component is often followed by a semantic parsing task that identifies the intent and slots of the transcribed utterance. In voice-based contexts, speech disfluencies are to be expected, and so a voice assistant must accurately support disfluent speech to support more natural user interaction. Despite the growing popularity of voice assistants, semantic parsing research to date has focused on written language. Most popular semantic parsing datasets only include written forms that were generated from grammars (Coucke et al., 2018) or crowdsourced (Gupta et al., 2018) and do not contain speech phenomena such as disfluencies.

One approach to parsing disfluent speech is to detect and remove transcribed disfluencies in a post-processing step after ASR with a disfluency detector (Zayats et al., 2016; Jamshid Lou et al., 2018). Alternatively, some ASR models attempt to directly produce fluent transcriptions from disfluent inputs (Jamshid Lou and Johnson, 2020) but have lower performance. We investigate semantic parsing of disfluent utterances directly, without ASR post-processing, by training a single semantic parsing model that handles both fluent and disfluent utterances. Our approach has the advantage of being simple and easier to implement than approaches that require multiple models in a pipeline.

We investigate semantic parsing of disfluent speech using the ATIS semantic parsing dataset (Price, 1990), which was originally collected as spontaneous speech. ATIS is a small dataset but currently the only semantic parsing dataset that contains speech disfluencies. As such, our findings are limited by dataset size and results may differ given more data, however, we still find interesting preliminary results. First, we compare performance of a state-of-the-art semantic parser on disfluent and fluent examples in ATIS and identify a performance gap of 79%. To address this gap, we experiment with augmenting the training data with real disfluencies, synthetically-generated disfluencies, and a combination of both. We find that adding synthetic disfluencies adds up to 39% improvement in exact-match accuracy for disfluent utterances. We also find that real disfluencies degrade perfor-

Fluent	please find a flight from detroit michigan to st. petersburg arriving before 10 pm
Speech Transcription	please find a flight <from> <saint> <petersburg> <excuse> <me> from detroit michigan to saint petersburg arriving before ten p m
Disfluent	please find a flight from st. petersburg excuse me from detroit michigan to st. petersburg arriving before 10 pm

Table 1: An example of a disfluent utterance transcribed in ATIS

mance on fluent data, while synthetic disfluencies do not. This demonstrates that adding synthetic but targeted disfluent training data can be more effective than adding real but noisier data to improve model performance on disfluent utterances.

2 ATIS

The Airline Travel Information System (ATIS) corpus (Price, 1990) is a widely used dataset in semantic parsing and spoken language understanding. ATIS contains human-computer dialogs in American English where speakers asked a computer system about hypothetical flight planning scenarios. In our experiments, we use the ATIS data splits from Tur et al. (2010)'s *All Train* setup with 4,978 training examples (of which 500 are for development) and 893 test examples selected from the wider corpus as those that are context independent. We use the target meaning representation format with slots and intents introduced by Gupta et al. (2018), with the same modification as Rongali et al. (2020) of custom end-brackets.

	Real	Synthetic
Contains Filled Pause(s)	43.1%	73.0%
Contains Repair(s)	68.7%	66.5%
Fluent avg token length	13.6	11.1
Disfluent avg token length	15.4	13.5

Table 2: Description of ATIS disfluencies

Unlike most semantic parsing datasets, the ATIS corpus contains recorded speech transcribed in detail, which has been used to research characteristics of disfluencies (Shriberg, 1996; Savova and Bachenko, 2003). However, most semantic parsing work on ATIS uses a cleaned version of the utterances where disfluencies are removed (Price, 1990). We use the original ATIS transcriptions to restore disfluencies to the dataset. We reintroduce deleted words in repairs, partial words longer than 1 character, and filled pauses ('mm', 'uh', 'ah', 'um'). Utterances identified as disfluent are manually verified. An example is shown in Table 1 and dataset statistics about the disfluencies are in Table 2. We map the disfluent utterances to the target meaning representation of their fluent counterpart. This results in 314 disfluent utterances in the train set, 36 in development, and 56 in the test set, accounting for 6.9% of the dataset.

3 Model Architecture

Hyperparameter	Value
Batch Size	1400
Learning Rate	0.05
Epochs	100
Max Seq Length	50
Beam Width	4

Table 3: Hyperparameters used when training semantic parsing models on the ATIS dataset

Our semantic parsing model architecture is a reimplementation of the sequence-to-sequence model with pointer generator network (Vinyals et al., 2015) proposed by Rongali et al. (2020), which achieved state-of-the-art performance on three public datasets including ATIS. We use a pre-trained RoBERTa language model (Liu et al., 2019) as the encoder and a transformer based on Vaswani et al. (2017) as the decoder. The encoder converts a sequence of words into a sequence of embeddings. Then at each time step, the decoder outputs either a symbol from the output vocabulary or uses a pointer generator network to generate pointers to tokens in the source sequence. A final softmax layer provides a probability distribution over all actions, and beam search maximizes the output sequence probability. We train on a single Nvidia Tesla v100 16GB GPU with the hyperparameters shown in Table 3.

4 Experiments

We run four experiments to evaluate how our semantic parsing model handles speech disfluencies. Each model is evaluated against three test sets: the *Original* ATIS test set of 893 fluent utterances, the *Disfluent* subset of 56 disfluent test set utterances identified in §2, and the *Fluent Subset* containing the fluent versions of these 56 utterances. The Fluent and Disfluent subsets are small, however we train multiple models and report results as the average exact-match accuracy over 5 runs with standard deviation. We also calculate slot-match accuracy for one model per setting on the disfluent subset, which measures whether the slots in the representation are correct. Finally, we provide a breakdown of performance based on disfluency type for a selection of models in Table 5.

4.1 Experiment 1: Are models trained on fluent data robust to disfluencies?

First, we investigate how a semantic parsing model trained on fluent data performs on disfluent utterances. We train a model with the original ATIS dataset and evaluate on all test sets. The results are in the first row of Table 4. These results show that our ATIS model is not robust to disfluencies, scoring 79% lower on the disfluent subset compared to the fluent subset (0.02 vs. 0.81) even though these are variations of the same utterances. In an error analysis, we find that most of the errors on the disfluent subset come from incorrect slots rather than intents, and so we also report the slot accuracy on the disfluent subset (0.29). Common errors include repairs within slots where they should be deleted (e.g. *[SL:TolocCityName um washington]*), or mislabeling filled pauses as airport or state codes.

4.2 Experiment 2: Can we improve performance on disfluencies with real disfluent data?

Next we experiment with adding real disfluent examples to improve model performance. We add the 314 disfluent examples identified in §2 into the train set and 36 into the dev set and fully retrain the model. As shown in the second row of Table 4, adding real disfluent examples improves model performance on the disfluent subset by 32% exact-match accuracy and 17% slot accuracy. This is promising, especially since only 7% of the train set was disfluent. However, this improvement comes at a cost: average performance drops by 6% on the original test set and by 4% on the fluent subset. We see errors where meaningful tokens are erroneously dropped from slots, such as omitting *"closest"* when parsing *"which airport is closest to ontario california"*, or *"city"* from *"kansas city"*.

4.3 Experiment 3: Can we improve performance on disfluencies with synthetic data?

Adding disfluent examples improved performance on the disfluent subset, but real disfluencies can be sparse and costly to collect with target labels, requiring expert annotators familiar with the meaning representation. Additionally, real examples can be complex with multiple disfluencies (e.g. *"beginning on april thirtieth and returning no beginning on april twenty fifth and beginning on may sixth returning on may sixth"*. The drop in performance on fluent examples observed in §4.2 could suggest that adding real disfluencies caused the model to overfit to noisier signals, thus leading to worse performance. We hypothesize that adding simpler and more targeted synthetic disfluencies may improve model performance. Previous studies have also illustrated the benefits of augmenting training data with generated synthetic data for disfluency detection and removal (Bach and Huang, 2019; Dong et al., 2019; Wang et al., 2019). And so our third experiment evaluates whether synthetically-generated disfluencies can improve model performance.

We generate synthetic disfluencies for each fluent utterance in the ATIS train and dev set. While real disfluencies can be affected by several factors, such as sentence length (Shriberg, 1994), word frequency (Hartsuiker and Notebaert, 2009; De Jong, 2016), and cognitive load (Oviatt, 1995), we try to generate disfluencies with a simple method. This lets us generate disfluencies quickly, and also makes our generation process easy to replicate and transfer to new domains and languages. We leave research on the generation of more complex and linguistically-guided disfluencies for future work.

For each fluent utterance *u* we randomly generate one of 3 disfluent variations:

1. **Filled Pause:** Add 1 random filled pause per 10 words inserted after a random token in *u*. Example: *"um show me flights from denver"*
2. **False start repair:** Select a random second utterance *u2*. Take the first *n* tokens of *u2* (where *n* is a random number between 1 and

+ real + 100% synth	0.78	0.21

Table 5: A breakdown of performance on the disfluent subset comparing Filled Pauses (FPs) vs. Repairs for select models. Examples containing both filled pauses and repairs are excluded.

5, no larger than 60% of the tokens in *u2*) and prepend them to *u*, along with a random interregnum (e.g. 'sorry'), filled pause, or nothing. Example: *"what's the earliest flight mm show me flights from denver to philadelphia"*

3 **Repeat repair:** Split *u* after a random character, ensuring the final token of the first part *p1* is at least 2 characters long. We repeat up to 2 of final full tokens in *p1* then append the remainder *p2* with the complete token if split. Example: *"show me flights from denver to phila denver to philadelphia"*

Statistics about the synthetic disfluencies are in Table 2. We incrementally add between 1% to 100% of the disfluent examples into the original train and dev sets and fully retrain the model. We also train a model on only synthetic disfluencies.

The results in Table 4 show that adding 10% of the synthetic disfluencies has comparable performance to adding the same number of real disfluencies on the disfluent subset and has less degradation on the fluent test sets. A model trained entirely on synthetic disfluencies only achieves 41% exact-match accuracy and 64% slot accuracy on the disfluent subset, indicating there is still work to be done in creating more robust models and better synthetic disfluencies. The improvements of the synthetic models on the disfluent subset come at little to no cost on the fluent test sets. This lack of degradation supports our hypothesis that real disfluencies may add more noise at training time than synthetic disfluencies.

In Table 5, we see that the performance boost from synthetic examples comes mostly from better handling of repairs. For disfluent utterances containing filled pauses, real disfluencies alone can get high exact-match accuracy (72%), while the addition of synthetic data increases this up to 78%.

For models trained with either real or synthetic disfluencies, performance for repairs is worse than for filled pauses, with 12% accuracy with real disfluencies and up to 26% accuracy with synthetic disfluencies. This suggests that repairs are generally harder for our semantic parser to handle. Still, synthetic disfluencies outperform real disfluencies on repairs by up to 13%. For example, the partial word "*phoe*" in "*flight between dallas and phoe phoenix*" is correctly dropped by synthetic models, whereas models trained on fluent or real disfluencies mistake "*phoe*" for an airport code.

4.4 Experiment 4: Combining real and synthetic disfluent data

In our final experiment, we investigate whether real disfluencies contribute alongside synthetic examples. We combine the fluent ATIS examples with the real ATIS disfluencies and then incrementally add between 1% to 100% of the synthetic examples. The results are in Table 4. These results show an initial exact-match accuracy advantage on the disfluent subset from using real and synthetic examples. Models with real disfluencies and 1% of the synthetic disfluencies score higher than 1% of the synthetic disfluencies alone (0.33 vs. 0.20), but synthetic disfluencies alone outperform after 10%. Performance on the original test set and fluent subset remain low. These results reveal that even if a dataset of real disfluencies is available, it can still be better to add only simpler synthetic disfluencies to training data to avoid adding noise to the model.

5 Conclusion

In this work, we evaluate semantic parsing of disfluent utterances in the ATIS dataset. We highlight the importance of considering spoken language phenomena when building semantic parsers by showing that a state-of-the-art semantic parsing model trained on fluent data is not robust to naturally occurring speech disfluencies. Although the ATIS dataset is small, we present preliminary results showing that adding real or synthetic disfluencies at training time can significantly improve performance by up to 39%. While adding real disfluencies comes with degradation in performance on fluent utterances, adding synthetic disfluencies improves performance on disfluent utterances with almost no degradation on fluent utterances and requires no additional costs for annotations or labeling. These findings show that adding simpler, targeted synthetic disfluencies can be a practical and effective way to improve a semantic parser's performance on disfluent utterances. With the release of more and larger spoken language semantic parsing datasets in the future, we hope to replicate and strengthen our findings in future work.

Abstract

In this work, we explore joint energy-based model (EBM) training during the finetuning of pretrained text encoders (e.g., Roberta) for natural language understanding (NLU) tasks. Our experiments show that EBM training can help the model reach a better calibration that is competitive to strong baselines, with little or no loss in accuracy. We discuss three variants of energy functions (namely *scalar*, *hidden*, and *sharp-hidden*) that can be defined on top of a text encoder, and compare them in experiments. Due to the discreteness of text data, we adopt noise contrastive estimation (NCE) to train the energy-based model. To make NCE training more effective, we train an autoregressive noise model with the masked language model (MLM) objective.

1 Introduction

Calibration refers to how well a classification model's confidence (reflected by its output posterior probability) aligns with its actual accuracy. As deep learning models achieve amazing accuracy in computer vision (He et al., 2015) or natural language processing (NLP) (Liu et al., 2019; Devlin et al., 2018), more research attention has been drawn to the calibration aspect of these models. As shown by Guo et al. (2017), the high accuracy from deep models does not always lead to better calibration. This motivates an important line of works attempting to achieve a better trade-off between accuracy and calibration.

Most existing calibration methods (Guo et al., 2017; Kumar et al., 2019; Zadrozny and Elkan, 2001) generally rescale the posterior distribution predicted from the classifier after training. Such post-processing methods require a held-out development set with a decent number of samples to be available. To overcome this constraint, Jung et al. (2020) uses a penalty term to encourage better calibration during training.

In another line of work, Grathwohl et al. (2019) shows that one can jointly train an energy-based model (EBM) during the standard training of a neural classifier. Although calibration is not explicitly addressed during EBM training, the calibration of the resulting model is shown to be greatly improved. Some intuitions of the underlying reasons will be given in Section 2.3. However, the training framework proposed by Grathwohl et al. (2019) is designed for image classifiers, and it can not be readily applied to discrete text data.

In this work, we propose a framework that uses noise contrastive estimation (NCE) to jointly train an energy-based model during the finetuning of pretrained text encoders (e.g., BERT (Devlin et al., 2018) or Roberta (Liu et al., 2019)) for NLU tasks. We compare several variants of energy functions that can be defined on top of the encoder. Our experiments show that the resulting models achieve competitive calibration results comparing to strong baselines, with little or no loss in accuracy.

2 Framework

2.1 Notations and Background

We focus on the finetuning of pretrained text encoder on NLU tasks. We assume samples from the data distribution P_D are in the form of (x, y) pairs, where x usually refers to a single or a pair of sentences, and y refers to the corresponding label. The number of classes are denoted by $|Y|$.

Given input x, we first use a text encoder model (e.g., BERT or Roberta) to encode it and we denote this embedding as $\text{enc}(x)$. For the target classification task, a classifier f_{CLS}, which could be a simple linear transform or a multi-layer perception (MLP), will be applied to $\text{enc}(x)$. We denote the output

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1754–1761
April 19 - 23, 2021.

logits as $f_{\text{CLS}}(\text{enc}(x))$, whose dimension is equal to the number of possible classes $|Y|$. The y-th logit is denoted by $f_{\text{CLS}}(\text{enc}(x))[y]$. The posterior distribution $P_\theta(y|x)$ is obtained by applying a softmax operation to the logits, where θ refers to the parameters in the model.

In standard finetuning, the cross-entropy (CE) loss and gradient based optimizers are used to train the classifier:

$$\mathcal{L}_{\text{CE}} = \underset{(x,y)\sim P_D}{\mathbb{E}} (-\log P_\theta(y|x)). \tag{1}$$

In the next few sections, we discuss how we define and jointly train an EBM on top of the text encoder.

2.2 Definitions of Energy Function

An energy-based model (LeCun et al., 2006) expresses $P_\theta(x)$ as:

$$P_\theta(x) = \frac{\exp(-E_\theta(x))}{Z}, \tag{2}$$

where Z is the normalization factor, and is usually intractable to compute. We refer to $E_\theta(x)$, which returns a scalar value, as *the energy function*. We now define three variants of energy functions.

Variant *scalar*: We introduce another linear layer g_{S} whose output is a scalar. And we use it to define the energy function:

$$\hat{E}_\theta(x) = g_{\text{S}}(\text{enc}(x)). \tag{3}$$

Variant *hidden*: As pointed out by Grathwohl et al. (2019), there's an EBM "hidden" in every neural classifier with softmax output, and the energy function for x can be derived[1] as:

$$\hat{E}_\theta(x) = -\text{LogSumExp}_{y=1}^{|Y|}(f_{\text{CLS}}(\text{enc}(x))[y]). \tag{4}$$

Different from the *scalar* variant, here the energy function directly uses the logits for prediction (visualized in Figure 1). Hence the impact on the model's classification behavior could be larger.

Variant *sharp-hidden*: The *hidden* variant has a potential weakness that, the correlation between input x and the prediction y is not addressed because the energy is distributed among all the logits. Motivated by this potential issue, we propose the following "sharp" variant:

$$\hat{E}_\theta(x) = -\max_y f_{\text{CLS}}(\text{enc}(x))[y]. \tag{5}$$

Note that (5) can be viewed as an approximation to (4), and we find it to work well in practice.

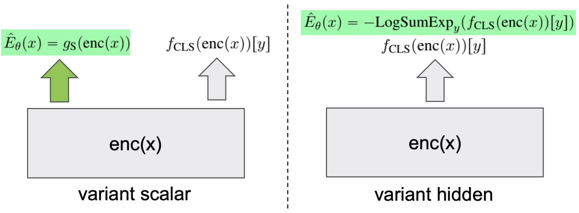

Figure 1: Comparison of the *scalar* and the *hidden* variants of energy functions. The modules introduced for EBM are shaded in green.

Finally, for each variant, we define the energy function to be $E_\theta(x) = \hat{E}_\theta(x) - \log P_N(x)$, where P_N is the *noise distribution* introduced for NCE. We will motivate this design choice below.

2.3 NCE Training

We use noise contrastive estimation (NCE) (Gutmann and Hyvärinen, 2010; Ma and Collins, 2018) to jointly train the energy model. NCE trains the model to discriminate between data samples and noise samples from a given noise distribution P_N. We formulate the NCE loss below:

$$\begin{aligned}\mathcal{L}_{\text{NCE}} = \underset{x_+\sim P_D}{\mathbb{E}} -\log \frac{\tilde{P}_\theta(x_+)}{\tilde{P}_\theta(x_+) + K \cdot P_N(x_+)} + \\ K \cdot \underset{x_-\sim P_N}{\mathbb{E}} -\log \frac{K \cdot P_N(x_-)}{\tilde{P}_\theta(x_-) + K \cdot P_N(x_-)},\end{aligned} \tag{6}$$

where K is the ratio of noise samples. Note that $\tilde{P}_\theta(x)$ does not need to be normalized by construction, therefore we set it to be $\tilde{P}_\theta(x) = \exp(-E_\theta(x))$. In our experiments, we mostly report results with noise ratio $K = 8$, while in some cases we find that a small ratio of $K = 1$ works slightly better. We have also tried with larger ratio such as 16, but the gain is minimal.

If we directly use the formulations of $\hat{E}_\theta(x)$ defined in last section as the energy function, the optimization will be difficult because of the $P_N(x)$ terms (which could be of very small value) in the NCE objective. To overcome this issue, we follow Deng et al. (2020) and define $E_\theta(x) = \hat{E}_\theta(x) - \log P_N(x)$. In this way, the $P_N(x)$ terms are canceled, and the objective is simplified to:

$$\begin{aligned}\mathcal{L}_{\text{NCE}} = \underset{x_+\sim P_D}{\mathbb{E}} -\log \frac{1}{1 + K \cdot \exp(\hat{E}_\theta(x_+))} + \\ K \cdot \underset{x_-\sim P_N}{\mathbb{E}} -\log \frac{K}{K + \exp(-\hat{E}_\theta(x_-))}.\end{aligned} \tag{7}$$

In training, we jointly optimize $\mathcal{L}_{\text{CE}}$ and $\mathcal{L}_{\text{NCE}}$ with the Adam optimizer (Kingma and Ba, 2014):

$$\mathcal{L}_{\text{joint}} = \mathcal{L}_{\text{CE}} + \mathcal{L}_{\text{NCE}}. \tag{8}$$

---

[1] Please see Appendix A for the detailed derivation.

Intuitively, joint EBM training makes the model aware of $P(x)$, instead of only focusing on predicting $P(y|x)$ as in standard finetuning. This awareness can potentially help with calibration because the model can be more conservative when it detects the input is out-of-distribution.

2.4 Construction of Noise Distribution

For the choice of noise distribution P_N, in our preliminary trials, we finetune the GPT-2 language model (Radford et al., 2019) with samples from the target training set using the standard LM objective. However during NCE training, we find that the energy model can easily discriminate between data samples and noise samples, which makes training ineffective. To alleviate this issue, we adopt an objective similar[2] to the masked language model (MLM) loss (Devlin et al., 2018) during the finetuning of the noise model (GPT-2): With a given mask ratio M, we randomly mask part of x, and train the model to complete it:

$$\mathcal{L}_{\text{MLM}} = \mathop{\mathbb{E}}_{x \sim P_D, x^m \sim P_{\text{mask}}(x^m|x;M)} -\log P_{\text{N}}(x|x^m). \quad (9)$$

During noise sample generation, adopting the same mask ratio M, we feed a masked x^m to the LM (x is from the training set), and use the generated sample as the noise sample. In this way, the noise distribution is made closer to the data distribution. In our experiments we set $M = 0.4$. During generation, we use top-k (Fan et al., 2018) sampling with $k = 20$. More details are provided in Appendix B.

3 Experiments

Setting We consider finetuning the Roberta-base model[3], on eight GLUE tasks (Wang et al., 2018). We do not include results on STS-B because it is a regression task. To measure calibration error, we follow Jung et al. (2020); Grathwohl et al. (2019) and use the expected calibration error (ECE) metric with B (number of bins) set to 20. To save space, we defer detailed definition of ECE to Appendix C.

For baseline or NCE training, we follow the recommended hyper-parameters (learning rate, batch size, etc.) for Roberta (Liu et al., 2019). Since NCE training requires more computation (because of the noise ratio), we have tried finetuning the baseline with more steps, but we find that gives worse ECE and very little or no improvement on accuracy.

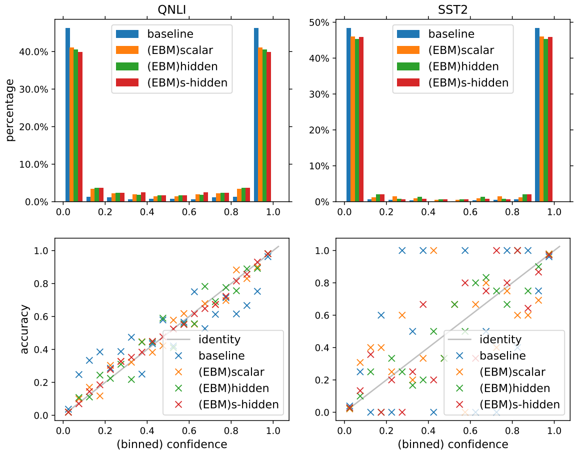

Figure 2: Visualization of calibration on QNLI and SST-2. In the histogram plots, we use 10 bins instead of 20 for better readability. An enlarged version of this figure is provided in Appendix D.

We compare EBM training with three strong baselines for calibration: *posterior calibrated training* (PosCal) (Jung et al., 2020), *temperature scaling* (T-Scal) (Guo et al., 2017), and *scaling-binning calibrator* (Scal-bin) (Kumar et al., 2019). For PosCal and Scal-bin, we use the published code.

Scal-bin and T-Scal require a development set for parameter learning and a test set for evaluation, but for each GLUE task we only have one labeled development set available. Therefore, in this work we treat half of the standard development set as test set, and keep the other half as development set.

Results In Table 1 and Table 2 we compare test-set accuracy[4] and ECE for different methods on the GLUE tasks. For fair comparison between Scal-bin / T-Scal and EBM training (which does not use the development set), we apply them to the whole training set. We also report their performance when applied to the development set for reference.

In most tasks, all three EBM variants get substantial improvement in ECE with little or no loss in accuracy comparing to the (strong) baseline methods. Moreover, the performance of EBM training is comparable to Scal-bin / T-Scal applied to the development set, while their performance degrades when the development set is not available. Among the three variants, on average, the *sharp-hidden* variant achieves the best accuracy, while the *hidden* variant achieves best calibration. We visualize the calibration error in Figure 2.

---

[2] The difference is that we still train the model to generate the full sentence, instead of only the masked words.

[3] Our code is based on `https://github.com/huggingface/transformers`.

[4] For CoLA we report with Matthews correlation coefficient (mcc).

Table 2: (Following Table 1) Main results on RTE and WNLI.

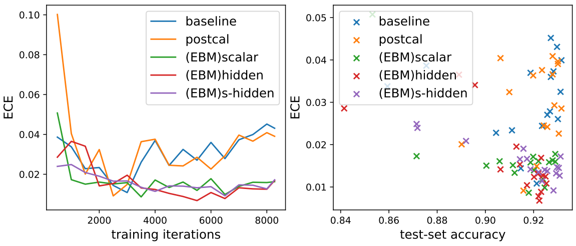

Figure 3: (QNLI) Left: How ECE changes during training. Right: The trade-off between accuracy and ECE for checkpoints (every 500 iterations) during training.

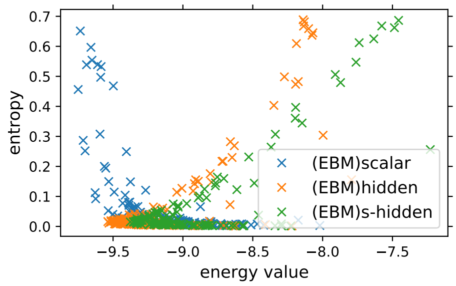

Figure 4: The entropy of the posterior ($P_\theta(\cdot|x)$) versus energy value $\hat{E}_\theta(x)$ for SST-2 test-set samples.

Text: *when the film ended, i felt tired and drained and wanted to lie on my own deathbed.* Label: 1 $\hat{E}_\theta(x)$: -9.37 Baseline: (.999, .001) → EBM: (.998, .002)
Text: *sit through this one, you won't need a magic watch to stop time; your dvd player will do it for you.* Label: 1 $\hat{E}_\theta(x)$: -7.57 Baseline: (.006, .994) → EBM: (.345, .655)

Table 3: The change of the model's confidence (posterior distribution) for low and high-energy data samples of SST-2. The EBM variant shown is *sharp-hidden*. We also provide QNLI examples in Appendix D.

In Figure 3, we plot how test-set ECE changes during training. It is shown as the training reaches the high-accuracy area, the calibration for baseline model becomes worse, while EBM training is able to reach a better trade-off between accuracy and calibration.

How does the model get better calibration? In Figure 4, we compute and plot the energy value $\hat{E}_\theta(x)$ versus the entropy of the posterior distribution $\mathcal{H}(P_\theta(\cdot|x)) = \sum_{y=1}^{|Y|} -P_\theta(y|x)\log P_\theta(y|x)$, for samples in the SST-2 test set. It is shown that models trained with the *hidden* and *sharp-hidden* variants tend to assign more conservative predictions (reflected by higher entropy) for higher-energy (less likely) samples. We suspect this is due to the strong coupling between the energy function and the classification logits. We provide concrete examples in Table 3. However, we need to mention that we do not observe this interesting trend (Figure 4) in all datasets (e.g., QNLI).

4 Related Works

Finally, we review applications of NCE or energy-based models in the NLP literature. Due to its self-normalizing property, NCE training has been used for faster inference (Mnih and Teh, 2012; Chen et al., 2015; Labeau and Allauzen, 2018) of autoregressive language models. It has also been used in an attempt to train a sentence-level bi-directional LM (He et al., 2016).

More closely related to our work, Deng et al. (2020) adopts NCE to train an EBM defined on top of a text encoder (the *scalar* variant), and uses it to improve language generation. EBM has also been recently used in non-autoregressive machine translation (Tu et al., 2020).

5 Conclusion

In this work, we explore joint EBM training during the finetuning of pretrained text encoders with noise contrastive estimation. We find that joint EBM training can greatly improve the calibration of NLU models, with little or no loss on accuracy.

Appendices

A Derivation of the *hidden* Variant

Remember from Section 2.1, the posterior distribution is obtained from a softmax operation on the logits, in other words:

$$P_\theta(y|x) \propto \exp(f_{\text{CLS}}(enc(x))[y]). \tag{10}$$

Without changing any parameters, one can reuse the logits to define an energy based model of the joint distribution of data point x and labels y via:

$$P_\theta(x, y) = \frac{\exp(f_{\text{CLS}}(enc(x))[y])}{Z(\theta)}, \tag{11}$$

where $Z(\theta)$ is the normalizing factor. Note that Equation 11 is **consistent** with Equation 10 in the sense that Equation 10 is a direct consequence of Equation 11.

Now by marginalizing out y, we get:

$$P_\theta(x) = \frac{\sum_{y=1}^{|Y|} \exp(f_{\text{CLS}}(enc(x))[y])}{Z(\theta)}, \tag{12}$$

which is equivalent to

$$P_\theta(x) = \frac{\exp(-E_\theta(x))}{Z(\theta)}, \tag{13}$$

where

$$E_\theta(x) = -\text{LogSumExp}_y(f_{\text{CLS}}(\text{enc}(x))[y]). \tag{14}$$

For more intuition behind this derivation we refer readers to Grathwohl et al. (2019).

B Details About the Noise Distribution

We show some examples of generated noise samples and the masking in Table 4. Note that the masks could be applied to a consecutive span of words (Masking is applied to each token independently with probability M).

Input: absolutely and completely `<M>` `(ridiculous)` **Gen:** absolutely and completely hilarious
Input: `<M>` `(as a)` young `<M>` `(woman)` of great charm, `<M>` `(generosity)` and diplomacy **Gen:** of a young man with a great charm, wit and diplomacy

Table 4: Example of generated noise samples on SST-2. The original words that are masked are also shown.

Another possible way to get noise samples is that we can sample from BERT or Roberta with masked input. However, due to the nature of masked language modeling and the architecture of BERT / Roberta, the sampled tokens will be independent of each other, which could result in unnatural noise samples. That is why we choose to utilize an auto-regressive LM (e.g., GPT-2).

C Definition of ECE

Given an input sample x, for each label y, we say that the model predicts that x belongs to label y with confidence $P_\theta(y|x)$. Assuming the test-set contains n samples, we will have $n \times |Y|$ predictions.

ECE first partitions all predictions into B equally-spaced bins by its confidence. Following Jung et al. (2020); Grathwohl et al. (2019), we set $B = 20$, which means the width of each bin is 0.05. For example, the first bin contains all predictions that have confidence in the range of $[0, 0.05)$. Then for each bin ECE computes how the average of confidence is different from its actual accuracy:

$$\text{ECE} = \frac{1}{|Y|} \sum_{y=1}^{|Y|} \sum_{b=1}^{B} \frac{|B_{yb}|}{n} |\text{acc}(B_{yb}) - \text{conf}(B_{yb})|, \tag{15}$$

where n is the number of samples in the test set, and $\text{acc}(B_{yb})$ is simply the ratio of samples (x) whose true label is indeed y in B_{yb}.

D Auxiliary Results and Examples

Examples of the model's confidence for low and high-energy data samples in QNLI are shown in Table 5.

The histogram of energy values $\hat{E}_\theta(x)$ for samples in the test set of QNLI and SST-2 are shown in Figure 5.

In Figure 6, we provide an enlarged version of Figure 2.

Text: *Q: What city north of New York was settled by Huguenots? A: Huguenot immigrants did not disperse or settle in different parts of the country, but rather, formed three societies or congregations; one in the city of New York, another 21 miles north of New York in a town which they named New Rochelle, and a third further upstate in New Paltz.* Label: 1 $\hat{E}_\theta(x)$: -8.48 Baseline: (.997, .003) → EBM: (.995, .005)
Text: *Q: What is the source of oxygen production through electrocatalytic means? A: A similar method is the electrocatalytic O2 evolution from oxides and oxoacids.* Label: 1 $\hat{E}_\theta(x)$: 4.22 Baseline: (.252, .748) → EBM: (.472, .527)

What Sounds “Right” to Me? Experiential Factors in the Perception of Political Ideology

Qinlan Shen

Carolyn P. Rosé
Carnegie Mellon University
cprose@cs.cmu.edu

Abstract

In this paper, we challenge the assumption that political ideology is inherently built into text by presenting an investigation into the impact of experiential factors on annotator perceptions of political ideology. We construct an annotated corpus of U.S. political discussion, where in addition to ideology labels for texts, annotators provide information about their political affiliation, exposure to political news, and familiarity with the source domain of discussion, Reddit. We investigate the variability in ideology judgments across annotators, finding evidence that these experiential factors may influence the consistency of how political ideologies are perceived. Finally, we present evidence that understanding how humans perceive and interpret ideology from texts remains a challenging task for state-of-the-art language models, pointing towards potential issues when modeling user experiences that may require more contextual knowledge.

1 Introduction

Social media companies, like Twitter, Facebook, and Reddit, play an important role in political discourse by providing a space for users to interact with different viewpoints. Understanding political discussion on these platforms often requires one to identify the ideologies behind texts, as understanding the viewpoints reflected in a text can provide insight into the partisanship of beliefs (Monroe et al., 2008) or the persuasive strategies used by different ideological groups (Tsur et al., 2015).

Prior research on political discussion often relies on a ”ground-truth” to aid in obtaining ideology labels for social media data. For example, due to the scale of political content on social media, a common paradigm is to obtain some ground-truth labels that are propagated to a larger set of texts using semi-supervised learning (Lin and Cohen, 2010; Zhou et al., 2011). The relationship between a social media artifact and various forms of established political knowledge can also be used to ground or validate ideology labels. Some examples of this include using author interactions with politicians with known party affiliations (Djemili et al., 2014; Barberá, 2015), ideological communities (Chandrasekharan et al., 2017; Shen and Rosé, 2019), and central users (Pennacchiotti and Popescu, 2011; Preotiuc-Pietro et al., 2017) as a starting heuristic, or evaluating a labeling approach by comparing geolocation tags attached to posts with historical voting patterns (Demszky et al., 2019).

A limitation of these approaches, however, is that behavior on social media does not evenly or uniformly reflect the held political beliefs of participants. While there is evidence that people tend to engage with others who share similar beliefs (Halberstam and Knight, 2016), people also commonly interact with or even seek out communities and users they do not agree with (Kelly et al., 2005; Tan et al., 2016). Additionally, the practice of displaying one’s political beliefs, which many grounding techniques rely on, varies in prevalence across online communities (Lampe et al., 2007; Zhong et al., 2017; Pathak, 2020). The concept of linguistic agency (Goffman et al., 1978) also challenges the idea that individual factors, such as ideology, are predictably presented in text. Based on an author’s social goals for participating in political discussion, it may not be contextually relevant to project a strong impression of their political ideology. People engaged in interactive political discussion, however, still form perceptions about the alignments of others based on how they sound, often relying on their own conceptions of ideology in the process.

The issue of perceiving ideology also plays a role when ideology labels are obtained using crowdsourced annotators. While making judgments, the

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1762–1771
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

annotator plays a similar role to a user participating in the discussion when perceiving the ideology of the speaker behind a text. However, annotators are expected to assign an explicit ideology label to a text with less contextual knowledge about how the text was produced. Thus, annotators may rely heavily on their own *experiential* factors, such as one's own beliefs or level of political engagement, when considering ideology. As a result, this process may introduce inconsistencies and biases in ideological labels used for political analysis.

In this paper, we present an exploration of how experiential factors play a role in how annotators perceive ideology in text. Building upon prior work investigating annotation bias (Zaidan and Callison-Burch, 2011; Waseem, 2016; Joseph et al., 2017; Ross et al., 2017; Schwartz et al., 2017; Geva et al., 2019), we construct an annotated corpus of posts from political subcommunities on Reddit but incorporate additional contextual information about the annotators making ideology judgments.[1] While previous work (Joseph et al., 2017) has shown that source-side contextual features, such as user profiles and previous tweets, can influence label quality in stance annotation, we focus our analyses on contextual factors on the side of annotators. Most similar to our work, Carpenter et al. (2017) and Carpenter et al. (2018) examine the impact of an annotator's identity and openness on their ability to accurately assess author attributes, including political orientation. In our work, however, we examine the impact of an annotator's political beliefs, knowledge, and Reddit familiarity, on their judgments, using factors more specific to political participation on Reddit. We additionally consider the issue of annotator bias in ideology labeling not as an issue of accuracy but rather an issue of social variability. Under this view, we evaluate the performance of a state-of-the-art language model on its capacity to mirror different human perceptions of ideology to examine whether extralinguistic factors introduced through annotation may degrade model performance compared to other labels.

2 Dataset Construction

Our dataset is drawn from the popular content aggregation and discussion platform Reddit. Political discussion on Reddit is centered on *subreddits*, subcommunities centered on support for specific political candidates, organizations, and issues. For our analyses, we aim to label political distinctions on Reddit along the left-right political spectrum in U.S. politics. Using the monthly dumps from May to September 2019 from the Reddit Pushshift API (Baumgartner et al., 2020), we collect all submissions and comments from the top political subreddits[2] by subscriber count. The collected subreddits were manually labeled as left or right, based on the subreddit description and top posts. We then select the top 12 left and top 12 right subreddits from the monthly dumps where discussion is primarily focused on U.S. politics.[3] The selected subreddits are shown in Table 3 (Supplementary Material).

2.1 Paired Ideology Ranking Task

Prior work on annotating viewpoints (Iyyer et al., 2014; Bamman and Smith, 2015) generally presents annotators with texts in isolation to label with an ideology of interest. One drawback of this approach is the high degree of political expertise annotators are required to have to recognize that a text matches an ideology. To reduce the amount of overhead in recruiting and training political annotators, we present annotators instead with a paired ideology ranking task. Rather than examining texts in isolation, annotators are shown two texts and asked to select the text that is more likely to be authored by someone with the ideology of interest.

For our setup, our goal is to pair a text authored by a left-leaning user with one by a right-leaning user. We use a heuristic-based semi-supervised approach to label texts based on the subreddit participation patterns of their authors. To expand the set of subreddits with ideological labels, we label all subreddits in the monthly dump data as left, neutral, or right based on user overlap with the 24 political subreddits with a known ideological slant (Section 2). For each subreddit, we calculate the z-score of the log odds ratio of a user participating in that subreddit and a known left-leaning subreddit vs. a right-leaning subreddit. A subreddit is labeled as either "left" or "right" if the calculated z-score satisfies a one-tailed Z test at $p = 0.05$ in the corresponding direction or "neutral" otherwise. Authors are then labeled based on their distribution of participation on the left vs. right subreddits. While

[2] `https://www.reddit.com/r/redditlists/comments/josdr/list_of_political_subreddits/`

[3] r/politics was not included due to its initial history as a default subreddit contributing to its high subscriber count.

users on Reddit have been shown to primarily engage with pro-social home communities (Datta and Adar, 2019) and similar heuristics have been used in prior work as an indicator of user interests and/or ideology (Olson and Neal, 2015; Chandrasekharan et al., 2017; Shen and Rosé, 2019), we emphasize that we use this heuristic to create a basis of comparison, rather than assuming that it provides "correct" ideology labels.

In order to ensure that the text comparison helps annotators to perceive ideological differences, rather than presenting two unrelated texts that are essentially considered in isolation, we want to present paired texts that are similar in content. As a first step for generating comparisons with similar content, we require paired texts to discuss the same entity, since political discussions are primarily centered on the politicians, organizations, and geopolitical entities influencing policy decisions. To identify entities of interest, we use Stanford Core NLP (Manning et al., 2014) to extract occurrences of people, locations, organizations, and ideologies over our corpus of 24 subreddits. We limit entities under consideration to those that have occurred at least 300 times in our corpus and are easy to disambiguate. The considered entities are shown in Table 4 (Supplementary Material).

To limit the impact of confounds, such as topic or entity salience, when comparing texts with the same entity, we use propensity score matching (Rosenbaum and Rubin, 1983) to match each left-aligned text with a right-aligned text that discusses the same entity in a similar context. A subset of 65 pairs was manually curated to use as screening questions to ensure that workers had a baseline knowledge of U.S. politics. These screening pairs were selected to be easier than the main task pairs – they are more limited in which entities discussed and express more explicit and/or extreme attitudes.

2.2 Annotation Task Details

We recruit workers on Amazon Mechanical Turk to complete our paired ideological ranking task. Given a pair of texts discussing the same highlighted political entity, we ask annotators to determine which of the two posts is more likely to have been written by someone who is either left-leaning or right-leaning. Annotators were instructed to use as many contextual cues as possible to form an impression of the political views held by the authors of the texts. To provide some guidance to annotators for what cues to consider, we train workers to consider the following features in the instructions:

- **Attitude:** evaluation in favor of or against an entity. Ex: *I trust Bernie* from someone who favors Bernie Sanders (left).
- **Positioning:** situating one's viewpoint with respect to the entity's. Ex: *Listen to the Dems* refers to Democrats as an out-group (right).
- **Jargon:** use of speciality in-group vocab. Ex: *Trump GEOTUS!* – "God-Emperor" abbreviation specific to Trump supporters (right).

The annotation task is shown in Figure 1 (Supplementary Material). Each worker was asked to annotate 18 pairs from our main task set and 8 screening questions, which were scattered throughout the assignment as an attention check. For each main task pair, we assign up to 5 workers for annotation. We restrict the worker pool to the U.S. and filter out workers who scored less than a 75% on the screening questions. Overall, we collect annotations for 630 non-screening pairs.

2.3 Annotator Background Post-Survey

After the annotation task, workers were asked to complete a survey (questions listed in Supplementary Material A) to assess their political affiliation, exposure to U.S. political news, and familiarity with political discussion on Reddit. Answers to the survey were inspected manually to assign annotators labels along three identifier categories:

- **Political ideology:** This category indicates the annotator's political ideology. Annotators are labeled as *left*, *center*, or *right* based on their self-identified ideology and affiliation with U.S. political parties.
- **News access:** This category indicates the annotator's exposure to political news. Annotators are labeled as *news* or *non-news* based on how frequently they access news on the 2020 U.S. presidential election.
- **Reddit familiarity:** This category indicates the annotator's familiarity with participation in political discussion on Reddit. Annotators are labeled as a *redditor* or a *non-redditor* based on their level of participation on Reddit in the past year. Redditors are further subdivided into *political* and *non-political* redditors based on their familiarity with the political subreddits included in our corpus.

		# workers	α
Overall	-	158	0.388
Ideology	left	89	0.427
	right	43	0.372
	center	26	0.325
News	news	126	0.393
	non-news	32	0.336
Reddit	redditor	114	0.393
	–political	86	0.389
	–non-political	28	0.430
	non-redditor	44	0.359

Table 1: Number of workers and Krippendorff's α agreement within the annotator groups over the full non-screening set. Agreement over other question sets can be found in Table 5 (Supplementary Material)

3 Dataset Statistics and Analysis

3.1 Annotator Demographics

Of the 180 recruited workers initially recruited for the task, 22 were discarded for answering fewer than 75% of the screening questions correctly, giving us a final pool of 158 annotators. Table 1 illustrates the distribution of the remaining workers across labels within the three categories. Labels across categories do not appear to be correlated (mean variance inflation factor = 1.043).

3.2 Agreement/Difference Results

We use Krippendorf's α (Krippendorff, 2004) to evaluate annotator agreement on our task to account for different user pools for each question. Despite a high degree of agreement across the pool of screening questions ($\alpha = 0.7311$), the overall agreement across annotators in our general, non-screening set is relatively low ($\alpha = 0.3878$), suggesting that the task of predicting the ideology of a text is nuanced and open to interpretation.

We also calculate agreement for workers within each of our annotator groups (Table 1) in order to examine whether annotators with similar backgrounds are more likely to perceive ideology similarly. Overall, in-group agreement remains around the same level as the general task. However, an interesting pattern across annotator labels is that workers who are less likely to be familiar with the expression of political ideology on Reddit – non-redditors ($\alpha = 0.359$), people who do not frequently read political news ($\alpha = 0.336$), and people who do not identify with the left or right ($\alpha = 0.325$) – have lower agreement. This suggests that familiarity with the norms of political discussion on Reddit may contribute to a more consistent perception of ideology for Reddit texts.

We additionally use McNemar's chi-squared test over pairwise comparisons of annotator groups under the same category to examine whether annotators with different backgrounds differ in their judgments. To ground the comparison, we evaluate annotator groups based on whether the majority of workers in the group gave the same answer as our semi-supervised labels (Section 2.1). Because these semi-supervised labels only provide a noisy estimate of ideology, we use these labels to create a basis of comparison. Rather than to check how "accurately" each group estimates ideology, this heuristic allows us to specifically quantify differences in judgments between groups. We find that for all comparison pairs, groups differ significantly in their answers over the same questions. In our pairwise comparisons, we also saw that the ideology of the annotator contributes heavily to variability in annotator judgments. The two groups with the highest percentage of questions with mismatched answers are left-leaning and right-leaning annotators, and 3 of the top 4 comparison pairs with the most mismatched answers are between ideology groups (Supplementary Material Table 6).

3.3 Sources of Variability

To examine possible explanations for the variability in annotator judgments across groups, we focus primarily on differences in judgments between left-leaning and right-leaning annotators. When examining differences at the entity-level, we find that the entities with the most mismatches tended to be highly visible entities that had a strong connection to a particular party during the 2020 election, such as highly visible political figures (e.g. Joe Biden, Nancy Pelosi) or the most common ideologies associated with each side (e.g. Republican Party, conservatism, liberalism), compared to less salient entities. This is unsurprising, as we expect people to develop different conceptions of salient entities building up to major events like elections, even with relatively limited media exposure.

Finally, to investigate what aspects of the posts themselves contributed to variations in judgments between left-leaning and right-leaning workers, we ran a salience (Monroe et al., 2008) analysis for mismatched question pairs with highly visible entities. We found that annotators were less likely to select a post that expresses explicit abuse towards an opposing entity as being authored by someone with the same political views as themselves. For example, a right-leaning annotator was less likely to consider a post calling Biden a "pedophile" as right-leaning compared to liberal annotator. This may suggest that social desirability bias (Krumpal, 2013), may have an impact on decision-making, even when the task is not directly related to collecting data about the annotator themselves.

4 Perceptions vs. Heuristic Labels

Prior work (Castelle, 2018) suggests that deep text classification models perform poorly when labels are influenced by extralinguistic contextual factors. While the semi-supervised labels that we generated are based on a behavioral heuristic outside of the text, our analyses of human judgments suggest that the annotation process introduced additional interactional factors into ideological labeling. We investigate whether these factors influence model performance by evaluating a BERT-based (Devlin et al., 2019) model on its ability to match human judgments on the paired ideology ranking task.

For our evaluation model, we finetune BERT-mask on the 24 subreddit corpus. Next, for each text, we average its contextual embeddings in two ways: over (a) all tokens in the text and (b) all entity-related tokens in the text. We then concatenate the averaged embeddings, then use the resulting vector as input to a pairwise logistic regression model. For each annotator group, we use the majority answer for each question as the group label.

Table 2 shows the performance of the model on the full 630 pair non-screening set. For all annotator groups, we found that the model has a significant drop in performance when asked to match human judgments vs. labels generated through our semi-supervised heuristic on the same dataset. To examine whether this drop in performance was due to inconsistencies in human judgments on particularly difficult or contentious distinctions, we additionally present results on a higher consensus subset ($\alpha = 0.6216$) of 459 text pairs, where at least 75% of workers select the same answer. We found that while there was a small increase in performance on matching human judgments on the high consensus subset for all groups, performance still dropped compared to the semi-supervised labels, suggesting that matching human understanding of ideology is challenging for these models.

	SS (F)	**H (F)**	**SS (C)**	**H (C)**

5 Conclusion and Future Work

In this paper, we reconsider the idea of ground-truth labels of political ideology and investigate the impact of experiential factors on human perception of ideology in text. We construct and analyze an annotated corpus that incorporates experiential information about annotators, finding evidence that annotator backgrounds influence the consistency of political ideology judgments and that current classification models struggle to match human perceptions of ideology across different groups. From our analyses on factors contributing to variations in judgments, there is a greater need for targeted recruiting of annotators that are familiar with and contextualized to the domain being annotated. In future work, we aim to extend our investigation to examine how stylistic elements of text contribute to people's perception of political ideologies in interaction. These analyses may provide further insight into the effectiveness of political communication strategies or the differences in how political groups interact with in-group and out-group members.

○ Post 2

Figure 1: Screenshot of a question in the paired ideological annotation task. Annotators are presented with two texts discussing the same highlighted entity in a similar context, one from a left-leaning user and another from a right-leaning user based on a semi-supervised labeling heuristic. Annotators are asked to select which of the two texts is more likely to be authored by someone with the highlighted ideology.

A Survey Questions

A.1 Political ideology

1. Please indicate where you identify on the liberal-conservative spectrum.
    - Liberal
    - Somewhat liberal
    - Moderate
    - Somewhat conservative
    - Conservative
    - I don't know
2. Please indicate how strongly you identify with the following U.S. political parties.
    - Parties
        - Democratic Party
        - Republican Party
        - Libertarian Party
        - Green Party
        - Constitution Party
        - Democratic Socialists of America
        - Reform Party
    - Responses
        - I do not identify with this party
        - Somewhat identify
        - Identify
        - Strongly identify
        - I don't know

A.2 News access

1. On average, how often did you check the news related to the 2020 presidential election in the U.S. in the past year?
    - Never
    - Less than once a month
    - A few times a month
    - Once a week
    - Several times a week
    - Once a day
    - Several times a day

A.3 Reddit familiarity

1. On average, how often have you visited Reddit in the past year?
    - Never
    - Less than once a month
    - A few times a month
    - Once a week
    - Several times a week
    - Once a day
    - Several times a day
2. On average, how often have you posted content to Reddit in the past year?
    - Never
    - Less than once a month
    - A few times a month
    - Once a week
    - Several times a week
    - Once a day
    - Several times a day
3. Please indicate your familiarity with the following subreddits (listed in Table 3).
    - I have never heard of this subreddit
    - I have heard of but never accessed this subreddit
    - I have accessed or posted on this subreddit at least once
    - I sometimes access or post on this subreddit
    - I often access or post on this subreddit

Language Models as Knowledge Bases:
On Entity Representations, Storage Capacity, and Paraphrased Queries

Benjamin Heinzerling[1, 2] and **Kentaro Inui**[2, 1]
[1]RIKEN AIP & [2]Tohoku University
benjamin.heinzerling@riken.jp | inui@tohoku.ac.jp

Abstract

Pretrained language models have been suggested as a possible alternative or complement to structured knowledge bases. However, this emerging LM-as-KB paradigm has so far only been considered in a very limited setting, which only allows handling 21k entities whose name is found in common LM vocabularies. Furthermore, a major benefit of this paradigm, i.e., querying the KB using natural language paraphrases, is underexplored. Here we formulate two basic requirements for treating LMs as KBs: (i) the ability to store a large number facts involving a large number of entities and (ii) the ability to query stored facts. We explore three entity representations that allow LMs to handle millions of entities and present a detailed case study on paraphrased querying of facts stored in LMs, thereby providing a proof-of-concept that language models can indeed serve as knowledge bases.

1 Introduction

Language models (LMs) appear to memorize world knowledge facts during training. For example, BERT (Devlin et al., 2019) correctly answers the query "Paris is the capital of [MASK]" with "France". This observation prompted Petroni et al. (2019) to ask if LMs can serve as an alternative or complement to structured knowledge bases (KBs), thereby introducing the idea of treating LMs as KBs: During training, the LM encounters world knowledge facts expressed in its training data, some of which are stored in some form in the LM's parameters. After training, some of the stored facts can be recovered from the LM's parameters by means of a suitable natural language query (Fig. 1). A LM with such a "built-in" KB is useful for knowledge-intensive tasks (Petroni et al., 2020) and question answering (Roberts et al., 2020), and could improve natural language interfaces to structured data (Hendrix et al., 1978; Herzig et al., 2020).

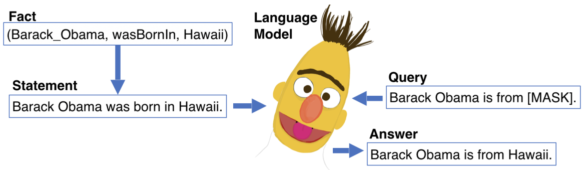

Figure 1: The LM-as-KB paradigm, introduced by Petroni et al. (2019). A LM memorizes factual statements, which can be queried in natural language.

However, this emerging LM-as-KB paradigm is faced with several foundational questions.

First question: KBs contain millions of entities, while LM vocabulary size usually does not exceed 100k entries. **How can millions of entities be represented in LMs?** Petroni et al. (2019) circumvent this problem by only considering 21k entities whose canonical name corresponds to a single token in the LM's vocabulary, e.g., entities like "France" or "Bert", but not "United Kingdom" or "Sesame Street". Hence, this approach cannot handle entities not contained in the vocabulary and a query like "Bert is a character on [MASK]" is not answerable in this simplified setting. To answer this first question, we compare three methods for scaling LM-as-KB to millions of entities:

1. Symbolic representation, i.e., extending the LM vocabulary with entries for all entities;
2. Surface form representation, i.e., each entity is represented by its subword-encoded canonical name, which is stored and queried by extending the LM with a sequence decoder; and
3. Continuous representation, i.e., each entity is represented as an embedding.

We find that, while all three entity representations allow LMs to store millions of world-knowledge facts involving a large number of entities, each representation comes with different trade-offs: Sym-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1772–1791
April 19 - 23, 2021.

bolic representation allows the most accurate storage, but is computationally expensive and requires entity-linked training data. Surface representation is computationally efficient and does not require entity-linked data, but is less accurate, especially for longer entity names. Continuous representation also requires entity-linked data, but is computationally more efficient than symbolic representation.

Second question: **What is the capacity of LMs for storing world knowledge?** Can a LM store, say, all relation triples contained in a KB like Wikidata (Vrandečić and Krötzsch, 2014)? Here we conduct experiments using synthetic data to study the scaling behaviour of current LM architectures. Varying the number of trainable model parameters and recording the number of relation triples memorized at a given accuracy level, we find that, e.g., a Transformer (Vaswani et al., 2017) with 125 million parameters (12 layers of size 768), has the capacity to memorize 1 million Wikidata relation triples with 95 percent accuracy or 5 million relation triples with 79 percent accuracy. Assuming linear scaling, this finding suggests that larger LMs with tens or hundreds of billions of parameters (Raffel et al., 2019; Brown et al., 2020) can be used to store sizable parts, if not all, of a KB like Wikidata.

Third question: **How robustly is world knowledge stored in LMs?** Is the LM able to recall a fact even if the query is slightly different than what was memorized during training? For example, if the LM memorized "Barack Obama was born in Hawaii" during training, can it answer queries like "Barack Obama is from [MASK]" or "Where was Barack Obama born? [MASK]"? Here we conduct experiments to measure how well the LM transfers knowledge from memorized statements to query variants, both in a zero-shot setting in which the model is not exposed to the target query variant during training, and a few shot setting, in which the model is finetuned on a small number of statements containing the target query variant. We observe zero-shot transfer in case of highly similar query variants, and see successful few-shot transfer after finetuning with 5 to 100 instances in case of less similar queries. This ability to handle soft, natural language queries, as opposed to hard, symbolic queries in a language like SQL or SPARQL, is one of the key motivations for using LMs as KBs.

Contributions. We formulate two requirements for treating LMs as KBs: (i) the ability to store a large number of facts involving a large number of entities and (ii) the ability to query stored facts. After providing background on world knowledge in LMs (§2), we make the following contributions:[1]

- A comparison of entity representations for scaling LM-as-KB to millions of entities (§3);
- Empirical lower bounds on LM capacity for storing world knowledge facts (§4); and
- A controlled study of knowledge transfer from stored facts to paraphrased queries (§5).

Terminology. In this work we are interested in storing and retrieving world knowledge facts in and from a LM. **World knowledge** is knowledge pertaining to entities, such as Barack_Obama. A **fact** is a piece of world knowledge that can be expressed with a concise natural language **statement**, such as the English sentence *Barack Obama was Born in Hawaii*, or with a **relation triple**, such as ⟨Barack_Obama, wasBornIn, Hawaii⟩. A relation triple, or relation for short, consists of a **subject** entity (Barack_Obama), a **predicate** (wasBornIn), and an **object** entity (Hawaii). A **knowledge base** is a set of relations. Knowledge bases, such as Wikidata, typically contain thousands of predicates, millions of entities, and billions of relations.

2 World Knowledge in Language Models

Large pretrained LMs have been the driver of recent progress in natural language processing (Peters et al., 2018; Howard and Ruder, 2018; Radford et al., 2019; Devlin et al., 2019). While the trend towards larger LMs is likely to continue (Raffel et al., 2019; Kaplan et al., 2020; Brown et al., 2020), it has limitations: (i) A model trained only on text lacks grounding in perception and experience and hence cannot learn meaning (Bender and Koller, 2020). (ii) Reporting bias leads to certain knowledge rarely or never being expressed in text. For example, a LM will easily learn to associate the phrase "Barack Obama" with the phrase "U.S. President", but might less likely learn that he is a "human being", since the latter fact is rarely stated explicitly in text. In contrast, this type of knowledge is readily available in KBs. (iii) A large number of rare entities (Hoffart et al., 2014; Derczynski et al., 2017; Ilievski et al., 2018) are, by definition, rarely mentioned, making it difficult for

---

[1] Code available at:
`https://github.com/bheinzerling/lm-as-kb`

LMs to acquire knowledge about this long tail of entities from text alone.

These limitations have motivated efforts to explicitly[2] equip LMs with world knowledge. Table 2 (Appx. A) situates these efforts on a spectrum from purely text-based LMs to representations of structured KBs. Models based on text generation (Raffel et al., 2019; Roberts et al., 2020) and retrieval (Guu et al., 2020) have proven most successful in knowledge-intensive tasks. However, we argue that models which reify entities (Logan et al., 2019), i.e., models in which entities are "first-class citizens" that can be directly predicted[3], are a promising research direction, since the direct links into a KB can be seen as a form of grounding. This is one of our main motivations for considering symbolic and continuous entity representations.

3 Entity Representations

How can millions of entities be represented in a LM? To answer our first question, we compare three types of entity representations: symbolic, surface form, and continuous.

Experimental setup. We evaluate entity representations by measuring how well they allow a LM to store and retrieve world knowledge facts. For example, if the LM's training data contains the statement "Bert is a character on Sesame Street", the model should memorize this statement and recall the correct object Sesame_Street when asked with a query like "Bert is a character on [MASK]."

Synthetic data. It is not a priori clear how many facts a text from the LM's training data, say, a Wikipedia article, expresses. Since we want to precisely measure how well a LM can store and retrieve facts, we create synthetic data by generating statements from KB relations and then train the model to memorize these statements. Using Wikidata as KB, we first define two sets of entities: A smaller set consisting of the top 1 million Wikidata entities according to node outdegree, and a larger set consisting of the roughly 6 million Wikidata entities that have an entry in the English Wikipedia.

Next, we manually create templates for the 100 most frequent Wikidata predicates. For example, for the predicate P19 ("place of birth"), we create the template *S was born in O* and generate English statements by filling the *S* and *O* slots with entities from the sets defined above for which this relation holds.[4] To make queries for an object unique given subject and predicate, we arbitrarily select exactly one fact if there are multiple objects and discard the other facts. This process yields 5 million statements involving up to 1 million entities, and 10 million statements involving up to 6 million entities. These statements then serve as training instances, i.e., given the query "Barack Obama was born in [MASK]", the model should predict Hawaii. As our goal is to store facts in a LM, there is no distinction between training and test data.

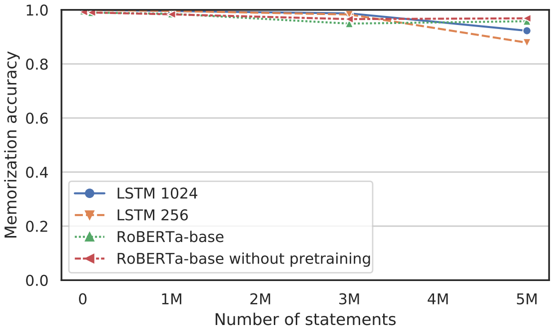

Figure 2: Accuracy of statement memorization with symbolic representation of 1 million entities.

Models and training. We consider two common LM architectures: LSTMs (Hochreiter and Schmidhuber, 1997) and Transformers (Vaswani et al., 2017). For LSTMs, we compare two configurations; a randomly initialized two-layer LSTM with layers size 256 (*LSTM 256*) and one with layer size 1024 (*LSTM 1024*). For Transformers, we compare a pretrained RoBERTa-base (Liu et al., 2019), and RoBERTa without pretraining, i.e., a randomly initialized Transformer of the same size. For consistent tokenization across all four models, we subword-tokenize statements with the RoBERTa tokenizer. To store statements in a LM, we train until the model reaches 99 percent memorization accuracy, i.e., overfits the training data almost perfectly, or stop early if accuracy does not improve for 20 epochs. See Appx. D for training details.

3.1 Symbolic Representation

With symbolic representation, each entity is represented as an entry in the LM's vocabulary. Prediction is done via masked language modeling (Devlin et al., 2019), by encoding the query with the LM, projecting the final hidden state of the [MASK] token onto the vocabulary and then taking a softmax

---

[2] As opposed to the LM acquiring world knowledge implicitly as a side effect of its training objective.

[3] As opposed to generating or retrieving a surface form which may or may not correspond to an entity.

[4] Templates and sample of statements in Appx. B and C.

over the vocabulary. As the results show (Fig. 2), symbolic representation yields very high memorization accuracies with a vocabulary of 1 million entities. Randomly initialized RoBERTa-base without pretraining works best, memorizing 97 percent of 5 million statements correctly.

Unfortunately, the softmax computation becomes prohibitively slow as the vocabulary size increases (Morin and Bengio, 2005), making symbolic representation with a softmax over a vocabulary consisting of the full set of 6 million Wikipedia entities impractical. Imposing a hierarchy is a common approach for dealing with large vocabularies, but did not work well in this case (See Appx. F.1).

3.2 Surface Form Representation

With surface form representation, each entity is represented by its canonical name.[5] Since this name generally consists of more than one token, we cast memorizing statements and querying facts as a sequence-to-sequence task (Sutskever et al., 2014): Given the source sequence “Bert is a character on [MASK]”, the model should generate the target sequence “Sesame Street”.[6] To make models memorize statements, we train until perplexity on the training data reaches 1.0 or does not improve for 20 epochs. For evaluation, we generate the target sequence – i.e., the answer to a given query – via a beam search with beam size 10. We measure perfect-match accuracy of the full entity name, i.e., there is no credit for partial token matches.

The four models under comparison are now treated as sequence-to-sequence encoders and extended with a decoder of the same size: LSTM decoders for LSTM encoders (*LSTM2LSTM*) and randomly initialized Transformers for Transformer encoders (*RoBERTa2Transformer*, *Transformer2Transformer*).

Unlike symbolic representation, surface representation can handle the entire set of 6 million Wikipedia entities. As with symbolic representation, the randomly initialized Transformer (Fig. 3, dash-dotted red line) has the highest capacity, memorizing 10 million statements with 90 percent accuracy. A pretrained encoder (*RoBERTa2Transformer*) appears to have a deleterious effect, yielding lower accuracies than the randomly initialized *Transformer2Transformer*. While the larger *LSTM2LSTM* (layer size 1024) almost matches the performance of the best Transformer model, the smaller one (layer size 256) has insufficient capacity, memorizing less than 50 percent of 5 million statements.

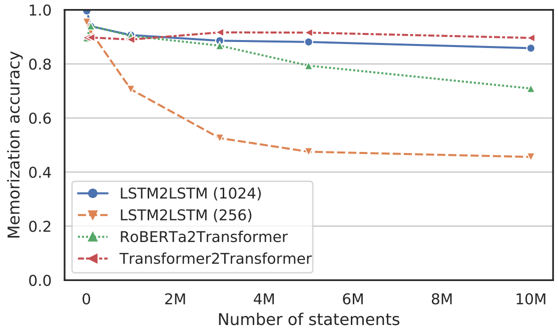

Figure 3: Accuracy of statement memorization with object entities represented by surface forms.

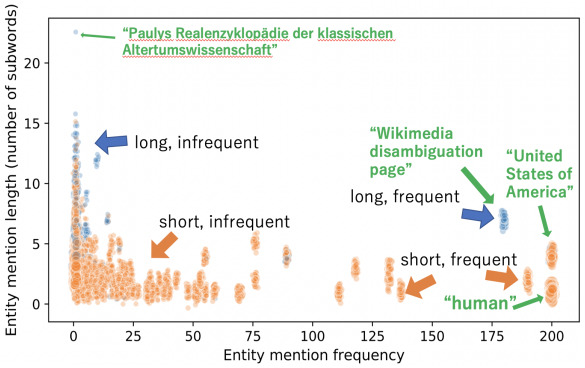

Figure 4: Error analysis of statements memorized via surface form representation. Correctly memorized statements orange, wrong ones blue. Selected clusters are annotated with the statement’s object entity (green). Frequencies clipped to 200, jitter applied for clarity.

Analysis of the Transformer2Transformer model (Fig. 4) reveals, perhaps unsurprisingly, that statements involving infrequent, long entity mentions are difficult to memorize.[7] For example, the model fails to memorize most entity mentions that occur only in one to ten statements and have a length of 12 or more subwords (blue cluster, upper left).

3.3 Continuous Representation

With continuous representation, an entity $e_i, i \in [1, N_{entities}]$ is represented by a d-dimensional embedding $\mathbf{y}_i \in \mathbb{R}^d$. After encoding a query with the LM, prediction is performed by projecting the final hidden state corresponding to the [MASK]

---

[5] We use English Wikidata labels as canonical names.

[6] The [MASK] token is included since the target entity does not always occur at the end of a statement.

[7] We speculate that this drawback can be mitigated by shortening canonical names while ensuring a one-to-one mapping to entities, but leave this to future work.

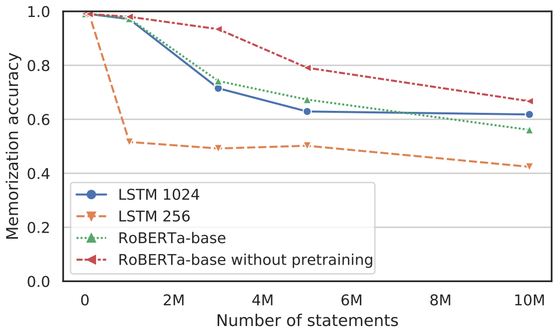

Figure 5: Accuracy of statement memorization with continuous entity representation.

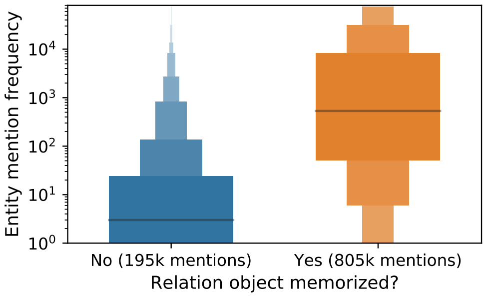

Figure 6: Error analysis of a sample of 1 million statements memorized by a randomly initialized Transformer with continuous representation.

token onto $\mathbb{R}^d$, obtaining the predicted embedding $\hat{\mathbf{y}} \in \mathbb{R}^d$. We use fixed, pretrained entity embeddings and train with cosine loss $L = 1 - \cos(\hat{\mathbf{y}}, \mathbf{y_i})$. At test time, the model prediction $\hat{\mathbf{y}}$ is mapped to the closest pretrained entity embedding $\mathbf{y}_i$ via nearest-neighbor search (Johnson et al., 2017).

Continuous prediction with fixed, pretrained embeddings. When training randomly initialized embeddings with a similarity objective, a degenerate solution is to make all embeddings the same, e.g., all-zero vectors. To prevent this, it is common practice to use negative samples (Bordes et al., 2013). When using fixed, pretrained embeddings as supervision signal, negative sampling is not necessary, since the target embeddings are not updated and therefore cannot become degenerate.

Wikidata embeddings. We train embeddings for 6 million Wikidata entities using feature-specific autoencoders to encode entity features such as names, aliases, description, entity types, and numeric attributes, following prior work on multi-modal KB embeddings (Pezeshkpour et al., 2018) and KB embeddings with autoencoders (Takahashi et al., 2018). Embedding training is detailed in Appx. E.

Results. Fig. 5 shows memorization accuracies achieved with continuous representation. Like surface representation, continuous representation scales to 6 million entities, and we see the same relative order of models, but with overall lower accuracies. RoBERTa without pretraining has the highest capacity for storing world knowledge statements, memorizing 67 percent of 10 million statements, while the small LSTM 256 model has the lowest capacity, memorizing 42 percent. Although far from fully understood, sequence-to-sequence architectures are relatively mature, with highly-optimized toolkits and hyperparameter settings publicly available (Ott et al., 2019). In contrast, prediction of continuous representations is still in an early stage of research (Kumar and Tsvetkov, 2019). We therefore see these results as lower bounds for LM capacity with continuous representations.

By design, memorization with continuous representations does not rely on entity names, and hence, in contrast to surface form representation, does not lead to difficulties in handling entities with long names. However, as with surface form representation, infrequent entities are more difficult to memorize than frequent ones. Most of the memorization errors (Fig. 6, blue, left) involve infrequent entities with a median frequency of 3, while most of the correctly memorized statements (orange, right) involve entities that occur more than 100 times.

4 LM Capacity for Storing Facts

We now turn to the second question, how model capacity scales with model size (Fig. 7, top). With a 12-layer Transformer of layer size 96 or 192 (top subfigure, solid red and dashed green lines), memorization accuracy quickly drops as the number of facts to memorize increases. Larger models can memorize more facts, but accuracy drops rather quickly, e.g., to 65 percent of 3 million facts memorized with a layer size of 384 (dotted orange line).

Assuming a desired memorization accuracy of 80 percent, we record the maximum number of facts a model of a given size can memorize at this level (Fig. 7, bottom). For the model sizes considered here, storage capacity appears to scale linearly, with a model of layer size 384 (55M parameters) storing one million facts and a model of layer size 960 (160M parameters) storing 7 million facts.

Apart from the number of facts to store, we hypothesize that successful storage depends on two more factors: the number of entities and the en-

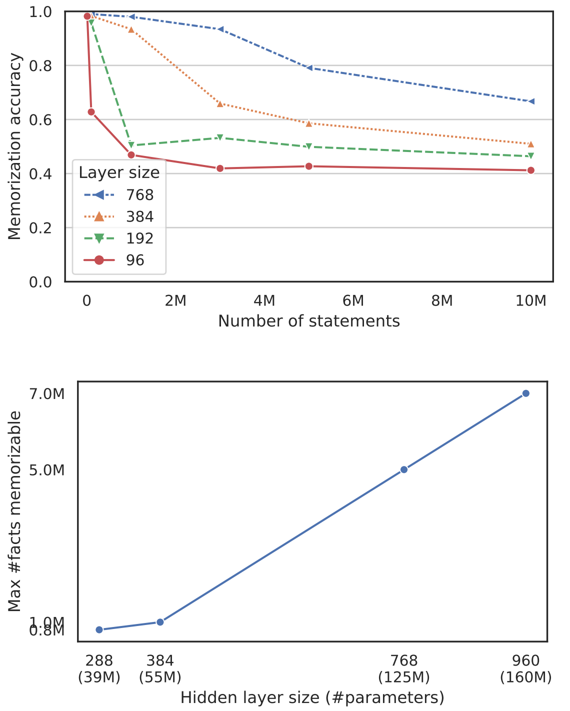

Figure 7: Scaling of storage capacity with model size. Memorization accuracy decreases as the number of facts grows (top). The maximum number of facts a model of a given layer size (parameter count) can memorize with an accuracy of 80 percent increases linearly (bottom). All models are 12-layer Transformer with continuous representation of 6 million entities.

Representation	Accuracy 1M	 6M
Symbolic	0.97	n/a
Surface	0.92	0.90
Continuous	0.85	0.79

Table 1: The number of entities (1M or 6M) impacts memorization accuracy. The model is a 12-layer Transformer, layer size 768, memorizing 1 million facts.

tropy of their distribution. As expected, a large number of entities makes memorization more difficult (Table 1). The number of entities has a small effect with surface representation (2 percent drop), but with continuous representation accuracy drops from 85 percent to 79 percent when the number of entities increases from 1 to 6 million. We also observe an impact of the entity distribution (Appx. G), but leave detailed analysis to future work.

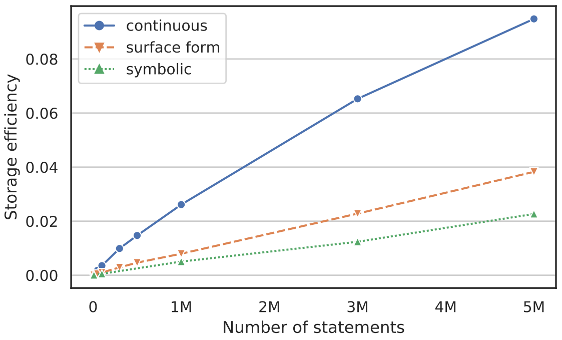

Figure 8: Storage efficiency with symbolic, surface form, and continuous representation of entities. In the setting considered in this work, continuous representation is most efficient.

4.1 Storage Efficiency

Our comparison of different entity representations (§3) does not control for the number of trainable model parameters. That is, we selected common architectures, such as a Transformer with 12 layers of size 768, but made no effort to ensure that, e.g., the number of trainable parameters introduced by the softmax layer in a model with symbolic representation matches the number of trainable parameters introduced by the addition of a sequence-to-sequence decoder component in a model with surface form representation. In order to more fairly compare entity representations across models with differing numbers of trainable parameters, we formulate the *storage efficiency* of a model designed to memorize statements:

$$\text{Storage efficiency} = \frac{\#statements \times accuracy}{\#parameters}$$

This measure expresses the intuition that a model is efficient if it requires few parameters to memorize a large number of statements with high accuracy. When quantifying efficiency with this measure, we find that continuous representation is the most efficient (Figure 8) and hence use this form of entity representation in the remainder of this work.

5 Querying Stored Facts

So far, we saw that it is possible to store millions of facts in a LM, by finetuning the model to predict the masked object of statements like *Barack Obama was born in [MASK]*. However, given the large number of model parameters and training effort, mere storage is not a compelling achievement: The underlying relations, here ⟨Barack_Obama, wasBornIn, Hawaii⟩, can be stored more compactly and with perfect accuracy in a structured KB.

One of the potential benefits of the LM-as-KB paradigm is the LM's ability to handle paraphrases. If the LM's representation of the statement above is sufficiently similar to its representation of queries like *Barack Obama is from [MASK]* or *Where is Barack Obama from? [MASK]*, this similarity could allow transfer from the memorized statement to these unseen queries. Is this soft querying of facts stored in a LM possible? We now conduct a controlled experiment to answer this question, expecting one of the following three outcomes:

1. **Rote memorization**. The model memorizes statements with little or no abstraction, so that even small, meaning-preserving changes to the query prevent the model from recalling the correct object.
2. **Generic association**. The model memorizes pairs of subject and object entities but disregards the predicate. For example, a model might predict Hawaii whenever the query contains the phrase *Barack Obama*, regardless of context. This pathological behaviour could be especially prevalent if the distribution of object entities co-occurring with a given subject is dominated by one object.
3. **Fact memorization**. The model memorizes facts expressed in statements by forming abstractions corresponding to entities and predicates. This allows retrieving a fact with a variety of queries.

Sections 3 and 4 already established that a model of sufficient size can perform rote memorization of millions of statements. We now design an experiment to test whether LMs are capable of fact memorization while taking care to distinguish this capability from generic association. Concretely, our goal is to test if a LM that has memorized a statement like *Barack Obama was born in Hawaii* can use this knowledge to answer a query like *Barack Obama is from [MASK]*. Conveniently, wasBornIn relations are among the most frequent in Wikidata and hold for a diverse set of subject and object entities. This diversity of entities makes this predicate a good candidate for our case study, since statements involving a predicate with a less diverse set of subject or object entities are easier to memorize.[8]

Statements and controls. We sample 100k statements generated by the template "S was born in O". To allow distinguishing if a model that memorizes these 100k facts does so by generic assocation or by fact memorization, we introduce *control* facts. Given a fact ⟨S, P, O⟩, its control ⟨S, P', O'⟩ involves the same subject S, but a distinct predicate P' and object O'. For example, a control for the fact ⟨Albert_Einstein, wasBornIn, Ulm⟩ is the fact ⟨Albert_Einstein, diedIn, Princeton⟩. We add 100k control statements generated from the template "S died in O"' and train RoBERTa-base to memorize all 200k statements with 98 percent accuracy. The combination of statements and controls counters generic association: To correctly answer the query "Albert Einstein died in [MASK]", the model needs to take into account the predicate, since two distinct objects are associated with Albert_Einstein.

Query variants. Next, we collect query variants, such as "S is from O" (row labels in Fig. 9, top). Expecting good transfer for variants that are similar to the original statement, we include variants with small changes, such as varying punctuation. As more diverse variants, we select frequent relation patterns, such as "S (b. 1970, O)", from the GoogleRE Corpus (Google, 2013), as well as a query in question form and queries with irrelevant or misleading distractors such as "S was born in O, but died somewhere else". For each variant, we generate 100k queries by filling the S and O slots with the same entity pairs as the original statements. To balance statements and controls, we create control templates (row labels in Fig. 9, bottom) and generate a matching number of control statements.

Transfer results. We evaluate knowledge transfer from memorized statements to query variants using RoBERTa-base (Fig. 9, top, left), measuring accuracy over the 100k statements generated with a target query variant template. To measure the effect of pretraining on transfer ability, we compare to RoBERTa-base without pretraining (Fig. 9, top, right). We consider zero-shot transfer without any finetuning towards the target query variant, and a finetuning setting, in which the LM is first trained to memorize all 100k original statements and then finetuned until it memorizes a small number of statements in the target query format.[9]

In the zero-shot setting (leftmost column), even small changes to the query lead to a drop in fact recall: Adding an ellipsis (4th row) causes the model to answer 95% of queries correctly, a 3% drop from 98% memorization of the original statements (first row). Adding an exclamation mark (5th row) results in a 8% drop. For other paraphrases, e.g., *S, who is from O* (7th row) and *S is from O*, zero-shot transfer works only in 35% and 20% of cases, and

---

[8] For example, with the predicate isA and relations like ⟨Barack_Obama, isA, human⟩ the model would do well by always predicting human if the subject mention matches a frequent person name pattern such as "two capitalized words".

[9] Our experiments, which test whether a LM can transfer a memorized fact to given target paraphrases, are converse to the probing setup by Jiang et al. (2020), which aims to find the best paraphrase for querying a given fact from a LM.

After their death in O , S was	0.00	0.00	0.00	0.01	0.00	0.00	0.03	0.03
S , who spent the last days of their life in O	0.03	0.02	0.01	0.02	0.03	0.08	0.27	0.60
S spent the last days of their life in O	0.03	0.02	0.02	0.01	0.04	0.02	0.18	0.63

Figure 9: Transfer from memorized statements (top: "S was born in O", bottom: "S died in O") to query variants.

the question format (11th row) allows zero-shot transfer with 32% accuracy. For the remaining paraphrases, e.g., those with parentheticals or the distractor *died*, zero-shot transfer is poor, with accuracies ranging from 3% to 13%.

A clear trend is visible: transfer works best for similar statements and worst for dissimilar ones. To quantify this trend, we compute a representation of a statement template by averaging over its 100k mean-pooled, LM-encoded statements, and then measure the Euclidean distance between the original template representation and the representation of a query variant template. Correlating Euclidean distance and accuracy of zero-shot transfer obtains a Pearson coefficient of -0.68, indicating a strong negative correlation. That is, transfer tends to work well for paraphrased queries the LM deems similar to the originally memorized statement, but fails if the LM's representation of a query is too dissimilar to its representation of the original statement. This trend is also reflected in the finetuning setting, with less similar variants requiring up to 500 instances until the model achieves 90 percent accuracy (last row), while transfer to more similar variants works well after finetuning on 5 to 50 target instances.

When using RoBERTa without pretraining to memorize statements, knowledge transfer to query variants is much worse. While transfer still works for the most similar variants (right, top rows), less similar variants require more finetuning compared to pretrained RoBERTa (right, middle rows). Transfer does not work for the least similar variants, with accuracies as low as 1 to 4 percent even after finetuning with 500 instances (right, bottom rows). Similar results for control statements are shown in Fig. 9 (bottom). We take these results as evidence that pretraining enables LMs to handle paraphrased queries and that LMs can memorize facts beyond mere rote memorization and generic association.

6 Limitations and Conclusions

Limitations. This work is not without limitations. We only use one KB in our experiments. Arguably, as the largest publicly available source of world knowledge, Wikidata is the most promising resource for equipping LMs with such knowledge, but attempts to store a KB with different structure might result in different outcomes, since some types of graphs are easier to memorize for a LM than others (See Appx. G).

While we use language like "*train* a LM to memorize statements" for simplicity throughout this work, what we do in case of pretrained LMs is more akin to adaptive pretraining (Gururangan et al., 2020). It is possible that integrating entity supervision directly into LM pretraining (Févry et al., 2020) allows more efficient fact storage.

Our analysis was focused on entity representations and ignored the question of how to represent relation predicates or entire relation triples. Here, relation learning (Baldini Soares et al., 2019) and LM pretraining on fact-aligned corpora (Elsahar et al., 2018) are avenues for future work.

Finally, we formulated the LM-as-KB paradigm in terms of storing and retrieving relation triples. While structured KBs such as Wikidata consist of such triples and hence our experiments showing storage and retrieval of triples LMs are sufficient as a proof-of-concept in principle, structured KBs allow more complex queries than the ones considered here, such as 1-to-n relations, multihop inference, queries involving numerical ranges, or facts qualified by time and location (Hoffart et al., 2013).

Conclusions. We gave a positive answer to Petroni et al. (2019)'s question if language models can serve as knowledge bases. Arguing that treating LMs as KBs requires representing a large number of entities, storing a large number of facts, and the ability to query a fact with a variety of queries, we showed that current LM architectures fulfill these requirements when extended with a component for representing entities. In addition to the ability to handle paraphrased queries, we envision further benefits from the LM-as-KB paradigm. For example, the fact-memorization and paraphrase-finetuning setting introduced in Section 5 allows precise control over which facts a LM learns.

A Overview: world knowledge in natural language processing

Paradigm / Task	Input	Output	Models and objectives
Language modeling	Text	Text	Next word prediction (Shannon, 1948; Elman, 1990; Bengio et al., 2003), masked token prediction (Devlin et al., 2019)
LM-as-KB?	Text	Text / single-token entity name	Closed-book QA (LAMA probe, Petroni et al., 2019)
Sequence-to-sequence	Text	Text	Text-to-text transformer (T5, Raffel et al., 2019), closed-book QA (Roberts et al., 2020)
Retrieval	Text	Text, answer span	Answer-span selection (Chen et al., 2017), retrieval-augmented LM (Guu et al., 2020), open-book QA
Entity replacement	Text, entity mention spans	Text	Detecting replaced entity mentions (Xiong et al., 2019)
Entity linking (EL)	Text, entity mention spans	Target entity	AIDA (Hoffart et al., 2011), neural EL (Francis-Landau et al., 2016; Kolitsas et al., 2018)
Entity embeddings	Text, entity mention spans	Entity embeddings	Joint embedding of entities and text (Yamada et al., 2016)
LM with entity embeddings	Text, linked entity mentions, entity embeddings	Text	ERNIE (Zhang et al., 2019), E-BERT (Poerner et al., 2019)
LM with integrated EL	Text, entity embeddings	Text	KnowBert (Peters et al., 2019)
LM-as-KB (this work)	Natural language query	Target entity	Fact memorization, paraphrased queries, closed-book QA
Knowledge-aware LM	Text, knowledge (sub)graph	Target entity, text	Neural Knowledge LM (Ahn et al., 2016), Reference-aware LM (Yang et al., 2017), Knowledge graph LM (Logan et al., 2019)
Semantic parsing	natural language query	meaning representation, target entity	SEMPRE (Berant et al., 2013), GNNs for KBQA (Sorokin and Gurevych, 2018)
Universal Schema	relation triples, text patterns	entity tuple and relation embeddings	Matrix factorization (Riedel et al., 2013)
Knowledge graph embeddings	relation triples	node and edge embeddings	Link prediction; RESCAL (Nickel et al., 2011), TransE (Bordes et al., 2013), ComplexE (Trouillon et al., 2016), ConvE (Dettmers et al., 2018)
Graph neural networks	nodes, node features, edges	node embeddings	DeepWalk (Perozzi et al., 2014), graph neural networks (Kipf and Welling, 2017)
Knowledge graphs	nodes, edges	nodes, edges	Storage and retrieval, SQL/SPARQL queries, symbolic reasoning (Coppens et al., 2013)

Table 2: Approaches for using world knowledge in natural language processing, ranging from unstructured, purely text-based approaches (top), over approaches that mix text and structured KBs to varying degrees (middle), to approaches operating on structured KBs (bottom).

B Templates for generating English statements from Wikidata relations

ID	Template
P31	S is an instance of O
P106	S has the occupation O
P17	S belongs to the country O
P131	S is located in the administrative territorial entity O
P27	S is citizen of O
P47	S shares a border with O
P19	S was born in O
P161	S has the cast member O
P421	S is located in time zone O
P166	S received the award O
P54	S is a member of the sports team O
P20	S died in O
P136	S has the genre O
P69	S was educated at O
P1412	S is a language spoken, written or signed in O
P190	S is a twinned administrative body of O
P641	S participates in the sport O
P150	S contains the administrative territorial entity O
P463	S is a member of O
P735	S has the given name O
P1343	S is described by source O
P361	S is a part of O
P159	the headquarters of S are located in O
P1344	S is participant of O
P495	S has the country of origin O
P39	S held the position of O
P910	S has the main category O
P105	S has the taxon rank O
P527	S has the part O
P108	S is employed by O
P279	S is a subclass of O
P171	S has the parent taxon O
P140	S has the religion O
P407	S is in the O language
P1303	S plays the instrument O
P1411	S has been nominated for O
P102	S is a member of political party O
P3373	S is a sibling of O
P1376	S is the capital of O
P509	S died because of O
P937	S works in O
P264	S was produced by the record label O
P119	S is buried in O
P138	S is named after O
P530	S has diplomatic relations with O
P40	S is a child of O
P155	S follows O
P276	S is located in O
P156	S is followed by O
P36	S has the capital O
P1196	S has the manner of death O
P127	S is owned by O
P101	S works in the field O
P607	S participated in the conflict O
P364	S is a film or TV show with the original language O
P6379	S has works in the collection O
P1346	S is a winner of the O
P22	S is the father of O
P137	S is operated by O
P413	S plays the position O
P26	S is spouse of O
P1830	S is owner of O
P1454	S has the legal form O
P206	S is located in or next to body of water O
P710	S is a participant of O
P1441	S is present in the work O
P1532	S represents O when playing sport O
P86	S was composed by O
P840	S is set in the location O
P172	S belongs to the ethnic group O
P175	S is performed by O
P57	S is directed by O
P1889	S is different from O
P162	S is produced by O
P118	S belongs to the league O
P58	S is screenwritten by O
P551	S has the residence O
P103	S has the native language O
P2789	S connects with O
P750	S has the distributor O
P725	S is voiced by O
P272	S is produced by the company O
P112	S was founded by O
P452	S belongs to the industrial sector O
P81	S is connected to line O
P97	S has noble title O
P740	S formed in the location O
P360	S is a list of O
P793	S is associated with the significant event O
P915	S was filmed at O

E Embeddings of Wikidata entities

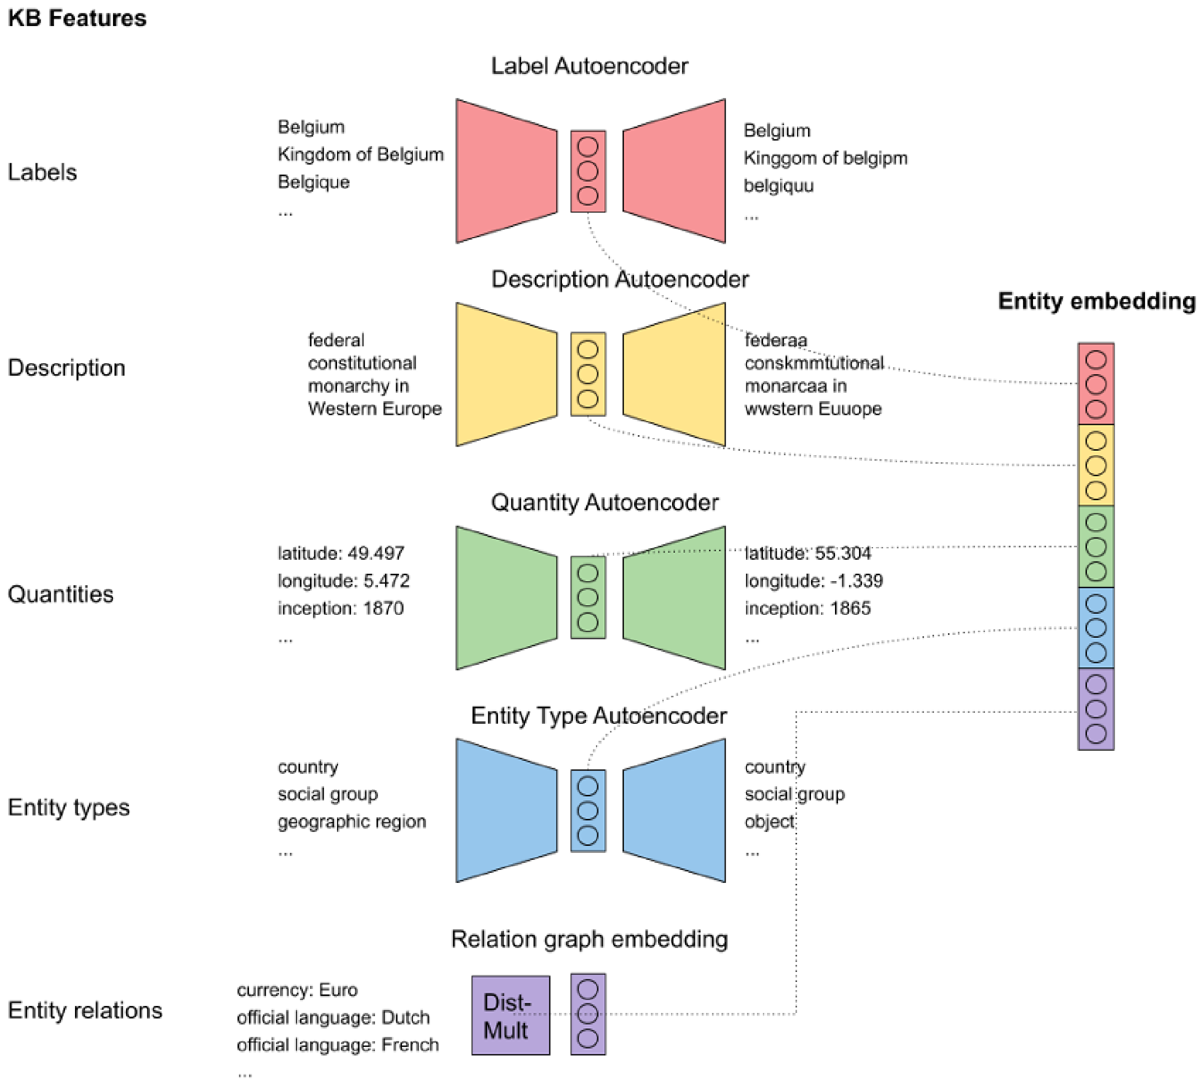

Figure 10: Training embeddings of Wikidata entities with feature-specific autoencoders.

We train the embedding of a given Wikidata entity by collecting its features from, encoding each feature to obtain a dense feature representation, and then concatenating feature representations. For textual features, we use RoBERTa-base as encoder and train corresponding decoders in a standard sequence-to-sequence auto-encoding setup. For quantities, we select the 100 most common quantity types to obtain a fixed-sized representation and then follow a standard auto-encoding setup. Similarly we obtain a fixed-size entity type representation by selecting the 1000 most common entity types. The concatenated feature-representations are then compressed to embedding size d, using a separate autoencoder. Preliminary experiments with embedding sizes $d \in \{64, 128, 192, 256\}$ showed similar memorization accuracies for all d, but faster convergence for smaller sizes. We set $d = 64$ in our main experiments.

F Things that didn't work

F.1 Hierarchical entity representation with binary codes

Since imposing a hierarchy is a common method for dealing with large vocabulary sizes (Morin and Bengio, 2005) in general, and large inventories of entities and entity types in particular (Raiman and Raiman, 2018; López et al., 2019), we created a hierarchy of all entities in Wikidata, using a given entity's position in this hierarchy as training signal. Specifically, we created the entity hierarchy by fitting a KD-tree (Bentley, 1975; Virtanen et al., 2020) with leaf size 1 over pretrained entity embeddings, thereby obtaining a binary partitioning of the embedding space in which each final partition contains exactly one entity embedding. The path from the KD-tree's root to a leaf can be represented as a binary code, which we use as training signal (Oda et al., 2017). Memorization accuracy of world knowledge facts with object entities represented in the form of these binary codes was substantially lower compared to the three approaches described in the main part of this work.

F.2 Training entity embeddings with negative sampling

Instead of using fixed, pretrained entity embeddings as training signal, we experimented with randomly initialized embeddings that are updated during training, using between 1 and 50 in-batch negative samples, which is a standard method in the knowledge base embedding literature (Bordes et al., 2013) and has been used successfully for entity retrieval (Gillick et al., 2019). However, compared to using fixed, pretrained entity embeddings without negative sampling, we observed lower memorization accuracies and slower convergence in our experiments.

F.3 Updating pretrained entity embeddings during training

Instead of using fixed entity embeddings, we tried updating them during training with in-batch negative sampling. This increased the number of trainable parameters, memory usage, and training time, but did not lead to higher memorization accuracies.

F.4 Continuous representation with Euclidean distance loss

Instead of normalizing entity embeddings to the unit hypersphere and training with cosine loss, we experimented with predicting the original pretrained entity embeddings and using the Euclidean distance as loss. Compared to using spherical entity embeddings as prediction targets, we observed slower convergence and lower memorization accuracies.

G Impact of graph type on memorizability

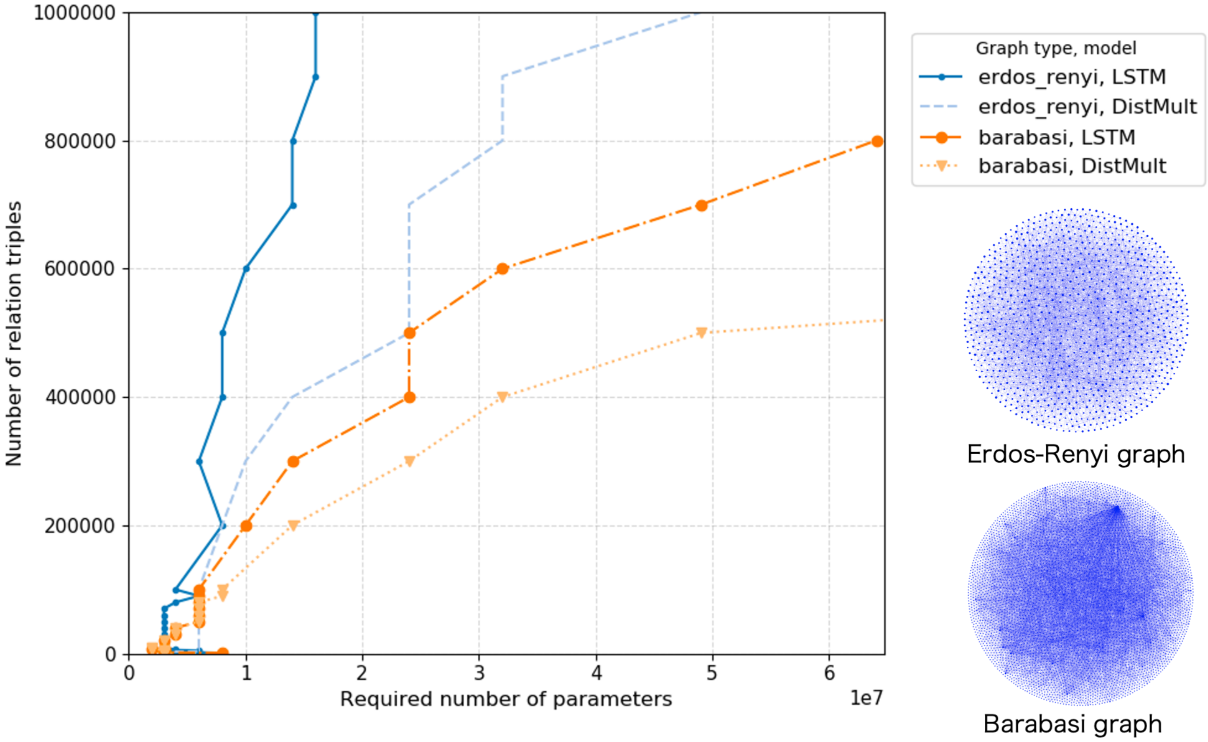

Figure 11: Impact of graph type on a model's ability to memorize the graph. We consider two types of random graphs, namely a uniform (Erdos-Renyi) graph, and a scale-free (Barabasi) graph. We interpret graph edges as relation triples in a knowledge graph and train models to predict the relation object, given subject and predicate, until memorization accuracy reaches 99 percent. For a given number of model parameters, we gradually increase the number of relation triples to memorizes and record the maximum number of relation triples memorized for this number of parameters. We compare an LSTM, as well as a bilinear KB embedding (DistMult). For a given parameter budget, models are able to memorize more triples from a Erdos-Renyi graph (blue) than from a Barabasi graph, indicating that the latter is more difficult to memorize.

Globalizing BERT-based Transformer Architectures for Long Document Summarization

Abstract

Fine-tuning a large language model on downstream tasks has become a commonly adopted process in the Natural Language Processing (NLP) (Wang et al., 2019). However, such a process, when associated with the current transformer-based (Vaswani et al., 2017) architectures, shows several limitations when the target task requires to reason with long documents. In this work, we introduce a novel hierarchical propagation layer that spreads information between multiple transformer windows. We adopt a hierarchical approach where the input is divided in multiple blocks independently processed by the scaled dot-attentions and combined between the successive layers. We validate the effectiveness of our approach on three extractive summarization corpora of long scientific papers and news articles. We compare our approach to standard and pre-trained language-model-based summarizers and report state-of-the-art results for long document summarization and comparable results for smaller document summarization.

1 Introduction

Language model pre-training has become a key component to improve performances on a majority of Natural Language Processing (NLP) tasks (Wang et al., 2019). Most of the recent competitive architectures (Devlin et al., 2019; Lan et al., 2020; Liu et al., 2019b; Radford et al., 2018) are based on the efficient transformer layer introduced in Vaswani et al. (2017). BERT (Devlin et al., 2019) is one of these architectures that has been widely adopted for comprehension and generation tasks. It is a multi-layer transformer network, pre-trained with different self-supervised objectives. Numerous variations of transformer architectures have been proposed to improve this approach (Lan et al., 2020; Liu et al., 2019b; Radford et al., 2018). However, this type of process is only evaluated on tasks composed of relatively short input text, GLUE (Wang et al., 2019), SQUAD (Rajpurkar et al., 2016), SWAG (Zellers et al., 2018). Indeed, for the tasks that require reasoning with longer documents, this approach exhibits several limitations. The transformer self-attention memory quadratically increases with the number of input tokens, making it technically impossible to compute on document-scale sequences. In addition, they usually require to define a fixed maximum input length, typically of 512 tokens, at the pre-training stage.

One solution is to pre-train the entire model on longer sequences. However, this will still require a massive computation power and will only push the length limitation further. Other alternatives have been proposed to extend multi-layer transformers architectures to longer sequences without modifying this maximum length limitation. The first one is to limit the input sequence to its first tokens by removing the text beyond the length limit. Obviously, it cannot be a reasonable solution to treat long documents that are consistently longer than this limit. The second alternative is to apply the model on a window that slides all over the document. It has been used in Wolf et al. (2019) to deal with SQUAD documents that are longer than the 512 token limitation and in Joshi et al. (2019) for a co-reference resolution task on long documents. This approach can only work if the tokens need to be contextualized only in their surroundings because there is no interaction between the different windows. It seems to be a solution for co-reference resolution (Joshi et al., 2019) as they usually can be solved with a reasonably sized window. Another

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1792–1810
April 19 - 23, 2021.

approach adopted to deal with long documents or multi-document is to select a sub-sample of the input that is small enough for the transformer model. Most of the state-of-the-art pipelines on the multi-hop question answering dataset HotpotQA (Yang et al., 2018) use a first model to retrieve the relevant pieces of text before feeding them to a transformer-based architecture (Fang et al., 2019a; Tu et al., 2019).

We argue that these solutions are not feasible to deal with tasks that require a global understanding of long documents. An example is extractive summarization, where the decision for each sentence should be based on the information of the complete document. To address these challenges, we propose a simple adaptation of the multi-layer transformer architecture that can scale to long documents and benefit from pre-trained parameters with a relatively small length limitation. The general idea is to independently apply a transformer network on small blocks of a text, instead of a long sequence, and to share information among the blocks between two successive layers. To the best of our knowledge, this is the first attempt to introduce hierarchical components directly between the layers of a pre-trained model and not only on top of it (Fang et al., 2019b; Zhang et al., 2019b; Tu et al., 2020). Between each of the transformer layers, we use a Bidirectional Gated Recurrent Unit (BiGRU) network (Cho et al., 2014) to spread global information across the blocks. Adding these propagation layers between the transformer layers preserves the original structure of the pre-trained model and makes it possible to transfer parameter weights from a large pre-trained language model with only few additional parameters to propagate information between blocks.

The contributions of this paper can be summarized as follows: (i) we propose a novel architecture dedicated to long documents which interweaves recurrent hierarchical modules with transformer layers and which exploits pre-trained language models like BERT, and (ii) we demonstrate that this architecture is able to build informative representations in the context of extractive summarization.

2 Global BERT-based Transformer Architecture

In this part, we briefly recall the transformer layer from Vaswani et al. (2017) and its integration in the BERT model (Devlin et al., 2019). Then we describe our modifications of this architecture that allow the model to read longer documents.

Transformers: The transformer architecture, based on a sequence of transformer layers, has been initially introduced in Vaswani et al. (2017). The key idea of this layer is to produce a contextualized representation of an input sequence of tokens. It is composed of the succession of a multi-head self-attention, a first normalizer, a feed-forward neural network, and a second normalizer. This model, which has originally been introduced for machine translation, has then been adopted for most natural language comprehension tasks. Most of the successful approaches (Devlin et al., 2019; Liu et al., 2019b; Lan et al., 2020) are composed of multiple stacked transformer layers. In the remainder, we denote by T^ℓ the transformation corresponding to the ℓ^{th}, $1 \leq \ell \leq L$, transformer layer (T^ℓ is a function from $\mathbb{R}^{N \times h}$ to $\mathbb{R}^{N \times h}$, where N denotes the length of the sequence and h the hidden dimension).

BERT (Devlin et al., 2019) is a multi-layer transformer encoder pre-trained on large text corpora. Two BERT architectures have been proposed in Devlin et al. (2019): $\text{BERT}_{\text{BASE}}$ composed of 12 stacked transformer layers with hidden dimension of 768 ($L = 12, h = 768$) and $\text{BERT}_{\text{LARGE}}$ composed of 24 layers of hidden dimension 1024 ($L = 24, h = 1024$). For both architectures, the input length is limited to 512 WordPiece tokens and the pre-training includes two self-supervised tasks, namely masked language modeling and next sentence prediction. For masked language modeling, 15% of all the WordPiece tokens of the input sequence are masked or corrupted, and the model is used to predict the original token with a cross-entropy loss. For next sentence prediction, the model is trained as a classifier to predict if two sentences are contiguous or not. The pre-training procedure uses the BooksCorpus (Zhu et al., 2015) and documents from English Wikipedia. It requires 4 days of optimization on 16 TPU chips for $\text{BERT}_{\text{BASE}}$ and 64 TPU chips for $\text{BERT}_{\text{LARGE}}$.

2.1 Stacked Propagation Layers

We propose a hierarchical structure that uses pre-trained transformers to encode local text blocks that will be used to compute document level representations. The novel contribution of this work, depicted in Figure 1, is to incorporate recurrent hierarchical modules between the different transformer layers and not only on top of the model, as proposed in

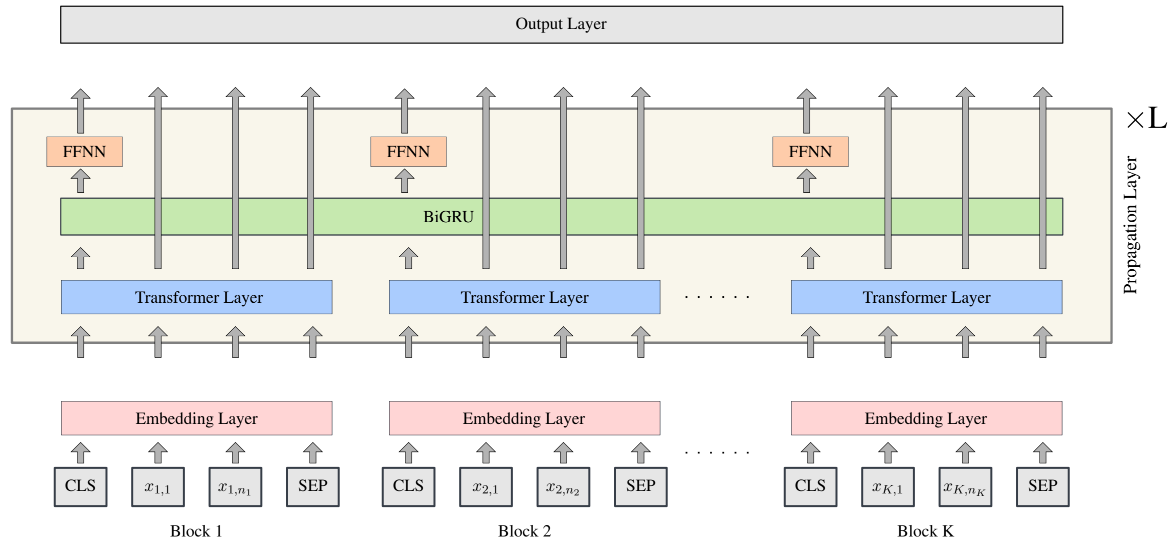

Figure 1: Our proposed modification of a multi-layer transformer architecture. The input sequence is composed of K blocks of tokens. Each transformer layer is applied within the blocks, and a bidirectional GRU network propagates information in the whole document by updating the [CLS] representation of each block.

several recent works (Fang et al., 2019b; Zhang et al., 2019b; Tu et al., 2020). Because we construct and propagate document level information between the layers, global and local information are fused at every level of the architecture. The text blocks can be sentences, paragraphs, or sections. We experiment using sentences as blocks because it generally does not exceed the maximum length allowed by pre-trained models and because BERT has demonstrated to be well adapted to represent such sequences.

We start by splitting the original sequence into multiple blocks. Let D be a document composed of K blocks, $D = \{B_1; B_2; \cdots ; B_K\}$ where a block B_k, $1 \leq k \leq K$, is composed of n_k tokens. To follow the convention of BERT, special tokens [CLS] and [SEP] are respectively added at the beginning and end of each block of the document, so that: $B_k = \{[\text{CLS}]; x_{k,1}; x_{k,2}; \cdots x_{k,n_k}; [\text{SEP}]\}$ where $x_{k,i}$ is the index of the WordPiece token i of block k. In the remainder, the index 0 (resp. $n_k + 1$) will be used to refer to the representation of the [CLS] (resp. [SEP]) token in each block.

Embedding Layer Because our goal is to reuse the available pre-trained BERT parameters, token representations are kept the same as in the original BERT and are composed of a token embedding, a segment embedding, and a positional encoding that represents the position of the token in its block. We will denote by E_k ($E_k \in \mathbb{R}^{(n_k+2)\times h}$, $1 \leq k \leq K$) the embedding representation of block k.

Propagation Layers Our model is composed of L stacked identical hierarchical layers, called *propagation layers*, that comprise a transformer layer, a BiGRU to propagate information across blocks and, finally, a feed-forward network. For any layer ℓ, $1 \leq \ell \leq L$, let $U_k^\ell \in \mathbb{R}^{(n_k+2)\times h}$ be the representation of block k after the $(\ell - 1)^{th}$ layer, the representation for the first layer being initialized with the output of the embedding layer: $U_k^1 = E_k, \quad \forall k \in \{1, \cdots, K\}$. We first apply the pre-trained transformer function T^ℓ individually on each block of the document to compute local, token-aware representations $V_k^\ell \in \mathbb{R}^{(n_k+2)\times h}$:

$$V_k^\ell = T^\ell(U_k^\ell), \quad \forall k \in \{1, \cdots, K\}.$$

The next step is to propagate information across all the blocks of the document in order to compute a global block-aware representation for the document at layer ℓ, denoted by $W^\ell \in \mathbb{R}^{K\times h}$, $1 \leq k \leq K$. To do so, we use a BiGRU network, fed with the representation vectors of the different blocks, and apply a feed-forward neural network to preserve the hidden dimension of the transformer. Each block k is represented by its [CLS] vector, *i.e.*, the vector (represented by $V_{k,0}^\ell \in \mathbb{R}^h$) at the first position in the local representation of the block. These representations are then concatenated to form the input to the BiGRU. The global, block-aware representation is then computed by applying the feed-forward neural network (FFNN) to all K outputs of the BiGRU:

$$W_k^\ell = \text{FFNN}(\text{BiGRU}_k([V_{1,0}^\ell; \cdots ; V_{K,0}^\ell])),$$

Datasets	avg. doc length sentences	avg. doc length words	avg. summary length sentences	avg. summary length words
arXiv	204	5038	5.6	165
PubMed	88	3235	6.8	205

Table 1: Statistics on arXiv, PubMed and CNN/DailyMail validation datasets in terms of documents and summary lengths.

where BiGRU_k denotes the k^{th} output of the Bi-GRU and $[;]$ is the concatenation operation.

At this stage, we have computed, for a given document, local block representations $V_k^\ell \, (1 \le k \le K)$ and a global representation W^ℓ. We combine them to build the output representation of the layer:

$$U_k^{\ell+1} = [W_k^\ell; V_{k,1}^\ell; \cdots ; V_{k,n_k+1}^\ell], \quad 1 \le k \le K.$$

As one can note, $U_k^{\ell+1} \in \mathbb{R}^{(n_k+2)\times h}$ is a representation of block k in which the [CLS] vector representation has been enriched with document level information propagated from other blocks. $U_k^{\ell+1}$ is then used as input for the next propagation layer.

2.2 Output Layer

In this work, we validate our approach on the task of extractive summarization described in Section 3. This task can be considered as a binary classification problem where each block has to be labeled as selected or not. We use a feed-forward neural network followed by a Softmax function on the top of the block level representations after the last layer L to compute $Y \in \mathbb{R}^{K\times 2}$.

$$Y_k = \text{Softmax}(\text{FFNN}(W_k^{L+1})).$$

Using a recurrent architecture to propagate information between blocks has two interesting properties. First, it allows our model to scale to long sequences of blocks without using an attention mechanism that would not scale. Second, it does not require to implement any positional encoding on block representations.

3 Experiments

We evaluate our approach, which we refer to as GBT-EXTSUM (for 'Global BERT-based Transformer for Extractive Summarization'), in the context of extractive summarization, the goal of which being to identify and extract from a document the pieces of text that are the most important (Kupiec et al., 1995). We view this task as a sentence-level classification problem where each sentence has to be labeled according to its belonging to the summary or not. To validate the effectiveness of our approach, we propose to test it on three summarization datasets, namely ArXiv, PubMed and CNN/DailyMail:

- The **ArXiv** and **Pubmed** datasets have been introduced in Cohan et al. (2018). They contain long scientific documents from `arXiv.org` and `PubMed.com` and use their abstracts as the ground-truth summaries. We use the original splits that respectively contain 203,037/6,436/6,440 samples in the training, validation, and test sets for arXiv, and 119,924/6,633/6,658 for PubMed.
- The **CNN/DailyMail** dataset contains news articles associated with short summaries. We use the splits of Hermann et al. (2015), where entities have not been anonymized. This dataset contains 287,226 training samples, 13,368 validation samples, and 11,490 test samples.

Table 1 presents some statistics on these three datasets. As one can note, for the scientific articles, the average number of tokens in the documents to summarize is way beyond the capabilities of a standard transformer pre-trained with BERT.

3.1 Evaluation Metrics

We evaluate the quality of the extracted summaries using the ROUGE metric (Lin, 2004), and more particularly ROUGE-1 (overlap of unigrams), ROUGE-2 (overlap of bigrams), ROUGE-3 (overlap of trigrams) and ROUGE-L (longest common subsequence between the produced summary and the gold-standard one).

3.2 Label Generation

In order to train extractive summarizers, one needs annotations in the form of sentence-level binary labels. To compute such annotations, we follow the work of Kedzie et al. (2018) and label all sentences by greedily optimizing the ROUGE-1 score of the extracted summary against the gold-standard summary associated with each article. These labels are only used at training time, the evaluation of the extracted summaries being done against the gold-standard summaries provided in the datasets.

Table 2: Summarization results on PubMed and arXiv. Except for BERT-based approaches, for Reformer-Ext and for Longformer-Ext, which we have reimplemented, the results of the baselines are taken from their associated paper as well as from Cohan et al. (2018). Bold results correspond to the best scores of extractive summarizers.

3.3 Baseline Models

We compare our approach to several well known published methods described below. These methods include SumBasic (Vanderwende et al., 2007), LexRank (Erkan and Radev, 2004), LSA (Steinberger and Jezek, 2004), Attn-Seq2Seq (Nallapati et al., 2016), Pntr-Gen-Seq2Seq (See et al.) and Discourse-aware summarizer (Cohan et al., 2018). The results for these models are the ones reported in the paper (Cohan et al., 2018). We also report the results of Sent-CLF and Sent-PTR, which are hierarchical sentence pointer and classifier, TLM-I+E (G,M) a mixed extractive/generative transformer language model from Subramanian et al. (2019), BigBird (Zaheer et al., 2020), PEGASUS (Zhang et al., 2019a) and DANCER (Gidiotis and Tsoumakas, 2020) which are three abstractive methods. Lastly, we developed several baseline models based on BERT, Longformer (Beltagy et al., 2020) and Reformer (Kitaev et al., 2020):

BERT Ranker: We used a BERT ranker, similar to Nogueira and Cho (2019) in which each sentence of the document is processed individually. We apply BERT on each sentence[1] and use a Sigmoid layer, the input of which consists of the [CLS] representation of the sentence, to model the probability of the sentence to be selected.

BertSumExt has been introduced in Liu and Lapata (2019b). This model is an adaptation of BERT for extractive summarization. Because this model takes as input the concatenation of all the tokens of the document, it cannot scale to the arXiv and PubMed datasets. We propose two variants: the first one is to take as input only the first 800 tokens of the document, as suggested in the original paper. This solution is displayed as BertSumExt in Table 2. The second is to apply BertSumExt per sliding windows on the original document and to use, as a token representation, its representation in the window that maximizes its surrounding context. We name this sliding window implementation BertSumExt (SW) in Table 2.

Longformer-Ext and Reformer-Ext: The Longformer and Reformer models were respectively introduced by Beltagy et al. (2020) and Kitaev et al. (2020). They both propose an adaptation of the Transformer self-attention that scale to long sequences. We add the same classification head as the one used in our model on top of the contextualized representation of the first token of each sentence to label them as selected or not in the summary.

---

[1] This is possible as no sentence exceeds BERT token limitation.

We also present the Oracle extractive results as an upper bound as well as the Lead baseline (which respectively select the first 3, 6, 7 sentences for CNN/DailyMail, arXiv and PubMed datasets). Several models are reported only on CNN/DailyMail dataset and not on arXiv/Pubmed as they do not scale to long documents.

3.4 Implementation details

We run all our experiments using the Pytorch library (Paszke et al., 2019). We built our model using the "bert-base-uncase"[2] version of BERT and its implementation in the HuggingFace library (Wolf et al., 2019). Our architecture is composed of $L = 12$ propagation layers with a transformer hidden dimension of $h = 768$. The hidden dimension of the BiGRU is set to 384 and we share its parameters among all the propagation layers. The FFNN inside the propagation layers maps the output of the BiGRU of dimension 2×384 to a vector of dimension 768. The FFNN of the output layer is a binary classifier that projects the sentence representations of dimension 768 to an output of dimension 2. We fine-tuned our model on the cross-entropy loss, for 5 epochs on 4 GPUs V100 and use Adam optimizer (Kingma and Ba, 2015) with the initial learning rate set to 3×10^{-5}, $\beta_1 = 0.9$, $\beta_2 = 0.999$, no learning rate warmup and a linear decay of the learning rate. We describe implementation details of BERTSUMEXT, Longformer-Ext and Reformer-Ext baselines in the Supplementary Material, Appendix A.

We used *Trigram Blocking* to avoid the repetition of trigrams in the extracted summaries as suggested in Paulus et al. (2018). Given the extracted summary so far, we only added candidate sentences that had no overlapping trigram with the current summary. We limited the summary to 3 sentences for the CNN/DailyMail dataset, 6 sentences for arXiv, and 7 for PubMed.

3.5 Results

Our main results are shown in Tables 2 and 3. On the arXiv and PubMed datasets, our model outperforms the baseline models on almost all of the reported metrics. Our approach manages to summarize long documents while preserving informativeness (evaluated by ROUGE-1) and fluency (evaluated by ROUGE-L) of the summaries. In addition to the previously published methods, our approach also improves over the BERT-based, Longformer-Ext and Reformer-Ext baselines we have developed. Among them, BERTSUMEXT, which focuses on a truncated version of the document, is the less effective. As documents are significantly longer than the 800 tokens limitation of this model, this result is not surprising. The sliding window adaptation of this model, that allows it to scale to long documents, is the one that achieves results that are the most comparable to ours. Our approach still outperforms this adaptation, demonstrating that summaries require to propagate information beyond a single BERT window.

Model	R-1	R-2	R-L
Oracle	56.22	33.74	52.19
Lead-3	40.11	17.54	36.32
LATENT (Zhang et al., 2018)	41.05	18.77	37.54

GBT-EXTSUM (Ours)	42.93	19.81	39.20

Table 3: Comparison of ROUGE scores on CNN/DailyMail wrt extractive models. All results are taken from original papers but Reformer-Ext and Longformer-Ext which we have reimplemented.

On the CNN/DailyMail dataset, one can see that our model outperforms all the models that do not use pre-trained parameters. This includes several transformer-based and hierarchical models. However, while having comparable results, we do not achieve stronger performance than the current extractive state of the art from Zhong et al. (2020). This is not surprising as the majority of the CNN/DailyMail examples contains their oracle summary sentences in the first positions of the articles, as shown in the Supplementary Material, Appendix B.

Lastly, we evaluate the impact of several elements of our proposed model in Table 4. We first study the influence of the underlying language model by considering both RoBERTa (Liu et al., 2019b) and PEGASUS (Zhang et al., 2019a) pre-trained models, respectively referred to as GBT-EXTSUM-RoBERTa and GBT-EXTSUM-

Table 4: Analysis of the influence of different key components of our proposed architecture.

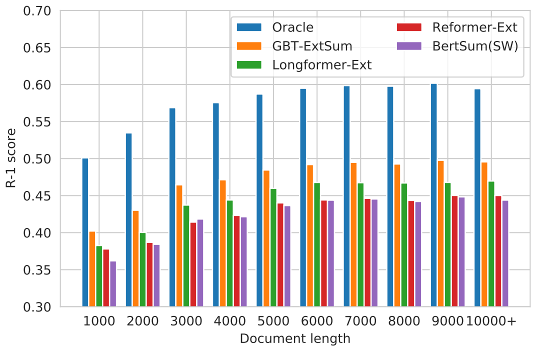

Figure 2: Average R-1 scores of extracted summaries according to the number of words in the input documents from arXiv test dataset.

PEGASUS. As one can see, the results show that BERT-base architecture performs best in terms of ROUGE scores on both arXiv and PubMed. One major difference between PEGASUS and BERT/RoBERTA pre-trained models is that BERT/RoBERTA are only encoders while PEGASUS is a pre-trained encoder/decoder architecture. This could explain why BERT/RoBERTA outperform PEGASUS on extractive summarization tasks. We then compare an alternative of our implementation of GBT-ExtSum in which the parameters of the BiGRU are not shared among all the propagation layers (GBT-ExtSum-NoShare) and found no clear difference with the version in which the parameters are shared. Lastly, we compare three architectures of propagation layers, including an average pooling of the [CLS] representations of the sentences, a Transformer layer between the [CLS] tokens (associated to a block position embedding), and a BiGRU layer. Among these three layers, the average pooling layer, which introduces no additional trainable parameters, performs the worst. Furthermore, the BiGRU layer slightly outperforms the Transformer layer in terms of ROUGE scores.

Analysis. In Figure 2, we compare the R-1 score of several models regarding the number of words in the source documents. One can see that GBT-ExtSum consistently outperforms BertSumExt (SW), Reformer-Ext and Longformer-Ext regardless of the number of words in the source documents.

We present in Table 5 two example summaries of a document from the PubMed test set (Kamio et al., 2009), respectively obtained by GBT-ExtSum and BertSumExt (SW). The numbers in the margin indicate the position of the sentences in the original document, which is composed of a total of 78 sentences. As one can observe, GBT-ExtSum extracts sentences from various parts of the document whereas BertSumExt (SW) mostly focuses on the beginning of the document. Among the sentences selected by the two models, the most meaningful one, in terms of ROUGE, is the last one selected by GBT-ExtSum. This sentence appears at position 66, in the last section (*Discussion*) of the original paper. In contrast, BertSumExt (SW) proposes sentences that are less relevant for summarization purposes. Additional summaries of the PubMed and arXiv articles are provided in the Supplementary Material, Appendices C and D.

To analyse the influence of the positions of the sentences in the input document, we present in Figure 3 the histograms of the positions of the sentences of the Oracle summary as well as that of the predicted positions of different models, on the PubMed test set. One can see that if most relevant sentences appear at the beginning of a document, other Oracle sentences are still relevant further down the document. GBT-ExtSum is the model that behaves the most closely to the Oracle, followed by BertSumExt (SW), Reformer-Ext and Longformer-Ext. These last two models tend to over-select sentences from the beginning while focusing less on the ones appearing later in the document. Our model remains influenced by the sentence position but is still able to select sentences from all over the document and is closer to the Oracle distribution.

4 Related Work

Hierarchical neural architectures have been competitive on a collection of NLP tasks that require to reason over long or multiple documents such as aspect-based sentiment analysis (Paulus et al., 2018), document summarization (Cheng and Lapata, 2016), document segmentation (Koshorek

GOLD		purpose : to investigate whether the glc3a locus harboring the cyp1b1 gene is associated with normal tension glaucoma (ntg) in japanese patients.materials and methods : one hundred forty two japanese patients with ntg and 101 japanese healthy controls were recruited . patients exhibiting a comparatively early onset were selected as this suggests that genetic factors may show stronger involvement . genotyping and assessment of allelic diversity was performed on 13 highly polymorphic microsatellite markers in and around the glc3a locus.results:there were decreased frequencies of the 444 allele of d2s0416i and the 258 allele of d2s0425i in cases compared to controls (p = 0.022 and p = 0.034 , respectively) . however , this statistical significance disappeared when corrected ($pc > 0.05$) . we did not find any significant association between the remaining 11 microsatellite markers , including d2s177 , which may be associated with cyp1b1 , and ntg ($p > 0.05$). conclusions : our study showed no association between the glca3 locus and ntg , suggesting that the cyp1b1 gene , which is reportedly involved in a range of glaucoma phenotypes , may not be an associated factor in the pathogenesis of ntg .
GBT-EXTSUM	1-	primary open angle glaucoma (poag) is the most common type of glaucoma .
	15-	we excluded individuals who were diagnosed under 20 or over 60 years of age and who had 8.0 d or higher myopic refractive error of spherical equivalence .
	17-	the cases exhibiting a comparatively early onset were selected as they suggest that genetic factors may show stronger involvement . during diagnosis ,
	30-	the probability of association was corrected by the bonferroni inequality method , ie , by multiplying the obtained p values with the number of alleles compared .
	63-	only two adjacent markers , d2s0416i and d2s0425i , were significantly positive , as shown in table 2 , and the frequency of the 444 allele of d2s0416i and the 258 allele of d2s0425i were decreased in cases compared to controls (p = 0.022 , or = 0.59 and p = 0.034 , or = 0.42 , respectively) .
	66-	the purpose of this study was to investigate whether the glc3a locus is associated with ntg in japanese subjects , based on results from recent studies reporting that the cyp1b1 gene , located at the glc3a locus on chromosome 2p21 , could be a causative gene in poag as well as pcg . to this end , we genotyped 13 microsatellite markers in and around the glc3a locus . here
BERTSUMEXT (SW)	1-	primary open angle glaucoma (poag) is the most common type of glaucoma .
	2-	normal tension glaucoma (ntg) is an important subset of poag ; while many poag patients have high iop,1 patients with ntg have statistically normal iop.24 the prevalence of ntg is higher among the japanese population than among caucasians , and recent studies reported that 92% of poag patients in japan had ntg.58 the diagnosis of glaucoma is based on a combination of factors including optic nerve damage and specific field defects for which iop is the only treatable risk factor .
	7-	of these subjects , 142 were diagnosed with ntg , and 101 were control subjects .
	20-	genomic dna was extracted using the qiaamp dna blood mini kit (qiagen , hilden , germany) or the guanidine method . in this association study , we selected 13 highly polymorphic microsatellite markers that are located in and around the glc3a locus as shown in figure 1 .
	28-	the number of microsatellite repeats was estimated automatically using the genescan 672 software (applied biosystems) by the local southern method with a size marker of gs500 tamra (applied biosystems) .
	22-	polymerase chain reaction (pcr) was performed in a reaction mixture with a total volume of 12.5 l containing pcr buffer , genomic dna , 0.2 mm dinucleotide triphosphates (dntps) , 0.5 m primers , and 0.35 u taq polymerase .

Table 5: An example of summary produced by our method compared to the gold summary and one produced by BERTSUMEXT (SW). With a red scale, we highlight the sentences with the highest ROUGE score when evaluated against the abstract. We show in the margin the position of the extracted sentence in the document. This document (Kamio et al., 2009) is 78 sentences long.

et al., 2018) and text classification (Yang et al., 2016). The hierarchical structure enables the model to learn local contextualized token representations in its lower hierarchy level, while higher-level representations can capture long-distance dependencies within the document. Liu and Lapata (2019a) have proposed a hierarchical modification of the transformer layer-based attention modules to model relations between documents for abstractive summarization but do not investigate parameter transfer form pre-trained language models. Chang et al. (2019) and Zhang et al. (2019b) suggested pre-training processes for hierarchical models, without however testing their approaches on long document summarization nor releasing their pre-trained models. We have not included these models in our comparison for this reason. Transformer-XH (Zhao et al., 2020) introduced an eXtra Hop attention to model dependencies between different transformer windows but requires a graph of related documents.

Long-Document Transformers: Multiple studies have investigated different self-attention mechanisms to extend transformers to long documents. Transformer-XL (Dai et al., 2019) introduced a recurrence between successive transformer windows which run from left to right through the document, preventing global information to bidirectionally flow through the document. Other approaches design the self-attention as a sparse layer, as sparse transformers (Child et al., 2019) or the recently proposed Longformer and BIGBIRD models (Beltagy et al., 2020; Zaheer et al., 2020). One major difference with our work is that these models compute the attention only between a limited set of randomly or *a priori* chosen tokens. Reformer (Kitaev et al., 2020) also tackles the problem of language modeling for long sequences, but it does so by computing the self-attention only between *similar*

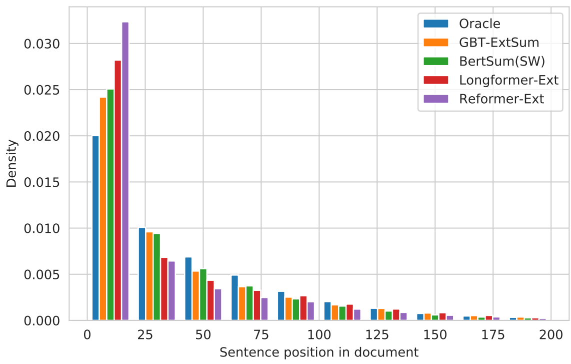

Figure 3: Proportion of the extracted sentences according to their position in the input document from PubMed test dataset.

tokens, based on locality-sensitive hashing.

5 Conclusion

In this paper, we have introduced a novel transformer-based model for long document summarization based on propagation layers that spread information between multiple transformer windows. This model preserves the architecture of commonly used pre-trained language models, thus allowing the transfer of parameters. An evaluation, conducted on top of the BERT model in the context of an extractive summarization task, further revealed its effectiveness in dealing with long documents compared to other adaptations of BERT and previously proposed models. In the future, we plan to adapt our model to other tasks that require understanding long documents, as question-answering and document-scale machine translation.

A Baselines: Implementation Details

BERTSUMEXT: For all experiments with BERTSUMEXT, we started with the original implementation[3] and adapted the code to build the sliding windows version. This implementation leverage *bert-base-uncased* pre-trained model and its associated hyperparameters. We use windows of width 800 with an overlap of 300 tokens between two following windows. If a sentence is in multiple windows, we select its [CLS] representation in the window that maximizes the number of surrounding tokens. We finetune the model for 5 epochs using Adam optimizer with an initial learning rate of 1×10^{-5}, $\beta_1 = 0.9$, $\beta_2 = 0.999$.

Longformer-Ext: We built the Longformer-Ext baseline from the Longformer implementation released by HuggingFace[4]. We use the official *longformer-base-4096* pre-trained model trained by AllenAI[5]. This model is based on *RoBERTa-base* and its associated hyperparameters. To increase the maximal position embedding, we drop the pre-trained positional embedding parameters and train a novel token embedding layer to scale Longformer-Ext input up to 12294 tokens. This model computes a sliding self-attention with a window size of 512 tokens on all its 12 Transformer layers. We finetune the model for 5 epochs with only local attention because of memory constraints, using Adam optimizer with an initial learning rate of 1×10^{-5}, $\beta_1 = 0.9$, $\beta_2 = 0.999$, no learning rate warmup and a linear decay of the learning rate.

Reformer-Ext: We started from the HuggingFace implementation of Reformer to build Reformer-Ext baseline. We use a Reformer configuration composed of six layers of attention. We use Locality-Sensitive Hashing Attention with 128 buckets on the input sequence and Local Self-attention on chunks of 64 tokens. We use hidden sates of dimension 256, a feed-forward layer of dimension 512, and 12 attention heads in Transformer encoders. We train this model for 5 epochs using Adam optimizer with an initial learning rate of 1×10^{-5}, $\beta_1 = 0.9$, $\beta_2 = 0.999$, no learning rate warmup and a linear decay of the learning rate.

B Datasets Statistics

Figure 4 presents the distribution of the document lengths in arXiv, PubMed and CNN/DailyMail, after tokenization with pretrained BERT-base tokenizer. It also provides the histograms of the position of the [CLS] tokens of the Oracle sentences in input documents. One can see that the three datasets contain an important number of documents longer than 512 tokens, the standard length limitation of pre-trained language models. However, one can also notice that CNN/DailyMail contains a large part of its Oracle sentences within this first window of 512 tokens. As a consequence, a model that is not able to ”read” beyond this limitation is not penalized. It is also a reason why Lead baseline is quite strong on this dataset. On the contrary, on arXiv and PubMed, one can see that a large part of Oracle sentences occur beyond this 512 windows. This explains why models capable of reading long sequences are required to achieve good results on these datasets.

C PubMed Summaries

Gold		aim . to investigate incidental adrenal enlargement clinical characteristics and functional status and analyze functional lesion risk factors . materials and methods . this retrospective study included 578 patients with adrenal imaging features showing enlargement . incidental adrenal enlargement cases (78) were considered eligible . demographics , functional diagnosis , adrenal imaging features , and concomitant diseases were analyzed . results . the number of adrenal enlargements and proportion of incidental adrenal enlargement increased each year . mean patient age was 50.32 years . thirty - nine cases had unilateral enlargement on the left side and 3 on the right side ; 36 had bilateral enlargement . routine medical checkup was found to have the greatest chance (43.59%) of revealing clinical onsets leading to discovery . biochemical and functional evaluation revealed 54 (69.23%) cases of nonfunctional lesions , 12 (15.38%) of subclinical cushing syndrome , 6 (7.69%) of primary hyperaldosteronism , 1 (1.28%) of metastasis , and 5 (6.41%) of unknown functional status . nodular adrenal enlargement (or , 7.306 ; 95% ci , 1.72728.667 ; p = 0.006) was a risk factor for functional lesions . age and lesion location were not significant factors . conclusion . incidental adrenal enlargement is a frequent radiographic finding and is accompanied by diverse clinical factors that require proper evaluation and management . nodular adrenal enlargement was a risk factor .
GBT-ExtSum	8-	data retrieved included patient demographics , final functional diagnosis , adrenal imaging features , and concomitant diseases .
	14-	smooth enlargement was defined as enlargement of the gland with a smooth contour and no measureable or diffuse nodules . after obtaining patient history and physical examination , all patients underwent biochemical evaluation to assess their functional status .
	16-	patients with an aldosterone - rennin ratio (arr) > 20 underwent any 1 of 3 confirmatory tests (saline infusion , captopril challenge , or postural stimulation) to confirm or exclude definitively primary hyperaldosteronism (pa) .
	25-	as shown in table 1 , routine medical checkup was found to have the greatest chance (43.59%) of revealing clinical onsets leading to the discovery of adrenal enlargement .
	29-	nodular adrenal enlargement (or 7.306 ; 95% ci , 1.72728.667 ; p = 0.006) was the risk factor for functional lesions .
	31-	our study shows that the proportion of incidental adrenal enlargement has gradually increased by year .
	46-	acth - independent macronodular hyperplasia (aimah) and primary pigmented nodular adrenal hyperplasia often manifest as adrenal hyperplasia . the clinical features of aimah tended to be atypical .
BertSumExt (SW)	4-	it is a common term for a variety of adrenal disorders , but its cause must be properly assessed so that patients needing treatment , such as those with hormone hypersecretion or malignant disease , can receive appropriate care . however , there is a lack of literature on functional status and its follow - up to provide comprehensive insight to these findings .
	5-	patients with incidental adrenal enlargement were evaluated in a tertiary referral hospital with endocrinological departments in china .
	7-	this retrospective study included 578 patients with adrenal imaging features showing adrenal enlargement who were hospitalized at the department of endocrinology in pla general hospital (beijing , china) between january 1993 and july 2013 .
	29-	nodular adrenal enlargement (or 7.306 ; 95% ci , 1.72728.667 ; p = 0.006) was the risk factor for functional lesions .
	36-	in addition , smooth enlargement was more common , in 53 (83%) cases , and together these statistics reflect the likelihood that adrenal enlargement will be bilateral , smooth , and found in men .
	37-	however , our study did not show this tendency , likely because the research goals and thus , study populations , differed between the 2 studies .
	38-	's study aimed to explore prevalence , while the present study aimed to evaluate functional status .

GOLD		background and objective . antimicrobial resistance is now a major challenge to clinicians for treating patients . hence , this short term study was undertaken to detect the incidence of multidrug - resistant (mdr) , extensively drug - resistant (xdr) , and pandrug - resistant (pdr) bacterial isolates in a tertiary care hospital . material and methods . the clinical samples were cultured and bacterial strains were identified in the department of microbiology . the antibiotic susceptibility profile of different bacterial isolates was studied to detect mdr , xdr , and pdr bacteria . results . the antibiotic susceptibility profile of 1060 bacterial strains was studied . 393 (37.1%) bacterial strains were mdr , 146 (13.8%) strains were xdr , and no pdr was isolated . all (100%) gram negative bacterial strains were sensitive to colistin whereas all (100%) gram positive bacterial strains were sensitive to vancomycin . conclusion . close monitoring of mdr , xdr , or even pdr must be done by all clinical microbiology laboratories to implement effective measures to reduce the menace of antimicrobial resistance .
GBT-EXTSUM	5-	multidrug resistant (mdr) was defined as acquired nonsusceptibility to at least one agent in three or more antimicrobial categories . extensively drug
	36-	no mdr or xdr strain was isolated from streptococcus sp . all (100%) gram positive cocci were sensitive to vancomycin and linezolid .
	38-	e. coli was the commonest isolate 261 (35%) , followed by pseudomonas aeruginosa 212 (28.4%) .
	40-	out of 200 klebsiella pneumoniae strains isolated , 75 (37.5%) and 25 (12.5%) were detected as mdr and xdr , respectively . out of 42 acinetobacter and other nonfermenter species isolated , 19 (45.2%) and 8 (19%) were mdr and xdr strains , respectively . amongst 250 gnb - mdr strains isolated ,
	62-	, it has been reported that most frequent mdr pathogens were pseudomonas aeruginosa followed by e. coli .
	67-	unless and until multidrug resistant organisms are detected and their incidence is known , the strategies for their control can not be adopted properly in healthcare setup . hence , detection , prevention of transmission of mdros by following infection control practices , antimicrobial surveillance , and stewardship are need of the hour .
	69-	we hereby conclude that early detection and close monitoring of mdr , xdr , or even pdr bacterial strains must be started by all clinical microbiology laboratories to reduce the menace of antimicrobial resistance which is now a global problem .
BERTSUMEXT (SW)	9-	this short term cross - sectional study was conducted in the department of microbiology from 15th of april to 15th of july , 2014 .
	10-	the bacterial strains were isolated from different clinical samples and were identified by conventional methods .
	17-	methicillin resistant staphylococcus aureus (mrsa) strains were detected by meca - mediated oxacillin resistance using cefoxitin disk (30 g) on mueller hinton (mh) agar plate inoculated with test strains as per standard disk diffusion recommendations and incubated at 3335c for 1618 hours .
	20-	an increase in diameter of 5 mm with ceftazidime plus clavulanic acid as compared to ceftazidime disk alone was considered positive for esbl detection .
	36-	no mdr or xdr strain was isolated from streptococcus sp . all (100%) gram positive cocci were sensitive to vancomycin and linezolid .
	38-	e. coli was the commonest isolate 261 (35%) , followed by pseudomonas aeruginosa 212 (28.4%) .
	65-	the limitation of this study is that this is a single center study for only three - month period in a tertiary care hospital in central india . to reflect the trend of infections caused by mdr and xdr strains of bacteria in the region , a multicenter study involving all types of healthcare setups for a minimum period of one year

GOLD		background suicide is a grave public health issue that is responsible for a high mortality rate among individuals aged 1544 years . attitudes toward suicide among medical staff members have been associated with appropriate therapeutic responses to suicidal individuals . the aim of this study was to examine the effects of parental rearing on attitudes toward suicide among japanese medical college students.methodswe examined the association between parental bonding and attitudes toward suicide in 160 medical college students in japan . the parental bonding instrument was used to assess the attitudes and behaviors of parents . the attitudes toward suicide were evaluated using the japanese version of the attitudes toward suicide questionnaire.resultsthe mean age of the subjects was 25.24.0 years old . the majority of the participants in our study agreed that anyone could commit suicide (88.8%) and that suicide is preventable (86.3%) . after adjusting for age and sex , multivariate regression analysis revealed that maternal care approached a statistically significant association with the right to suicide attitude . under the same conditions , maternal care was shown to be significantly associated with the common occurrence attitude . no other significant relationships were observed between parental bonding and attitudes toward suicide.conclusionthis study suggests that a higher level of maternal care ensures that children think that suicide occurs less commonly . the promotion of best practices for suicide prevention among medical students is needed . child rearing support might be associated with suicide prevention .
GBT-EXTSUM	3-	previous studies have shown that difficulties with parental bonding during childhood could be a predisposing factor for the onset of many psychiatric conditions , such as anxiety , depressive states , and maladjusted behaviors.68 parental bonding and premorbid personality traits play an important role in shaping the developmental trajectory of an individual , including his / her ability to adjust to stressful events .
	5-	the objective of this study was to investigate whether parental bonding is associated with attitudes toward suicide among medical college students in japan .
	8-	the demographic data (age and sex) were obtained from self - questionnaires and interviews .
	14-	higher scores on the care and protection dimensions reveal that participants perceive their parents to be more caring and/or protective .
	39-	right to suicide was significantly associated with common occurrence , unjustified behavior , and preventability / readiness to help .
	43-	the majority of the participants in our study agreed that anyone could commit suicide (88.8%) and that suicide is preventable (86.3%) .
	44-	in addition , the multiple regression analysis revealed that participants who reported a higher level of maternal care thought that suicide was a common occurrence and tended to think that people do not have the right to commit suicide .
BERTSUMEXT (SW)	6-	students in their fifth year of medical school at hirosaki university , hirosaki , japan , participated in the study .
	7-	the surveys were distributed to 226 medical students . of the distributed 226 surveys , 160 questionnaires (116 males and 44 females)
	13-	the overprotection dimension of the pbi reflects parental overprotection and control in contrast to the encouragement of autonomy .
	14-	higher scores on the care and protection dimensions reveal that participants perceive their parents to be more caring and/or protective .
	15-	we employed the japanese version of the attitudes toward suicide questionnaire (atts) to assess the attitudes toward suicide held by the study participants.12 we employed a six factor model that was previously developed in studies of japanese attitudes , including
	16-	common occurrence , suicidal expression as mere threat , unjustified behavior ,
	17-	impulsiveness.12,13 each item , with the exception of items 10 and 28 , was scored on a five point scale from 1 (strongly agree) to 5 (strongly disagree) .

D ArXiv Summaries

Gold		in vivo calcium imaging through microscopes has enabled deep brain imaging of previously inaccessible neuronal populations within the brains of freely moving subjects . however , microendoscopic data suffer from high levels of background fluorescence as well as an increased potential for overlapping neuronal signals . previous methods fail in identifying neurons and demixing their temporal activity because the cellular signals are often submerged in the large fluctuating background . here we develop an efficient method to extract cellular signals with minimal influence from the background . we model the background with two realistic components : (1) one models the constant baseline and slow trends of each pixel , and (2) the other models the fast fluctuations from out - of - focus signals and is therefore constrained to have low spatial - frequency structure . this decomposition avoids cellular signals being absorbed into the background term . after subtracting the background approximated with this model , we use constrained nonnegative matrix factorization (cnmf , @xcite) to better demix neural signals and get their denoised and deconvolved temporal activity . we validate our method on simulated and experimental data , where it shows fast , reliable , and high quality signal extraction under a wide variety of imaging parameters .
GBT-ExtSum	1-	. continued advances in optical imaging technology are greatly expanding the number and depth of neuronal populations that can be visualized .
	2-	specifically , in vivo calcium imaging through microendoscopic lenses and the development of miniaturized microscopes have enabled deep brain imaging of previously inaccessible neuronal populations of freely moving mice (@xcite) . while these techniques have been widely used by neuroscientists ,
	20-	like the proposed cnmf in @xcite , our extended cnmf for microendoscopic data (cnmf - e) also has the capability of identifying neurons with low signal - to - noise ratio (snr) and simultaneously denoising , deconvolving and demixing large - scale microendoscopic data . to accomplish this : (1) we replace the rank-1 nmf approximation of the background with a more sophisticated approximation , which can better account the complex background and avoid absorbing cellular signals , and (2) we develop an efficient initialization procedure to extract neural activities with minimal influence from the background .
	71-	@xmath56 is a template matching filter to detect spatial structures with similar shapes and sizes . for flat structures in the small regions , like background , filtering them with @xmath56
	134-	in this paper , we proposed an efficient method for extracting cellular signals from microendoscopic data ; such methods are in very high demand in the neuroscience community .
	136-	our method shows credible performances in recovering the real neuronal signals and outperforms the previous standard pca - ica method .
BertSumExt (SW)	0-	monitoring the activity of large - scale neuronal ensembles during complex behavioral states is fundamental to neuroscience research
	11-	our work is based on a matrix factorization approach , which can simultaneously segment cells and estimate changes in fluorescence in the temporal domain .
	26-	the video data we have are observations from the optical field for a total number of @xmath2 frames .
	64-	we estimate the temporal component of one neuron @xmath15 from spatially filtered data and then use it to extract the corresponding spatial footprint @xmath14 from the raw data . in the step of estimating @xmath14 , we re - order all frames to make nearby frames share the similar local background levels and then take the temporal differencing to remove the background signals temporally .
	105-	we also display @xmath98 tightly clustered neurons in the simulated data (figure [fig : sim]e) to demonstrate that our cnmf - e approach can accurately detect and demix their activity (figure [fig : sim]g) .
	107-	in contrast , pca - ica based detection can only detect two neurons and the calcium traces have high level of noise .

GOLD		statistical learning theory chiefly studies restricted hypothesis classes , particularly those with finite vapnik - chervonenkis (vc) dimension . the fundamental quantity of interest is the sample complexity : the number of samples required to learn to a specified level of accuracy . here we consider learning over the set of all computable labeling functions . since the vc - dimension is infinite and a priori (uniform) bounds on the number of samples are impossible , we let the learning algorithm decide when it has seen sufficient samples to have learned . we first show that learning in this setting is indeed possible , and develop a learning algorithm . we then show , however , that bounding sample complexity independently of the distribution is impossible . notably , this impossibility is entirely due to the requirement that the learning algorithm be computable , and not due to the statistical nature of the problem .
GBT-EXTSUM	6-	an alternative approach , and one we follow in this paper , is simply to consider a single learning model that includes all possible classification methods .
	8-	since the vc - dimension is clearly infinite , there are no uniform bounds (independent of the distribution and the target concept) on the number of samples needed to learn accurately @xcite .
	10-	, it is natural to allow the learning algorithm to decide when it has seen sufficiently many labeled samples based on the training samples seen up to now and their labels . since the above learning model includes any practical classification scheme , we term it universal (pac-) learning .
	11-	we first show that there is a computable learning algorithm in our universal setting .
	19-	our results imply that computable learning algorithms in the universal setting must waste samples " in the sense of requiring more samples than is necessary for statistical reasons alone .
	81-	then we will contrast this to the case of an uncomputable learning algorithm .
BERTSUMEXT (SW)	50-	(semantic requirements) for any @xmath27 , for any concept @xmath8 , and distribution @xmath9 over @xmath2 , if the oracle returns pairs @xmath28 for @xmath29 drawn iid from @xmath9 , then @xmath0 always halts , and with probability at least @xmath12 outputs a hypothesis @xmath13 such that @xmath30 ¡ { varepsilon}$]
	64-	suppose @xmath36 is an infinite sequence of iid samples drawn from @xmath9 .
	75-	the learning algorithm queries the oracle as necessary for new learning samples and their labeling .
	78-	note that it seems necessary to expand the hypothesis space to include all partial recursive functions because the concept space of total recursive functions does not have a recursive enumeration (it is uncomputable whether a given program is total recursive or not) .
	79-	we will see in theorem [thm : nobound] that there is no bound @xmath55 on the number of samples queried by any computable learning algorithm in our setting .
	80-	let us obtain some intuition for why that is true for the above learning algorithm .

GOLD		in this paper , we propose majority voting neural networks for sparse signal recovery in binary compressed sensing . the majority voting neural network is composed of several independently trained feedforward neural networks employing the sigmoid function as an activation function . our empirical study shows that a choice of a loss function used in training processes for the network is of prime importance . we found a loss function suitable for sparse signal recovery , which includes a cross entropy - like term and an @xmath0 regularized term . from the experimental results , we observed that the majority voting neural network achieves excellent recovery performance , which is approaching the optimal performance as the number of component nets grows . the simple architecture of the majority voting neural networks would be beneficial for both software and hardware implementations .
GBT-EXTSUM	40-	requires only several matrix - vector products to obtain an output signal , which is an estimate signal of the sparse vector @xmath12 .
	48-	the signal propagates from left to right and the output signal @xmath17 eventually comes out from the output layer . the network should be trained so that the output signal @xmath17 is an accurate estimation of the original sparse signal @xmath12 .
	168-	in this paper , we proposed sparse signal recovery schemes based on neural networks for binary compressed sensing .
	169-	our empirical study shows a choice of the loss function used for training neural networks is of prime importance to achieve excellent reconstruction performance .
	170-	we found a loss function suitable for this purpose , which includes a cross entropy like term and an @xmath0 regularized term .
	173-	the simple architecture of the majority voting neural network would be beneficial for both software and hardware implementation .

Abstract

Given the potential misuse of recent advances in synthetic text generation by language models (LMs), it is important to have the capacity to attribute authorship of synthetic text. While stylometric organic (i.e., human written) authorship attribution has been quite successful, it is unclear whether similar approaches can be used to attribute a synthetic text to its source LM. We address this question with the key insight that synthetic texts carry subtle distinguishing marks inherited from their source LM and that these marks can be leveraged by machine learning (ML) algorithms for attribution. We propose and test several ML-based attribution methods. Our best attributor built using a fine-tuned version of XLNet (XLNet-FT) consistently achieves excellent accuracy scores (91% to near perfect 98%) in terms of attributing the parent pre-trained LM behind a synthetic text. Our experiments show promising results across a range of experiments where the synthetic text may be generated using pre-trained LMs, fine-tuned LMs, or by varying text generation parameters.

1 Introduction

Recent advancements in natural language processing have enabled *synthetic* text generation that is often of comparable quality to the organic text (Ippolito et al., 2020; Radford et al., 2019; Zellers et al., 2019; Gehrmann et al., 2019). This capability has the potential to be misused by malicious actors to launch misinformation, spam, and phishing campaigns (Solaiman et al., 2019; Brown et al., 2020). To prevent potential misuse, prior research has shown considerable success in building machine learning (ML) algorithms that detect (Zellers et al., 2019) or assist humans in detecting (Gehrmann et al., 2019) synthetic text.

While prior research has shown promise in distinguishing between synthetic and organic text, very little has been done on attributing the authorship of the language model (LM) generating the synthetic text (Pan et al., 2020). It is important to be able to track the provenance of synthetic text to the source LM. This can be useful in identifying perpetrators of potential misuse and the unauthorized use of an LM (e.g., in case it is stolen through sophisticated model inversion attacks (Fredrikson et al., 2015) or outright security breaches).

It is particularly challenging to attribute the authorship of the synthetic texts because of the variety and number of available LMs and configurations. While there are only a handful of public pre-trained LMs, it is common to further fine-tune them before using them to generate synthetic text (Devlin et al., 2019; Sanh et al., 2020). Fine-tuning can significantly impact the characteristics of the generated text (Howard and Ruder, 2018; Cruz and Cheng, 2019). Moreover, variations in the sampling parameters used while generating synthetic text whether from pre-trained or fine-tuned LMs can further impact text characteristics (Zellers et al., 2019).

In this paper, we design and evaluate ML-based techniques for attributing the LM and configuration used to generate a synthetic text. We do this in the context of four problem scenarios, each representing a variation of a threat posed by an adversary or malicious user. The scenarios vary in terms of what information the LM attribution system has about the adversary's strategy for generating fake text.

Methodologically, our key insight for attributing the LM used by the adversary is that differences between LM architecture (i.e., layers, parameters), training (i.e., pre-training and fine-tuning), and generation techniques (i.e., sampling parameters) will leave their subtle mark on the generated synthetic texts. The success of our attributors at identifying the LM and configuration used relies on the presence of these subtle distinguishing marks and on the ability to exploit them effectively. As our re-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1811–1822
April 19 - 23, 2021.

sults indicate, this success holds especially in terms of attributing pre-trained models used to generate text even under varying conditions.

In summary, our key contributions are:

- We evaluate a variety of attribution techniques on their ability to attribute the LM and configuration used to generate text. These include attributors making use of stylometric features as well as static and dynamic embeddings.
- We evaluate these attributors on a corpus of 350,000 synthetic texts that we generated in a controlled manner using combinations of LMs, sampling parameters, and fine-tuning.
- Our best attributor built on top of a fine-tuned version of XLNet (XLNet-FT) performs excellently at identifying pre-trained LM used to generate coherent synthetic texts. Accuracy ranges between 91% and close to perfect 98%. This performance holds for various experiments where we use fine-tuning and different sampling parameters. However, the performance is mediocre when attributing the fine-tuned LM used to generate the text.

Paper Organization: The rest of the paper is organized as follows. Section 2 presents the different threat models based on the adversary's strategy for generating synthetic text and assumptions made by the attributor. We then describe our data and attribution methods in Section 3. Experimental results are in Section 4. Section 5 contextualizes our work with respect to prior literature. Section 6 concludes the paper with an outlook on future work.

2 Threat Model

This section describes different threat models that we consider in this paper. The adversary's goal is to generate synthetic text using language models (LMs). The attributor's goal is to attribute the synthetic text to the source LM used by the adversary. All of the threat models operate under the closed world scenario, where the attributor is assumed to know the universe of LMs. The threat models differ based on the adversary's LM training (i.e., pre-training or fine-tuning) and sampling strategies.

2.1 Attributing pre-trained LMs

In the first scenario, the adversary uses a pre-trained LM to generate synthetic text. The attributor trains a classifier to attribute the synthetic text to the source pre-trained LM. We assume a closed-world scenario where both the adversary and attributor have access to the set of off-the-shelf pre-trained LMs such as GPT-2.[1]

More formally, the scenario can be described as: *Given* n *pre-trained LMs* $PM_1, PM_2, ..., PM_n$*, the goal is to train a* n*-class attributor to attribute test instances to the correct source pre-trained LM. In this scenario, the adversary generates texts using* PM_k *where* $1 \leq k \leq n$ *and the attributor's goal is to predict label* PM_k *for the generated texts.*

2.2 Attributing fine-tuned LMs to parent pre-trained LMs

In this scenario, the adversary fine-tunes a pre-trained LM to generate synthetic text. The attributor trains a classifier to attribute the synthetic text to the source pre-trained LM. The main difference from the first scenario is that the attributor is unaware of the fine-tuning used by the adversary before generating text. Note that the goal of the attributor is to detect the source pre-trained LM rather than the fine-tuned LM that is used to generate synthetic text.

More formally, the scenario can be described as: *Given* n *pre-trained LMs* $PM_1, PM_2, ..., PM_n$*, and a LM* FM_k*, generated by fine-tuning* PM_K *where* $1 \leq k \leq n$*, the goal is to train a* n*-class attributor to attribute test instances to the correct source pre-trained LM. In this scenario, the adversary generates text using fine-tuned LM* FM_k *and the attributor's goal is to predict label* PM_k *for generated text.*

2.3 Attributing pre-trained or fine-tuned LMs with different sampling parameters

In this scenario, the attributor trains a classifier to attribute the synthetic text generated by the adversary using a pre-trained or fine-tuned LM. The main difference from the first scenario is that the adversary potentially uses different sampling parameters for text generation than those used by the attributor to train the classifier.

More formally, the scenario can be described as: *Given* n *pre-trained or fine-tuned LMs* $M_1, M_2, ..., M_n$*, the goal is to train a* n*-class attributor to attribute test instances to the correct source model. As per this scenario the adversary*

---

[1] This assumption holds for the rest of the paper, unless stated otherwise.

generates texts using model M_k, $1 \leq k \leq n$, with sampling parameters S_k that are unknown to the attributor, and the attributor's goal is to predict label M_k for the generated text.

2.4 Attributing fine-tuned variants of a pre-trained LM

In this scenario, the adversary fine-tunes a pre-trained LM to generate synthetic text. The attributor trains a classifier to attribute the synthetic text to the source fine-tuned LM. The main difference as compared to the second scenario is that the attributor is aware of the fine-tuning used by the adversary. Note that there are multiple fine-tuned variants of the same parent pre-trained LM.

More formally, the scenario can be described as: *Given n fine-tuned LMs $FM_1, FM_2, ..., FM_n$, the goal is to train a n-class attributor to attribute test instances to the correct fine-tuned LM. As per this scenario, the adversary generates text using a fine-tuned LM FM_k and the attributor's goal is to predict label FM_k for the generated text.*

3 Data & Methods

In this section, we present details about (1) the text generating language models (LMs) and their configurations, and (2) about the attributors studied. To address our research goals, we need a dataset of synthetic texts generated by various pre-trained and fine-tuned LMs under different configurations. Publicly available datasets are unsuitable because there can be high variability in the conditions under which text was generated [2]. It is crucial for us to be able to control the underlying conditions such as: the architecture of LM, prompt used for text generation, sampling parameters, and the data size and topics used for fine-tuning. Details about this generated dataset are also provided in this section.

3.1 Text Generation: LMs, parameters, and configurations

We used four pre-trained LMs: OpenAI GPT (Radford et al., 2018), OpenAI GPT2 (Radford et al., 2019), XLNet (Yang et al., 2019), and BART (Lewis et al., 2020). BART and XLNet are both based on the BERT architecture, which makes use of the bidirectional context of input text to develop a deep understanding of language. XLNet improves on BERT with a form of generalized auto-regressive pre-training using permutation modeling. It outperforms BERT on several classification tasks (Yang et al., 2019). BART combines the bidirectional encoder used by BERT with an auto-regressive decoder used by GPT, which, through a noising and text reconstruction pre-training task, achieves good performance in both language understanding and language generation tasks. In other words, both BART and XLNet augment their training strategies to make up for the lack of language generation capabilities in BERT. GPT and GPT2 are architecturally identical LMs with GPT2 trained on 10 times the data used for training original GPT LM. These use a more traditional generative pre-training approach, looking only at the context coming before a part of the text and not after (Radford et al., 2019). All four pre-trained LMs are publicly available.

3.1.1 Text generation parameters

Three key parameters when generating texts are: *p*, *k*, and *temperature*. The range of values tested are given in Table 1, with default values emphasized in boldface. Note that one chooses to use either *p-value* or *k-value* sampling since they have the same goal - controlling the number of words taken into consideration while sampling text from an LM.

With *top-k* sampling, the LM randomly chooses one from the top *k* words. With *top-p* sampling, it chooses from the set of words whose cumulative probability exceeds *p*. Both Zellers et al. (2019) and Holtzman et al. (2020) conclude that synthetic text matches organic text closely when the *p-value* is kept in range [0.9, 1.0]. Higher values lead to repetitions as the length of text increases. Thus, we choose the lower limit of *p* from the range [0.9, 1.0].

For *top-k* sampling, we use a range of values both higher and lower than 40, which is used as the default for text generation by Radford et al. (2019) in their breakthrough GPT2 paper. Between a choice of *top-p* or *top-k* sampling, we chose *top-p* (p = 0.9) as default due to its lower dependency on vocabulary size and extensive use in previous research on GPT2 (Radford et al., 2019; Zellers et al., 2019; Ippolito et al., 2020).

Temperature controls the likelihood of low probability words appearing in the final pool of words used for random selection (Holtzman et al., 2020). Higher temperatures produce text containing highly unusual words that are normally not favored by *top-k* or *top-p* sampling. At the other end, Holtzman et al. (2020) note that temperatures below 1 reduce

word diversity but at the cost of increasing word repetition. To avoid this we set temperature as 1 in experiments where evaluation of its effect on synthetic text is not of concern.

#	**Parameter**	**Values**

6	k-value	1, 20, 40, 80, 160

Table 1: The parameters explored (defaults in bold)

3.1.2 Data for fine-tuning

For scenarios where we need synthetic text generated using fine-tuned LMs, we limit text generation to the GPT2 LM. GPT2 has been shown to have state of the art performance in language generation tasks (Radford et al., 2019; Klein and Nabi, 2019). Data from four Reddit communities was used for fine-tuning LMs: *r/relationships*, *r/technology*, *r/changemyview*, and *r/conspiracy*. These subreddits were chosen based on qualitative differences between their content. r/technology contains technical jargon, while r/relationships focuses on personal pronouns and adopts a critical approach towards writing. r/changemyview has confrontational content with members attempting to challenge and disprove each other's views, while r/conspiracy focuses on hyperbolic statements. In essence, each subreddit is considered a different *topic* area. Table 2 shows the number of posts and comments scraped from each subreddit.

3.1.3 Dataset details

We generate text of three different lengths: *short* (up to 40 words), *medium* (between 40 and 100 words), and *long* (above 100 words). In experiments where length is not the focus, we use *medium* as the default. Each synthetic text is generated using a randomly selected subreddit submission as a prompt. We start by sampling words equal to the length of the prompt from the LM. We trim the generated text to follow standard sentence structure such as start capitalization and end punctuation, after which text is sorted into one of three length

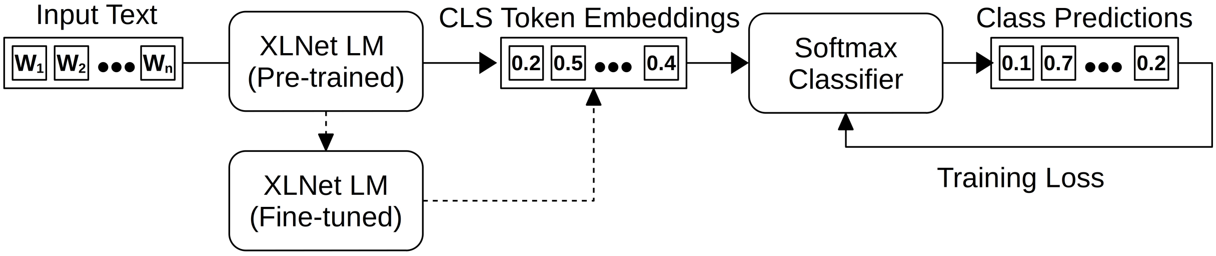

Figure 2: Attributor training on XLNet embeddings. The dashed lines are part of the fine-tuned pathway.

categories.

We generated 10,000 synthetic texts for each target class in our experiments. For example, when evaluating the performance of attributors against fine-tuned LMs, we generated 10,000 samples for each of four GPT2 LMs fine-tuned on one of the four Reddit topics mentioned previously. In total, 35 distinct sets of synthetic documents, each with 10,000 examples, were used for a total of 350,000 unique synthetic documents[3]. We build training and test datasets that are balanced in classes for each scenario because while there is growing evidence that synthetic text is appearing in the wild, there is little to no information about the relative impact of the source LMs. Thus, any split beyond an even split across classes has little justification.

Subreddit	Posts	Comments	Total
r/changemyview	136,775	321,527	458,302
r/relationships	200,047	167,219	367,266
r/technology	174,431	143,199	317,630
r/conspiracy	99,302	161,993	261,295

Table 2: Data scraped per each subreddit.

3.2 Attributors

We test six attributors in their ability to identify the source LMs. The first attributor is a decision tree classifier with Writeprints (Abbasi and Chen, 2008) feature set, second is a CNN with GloVe (Pennington et al., 2014) embeddings as the feature set. The next four attributors are softmax classifiers, with the first two built on top of pre-trained XLNet and GPT2, and the other two on top of XLNet and GPT2 fine-tuned on training data used in the corresponding scenario.

3.2.1 Decision tree with Writeprints features

The Writeprints features have been used extensively and successfully for authorship attribution. (Abbasi and Chen, 2008; Mahmood et al., 2020) When combined with SVMs and decision trees these have shown good performance in attribution tasks (Abbasi and Chen, 2008; Pearl and Steyvers, 2012). Due to ease of interpretability of features, we implement a decision tree classifier with Writeprints features to test our intuition that stylistic, rather than topical, differences contribute towards the attribution of synthetic text.

3.2.2 CNN with GloVe embeddings

Pre-trained GloVe embeddings have been shown to outperform word frequency and count-based embeddings for sentence and sequence classification tasks (Pennington et al., 2014; Le-Hong and Le, 2018). Also, the use of GloVe with CNNs has shown good results in classification tasks like newsgroup identification (Gupta et al., 2018).

3.2.3 Attributors from LM embeddings

Embeddings generated through LMs like BERT, XLNet, and GPT2 have been shown to capture language semantics and context much better than static embeddings generated through GloVe and other word count or frequency-based embeddings generators (Sun et al., 2020; Howard and Ruder, 2018). Because of their extensive pre-training, these LMs can capture long-term dependencies and incorporate contextual and hierarchical relations between words better than pre-computed static embeddings.

LMs such as XLNet make use of a special *[CLS]* token to get pooled output representing a complete text sequence. We use the final network layer embeddings of this token for attribution. Specifically, we train a softmax output layer that takes as input XLNet's *[CLS]* token embeddings and generates probabilities for each decision class in the experiment setup. For GPT2 we use a parallel strategy with pooled output from the complete final layer of the model for a particular input text. Again this output is connected to a softmax output layer which, similar to our strategy with XLNet, is trained to

---

[3] We will make this dataset available for research upon publication of our paper

generate class predictions based on the input embeddings.

In addition to using the pre-trained versions of XLNet and GPT2, we also evaluate attributors built from fine-tuned versions of these LMs. Note that here fine-tuning is on training data used to train all attributors in the corresponding experiment. Figure 2 illustrates these strategies with XLNet as an example. The sequence with dashed lines represents the fine-tuned versions.

4 Results

We present attribution accuracy results in the same order of scenarios described earlier in Section 2.[4]

4.1 Attributing pre-trained LMs

Table 3 presents the accuracy results for short (up to 40 words), medium (between 40 and 100 words), and long (more than 100 words) synthetic text generated using pre-trained GPT, GPT2, XLNet, and BART language models (LMs). Decision tree and the two XLNet versions achieve accuracy between 82 and, near perfect 98%, across the three types of texts. In comparison, CNN and GPT2 attributors lag behind.

While both XLNet attributors score higher than decision tree, XLNet-FT has the best performance which when compared with the next best XLNet-PT ranges from 3% to 7%. Note that apart from the pre-trained GPT2 attributor, all show marked improvement in accuracy scores with an increase in text length. Similar results showing direct proportionality of classifier performance with text length were also observed by Ippolito et al. (2020) in experiments detecting synthetic text.

Prior work has shown that uni-directional LMs are more suited for language generation due to generative pre-training (Lewis et al., 2020) where the LM learns to predict the next word based on the previous context. Bidirectional LMs like BERT and XLNet excel at classification as they make use of masked modeling and next sentence prediction tasks to improve understanding of necessary language attributes (Devlin et al., 2019; Yang et al., 2019). Our results are consistent in that XLNet performance is better than GPT2.

Interestingly, the decision tree with Writeprints outperforms GPT2 based attributors in all three text lengths. Our investigation into specific Writeprints features emphasized by the decision tree (**see appendix A.1**) reveals a greater emphasis on stylistic features. This gives further credence to our intuition that variations between texts generated by different LMs are more stylistic than topical in nature. Our results suggest that GPT2 based attributors are not adept at capturing such stylistic differences.

4.2 Attributing fine-tuned LMs to the parent pre-trained LMs

Our goal in this scenario is to attribute the synthetic text generated using a fine-tuned variant (using an unknown dataset) of a pre-trained LM. Note that the attributor is unaware of fine-tuning. We limit fine-tuned text generation in this experiment to just GPT2 for reasons described in Section 3.

The first row in Table 4 reports the accuracy results. We note that XLNet-FT again performs the best with XLNet-PT in the second place. CNN has the weakest results. Interestingly, Writeprints continues to do fairly well – once again emphasizing the role of style in identifying source LM. Comparing these results with Table 3 (for medium length texts), we see all accuracies drop slightly as expected when the adversary chooses to fine-tune the LM that is unknown to the attributor.

We run a second variation of the same experiment – one where the attributor has partial knowledge of the adversary's strategy. Specifically, the fact that the adversary is using a fine-tuned LM to generate text is known but the dataset used for fine-tuning remains unknown. In response, we pick some dataset (here r/relationships) to add fine-tuned LM generated texts to our training data. Note that the adversary uses r/changemyview. The second row in Table 4 reports similar results as the first row. Thus, it seems that this additional knowledge does not help improve attribution accuracy.

In sum, the accuracy for XLNet-FT across all experiments thus far is above 90%. This indicates that even when the adversary fine-tunes the LM for text generation, the parent pre-trained LM is still identifiable. This result confirms our intuition that as fine-tuning is known to leave the majority of layers unchanged, the text generated retains characteristics of the parent pre-trained LM, making accurate attribution possible.

---

[4] We measured performance using F1 score as well. However, since there were no remarkable differences, we only report accuracy results to be concise.

Synthetic Text Length	**DT (Writeprints)**	**CNN (GloVe)**	**XLNet-PT**	**XLNet-FT**	**GPT2-PT**	**GPT2-FT**
Short (Upto 40 Words)	82	68	85	**91**	72	74
Medium (40 to 100 words)	86	73	90	**96**	71	72
Long (Above 100 words)	93	83	95	**98**	72	72

Table 3: Accuracy percentages for attributing source pre-trained LMs. Datasets contain synthetic texts of different lengths generated using pre-trained BERT, GPT, GPT2 and XLNet.

Training data includes	**Test data includes**	**DT (Writeprints)**	**CNN (GloVe)**	**XLNet-PT**	**XLNet-FT**	**GPT2-PT**	**GPT2-FT**
GPT2 (PT)	GPT2 (FT-r/changemyview)	78	64	86	**93**	70	71
GPT2 (FT-r/relationships)	GPT2 (FT-r/changemyview)	77	67	86	**91**	70	70

Table 4: Accuracy percentages in attributing source pre-trained LM when adversary generates synthetic text using a fine-tuned LM. In addition to GPT2 variants mentioned in columns 1 and 2, training and testing data also includes classes representing XLNet, BART, and GPT.

4.3 Attributing LM with different sampling parameters

Here we consider the scenario where both the attributor and the adversary use the same LM but they differ in parameter choices when generating texts. We run this experiment assuming the adversary uses GPT2 fine-tuned on r/changemyview. The attributor is aware of this but not the sampling parameters. Selecting parameter values that are quite different from each other we see from Table 5 that there is virtually no performance drop for XLNet-FT. That is, our best performing attributor is resilient to these differences. Temperature sampling shows weaker results all around. This is not a concern as discussed later in this section.

We next explore the parameter differences angle further to get a sense of what would happen if the adversary chose a parameter value other than the ones explored in Table 5. The different values for k, p, and temperature are as listed in Table 1. We remind the reader that one uses either $top-k$ or $top-p$ sampling to control the number of words under consideration during text generation. We use $top-p$ sampling as the default strategy. When varying k or p, the temperature is fixed at the default value. When varying temperature, p is kept at the default value.

The results in Table 6 show that it is challenging to tell apart synthetic texts generated by different values of k and p. Given their strong similarities we expect to see results as in Table 5 when the adversary picks other parameter values. With temperature variations we get accuracy above 80%, indicating marked differences between texts generated at different temperatures. However, taking a closer look at the text reveals a serious problem: temperature > 1 produces erratic and confusing text. This problem becomes more acute as the temperature approaches its upper limit. This is consistent with the observation by Holtzman et al. (2020) showing that temperatures above 1 produce incoherent and confusing text. This reduces viability in a setting where the synthetic text is to be used as a suitable replacement for organic text.

We conclude from Tables 5 and 6 that our attributors should be resilient even when the adversary chooses parameter values for text generation beyond the ones explicitly tested here.

4.4 Attributing fine-tuned variants of a pre-trained LM

Finally, we explore the scenario where the adversary is using different fine-tuned LMs with the same parent pre-trained LM. The attributor is aware of this fine-tuning and is attempting to tell apart these fine-tuned LMs. Table 7 presents the accuracy results when synthetic text is generated by fine-tuning GPT2 on 4 different subreddits (r/changemyview, r/technology, r/relationships, r/conspiracy). XLNet-FT again achieved the best accuracy, however, this time it is less than 60%. Curiously, CNN which was the least successful in earlier experiments performed almost identically to XLNet-FT. GPT2 performed just slightly better than a random attributor (1/4, i.e., 25%). Overall, variations between texts generated by different fine-tuned variants of the same pre-trained LM are not

Training data includes	Test data includes	DT (Writeprints)	CNN (GloVe)	XLNet-PT	XLNet-FT	GPT2-PT	GPT2-FT
GPT2 (k=20)	GPT2 (k=160)	76	71	88	**95**	71	71

pronounced enough to be leveraged by the attribution techniques we consider. Our preliminary analysis shows that there is some correlation between the attributor's mistakes and the vocabulary similarity of the corresponding subreddits. However, further research is needed to probe the causes of this lackluster performance and devise ways to improve the attribution of text produced by fine-tuned LMs.

5 Related Work

We contextualize our work with respect to prior literature on detection and attribution of organic and synthetic text.

5.1 Synthetic text detection

There has been a lot of recent interest in developing ML approaches to distinguish between organic and synthetic text. GLTR (Giant Language Model Test Room) leveraged the statistical tendency of LMs to produce words with higher probability of occurrence to help users differentiate between synthetic and organic text (Gehrmann et al., 2019). Grover used a purpose-built LM to train a classifier for synthetic and organic text (Zellers et al., 2019). Bakhtin et al. (2019) proposed energy based models for differentiating between synthetic and organic text. Our work takes this line of work a step further by trying to attribute synthetic text to the source LM.

5.2 Synthetic text attribution

Pan et al. (2020) proposed a dynamic embedding based approach to attribute synthetic text generated by a pre-trained LM as part of their broader investigation of sensitive information exposed by LMs. We significantly build on this work from both the methodological and application perspectives. Differently from this work, we use stylometric as well as static and dynamic embeddings. We also consider more realistic threat models where the synthetic text is generated by either pre-trained or fine-tuned LMs and using different sampling parameters.

5.3 Organic text attribution

There is a rich body of literature on authorship attribution of organic text using stylometric features. We discuss a few classic papers here. Mosteller and Wallace (1964) used word frequency analysis for authorship attribution. Abbasi and Chen (2008) proposed a ML-based approach for authorship attribution using an exhaustive stylometric feature set called Writeprints. While there is impressive progress in stylometric organic text attribution (e.g., Narayanan et al., 2012; Ruder et al., 2016), these approaches do not work as effectively for synthetic text attribution. As our evaluation showed, Writeprints were significantly outperformed by other approaches for synthetic text attribution. This is because LMs are trained on large text corpora from different authors thus there are no clear-cut stylometric differences in synthetic text generated by different LMs.

5.4 Synthetic image attribution

Recent advances in Generative Adversarial Networks (GANs) have led to impressive results in synthetic image generation (Bao et al., 2017; Taigman et al., 2017; Ma et al., 2017). For example, Chen et al. (2020) proposed image models similar to pre-trained LMs to learn an unsupervised representation of images for various downstream tasks. Most related to our work, Yu et al. (2019) proposed an ML approach to attribute synthetic images generated by GANs with different architectures and parameters. At the most basic level, the problem of synthetic image attribution differs from synthetic text attribution because images are smooth and local where words in a text document may be correlated even if they are far apart (Sharir et al., 2020). For instance, Yu et al. (2019) showed that their ML classifier could use only part of the synthetic image for attribution. In contrast, we observed a large drop in accuracy when we make use of only part of input synthetic text.

6 Conclusion

In this paper, we presented an ML approach to attribute authorship of synthetic text to its source LM. Our results showed that an attributor based on fine-tuned XLNet embeddings outperformed other approaches based on stylometric features as well as static and dynamic embeddings. Our results also showed there is significant room for improvement in distinguishing between synthetic text generated by different fine-tuned variants of an LM. Further research is also needed for effective attribution of synthetic text generated by more diverse fine-tuned LMs in both closed-world and-open world settings. Finally, future research on synthetic text attribution should also consider more sophisticated LMs (e.g., GPT-3 with 175 billion parameters (Brown et al., 2020) and Google's trillion parameter LM (Fedus et al., 2021)) when they are publicly released.

A Appendix

A.1 Analysis of importance given by Decision Tree to Writeprints

Synthetic texts generated by pre-trained LMs are distinguishable to a high degree. This holds even when the adversary decides to use a fine-tuned LM or varies text generation parameters like p-value, k-value, or temperature. Thus, these texts carry exploitable model fingerprints.

Most challenging is the ability to tell apart texts generated by different fine-tuned versions of the same pre-trained model. XLNet fine-tuned on the training data yields excellent results; except for attributing fine-tuned models accuracies are almost entirely above 90%. Interestingly, decision trees fare quite well offering the advantage of interpretability of decisions. Decision Tree based classifier focusing only on stylistic differences achieves an accuracy of higher than 80% in all three configurations. Investigating the importance given by classifier to different Writeprints show stylistic features like spaces, percentage of characters, and special characters being given the highest importance.

Figure 3 shows a comparison of importance given by a decision tree based attributor to features before and after eliminating whitespace as a feature. Running the experiment again after eliminating the highest rated feature (frequency of white space) results in minimal drop in performance (within a range of 1%- 2%) and shows continued focus on more stylistic language features as key indicators of differences between these texts. This confirms our intuition that different pre-trained versions of language models have different writing styles which are discernible through text classification techniques. Moreover, our experiments showed that fine-tuned LMs retained characteristics from their parent pre-trained LM, allowing an attributor trained entirely on pre-trained text to successfully attribute fine-tuned LM text with above 90% accuracy even in a worst case scenario.

Comparing importance maps from a decision tree attributor trained on Writeprints from pre-trained and fine-tuned GPT2 LMs shows interesting results. From figure 4, it is apparent that top two most important features are common among pre-trained and fine-tuned variants, with a number of other similarities in features given relatively less importance. It shows that there are certain stylistic characteristics that are passed down from a pre-trained LM to its fine-tuned variant.

A.2 Details of pre-trained language models used

In our experiments we have made use of four publicly available pre-trained language models: XLNet, BART, GPT, GPT2. Details about those are given in Table 8. Comparing sizes, XLNet is trained on largest dataset with over 142 GB of documents. Although no explicit size is mentioned for GPT2, it is said to be trained on 10 times more data than GPT.

We Need to Talk About Random Splits

Anders Søgaard[1,2] **Sebastian Ebert**[1] **Jasmijn Bastings**[1] **Katja Filippova**[1]
[1]: Google Research, Berlin
[2]: University of Copenhagen
{soegaard|eberts|bastings|katjaf}@google.com

Abstract

Gorman and Bedrick (2019) argued for using random splits rather than standard splits in NLP experiments. We argue that random splits, like standard splits, lead to overly optimistic performance estimates. We can also split data in biased or adversarial ways, e.g., training on short sentences and evaluating on long ones. Biased sampling has been used in domain adaptation to simulate real-world drift; this is known as the covariate shift assumption. In NLP, however, even worst-case splits, maximizing bias, often under-estimate the error observed on new samples of in-domain data, i.e., the data that models should minimally generalize to at test time. This invalidates the covariate shift assumption. Instead of using multiple random splits, future benchmarks should ideally include multiple, independent test sets instead; if infeasible, we argue that multiple biased splits leads to more realistic performance estimates than multiple random splits.

1 Introduction

It is common practice in NLP to collect and annotate a text corpus – and split it into training, development and test data. These splits are often based on the order in which texts were published or sampled, and are referred to as 'standard splits'. Gorman and Bedrick (2019) recently showed that system ranking results based on *standard* splits differ from results based on *random* splits and used this to argue in favor of using random splits. While perhaps less common, random splits are already used in probing (Elazar and Goldberg, 2018), interpretability (Pörner et al., 2018), as well as core NLP tasks (Yu et al., 2019; Geva et al., 2019).[1]

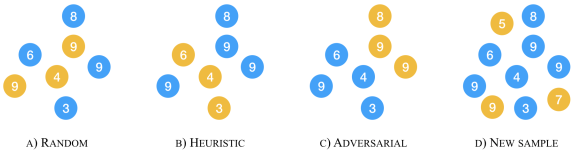

Figure 1: Data splitting strategies. Each ball corresponds to a sentence represented in (two-dimensional) feature space. Blue (dark)/orange (bright) balls represent examples for training/test. Numbers represent sentence length. Heuristic splits can, e.g., be based on sentence length; adversarial splits maximize divergence.

Gorman and Bedrick (2019) focus on whether there is a significant performance difference δ between systems S_1 and S_2; $\mathcal{M}(G_{test}, S_1) - \mathcal{M}(G_{test}, S_2)$, in their notation. They argue McNemar's test (Gillick and Cox, 1989) or bootstrap (Efron, 1981) can establish that $\delta \neq 0$, using random splits to sample from G_{test}. This, of course, relies on the assumption that data is representative, i.e., was sampled i.i.d. (Wolpert, 1996).

In reality, what Gorman and Bedrick (2019) call *the true difference in system performance*, i.e., $\delta = \mathcal{M}(G_{test}, S_1) - \mathcal{M}(G_{test}, S_2)$, is the system difference on *data that users would expect the systems to work well on* (see §2 for practical examples) – and not just on the corpus that we have annotations for. Our corpus-based estimates of δ can in fact be very misleading, i.e., very different from performance on new samples of data. In this paper, we investigate *how* misleading our estimates can be: We show that random splits consistently over-estimate performance at test time. This favors systems that overfit. We investigate alternatives across a heterogeneous set of NLP tasks. Based on our experiments, our answer to community-wide overfitting to standard splits is *not* to use random splits but to collect more diverse data with different biases – or if that is not feasible, split your data in adversarial, not random, ways. In general, we observe that estimates of test time error are worst for random splits, slightly better for standard splits

Table 1: Data used in our experiments. *: We time slice the original data to create different samples.

(if those exist), better for heuristic and adversarial splits, but error still tends to be higher on new (in-domain) samples; see Figure 1.

Our results not only refute the hypothesis that δ can be estimated using random splits (Gorman and Bedrick, 2019),[2] but also the covariate shift hypothesis (Shimodaira, 2000; Shah et al., 2020) that δ can be estimated using reweightings of the data. While biased splits are useful in the absence of multiple held-out samples, and have been proposed before (Karimi et al., 2015),[3] they often overestimate performance in the wild. Our code is made publicly available at `https://github.com/google-research/google-research/talk_about_random_splits`.

2 Experiments

We consider 7 different NLP tasks: POS tagging (like Gorman and Bedrick (2019)), two sentence representation probing tasks, headline generation, translation quality estimation, emoji prediction, and news classification. We experiment with these tasks, because they a) are diverse, b) have not been subject to decades of community-wide overfitting (with the exception of POS tagging), and c) three of them enabled temporal splits (see Appendix §A.5).

Data splits The datasets which we will use in our experiments are presented in Table 1. For all seven tasks, we will present results for standard splits when possible (POS, PROBING,QE, HEADLINES), random splits, heuristic and adversarial splits, as well as on new samples. In the case of EMOJIS, HEADLINES and NEWS, which are all time-stamped datasets, we leave out historically more recent data as our new samples. All **new samples** are in-domain samples of data where models are supposed to generalize, i.e, samples from similar text sources.[4] This is a key point: These are *samples that any end user would expect decent NLP models to fair well on*. Examples include a sample of newspaper articles from newspaper A for a POS tagger trained on articles from newspaper B; tweets sampled the day after the training data was sampled; or news headlines sampled from the same sources, but a year later.

We resample **random** splits multiple times (3-10 per task) and report average results. The **heuristic** splits are obtained by finding a sentence length threshold and putting the long sentences in the test split. We choose a threshold so that approximately 10% of the data ends up in this split. The idea of checking whether models generalize to longer sentences is not new; on the contrary, this goes back, at least, to early formal studies of recurrent neural networks, e.g., Siegelmann and Sontag (1992). In the §A.3, we present a few experiments with alternative heuristic splits, but in our main experiments we limit ourselves to splits based on sentence length.

Finally, the **adversarial** splits are computed by approximately maximizing the Wasserstein distance between the splits. The Wasserstein distance is often used to measure divergence between distributions (Arjovsky et al., 2017; Tolstikhin et al., 2018; Shen et al., 2018; Shah et al., 2018), and while alternatives exist (Ben-David et al., 2006; Borgwardt et al., 2006), it is easy to compute and parameter-free. Since selecting *the* worst-case split is an NP-hard problem (e.g., by reduction of the knapsack problem), we have to rely on an approximation. We first compute a ball tree encoding the Wasserstein distances between the data points in our sample. We then *randomly* select a centroid for our test split and find its k nearest neighbors. Those k nearest neighbors constitute our test split; the rest is used to train and validate our model. We repeat these steps to estimate performance on worst-case splits of our sample. See §A.4 for an algorithm sketch. Random, heuristic, and adversarial results are averaged across five runs.

---

[2] Or cross-validation, as more recently proposed in Szymański and Gorman (2020). In this very interesting follow-up paper, about Bayesian inference of δ, the authors write that their "estimates are valid insofar as the data sets used to estimate the Bayesian models comprise a representative sample of a coherent population of data sets." Our results show how *off* this assumption is.

[3] Karimi et al. (2015) discuss temporal splits and splits based on neighbor-based heuristics that are similar in spirit to our worst-case splits.

[4] Domains are commonly defined as collections of similar text sources (Harbusch et al., 2003; Koehn and Knowles, 2017). In addition to using similar sources, we control for low $\mathcal{A}$-distance (Ben-David et al., 2006) by looking at separability; e.g., a simple linear classifier over frequent unigrams can distinguish between Penn Treebank development and test sections with an accuracy of 64%; and between the development and our new sample with an accuracy of 69%.

POS tagging We first consider the task in Gorman and Bedrick (2019), experiment with heuristic and adversarial splits of the original Penn Treebank (Marcus et al., 1993), and add the Xinhua section of OntoNotes 5.0[5] as our **New Sample**. Our tagger is NCRF^{++} with default parameters.[6]

Probing We also include two SentEval probing tasks (Conneau et al., 2018) with data from the Toronto Book Corpus: PROBING-WC (word classification) and PROBING-BSHIFT (whether a bigram was swapped) (Conneau et al., 2018). Unlike the other probing tasks, these two tasks do not rely on external syntactic parsers, which would otherwise introduce a new type of bias that we would have to take into account in our analysis. We use the official SentEval framework[7] and BERT (Devlin et al., 2019) as our sentence encoder. The probing model is a logistic regression classifier with L_2 regularization, tuned on the development set. As our **New Samples**, we use five random samples of the 2018 Gutenberg Corpus[8] for each task, preprocessed in the same way as Conneau et al. (2018).

Quality estimation We use the WMT 2014 shared task datasets for QUALITY ESTIMATION. Specifically, we use the Spanish-English data from Task 1.1: scoring for perceived post-editing effort. The dataset comes with a training and test set, and a second, unofficial test set, which we use as our **New Sample**. In the §A.2, we also present results training on Spanish-English and evaluating on German-English. We present a simple model that only considers the target sentence, but performs better than the best shared task systems: we train an MLP over a LASER sentence embedding (Schwenk et al., 2019) with the following hyper-parameters: two hidden layers with 100 parameters each and ReLU activation functions, trained using the Adam stochastic gradient-based optimizer (Kingma and Ba, 2015), a batch size of 200, and L_2 penalty of strength $\alpha = 0.01$.

Headline generation We use the standard dataset for headline generation, derived from the Gigaword corpus (Napoles et al., 2012), as published by Rush et al. (2015). The task is to generate a headline from the first sentence of a news article. Our architecture is a sequence-to-sequence model with stacked bi-directional LSTMs with dropout, attention (Luong et al., 2015) and beam decoding; the number of hidden units is 128; we do not pre-train. Different from Rush et al. (2015), we use subword units (Sennrich et al., 2016) to overcome the OOV problem and speed up training. The ROUGE scores we obtain on the standard splits are higher than those reported by Rush et al. (2015) and comparable to those of Nallapati et al. (2016), e.g., ROUGE-1 of 0.321. As our **New sample**, we reserve 20,000 sentence-headline pairs each from the first and second halves of 2004 for validation and testing; years 1998-2003 are used for training. For all the experiments we report the error reduction in ROUGE-2 of the model over the IDENTITY baseline, which simply copies the input sentence (other ROUGE values are reported in the §A.1). In §5, we will explore how much of a performance drop on the fixed test set is caused by shifting the *training* data by only five years to the past.

Emoji prediction Go et al. (2009) introduce an emoji prediction dataset, collected from Twitter and is time-stamped. We use the 67,980 tweets from June 16 as our **New Sample**, and tweets from all previous days for the remaining experiments. For this task, we again train an MLP over a LASER embedding (Schwenk et al., 2019) with hyper-parameters: two hidden layers with 50 parameters each and ReLU activation functions, trained using the Adam stochastic gradient-based optimizer (Kingma and Ba, 2015), a batch size of 200, and L_2 penalty of strength $\alpha = 0.01$. See §5 for a discussion of temporal drift in this data.

News classification We use a UCI Machine Learning Repository text classification problem.[9] Our datapoints are headlines associated with five different news genres. We use the last year of this corpus as our **New Sample**. We sample 100,000 headlines from the rest and train an MLP over a LASER embedding (Schwenk et al., 2019) with the following hyper-parameters: two hidden layers with 100 parameters and ReLU activation functions, trained using the Adam stochastic gradient-based optimizer (Kingma and Ba, 2015), dynamic batch sizes, and L_2 penalty of strength $\alpha = 0.01$.

Table 2: Error reductions over random baselines on **Standard** (original) splits, if available, **Random** splits (obtained using cross-validation), **Heuristic** splits resulting from a sentence length-based threshold, **Adversarial** splits based on (five) approximate maximizations of Wasserstein differences between splits, and on **New Samples**. We bold face the **lowest** error reduction, i.e., where results differ the most from the random baseline. **We see that standard and random splits consistently over-estimate *real* performance on new samples, which is sometimes even lower than performance on adversarial splits.** We also report the mean squared error (MSE) with respect to **New Samples**, which shows **Adversarial** estimates empirical error best. Note: *While annotator bias could explain POS tagging results, there is no annotator bias in the other tasks.* *: For HEADLINES we use an identity baseline. Scores are ROUGE-2; see §A.1 for more. †: For QUALITY ESTIMATION, we report RMSE. The WMT QE 2014 best system obtained RMSE of 0.64; our system is significantly better with 0.50 on the standard split.

3 Results

Our results are presented in Table 2. Since the results are computed on different subsamples of data, we report *error reductions over multinomial random* (or, for HEADLINES, *identity*) *baselines*, following previous work comparing system rankings across different samples (Søgaard, 2013). More formally, we present error reduction as $r = \frac{p_s - p_b}{1 - p_b}$, where p_s and p_b are the performances of the system at hand and the multinomial random baseline.

Our main observations are the following: (a) **Random splits (and standard splits) consistently under-estimate error on new samples**. The absolute differences between error reductions over random baselines for random splits and on new samples are often higher than 20%, and in the case of PROBING-BSHIFT, for example, the BERT model reduces 80% of the error of a random baseline when data is randomly split, but only 45% averaging over five samples of new data from the same domain. (b) Heuristic splits sometimes under-estimate error on new samples. Our heuristic splits in the above experiments are quite aggressive. We only evaluate our models on sentences that are longer than any of the sentences observed during training. Nevertheless for 5/7 tasks, this leads to more optimistic performance estimates than evaluating on *new* samples! (c) The same story holds for adversarial splits based on approximate maximization of Wasserstein distances between training and test data. While adversarial splits are very challenging, results on adversarial splits are more optimistic than on new samples in 4/7 cases. Note the fact that random splits over-estimate real-life performance also leads to misleading **system rankings**. If, for example, we remove the CRF inference layer from our POS tagger, performance on our **Random** splits drops to 0.952; on the **New Sample**, however, performance is 0.930, which is significantly better than *with* a CRF layer.

Discussion In the spirit of earlier work (Sakaguchi et al., 2017; Madnani and Cahill, 2018; Gorman and Bedrick, 2019), we provide recommendations for future evaluation protocols: (i) In the absence of multiple held-out samples, using **biased splits** better approximates real-world performance and can help determine what data characteristics affect performance. (ii) Evaluating on **new samples** is superior and also enables significance testing across datasets (Demsar, 2006), providing confidence estimates. Several benchmarks already provide multiple, diverse test sets (e.g. Hovy et al., 2006; Petrov and McDonald, 2012; Williams et al., 2018); we hope more will follow. What explains the high variance across samples in NLP? One reason is the dimensionality of language (Bengio et al., 2003), but in §A.5 we also show significant impact of temporal drift.

Conclusions We have shown that out-of-sample error can be hard to estimate from random splits, which tend to underestimate error by some margin, but even biased and adversarial splits sometimes underestimate error on new samples. We show this phenomenon across seven very different NLP tasks and provide practical recommendations on how to best bridge the gap between experimental practices and what is needed to produce truly robust NLP models that perform well in the wild.

	ROUGE-1	ROUGE-2	ROUGE-L
Standard	0.080	0.073	0.097
Random	0.109	0.095	0.127
Heuristic	0.091	0.062	0.109
Adversarial	0.060	0.040	0.080
New Sample	0.067	0.069	0.091

Table 3: Error reduction as compared with an identity baseline (output as input) for three ROUGE metrics. Random is a five-fold cross-validation result.

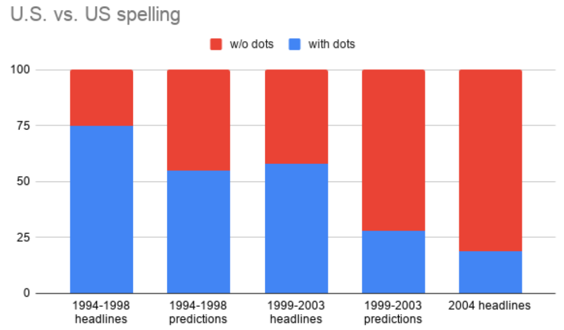

Figure 2: Proportions of *US* vs. *U.S.* spellings in the headlines for two training sets and the test set (2004) as well as in the two models' predictions on the test set.

A Appendices

We present supplementary details about two of our tasks in §A.1 and §A.2 and discuss variations over heuristic splits in §A.3. In §A.4, we present the pseudo-algorithm for how we compute adversarial splits, and finally, in §A.5, we present our results documenting temporal drift.

A.1 Headlines

Table 3 reports the error reduction in ROUGE-1, ROUGE-2 and ROUGE-L over the identity baseline (see §2) for the different data splits. The results are consistent with Table 2. Figure 2 gives more details on an interesting drift phenomenon, which contributed to the superior performance of the model trained on the most recent five years (1999-2003). Apparently, the dotless spelling of *U.S./US* ('United States') became more common over time. Consequently, the model trained on the 1999-2003 part generated *US* more frequently than the model trained on 1994-1998.

A.2 Quality Estimation

In the results above, we train and test our quality estimation regressor on Spanish-English from WMT QE 2014. We also ran a similar experiment where we used the German-English test data as our **New Sample**. Here, we see a similar pattern to the one above: The RMSE on the **Standard** split was 0.630, which is slightly higher than for Spanish-English; with our **Heuristic** split, RMSE is 0.652; for **Adversarial**, it is 0.626 (which is slightly better than with standard splits), and on our **New Sample**, RMSE is 0.813.

A.3 Alternative Heuristic Splits

For both SentEval tasks we experimented with the following alternatives for heuristic splits.

Bootstrap Resampling Instead of cross-validation, a random split can be generated by bootstrap resampling. For this we randomly select 10% of the data as test set and then randomly sample (with replacement) a new training and dev set from the remaining examples.

Random Length As alternative to the length threshold heuristic in earlier experiments we randomly sample a length and select all examples having this length to be part of the test set. We repeat this procedure until approximately 10% of the data ends up in the test set. With this procedure we create 5 different test sets. We included this heuristic in order to see how fragile the probing setup is.

Rare Words Another alternative for heuristic splits is to use word frequency information. Here we assign those sentences containing at least one of the rarest words of the dataset to the test set. This way we end up again with approximately 10% of the data in the test set. Note that this way we create only 1 dataset, because it's not a random process.

Results Table 4 lists the results. While bootstrap resampling leads to slightly lower error reduction than cross-validation we decided to report the latter in the main part of this paper, because it is a more wide-spread way to randomly split datasets. Random Length results are comparable to standard splits results. The split based on word frequency (Rare Words) leads to considerable drop in both tasks. However, it is not as strong as the drop of the heuristic split (length threshold) in the main part of the paper.

A.4 Computing adversarial splits

We present the pseudo-algorithm of our implementation of approximate Wasserstein splitting in Algorithm 1. We also make the corresponding code available as part of our code repository for this paper.

Task	Model	Splits Standard	 Bootstrap	 Random Length	 Rare Words
PROBING-WC	BERT	0.520	0.504	0.554	0.339
PROBING-BSHIFT		0.800	0.807	0.798	0.731

Table 4: Error reductions over random baselines on **Standard** (original) splits, if available, **Bootstrap** splits, **Random Length** splits resulting from a sentence length-based separation, **Rare Words** splits based on word frequency.

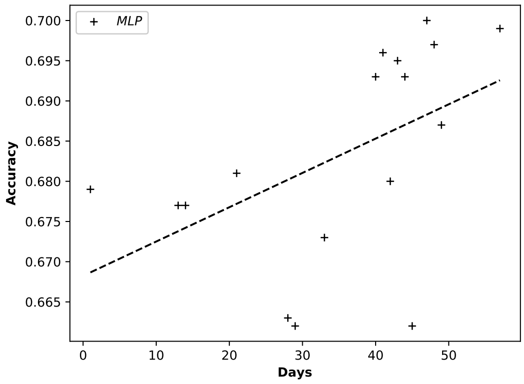

Figure 3: Temporal drift in emoji prediction. The correlation between temporal gap and performance is significant ($p < 0.05$).

```
Data: Dataset $G_{train}$
Result: Adversarial split: $G_{train}$ and $G_{test}$
$T \leftarrow WassersteinBallTree(G_{train})$;
$G_{test} \leftarrow \{\langle x, y\rangle \sim G_{train}\}$;
$G_{train} \leftarrow G_{train}/\{\langle x, y\rangle\}$;
while $i \leq k$ do
    $\langle x_i, y_i\rangle = \min_{\langle x', y'\rangle} T(x, x')$;
    $G_{train} \leftarrow G_{train}/\{\langle x_i, y_i\rangle\}$;
    $G_{test} \leftarrow G_{test} \cup \{\langle x_i, y_i\rangle\}$;
    $i+ = 1$;
end
```

Algorithm 1: Computing adversarial splits

	ROUGE-1	ROUGE-2	ROUGE-L
Identity baseline	0.302	0.110	0.260
50% of 1994-2003	0.409	0.205	0.386
1994-1998	0.346	0.161	0.329
1999-2003	0.413	0.208	0.388

Table 5: Performance of three seq2seq models trained on different samples, evaluated on 2004 data.

A.5 The significance of drift

Some of our splits in the main experiments were based on slicing data into different time periods (HEADLINES, EMOJIS). Since temporal drift is a potential explanation for sampling bias, we analyze this in more detail here. We show that temporal drift is pervasive and leads to surprising drops in performance. We note, however, that temporal drift is not the only cause of sampling bias, of course. Since we have time stamps for two of our datasets we study these in greater detail. For similar studies of temporal drift, see Lukes and Søgaard (2018); Rijhwani and Preotiuc-Pietro (2020).

Headline generation Our headline generation data covers the years 1994 to 2004. Having reserved 20,000 sentence-headline pairs from the first half of 2004 for validation and the same amount from the second half for testing, we use 50% of the years 1994-2003 for training three models. The models' architectures and parameters are identical (same as in Sec. 3). The only difference is in what the models are trained on: (a) a random half, (b) the first, or (c) the second half of 1994-2003. The training data sizes are comparable (1.63-1.76M), the publisher distributions (AFP, APW, CNA, NYT or XIN) are also similar. Hence, the models are expected to perform similarly on the same test set.

As Table 5 indicates, shifting the training data by five years to the past results in a big performance drop. Sampling training data randomly or taking the most recent period produces models with similar ROUGE scores, both much better than the identity baseline. However, about half of the gap to the identity baseline disappears when older training data is taken. In the §A.1, we give an example of temporal drift in the HEADLINES data: *US* largely replaces *U.S.* in the newer training set and the test set.

Emoji prediction For emoji prediction, Go et al. (2009) provide data for a temporal span of 62 days. We split the data into single days and keep the splits with more than 25,000 datapoints in which both classes are represented. We use the last of these, June 16, as our test sample and vary the training data from the first day to the day before June 16. Figure 3 (left) visualizes the results.

Abstract

In this work, we consider the problem of uncertainty estimation for Transformer-based models. We investigate the applicability of uncertainty estimates based on dropout usage at the inference stage (Monte Carlo dropout). The series of experiments on natural language understanding tasks shows that the resulting uncertainty estimates improve the quality of detection of error-prone instances. Special attention is paid to the construction of computationally inexpensive estimates via Monte Carlo dropout and Determinantal Point Processes.

1 Introduction

Quantifying the uncertainty of machine learning models is an important aspect of trustworthy, reliable, and accountable natural language understanding (NLU) systems. Obtaining measures of uncertainty in predictions (also known as *uncertainty estimations*, UE) helps to detect out-of-domain (Malinin and Gales, 2018), adversarial, or error-prone instances that require special treatment. For example, such instances can be additionally checked by human experts or another more advanced system or alternatively rejected from classification (Herbei and Wegkamp, 2006). Besides, uncertainty estimation is an essential component of various applications such as active learning (Shelmanov et al., 2021) and outlier/error detection in a dataset (Larson et al., 2019).

Many modern NLU methods take advantage of deep pre-trained models that are based on the Transformer architecture (Vaswani et al., 2017) (e.g., BERT (Devlin et al., 2019) or ELECTRA (Clark et al., 2020)). Obtaining reliable uncertainty estimations for such neural networks (NNs) can, therefore, directly benefit a wide range of NLU tasks, yet implementing UEs, in this case, is challenging due to the huge number of parameters in these deep learning models. The approximations of Bayesian inference based on dropout usage at the inference stage – Monte Carlo (MC) dropout (Gal and Ghahramani, 2016), provide a realizable approach to quantifying UEs of deep models. However, they are usually accompanied by serious computational overhead due to the necessity of performing multiple stochastic predictions. Importantly, training ensembles of independent models (Lakshminarayanan et al., 2017) leads to even more prohibitive overheads.

In this work, we investigate various MC dropout-based approaches to uncertainty quantification of NLU models on the widely-used General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2018). The main contributions of our work are two-fold:[1]

- We show that the use of the MC dropout with pre-trained Transformer models significantly improves the quality of UEs in NLU tasks compared to deterministic baselines.
- We are the first to our knowledge to apply a modification of the MC dropout based on determinantal point processes (DPP; Tsymbalov et al. (2020)) to Transformers and show that this approach allows obtaining the UEs competitive to the standard MC dropout at a fraction of its cost. To improve the stability of the DPP-based dropout for Transformer-based models, we extend the method presented in Tsymbalov et al. (2020) by averaging multiple dropout masks sampled with DPP.

2 Related Work

Three dominating approaches to uncertainty estimation in neural networks exist: (i) interpretation of the model's logits from the uncertainty estimation perspective (Gal, 2016), which is the basic one; (ii) ensembling, where a discrepancy

between models' predictions are interpreted as a sample variance (Lakshminarayanan et al., 2017); (iii) Bayesian neural networks (Teye et al., 2018), which have a built-in mechanism to capture uncertainty via a single model.

There are a few recent works that investigate uncertainty quantification for NLP models and use MC dropout techniques. Dong et al. (2018) use Bayesian UEs for the analysis of semantic parser predictions for correctness. Zhang et al. (2019) propose an additional training loss component that facilitates smaller inter-class and bigger intra-class distances in the vector space of the output layer. Experiments with convolutional NNs on text classification datasets show that this modification helps to improve error detection using MC dropout UEs. For quantifying model data uncertainty, Xiao and Wang (2019) use NNs to parameterize a probability distribution (mean and variance) instead of making a prediction directly. For quantifying model uncertainty, the authors leverage the MC dropout. Modeling both types of uncertainties in convolutional and recurrent NNs helped them to improve the performance in regression and classification NLP tasks. Kochkina and Liakata (2020) apply UEs to the problem of rumor verification.

3 Uncertainty Estimation of Deep Transformer Neural Networks

In this section, we describe types of dropout, uncertainty estimation methods, and the Transformer-based neural classifier used in our experiments.

3.1 Types of Dropout

We use two types of dropout described below.

Monte Carlo Dropout The dropout (Srivastava et al., 2014) has emerged as a powerful and universal regularization technique applicable to most DL architectures, with the Transformers not being an exception. Despite originally being an empirical, engineering way to fight the overfitting, it then obtained a theoretical explanation as a special case of Bayesian NNs, where activations are drawn from the Bernoulli distribution (Gal, 2016). This allows to represent a vector of outputs x_h of the h-th layer of the network as a function of its weights W_h, activation function σ, and a dropout mask M_h:

$$x_h = \sigma(x_{h-1} \mid W_h, M_h), M_h \sim Bernoulli(1{-}p),$$

where $p \in [0; 1]$ is the dropout rate.

This theoretical explanation enables the use of the dropout not only at the training stage but also at the inference stage via sampling of multiple masks $M_h^{(t)}, t = 1, \dots, T$ for each dropout layer of the network h and subsequently providing an ensemble of models parameterized by these masks: $f_t(x) = f\big(x \mid \{M_h^{(t)}\}\big)$. The obtained UEs are relatively fast, convenient, and applicable to various tasks, such as regression (Tsymbalov et al., 2018), image classification (Gal and Ghahramani, 2016), and active learning (Gal et al., 2017; Siddhant and Lipton, 2018).

Monte Carlo Dropout with Determinantal Point Processes The models obtained from the standard dropout masks usually show a high degree of correlation in predictions between them, limiting the power of the resulting ensemble. Recently, it was proposed to improve the diversity of predictions by considering the correlations between neurons and sampling the diverse neurons via the mechanism of Determinantal Point Processes (DPP; Kulesza and Taskar (2012)), an approach for sampling diverse elements from a set of points. This setup was proposed by (Tsymbalov et al., 2020) and evaluated for the simple multilayer perceptrons and CNNs. In this work, we aim to extend this approach to Transformer models.

DPP-based dropout masks M_h^{DPP} for the h-th layer are constructed using the correlation matrix C_h between neurons as a likelihood kernel for the DPP: $M_h^{\mathrm{DPP}} \sim DPP\big(C_h\big)$. The probability to select a set S of activations on the layer h is given by

$$P[M_h^{\mathrm{DPP}} = S] = \frac{\det C_h^S}{\det\big(C_h + I\big)},$$

where C_h^S is a square submatrix of C_h obtained by keeping only rows and columns indexed by the sample S. The matrix of correlations between activations of the h-th layer C_h is estimated empirically based on some set of points, which represents the data distribution well enough (i.e. training set). The key feature of the approach is that DPP tends to sample neurons with low correlations between them, which in turn improves the overall diversity of the obtained models. More information about DPP is presented in Appendix B.

To improve the stability of the DPP-based dropout for Transformer-based models, we create a final dropout mask by sampling from DPP and averaging multiple initial masks.

3.2 Uncertainty Estimates

Let T be a number of stochastic passes, i.e., the number of dropout masks to be sampled. We use the three following UEs (also known as *acquisition methods*) for the classification with C classes:

- **Sampled maximum probability**:

  $$1 - \max_c \bar{p}_T(y = c \mid x),$$

  where $\bar{p}_T$ is an average probability for the class c prediction over multiple stochastic passes $t = 1, \ldots, T$.

- **Probability variance** averaged over classes:

  $$\frac{1}{T}\sum_{c=1}^{C}\sum_{t=1}^{T}\big(p_t(y = c \mid x) - \bar{p}_T(y = c \mid x)\big)^2.$$

- Bayesian Active Learning by Disagreement (**BALD**) proposed by Houlsby et al. (2011) describes the mutual information between outputs and model parameters:

  $$H(x) + \frac{1}{T}\sum_{c=1}^{C}\sum_{i=1}^{T} p(y = c \mid x) \log\big(p(y = c \mid x)\big),$$

  where $H(x)$ is the entropy of the ensemble mean.

We would like to note that all these estimates can be used for any ensembling technique, including the MC dropout and the DPP-based dropout.

3.3 Classification Models

In this work, we focus on the **ELECTRA** (Clark et al., 2020) model, which is a recent successor to BERT (Devlin et al., 2019). It is based on the same Transformer architecture but takes advantage of the harder "replaced token detection" objective instead of the "masked language model" objective. This gives better pre-training capabilities and makes ELECTRA the state-of-the-art Transformer in natural language understanding benchmarks. We should note that ELECTRA is regularized with multiple dropout layers, which facilitates the usage of the MC dropout. For example, the body of the "ELECTRA-base" model has 37 dropout layers.

We also experiment with **DistilBERT** (Sanh et al., 2019), which is a smaller Transformer obtained from the middle-size BERT (Devlin et al., 2019) via a distillation procedure (Hinton et al., 2015). This model provides the faster inference and has smaller memory requirements but retains 97% of the language understanding capabilities of the original model according to Sanh et al. (2019).

4 Experiments

4.1 Experimental Setup

We evaluate the UEs on the basis of their ability to detect misclassification. High UEs should indicate potential errors in the model output, while low uncertainties should correspond to correctly classified instances. In this vein, we transform the original task into a binary classification task by comparing predictions of a model with the ground truth labels in the validation dataset. Uncertainty estimates on the validation dataset are treated as the outputs of the binary classifier that is trained to look for potential errors. We calculate the ROC AUC score using the new ground truth labels and UEs and use this score as the main evaluation metric.

The baseline in this task is the UE calculated based on the maximal probability of the original deterministic model. We compare it to the estimates obtained using multiple stochastic predictions with activated dropout layers. Three variants of estimates are calculated: 1) based on the model, in which MC dropout is applied to all dropout layers; 2) based on the model with the MC dropout applied only to the last layer; 3) based on the model with the DPP-based sampling applied to the last dropout layer. For calculating these UEs, we conduct 20 stochastic predictions. The dropout rate in these passes for the MC dropout is 0.1, which is shown to be optimal in the preliminary experiments. For the DPP dropout, we sample and average multiple masks produced by DPP. In experiments with SST-2 and ELECTRA, we average as many masks so at least 30% of neurons remain active during the pass (this roughly can be considered as a "dropout rate" of 0.7). For MRPC, we choose the "dropout rate" equal to 0.2 and for CoLA: 0.4. For DistilBERT, we use the "dropout rate" of 0.4 in all tasks.

We train three versions of models with different random seeds. For each model, another five random seeds are used to produce predictions for stochastic methods. Multiple models and predictions are used for estimating the standard deviation and conducting the statistical significance testing.

4.2 Datasets

We evaluate UEs and dropout variants on the widely used NLU benchmark GLUE (Wang et al., 2018). Specifically, we perform experiments on three tasks: Stanford Sentiment Treebank (SST-2; Socher et al. (2013)), Corpus of Linguistic Acceptability (CoLA; Warstadt et al. (2019)), and

Dropout Type	Model Acquisition	Dropout Layers	Tasks SST-2	MRPC	CoLA
No (baseline)	Max. probability	-	79.7±3.4	78.6±4.1	78.7±2.0
MC	Sampled max. probability	last	-0.1±0.2	-0.5±0.4	-0.1±0.1
MC	Probability variance	last	-1.9±1.0	-3.0±0.7	-1.4±0.7
MC	BALD	last	-5.0±1.7	-5.6±1.3	-3.9±1.3
DPP	Sampled max. probability	last	**3.2**±**2.4**	0.0±0.7	-0.4±0.7
DPP	Probability variance	last	**2.7**±**3.1**	**1.5**±**2.3**	-1.1±1.3
DPP	BALD	last	0.7±2.7	**2.1**±**3.1**	-2.0±2.1
MC	Sampled max. probability	all	**3.2**±**1.6**	**5.5**±**2.6**	**3.2**±**0.6**
MC	Probability variance	all	**4.7**±**2.1**	**7.2**±**3.1**	**2.9**±**0.4**
MC	BALD	all	**5.2**±**2.4**	**7.5**±**3.3**	**2.8**±**0.4**

Table 1: The misclassification detection performance (ROC AUC) (±SD) for the baseline with the ELECTRA model and performance improvements over the baseline for various UE methods. Statistically significant improvements (p-value$\leq$ 0.05) are highlighted.

Microsoft Research Paraphrase Corpus (MRPC; Dolan and Brockett (2005)). The SST-2 task is to predict the sentiment of a given sentence (positive/ negative). The SST-2 dataset was randomly subsampled to 2% of the original size to emulate the situation with a small amount of training data. The CoLA task is to determine whether the given sentence is grammatical or not. The MRPC task is to predict whether two given sentences are semantically similar or not. We select these three datasets for their compact size.

4.3 Model and Training Details

We use the middle-size pre-trained ELECTRA-base model with 110 million parameters and the DistilBERT model with 66 million parameters obtained from the middle-size BERT. The implementation of the models is provided by the Huggingface Transformers library (Wolf et al., 2020). For fine-tuning models, we follow the approach described by Clark et al. (2020) and Devlin et al. (2019): train for 4 epochs with 10% warm-up and a linear learning rate scheduler. For all models and tasks, we use the same learning rate equal to 5e-5. For ELECTRA and SST-2 and MRPC tasks, the batch size is 16. For ELECTRA and CoLA, the batch size is 32. For DistilBERT, the batch size is 32 for all tasks. Although calibrating these hyperparameters can yield some performance improvements, the aforementioned settings allow achieving good results across all tasks.

4.4 Results and Discussion

ROC AUC scores for the misclassification detection task and ELECTRA are presented in Table 1. The results for DistilBERT are presented in Table 3 in Appendix A. While the classifier performance does not significantly variate across multiple versions of the fine-tuned models, the difference in the misclassification detection performance is statistically significant. Therefore, we present the absolute values of the performance only for the baseline (UE based on maximum probability), while for other methods, we present the improvement over the baseline across multiple runs. Tables with results also present the standard deviation of scores.

We note that the UE based on the maximum probability of the deterministic model is a strong baseline. Overall, Transformers are able to indicate their potential mistakes with just the probability from the softmax layer. Applying the MC dropout to all dropout layers in the network always gives a reliable boost in the misclassification detection. For SST-2 and MRPC tasks, UE based on BALD demonstrates better performance than sampled maximum probability and variance, while on CoLA, all UEs perform comparably well. The biggest improvement can be achieved for MRPC and ELECTRA: up to 7.5% ROC AUC.

On the contrary, the UEs based on the MC dropout applied only to the last layer do not perform well. We see that the misclassification detection performance always deteriorates compared to the baseline, especially, for variance and BALD.

UEs that take advantage of the DPP-based masks applied to the last dropout layer are somewhere in the middle in terms of quality compared to the MC dropout variants. Although this method also does not give any improvement for CoLA, unlike the last layer MC dropout, DPP gives a significant advantage over the baseline on the SST-2 task for both models and on the MRPC task for ELECTRA. We note that although DPP-based sampling and the last layer MC dropout diverge in terms of "dropout rate" (e.g., in the experiment on the SST-2 task with ELECTRA, 0.7 for the DPP dropout versus 0.1 for the MC dropout), this aspect does not explain the performance difference. Applying dropout rates higher than 0.1 to the MC dropout downgrades the performance of the misclassification detection due to the overall decrease of the model quality, while for DPP, only 30% of neurons is more than enough to retain the model performance and obtain better UEs on the SST-2 task.

Despite the fact that the DPP-based approach appears to be worse than applying the MC dropout on all layers, it is much faster since it is applied to only the last dropout layer. For practical applications, obtaining UEs normally should not cause a significant overhead compared to the standard model inference time. This strikes the methods based on the MC dropout since they require multiple stochastic predictions. However, for most of the pre-trained Transformers, if only the last dropout is replaced with the MC variant, the outputs of the massive Transformer "body" are not affected during the stochastic predictions. This means that the body outputs can be calculated only once, and only the last linear layer with the softmax activation should be recalculated multiple times. As the last layer contains less than 1% of total parameters, this favors the UEs that do not use stochastic inference on dropout layers except the last. Compared to masks generated uniformly with the MC dropout, sampling masks with DPP has some insignificant computation overhead, but, as we showed, it can give a useful contribution to the misclassification performance (for MRPC and SST-2) even if it is used only in the last dropout layer.

We performed an investigation of computation time overhead for calculating UEs with various MC dropout options for the development dataset. The results for ELECTRA are presented in Table 2. The computations were conducted with the Nvidia 2080ti GPU and the Intel Xeon 5217 CPU. We use BALD as an acquisition function, but other functions have comparable execution time. The MC dropout placed on all layers of Transformers gives better improvements, but it causes roughly 2,000% overhead (in the case of 20 stochastic passes), with less than 10% overhead for the last layer MC and DPP. Therefore, DPP can provide a better trade-off between computation time and performance of error detection.

UE Method	**Inference time, sec.** **SST-2**	 **MRPC**
Deterministic, –	3.07 ± 0.03	1.43 ± 0.04
MC dropout, all	65.5 ± 0.7	30.2 ± 0.2
MC dropout, last	3.17 ± 0.06	1.51 ± 0.05
DPP dropout, last	3.33 ± 0.02	1.57 ± 0.01

Table 2: The inference time of the ELECTRA model on the development dataset with BALD UE.

5 Conclusion

In this work, we evaluated several UEs for the state-of-the-art Transformer model ELECTRA and the speed-oriented DistilBERT model in the text classification tasks. To obtain estimates, we leverage multiple stochastic passes using the MC dropout, and the DPP-based dropout proposed by (Tsymbalov et al., 2020). We show that by activating all dropouts in the model for stochastic predictions, one can beat the baseline deterministic uncertainty estimate by the significant margin in the binary misclassification detection task. We also demonstrate that replacing the last dropout layer with the DPP dropout can yield significant improvements over the baseline in some cases, but less than the usage of the MC dropout on all dropout layers. Despite being inferior compared to the latter, the DPP dropout can provide a better trade-off between computation time and performance of error detection, which can be important for practical use cases.

In future work, we are seeking to improve UEs quality obtained using the DPP dropout with the help of calibration (Safavi et al., 2020) and conduct experiments on sequence tagging tasks.

Acknowledgments

We thank the reviewers for their valuable feedback. The development of uncertainty estimation algorithms for Transformer models (Section 3) was supported by the joint MTS-Skoltech lab. The development of a software system for the experimental study of uncertainty estimation methods and its application to NLP tasks (Section 4) was supported by the Russian Science Foundation grant 20-71-10135. The Zhores supercomputer (Zacharov et al., 2019) was used for computations.

B Determinantal Point Processes

Determinantal point processes (DPPs) are specific probability distributions over a set of points. They allow choosing the subset of points enforcing the diversity between the samples. The DPPs were introduced for the needs of statistical physics (Macchi, 1975), and found their applications in machine learning (Kulesza and Taskar, 2012)

For example, consider the situation where we observe N news from different outlets during one specific day. Let us also assume that we can measure the corresponding texts' pairwise similarity. In this case, DPPs allow choosing a number $n \ll N$ of most non-similar news for the day, giving a good representation of the agenda. Most importantly, DPPs have efficient implementation for the exact sampling and several even more efficient approximate solutions. We also note that DPP sampling is stochastic, i.e., it provides a different result for each repetition. That is an essential property for the uncertainty estimation problems we consider in this work.

Formally, let us assume that the kernel matrix K of pairwise similarities between the considered points X is given. DPPs are similar to the algorithm of finding maximum volume submatrix of K (Goreinov et al., 2010; Çivril and Magdon-Ismail, 2009) as geometrically determinant of the matrix is equal to the scaling volume of a corresponding linear transformation. In this case, a large volume is good because it corresponds to orthogonal vectors (i.e. non-similar vectors). Likewise, DPPs sample points S with probabilities:

$$P[S \subset X] = \det K_S,$$

where K_S is the submatrix of the matrix K corresponding to points S.

As probability takes values between 0 and 1, the matrix K needs to be positive semidefinite and should not have minors with determinant larger than 1. In practice, usually only some unnormalized likelihood matrix L is given. The standard approach is to normalize it in the following way:

$$K = L(L + I)^{-1}.$$

In this case, we can directly calculate the submatrix probabilities:

$$P[X = S] = \frac{\det L_S}{\det(L + I)}.$$

Alignment verification to improve NMT translation towards highly inflectional languages with limited resources

Abstract

The present article studies translation quality when limited training data is available to translate towards morphologically rich languages. The starting point is a neural MT system, used to train translation models with only publicly available parallel data. An initial analysis of the translation output has shown that quality is sub-optimal, mainly due to the insufficient amount of training data. To improve translation, a hybridized solution is proposed, using an ensemble of relatively simple NMT systems trained with different metrics, combined with an open source module designed for low-resource MT that measures the alignment level. A quantitative analysis based on established metrics is complemented by a qualitative analysis of translation results. These show that over multiple test sets, the proposed hybridized method confers improvements over (i) both the best individual NMT and (ii) the ensemble system provided in the Marian-NMT package. Improvements over Marian-NMT are in many cases statistically significant.

1 Introduction

The state of the art in MT involves corpus-based systems developed with machine-learning methods. These methods learn from corpora the models needed for translation. A key strength of this approach is that the system is adapted specifically towards the data it is trained with.

For many years, the most successful data-driven approaches were phrase-based and syntax-based Statistical MT (SMT; Koehn, 2009). However, lately Neural MT (NMT) based on the encoder-decoder architecture and the concept of attention (Sutskever et al., 2014; Bahdanau et al., 2016) has become very popular. Indeed, since 2015, in MT shared tasks (Cettolo et al., 2015; Bojar et al., 2015; Bojar et al., 2016) most top-performing systems have been NMT systems. This trend is confirmed in the most recent MT shared task (Barrault et al., 2019), where 80% of participating systems are of NMT type. Though NMT represents the state of the art for MT, specific weaknesses have been reported:

- NMT performance suffers from the lack of data resources (Koehn and Knowles, 2017), giving lower translation performance, especially when training with out-of-domain rather than in-domain data.
- Recent advances in NMT models have been shown (Sennrich and Zhang, 2019) to allow good translations to be achieved with smaller parallel corpora of typically 10^5 sentences, though substantial improvements are achieved when the corpus size reaches 10^6 sentences. However, training sets of such sizes are not available for all languages.
- Translation performance is affected by non-parallel texts and non-literal translations (Carpuat et al., 2017).
- The integration of multiple algorithms into an NMT system does not necessarily improve translation (Denkowski and Neubig, 2017).
- The time complexity of training a new NMT system can be very high, with training sessions of the order of weeks.

NMT requires very large amounts of parallel data, measured in millions of parallel sentences. This is reflected by the separate studies carried out for MT with limited resources, which includes initiatives such as Lorelei [1]. In the case of morphologically-rich languages, the requirements for parallel corpora are further exacerbated.

[1] https://www.darpa.mil/program/low-resource-languages-for-emergent-incidents

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1841–1851
April 19 - 23, 2021.

Proposed approaches for translating towards low-resource and morphologically-rich languages have included transfer learning (Zoph et al., 2016) as well as multilingual and multi-way NMT (Rikters et al., 2018).

In this paper, an effort to improve the translation quality is presented, when translating towards a morphologically-rich language, while reducing the training time. This approach combines the output of multiple NMT systems with an NLP module developed for an example-based MT paradigm, resulting in a hybridized solution. The latter module is fast and runs independently of its original MT system and thus the computational complexity of the proposed hybrid solution is not substantially increased over the base NMT system.

The idea of combining multiple MT models to produce a higher performing MT system has been studied extensively in the area of MT. For instance in the recent shared task (Barrault et al., 2019) more than 20 entries consist of ensembles of multiple NMT systems. Ensembles of weaker NMT systems of the same general architecture have been proposed by Freitag et al. (2017) to train a higher performing NMT system. In addition ensembles of factored NMT models have been proposed for automatic post-editing and quality estimation (for example Hokamp, 2017).

This base NMT system is described in section 2. The training data used is reported in section 3. The proposed hybridization is presented in section 4, whilst the improvements attained are presented in section 5. Future developments are discussed in section 6.

2 Overview of the Base NMT System

Since NMT systems have achieved the highest translation quality in recent evaluation contests, the Marian-NMT package (Junczys-Dowmunt et al., 2018) is adopted for experimentation here. Marian-NMT development was funded by the European Commission to consolidate NMT research and incorporates the most recent advances in NMT. Its code is optimized to reduce the CPU/GPU time required to complete the simulations of NMT systems.

For creating NMT systems, three of the models provided by Marian-NMT were chosen, termed as the "transformer", "amun" and "s2s" models. The "transformer" model has been based on the work of Vaswani et al. (2017) and uses a simple structure incorporating attention mechanisms and dispensing with recurrence to implement a fast NMT system. The other two models are more conventional, using a recurrent neural network to implement the translation. The "amun" model follows the approach of Bahdanau et al. (2016), employing a recurrent neural network but allowing the model to automatically search for wider ranges of the source language (SL) to connect with the target language side (TL) words. Finally, "s2s" implements a recurrent neural network-based encoder-decoder model with attention mechanism, using the architecture proposed in (Sennrich et al., 2017). Hereafter, the three models are identified via the names used within Marian-NMT, which are also used in evaluations (cf. Bojar et al., 2018).

The main configuration parameters used for each model are depicted in Table 1, to enable replication of experiments. For each model, different optimization options from Marian-NMT during the validation phase are used to create three NMT variants of each model, namely optimizing with (i) BLEU, (ii) entropy and (iii) word-wise normalized cross-entropy (denoted as "ce-mean" and representing the default optimization for Marian-NMT).

Regarding the main NMT parameters, all recurrent networks comprise 1,024 units in the hidden layer, an encoder depth of 6 layers and an embedding size of 512. All cells used both in the encoder and decoder side are gated recurrent units (GRU). The transformer dimension is set to 2,048. To reduce the lexicon size, a total of 85,000 merge operations are allowed using the BPE (Byte Pair Encoding) method proposed in (Sennrich et al., 2016), this being the default setting for marian-nmt applications.

Initially, the three Marian-NMT models are trained to provide the base NMT systems. Typically, for a single-GPU system (equipped with an NVIDIA Titan XP GTX1080 GPU card driven by an Intel i-9700K CPU), 24 hours are required for training the transformer, 130 hours for amun and 308 hours for s2s. This is equivalent to a ratio of 1:5:12 to train the respective systems.

3 Experimental Set-up

The experiments aim to improve the translation accuracy of an NMT system, taking into account limited training data and constrained computing resources. In order to investigate translation into a lesser-used and highly inflectional language, we

have chosen the English-to-Greek language pair.

When selecting the training corpora, it has been decided to refrain from using expensive language resources such as specialized or hand-built parallel corpora. Instead, only standard publicly available parallel corpora have been adopted, namely the Europarl and DGT-Acquis corpora[2], as listed in Table 2.

The largest part of the Europarl corpus and the entire DGT-Acquis corpus are used to train the NMT system. Three small portions of the Europarl corpus have been reserved for test and validation purposes. More specifically, two independent sets of approx. 3,000 Europarl sentences each are excluded, to ensure that the NMT evaluation is unbiased. In the present experiment, one of these sets is used for in-training validation. The other set is reserved to allow additional cross-evaluation of experiments in the future, without invalidating the previously trained models. Finally, a sample of 1,000 sentences from Europarl (Testset2) is retained to provide an unseen in-domain test set.

Another independent test set was drawn from the PRESEMT project resources, comprising 200 sentences which have not been used to either train an MT model or create any resources used herewith (denoted as Testset1).

A preliminary analysis of the NMT outputs has shown that translations are commendably fluent, though errors are evident. A sample of amun translations is shown in Figure 1. In sentence #1, the term “Αμεριϰανοί” (Transl. “Americans”) is erroneously used as a translation of the terms “American”, “European”, and “Japanese monopolies”. Similarly, in sentence #2, the phrase “η ϰαταπολέμηση της φτώχειας” (meaning “the reduction of poverty”) is used to translate semantically diverse phrases, including “genetically modified organisms”, and “the negative social effects of unbridled, unregulated globalization”. Repetition is a widely reported weakness of NMT systems, most frequently attributed to insufficient training data.

An additional problem concerns the translation of rare words (i.e. words with low frequency in the corpus), due to the limited vocabulary that NMT systems can directly handle. This is especially severe when translating towards languages with complex morphology, which increases the effective vocabulary size. For example the word “ostensibly” is translated into Greek as “ostenfigher” (ungrammatical). Similarly the word “room” is translated as “δωματείο” instead of the correct “δωμάτιο” (meaning room), whilst the word “indistinct” is translated as “άχωρος” which is not a valid Greek word.

Another issue is that entire phrases present in the source text may be omitted in the translation. For instance the sentence “Businesses have undertaken the education” is translated by a transformer NMT as “Η εϰπαίδευση έχει αναλάβει≫, [meaning “education has undertaken”]. Hence, the subject “business” has been deleted.

4 Improving NMT via the Alignment Verification Method (AVM)

4.1 Aim of AVM

To improve translation accuracy, the main errors need to be identified in an automated manner. The idea is that a poor alignment between source text and translation indicates substantial loss of meaning during translation. On the contrary a high alignment score is indicative of a high likelihood that

#1 Input: Obviously, he wants to downplay them, and tell us that whatever the people do, the American, European, Japanese monopolies and the rest will impose their will and overcome these reactions together.

#1 Translation: ωστόσο , πρέπει να διαδραματίσει επίσης τον ρόλο του , και να μας πει ότι , όταν οι άνθρωποι κάνουν , οι αμερικανοί , οι ευρωπαίοι , οι Αμερικανοί και οι Αμερικανοί θα έχουν τη βούλησή τους και θα έχουν την πλήρη υποστήριξή τους .

#1 Gloss: however, he must also play his part, and tell us that when the people do, the Americans, the Europeans, the Americans and the Americans will have their free will and will have their full support.

#2 Input: In reality, the problems and contradictions of the global economy are still there, unresolved and still relevant: doubts about genetically modified organisms, child labour, the negative social effects of unbridled, unregulated globalisation.

#2 Translation: επιπλέον , οι στόχοι και οι στόχοι της παγκόσμιας οικονομίας είναι σημαντικοί εκεί, η απασχόληση και η κοινωνική συνοχή : η καταπολέμηση της φτώχειας , η καταπολέμηση της φτώχειας , η καταπολέμηση της παιδικής φτώχειας , η καταπολέμηση της φτώχειας , η καταπολέμηση της φτώχειας .

#2 Gloss: moreover, the goals and the goals of the world economy are important there, employment and social cohesion: the fight against poverty, the fight against poverty, the fight against child poverty, the fight against poverty, the fight against poverty.

Figure 1: Example translations generated by amun, with repetitions of texts highlighted in grey

the NMT output is an accurate translation.

To this end a module will be added to implement alignment verification (AVM), by determining the match between the input sentence and its translation. The establishment of representative alignment scores allows in turn the combination of multiple NMT models, using AVM to evaluate the accuracy of each candidate translation and thus select the best translation on a sentence-by-sentence basis. For this research, MT software and tools released via open-source code have been surveyed and the Phrase Aligner Module (PAM, cf. Troullinos, 2013) has been selected. The architecture of the proposal hybrid NMT is depicted in Figure 2.

4.2 PRESEMT essentials

PAM was developed as part of the PRESEMT hybrid MT methodology (Tambouratzis et al., 2017 (Tambouratzis et al., 2017)). PRESEMT was designed to create MT systems requiring only very limited amounts of specialized, expensive linguistic resources. Frequently, the most expensive resource is the parallel corpus of SL – TL sentences. PRESEMT uses parallel corpora of only a few hundred sentences, augmented by very extensive but comparatively inexpensive monolingual corpora.

Within the PRESEMT methodology, the small parallel corpus serves to establish the transformation from the SL structure to the TL one, using the Phrase Aligner module. This module, handling sentence pairs from this parallel corpus, identifies the correspondence of words and phrases from SL to TL, to determine the translation accuracy.

4.3 Description of the PAM module

PAM utilizes a limited-size bilingual lexicon (of typically 30 to 40 thousand token pairs) together with a publicly available parser. Details on these resources are reported in section 4.4, as their choices are language-specific. Based on these resources, PAM establishes for the set of parallel sentences the alignment of both words and phrases from SL to TL, in three hierarchically ordered stages:

1. Within the first stage, the alignment of words is based on equivalences provided by the bilingual lexicon. Dedicated PAM processes resolve cases where (i) words have multiple appearances within a sentence and (ii) multiple potential translations of an SL word exist in the TL side.

2. Within the second stage, words are aligned by establishing statistical correspondences between grammatical features across the SL and TL pair. These correspondences are automatically extracted from the lexicon.

3. Within the third stage, any remaining words are aligned and grouped into phrases on the basis of the alignments of their neighboring words that are successfully aligned. To implement this, the principle of locality across languages is adopted (words at a small distance to each other in SL also tend to be located close to each other in TL).

The key PAM principle is that decisions made at a later stage have a lower degree of confidence than those made at an earlier stage (Troullinos, 2013).

4.4 Using PAM for Alignment Verification

In the current application, PAM determines the suitability of each candidate translation, based on its match with the source sentence. Thus, the assumption made is that the input sentence and the candidate translation represent the corresponding SL and TL entries of a parallel corpus and PAM determines their level of parallelism.

As the requirement is to grade various translations, the PAM operation is reversed, to identify the quality of match between the input sentence and the generated translations. When PAM was used in PRESEMT, sentence pairs from the parallel corpus with a very low percentage of successful alignments were discarded without measuring their degree of parallelism, as poor exemplars of the structural transformations from SL to TL. Here, PAM is modified so that for all pairs of input sentence and NMT-translation the word alignments and assignments of words to phrases are calculated. This allows the re-roled PAM to grade any source/translation pair, no matter how poor the match of the two sentences is.

Two metrics have been established to calculate divergence between the SL sentence and its NMT-derived translations. The first metric (*Uscore*) calculates the number of unaligned words of the source sentence, after PAM is applied. The aim is to have as few unaligned words as possible, so the lower *Uscore* is, the better the translation is.

$$Uscore = \#unaligned\_words \tag{1}$$

The second metric (*Wscore*) is a weighted combination of several indicators of alignment between source sentence and candidate translation. This summarizes in one measurement the type of alignments and the stage at which they were achieved. Hence, for a sentence with *K* words, *Wscore* is defined as:

$$Wscore = \sum_{i=1}^{K} (w_{\mathrm{i}} * align\_stage_{\mathrm{i}}) \tag{2}$$

In equation (2), *align-stage*$_i$ denotes the stage (cf. section 4.3 for the different stages) at which the i-th SL word is aligned successfully to a TL word, and w_i denotes the relevant weight for this stage. In the case of the weighted metric Wscore, the higher the score, the more accurate the corresponding translation is. The actual weight values must reward the establishment of alignments at an earlier rather than a later stage. Thus, w_i should be larger than w_j , for *i* smaller than *j*. For the purposes of the present article, w_i is set to integer values of 5, 2 and 1 for the first, second and third stage respectively (other sets of weight values that follow this reasoning produce similar results to those reported here). The code of PAM has been modified to integrate *Wscore* and *Uscore* calculation, though the actual alignment algorithms within PAM have remained intact. The associated PAM resources (the TL-side parser and bilingual lexicon) remain unchanged. For processing the SL language, Treetagger (Schmid, 1994) is used, with a reported tagging accuracy exceeding 96%.

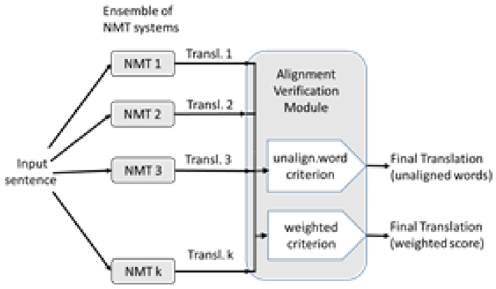

Figure 2: Proposed hybrid NMT approach

5 Experimental Results

To determine the quality of the NMT-based translations (amun-, s2s- and transformer-based models), two widely used MT evaluation metrics are utilised, namely BLEU (Papineni et al., 2002) and NIST (Doddington, 2002). To calculate both these metrics, the mt-eval package (version 13a) is used.

For PAM, the PRESEMT bilingual lexicon from Greek to English is used, which contains approx. 8,000 lemmas and 40,000 Greek-English token pairs. This lexicon is from the same domain as testset1 and is thus out-of-domain for testset2, providing a more limited coverage for this testset.

Two different types of experiments are possible, depending on whether the ensemble comprises multiple NMT architectures, or only one type of architecture. The first experiment reported here involves NMT ensembles that all share the same architecture, but are optimized with different criteria. The second type of experiment studies ensembles which consist of systems with different architectures, to investigate if their combination results in a better translation quality.

5.1 NMT Ensembles of a single architecture

The results obtained for testset1 of the English-to-Greek translation pair are depicted in Table 3, when running the single transformer, amun and s2s models respectively, as well as their ensembles. The corresponding results for testset2 are depicted in Table 4.

In Tables 3 and 4, the first 3 rows correspond to single NMT models generated when Marian-NMT is trained to optimise (i) BLEU, (ii) entropy and (iii) the word-wise normalised cross-entropy (this is denoted as "ce-mean").

The final three rows of Tables 3 and 4 report the accuracy of translations obtained by NMT ensembles. Marian-NMT implements a standard ensemble method, which allows the user to combine different models provided they use the same lexicon. The user may specify weighting factors to boost selection of the models deemed to be better. For this article, this ensemble combines the three aforementioned NMT models (i), (ii) and (iii), with equal weights for all NMTs. The last two rows report the accuracy of ensembles using PAM with (i) Uscore and (ii) Wscore, respectively.

A key difference of the Marian-NMT ensemble is that it is able to recombine partial results of the translation process from each NMT model and thus may generate a new translation that is different from all the translations of single-NMT systems. On the contrary, Uscore and Wscore grade the translations generated by single-NMT models in the ensemble, and then select the highest-scoring translation to be the translation produced by the PAM-based ensemble.

To evaluate the quality of translations produced by the PAM-based ensembles, two baselines are selected. The first baseline is the "ce-mean" option of the Marian-NMT translation system.The second, and stronger, baseline is the Marian-NMT ensemble (referred to as "Marian-ensemble" hereafter). Entries that exceed the first baseline are depicted in bold. Entries with scores that exceed the stronger Marian-ensemble baseline are annotated with an asterisk.

Based on Table 3, for testset1 the best BLEU scores are achieved by the Marian-NMT ensemble in comparison to single-NMT models. The PAM-Wscore ensemble gives a higher accuracy than the Marian-NMT ensemble, whilst the accuracy of PAM-Uscore is lower than PAM-Wscore. On the whole, it is Marian-ensemble and PAM-Wscore that generate the best NIST and BLEU scores.

A broadly similar situation is found when using testset2 (Table 4). Here, the improvement conferred by the ensemble methods over the three base models is much more marked. For instance, for BLEU, the score is only 19.0 to 20.0 for single NMT models, but rises to more than 28.0 for the ensembles, which equates to more than eight BLEU percentage points of improvement.

5.2 Statistical analysis of ensemble results

One question is whether the improvements conferred by the ensembles are statistically significant. To that end, the BLEU and NIST scores of all the independent sentences are assembled, forming two populations of scores (one for BLEU and one for NIST) for each experimental run. Then the Wilcoxon and sign tests are used to determine if these populations have significant differences.

For testset1, the scores of the single NMT systems and the NMT-ensembles are relatively close, differing by less than 2 BLEU points. Applying the sign and Wilcoxon tests, Marian-ensemble produces statistically better NIST scores (at a 0.05 level) than the default Marian-NMT output for amun and s2s models, but not for the transformer model.

For the transformer and s2s models, the scores generated by PAM-Wscore are significantly better that those of single-model Marian-NMT, according to both the Wilcoxon and sign tests (at a 0.05 level). Similarly, PAM-Uscore gives statistically superior results to Marian-NMT (ce-mean optimization) for the s2s model (at a significance level of 0.05).

Comparing the ensembles to each other, Wscore consistently produces higher scores than Uscore. This superiority is statistically significant at a 0.05 level according to both Wilcoxon and sign tests, for the transformer and the amun models.

PAM-Wscore achieves consistently higher translation scores than Marian-ensemble for both BLEU and NIST. According to the Wilcoxon test, these differences are statistically significant, at a 0.05 level, only for the s2s (BLEU score) and the transformer model (both BLEU and NIST scores).

Turning to testset2, the results are more clearly separated. All three ensembles (i.e. PAM-Wscore, PAM-Uscore and Marian-ensemble) have statistically superior scores to Marian (optimised with ce-mean) for both BLEU and NIST, at a significance level of 0.01. This extends to all three NMT models (amun, transformer and s2s), and indicates that both Marian-ensemble and the two PAM-based ensembles give substantially higher scores than single Marian-NMT models.

On the other hand, when comparing PAM-Wscore to PAM-Uscore for testset2, no statistically significant difference (at a 0.05 level of significance) between the two systems is discerned by either the Wilcoxon or sign test. Similarly, no statistically significant differences at a 0.05 level are found between the PAM-based ensembles and the Marian-ensemble and only small differences at a 0.10 level. Thus, even though PAM-based ensembles achieve scores higher than Marian-ensemble, differences are not significant.

5.3 Measuring improvement over baselines

To quantize the improvements achieved by the proposed PAM-Wscore approach, in this section the computational requirements posed by each NMT system are also considered. To this end, the most accurate NMT system is defined for each dataset and metric combination. Two baselines are chosen, namely the most accurate NMT model and the most accurate Marian-ensemble.

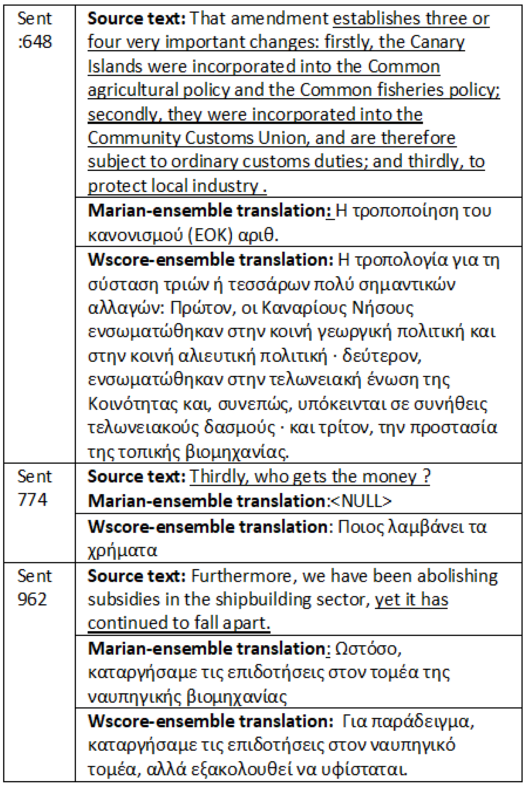
We focus on the transformer model, which is the least expensive model to train. For each ensemble using transformers, the aim is to determine how close to the Marian-ensemble baseline this is. Results are shown in Table 5, where the accuracy of each transformer NMT is expressed as a fraction of the Marian-ensemble score.

The best single transformer model achieves for testset1 88.7% of the baseline BLEU score and 93.1% of the NIST score. Using the Wscore ensembling method, this rises to 90.7% for BLEU and 95.2% for NIST, showing a gain of 2%.

Turning to dataset2, the single transformer scores just 70.5% in comparison to the baseline BLEU score and 73.4% of the NIST score (therefore it is 27% to 30% lower). The Wscore ensemble improves relative scores, reaching 92.7% and 94.5% of the baseline scores for BLEU and NIST respectively. This equates to an increase of ca. 22% in both scores, making the final result directly comparable to s2s, though GPU training requirements are reduced by a factor of 12.

5.4 Subjective studies

A second type of evaluation moves away from metrics to focus on analysing the translation errors by different models, with subjective methods. For instance, when transformer NMT models are tasked to translate testset1, the BLEU-optimised NMT generates 26 ungrammatical words, the entropy-optimised NMT generates 24 ungrammatical words and the cross-entropy optimised model produces 23 ungrammatical words. The Wscore-ensemble reduces the ungrammatical words to 21, improving translation. The ungrammatical words were determined in all cases by visual inspection of the body of translations complemented by spell-checking tools to aid detection.



Sent :648	**Source text:** That amendment establishes three or four very important changes: firstly, the Canary Islands were incorporated into the Common agricultural policy and the Common fisheries policy; secondly, they were incorporated into the Community Customs Union, and are therefore subject to ordinary customs duties; and thirdly, to protect local industry .

	Wscore-ensemble translation: Για παράδειγμα, καταργήσαμε τις επιδοτήσεις στον ναυπηγικό τομέα, αλλά εξακολουθεί να υφίσταται.

Figure 3: Examples of poor translations produced by Marian-ensemble (omitted parts are underlined in source).

Further inspection of translation quality has involved comparing the Marian-ensemble and Wscore-ensemble outputs. The length (in words) of translations per test sentence is found to differ substantially between the two ensembles, with the difference being more than 1/10 for 9% of sentences, more than 1/4 for 2.5% of sentences and more than 1/2 for 1% of sentences (close to identical results are obtained for testset1 and testset2). As such deviations are unexpectedly large, an analysis was performed, with typical examples being shown in Figure 3. As can be seen, PAM assists the Wscore-ensemble in retaining all phrases of the sentence. On the contrary, Marian-ensemble fails to ensure this, and frequently discards portions of the input sentence. In one case (sentence #774) Marian-ensemble results in a null-length translation, and in another (sentence #648) the final translation covers less than 10% of the input text, radically distorting meaning. Both PAM-ensembles are unaffected by such phenomena.

6 Conclusions and Future Work

This article has studied the creation of translation systems towards highly inflectional languages, when the amount of in-domain training data is limited. Emphasis has been placed on improving the translation accuracy of NMT models that can be trained more rapidly and cost-effectively (in terms of CPU processing power) and rendering this performance comparable to that of more complex models. The Marian-NMT package has been chosen as the starting point to create NMT models for the English to Greek language pair. Using only publicly available text corpora, the NMT models produce commendably fluent translations. Identified errors in the NMT translations are typical of a lack of training data.

A hybrid methodology has been proposed that samples an ensemble of NMT models to select the final translation, chosen by a module calculating the alignment level between the input sentence and each translation. This module was developed for resource-poor MT systems.

The proposed hybrid approach has resulted in higher BLEU and NIST scores, compared to those of single NMT models. Improvements are in many cases statistically significant even over the ensemble system provided within the Marian-NMT package, indicating the promising nature of the hybrid approach. Also, the translation process is found to be more robust, giving more consistent translations in comparison to the Marian-NMT ensemble system, which occasionally omits large portions of the input text from the translation.

One of the advantages of the proposed method is that it is general-purpose and does not rely on the use of ensembles of Neural MT systems with a specific architecture. Instead, it can be used to combine the results of different types of Neural MT systems, or MT systems that belong to different paradigms, or even to combine human translations.

In addition the proposed method can be used to clean up a corpus of parallel sentences or several such corpora, by removing sentence pairs for which the source and target-language texts do not have a high degree of parallelism. Similarly, the proposed method may be used to filter a corpus consisting of original text and its MT-derived translation, to produce a parallel corpus for training of other MT systems, fulfilling a role similar to that proposed by (Rikters and Fishel, 2017). One point for future research is how effective a filtering system based on PAM would be, in comparison to already proposed systems.

Future work involves some relatively simple activities that can be imminently implemented, such as releasing the modified version of PAM for experimentation by interested parties. Another short term activity involves using the proposed method with sacreBLEU instead of the BLEU and NIST metrics provided by mt-eval. Future experiments will investigate the effectiveness of this hybrid approach for other language pairs. One area of interest would be to determine the effectiveness of the PAM-based method when very limited dictionaries are available as well as the limitations when the accuracy of the parser used is relatively low. All these represent issues for the future.

It is also planned to study the approach using systematic optimisation of the PAM parameters, to identify in more detail configurations that produce more accurate translations. Another possibility is to use PAM to detect sub-sentential parts of the translated sentences with particularly poor alignments between input and translation and seek better translations of only these specific parts.

Another direction is to investigate more extensively cases where the translation is not sufficiently close to the input sentence. Then, comparisons to other low-scored translations are more difficult and result in a reduced level of confidence of the chosen translation. Such a line of study will evaluate more thoroughly the robustness of the proposed method.

Data Augmentation for Voice-Assistant NLU using BERT-based Interchangeable Rephrase

Akhila Yerukola[*] **Mason Bretan**[*] **Hongxia Jin**

Abstract

We introduce a data augmentation technique based on byte pair encoding and a BERT-like self-attention model to boost performance on spoken language understanding tasks. We compare and evaluate this method with a range of augmentation techniques encompassing generative models such as VAEs and performance-boosting techniques such as synonym replacement and back-translation. We show our method performs strongly on domain and intent classification tasks for a voice assistant and in a user-study focused on utterance naturalness and semantic similarity.

1 Introduction

With conversational assistants becoming more and more pervasive in everyday life, task-oriented dialogue systems are rapidly evolving. These systems typically consist of Spoken Language Understanding (SLU) models, tasked with determining the domain category and the intent of user utterances at each turn of the conversation.

The ability to quickly train such models to meet changing and evolving user needs is necessary. However, developers often find themselves in situations with access to very little labeled training data. This is especially true when new functions are deployed, and a large user base has not had a chance to utilize the function, thus, limiting the number of available utterances that can be labeled for training. Furthermore, the process of labeling large amounts of data can be time consuming and expensive. More recently, these challenges have been both enhanced and complicated by privacy concerns and legislation that may prevent the use of user utterances for training.

Much of the recent research addressing data paucity has focused on pre-training using self-supervision and vast amounts of unlabeled data (Devlin et al., 2018; Radford et al., 2018, 2019). Pre-trained models can later be fine-tuned with a much smaller amount of labeled data for specific tasks. In this work, instead of pre-training, we explore methods that enhance and expand the task-specific training set by using data augmentation. While models such as BERT prove to be both useful and relevant, we show that data augmentation during the fine-tuning stage can boost performance even on these large pre-trained models. We implement and compare several pre-existing techniques for data augmentation on Natural Language Understanding (NLU) tasks such as domain classification (DC) and intent classification (IC) for a voice assistant. We also introduce a new method of data augmentation called *Interchangeable Rephrase* (IR) with the goal of "rephrasing" an existing utterance using new language while maintaining the original intent or goal (see Table 1).

Utterance	how do I make a margherita pizza
Domain	Recipe
Intent	Return_Recipe
Rephrase	show me how to cook a margherita pizza
Utterance	can you check air quality in santa rosa
Domain	Weather
Intent	Air_Quality
Rephrase	is it possible to check air quality in santa rosa
Utterance	delete all emails which have come from hotel.com
Domain	Email
Intent	Delete_Emails
Rephrase	get rid of all emails which have come from hotel.com

Table 1: An illustrative example of a generated rephrase using our Interchangeable Rephrase, while still maintaining the original domain and intent.

2 Related Work

Recurrent neural network (RNN)-based VAE generative models (Kingma and Welling, 2013; Bowman et al., 2015) explicitly model properties of utterances like topic, style, and other higher-level syntactic features. The variational component helps in generating diverse text, thus, we use VAEs as a candidate for transforming and augmenting text

April 19 - 23, 2021.

data in our experiments.

Building upon unconditioned text generation, Conditional VAE (CVAE) (Sohn et al., 2015; Hu et al., 2017) generates more relevant and diverse text conditioned on certain control attributes, e.g. tense, sentiment (Hu et al., 2017), style (Ficler and Goldberg, 2017). In this work, our goal is to maintain semantic similarity, therefore, we generate text by conditioning on the original intent or goal.

Guu et al. generate novel sentences from prototypes by exploiting analogical relationships of sentences. They have shown that generated sentences have a varied style. We extend this idea by using prototype utterances and then editing it into a new utterance or rephrase, using both the VAE and CVAE architecture, to generate augmented rephrase data. We call these models VAE-edit and CVAE-edit.

Back translation (BT) is the process of translating an utterance in a certain language to another language and then translating it back to the original language. Certain question answering (QA) models (Yu et al., 2018) have observed that back-translation generates diverse paraphrases, while preserving the semantics of the original sentences. In our case, we use back-translations as rephrases to augment data.

Another form of simple augmentation techniques is EDA: easy data augmentation (Wei and Zou, 2019). They consist of four operations: synonym replacement, random insertion, random swap and random deletion. They show a boost in text classification tasks with these operations on smaller datasets. Since the number of labeled of spoken utterances are limited, we compare to this approach for our NLU tasks.

Automatic speech recognition (ASR) module, which converts audio input into text, introduces some errors in the process before feeding it into downstream NLU tasks. Without modifying ASR or NLU components, an utterance correction module can be used to help with denoising data (Freitag and Roy, 2018). The reconstructed utterances can be further used as data augmentation.

PPDB is a well known paraphrase database consisting of automatically generated paraphrases (Ganitkevitch et al., 2013). We use this database to rephrase utterances by identifying short phrases within the utterance and replacing them with a related phrase according to the database and POS (e.g. “there is a lot of” → “there are plenty of”).

3 Interchangeable Rephrase

BERT is pre-trained using two tasks: Masked LM (MLM) and Next Sentence Prediction (NSP). In our rephrase task, the end-objective is almost identical to the MLM training, and only this procedure is used to train our self-attention model. MLM training allows the model to predict appropriate word(s) to replace the masked token depending on the context of the rest of the phrase. Each input token corresponds to a final hidden vector that is fed into an output softmax over the vocabulary. Thus, to rephrase an utterance that has more or fewer tokens than the original, the desired number of tokens for the rephrase must be known a priori.

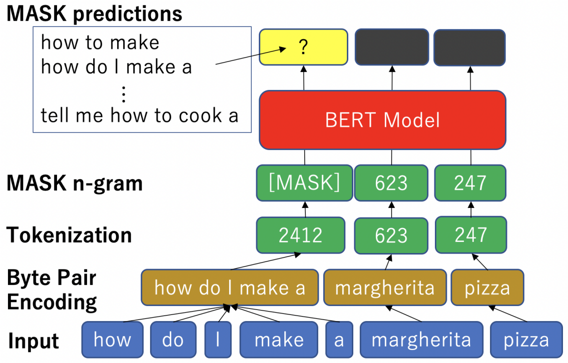

Figure 1: Overview of BERT based interchangeable rephrase (BERT-IR) - BPE is used is to encode n-grams into a single token. Thus, the model’s vocabulary is comprised of tokens representing both single words and sequences of words. The model then computes a softmax over the vocabulary representing the vector of the masked input token allowing for a final output that may be a different word length than the original input.

To allow rephrases with unknown lengths, we use byte pair encoding (BPE) to group word n-grams into single tokens (Sennrich et al., 2015). By using BPE, an individual token may represent a sequence of several words, but the model can still be trained to predict only a single token. We perform BPE on a set of training relevant to the end tasks to get the most frequent n-gram sequences and include these in the model’s vocabulary. Similarly to PPDB, we assume that many of these n-grams are synonyms and are interchangeable. For example, in the context of a virtual assistant skill that enables finding and reciting recipes, n-gram short phrases such as a “how to make”, “tell me how to cook” and “teach me to make” can all be used in the place of the n-gram “how do I make” in the utterance “how do I make a margherita pizza.” This interchangeable property is the foundation of our rephrase and data augmentation system.

The BERT-like self-attention model allows for the predictions to be made based on the context of the input utterance and BPE tokenization allows for variable-length outputs while still only having to predict a single token. Though the new BPE-based vocabulary requires re-training of the model (pre-trained BERT cannot be used), it remains structurally the same as the original BERT model. We refer to our BERT based interchangeable rephrase model as **BERT-IR**. Figure 1 provides an overview of the rephrase model.

In order to maintain intent such that the bigram "turn on" in the utterance "turn on the lights" is not inadvertently replaced with "turn off", negative examples and an intent feature are included in a fine-tuning step. The fine-tuning process minimizes a loss function based on the cosine similarity function

$$sim(\tilde{X}, \tilde{Y}) = \frac{\tilde{X}^T \cdot \tilde{Y}}{|\tilde{X}||\tilde{Y}|} \tag{1}$$

where $\vec{X}$ and $\vec{Y}$ are two equal length vectors and negative examples are included through a softmax function

$$P(\tilde{R}|\tilde{Q}) = \frac{\exp(sim(\tilde{Q}, \tilde{R}))}{\sum_{\tilde{d} \epsilon D} \exp(sim(\tilde{Q}, \tilde{d}))} \tag{2}$$

where $\vec{Q}$ is a one hot ground truth token label derived from the input Q, and $\vec{R}$ represents the output vector of Q. D is the set of three vectors that includes $\vec{R}$ and two vectors derived from two negative examples in the training set. The network then minimizes the following differentiable loss function using gradient descent

$$-log \prod_{(Q,R)} P(\tilde{R}|\tilde{Q}) \tag{3}$$

We emphasize that it is not necessary to use a BERT model for this rephrase method. It is technically possible to use a model architecture identical to that of BERT. However, given that this is not a fine-tuning task and the model needs to be fully re-trained to support the new n-gram tokens a less resource intensive and data hungry model is preferred. In our experiments we use a BERT-like model that leverages self-attention, but has only a fraction of the total parameters of BERT.

4 Experiments

In the following experiments, we examine and compare our proposed method with various data augmentation techniques in the context of utterance generation (rephrase) for voice assistants.

First, we study the properties of the utterances the systems are capable of generating. An ideal data augmentation method should create data that either expands upon or fills in missing gaps of the original training distribution, while still being inherently natural and meaningful. In this context, given an input utterance (from the original distribution), the goal is to generate rephrases that are semantically similar, yet, different enough to positively alter the original training distribution. This is measured in our next two experiments in which we compare the performance of augmented datasets by training an utterance domain classifier (DC) and an intent classifier (IC).

Finally, we perform a user study to examine the quality of utterance generation in terms of naturalness and semantic similarity.

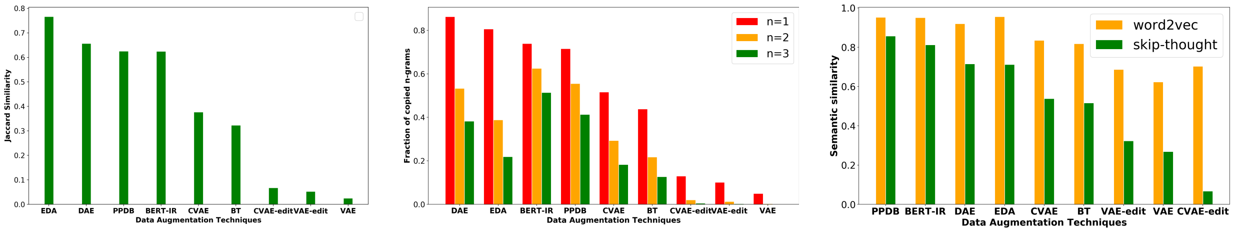
Data. We use an original dataset comprised of utterances for a set of 63 skills (domains) for a voice assistant. The skills range from playing a song on Spotify to turning on/off in-home appliances to providing the weather. The developer of each skill provides a set of training utterances that users can say as an entry point to the function. Each utterance is annotated with an intent, and on average there are 530 utterances per skill (maximum 2000 and minimum 9).

For the DC task, of the 43540 utterances in the dataset, 6590 are held out for validation and the remaining utterances are used for training and processed for augmentation. Additionally, we use a separate test set that was collected and labeled through user trials and crowd sourcing. Each domain in this test set has roughly 900 test utterances.

For the IC task, we consider 5 different skills (domains) from the above dataset: Weather, SystemApp, SmartThings, TvControl and TvSettings. We allocate 30% of the data in each skill for testing and use the remaining for training including augmentation. (see Appendix A.3 for more details).

4.1 Experimental Settings

Our BERT-based interchangeable rephrase model uses an architecture that is similar in size and structure to DistilBERT (Sanh et al., 2019). It is possible to use alternative types of models, but we are motivated by the power of self-attention mechanisms for sequential tasks. Our model is pre-trained with roughly 500k utterances from user data (in



(a) **Jaccard Similarity:** ↓ lower is better

(b) **Copied n-gram fraction:** ↓ lower is better

(c) **Semantic Similarity:** ↑ higher is better

Figure 2: Evaluation of automatic metrics: Averaged across all the generated rephrases for each model.

USA) for the voice assistant. The vocabulary is established using a combination of the developer training data and the usage data. After the byte-pair-encoding process, we prune the resulting pairs so that only pairs occurring more than 100 times are used in the final vocabulary. All unigrams appearing two or more times are also included in the vocabulary.

Baselines. Our first baseline is a classifier that is finetuned solely on the original training data with no augmentation. We compare with existing work on data augmentation via VAE/CVAE, VAE/CVAE-edit, back-translation, denoising autoencoder (DAE), easy data augmentation (EDA) and PPDB. We refer the reader to Appendix A.1 for experimental details of the above augmentation techniques.

4.2 Analysis and Comparison of Methods

We apply several automated linguistic metrics to examine differences in quality of generated rephrases. We evaluate the generated rephrases based on how *related* they are to the original utterances. A model which minimizes the word-level overlap (i.e more variation) and increases the semantic similarity the most is presumably ideal.

Jaccard similarity (Jaccard, 1912; Roemmele et al., 2017) is used to measure the proportion of overlapping words between the rephrase and the original utterance. Additionally, for $n = 1, 2, 3$, we measure the proportion of generated n-grams that also appear in the original utterance i.e amount copied from original utterance (See et al., 2019).

We measure semantic similarity at the word-level and sentence-level. We compute the the mean cosine similarity of the word2vec vectors of all pairs of words between a rephrase and the original utterance. We also measure the cosine similarity of the sentence encodings, generated by the skip-thought model (Kiros et al., 2015), of the rephrase and the original utterance (see Figure 2c). The skip-thought model maps sentences sharing semantic and syntactic properties to similar vector representations.

MODEL	HELD OUT	TEST ACC
NO - AUGMENTATION	0.9229	0.8251
VAE	0.9212	0.8379
CVAE	0.9277	0.8447
VAE-EDIT	0.84	0.6891
CVAE-EDIT	0.8617	0.7469

DAE	0.9307	0.8765
EDA	0.9896	0.8921
PPDB	0.9341	0.8764
BERT-IR	0.9738	**0.9062**

Table 2: Domain classification results.

We average all these metrics across all the generated rephrases for each model (see Figure 2).

4.3 Domain and Intent Classification

The data generated from each augmentation technique is used to train a domain classifier and an intent classifier. Ten classifiers are trained for each task, using the same distribution of training and held out data described previously. Though several of the augmentation techniques are capable of generating more than one utterance per input, here we generate augmented data in a 1-1 fashion i.e, for each original utterance in the training set, a single rephrase is generated (see Figure 3).

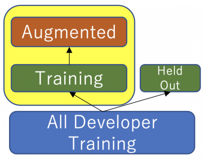

Figure 3: Training distribution for domain and intent classification. All data within yellow boundary box is used for training the classifier.

For both the tasks, we train a classifier on top of the base uncased DistilBERT [1] model (see A.2).

---

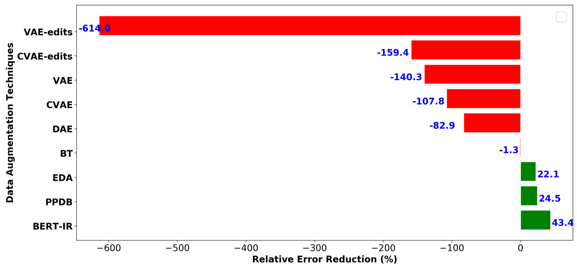

Figure 4: Intent Classification: Relative error reduction of each augmentation type compared to the original "no augmentation" classifier. A positive value (green bar) indicates better performance.

SOURCE	AVG. NATURALNESS	INTENT ACCURACY
HUMAN	3.9	84.5
PPDB	3.1	72.3
OURS	3.4	78.6

Table 3: User study results. The average likert naturalness (where 5 is very natural and 1 is very unnatural) and intent matching accuracy are reported for each of the three utterance sources.

The results on DC task are shown in Table 2. In Figure 4, we show the relative error reduction of each augmentation technique achieved on IC, averaged across all 5 skills (see Appendix A.4 for complete details).

4.4 User study

We performed an online user study where participants completed two tasks. In the first task, participants answered a three item Likert survey regarding the naturalness of the utterance (see Appendix A.5). We compared results for utterances that came from the original developer training (i.e. human-generated), our proposed BERT-IR, and a baseline rephrase using PPDB.

In the second task, users were given a reference utterance and four candidate utterances. Of the four candidates, one of them had an identical intent as the reference, but with different wording, and the other three were random utterances with different intents. The participants were asked to select the candidate with the same intent as the reference. The "correct" candidate was generated from one of the three sources: human, our rephrase, or PPDB rephrase. There were 88 participants, and each participant completed each task 30 times. Results for both tasks are shown in Table 3. Using a 3-way ANOVA, we found significant differences between all three methods on a $p < .05$ level.

5 Discussion

In our experiments, we show that VAE models are capable of generating diverse rephrases. However, these rephrases do not preserve the original meaning. This likely contributed to poorer performance on DC and IC. The discriminator of CVAE models trained to condition on a domain (DC) or intent (IC) helps improve semantic similarity resulting in slightly improved performance of NLU tasks. The VAE-edit and CVAE-edit models perform quite poorly on all comparisons as they don't necessarily preserve the meaning of the utterance when transforming them into an altered style.

Back-translation yields relatively diverse rephrases; however, it poorly conserves the original meaning. DAE just tends to copy a higher fraction of n-grams, while not changing the meaning of the utterance. EDA has boosted the DC and IC performance, compared to other methods. However, it merely changes a small percent of words in utterances by replacement operations, which are not always grammatically sound.

Our BERT-IR yields the best performance on the NLU tasks, with a relative error reduction of 46.26% on DC and 43.4% on IC as compared to no additional augmentation. Similar to PPDB, our approach generates rephrases with a lower word-overlap and a significantly higher semantic similarity with the original utterance. The user study reveals that BERT-rephrase is an improvement over the PPDB baseline, but does not perform at the level of human generated utterances in terms of naturalness and intelligibility.

For examples of generated rephrases see Table 8 in the Appendix.

6 Conclusion

We introduced BERT-IR, a simple augmentation strategy based on byte pair encoding and a BERT-like self-attention model to generate diverse, natural and meaningful rephrases in the context of utterance generation for voice assistants. We demonstrate that BERT-IR performs strongly on spoken understanding tasks like domain classification and intent classification and in a user-study focused on evaluating quality of rephrases based on naturalness and interpretability (intent preservation).

A Appendices

A.1 Implementation and Training Details of Augmentation Strategies

VAE: The decoder and encoder of the VAE model are set as single-layer GRU RNNs with input/hidden dimension of 100/150 and max sample length of 15. Larger input/hidden dimension models performed similarly. To avoid vanishingly small KL term in the VAE module, we use a KL term weight linearly annealing from 0 to 0.15 during training (similar to training procedure in Hu et al.). Training a larger VAE model yielded comparable results.

CVAE: The discriminator is set as ConvNets similar to Hu et al.. Balancing parameters are set to $\lambda_c = \lambda_z = \lambda_u = 0.1$. Training procedure is exactly as Hu et al..

VAE edit, CVAE-edit: We match tuples of utterances which have the same domain and intent. These pairs are used as the prototypes and new utterances during training of VAE-edit and CVAE-edit (similar to training procedure in Guu et al. by constructing edit vectors and concatenating it with z before feeding into the decoder).

Denoising Auto-encoder: The decoder and encoder of the denoising auto-encoder are set as single-layer GRU RNNs with input/hidden dimension of 300/512 with Luong attention. We follow a similar utterance corruption as Freitag and Roy by dropping words randomly whose frequency was greater than 100 (i.e non-content words like "the"), followed by shuffling of its bigrams while not splitting bigrams that also exist in the original utterance. We train a DAE using this corrupted data. We use the corrected utterance/rephrases generated as augmentation data.

We train the above models until convergence on 2 NVIDIA Tesla V100 GPUs.

Back-translation: We use the open-sourced back-translation system from (Xie et al., 2019). Specifically, we use pre-trained WMT'14 English-French translation models (in both directions) to perform back-translation on each utterance.

EDA: We followed three strategies by Wei and Zou: random insertion, random replacement and random swap.

PPDB: The PPDB [2] database consists of 1 paraphrase rule per line. A standard format of a line is:

```
LHS ||| PHRASE ||| PARAPHRASE |||
(FEATURE=VALUE )* ||| ALIGNMENT |||
ENTAILMENT
```

If a PHRASE exists in the utterance, we replace it with the PARAPHRASE. Since it's a 1-1 data augmentation, we sample a rephrase from the list of all possible generated rephrases. We use the English-Phrasal PPDB database .

Refer to Table 4 for the average run time for the different augmentations techniques.

MODEL	TIME
VAE (GPU)	1 MINUTE
CVAE (GPU)	1.5 MINUTES
VAE-EDIT (GPU)	2 MINUTES
CVAE-EDIT (GPU)	3 MINUTES
BACK-TRANSLATION (GPU)	30 MINUTES
DAE (GPU)	1 MINUTE
EDA (CPU)	3 MINUTES
PPDB (CPU)	11 MINUTES
BERT-REPHRASE (GPU)	7 MINUTES

Table 4: Average time to run inference for augmentation over the training set (36,950 utterances) assuming one generated output per utterance.

A.2 Domain Classification and Intent Classification

For domain classification and intent classification, we train a classifier on top of the base uncased DistilBERT model. We use a maximum sequence length of 128, a dropout rate of 0.1, and a learning rate of 2e-5. We train the classifier for 15 epochs and batch size of 32 on a single NVIDIA Tesla V100.

SPLITS	NUM. OF UTTERANCES
TRAIN	36950
HELD OUT	6590
TEST	56820

Table 5: Domain Classification Data Statistics

A.3 Training Data Statistics

Domain Classification: Table 5 shows the counts for each training, development (held out), and test set. The partition used for training is also the partition that is augmented (and subsequently also used for training in domain classification, see Figure 3). Each utterance has an average of 6 words. There are 63 different domains in our dataset like music, calendar, calculator, weather etc. We evaluate the automatic metrics from Section 4.2 on the same data used for training the domain classifier.

TVCONTROL	19	392	168
TVSETTINGS	40	834	357

Table 6: Intent Classification Data Statistics

Intent Classification: Table 6 shows the training split counts for each of the 5 different domains. Similar to domain classification, the partition used for training is also the partition that is augmented (and subsequently also used for training in intent classification, see Figure 3).

A.4 Intent Classification Results

As shown in Table 6, the amount of training data available to train an intent classifier for each domain is very less. This can explain the poor performance of VAE models and its variations on IC since they require a lot more training data to perform well. This is also illustrated in the results of domain classification where these VAE based models achieve a slight improvement since there is a higher amount of training data available. Please refer to Table 7 for the fine-grained performance results of the augmentation techniques on the 5 domains.

A.5 User Study Details

Participants responded to three items on a Likert-scale of one to five:

1. This utterance is natural. (disagree to agree)
2. It is easy to understand the intent. (disagree to agree)
3. A person is likely to say this to a voice assistant to achieve the underlying goal. (disagree to agree)

How to Evaluate a Summarizer: Study Design and Statistical Analysis for Manual Linguistic Quality Evaluation

Julius Steen Katja Markert
Department of Computational Linguistics
Heidelberg University
69120 Heidelberg, Germany
(steen|markert)@cl.uni-heidelberg.de

Abstract

Manual evaluation is essential to judge progress on automatic text summarization. However, we conduct a survey on recent summarization system papers that reveals little agreement on how to perform such evaluation studies. We conduct two evaluation experiments on two aspects of summaries' linguistic quality (coherence and repetitiveness) to compare Likert-type and ranking annotations and show that best choice of evaluation method can vary from one aspect to another. In our survey, we also find that study parameters such as the overall number of annotators and distribution of annotators to annotation items are often not fully reported and that subsequent statistical analysis ignores grouping factors arising from one annotator judging multiple summaries. Using our evaluation experiments, we show that the total number of annotators can have a strong impact on study power and that current statistical analysis methods can inflate type I error rates up to eight-fold. In addition, we highlight that for the purpose of system comparison the current practice of eliciting multiple judgements per summary leads to less powerful and reliable annotations given a fixed study budget.

1 Introduction

Current automatic metrics for summary evaluation have low correlation with human judgements on summary quality, especially for linguistic quality evaluation (Fabbri et al., 2020). As a consequence, manual evaluation is still vital to properly compare the linguistic quality of summarization systems.

While the document understanding conferences (DUC) established a standard manual evaluation procedure (Dang, 2005), we conduct a comprehensive survey of recent works in text summarization that reveals a wide array of different evaluation questions and methods in current use. Furthermore, DUC procedures were designed for a small set of expert judges, while current evaluation campaigns are often conducted by untrained crowd-workers. The design of the manual annotation, specifically *the overall number of annotators* as well as *the distribution of annotators to annotation items*, has substantial impact on power, reliability and type I errors of subsequent statistical analysis. However, most current papers (see Section 2) do not consider the interaction of annotation design and statistical analysis. We investigate the optimal annotation methods, design and statistical analysis of summary evaluation studies, making the following contributions:

1. We conduct a comprehensive survey on the current practices in manual summary evaluation in Section 2. Often, important study parameters, such as the total number of annotators, are not reported. In addition, statistical significance is either not assessed at all or with tests (t-test or one-way ANOVA) that lead to inflated type I error in the presence of grouping factors (Barr et al., 2013). In summarization evaluation, grouping factors arise whenever one annotator rates multiple summaries.

2. We carry out annotation experiments for coherence and repetition. We use both Likert- and ranking-style questions on the output of four recent summarizers and reference summaries. We show that ranking-style evaluations are more reliable and cost-efficient for coherence, similar to prior findings by Novikova et al. (2018) and Sakaguchi and Van Durme (2018). However, on repetition, where many documents do not exhibit any problems, Likert outperforms ranking.

3. Based on our annotation data, we perform

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1861–1875
April 19 - 23, 2021.

Monte-Carlo simulations to show the risk posed by ignoring grouping factors in statistical analysis and find up to eight-fold increases in type I errors when using standard significance tests. As an alternative, we propose to either use mixed effect models (Barr et al., 2013) for analysis or to design studies in such a manner that results can be aggregated into independent samples, amenable to simpler analysis tools.

4. Finally, we show that the common practice of eliciting repeated judgements for the same summary leads to less reliable and powerful studies for system-level comparison when compared to studies with the same budget but only one judgement per summary.

Code and data for our experiments is available at `https://github.com/julmaxi/summary_lq_analysis`.

2 Literature Survey

We survey all summarization papers in ACL, EACL, NAACL, ConLL, EMNLP, TACL and the *Computational Linguistics* journal in the years 2017-2019. We choose this timeframe as we are interested in current practices in summarization evaluation: 2017 marks the publication of the pointer generator network (See et al., 2017), which has been highly influential for neural summarization. We focus our analysis on papers that present *a novel system* for single- or multi-document summarization and take a single or multiple full texts as input and also output text (SDS/MDS). This allows us to concentrate on recommendations for human evaluation of newly developed summarization systems.[1]

Out of the resulting **105** SDS/MDS system papers, we identify all papers that conduct at least one new comparative system evaluation with human annotators for further analysis, leading to **58** papers in the survey. The fact that this is only about half of all papers is troubling given that it has been recently demonstrated that current automatic evaluation measures such as ROUGE (Lin, 2004) are

Table 1: Our survey for 58 system papers with 95 manual evaluation studies (2017-2019). We show numbers both for individual studies and per paper. As a paper may contain several studies with different parameters, counts in the paper column do not always add up.

---

[1] Excluded from the analysis are sentence summarization or headline generation papers, although most of the points we make hold for their evaluation campaigns as well. Summarization evaluation papers that do not present a new system but concentrate on sometimes large-scale system comparisons are discussed in the Related Work section instead. Lists of all included and excluded papers are given in Supplementary Material, which also contains exact evaluation parameters per paper in a spreadsheet.

not good at predicting summary scores for modern systems (Schluter, 2017; Kryscinski et al., 2019; Peyrard, 2019).

We assess both *what* studies ask annotators to judge, as well as *how* they elicit and analyse judgements. The survey was conducted by one of the authors: for most papers, the categories they fell into were obvious. For difficult cases (unclear specifications, papers that do not fit the normal mould) the two authors discussed the categorisations. Survey results are given in Table 1. Further details about the choices made in the survey, including category groupings/definitions and what is included under *Other*, can be found in Appendix B. As many papers conduct more than one human evaluation (for example on different corpora), we also list individual annotation studies (a total of 95).

Of the systems that do have human evaluation, many focus on *content*, including informativeness, coverage, focus, and relevance. Where linguistic quality is evaluated, most focus on general questions about fluency/readability, with a smaller number of papers evaluating coherence and repetition.

In the rest of this section we focus on the three aspects of evaluation we cover in this paper: How to elicit judgements, how these judgements are analysed statistically and how studies are designed.

2.1 Methods

The majority of evaluations is conducted using Likert-type judgements, with the second most frequent method being rank-based annotations, including pairwise comparison. Best-worst scaling (BWS) is a specific type of ranking-oriented evaluation that requires annotators to specify only the first and last rank (Kiritchenko and Mohammad, 2017). QA (Narayan et al., 2018) is used for content evaluation only. This motivates us to compare both Likert and ranking annotations in Section 4.1.

2.2 Statistical Analysis

If a significance test is conducted, most papers analyse their data either using ANOVA or a sequence of paired t-tests. Both tests are based on the assumption that judgements (or pairs of judgements, in case of paired t-test) are sampled *independently* from each other. However, in almost all studies, annotators give judgements on more than one summary from the same system. Thus the resulting judgements are only independent if we assume that all annotators behave identically. Given that prior work (Gillick and Liu, 2010; Amidei et al., 2018), as well as our own reliability analysis in Section 4.1, show that especially crowd-workers tend to disagree about judgements, this assumption does not seem warranted. As a consequence, traditional significance tests are at high risk of inflated type I error rates. This is well known in the broader field of linguistics (Barr et al., 2013), but is disregarded in summarization evaluation. We show in Section 5 that this is a substantial problem for current summarization evaluations and suggest alternative analysis methods.

2.3 Design

Most papers only report the number of documents in the evaluation and the number of judgements *per summary*. This, however, is not sufficient to describe the design of a study, lacking any indication about the overall number of annotators that made these judgements. A study with 100 summaries and 3 annotations per summary can mean 3 annotators did all judgements in one extreme, or a study with 300 distinct annotators in the other. Only 26 of the 95 studies describe their annotation design in full, almost all of which use designs in which a small number of annotators judge all summaries. Only **6** of **49** crowdsourced studies report the full design.

We show in Section 5 that a low total number of annotators aggravates type I error rates with improper statistical analysis. In Section 6 we further show that with proper analysis, a low total number of annotators leads to less powerful experiments. Almost all analysed papers choose designs with multiple judgements per summary. However, we show in Section 6.2 that this — for the purpose of system ranking — leads to loss of reliability as well as power when compared to a study with the same budget and only one annotation per summary.

3 Coherence and Repetition Annotation

To elicit summary judgements for analysis, we conduct studies on two linguistic quality tasks. In the first, we ask annotators to judge the *coherence* of the summaries, while in the second we ask for the *repetitiveness* of the summary. We select these two tasks over the more frequent *Fluency* task as we found in preliminary investigations that many recent summarization systems already produce highly fluent text, making them hard to differentiate. We do not evaluate *Overall* and *Content* as both require access to the input document, which differentiates these questions from the linguistic quality evaluation of the summaries.

For both tasks, we conduct one study using a seven-point Likert-scale (`Likert`) and another using a ranking-based annotation method (`Rank`), where annotators rank summaries for the same document from best to worst. Screenshots of the interfaces for both approaches and full annotator instructions are given in Appendix A.

Corpus and Systems. Mirroring a common setup (see Section 2), we select four abstractive summarization systems and the reference summaries (`ref`) for analysis.

- The pointer generator summarizer (`PG`) (See et al., 2017), which is still often used as a baseline for abstractive summarization
- The abstractive sentence rewriter (`ASR`) of Gehrmann et al. (2018), which is a strong summarization system that does not rely on external pretraining for its generation step
- `Seneca` (Sharma et al., 2019), a system that combines explicit modelling of coreference information with an external coherence model
- `BART` (Lewis et al., 2020), a transformer network that achieves SotA on CNN/DM.

We randomly sample 100 documents from the popular CNN/DM corpus (Hermann et al., 2015) with corresponding summaries from all systems to form the item set for all our studies.

Study design. We ensure a sufficient total number of annotators by using a block design. We separated our corpus into 20 blocks of 5 documents and included all 5 summaries for each document in the same block, which results in 5 × 5 = 25 summaries per block.

All items in a block were judged by the same set of three annotators. No annotator was allowed to judge more than one block. This results in a total of 3 × 20 = 60 annotators and 1500 judgements per task. Figure 1 shows a schematic overview of our design, which balances the need for a large enough annotator pool with a sufficient task size to be worthwhile to annotators.

We recruited native English speakers from the crowdsourcing platform Prolific[2] and carefully adjusted the reward to be no lower than £7.50 per hour based on pilot studies. Summaries (or sets of summaries for `Rank`) within a block were presented in random order.

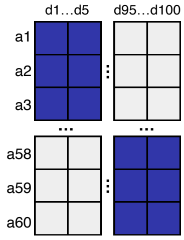

Figure 1: Schematic representation of our study design. Rows represent annotators, columns documents. Each blue square corresponds to a judgement of the summaries of all five systems for a document. Every rectangular group of blue squares forms one block.

4 Ranking vs. Likert

Table 2 shows the average Likert scores and the average rank for all systems, tasks and annotation methods. We use mixed-effect ordinal regression to identify significant score differences (see Section 5 for details). Both annotation methods provide compatible system rankings for the two tasks, though for the repetition task both methods struggle to differentiate between systems. If we were interested in the true ranking, we could conduct a power analysis given some effect size of interest and elicit additional judgements to improve the ranking. However, as we are concerned with the *process* of system evaluation and not the evaluation itself, we do not conduct any further analysis.

In the remainder of this section, we focus on the reliability of the two methods as well as their cost-effectiveness.

4.1 Reliability

Traditionally, reliability is computed by chance-adjusted agreement on individual instances. However, for NLG evaluation, Amidei et al. (2018) argue that a low agreement often reflects variability in language perception. Additionally, we are not interested in individual *document scores*, but in whether independent runs of the same study would result in consistent *system scores*. In Table 3 we thus report split-half reliability (SHR) in addition to Krippendorffs α (Krippendorff, 1980). To compute SHR, we randomly divide judgements into two groups that share neither annotators nor documents, i.e. two independent runs of the study. We

---

ASR	$4.17^{(3/4)}$	$3.17^{(3/4)}$	$4.88^{(4/5)}$	$3.51^{(4/5)}$
PG	$4.81^{(2)}$	$2.68^{(2)}$	$5.63^{(3)}$	$2.92^{(3/4)}$
seneca	$3.52^{(5)}$	$4.11^{(5)}$	$5.16^{(4/5)}$	$3.27^{(3/4/5)}$

Table 2: Results of our annotation experiment. Numbers in brackets indicate rank for a system for a given annotation method. Multiple ranks in the brackets indicate systems at these ranks are not statistically significantly different ($p \geq 0.05$, mixed-effects ordinal regression).

System	α	SHR
Coh: Likert	0.22	0.96
Coh: Rank	0.43	0.98
Rep: Likert	0.27	0.95
Rep: Rank	0.18	0.91

Table 3: Krippendorffs α with ordinal level of measurement and Split-Half-Reliability for both annotation methods on the two tasks.

then compute the correlation[3] between the system scores in both halves. The final score is the average correlation after 1000 trials.

Though agreement on individual summaries is relatively low for all annotation methods, studies still arrive at consistent system scores when we average over many annotators as demonstrated by the SHR. This reflects similar observations made by Gillick and Liu (2010).

We find that on coherence, Rank is more reliable than Likert, though not on repetition. An investigation of the Likert score distributions for both tasks in Figure 2 shows that coherence scores are relatively well differentiated whereas a majority of repetition judgements give the highest score of 7, indicating no repetition at all in most summaries. We speculate overall agreement suffers, because ranking summaries with similarly low level of repetition (and not allowing ties) is potentially arbitrary.[4]

4.2 Cost-efficiency

While more reliable annotation methods allow for fewer annotations, the cost of a study is ultimately determined by the work-time that needs to be invested to achieve a reliable result. To investigate this, we randomly sample between 2 and 19 blocks from our annotations and compute the total time annotators spent to complete each sample. We also compute the Pearson correlation of the system scores in each sample with the scores on the full annotation set. We relate time spent to similarity between sample and full score in Figure 3.

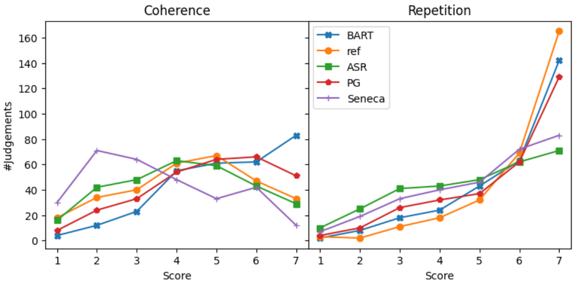

Figure 2: Score distribution of Likert for both tasks. Each data point shows the number of times a particular score was assigned to each system.

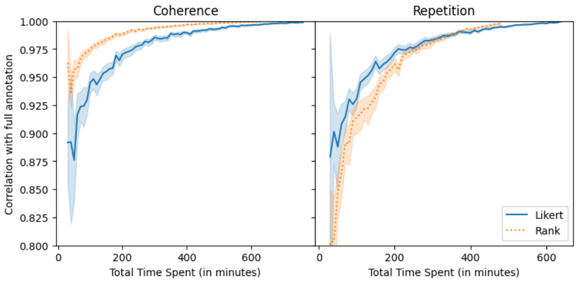

Figure 3: Time spent on annotation (in minutes) vs. correlation with the full-sized score. We gather annotation times in buckets with a width of ten minutes and show the 95% confidence interval for each bucket.

For coherence, Rank is more efficient than Likert. On repetition, the lower reliability of Rank also results in lower efficiency. However, with additional annotation effort, reliability becomes on-par with Likert. This is a consequence of the overall lower annotator workload for Rank.

---

[3] We use the Pearson correlation implementation of scipy (Virtanen et al., 2020).

[4] This is supported by feedback we received from annotators that the summaries were difficult to rank as they mostly avoided repetition well.

5 Statistical Analysis and Type I Errors

The two most common significance tests in summarization studies, ANOVA and t-test (see Table 1), both assume judgements (or pairs of judgements, in the case of t-test) are independent. This is, however, not true for most study setups as a single annotator typically judges multiple summaries and multiple summaries are generated from the same input document. Both documents and annotators are thus grouping factors in a study that must be taken into account by the statistical analysis. Generalized mixed effect models (Barr et al., 2013) offer a solution but have, to the best of our knowledge, not been used in summarization evaluation at all. We choose a mixed effect ordered logit model to analyse our Likert data for both tasks.[5] We will show that traditional analysis methods have a substantially elevated risk of type I errors, i.e. differences between systems found in manual analysis might be overstated.

Method. The ordered logit model we employ can be described as follows:

$$\begin{aligned} &logit(P(Y \leq c)) \\ &= \mu_c - (X\beta + Z_a u_a + Z_d u_d) \end{aligned}$$

where $P(Y \leq c)$ is the probability that the score of a summary is at most c. μ_c is the threshold coefficient for level c, β is the vector of fixed effects and u_a, u_d are the vectors of annotator- and document-level random effects respectively, where u_a, u_d are both drawn from normal distributions with mean 0. Finally, X, Z_a, Z_d are design matrices for fixed and random effects. As the only fixed effect, we use a dummy-coded variable indicating the system that has produced the summary, with `ref` as the reference level. We estimate both random intercepts and slopes for both documents and annotators following advice of Barr et al. (2013) to always specify the maximal random effect structure. In practical terms this means that we allow annotators to both differ in how harsh or generous they are in their assessment, as well as in which system they prefer. Similarly, we allow system performance to vary per-document, leading to both generally higher or lower scores, as well as different system rankings per document.

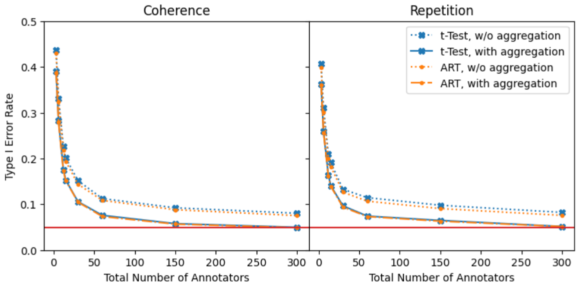

Figure 4: Relation of type I error rates at $p < 0.05$ to the total number of annotators for different designs, all with 100 documents and 3 judgements per summary. We conduct the experiment with both the t-test and approximate randomization test (ART). We show results both with averaging results per document and without any aggregation. We run 2000 trials per design. The red line marks the nominal error rate of 0.05.

We fit all models using the `ordinal` R-package (Christensen, 2019) and compute pairwise contrasts between the parameters estimated for each system using the `emmeans`-package (Lenth et al., 2018) with Tukey-adjustment.

To demonstrate the problem of ignoring the grouping factors, we can now sample artificial data from the model distribution and try to analyse it with inappropriate tests. This Monte-Carlo simulation is similar to the more general analysis of Barr et al. (2013).

We set β to 0 so all systems perform equally well on the population level and only keep the (zero-mean) document and annotator effects in the model. The false-positive rate of statistical tests on this artificial data should thus be no higher than the significance level. We then repeatedly apply both the t-test and the approximate randomization test (ART) (Noreen, 1989), a non-parametric test, to samples drawn from the model and determine the type I error rate at $p < 0.05$. We set the number of documents to 100 and demand 3 judgements per summary to mirror a common setup in manual evaluation. We then vary the total number of annotators between 3 and 300 by changing how many summaries a single annotator judges.

Results. We report results given the model estimated for `Likert` in Figure 4. Ignoring the dependencies between samples leads to inflated type I error rates, whether using the t-test or the ART. This is especially severe when only few annotators judge the whole corpus. In the extreme case with only three annotators in total, the null-hypothesis is rejected in about 40% of trials at a significance

---

[5] We do not include Rank data as the ordinal regression model does not generate ranks.

level of 0.05 in both tasks. Even our original design with 60 annotators still sees an increase of the type I error rate by about 3%. Only if every annotator judges a single document and annotations are averaged per document, samples are independent and thus the real error is at the nominal 0.05 level. This design, however, is unrealistic given that annotators must be recruited and instructed.

We suggest two solutions to this problem: Either use mixed effect models or aggregate the judgements so samples become independent. This allows the assumptions of simpler tools such as ART to be met. In our study, we could average judgements in every block to receive independent samples. This is only possible, however, if the design of the study considers this problem in advance: a crowd-sourcing study that allows annotators to judge as many samples as they like is unlikely to result in such a design.

6 Study Design and Study Power

When conducting studies for system comparison, we are interested in maximizing their power to detect differences between systems. For traditional analysis, the power is ultimately determined by the number of documents (or judgements, when no aggregation takes place) in the study. However, when analysis takes into account individual annotators, power becomes additionally dependent on the total number of annotators and how evenly they participated in the study. This gives additional importance to the design of evaluation studies. In this section, we thus focus on how to optimize studies for power and reliability.

We first show that for well-powered experiments, we need to ensure that a sufficient total number of annotators participates in a study. In the second part of this section, we will then demonstrate studies can improve their power by not eliciting multiple judgements per summary.

6.1 Overall Number of Annotators

To demonstrate the difference in power caused by varying the total number of annotators in a study, we determine the power for a design with the same total number of documents and judgements per document but different total numbers of annotators.

We run the experiment both with regression and ART with proper aggregation of dependent samples as described in Section 5. We refer to the latter as `ARTagg` to differentiate it from normal ART.

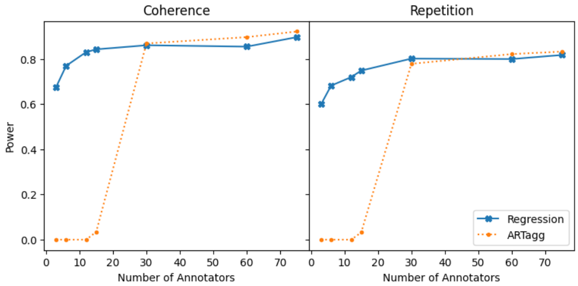

Figure 5: Power for 100 documents and 3 judgements per summary with different number of total annotators.

For each design we repeatedly sample artificial data from the `Likert` model and apply both tests to the data. The process is the same as in Section 5 except we do not set β to zero and count acceptances of the null-hypothesis.[6]

We again set the number of documents to 100 and the number of repeat judgements to 3 and vary the total number of annotators between 3 and 75 by varying the number of blocks between 1 and 25. We test for power at a significance level of 0.05.

Figure 5 shows how power drops sharply when only few annotators take part in the study. This is in line with the theoretical analysis of Judd et al. (2017) that shows that the number of participants is crucial for power when analysing studies with mixed effect models. The drop is worse for `ARTagg` as fewer annotators mean fewer independent blocks and thus a lack of datapoints for the analysis.

6.2 Annotator Distribution

Most studies elicit multiple judgements per summary, following best practices in NLP for corpus design (Carletta, 1996). While this leads to better judgements per *document*, the goal of many summarization evaluations is a per *system* judgement.

For this kind of study, Judd et al. (2017) show that for mixed models that include both annotator and target (in our case, input document) effects, a design where targets are *nested* within annotators, i.e. every annotator has its own set of documents, is always more powerful than one where they are (partially) *crossed* with annotators, i.e. a study with multiple annotations per summary, *given the same total number of judgements*. In fact, power could be maximized by having each annotator judge the sum-

---

[6] As this is an observed power analysis it probably overestimates the power of our analysis for the true effect. The analysis is thus only useful to compare designs under our best estimate of actual effect sizes.

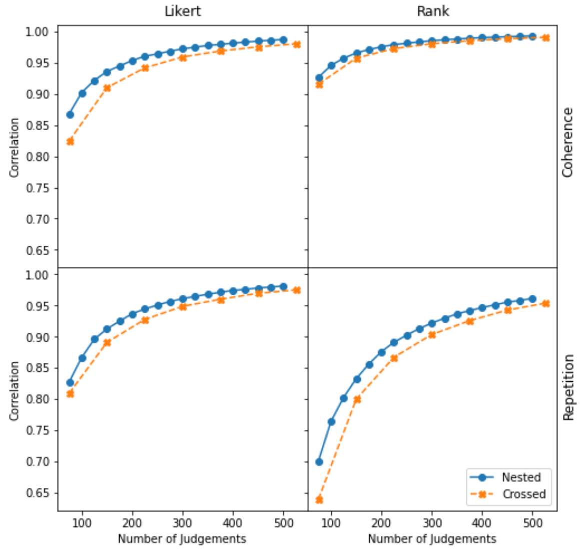

Figure 6: Reliabilities of nested vs. crossed designs for `Rank` and `Likert` for both tasks.

maries for only a single, unique document. However, this is usually not realistic due to the fixed costs of annotator recruitment and instruction. We demonstrate on our dataset how both reliability and power are affected by nested vs. crossed design.

To compare reliability, we randomly sample both nested and crossed designs from our full study and then compute the Pearson correlation of the system scores given by this smaller annotation set with the system scores given by the full study. As shown in Figure 6, nested samples are always at least as good and mostly better at approximating the results of the full annotation compared to a crossed sample with the same annotation effort.

We also conduct a power analysis for regression and `ARTagg` comparing nested and crossed designs. We again turn to Monte-Carlo simulation on the `Likert` models and sample nested and crossed designs with the same total number of judgements (i.e. the same cost). We keep the block size constant at 5 and vary the number of annotators between 3 and 60. For nested designs, we drop the document-level random effects from the ordinal regression, as document is no longer a grouping factor in nested designs.

Figure 7 shows that nested designs always have a power advantage over crossed designs, especially when few judgements are elicited. We also find that ART can be used to analyse data without loss of power when there are enough independent blocks. This might be attractive as ART is less computationally expensive than ordinal regression.

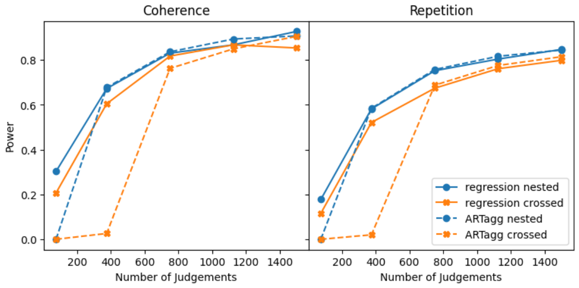

Figure 7: Power for $p < 0.05$ of nested and crossed designs for `ARTagg` and regression. X-axis shows the number of judgements elicited, Y-axis the power-level.

7 Related Work

Human evaluation has a long history in summarization research. This includes work on the correlation of automatic metrics with human judgements (Lin, 2004; Liu and Liu, 2008; Graham, 2015; Peyrard and Eckle-Kohler, 2017; Gao et al., 2019; Sun and Nenkova, 2019; Xenouleas et al., 2019; Zhao et al., 2019; Fabbri et al., 2020; Gao et al., 2020) and improving the efficiency of the annotation process (Nenkova and Passonneau, 2004; Hardy et al., 2019; Shapira et al., 2019). The impact of annotator inconsistency on system ranking has been studied both by Owczarzak et al. (2012) and Gillick and Liu (2010). To the best of our knowledge, we are the first to investigate the implications of annotator variance on the statistical analysis and the design in summarization system comparison studies.

For general NLG evaluation, van der Lee et al. (2019) establish best practices for evaluation studies. We extend on their advice by conducting experimental studies specifically for summary evaluation. In addition, we show the importance of study design and consideration of annotator-effects in analysis on real world data. The advice of Mathur et al. (2017) regarding annotation sequence effects should be taken into account in addition to our suggestions.

Method Comparison. Ranking has been shown to be effective in multiple NLP-tasks (Kiritchenko and Mohammad, 2017; Zopf, 2018), including NLG quality evaluation (Novikova et al., 2018). In this work we confirm this for coherence evaluation, although we find evidence that ranking is less efficient on repetition, where many documents do not exhibit any problems. We also add the dimension of annotator workload as a primary determinant of cost to the analysis of the comparison.

Multiple methods have been suggested to reduce study cost by sample selection (Sakaguchi et al., 2014; Novikova et al., 2018; Sakaguchi and Van Durme, 2018; Liang et al., 2020) or integration with automatic metrics (Chaganty et al., 2018). These efforts complement ours, as care still needs to be taken in analysis and study design.

Recently, rank-based magnitude estimation has been shown to be a promising method for eliciting judgements in NLG tasks and offers a combination of ranking and rating approaches (Novikova et al., 2018; Santhanam and Shaikh, 2019). However, it has not yet found widespread use in the summarization community. While magnitude estimation has been shown to reduce annotator variance, our advice regarding experimental design and grouping factors in statistical analysis applies to this method as well, as annotators can still systematically differ in which systems they prefer.

Statistical analysis. With regard to statistical analysis of experimental results, Dror et al. (2018) give advice for hypothesis testing in NLP. However, they do not touch on the problem of dependent samples. Rankel et al. (2011) analyse TAC data and show the importance of accounting for input documents in statistical analysis of summarizer performance and suggest the use of the Wilcoxon signed rank test for analysis. Sadeqi Azer et al. (2020) argue that p-values are often not well understood and advocate bayesian methods as an alternative. While the analysis in our paper is frequentist, the mixed effect model approach can also be integrated into a bayesian framework. Kulikov et al. (2019) model annotator bias in such a framework but do not account for differences in annotator preferences. In work conducted in parallel to ours, Card et al. (2020) show that many human experiments in NLP underreport their experimental parameters and are underpowered, including Likert-type judgements. Their simulation approach to power analysis is very similar to our experiments. In addition to their analysis, we show that ignoring grouping factors in statistical analysis of human annotations leads to inflated type I error rates. We also show that power can be increased by choosing nested over crossed designs with the same budget. The problem of underpowered studies has also been tackled outside of NLP by Brysbaert (2019).

For psycholinguistics, Barr et al. (2013) demonstrate how generalizability of results is negatively impacted by ignoring grouping factors in the analysis. Mixed effect models have found use in NLP before (Green et al., 2014; Cagan et al., 2017; Karimova et al., 2018; Kreutzer et al., 2020), but to the best of our knowledge they have not been used in summary evaluation.

8 Conclusion

We surveyed the current state of the art in manual summary quality evaluation and investigated methods, statistical analysis and design of these studies. We distill our findings into the following guidelines for manual summary quality evaluation:

Method. Both ranking and Likert-type annotations are valid choices for quality judgements. However, we present preliminary evidence that the optimal choice of method is dependent on task characteristics: If many summaries are similar for a given aspect, Likert may be the better option.

Analysis. Analysis of elicited data should take into account variance in annotator preferences to avoid inflated type I error rates. We suggest the use of mixed effect models for analysis that can explicitly take into account grouping factors in studies. Alternatively, traditional tests can be used with proper study design and aggregation.

Study Design. Study designers should control the number of annotators and how many summaries each individual annotator judges to ensure sufficient study power. Additionally, to ensure reliability of results, studies should report the design and the total number of annotators in addition to the number of documents and repeat judgements. Studies with repeat judgements on the same summary do not provide any advantage for system comparison and are less reliable and powerful than nested studies of the same size.

We hope that these findings will help researchers plan their own evaluation studies by allowing them to allocate their budget better. We also hope that our findings will encourage researchers to take more care in the statistical analysis of results. This prevents misleading conclusions due to ignoring the effect of differences in annotator behaviour.

Acknowledgements

We would like to thank Stefan Riezler for many fruitful discussions about the applications of mixed effect models.

We show screenshots of the instructions for both annotation methods and tasks in Figure 8 and interfaces in Figure 9.

B Survey

B.1 Categories

While most categories are self-explanatory, we elaborate on some of the decisions we made during the survey in this section.

Evaluation Questions. We allow a single study to include multiple evaluation questions, as long as all questions are answered by the same annotators and use the same method. We make no distinction between informativeness, coverage, focus and relevance and summarize them under *Content*. Similarly, we summarize fluency, grammaticality and readability under *Fluency*. *Other* includes:

- One study with a specialized set of evaluation questions evaluating the usefulness of a generated related work summary
- One study of *polarity* in a sentiment summarization context
- One study where annotators were asked to identify the aspect a summary covers in the context of review summarization
- Two studies evaluating formality and *meaning similarity* of reference and system summary
- One study evaluating diversity
- One study conducting a Turing test
- One study asking paper authors whether they would consider a sentence part of a summary of their own paper.
- One study evaluating structure and topic diversity

Evaluation Method. *Binary* includes any task with a yes/no style decision, while *pairwise* includes any method in which two systems are ranked against each other. *Other* includes

- The aspect identification task mentioned above
- One study in which participants selected a single best summary out of a set of summaries

Annotator Recruitment. *Other* includes any recruitment strategy that does not rely on crowdsourcing. This includes cases in which the recruitment was not specified, students, experts, the authors themselves and various kinds of volunteers.

Statistical Evaluation. *Other/unspecified* includes

- Four studies which reported statistical significance without reporting the test used
- Two studies using the approximate randomization test
- One study using the chi-square test
- One study using a Tukey test without prior ANOVA.

B.2 Survey Files

All papers we considered for the survey are listed in the supplementary material in the file `all_papers.yaml` by their id in the ACL anthology bib-file. The 58 SDS/MDS system papers that contain new human evaluation studies and are thus included in the survey are listed in the category `with_human_eval`.

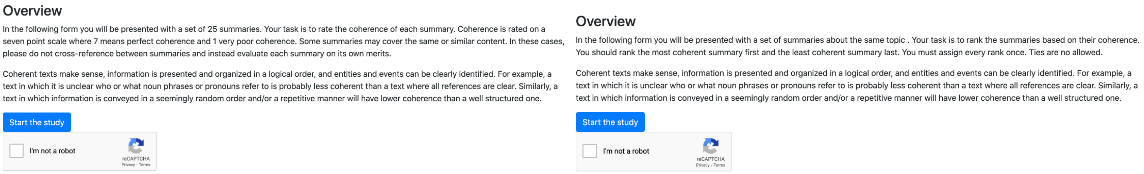
For the sake of completeness, we further list summarization papers we did not include in our survey. We separate them into the following categories:

no_human_eval 47 SDS/MDS system papers without human evaluation

sentsum 27 Sentence summarization and headline generation papers

non_system 34 summarization papers that do not introduce new systems, like surveys, opinion pieces and evaluation studies

other 10 Papers that conduct summarization with either non-textual input or non-textual output



Overview

In the following form you will be presented with a set of 25 summaries. Your task is to rate the coherence of each summary. Coherence is rated on a seven point scale where 7 means perfect coherence and 1 very poor coherence. Some summaries may cover the same or similar content. In these cases, please do not cross-reference between summaries and instead evaluate each summary on its own merits.

Coherent texts make sense, information is presented and organized in a logical order, and entities and events can be clearly identified. For example, a text in which it is unclear who or what noun phrases or pronouns refer to is probably less coherent than a text where all references are clear. Similarly, a text in which information is conveyed in a seemingly random order and/or a repetitive manner will have lower coherence than a well structured one.

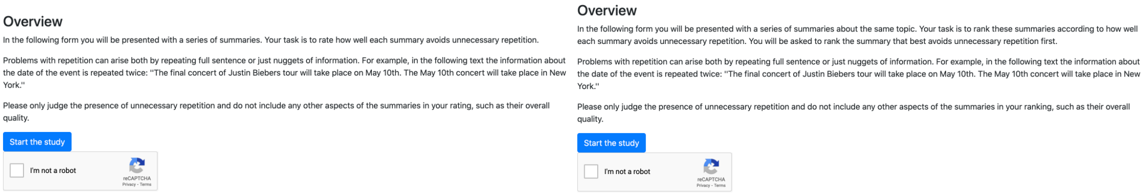
Overview

In the following form you will be presented with a set of summaries about the same topic . Your task is to rank the summaries based on their coherence. You should rank the most coherent summary first and the least coherent summary last. You must assign every rank once. Ties are no allowed.

Coherent texts make sense, information is presented and organized in a logical order, and entities and events can be clearly identified. For example, a text in which it is unclear who or what noun phrases or pronouns refer to is probably less coherent than a text where all references are clear. Similarly, a text in which information is conveyed in a seemingly random order and/or a repetitive manner will have lower coherence than a well structured one.

(a) `Likert` - Coherence

(b) `Rank` - Coherence



Overview

In the following form you will be presented with a series of summaries. Your task is to rate how well each summary avoids unnecessary repetition.

Problems with repetition can arise both by repeating full sentence or just nuggets of information. For example, in the following text the information about the date of the event is repeated twice: "The final concert of Justin Biebers tour will take place on May 10th. The May 10th concert will take place in New York."

Please only judge the presence of unnecessary repetition and do not include any other aspects of the summaries in your rating, such as their overall quality.

Overview

In the following form you will be presented with a series of summaries about the same topic. Your task is to rank these summaries according to how well each summary avoids unnecessary repetition. You will be asked to rank the summary that best avoids unnecessary repetition first.

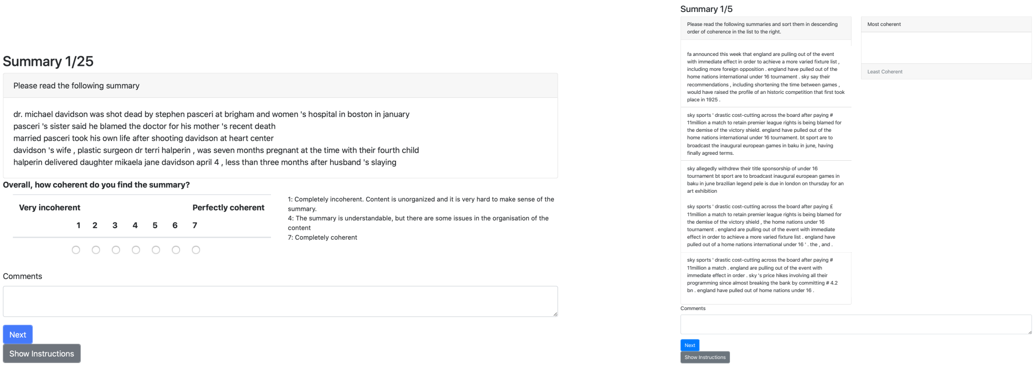
Problems with repetition can arise both by repeating full sentence or just nuggets of information. For example, in the following text the information about the date of the event is repeated twice: "The final concert of Justin Biebers tour will take place on May 10th. The May 10th concert will take place in New York."

Please only judge the presence of unnecessary repetition and do not include any other aspects of the summaries in your ranking, such as their overall quality.

(c) `Likert` - Repetition

(d) `Rank` - Repetition

Figure 8: Screenshots of the Annotator Instructions.



Summary 1/25

Please read the following summary

dr. michael davidson was shot dead by stephen pasceri at brigham and women 's hospital in boston in january
pasceri 's sister said he blamed the doctor for his mother 's recent death
married pasceri took his own life after shooting davidson at heart center
davidson 's wife , plastic surgeon dr terri halperin , was seven months pregnant at the time with their fourth child
halperin delivered daughter mikaela jane davidson april 4 , less than three months after husband 's slaying

Overall, how coherent do you find the summary?

Very incoherent **Perfectly coherent**
1 2 3 4 5 6 7
○ ○ ○ ○ ○ ○ ○

1: Completely incoherent. Content is unorganized and it is very hard to make sense of the summary.
4: The summary is understandable, but there are some issues in the organisation of the content
7: Completely coherent

Comments

Summary 1/5

Please read the following summaries and sort them in descending order of coherence in the list to the right.

fa announced this week that england are pulling out of the event with immediate effect in order to achieve a more varied fixture list , including more foreign opposition . england have pulled out of the home nations international under 16 tournament . sky say their recommendations , including shortening the time between games , would have raised the profile of an historic competition that first took place in 1925 .

sky sports ' drastic cost-cutting across the board after paying # 11million a match to retain premier league rights is being blamed for the demise of the victory shield. england have pulled out of the home nations international under 16 tournament. bt sport are to broadcast the inaugural european games in baku in june, having finally agreed terms.

Abstract

Linguistic accommodation is the process in which speakers adjust their accent, diction, vocabulary, and other aspects of language according to the communication style of one another. Previous research has shown how linguistic accommodation correlates with gaps in the power and status of the speakers and the way it promotes approval and discussion efficiency. In this work, we provide a novel perspective on the phenomena, exploring its correlation with the open-mindedness of a speaker, rather than to her social status. We process thousands of unstructured argumentative discussions that took place in Reddit's Change My View (CMV) subreddit, demonstrating that open-mindedness relates to the assumed role of a speaker in different contexts. On the discussion level, we surprisingly find that discussions that reach agreement present lower levels of accommodation.

1 Introduction

1.1 Linguistic Accommodation

Accommodation in personal communication refers to the unconscious process in which a speaker changes (accommodates) her communicative behavior with respect to the communication partner. The change can be manifested across many dimensions, e.g., posture (Condon and Ogston, 1967), nodding (Hale and Burgoon, 1984), pauses (Jaffe and Feldstein, 1970), and linguistic style (Niederhoffer and Pennebaker, 2002). From the perspective of sociolinguistic and social-psychology, accommodation is argued to increase cognitive efficiency (Street and Giles, 1982), provide approval and validation (Giles, 2008), and project the speaker's positive image (Infante et al., 1997).

In this work we focus on the accommodation of the linguistic style – the usage of stylistic markers and function words, such as auxiliary verbs and prepositions. Tausczik and Pennebaker (2010) estimated that style and function words make up for 55% of the words we use. These markers shape the conversation regardless of its topical content. Analysis of function-word usage is common in many NLP tasks, e.g., gender detection (Koppel et al., 2002; Mukherjee and Liu, 2010; Bortolato, 2016), forensic linguistics (Juola, 2008; Boukhaled and Ganascia, 2015; Kestemont, 2014) and personality type detection (Argamon et al., 2005, 2009; Litvinova et al., 2016), among others.

Accommodation is not necessarily a symmetric process. One party in a communication can accommodate while the other party can either accommodate as well (converge), sustain her behavior, or actively diverge. Linguistic style accommodation was first studied quantitatively by Niederhoffer and Pennebaker (2002), analyzing the linguistic style accommodation in a small scale dataset. Large scale datasets and advanced statistical and algorithmic methods were explored by Danescu-Niculescu-Mizil et al. (2011); Guo et al. (2015); Muir et al. (2017), among others. Differences in the social status of the speakers were found to dominate accommodation (Danescu-Niculescu-Mizil et al., 2012).

In this paper we explore linguistic accommodation from a novel perspective. We argue that the speaker's *open-mindedness* drives her linguistic coordination. While the speaker's open-mindedness can be "socially forced" by power relations – it is also inherent to one's character and her actively assumed social role.

1.2 Open Mindedness

"To be open-minded is... to be critically receptive to alternative possibilities, to be willing to think again despite having formulated a view, and to be concerned to defuse any factors that constrain one's thinking in predetermined ways" (Hare, 2003).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1876–1886
April 19 - 23, 2021.

Open-mindedness is closely related to the concepts of dialogism (Bakhtin, 1981) and the development of dialogic agency (Parker, 2006), vital in a liberal and multi-cultural society. Open-mindedness is found to help in conflict resolution (Tjosvold and Morishima, 1999; Tjosvold and Poon, 1998), boost creativity (Mitchell and Nicholas, 2006; Keskin, 2006), increase rationality and neutrality, and play a significant role in the theory of education (Hare, 1993).

From a practical perspective, the significant role open-mindedness plays in a range of situations, from the negotiation table to political debates and the classroom, requires an efficient way to detect open-mindedness or the lack-of, allowing intervention by a moderator or a teacher (Zakharov et al., 2020). We show the level accommodation is simple to compute and can be used as a proxy for open-mindedness.

1.3 Reddit's CMV

The Change My View (CMV) is a subreddit (forum) on the forum-based Reddit platform. The forum is self described as *"A place to post an opinion you accept may be flawed, in an effort to understand other perspectives on the issue. Enter with a mindset for conversation, not debate."*[1]. Each discussion thread in CMV evolves around the topic presented in the submission by the Original Poster (OP). A discussion, therefore, takes the structure of a tree with the *submission* at the root and the various comments (replies) stemming from it. One unique feature of the CMV subreddit is the *Delta* Δ – a way to acknowledge a convincing argument. A Delta can be awarded by any user, OP or not, to a comment made by any other user, and should be explicitly justified. A user can award a Delta only to users holding an opposing view to her own. A delta can signify "good point" and does not have to reflect a complete reversal of opinion. CMV is heavily moderated to maintain a high level of discussion and to ensure that Deltas are awarded with proper reasoning. Table 1 provides a partial and truncated example of a submission from CMV.

Open-mindedness in CMV We use CMV discussions to study the relation between linguistic accommodation and open-mindedness. While open-mindedness is an informal prerequisite of all CMV participants, we use two explicit indications of open-mindedness: (i) Being an OP – Stating an opinion and literally declaring the willingness to change a presupposition, and (ii) The use of Δ, explicitly acknowledging a convincing argument made by an opposing party.

It could be argued that the OPs are not necessarily open-minded and only respond to people that agree with them. Fortunately, CMV rules strive to create a constructive conversation and CMV is a heavily moderated subreddit. The rule states an OP is obliged to reply to opposing views and show open-mindedness.

Dataset Our corpus consists of 9,374 English discussions initiated by 4873 OPs between January 2018 and June 2020. It contains 1,301,545 posts (utterances) by 86,941 unique users. 8,659 Deltas were awarded, 877 of them by users that are not the OP. The mean number of speakers in each submission is 42, max and min are 898 and 3 respectively, and the median is 26. The mean number of comments in each submission is 138, max and min being 2559 and 26 respectively, and the median is 88. The mean numbers of word in CMV comment is 83 and the median is 50.

1.4 Research Questions

Based on the indications described above, we explore the relations between open-mindedness and accommodation through the following research questions:

RQ1: Do OPs present higher levels of linguistic accommodation? By definition, OPs are open to change their view, hence open-minded. We expect to observe higher levels of linguistic coordination presented by the OP of a discussion than by other participants.

RQ2: Do Delta givers present higher levels of linguistic accommodation? Delta givers explicitly express open-mindedness by awarding a Δ upon recognizing convincing argumentation. We expect to observe higher levels of linguistic coordination presented by the Delta givers than by other participants. In the scope of this research question, we will focus on delta givers that are not the OPs of the discussion in which they awarded the Delta. By doing so we examine delta givers that unlike OPs, have no status – they are not the initiators of the discussion, are not entitled to give the 'final verdict', and can choose to opt-in or out. Since previous work explains accommodation in terms of

---

Speaker	Text	Gave delta
A	**CMV: Money needs to get out of politics** I am genuinely curious about the counter arguments as I haven't heard any and I want to know if I'm wrong. This began with this case: Buckley v. Valeo, 424 U.S. 1 (1976), was a landmark decision of the US Supreme Court on campaign finance...	
B	> ...There's a lot of attention given to the massive amount of money that come from wealthy individuals or special interest groups but ordinary people can make campaign contributions to the candidates they support, too. Bernie Sanders only accepted donations from small-dollar donors and outspent Joe Biden in primary at a whopping $200 million...	
A	>> You gave a good counter argument. I meant more big money, but I see it's hard to separate the two. Δ	Yes
C	> There have actually been a lot of studies suggesting that political donations don't swing votes...	

Table 1: Partial and truncated example of a submission from CMV

power differences, delta givers serve as a control group, lacking any formal power or privilege.

RQ3: Are Deltas correlated with accommodation on the *discussion level*, rather than on the user level? We hypothesize that Delta awards may be correlated with the general accommodation observed in a discussion, rather with the open-mindedness of a specific user – the Delta giver. In order to test this hypothesis we compare the accommodation of all users in branches (of the discussion tree) in which Deltas were awarded, to the accommodation in branches in which no Delta was awarded.

The formal definitions of user, group and aggregate coordination are presented in Section 3.1, and the hypotheses promoted by research questions above are formally defined in Section 3.2 and tested in Section 4. Further analysis and refined hypotheses are proposed and tested in Section 4.2.

2 Related Work

Linguistic coordination, sometimes referred to as 'accommodation' or 'matching', is mainly studied from two perspectives – social (-psychology) and computational. Linguistic style matching in social interactions and its correlation to various psychometric properties of language was first studied by Niederhoffer and Pennebaker (2002). This approach was later generalized to discussions in small groups by (Gonzales et al., 2010). These metrics were applied to social media data by Danescu-Niculescu-Mizil et al. (2011).

Mukherjee and Liu (2012) analyzed a large corpus of online debate, reporting that debaters using agreement expressions (e.g., 'I agree with that point', 'rightly said') as a debate strategy show higher linguistic accommodation than debaters that explicitly express disagreement (e.g., 'I don't buy it', 'I disagree', 'nonsense'). However, the use of agreement/disagreement expressions in a formal debate setting is a strategic choice and does not imply actual agreement or open-mindedness. Moreover, the stated objective in a formal debate is winning the debate, rather than self-reflection through convincing argumentation.

Power differences were found to drive linguistic coordination toward the speaker with the higher status (Danescu-Niculescu-Mizil et al., 2012), and a particular configurations of personal traits (e.g., agreeableness, Machiavellianism, low self-consciousness) combined with low-power position were shown to increase the likelihood of coordination (Muir et al., 2016, 2017). Guo et al. (2015) proposed Bayesian inference approach to capture influence manifested through linguistic accommodation.

This work is the first to explore coordination through the lens of open-mindedness, rather than through self-awareness, power, influence or strategic manipulation.

3 Measuring Linguistics Accommodation

3.1 Linguistic Style Coordination

We adopt the common coordination metric used in previous studies by Danescu-Niculescu-Mizil et al. (2011, 2012); Mukherjee and Liu (2012) and others. The metric quantifies the accommodation of an individual along a linguistic category by looking at the shifting usage of terms of that category, compared to other speakers. The linguistic categories include Articles, Adverbs, Quantifiers, Conjunctions, Indefinite Pronouns, Personal Pronouns, Prepositions and Auxiliary Verbs as well as other psycho-linguistic categories from the widely used LIWC dictionary (J. W. Pennebaker, 2015).

Speaker's accommodation Given users a and b, and a linguistic marker m, we want to measure how the usage of m by a triggers (or suppresses) the occurrence of m in the direct responses of b.

Given a set $S_{a,b} : (a : u_1, b : u_2)$ of exchanges where u_1 denotes an utterance (comment) by a and u_2 is a direct reply by b we define coordination of b towards a on marker m as:

$$C^m(b,a) = P(\xi^m_{u_2\to u_1} | \xi^m_{u_1}) - P(\xi^m_{u_2\to u_1}) \quad (1)$$

Where $P(\xi^m_{u_1})$ is the probability of speaker a using marker m; $P(\xi^m_{u_2\to u_1})$ is the probability of speaker b using m in replying to u_1 (made by a), and $P(\xi^m_{u_2\to u_1} | \xi^m_{u_1})$ is the probability of speaker b using m in replying to an utterance u_1 in which a also used m. Equation 1 bears three important properties:

1. It is asymmetric, that is $C^m(b,a) \neq C^m(a,b)$, allowing us to realize which user is accommodating toward the other.
2. $C^m(b,a) = 0$ if any of the speakers uses m in every utterance, since no turn-taking influence could be modeled in this scenario.
3. $C^m(b,a) \xrightarrow[|S^{\neg m}_{a,b}|\to\infty]{} 1$ if b uses m in a response to a *if and only if* a used m, where $S^{\neg m}_{a,b}$ is the set of exchanges between a and b the do not contain m.

Group Coordination The definition of coordination is extended to address the coordination of a group of speakers. This enables us to measure (i) The coordination of a speaker b toward a group of speakers A, and (ii) The coordination of a group B toward a group of speakers A.

We accomplish (i) by simply looking at the set of consecutive utterances: $S_{A,b} : (A : u_1, b : u_2)$ that includes the responses of speaker b to every speaker $a \in A$. The coordination of b toward the group A is therefore defined as:

$$C^m(b,A) = P(\xi^m_{u_2\to u_1} | \xi^m_{u_1}) - P(\xi^m_{u_2\to u_1}) \quad (2)$$

To accomplish (ii), the coordination of speakers in group B to targets in group A, we calculate the average coordination of speakers in B toward targets speakers A:

$$C^m(B,A) = \langle C^m(b,A) \rangle_{b\in B} \quad (3)$$

Aggregated coordination The coordination measures defined above apply to a specific marker m. Previous studies report that accommodation is not necessarily correlated across markers as user b can accommodate toward a on m and diverge on m' (Street and Giles, 1982; Bilous and Krauss, 1988). Therefore, having an aggregated coordination metric may provide a fuller picture regarding the overall accommodation across markers M and groups. Three types of *aggregated* coordination measure are considered:

1. *Aggregate 1*: We first compute $C(b,A)$ as the macro average of $C^m(b,A)$ for all $m \in M$, then use it to compute $C(B,A)$ as described in Equation 3. However, we wish to note that $C^m(b,A)$ can only be computed if there is a sufficient number of exchanges between b and A with the marker m (we enforce $\delta > 3$), and therefore, *Aggregate 1* is calculated *only* using those $b \in B$ where $C^m(b,A)$ is defined for every m. This aggregation provides the most accurate generalized coordination, but relies only on a subset of the speakers. In order to compensate for cases in which $C^m(b,A)$ is undefined we propose the two aggregated measures below.

2. *Aggregate 2*: Assuming group homogeneity, we approximate $C^m(b,A)$ by averaging $C^m(B,A)$ over all $b \in B$ for whom $C^m(b,A)$ is defined.

3. *Aggregate 3*: Assuming speakers tend to present the same behaviour across markers, the undefined $C^m(b,A)$ can be approximated by averaging $C^{m'}(b,A)$ over all $m' \in M$ for which $C^{m'}(b,A)$ could be computed directly. While this assumption does not always hold, this definition of aggregated coordination has proved useful in Danescu-Niculescu-Mizil et al. (2012).

We used the ConvoKit toolkit for conversation analysis (Chang et al., 2020) in preprocessing and measuring coordination.

Notation	Definition	Used in
U	The set of all users (speakers) in the data	all
G^{OPs}	The set of all OPs	$H_{1.1}$, $H_{1.2}$, $H_{4.3}$
$G^{\overline{OPs}}$	The set of all users in a submission that are not the OP (AKA regulars)	$H_{1.1}$, $H_{4.3}$
$G^{\overline{r}}$	Regulars users in a submission that are OPs in other submissions	$H_{1.2}$
$G^{\Delta_{reg}}$	The set of Delta givers $\notin G^{OPs}$. That is: Delta givers that are not the OP of the submission	H_2, $H_{4.1}$
$G^{\Delta_{OP}}$	The set of Delta givers $\in G^{OPs}$. That is: OPs that gave Delta in their own submission	$H_{4.2}$
$G^{\overline{\Delta}}$	The set of users that did not award a Δ in the submission	H_2, H_4, $H_{4.1}$
$C^{\Delta}(\circ,\circ)$	Coordination is measured only for discussion branches in which a Δ was awarded	H_3
$C^{\overline{\Delta}}(\circ,\circ)$	Coordination is measured only for discussion branches in which a Δ was *not* awarded	H_3
G^{Δ}	The set of Delta givers in a submission regardless of role	H_4
$G^{\overline{OP_{\Delta}}}$	The set of OPs that did not give delta in their own submission	$H_{4.2}$

Table 2: Notations and definitions for groups of speakers assuming different roles in the CMV data.

3.2 Formalizing the Research Questions

Notation Before using the definitions above to formalize the research questions presented in Section 1.4, we introduce a few more notations, presented in Table 2 for convenience. An important aspect to note is that for each Reddit user a, we produce dummy users for each submission she takes part in. Formally: a user a participating in n discussions will have n dummy users $\{a_i\}_{i=1\ldots n}$, one for each discussion. Different dummy representations of a user may be part of different groups, for example, in a discussion she initiated: $a_i \in G^{OPs}$ and in another discussion she participates (but didn't initiated) $a_j \in G^{\overline{OPs}}$. These dummy representations allows us to explore the coordination of a user in different contexts.

We provide the following example of a conversation to familiarize with the notations: Given a submission opened by Bobby, comments by Jess, Arnold and a delta given by both Bobby and Ava. We can attribute our speakers to the groups accordingly: Bobby is in the group of OPs, the group of delta givers and the group of OPs that gave delta - $Bobby_1 \in G^{OPs}, G^{\Delta}, G^{\Delta_{OP}}$. Jess and Arnold are in the group of users that did not give delta - $\{Jess_1, Arnold_1\} \subseteq G^{\overline{\Delta}}$. Ava is in the group of delta givers and the group of delta givers that are not OPs - $Ava_1 \in G^{\Delta}, G^{\Delta_{reg}}$.

RQ1: Do OPs present higher levels of linguistic accommodation? In order to answer positively we need to reject the null hypothesis:

$$C(G^{OPs}, U) = C(G^{\overline{OPs}}, U) \qquad (H_{1.1})$$

and verify that $C(G^{OPs}, U) > C(G^{\overline{OPs}}, U)$, showing that coordination of OPs (in discussions they initiated) towards all other users is higher than the coordination of regular users toward all other users.

We further explore the behaviour of OPs putting forward the following null hypothesis:

$$C(G^{OPs}, U) = C(G^{\overline{r}}, U) \qquad (H_{1.2})$$

Namely, we test whether OPs present different levels of coordination in discussions they initiated and in discussions they participate without assuming the role of the OP.

RQ2: Do Delta givers present higher levels of linguistic accommodation? A positive answer is validated by rejecting the following null hypothesis:

$$C(G^{\Delta_{reg}}, U) = C(G^{\overline{\Delta}}, U) \qquad (H_2)$$

and verifying that $C(G^{\Delta_{reg}}, U) > C(G^{\overline{\Delta}}, U)$.

It is important to note that $G^{\Delta_{reg}}$ only includes Δ-givers that are not OPs (see definitions in Table 2). This distinction is important due to the fact that a user in an OP role declares her flexibility by inviting other users to change her mind, while other Δ-givers do not assume this flexibility.

RQ3: Are Deltas correlated with accommodation on the discussion level, rather than on the user level? That is we check whether Deltas are awarded more generously in discussions with higher levels of accommodation, not necessarily by or toward the Δ-giver. We put forward the following null hypothesis:

$$C^{\Delta}(U,U) = C^{\overline{\Delta}}(U,U) \qquad (H_3)$$

Validating H_3 shows that the general accommodation level is not correlated with Δ awards.

4 Results and Analysis

All of the hypothesis presented above are tested using the two-sample t-test. We report significance values for the following p-values: 0.05, 0.01 and 0.001. Conversations are extracted from the discussion data described in Section 1.3, containing 1.3M utterances by 87K unique users participating in 9.3K discussions.

4.1 Open-mindedness

OPs present higher coordination (RQ1) Figure 1 presents the coordination values for a number of marker types and for the three aggregate measures. We reject the null hypothesis $H_{1.1}$ with $p < 0.001$ for all markers and measures and confirm that OPs present significantly higher levels of coordination, compared to regular users (Figure 1a). Similarly, we reject the null hypothesis $H_{1.2}$, though significance values vary between markers (Figure 1b).

The results above show that the open-mindedness of an OP is not an inherent personal capacity but depends on the role assumed in a specific context. We further validated this by testing the coordination of OPs in discussions they did not initiate ($G^{\bar{r}}$) to the coordination level of users that never initiated a discussion as OPs. Indeed, we find no significant difference between their coordination levels.

Delta givers present higher coordination (RQ2) We reject the null hypothesis (H_2) for most markers and all aggregate types (Figure 2). This result confirms that non-OP Delta givers present higher levels of coordination compared to users that did not give Delta.

Coordination varies on branch level (RQ3) We reject the null hypothesis (H_3) for most markers and all aggregate measures, asserting that coordination levels in branches in which a Δ was awarded are significantly different from those in branches without any Δ. Surprisingly, we find that the levels of accommodation are higher in branches where no Delta was awarded (see figure 3). In the next subsection we further explore this surprising result.

4.2 Accommodation Effect on Delta Giving

In the previous section we have established that on the user-level, Δ-givers present higher coordination than other users, however, on the discussion level, Δ is more likely to be awarded in non-coordinated branches. In order to understand these dynamics, we test the coordination *toward* Δ-givers (G^{Δ}). We test the following hypothesis:

$$C(U, G^{\Delta}) = C(U, G^{\overline{\Delta}}) \qquad (H_4)$$

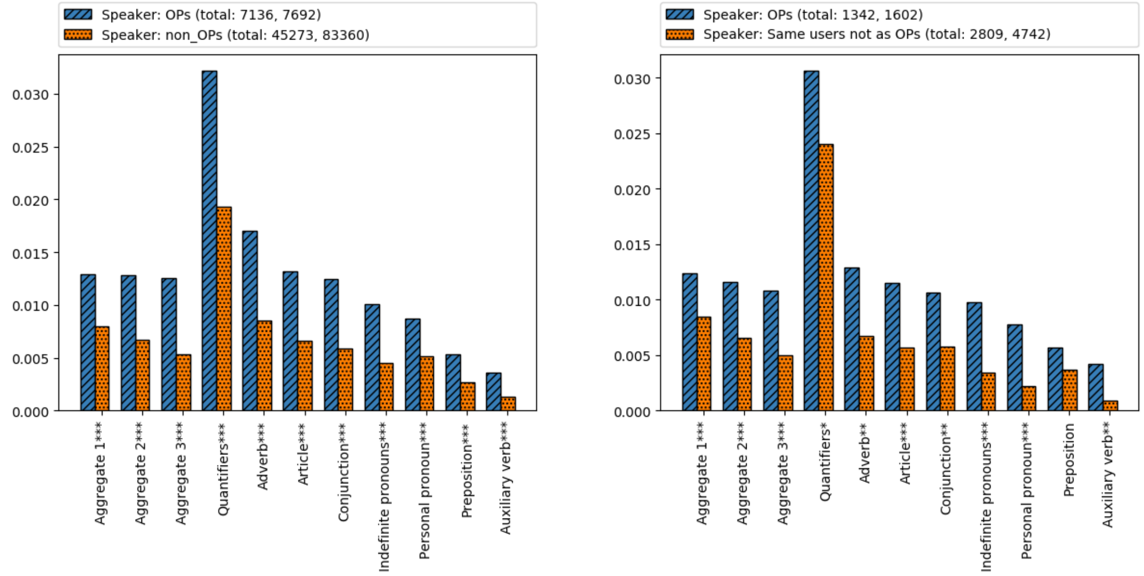
It is important to note that C is calculated only on utterances made *before* the Δ was awarded. Using the two-sample t-test we get mixed results (Figure 4). Significance is observed for some markers (quantifiers, adverbs, prepositions and personal pronouns) and for Aggregate 1 and 2, but not for Aggregate 3 and the other markers that proved to be highly distinctive in RQ1-3.

Following the inconclusive result for H_4, we divide G^{Δ}, the group of Δ-givers, to two distinct sets – OPs ($G^{\Delta_{OP}}$) and Δ-givers that are not OPs ($G^{\Delta_{reg}}$). We can now test whether Δ-giving OPs respond differently than other Δ-givers when *accommodated to*. The idea behind this split is to find out if one group is more susceptible to accommodation than the other. We consider two settings: (i) Accommodation toward non-OP Δ-givers ($G^{\Delta_{reg}}$) vs. accommodation toward non-Δ-givers ($G^{\overline{\Delta}}$), for which we test $H_{4.1}$, and (ii) Accommodation toward Δ-giving OPs ($G^{\Delta_{OP}}$) vs. the accommodation toward OPs that did not award a Δ ($G^{\overline{OP_{\Delta}}}$), for which we test $H_{4.2}$. In both settings we calculate the coordination on utterances made *before* the Δ was awarded, similar to (H_4).

$$C(U, G^{\Delta_{reg}}) = C(U, G^{\overline{\Delta}}) \qquad (H_{4.1})$$

$$C(U, G^{\Delta_{OP}}) = C(U, G^{\overline{OP_{\Delta}}}) \qquad (H_{4.2})$$

While we cannot reject $H_{4.1}$ (Figure 5a), we do reject $H_{4.2}$ (Figure 5b), as significance ($p < 0.001$) is observed for all markers and aggregate measures but for adverbs. That is, while regular Δ-givers do not experience any special accommodation, we do observe a dramatic difference in accommodation patterns toward Δ-giving OPs vs. OPs that did not award a Δ – OPs are inclined to award a Δ in discussion threads that are accommodating toward them, and reserve themselves from awarding a Δ in case the use of style markers diverges over time, rather than coordinated toward them.



(a) OP vs non-OP coordination to others. Testing ($H_{1.1}$)

(b) OP vs OP as regular participants coordination to others. Testing ($H_{1.2}$)

Figure 1: Parentheses in figure legends denote (number of speakers used in type 1 aggregation, number of speakers used in aggregations of type 2 and 3). Asterisks denote significance using independent t-test: */**/*** for $p < 0.05/0.01/0.001$, respectively.

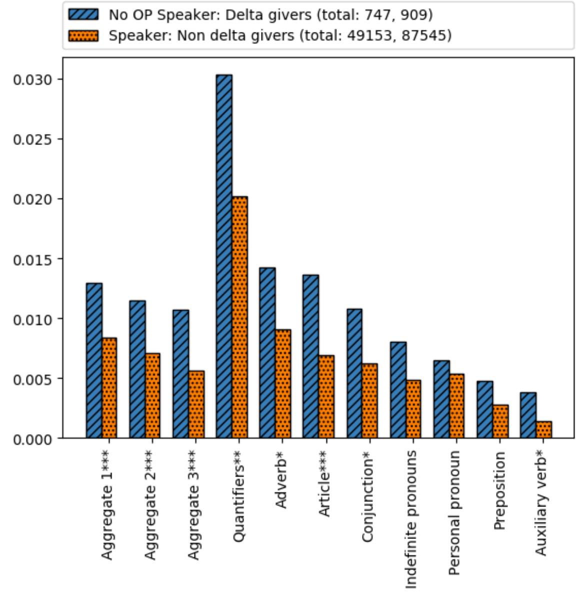


Figure 2: Non-OP Delta givers vs Users that did not give Delta. Test (H_2)

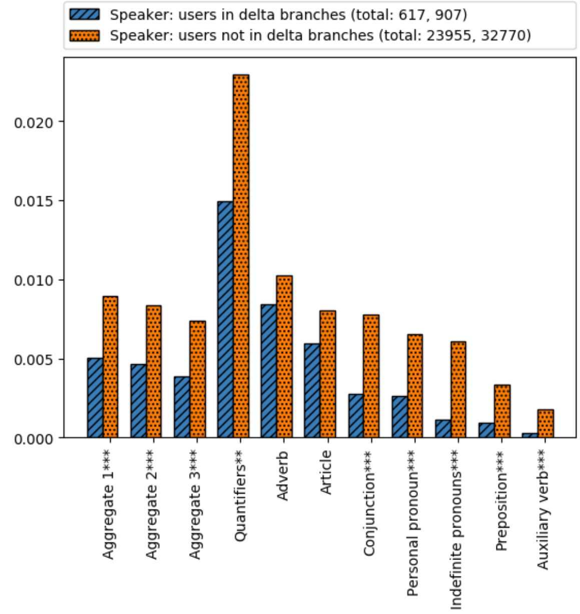

Figure 3: Delta branches vs Non-Delta branches. Test (H_3)

Finally, we complement this analysis by looking at accommodation toward OPs in their own submissions (G^{OPs}) and non-OPs ($G^{\overline{OPs}}$). The null hypothesis, asserting that OPs do not experience higher levels of accommodation toward them is formalized as:

$$C(U, G^{OPs}) = C(U, G^{\overline{OPs}}) \qquad (H_{4.3})$$

This hypothesis is rejected with significance of $p < 0.001$ for all markers. However, we see that users tend to diverge from the OPs, rather than accommodate toward them (Figure 6). This result

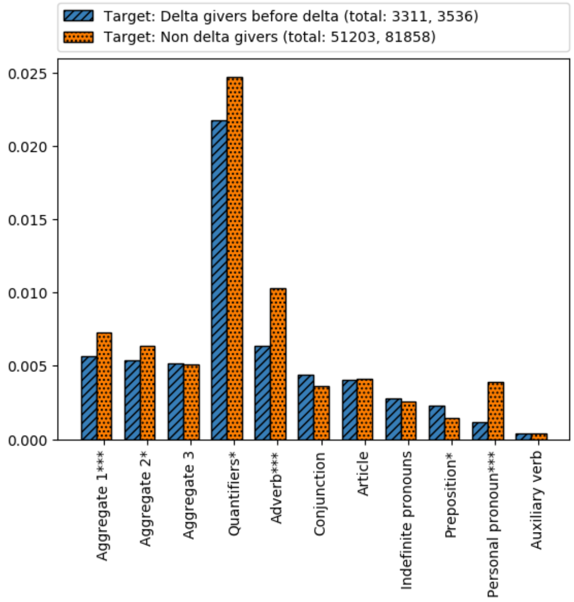

Figure 4: Accommodation towards delta givers vs Non-Delta givers. Test (H_4)

coupled with the results of H_4, $H_{4.1}$ and $H_{4.2}$ highlights the importance of accommodation to achieve persuasion, as we briefly discuss on below.

4.3 Discussion

Open-mindedness or power and status Previous work promoted the social framework of power-relations as the force behind linguistic style accommodation. Our results suggest that accommodation is related to the willingness of an individual to examine her or his beliefs, consider alternative viewpoints, appreciate convincing argumentation, and ultimately "convert". This correlation between open-mindedness and accommodation is observed for OPs and Δ-givers alike – both present higher accommodation levels *toward* their conversation partners.

Dynamic Open-mindedness Analysing the accommodation of OPs toward others, we observed that they present significant accommodation in the discussions they initiated, but present accommodation levels similar to other users in the discussions they only take part of as regular users. These results suggest that open-mindedness can be context-dependent, rather than an inherent personal trait. This view could also accommodate (pun intended) previous works promoting the power-structure hypothesis, as the power difference implicitly imposes open-mindedness – the expected state-of-mind of a subordinate, given our social norms.

Accommodation on the discussion level Surprisingly we found that discussion convergence (reflected by a Δ awarded by the OP) does not positively correlate with accommodation. In fact, Δ-givers that are not OPs are more likely to award the Δ in discussions that are characterized by style *divergence*, rather than coordination. We hypothesize that Deltas serve a subtle, secondary, social function, beyond the acknowledgment of a convincing argument. Users may be inclined to award a Δ in a subconscious effort to ease tensions that are manifested by the divergence of style. This is in line with previous work by Mukherjee and Liu (2012), showing that strategic expressions of an agreement by debaters are correlated with high accommodation. Similarly, we observe the "strategic" impact of style coordination in promoting agreement – as OPs are more likely to award a Δ if they are accommodated to.

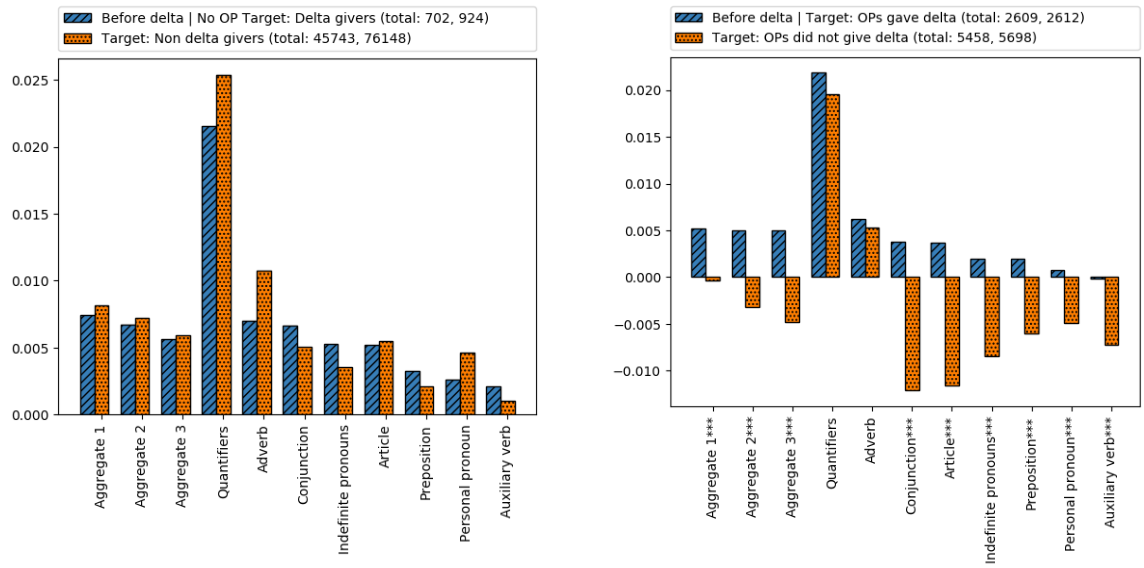
5 Conclusions and Future Work

5.1 Conclusions

We have proposed a novel hypothesis, asserting that linguistic style accommodation correlates with *open-mindedness*. We have provided evidence that supports this hypothesis through a series of experiments. We further demonstrated that open-mindedness is context-dependent, and argued that previous frameworks through which accommodation is studied could be viewed as a special case under the umbrella framework of open-mindedness we have proposed.

In future work we aim to further explore the different accommodation levels between some of the markers, and the way these are correlated with the conversational discourse structure, as proposed by (Zakharov et al., 2020).

Additionally, another area we believe is worth exploring and that is the effect of 'performance' as studied by Goffman (1967). OPs, being in a sort of formal role maybe "acting" and their accommodation might be altered for it. In this work we used the delta users as a control group that is not affected by this effect. Still, it is interesting to research how accommodation is affected when "acting" compared to genuine behavior. Further exploration of the shifting performative roles of the users, their dynamic roles, their assumed persona should be addressed in future work through a controlled experiment.



(a) Accommodation towards non-OPs that gave delta vs users that did not give Delta. Test ($H_{4.1}$)

(b) Accommodation towards OPs that gave delta vs OPs that did not give Delta. Test ($H_{4.2}$)

Error Analysis and the Role of Morphology

Abstract

We evaluate two common conjectures in error analysis of NLP models: (i) Morphology is predictive of errors; and (ii) the importance of morphology increases with the morphological complexity of a language. We show across four different tasks and up to 57 languages that of these conjectures, somewhat surprisingly, only (i) is true. Using morphological features *does* improve error prediction across tasks; however, this effect is *less* pronounced with morphologically complex languages. We speculate this is because morphology is more discriminative in morphologically simple languages. Across all four tasks, case and gender are the morphological features most predictive of error.

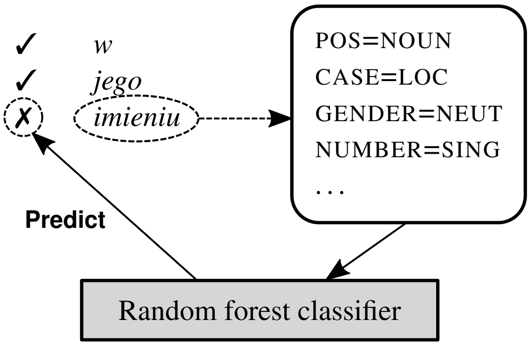

Figure 1: Overview of our methodology: We map each token to a set of morphological features and, based on this representation, predict whether some NLP system (e.g., a dependency parser) was correct (✓) or made an error (✗) on that token.

1 Introduction

In error analysis, we often blame morphology (Nivre, 2007; Bender, 2009), i.e., the productive inflection and derivation of new word forms. Morphology has been argued to be a major source of error in syntactic parsing (Tsarfaty et al., 2020), semantic parsing (Şahin and Steedman, 2018), machine translation (Irvine et al., 2013; Burlot and Yvon, 2017) and a range of other tasks, in particular in morphologically complex languages (Bender, 2009; Søgaard et al., 2018; Tsarfaty et al., 2020). This paper presents a large-scale study showing that morphology *is*, as commonly conjectured, an important source of error across tasks, but somewhat surprisingly, that morphology is *less* predictive of errors in morphologically complex languages.

English is a morphologically *simple* language, showing very limited inflection and expressing most concepts through syntactic structure instead; it is also the most-represented language at major natural language processing (NLP) venues and that with the largest amount of language resources available (Bender, 2011; Joshi et al., 2020). This makes it easy to ignore morphology when designing model architectures. As a consequence, we frequently observe that performance of NLP systems on morphologically more complex languages lags behind that for English (e.g. Czarnowska et al., 2019; Tsarfaty et al., 2020).

Complex morphology leads to the occurrence of rare inflected word forms. Polish nouns, for example, can inflect for number and seven different cases; this makes it less likely that all of these inflected word forms appear in the training data for our NLP models. Consequently, a model that correctly handles *imię* 'name' (NOM.SG) might not have seen the less frequent form *imionami* (INST.PL), potentially resulting in errors. If the model has generally seen fewer words in instrumental case, this can lead to systematic errors on this class of inflections.

Nowadays, many NLP systems use statistically learned subword units such as byte-pair encodings (Sennrich et al., 2016) or use characters as input representations, which could allow a system to generalize to individual affixes. However, in practice, these approaches are often found to be in-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1887–1900
April 19 - 23, 2021.

sufficient at capturing morphological structure (Vania and Lopez, 2017; Bostrom and Durrett, 2020; Klein and Tsarfaty, 2020).

Contributions In this study, we revisit two common conjectures about the role of morphology that are made in error analysis of NLP systems. Specifically, we ask whether (i) whether morphology is generally predictive of errors across tasks and languages; and (ii) whether the extent to which morphology is predictive depends on the morphological complexity of the language in question. These conjectures are common throughout the literature (Nivre, 2007; Bender, 2009; Manning, 2011).

Looking at data from four shared tasks on semantic role labeling (Hajič et al., 2009), dependency parsing (Zeman et al., 2018), verbal multi-word expression identification (Ramisch et al., 2018), and quality estimation (Fonseca et al., 2019), we map each token in the input data to *a set of morphological features*. Using only this feature set, and *without* using any orthographic or distributional representation of the input, we train random forest classifiers to predict whether a system has made an error on an input token. Figure 1 illustrates this approach.

Using this methodology, we find that, somewhat surprisingly, our results only support the first conjecture. In other words, (i) while morphology *is* helpful in predicting such errors, (ii) the degree to which morphology helps does not increase with the morphological complexity of the language. Moreover, we find and discuss task-specific differences between which morphological features are predictive of error. In general, part of speech, case and gender are most predictive of error.

The code for obtaining the datasets and running the experiments is made publicly available.[1]

2 Background

Morphology is frequently identified as a source of error during qualitative evaluations of NLP systems. Honnibal et al. (2010) observe that inflectional variants cause problems for statistical CCG tagging due to training data sparseness, and explicit morphological analysis helps, even for English. For dependency parsing, Seeker and Kuhn (2013) identify case syncretism as a source of error propagation in data from Czech, German, and Hungarian. Tsarfaty et al. (2020) give a broader overview of the challenges that rich morphological structure presents for dependency parsing, and Şahin and Steedman (2018) discuss the importance of morphology in semantic parsing.

Many observations of the effect of morphology come from evaluating machine translation (MT) systems. Federico et al. (2014) show that morphological errors are common for MT into Arabic and Russian and strongly affect human quality judgement. For English–Romanian MT, Peter et al. (2016) find that tense and verb form on the target side are a common source of error. Klubička et al. (2017) find that errors in English–Croatian MT are more common for some morphological categories, such as case. In a similar vein, Burlot and Yvon (2017) evaluate morphological competence of MT systems using contrast pairs and show that systems have different strengths and weaknesses for different morphological phenomena. Beyond parsing and MT, morphology has also been shown to present a challenge for tasks such as Arabic handwriting recognition (Habash and Roth, 2011) or Russian anaphora resolution (Toldova et al., 2016).

Most of the studies cited above predate contextual embedding models such as BERT (Devlin et al., 2019), which are now considered state-of-the-art for many NLP tasks. So far, few studies have explicitly analysed BERT with regard to morphology. Edmiston (2020) analyses morphological content in BERT-style models for five languages and finds that "[morphological] ambiguity is negatively correlated with performance on classification, and to a significant degree in many cases", suggesting that morphology is still a significant source of error in these models. We go significantly beyond this work by studying a much larger set of morphological variables, across several architectures and tasks, and across up to 57 languages.

3 Datasets

We collect datasets from shared tasks that (i) publish system outputs along with their gold annotations, (ii) span a variety of languages, and (iii) cover different NLP tasks. Based on these criteria, we pick datasets from the following shared tasks:

- **SEM**: CoNLL-2009 Shared Task on Semantic Dependencies (Hajič et al., 2009), covering semantic role labeling for seven languages.

---

[1] `https://github.com/coastalcph/eacl2021-morpherror`

- **UDP**: CoNLL-2018 Shared Task on Universal Dependencies Parsing (Zeman et al., 2018), covering syntactic parsing for 57 languages.

- **VMWE**: PARSEME 2018 Shared Task on Automatic Identification of Verbal Multiword Expressions (MWE; Ramisch et al., 2018), covering nine languages.

Additionally, we use the following dataset for its *gold* annotations:

- **MT**: WMT 2019 Shared Tasks on Quality Estimation (Fonseca et al., 2019), covering word-level quality estimation for English–German and English–Russian machine translation.

Here, we are not interested in the system outputs from the shared task; instead, we use the gold annotations for the quality estimation, which give us token-level error labels for the underlying machine translation outputs. Section 4.2 describes in detail how we assign error labels to these datasets.

4 Methodology

We train a classifier to predict errors made by NLP systems based on morphological features of the input tokens, in order to then analyze which morphological features (if any) are most predictive of such errors. We first describe how we obtain these features (Sec. 4.1) and how we classify when an NLP system has made an error (Sec. 4.2), then describe the classifier itself (Sec. 4.3).

4.1 Feature Extraction

We represent each token in the input data using a binary feature set. Each individual feature is named using the convention of {CATEGORY}={VALUE}, where the former is a feature category (such as POS for "part of speech") and the latter is a value within that category (e.g. VERB). We encode these features in a binary manner, i.e., for each feature in our inventory, that feature is either present or not present. Importantly, the classifier itself has no notion of "feature categories" as it only sees a single, binary feature vector.

The full feature inventory is summarized in Table 1; what follows is a description of these features and how we derived them.

Morphological features Our *morphological feature inventory* consists of (i) Universal Dependencies (UD) features, (ii) lexical features, and (iii) string-based features.

UD features include the universal part-of-speech (POS) category and the universal feature set as defined by Universal Dependencies; e.g. U:POS=VERB or U:TENSE=PAST.[2] The UDP shared-task gold data already provides this annotation; for the other tasks, we obtain these features by running UDPipe[3] (Straka and Straková, 2017) with the largest pre-trained model for the language in question.[4]

We complement this with the following additional *lexical features*: (i) SYNCRETIC specifies to what extent a token can be representative for several morphological feature sets: e.g., *ask* can be either U:MOOD=IND or U:MOOD=IMP, depending on context; (ii) $\text{AMBIG}_{\text{POS}}$ specifies to what extent the universal part-of-speech tag of the token can differ based on context: e.g., *book* could be either U:POS=VERB or U:POS=NOUN; and (iii) $\text{AMBIG}_{\text{LEX}}$ specifies whether or not the token belongs to multiple lexemes: e.g., *ruling* is a form of both '(to) rule' and '(the) ruling'. To determine these features for a given token, we use UDLexicons[5] (Sagot, 2018); in case a language is not covered by UDLexicons, we fall back to UniMorph[6] (Kirov et al., 2018).

Finally, we define purely *string-based features* based on comparing the token with its lemma. We perform character-based string alignment using Edlib (Šošić and Šikić, 2017) and derive the following features: (i) EDIT=PRE and EDIT=SUF when there is an edit at the beginning or the end of the sequence, respectively; (ii) EDIT=IN when there is an edit in the middle of the sequence; and (iii) EDIT=FULL when there is no character alignment between the strings. These features are intended to approximate prefixation, suffixation, infixation or other word-internal processes, and suppletion, respectively.

Control features To estimate the relative importance of our morphological features for the error prediction task, we additionally introduce a set of *control features* that are not morphologically motivated (cf. Tab. 1). These are (i) string length fea-

---

[2] The U: prefix serves to distinguish them from the other features we define. For the full feature set, see: `https://universaldependencies.org/u/feat/`

[3] `http://ufal.mff.cuni.cz/udpipe`

[4] The VMWE task only provides POS and morphology annotation for a subset of its languages, so for consistency, we choose to run UDPipe for all languages in this task as well.

Feature	**Definition**	
Morphological features		
U:POS={VALUE}	universal part-of-speech tag, e.g. U:POS=VERB	
U:{FEAT}={VALUE}	universal feature according to the UD specification, e.g. U:TENSE=PAST	
AMBIG$_{\text{POS}}$=NO	$\lvert P_t \rvert = 1$	where P_t is the set of all observed universal POS tags for t
AMBIG$_{\text{POS}}$=YES	$1 < \lvert P_t \rvert < 5$	
AMBIG$_{\text{POS}}$=HIGH	$\lvert P_t \rvert \geq 5$	
AMBIG$_{\text{LEX}}$=NO	$\lvert L_t \rvert = 1$	where L_t is the set of all observed lemmata for t
AMBIG$_{\text{LEX}}$=YES	$\lvert L_t \rvert > 1$	
SYNCRETIC=NO	$\lvert M_t \rvert = 1$	where M_t is the set of all observed morphological feature combinations for t
SYNCRETIC=YES	$1 < \lvert M_t \rvert < 5$	
SYNCRETIC=HIGH	$\lvert M_t \rvert \geq 5$	
EDIT=PRE	$x_0 \neq \text{MATCH}$	where $[x_0, \ldots, x_n]$ is the sequence of edit alignments between t and l, $x_i \in \{\text{MATCH}, \text{MISMATCH}, \text{GAP}\}$
EDIT=SUF	$x_n \neq \text{MATCH}$	
EDIT=IN	$\exists i, j, k : i < j < k$	
	$\wedge x_i = \text{MATCH}$	
	$\wedge x_j \neq \text{MATCH}$	
	$\wedge x_k = \text{MATCH}$	
EDIT=FULL	$\forall i : x_i \neq \text{MATCH}$	
Control features		
LEN=1-3	$1 \leq \lvert t \rvert \leq 3$	where $\lvert t \rvert$ is the string length of t
LEN=4-6	$4 \leq \lvert t \rvert \leq 6$	
LEN=7-9	$7 \leq \lvert t \rvert \leq 9$	
LEN=10+	$\lvert t \rvert \geq 10$	
FREQ=99	$P_{99} \leq f(t)$	where $f(t)$ is the absolute frequency count of t and P_n is the n-th percentile of the frequency distribution
FREQ=98	$P_{98} \leq f(t) < P_{99}$	
FREQ=95	$P_{95} \leq f(t) < P_{98}$	
FREQ=90	$P_{90} \leq f(t) < P_{95}$	
FREQ=UNCOMMON	$4 \leq f(t) < P_{90}$	
FREQ=RARE	$f(t) < 4$	

Table 1: Inventory of extracted features (cf. Sec. 4.1). t always denotes the token, l its lemma.

tures, where each token is assigned exactly one such feature depending on its length; and (ii) token frequency bins. For the latter, we count token frequencies in the Universal Dependencies treebanks and assign each token a frequency feature. These features are based on frequency bins that we manually curated to provide a roughly balanced distribution of tokens to bins: e.g., FREQ=99 denotes a token that is in the 99th percentile of the frequency distribution of all types, while FREQ=RARE denotes a token occurring less than four times overall (see Table 1 for all definitions).

Pruning and statistics Since very rare features are not very informative, for any given dataset, we remove features that occur less than 10 times in that dataset. Depending on the task and language, we generate between 17 and 120 unique features this way, with an average of 68.

4.2 Classifying errors in system outputs

The target variable for our classifier is a binary label corresponding to whether or not the shared-task system has made an error on the input token. This requires comparing the outputs of a system to the gold data and classifying each token as either *correct* or *incorrect*. We will also refer to the latter as the *error* class. This classification follows the original evaluation criteria by the shared tasks to the extent possible.

For SEM, a prediction is classified as "correct" *iff* the semantic dependencies and label columns are an exact match with the gold data. For UDP, we do the same with the syntactic head and dependency relation columns; this is the same criterion that underlies the labeled attachment score (LAS) commonly used to evaluate dependency parsing. VMWE is a little more challenging since its prediction involves a set of tokens within a sentence. For each sentence, we match up each gold MWE with the predicted MWE that has the same label and the largest token overlap. We then consider a token "incorrectly" predicted if has a MWE annotation that does not belong to one of these matched MWEs, or if it lacks a MWE annotation that it should have according to the gold data.

As mentioned before, we treat the MT data a little differently: here, the *gold data* provides binary labels in the form of "OK" and "BAD" tags, corresponding to the correctness of some machine translation system. These tags are provided both for tokens and gaps between tokens (to account for the deletion/insertion of words in machine translation). We use the token-level tags from the gold data directly as our error classification labels.

Appendix A gives an example for the error classification approach on VMWE and MT.

4.3 Training classifiers

With the extracted features (from Sec. 4.1), we can now train classifiers to predict the error variable (from Sec. 4.2). Concretely, we train *random forest classifiers* (Breiman, 2001) as implemented by Scikit-learn[7] (Pedregosa et al., 2011) on each output file provided by each shared task. Random forests are ensembles of decision trees and are quick to train: the average training time on our datasets was 14 seconds on CPU, with no single run taking longer than five minutes.

As an alternative to random forests, we also experimented with randomized logistic regression classifiers followed by *stability selection* (Meinshausen and Bühlmann, 2010) to select predictive features. In our trials, this approach showed a worse performance (in terms of F_1-score) compared to random forests, while also taking considerably longer to run (averaging 7 minutes per dataset). We therefore only report results with random forest classifiers.

5 Analysis

For each shared task (Sec. 3), we ran our classification pipeline (Sec. 4) separately for each combination of (i) system submission and (ii) language evaluated on. Since random forests are largely interpretable, our analysis focuses on the important features in our learned models.

First, though, we look at the overall F_1-score of the individual classifiers, which we evaluate via stratified 5-fold cross-validation on each data point (Sec. 5.1). Additionally, to better estimate the importance of morphology, we run our cross-validation pipeline a second time *without* the morphological features, i.e., only providing the classifiers with the "control features" shown in Tab. 1. We refer to these two feature sets as "full" and "control" settings, respectively, and analyze their differences in F_1-score (Sec. 5.2).[8] Finally, we analyse the importance of individual morphological features (Sec. 5.3).

5.1 How well do the classifiers predict errors?

To evaluate how well the full classifiers learned the task, we consider their F_1-score for predicting the "error" class. Across all of our datasets, we observe a mean F_1 of 0.43 with a standard deviation of ± 0.18. Note that our setup is not comparable to most other NLP classification tasks: we evaluate a classifier trained to detect the errors of state-of-the-art systems, which means that (i) the task is inherently hard, as those systems are optimized to fix easily detectable errors, and (ii) there is no reason to assume a priori that this task is well learnable from morphological input features alone. Therefore, we believe an F_1 score of 0.43—albeit with considerable variance in performance across tasks and languages—is a strong result.

Error rate There is one important aspect to consider: the frequency of the "error" class depends on the system performance of the data point we look at, and as such our class distribution can be highly imbalanced and varied. Indeed, F_1-score and frequency of the error class correlate very strongly with Pearson's $r = 0.93$. Figure 2 plots this relationship.[9] This suggests that the errors introduced by state-of-the-art NLP systems, unsurprisingly, become harder and harder to predict the better the underlying systems perform.

Note that data imbalance is in the nature of the error prediction task, as we expect errors in state-of-the-art systems to be rare. Additionally, different

---

[7] We use the default parameters in Scikit-learn 0.23, with the exception of setting class weights to be "balanced" according to their frequencies in the input data.

[8] To complement the results and analyses presented here, we also provide a detailed table with the results for all task/language pairs in Appendix B.

[9] It might look surprising that many data points have very high error rates, with some even going above 0.95; i.e., more than 95% of all predictions in the respective file are deemed to be "incorrect" according to the criteria in Sec. 4.2. Spot-checking reveals that this is, however, plausible: for example, in UDP, the average labeled attachment score (LAS) on the Thai TH_PUD treebank was only 1.38 (Zeman et al., 2018, Table 15), with 23 systems achieving a LAS of only 0.77 or lower (out of 100; cf. `http://universaldependencies.org/conll18/results-las.html`), which is reflected by an error rate of $\geq$99.23% in our data.

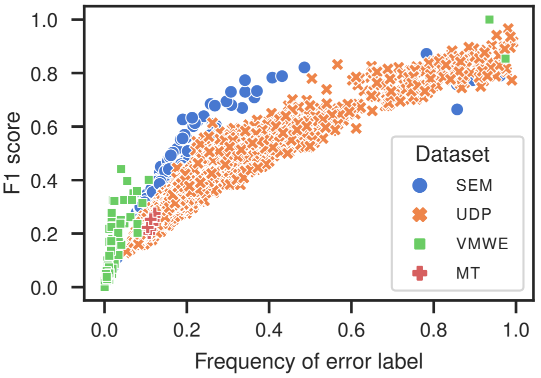

Figure 2: F_1-scores of trained error classifiers in relation to the frequency of error, i.e. the error rate of the original model (cf. Sec. 4.2).

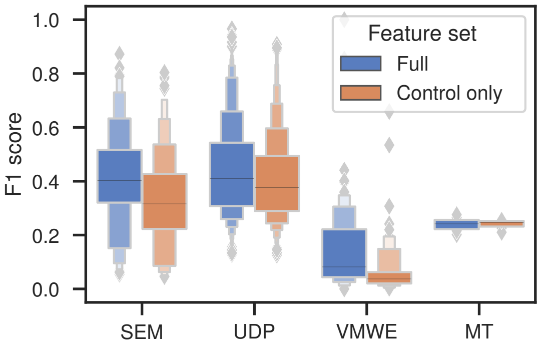

Figure 3: Quantiles of the F_1 distribution by dataset, and whether the classifiers were trained using the full feature set from Tab. 1 (blue) or only the control features (orange).

languages have differently-sized morphological tag inventories, affecting the total number of input features for the classifier. We do not attempt to apply data balancing techniques to counteract this, since this would make the task artificially easy and our results overly optimistic.

5.2 How important is morphology for predicting errors?

Figure 3 provides an alternative view of the F_1-scores presented in Fig. 2, this time as a letter-value plot (Hofmann et al., 2017) showing quantiles of the F_1 distribution. Additionally, we compare the classifier with the full feature set to the control set where morphological features were not included.

We observe that the classifiers learn best on UDP followed by SEM, while classifier F_1 is relatively poor on VMWE data. A probable explanation for this is the generally low error rate in VMWE (cf. Fig. 2). The other important observation is that classifiers in the "control" setting score consistently lower than the classifiers that have access to morphological features.

Importance by language For looking at individual languages, we restrict ourselves to the UDP data. Firstly, UDP covers 57 languages—more than any other task in our comparison—and there are no languages in the other tasks that are not also contained in UDP. Secondly, our classifier performance is generally highest on UDP (cf. Fig. 3), allowing for a more meaningful interpretation of results, particularly of selected features.

Furthermore, to factor out the effect of a data point's error rate (as discussed in Sec. 5.1), we look at the *difference* between the F_1-score of the full classifier and the control classifier trained on the same data point. In other words, we define

$$\Delta F_1 = F_1(g_f) - F_1(g_c) \qquad (1)$$

where g_f and g_c are the classifiers with the full and the control feature set, respectively. This gives us a way to judge the importance of morphological features relative to the non-morphological ones while minimizing the effect of the error rate on the results, since ΔF_1 no longer shows a strong correlation with the error rate ($r = 0.29$).

Figure 4 (bottom half) shows the quartiles of ΔF_1 scores by language in the UDP dataset. They span a wide range of values, with the median ΔF_1 varying gradually between -0.03 (for Turkish, TUR) and 0.24 (for Nigerian Pidgin, PCM). Morphological features appear to be important for some languages while being unhelpful, and sometimes even detrimental, for others.

Morphological complexity Are the differences in ΔF_1 scores (in Fig. 4) somehow related to the morphological complexity of the languages? To analyze this relationship more systematically, we use the measure of *morphological feature entropy* (MFE) introduced by Çöltekin and Rama (2018). MFE is sensitive to both the size of a language's morphological feature inventory as well as its distribution, with a more uniform distribution of features resulting in a higher MFE. Since MFE is a treebank measure that relies on the association between tokens and morphological tags, it is affected by tokenization and annotation choices of the treebank used to calculate it; therefore, it can only be considered a rough approximation of the underlying language's complexity. Like Çöltekin

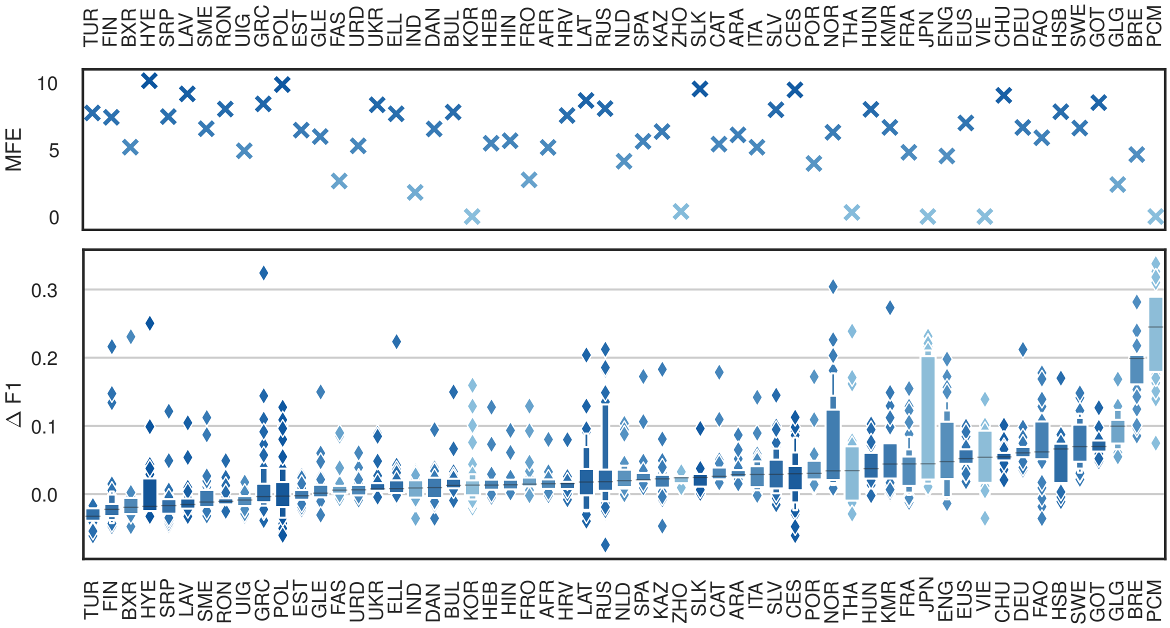

Figure 4: Classifier performance on UDP by language, sorted by median ΔF_1, where ΔF_1 is the difference in F_1-scores between training with the full and the control feature set (cf. Eq. 1). Bottom half shows the quartiles of the ΔF_1 distribution, top half shows the morphological feature entropy (MFE) for the given language; color shading is also based on MFE (with darker shade = higher MFE). Full names for all language codes as well as exact numeric values can be found in Appendix B.

and Rama (2018), we calculate the MFE score for each language on the UD treebanks.[10]

The MFE score for each language is shown in the top half of Fig. 4. Surprisingly, we find a slight, negative correlation between MFE and ΔF_1 (Pearson's $r = -0.24$). While languages with high MFE appear across the whole range of the ΔF_1 distribution, a number of languages with low MFE—and thus deemed to be more morphologically simple, such as Thai (THA), Japanese (JPN), or Nigerian Pidgin (PCM)—are found to profit *more* from the inclusion of morphological features. One possible explanation is that the control features are already very strong, which we will look at more closely in Sec. 5.3. Another possible factor is that morphologically complex languages introduce a much larger set of morphological features; if, for a given language, most of them are not relevant for predicting errors in the UDP task, they might hurt the overall classifier performance.

5.3 What morphological features are most predictive of errors?

Morphological features provide a helpful signal to the classifiers, though its overall magnitude differs by language (cf. Sec. 5.2). Now, we ask *which* of the morphological features are particularly relevant for error prediction. Since plain feature importances of trained random forest classifiers can be misleading (Strobl et al., 2007; Parr et al., 2018), we follow the approach of explicitly removing features and retraining (Parr et al., 2018; Hooker and Mentch, 2019). Unlike the analyses above, we are not concerned with generalization here, but with identifying features that are especially predictive for the error variable on each dataset as a whole. Therefore, we do not use a cross-validation strategy, but rely on the full dataset for both training and obtaining feature importances.

Concretely, for each feature *category* (as introduced in Sec. 4.1), we retrain the model *without* features from that category and note the drop in error-class F_1-score compared to the model with the full feature set. Formally, let Φ be the full feature set and $\phi_c \subset \Phi$ the subset of features belonging to category c (e.g., c = U:TENSE). The *importance* of category c is then defined as

$$f(c) = F_1(C_\Phi) - F_1(C_{\Phi \setminus \phi_c}) \qquad (2)$$

where C_X is a random forest classifier trained using feature set X. Higher values for $f(c)$ mean a higher importance of category c, while negative values

Table 2: Top 10 feature categories by *average* feature importance (FI) for each task. All FI scores given $\cdot 10^{-3}$

mean that including c is actually detrimental to the F_1-score.

Average feature importances Table 2 shows the top 10 feature categories for each task, averaged over all languages and datasets. The two control features, FREQ and LEN, always appear among the three most important categories, only trumped by U:POS for the UDP and SEM tasks. Notably, these three are the only feature categories that are *guaranteed* to appear with every token. It is no surprise that token frequency is strongly related to the likelihood of errors, while Zipf's law tells us that token length is strongly correlated with frequency.

Figure 5 shows the *distribution* of feature importances for the top 10 categories of UDP (cf. Tab. 2b). U:POS spans a much wider range of FI values than any of the other categories, although the outliers at the upper end all come from Nigerian Pidgin (PCM). Moreover, categories with a low average FI (e.g., U:ASPECT or SYNCRETIC) do not show outliers, i.e., are of low importance across languages. This is also true for the remaining feature categories.

Individual part-of-speech tags Since U:POS is an important feature category across tasks (cf. Tab. 2), we also look at feature importances for *individual* POS tags. For this, we use the same approach as for the feature categories (cf. Eq. 2), except that we now only remove a single U:POS feature from Φ at a time.

Table 3 shows the average feature importances for individual U:POS features, though this time we restrict ourselves to the subset of languages in UDP that are also covered in SEM.[11] This way, we can better isolate the *task-specific* differences in FI scores, without conflating them with the different *language-specific* distributions of part-of-speech tags that may affect these results. We find that adverbs (ADV) are the most important part-of-speech category for both tasks, while INTJ and PART are found to be important for predicting errors in UDP, but not in SEM. This aligns with our intuitions about what is hard in syntactic and semantic parsing, further supporting the validity of our approach.

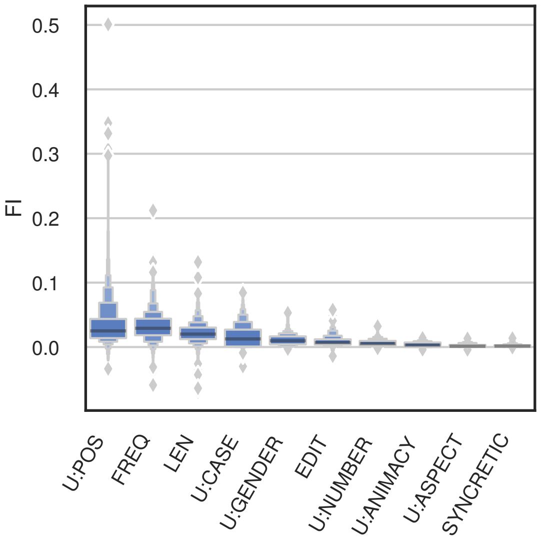

Figure 5: Quartiles of the top 10 feature categories on UDP by average feature importance (FI).

6 Conclusion

We presented a large-scale error analysis focusing on the role of morphology. Our analysis spans a range of morphological variables, four NLP tasks, and up to 57 languages. We confirm the common conjecture that morphological variables—especially case and gender—are predictive of errors across NLP tasks and languages. Somewhat sur-

prisingly, we found that the usefulness of morphological variables is *negatively* correlated with the morphological complexity of the language in question. We speculate this is because morphological information is more discriminative in morphologically simple languages.

(b) MT example from German

Table 4: Examples for how tokens are classified as correct (✓) or incorrect (✗) in our experiments. GOLD shows gold annotations, SYS shows output from an NLP system participating in the respective shared task.

A Examples for error classification

Table 4a shows an example for how we classify errors (cf. Sec. 4.2) in the VMWE dataset on verbal multi-word expression (MWE) identification. In the gold data, a single MWE (*'postawienie sprawy'*) is annotated, while the NLP system has incorrectly identified the MWE as being *'to … postawienie'*. The annotation "1" here is an ID in case there are multiple MWEs within the same sentence. We annotate both *'to'*, which was mistakenly identified as part of the MWE, as well as *'sprawy'*, which was mistakenly left out, as an error (✗). All remaining tokens are marked as correct (✓).

Table 4b shows an example from the MT dataset on quality estimation for machine translation (MT). Here, the gold data provides us with "OK" and "BAD" labels for the individual tokens of the machine-generated translation as well as for the *gaps* between the tokens. The latter is done to be able to annotate missing passages in the machine translation output; i.e., a gap between tokens would be labelled "BAD" if the MT system should have produced more output at a given position in a sentence than it did. Since it is unclear to which (existing) tokens these "gap annotations" should be ascribed to, we do not consider them for the error classification, and only consider "OK/BAD" labels for the tokens that *do* appear in the data.

B Statistics and classifier results

Table 5 presents statistics and classifier results, corresponding to the analyses in Secs. 5.1 and 5.2, for each task/language pair. The column "Avg. error rate" corresponds to the error rates plotted in Fig. 2, while the "MFE" column shows the morphological feature entropy (cf. Sec. 5.2) for the respective language. "Avg. F_1" shows the average F_1-score after stratified 5-fold cross-validation (cf. Sec. 5.1), while "Avg. ΔF_1" corresponds to the ΔF_1-measure defined in Eq. (1).

Applying the Transformer to Character-level Transduction

Shijie Wu[ʒ] **Ryan Cotterell**[ʕ,ɒ] **Mans Hulden**[χ]

Abstract

The transformer (Vaswani et al., 2017) has been shown to outperform recurrent neural network-based sequence-to-sequence models in various word-level NLP tasks. Yet for character-level transduction tasks, e.g. morphological inflection generation and historical text normalization, there are few works that outperform recurrent models using the transformer. In an empirical study, we uncover that, in contrast to recurrent sequence-to-sequence models, the batch size plays a crucial role in the performance of the transformer on character-level tasks, and we show that with a large enough batch size, the transformer does indeed outperform recurrent models. We also introduce a simple technique to handle feature-guided character-level transduction that further improves performance. With these insights, we achieve state-of-the-art performance on morphological inflection and historical text normalization. We also show that the transformer outperforms a strong baseline on two other character-level transduction tasks: grapheme-to-phoneme conversion and transliteration.

1 Introduction

The transformer (Vaswani et al., 2017) has become a popular architecture for sequence-to-sequence transduction in NLP. It has achieved state-of-the-art performance on a range of common word-level transduction tasks: neural machine translation (Barrault et al., 2019), question answering (Devlin et al., 2019) and abstractive summarization (Dong et al., 2019). In addition, the transformer forms the backbone of the widely-used BERT (Devlin et al., 2019). Yet for character-level transduction tasks like morphological inflection, the dominant model has remained a recurrent neural network-based sequence-to-sequence model with attention (Cotterell et al., 2018). This is not for lack of effort—but rather, it is the case that the transformer has consistently underperformed in experiments on average (Tang et al., 2018b).[1] As anecdotal evidence of this, we note that in the 2019 SIGMORPHON shared task on cross-lingual transfer for morphological inflection, no participating system was based on the transformer (McCarthy et al., 2019).

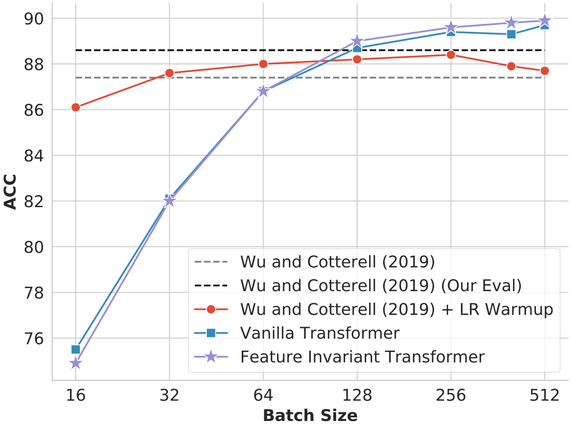

Figure 1: Development set accuracy for 5 languages on morphological inflection with different batch sizes. We evince our two primary contributions: (1) we set the **new state of the art** morphological inflection using the transformer and (2) we demonstrate the transformer's **dependence on the batch size**.

Character-level transduction models are often trained with less data than their word-level counterparts: In contrast to machine translation, where millions of training samples are available, the 2018 SIGMORPHON shared task (Cotterell et al., 2018) high-resource setting only provides ≈ 10k training examples per language. It is also not obvious that non-recurrent architectures such as the transformer

---

should provide an advantage at many character-level tasks: For instance, Gehring et al. (2017) and Vaswani et al. (2017) suggest that transformers (and convolutional models in general) should be better at remembering long-range dependencies. In the case of morphology, none of these considerations seem relevant: inflecting a word (a) requires little capacity to model long-distance dependencies and is largely a monotonic transduction; (b) it involves no semantic disambiguation, the tokens in question being letters; (c) it is not a task for which parallelization during training appears to help, since training time has never been an issue in morphology tasks.[2]

In this work, we provide state-of-the-art numbers for morphological inflection and historical text normalization, a novel result in the literature. We also show the transformer outperforms a strong recurrent baseline on two other character-level tasks: grapheme-to-phoneme (g2p) conversion and transliteration. We find that a single hyperparameter, batch size, is largely responsible for the previous poor results. Despite having fewer parameters, the transformer outperforms the recurrent sequence-to-sequence baselines on all four tasks. We conduct a short error analysis on the task of morphological inflection to round out the paper.

2 The Transformer for Characters

The Transformer. The transformer, originally described by Vaswani et al. (2017), is a self-attention-based encoder-decoder model. The encoder has N layers, consisting of a multi-head self-attention layer and a two-layer feed-forward layer with ReLU activation, both equipped with a skip connection. The decoder has a similar structure as the encoder except that, in each decoder layer between the self-attention layer and feed-forward layer, a multi-head attention layer attends to the output of the encoder. Layer normalization (Ba et al., 2016) is applied to the output of each skip connection. Sinusoidal positional embeddings are used to incorporate positional information without the need for recurrence or convolution. Here, we describe two modifications we make to the transformer for character-level tasks.

A Smaller Transformer. As the dataset sizes in character-level transduction tasks are significantly smaller than in machine translation, we employ a smaller transformer with $N = 4$ encoder-decoder layers. We use 4 self-attention heads. The embedding size is $d_{model} = 256$ and the hidden size of the feed-forward layer is $d_{FF} = 1024$. In the preliminary experiments, we found that using layer normalization before self-attention and the feed-forward layer performed slightly better than the original model. It is also the default setting of a popular implementation of the transformer (Vaswani et al., 2018). The transformer alone has around 7.37M parameters, excluding character embeddings and the linear mapping before the softmax layer. We decode the model left to right in a greedy fashion.

Feature Invariance. Some character-level transduction is guided by features. For example, in the case of morphological reinflection, the task requires a set of morphological attributes that control what form a citation form is inflected into (see Fig. 2 for an example). However, the order of the features is irrelevant. In a recurrent neural network, features are input in some predefined order as special characters and pre- or postpended to the input character sequence representing the citation form. The same is true for a vanilla transformer model, as shown on the left-hand side of Fig. 2. This leads to

---

[2] Many successful CoNLL–SIGMORPHON shared task participants report training their models on laptop CPUs.

LS	β_2	Vanilla	Feature Invariant
0	0.999	89.34	89.80
0	0.98	89.62	89.92
0.1	0.999	89.48	90.02
0.1	0.98	89.98	90.28

Table 1: Average development accuracy on morphological inflection with different LS and β_2, which denote hyperparameter of label smoothing and Adam optimizer respectively.

different relative distances between a character and a set of features.[3] To avoid such an inconsistency, we propose a simple remedy: We set the positional encoding of features to 0 and only start counting the positions for characters. Additionally, we add a special token to indicate whether a symbol is a word character or a feature. The right-hand side of Fig. 2 evinces how we have the same relative distance between characters and features.

3 Empirical Findings

Tasks. We consider four character-level transduction tasks: morphological inflection, grapheme-to-phoneme conversion, transliteration, and historical text normalization. For morphological inflection, we use the 2017 SIGMORPHON shared task data (Cotterell et al., 2017) with 52 languages. The performance is evaluated by accuracy (ACC) and edit distance (Dist). For the g2p task, we use the unstressed CMUDict (Weide, 1998) and NETtalk (Sejnowski and Rosenberg, 1987) resources. We use the splits from Wu et al. (2018). We evaluate under word error rate (WER) and phoneme error rate (PER). For transliteration, we use the NEWS 2015 shared task data (Zhang et al., 2015).[4] For historical text normalization, we follow Bollmann (2019) and use datasets for Spanish (Sánchez-Martínez et al., 2013), Icelandic and Swedish (Pettersson et al., 2013), Slovene (Scherrer and Erjavec, 2013, 2016; Ljubešic et al., 2016), Hungarian and German (Pettersson, 2016).[5] We evaluate using accuracy (ACC) and character error rate of incorrect prediction (CER$_i$).

Optimization. We use Adam (Kingma and Ba, 2014) with a learning rate of 0.001 and an inverse square root learning rate scheduler (Vaswani et al., 2017) with 4k steps during the warm-up. We train the model for 20k gradient updates and save and evaluate the model every 400 gradient updates. We select the best model out of 50 checkpoints based on development set accuracy. The number of gradient updates and checkpoints are roughly the same as Wu and Cotterell (2019), the single model state of the art on the 2017 SIGMORPHON dataset. We use their model as a baseline model. For all experiments, we use a single predefined random seed.

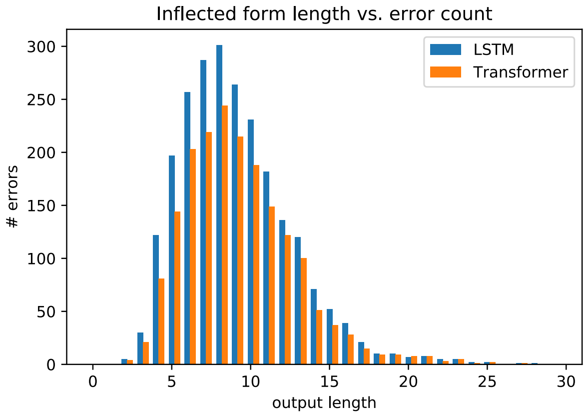

Figure 3: Distribution of incorrectly inflected forms in the test set of the inflection task over all 52 languages grouped by desired output word length.

3.1 A Controlled Hyperparameter Study

To demonstrate the importance of hyperparameter tuning for the transformer on character-level tasks, we perform a small controlled hyperparameter study. This is important since researchers had previously failed to achieve high-performing results with the transformer on character-level tasks. Here, we look at morphological inflection on the five languages in the 2017 SIGMORPHON dataset where submitted systems performed the worst: Latin, Faroese, French, Hungarian, and Norwegian (Nynorsk). We set the dropout to 0.3, β_2 of Adam to 0.999 (the default value), and do not use label smoothing. We do not tune any other hyperparameter except the following three hyperparameters.

The Importance of Batch Size. While recurrent models like Wu and Cotterell use a batch size of 20, halving the learning rate when stuck and employing early stopping, we find that a less aggressive learning rate scheduler, allowing the model to train longer, outperforms these hyperparameters. Fig. 1 shows that the *significant impact of batch size on the transformer*. The transformer performance in-

---

[3] While the features could be encoded with a binary vector followed by MLP, it introduces a representation bottleneck for encoding features.

Table 2: Average test performance on morphological inflection of Transformer against models from the literature. * denotes model ensembling.

creases steadily as the batch size is increased, similarly to what Popel and Bojar (2018) observe for machine translation. The transformer only outperforms the recurrent baseline when the batch size is at least 128, which is much larger than batch size commonly used in recurrent models.[6] Note that the model of Wu and Cotterell has 8.66M parameters, 17% more than the transformer model. To get an apples-to-apples comparison, we apply the same learning rate scheduler to Wu and Cotterell; this does not yield similar improvements and underperforms with respect to the traditional learning rate scheduler. Our feature invariant transformer also outperforms the vanilla transformer model. We set the batch size to 400 for our main experiments. Note the batch size of 400 is especially large (4% of training data) considering the training size is only 10k.

Other Hyperparameters. Vaswani et al. (2017) applies label smoothing (Szegedy et al., 2016) of 0.1 to the transformer model and shows that it hurts perplexity, but improves BLEU scores for machine translation. Instead of the default 0.999 β_2 for Adam, Vaswani et al. (2017) uses 0.98 and we find that both choices benefit character-level transduction tasks as well (see Tab. 1).

3.2 New State-of-the-Art Results

We train our feature invariant transformer on the four character-level tasks, exhibiting state-of-the-art results on morphological inflection and historical text normalization.

Table 4: Average test performance on Grapheme-to-Phoneme and dev performance on Transliteration of Transformer against models from the literature.

Morphological Inflection. As shown in Tab. 2, the feature invariant transformer produces state-of-the-art results on the 2017 SIGMORPHON shared tasks, improving upon ensemble-based systems by 0.27 points. We observe that as the dataset decreases in size, a model with a larger dropout value performs slightly better. A brief tally of phenomena that are difficult to learn for many machine learning models, categorized along typical linguistic dimensions (such as word-internal sound changes, vowel harmony, circumfixation, ablaut, and umlaut phenomena) fail to reveal any consistent pattern of advantage to the transformer model. In fact, errors seem to be randomly distributed with an overall advantage of the transformer model. Curiously, errors grouped along the dimension of word length reveal that as word forms grow longer, the transformer advantage shrinks (Fig. 3).

Historical Text Normalization. Tab. 3 shows that the transformer model with dropout of 0.1, as in the case of morphological inflection, improves upon the previous state of the art, although the model with a dropout of 0.3 yields a slightly better CER$_i$.

G2P and Transliteration. Tab. 4 shows that the transformer outperforms previously published strong recurrent models on two tasks despite having fewer parameters. A dropout rate of 0.3 yields

---

[6] It is also large in the context of character-level tasks, which typically have around 10k training examples. Batch size of 400 would imply approximately 4% of training data in a single gradient update.

significantly better performance on the transliteration task while a dropout rate of 0.1 is stronger on the g2p task. This shows that transformers can and do outperform recurrent transducers on common character-level tasks when properly tuned.

4 Related Work

Character-level transduction is largely dominated by attention-based LSTM sequence-to-sequence (Luong et al., 2015) models (Cotterell et al., 2018). Character-level transduction tasks usually involve input-output pairs that share large substrings and alignments between these are often monotonic. Models that address the task tend to focus on exploiting such structural bias. Instead of learning the alignments, Aharoni and Goldberg (2017) use external monotonic alignments from the SIGMORPHON 2016 shared task baseline Cotterell et al. (2016). Makarov et al. (2017) use this approach to win the CoNLL-SIGMORPHON 2017 shared task on morphological inflection (Cotterell et al., 2017). Wu et al. (2018) shows that explicitly modeling alignment (hard attention) between source and target characters outperforms soft attention. Wu and Cotterell (2019) further shows that enforcing monotonicity in a hard attention model improves performance.

5 Conclusion

Using a large batch size and feature invariant input allows the transformer to achieve strong performance on character-level tasks. However, it is unclear what linguistic errors the transformer makes compared to recurrent models on these tasks. Future work should analyze the errors in detail as Gorman et al. (2019) does for recurrent models. While Wu and Cotterell shows that the monotonicity bias benefits character-level tasks, it is not evident how to enforce monotonicity on multi-headed self-attention. Future work should consider how to best incorporate monotonicity into the model, either by enforcing it strictly (Wu and Cotterell, 2019) or by pretraining the model to copy (Anastasopoulos and Neubig, 2019).

Abstract

Reinforcement Learning (RL) is a powerful framework to address the discrepancy between loss functions used during training and the final evaluation metrics to be used at test time. When applied to neural Machine Translation (MT), it minimises the mismatch between the cross-entropy loss and non-differentiable evaluation metrics like BLEU. However, the suitability of these metrics as reward function at training time is questionable: they tend to be sparse and biased towards the specific words used in the reference texts. We propose to address this problem by making models less reliant on such metrics in two ways: (a) with an entropy-regularised RL method that does not only maximise a reward function but also explore the action space to avoid peaky distributions; (b) with a novel RL method that explores a dynamic unsupervised reward function to balance between exploration and exploitation. We base our proposals on the Soft Actor-Critic (SAC) framework, adapting the off-policy maximum entropy model for language generation applications such as MT. We demonstrate that SAC with BLEU reward tends to overfit less to the training data and performs better on out-of-domain data. We also show that our dynamic unsupervised reward can lead to better translation of ambiguous words.

1 Introduction

Autoregressive sequence-to-sequence (seq2seq) neural architectures have become the *de facto* approach in Machine Translation (MT). Such models include Recurrent Neural Networks (RNN) (Sutskever et al., 2014; Bahdanau et al., 2014) and Transformer networks (Vaswani et al., 2017), among others. However, these models have as a serious limitation the discrepancy between their training and inference time regimes. They are traditionally trained using the Maximum Likelihood Estimation (MLE), which aims to maximise log-likelihood of a categorical ground truth distribution (samples in the training corpus) using loss functions such as cross-entropy, which are very different from the evaluation metric used at inference time, which generally compares string similarity between the system output and reference outputs. Moreover, during training, the generator receives the ground truth as input and is trained to minimise the loss of a single token at a time without taking the sequential nature of language into account. At inference time, however, the generator will take the previous sampled output as the input at next time step, rather than the ground truth word. MLE training thus causes: (a) the problem of "exposure bias" as a result of recursive conditioning on its own errors at test time, since the model has never been exclusively "exposed" to its own predictions during training; (b) a mismatch between the training objective and the test objective, where the latter relies on evaluation using discrete and non-differentiable measures such as BLEU (Papineni et al., 2002).

The current solution for both problems is mainly based on Reinforcement Learning (RL), where a seq2seq model (Sutskever et al., 2014; Bahdanau et al., 2014) is used as the policy which generates actions (tokens) and at each step receives rewards based on a discrete metric taking into account importance of immediate and future rewards. However, RL methods for seq2seq MT models also have their challenges: high-dimensional discrete action space, efficient sampling and exploration, choice of baseline reward, among others (Choshen et al., 2020). The typical metrics used as rewards (e.g., BLEU) are often biased and sparse. They are measured against one or a few human references and do not take into account alternative translation options that are not present in the references.

One way to address this problem is to use

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1908–1920
April 19 - 23, 2021.

entropy-regularised RL frameworks. They incorporate the entropy measure of the policy into the reward to encourage exploration. The expectation is that this leads to learning a policy that acts as stochastically as possible while able to succeed at the task. Specifically, we focus on the Soft Actor-Critic (SAC) (Haarnoja et al., 2018a,b) RL framework, which to the best of our knowledge has not yet been explored for MT, as well as other natural language processing (NLP) tasks. The main advantage of this architecture, as compared to other entropy regularised architectures (Haarnoja et al., 2017; Ziebart et al., 2008), is that it is formulated in the off-policy setting that enables reusing previously collected samples for more stability and better exploration. We demonstrate that SAC prevents the model from overfitting, and as a consequence leads to better performance on out-of-domain data.

Another way to address the problem of sparse or biased reward is to design an unsupervised reward. Recently, in Robotics, SAC has been successfully used in unsupervised reward architectures, such as the "Diversity is All You Need" (DIAYN) framework (Eysenbach et al., 2018). DIAYN allows the learning of latent-conditioned sub-policies ("skills") in unsupervised manner, which allows to better explore and model target distributions. Inspired by this work, we propose a formulation of an unsupervised reward for MT. We thoroughly investigate effects of this reward and conclude that it is useful in lexical choice, particularly the rare sense translation for ambiguous words.

Our **main contributions** are thus twofold: (a) the re-framing of the SAC framework such that it can be applied to MT and other natural language generation tasks (Section 3). We demonstrate that SAC results in improved generalisation compared to the MLE training, leading to better translation of out-of-domain data; (b) the proposal of a dynamic unsupervised reward within the SAC framework (Section 3.4). We demonstrate its efficacy in translating ambiguous words, particularly the rare senses of such words. Our datasets and settings are described in Section 4, and our experiments in Section 5.

2 Related Work

Reinforcement Learning for MT RL has been successfully applied to MT to bridge the gap between training and testing by optimising the sequence-level objective directly (Yu et al., 2017; Ranzato et al., 2015; Bahdanau et al., 2016). However, thus far mainly the REINFORCE (Williams, 1992) algorithm and its variants have been used (Ranzato et al., 2015; Kreutzer et al., 2018). These are simpler algorithms that handle the large natural language action space, but they employ a sequence-level reward which tends to be sparse.

To reduce model variance, Actor-Critic (AC) models consider the reward at each decoding step and use the Critic model to guide future actions (Konda and Tsitsiklis, 2000). This approach has also been explored for MT (Bahdanau et al., 2016; He et al., 2017). However, more advanced AC models with Q-Learning are rarely applied to language generation problems. This is due to the difficulty of approximating the Q-function for the large action space. The large action space is one of the bottleneck for RL for text generation in general. Pre-training of the agent parameters to be close to the true distribution is thus necessary to make RL work (Choshen et al., 2020). Further RL training of the agent makes the overfitting problem even more pronounced resulting in peaky distributions. Such problems are traditionally addressed by entropy regularised RL.

Entropy Regularised RL The main goal of this type of RL is to learn an efficient policy while keeping the entropy of the agent actions as high as possible. The paradigm promotes exploration of actions, suppresses peaky distributions and improves robustness. In this work, we explore the effectiveness of the maximum entropy SAC framework (Haarnoja et al., 2018a).

The work closest to ours is of Dai et al. (2018) where the Entropy-Regularised AC (ERAC) model leads to better MT performance. The major difference between ERAC and SAC is that the former is an on-policy model and the latter is an off-policy model. On-policy approaches use consecutive samples collected in real-time that are correlated to each other. In the off-policy setting, our SAC algorithm uses samples from the memory that are taken uniformly with reduced correlation. This key characteristic of SAC ensures better model generalisation and stability (Mnih et al., 2015). There are also differences in the architectures of SAC and ERAC, i.a., using 4 Q-value networks instead of two. These differences will be covered in detail in Section 3.

Unsupervised reward RL Significant work has been done in Robotics to improve the learning capability of robots. These approaches do not rely on a single objective but rather promote intrinsic motivation and exploration. Such an approach to learn diverse skills (latent-conditioned sub-policies, in practice, skills like walking or jumping) in unsupervised manner was recently proposed by Eysenbach et al. (2018). The approach relies on the SAC model and inspired our approach to designing our unsupervised reward for MT. We are not aware of other attempts to design dynamic unsupervised RL rewards (learnt together with the network) in seq2seq in general, or MT in particular. Recent work on unsupervised rewards in NLP (Gao et al., 2020) explores mainly static rewards computed against synthetic references.

3 Methodology

In this section we start by describing the underlying MT architecture and its variant using RL, to then introduce our SAC formulation and the reward functions used.

3.1 Neural Machine Translation (NMT)

A typical Neural Machine Translation (NMT) system is a seq2seq architecture (Sutskever et al., 2014; Bahdanau et al., 2014), where each source sentence $\mathbf{x} = (x_1, x_2, \cdots, x_n)$ is encoded by the encoder into a series of hidden states. At each decoding step t, a target word y_t is generated according to $p(y_t|y_{<t}, x)$ conditioned on the input sequence x and decoded sequence $\mathbf{y}_{<t} = (y_1, \cdots, y_{t-1})$ up to the t-th time step. Given the corpus of pairs of source and target sentences $\{x_i, y_i\}_{i=1}^{N}$, the training objective function - maximum likelihood estimation (MLE) is defined as:

$$\mathcal{L}_{\text{MLE}} = -\sum_{i=1}^{N}\sum_{t=1}^{T} p(y_t^i|y_1^i, ..., y_{t-1}^i, x^i) \tag{1}$$

3.2 Reinforcement Learning for NMT

Within the RL framework, the task of NMT can be formulated as a sequential decision making process, where the **state** is defined by the previously generated words ($\mathbf{y}_{<t}$) and the **action** is the next word to be generated. Given the state s_t, the agent picks an action a_t (for seq2seq it is the same as y_t), according to a (typically stochastic) **policy** π_θ and observes a reward r_t for that action. The reward can be calculated based on any evaluation metric, *e.g.* BLEU.

The objective of the RL training is to maximise the expected reward:

$$\mathcal{L}_{RL} = \mathbb{E}_{a_1,\cdots,a_T \sim \pi_\theta(a_1,\cdots,a_T)}[r(a_1, \cdots, a_T)] \tag{2}$$

Under the policy π, we can also define the values of the state-action pair $Q(s_t, y_t)$ and the state $V(s_t)$ as follows:

$$\begin{aligned} Q_\pi(s_t, a_t) &= \mathbb{E}[r_t|s = s_t, a = a_t] \\ V_\pi(s_t) &= \mathbb{E}_{a\sim\pi(s)}[Q_\pi(s_t, a = a_t)] \end{aligned} \tag{3}$$

Intuitively, the value function V measures how good the model could be when it is in a specific state s_t. The Q function measures the value of choosing a specific action when we are in such state.

Given the above definitions, we can define a function called *advantage* – denoted by A_π – relating the value function V and Q function as follows:

$$A_\pi(s_t, a_t) = Q_\pi(s_t, a_t) - V_\pi(s_t) \tag{4}$$

Therefore, the focus is on maximising one of the following objectives:

$$\max_a A_\pi(s_t, a_t) \rightarrow \max_a Q_\pi(s_t, a_t) \tag{5}$$

Different RL algorithms have different ways to search for the optimal policy. Algorithms such as REINFORCE, as well as its variant MIXER (Ranzato et al., 2015), popular in language tasks, search for the optimal policy via Eq. 2 using the Policy Gradient. Actor-Critic (AC) models typically improve the performance of Policy Gradient models by solving Eq. 5 (left part) (Bahdanau et al., 2016). Q-learning models that aim at maximising the Q function (Eq 5, right part) to improve over both the Policy Gradient and AC models (Dai et al., 2018).

3.3 Soft Actor-Critic (SAC)

The SAC algorithm (Haarnoja et al., 2018a) adds to the Eq. 2 an entropy term:

$$\mathcal{L}(\pi) = \sum_{t=1}^{T} \mathop{\mathbb{E}}_{a_t\sim\pi(\cdot|s_t)} [r(s_t, a_t) + \alpha\mathcal{H}(\pi(\cdot|s_t))] \tag{6}$$

where α controls the stochasticity of the optimal policy, a trade-off between the relative importance of the entropy term $\mathcal{H}$ and the reward $r(s_t, a_t)$ that the agent receives by taking action a_t when the state of the environment is s_t. Its aim is to maximise the entropy of actions at the same time as maximising the rewards.

As mentioned earlier, SAC is an off-policy Q-learning AC algorithm. As other AC algorithms it consists of two parts: the actor (the policy function) and the critic – action-value function (Q), parameterised by ϕ and θ, respectively.

During off-policy learning, the history of states, actions and respective rewards are stored in a memory (D), *a.k.a.* the replay buffer.

- **Critic Training**

The Q-function estimates the value of an action at a given state based on its future rewards. The soft-Q value is computed recursively by applying a modified Bellman backup operator:

$$Q(s_t, a_t) = r(s_t, a_t) + \gamma \mathop{\mathbb{E}}_{s_{t+1} \sim D}[V(s_{t+1})] \tag{7}$$

where

$$V(s_t) = \mathop{\mathbb{E}}_{a_t \sim \pi}[Q(s_t, a_t) - \alpha \log \pi(a_t|s_t)] \tag{8}$$

is the expected future reward of a state and $\log(\pi(a_t|s_t))$ is the entropy of the policy.

The parameters of the Q-function are updated towards minimising the mean squared error between the estimated Q-values and the assumed ground-truth Q-value. The assumed ground-truth Q-values are estimated based on the current reward ($r(s_t, a_t)$) and the discounted future reward of the next state ($\gamma V_{\bar{\theta}}(s_{t+1})$). This mean squared error objective function of the Q network is as follows:

$$\mathcal{L}(\theta) = \mathop{\mathbb{E}}_{s_t, a_t, r_t, s_{t+1} \sim D, a_{t+1} \sim \pi_\phi} \Big[\big(Q_\theta(a_t, s_t) - \\ [r(s_t, a_t) + \gamma \mathop{\mathbb{E}}_{s_{t+1} \sim D}[V_{\bar{\theta}}(s_{t+1})]]\big)^2 \Big] \tag{9}$$

Note that the parameters of the networks are denoted as θ and $\bar{\theta}$ respectively. This is the best practice where the critic is modeled with two neural networks with the exact same architecture but independent parameters (Mnih et al., 2015).

The parameters of the target critic network ($Q_{\bar{\theta}}$) are iteratively updated with the exponential moving average of the parameters of the main critic network (Q_θ). This constrains the parameters of the target network to update at a slower pace toward the parameters of the main critic, which has been shown to stabilise the training process (Lillicrap et al., 2016).

Another advantage of SAC is the double Q-learning (Hasselt, 2010). In this approach, two Q networks for both of the main and the target critic functions are maintained. When estimating the current Q values or the discounted future rewards, the minimum of the outputs of the two Q networks is used. Thus the estimated Q values do not grow too large, which improves the policy training (Haarnoja et al., 2018a).

- **Actor Training**

SAC updates the policy to minimise the KL-divergence to make the distribution of $\pi_\phi(s_t)$ policy function look more like the distribution of the Q function:

$$\mathcal{L}_\pi(\phi) = \mathop{\mathbb{E}}_{s_t \sim D}[\pi_t(s_t)^T [\alpha \log(\pi_\phi(s_t)) - Q_\theta(s_t)]] \tag{10}$$

where softmax is used in the final layer of the policy to output a probability distribution over the actions.

We note that some versions of the SAC algorithm allow to automatically tune the α parameter so that while maximising the expected return, the policy should satisfy the minimum entropy criteria. In our experiments we however used a fixed α. Updating α during training resulted in too short sentences in the output.

Finally, we note that Eq. 10 does *not* simply add an entropy term to the standard Policy Gradient. The critic Q_θ trained by Eq. 9 additionally captures the *entropy from future steps*.

For more details on SAC for the discrete setting (like MT) we refer to Christodoulou (2019). For more formal details on the architecture, see Haarnoja et al. (2018a,b).

3.4 Reward functions

Below we define the reward functions we use in our SAC architecture.

Supervised BLEU reward: - `SAC BLEU` In the supervised setup, we employ the sequence-level BLEU score (Papineni et al., 2002) with add-1 smoothing (Chen and Cherry, 2014). As an additional length constraint at each time step, we deduct from the respective score the length penalty: $lp = |l_{\mathbf{y}} - l_{\hat{\mathbf{y}}}|$, where $\mathbf{y}$ is the reference translation. This penalty prevents longer translations that are not penalised by the brevity penalty of BLEU.

BLEU has been chosen in our study to ensure better comparability with the related work in RL MT traditionally using the BLEU reward (Bahdanau et al., 2016; Dai et al., 2018).

Unsupervised reward - `SAC unsuper` As discussed above, using automatic metrics as reward function can lead to a number of issues, *e.g.* reward sparsity, overfitting towards single reference. Moreover, designing a good reward can be challenging.

Inspired by recent work on the SAC algorithm in unsupervised RL (Eysenbach et al., 2018), we have designed an unsupervised reward that *balances the quality and diversity in the model search space*.

The pseudo-reward function we use is as follows:

$$r_z(\mathbf{x}, a) = \log q_\delta(z|\mathbf{x}, a) - \log p(z) \qquad (11)$$

where $p(z)$ is a categorical uniform distribution for a latent variable z.

$q_\delta(z|\mathbf{x}, a)$ is provided by a discriminator parametrised by a neural network. z is randomly assigned to a word sampled at each step from the actor distribution. The discriminator is a Bag-of-Words model that takes as input the encoded source sequence and the word itself to predict its z.

More intuitively, every time a word appears in the translation hypothesis for a source sentence (within the Bag-of-Words formulation) it is randomly assigned a certain value of z. The more times this word appears in the sampled hypotheses (for a given source) the closer will be $\log q_\delta(z|\mathbf{x}, a)$ to the uniform prior $p(z)$, hence reward $r_z(\mathbf{x}, a)$ will be close to 0. Thus, frequent translations will be suppressed and search for less frequent translations will be encouraged in order to receive a reward larger than 0.

Such a reward is less sparse than the traditional ones and is also dynamic which prevents memorising and overfitting.

4 Experimental Setup

4.1 Data

We perform experiments on the **Multi30K** dataset (Elliott et al., 2016)[1] of image description translations and focus on the English-German (EN-DE) and English-French (EN-FR) (Elliott et al., 2017) language directions. Following best practises, we use sub-word segmentation (BPE (Sennrich et al., 2016)) only on the target side of the corpus. The dataset contains 29,000 instances for training, 1,014 for development, and 1,000 for testing. We use **flickr2016** (**2016**), **flickr2017** (**2017**) and **coco2017** (**COCO**) test sets for model evaluation.

2016 is the most **in-domain** test set since it was taken from the same superset of descriptions as the training set, whereas **2017** and **COCO** are from different image description corpora and are thus considered **out-of-domain**.

For more fine-grained assessment of our models with unsupervised reward, we use the **MLT** test set (Lala and Specia, 2018; Lala et al., 2019), an annotated subset of the **Multi30K** corpus where each instance is a 3-tuple consisting of an **ambiguous** source word, its textual context (a source sentence), and its correct translation. The test set contains 1,298 sentences for English-French and 1,708 for English-German. It was designed to benchmark models in their ability to select the right lexical choice for words with multiple translations, especially when some of these translations are rarer.

Additionally, to allow for comparison with previous work, we evaluate on the **IWSLT 2014** German-to-English dataset (Cettolo et al., 2012) from TED talks, which has been used as testbed in most work on RL for MT. The training set contains $153K$ sentence pairs. We followed the pre-processing procedure described in (Dai et al., 2018).

When compared to the **IWSLT 2014** dataset, all the three **Multi30K** test sets are more out-of-domain. This was found by the analysis of perplexities of language models trained with respective training data for each dataset (see Appendix A.4).

4.2 Training

We modify the original SAC architecture to adapt it to MT following best practices (Bahdanau et al., 2016) in the area. The functions π_ϕ and Q_θ are parameterised with neural networks: π_ϕ is an RNN seq2seq model with a 2-layer GRU (Cho et al., 2014) encoder and a 2-layer Conditional GRU decoder (Sennrich et al., 2017) with attention (Bahdanau et al., 2014). For `SAC BLEU`, Q_θ duplicates the structure of the former, but encodes the reference instead of the source sentence to mimic inputs to the actual BLEU function.

We first pretrain the actor and then pretrain the critic, before the actor-critic training. The pretraining of actors is done until convergence according

to the early stopping criteria of 10 epochs wrt. to the MLE loss. We have also found that our critics require much less pretraining (3-5 epochs as compared to 10-20 epochs in general for AC architectures with the MSE loss). Also, to prevent divergence during the actor-critic training, we continue performing MLE training using a smaller weight λ_{mle}. We set α to 0.01. Following Haarnoja et al. (2018a), we rescale the reward to the value inverse to α. Note that we did not find it useful to add to SAC the smoothing objective minimising variance of Q-values (Bahdanau et al., 2016; Dai et al., 2018). We presume that the double Q-learning significantly contributes to the stability of the network and additional smoothing is not required.

For `SAC unsuper`, we parameterise q_δ by a 2-layer feed-forward neural network, which takes the source as encoded by the actor and a_t and outputs $q_\delta(z|\mathbf{x}, a)$. We set z to take one of 4 values.[2] For this unsupervised setting, we do not train a Q-function. We instead operate in the oracle mode and following (Keneshloo et al., 2018) define true Q-value estimates and use it to update our actor. Details on training are given in Appendix A. We use `pysimt` (Caglayan et al., 2020) with PyTorch (Paszke et al., 2019) v1.4 for our experiments.[3]

4.3 Evaluation

We use the standard set of MT evaluation metrics: BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014) and TER (Snover et al., 2006). We perform significance testing via bootstrap resampling using the `Multeval` tool (Clark et al., 2011).

For the lexical translation task, we measure the **Lexical Translation Accuracy (LTA)** score (Lala et al., 2019). The score provides an average estimation of how accurately the words have been translated. For each ambiguous word, a score of +1 is awarded if the correct translation of the word is found in the output translation; a score of 0 is assigned if a known incorrect translation is found, or none of the candidate words are found in the translation. We also propose a metric that not only rewards correctly translated ambiguous words, but also penalises words translated with the wrong sense: the **Ambiguous Lexical Index (ALI)**. ALI assigns -1 for wrong translations in the given context, whereas LTA simply does not reward them.

5 Results

5.1 Comparison to state-of-the-art

We first compare our SAC models against the MLE model (baseline) and ERAC[4] (state-of-the-art – SOTA) both trained and tested on the **Multi30K** data (Table 1). Compared to SAC, ERAC differs in that it uses the on-policy setting (i.e., using samples collected in real time). Our SAC algorithm is an off-policy algorithm and uses samples from the memory to promote generalisation.

We clearly observe the tendency of ERAC models to perform better on the more in-domain **2016** data (+1.9 BLEU, +1.6 METEOR, -0.8 TER

---

[2] This hyperparameter is tuned on the validation set. It typically varies from 2 to several hundreds in the related work (Haarnoja et al., 2018b).

[3] https://github.com/ImperialNLP/pysimt

[4] For ERAC, we present results that we reproduced ourselves using the code publicly provided by the authors. We had to perform several modifications to this code to make it conform recent deep learning framework software updates. The performance of this model is on pair with this reported by the authors.

against MLE for EN-FR) and the tendency of SAC BLEU models to outperform other models on more out-of-domain **2017** and **COCO** sets (+2.7 BLEU and +3.0 METEOR, -1.5 TER against ERAC on **COCO** for EN-DE).

SAC unsuper results are however worse than the baseline and SOTA. We focus thus on the investigation of SAC BLEU and come back to SAC unsuper in Section 5.2.

To further confirm our hypothesis that SAC reduces overfitting and performs better on the out-of-domain data, we train our models on the **IWSLT 2014** train set and test on the out-of-domain **Multi30K** test sets (in the reverse direction, German into English, Table 2).

We observe similar performance for complete set of outputs (including sentences with UNK tokens) for MLE and SAC BLEU. If the lines with UNK words are not taken into account,[5] we observe an improvement for the **2016** and **2017** test sets (+0.5 BLEU, +0.1 METEOR, -0.5 TER on average), and a much bigger improvement for the more out-of-domain **COCO** set (+2.5 BLEU, +0.3 METEOR, -2 TER on average). This confirms our hypothesis that SAC helps to reduce overfitting.

Finally, we compare SAC to the SOTA AC-base RL architectures, namely ERAC and AC, on the **IWSLT 2014** set that is commonly used for this task. Compared to SAC, AC differs in that it does not use entropy regularisation. We also provide the performance for the popular MIXER algorithm. Results are shown in Table 3.

In terms of the general performance, our SAC performs on pair with the MLE model. SAC BLEU even slightly lowers this score (-0.2 BLEU, -0.2 METEOR). We note that SAC BLEU results contain an increased count of UNK words as compared to MLE (+2.8%) This increased generation of UNK words due to the entropy regularisation is partially responsible for this similar performance. Another cause is that SAC does not overfit to the BLEU distribution of the target data.[6]

Model	BLEU	METEOR	TER

Bold highlights best RL results. MIXER, AC and ERAC scores were taken from original papers. ERAC (ours) indicates our results using the code provided in (Dai et al., 2018).

5.2 Translation of ambiguous words

To further investigate the effect of the unsupervised reward, we have evaluated SAC unsuper on the **MLT** dataset. Results are shown in Table 4. We calculate the scores on two conditions: **All Cases** takes into account all possible lexical translations; while for **Rare Cases**, only the instances where the gold-standard translation is not the most frequent translation for that particular ambiguous word. We observe that both SAC BLEU and SAC unsuper

---

[5] The original corpus pre-processing pipeline that we followed to increase comparability does not include subword segmentation. We take the intersection of hypotheses sentences across **Multi30K** test setups that contain no generated UNK token wrt. the **IWSLT 2014** vocabulary. Reference files may still contain the UNK token, we focus on the generated text here.

[6] We mean that the model would have a tendency to select certain words to simply boost BLEU rather than picking words to reflect the correct meaning.

Table 4: Performance of `SAC BLEU` on the **MLT** test sets (EN-FR, EN-DE). We report Ambiguous Words Accuracy: LTA and ALI. **Rare Cases** indicates the cases where the correct translation is *not* the most frequent translation in the training set.

outperform the MLE baseline across metrics in all setups except for the **COCO** EN-FR translation in Rare Cases, where MLE performs better. For `SAC BLEU`, this observation is also shown by general evaluation metrics BLEU, METEOR and TER on all **MLT** test sets (see Table 9 in Appendix).

Moreover, `SAC unsuper` is particularly successful when evaluated on **2016** and **2017** and outperforms both MLE and `SAC BLEU` across setups. This demonstrates the potential of the unsupervised reward function for the cases when we have to choose between possible translations for an ambiguous word (i.e., better exploration of the search space). BLEU reward, on the other hand, is more reliable when we have to adjust distributions to produce one single possible translation. Manual inspection of these `SAC unsuper` improvements confirmed their increased accuracy (see Table 5). For example, the ambiguous French source word 'hill' ('colline') is translated as 'pente'('slope') by both MLE and `SAC BLEU`, while only `SAC unsuper` produces the correct sentence: 'adolescent saute la *colline* 'hill' avec son vélo'.

5.3 Qualitative analysis

To get further insights into the general results, we also performed human evaluation of the outputs for MLE, `SAC BLEU`, and `SAC unsuper` using professional in-house expertise. This was done for **COCO** EN-FR and **2016** EN-DE as two sets with contrastive results in the lexical translation experiment.

For this human analysis, we randomly selected test samples (50 samples per language pair per group) with source words of different frequency in the training data: rare words (frequency 1) and other words (frequency ≥ 10). These other words are randomly chosen from the sentences that differ in their translation across setups. The resulting average frequency of those words is around 40 for both language pairs. A rank of quality (both fluency and adequacy together) is assigned by the human evaluator from 1 to 3, allowing ties. Following the common practice in MT, each system was then assigned a score which reflects how often it was judged to be better or equal to other systems (Bojar et al., 2017).

Results are in Table 6. We observe a tendency of `SAC BLEU` to do well on the translation of rare source words, but not so well on the translation of words in the middle frequency range (this observation is confirmed by the analysis of the frequency of output words, see Appendix A.5, see Table 10). Our unsupervised reward tends to increase the performance on more frequent words ('Other' in Table 6) by promoting their less common translations in the distribution, hence better translations for ambiguous words from our previous experiment. These ambiguous words are quite frequent, they potentially have multiple possible translations but only one correct translation in a given context.

6 Conclusions

We propose and reformulate SAC reinforcement learning approaches to help machine translation through better exploration and less reliance on the reward function. To provide a good trade-off between exploration and quality, we devise two reward methods in the supervised and dynamic unsupervised manner. The maximum entropy off-policy SAC algorithm mitigates the overfitting problem when evaluated in the out-of-domain space; both rewards introduced in our SAC architecture can achieve better quality for lexical translation of ambiguous words, particularly the rare senses of

EN-FR	source word	hill
	gold target word	colline

words. The formulation of the unsupervised reward and its potential to influence translation quality open perspectives for future studies on the subject. We leave the exploration of how those supervised and unsupervised rewards could be combined to improve MT for future work.

Acknowledgments

The authors thank the anonymous reviewers for their useful feedback. This work was supported by the MultiMT (H2020 ERC Starting Grant No. 678017) and the Air Force Office of Scientific Research (under award number FA8655-20-1-7006) projects. A Training Details

A.1 Hyperparameters

For the NMT RNN agent, the dimensions of embeddings and GRU hidden states are set to 200 and 320, respectively. The decoder's input and output embeddings are shared (Press and Wolf, 2017). We use Adam (Kingma and Ba, 2014) as the optimiser and set the learning rate and mini-batch size to 0.0004 and 64, respectively. A weight decay of $1e{-}5$ is applied for regularisation. We clip the gradients if the norm of the full parameter vector exceeds 1 (Pascanu et al., 2013). The four Q-networks are identical to the agent (see Table 7).

For the unsupervised reward setting, we use 2 two-layer feed-forward neural network (both dimensionalities are equal to 100). We use again Adam as the optimiser and set the learning rate and mini-batch size to 0.0001 and 64, respectively.

Hyper-parameters	
Pre-train Critic	
optimiser	Adam
learning rate	0.0003
batch size	64
τ (target net speed)	0.005
α (entropy regularization)	0.001
buffer size	1000
length penalty	0.0001
Joint Training	
optimiser	Adam
learning rate	0.0004
batch size	64
τ (target net speed)	0.005
α (entropy regularization)	0.001
buffer size	1000
length penalty	0.0001
λ_{MLE}	0.1

Table 7: Hyper-parameters for SAC training.

A.2 Training

We use PyTorch (Paszke et al., 2019) (v1.4, CUDA 10.1) for our experiments. We early stop the actor training if validation loss does not improve for 10 epochs, we pretrain critics for 5 epochs for the **Multi30K** datasets and for 3 epochs for the larger **IWSLT 2014**. We early stop the SAC training if validation BLEU does not improve for 10 epochs. For all the setups, we also halve the learning rate if no improvement is obtained for two epochs. On a single NVIDIA RTX2080-Ti GPU, it takes around 5-6 hours up to 36 hours to train a model depending on the data size and the language pair. The number of learnable parameters is about 7.89M for smaller Multi30K models and about for 15.64M for the bigger IWSLT model. All models were re-trained 3 times to ensure reproducibility.

A.3 Soft Actor-Critic Training Algorithm

We describe the main steps of SAC training in Algorithm 1.

Algorithm 1: Soft Actor-Critic.

```
Initialise parameters:
Q function: $\theta$;
Policy: $\phi$;
Unsupervised Reward: $\delta$;
Replay Buffer: $\mathcal{D} \leftarrow \emptyset$;
for each iteration do
    for each translation step do
        $a_t \sim \pi_\phi(a_t, s_t)$;
        $s_{t+1} \sim p(s_{t+1}|s_t, a_t)$;
        $\mathcal{D} \leftarrow \mathcal{D} \cup \{s_t, a_t, r(s_t, a_t), s_{t+1}\}$ ;
    end
    for each gradient step do
        $\theta_i \leftarrow \theta_i - \lambda_Q \nabla_{\theta_i} L(\theta_i)$ for $i \in \{1, 2\}$;
        $\phi \leftarrow \phi - \lambda_\pi \nabla_\phi J(\phi)$;
        $\alpha \leftarrow \alpha - \lambda_\pi \nabla_\alpha J(\alpha)$;
        $\theta_i \leftarrow \tau\theta_i + (1 - \tau)\bar{\theta}_i$ for $i \in \{1, 2\}$;
        if unsupervised reward then
            $\delta \leftarrow \delta - \lambda_z \nabla_\delta r(\delta)$;
        end
    end
end
```

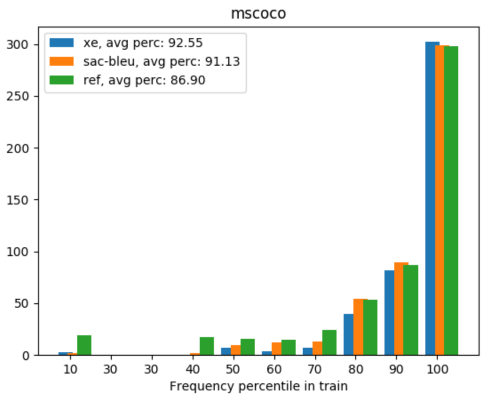

Figure 1: Training frequency for **COCO** words as translated by MLE and `SAC BLEU`. We also report reference frequencies.

the **IWSLT 2014** training set.[7] Table 8 shows language model perplexities on the Mutli30k test data. With respect to the **IWSLT 2014** model, **Multi30K** test sets are clearly very different from the training data. With respect to the Multi30K model, **2017** and **COCO** are more distant from the train partition than 2016 testset.

A.5 Analysis of distributions

We argue that the improvement over MLE can be partially attributed to a better handling of less frequent words. It has been shown that rare words tend to be under-represented in NMT (Koehn and Knowles, 2017; Shen et al., 2016). RL training with regularized entropy might mitigate this issue due to a better exploration of the action space. To illustrate this point, we compute the training frequency of the words generated by the NMT systems for the sentences where an improvement over MLE is observed. Figure 1 shows the training frequency percentiles for MLE and `SAC BLEU` English-French translations of the **COCO** testset. Reference frequencies are also provided for comparison. We observe that although both MLE and SAC contain more frequent words than the reference, this tendency is less pronounced for SAC. We relate this observation to the fact that our SAC outperforms MLE for the ambiguous word translation (Table 4) where the most frequent translation is not always the correct one.

Abstract

Computational modelling of political discourse tasks has become an increasingly important area of research in natural language processing. Populist rhetoric has risen across the political sphere in recent years; however, computational approaches to it have been scarce due to its complex nature. In this paper, we present the new *Us vs. Them* dataset, consisting of 6861 Reddit comments annotated for populist attitudes and the first large-scale computational models of this phenomenon. We investigate the relationship between populist mindsets and social groups, as well as a range of emotions typically associated with these. We set a baseline for two tasks related to populist attitudes and present a set of multi-task learning models that leverage and demonstrate the importance of emotion and group identification as auxiliary tasks.

1 Introduction

Political discourse is essential in shaping public opinion. The tasks related to modelling political rhetoric have thus been gaining interest in the natural language processing (NLP) community. Many of them focused on automatically placing a piece of text on the left-to-right political spectrum. For instance, much research has been devoted to detecting bias in news sources (Kiesel et al., 2019) and predicting the political affiliation of politicians (Iyyer et al., 2014) and social media users, more generally (Conover et al., 2011; Pennacchiotti and Popescu, 2011; Preoţiuc-Pietro et al., 2017). Other works conducted a more fine-grained analysis, identifying the framing of political issues in news articles (Card et al., 2015; Ji and Smith, 2017). Recently, the field has also turned attention towards modelling the spread of political information in social media, such as detecting fake news or political perspectives (Li and Goldwasser, 2019; Chandra et al., 2020; Nguyen et al., 2020).

Populism has taken the spotlight in political communication in recent years. Various countries around the globe have experienced a surge of populist rhetoric (Inglehart and Norris, 2016) in both the public and political space. Despite this, approaches to computational modelling of populist discourse have so far been scarce. Due to the flexible nature of populism, annotating populist rhetoric in text is challenging, and the existing research in this area has relied on small-scale analysis by experts (Hawkins et al., 2019). In this paper, we present a new dataset[1] of *Reddit* comments annotated for populist attitudes and the first large-scale computational models of this phenomenon. We rely on research in social- and behavioural sciences (e.g., political science and social psychology) to operationalise a definition of populism and an annotation procedure that allows us to capture and generalise the crucial aspects of populist rhetoric at scale.

In social sciences, populism is essentially described as a not fully developed political ideology and a series of background beliefs and techniques (Aslanidis, 2016), traditionally centred around the *Us vs. Them* dichotomy. In one of the first attempts to fully define populism (Mudde, 2004), it is described as a thin ideology around the distinction between 'the people', which includes the 'Us', and 'the elites' describing the 'Them', and with politics being a tool for 'the people' to achieve the common good or 'the popular will' (Kyle and Gultchin, 2018; Rodrik, 2019). Through different platforms, populism uses this rhetoric that revolves around social identity (Hogg, 2016; Abadi, 2017) and the *Us vs. Them* argumentation (Mudde, 2004). While right-wing populism tends to be characterised by *fear*, *resentment*, *anger* and *hatred*, left-wing populism is associated with *shame* and *guilt* (Otjes and

April 19 - 23, 2021.

Louwerse, 2015; Salmela and von Scheve, 2017a). Moreover, emotions have been shown to be crucial in shaping public opinion more generally (Marcus, 2002, 2003; Demertzis, 2006; Rico et al., 2020).

The design of our annotation scheme and the dataset are inspired by this research, particularly the link between populist rhetoric and both social identity and emotions. Our dataset consists of comments posted on Reddit that explicitly mention a social group. We collect the comments posted in response to news articles across the political spectrum. Through crowd-sourcing, we annotate supportive, critical and discriminatory attitudes towards the group, as well as a range of emotions typically associated with populist attitudes. At the same time, given the relevance of news in the spread of such mindsets, we investigate the relationship between news bias and the *Us vs. Them* rhetoric. Our data analysis reveals interesting interactions between populist attitudes, specific social groups and emotions.

We also present a series of computational models, automatically identifying populist attitudes, based on *RoBERTa* (Liu et al., 2019). We experiment in a multi-task learning framework, jointly modelling *supportive* vs. *discriminatory* attitudes towards a group, the identity of the group and emotions towards the group. We demonstrate that joint modelling of these phenomena leads to significant improvements in detection of populist attitudes.

2 Related work

2.1 Psychology research on populism

Populist rhetoric revolves around social identity (Hogg, 2016; Abadi, 2017; Marchlewska et al., 2018; Bos et al., 2020) and the *Us vs. Them* argumentation (Mudde, 2004). Social identity explores the relations of individuals to social groups. Turner and Reynolds (2010) study the evolution of research into social identity and explain the *Us vs. Them* as an inter-group phenomenon, exposing its relation to social identity where the “self is hierarchically organised and that it is possible to shift from intra-group (‘we’) to inter-group (‘us’ versus ‘them’) and vice versa.”

Emotions constitute a part of the populist rhetoric and have been essential for information processing and the formation of (public) opinion among citizens (Marcus, 2002; Götz et al., 2005; Demertzis, 2006). While social identity and socio-economic factors have been considered primary indicators of populism’s growth (Rooduijn and Burgoon, 2018), emotional factors have lately become a focus within empirical studies, particularly regarding the reactions and spread of populist views (Hameleers et al., 2017). Specific appraisal patterns have characterised emotions, i.e. an adverse event for which one blames the other is felt as anger - a pattern of appraisals is referred to as *Core Relational Themes* (Smith and Lazarus, 1993; Lazarus, 2001), which are the central (therefore core) harm or benefit that underlies each of the negative and positive emotions (Smith and Lazarus, 1993; Moors et al., 2013). Latest attempts to scrutinise populism from the communication science and social psychological perspective have described populist communication and language (Abadi et al., 2016; Rico et al., 2017) and demonstrated its operationalisation through experimental research (Wirz et al., 2018) as being successful in inducing emotions (Bakker et al., 2020). According to the concept of media populism (Krämer, 2014; Mazzoleni and Bracciale, 2018), media effects can further evoke hostility toward the perceived ‘elites’ and (ethnic/religious) minorities, as it contributes to the construction of social identities, such as in-groups and out-groups (i.e., *Us vs. Them*).

2.2 Modelling political discourse in NLP

Handcrafted features such as word-frequency (Laver et al., 2003) were initially the base of NLP approaches to model political data. Thomas et al. (2006) introduced the *Convote* dataset of US congressional speeches, and applied an *support-vector machine* (SVM) classifier leveraging discourse information to identify policy stances in it. One of the first uses of neural networks on political text was the work of Iyyer et al. (2014), who used a *recurrent neural network* (RNN) to identify the party affiliation on the *Convote* dataset. Li and Goldwasser (2019) detected the political perspective of news articles using a *long short-term memory* (LSTM) and a *graph convolutional network* (GCN) on user data from Twitter. Other research investigated the *framing effect* in news articles, which is a mechanism that promotes a particular perspective (Entman, 1993). Card et al. (2015) presented the *Media Frame Corpus*, which explores policy framing within news articles. Ji and Smith (2017) developed a discourse-level Tree-RNN model to identify the framing in each article, by using this corpus dataset. Huguet Cabot et al. (2020) addressed this task by leveraging emotion and metaphor detection in an MTL setup. Other works have also explored sentence-level framing (Johnson et al., 2017; Hartmann et al., 2019).

Hate speech detection is not limited to the analysis of political discourses. However, it is related to exposing populist rhetoric in digital communication (Meret and Pajnik, 2017; Estelles and Castellví Mata, 2020). Several NLP approaches (Mishra et al., 2020), as well as recent shared tasks (Zampieri et al., 2019, 2020) have been proposed to tackle this widespread problem.

While political bias and framing have been widely explored, research on modelling populist rhetoric is still in its nascent stages. Previous work in this area focused on a general description of populism to determine whether a particular text, such as a party manifesto or a political speech contains what is understood as populist rhetoric or attitudes (Hawkins, 2009; Rooduijn and Pauwels, 2011; Manucci and Weber, 2017). Manual annotation was necessary to perform this analysis, often by experts, which also limited the scope and amount of data used, while the resulting datasets are not sufficiently large to train current machine learning models. Furthermore, the description of what constitutes populist rhetoric is still diffuse and covers many different aspects. Hawkins et al. (2019) used holistic grading to assess whether a text is populist or not, to later determine the degree of 'populism' of individual political leaders, thus creating the only existing dataset of populist rhetoric, the *Global Populist Database*.

3 Dataset creation

Data collection. By annotating Reddit comments that refer to a social group, we monitored how online discussions target them and whether the text showed a positive or negative attitude towards that social group, ranging from support to discrimination. While this process did not ensure capturing the complexity behind the *Us vs. Them* rhetoric, we detected comments directed at certain groups (out-groups) and the attitude towards them within an online community (in-group). We restricted this to six specific groups that populist rhetoric has targeted as an out-group, **Immigrants**, **Refugees**, **Muslims**, **Jews**, **Liberals** and **Conservatives**. Current research has shown these groups are common targets of populism in the US, UK and across Europe (Inglehart and Norris, 2016; Mudde and Kaltwasser, 2018). Note that to annotate sufficient comments per group we limit the current work to six groups, which is by no means a complete list of targeted groups. We encourage future research to broaden the scope of groups covered.

We chose to extract data from Reddit, (1) due to its availability through the *Pushshift* repository[2] (Baumgartner et al., 2020) and the *Google Bigquery* service, (2) its social identity dynamics (in-group vs. out-group) as close-nit communities created by sub-Reddits, (3) its nature as a social news aggregation platform, and (4) that it has been shown to encourage toxic communication between users and hate speech towards social groups (Massanari, 2017; Salminen et al., 2020; Munn, 2020). To filter the data for annotation, we followed several steps. (1) We identified submissions in Reddit which shared a news article from a news source listed at the *AllSides* website[3], (2) we extracted comments which are direct replies to the submission where both the news article title and the comment match any of the keywords for our groups. Keywords were devised using online resources from the *Anti Defamation League*[4] as well as by consulting social scientists. The full list of keywords can be found in Appendix A Table 4. (3) We selected comments with a minimum of 30 words and a maximum of 250 words, and sampled from specific periods during which each group was actively discussed on Reddit. See Appendix A Table 3 for details. (4) We removed comments that contained keywords from multiple social groups to make the annotation process more straightforward. (5) We randomly sampled 300 comments per group and news source bias according to *AllSides* (left, centre-left, centre, centre-right, right), resulting in a total of 9000 Reddit comments. Note that the bias is not directly related to individual comments, but rather to the news article the comment responded to.

Annotation procedure. To capture the *Us vs. Them* rhetoric, we asked: **What kind of language does this comment contain towards _*group*_?**, where _*group*_ corresponds to the specific social group that comment refers to. Respondents had four options: **Discriminatory**, **Critical**, **Neutral** or **Supportive**. An extended description and an example as presented to annotators can be found in Appendix A.2, and Figure 5. We asked anno-

[3] https://www.allsides.com/unbiased-balanced-news

[4] https://www.adl.org/

tators a second question to capture the emotions expressed towards the group in the same comment. We extended Ekman's model of 6 *Basic Emotions* (Ekman, 1992) to a 12-emotions model, which includes a balanced set of positive and negative sentiments. Specifically, we included emotions previously shown to be associated with populist attitudes (Demertzis, 2006). We also provided the annotators with a brief description of each emotion, inspired by the concept of *Core Relational Themes* (Smith and Lazarus, 1990). The positive emotions are **Gratitude**, **Happiness**, **Hope**, **Pride**, **Relief** and **Sympathy**, and the negative emotions are **Anger**, **Fear**, **Contempt**, **Sadness**, **Disgust** and **Guilt**. Detailed descriptions can be found in Appendix A.2 along with an example 6. The annotation was conducted on *Amazon Mechanical Turk* (MTurk) and its framework can be accessed here.

Annotation reliability. Once the MTurk annotation was completed, we deployed the *CrowdTruth 2.0* toolkit (Dumitrache et al., 2018) to assess the quality of annotations and to identify unreliable workers. *CrowdTruth* includes a set of metrics to analyse and obtain probabilistic scores from crowdsourced annotations. *Worker Quality Score* (WQS) is a metric that measures each worker's performance, by leveraging their agreement with other annotators and the difficulty of annotation. The *Media Unit Annotation Score* (UAS) is given for each comment and possible answer, indicating the probability with which each option could be the gold label. Finally, *Media Unit Quality score* (UQS) describes the quality of annotation for each comment. We removed annotations by workers with a WQS lower than 0.1 and those with high disagreement after manually checking their responses, and recomputed the metrics. We removed comments left with only one annotator and comments with a UQS lower than 0.2. This resulted in 4278 comments with 5+ annotators, and 2564 comments with less, which constitute our final dataset.

Following the same procedure as Demszky et al. (2020), we computed inter-rater correlation (Delgado and Tibau Alberdi, 2019) by using Spearman correlation. We took the average of the correlation between each annotator's answers and all other annotators' average answers that labelled the same items. We obtain a range between 0.5 and 0.13 per emotion. The lowest agreement is for *Relief* (0.13), in line with Demszky et al. (2020), where the lowest value for correlation agreement being 0.16, and 0.17 for *Relief*. The full distribution can bee found in Appendix A.3 Figure 7.

Of course Dems are stealing the elections. They are playing by a different set of rules - being ruthless and violent. Dems take no prisoners and show no mercy to their enemies. The sooner GOP realizes it, the better. Because we have to up our game. If things go this way, we have only one way to save this country - Martial Law and kick every single liberal out!

Label	**UsVsThem**	**Group**	**Emotions**
Discriminatory	1	Liberals	Contempt, Disgust & Fear

You do realize it's sad to celebrate the US cutting the number of refugees down, right? These are people who come here seeking a safe haven from the violence or despair of their home countries, and we're turning them away.

Label	**UsVsThem**	**Group**	**Emotions**
Supportive	0	Refugees	Sympathy

Figure 1: Two samples of our *Us Vs. Them dataset.*

4 Data analysis

4.1 UsVsThem scale

For the *Us vs. Them* question, we aggregated the answers into a continuous scale. To obtain a score for each comment, we computed the *CrowdTruth* UAS for each of the labels assigned to it and then take a weighted sum. We assigned the weight of 0 to the *Supportive* label, $1/3$ to *Neutral*, $2/3$ to *Critical* and 1 to *Discriminatory*. The frequency distribution of comments on this scale can be seen in Appendix A.4 Figure 8. From now on, we will refer to it as the *UsVsThem* scale.

The scale is skewed, with an overall mean of 0.551 ± 0.265. Although our data selection was random across the selected news sources and groups, there are more comments with *negative* attitudes towards selected groups than positive or neutral ones due to its nature and our keyword selection.

We performed a two-way ANOVA (*Analysis of Variance*) test (Fujikoshi, 1993) on news bias and social groups as independent variables and the *UsVsThem* scale as the dependent variable to see whether the interactions between groups and news bias are significant. One-way tests show statistical significance. Interestingly, there was a statistically significant interaction between the effects of social groups and bias on the *UsVSThem* scale, $F(1, 20) = 12.33, p < 0.05$. Values can be found in Appendix A.4 Table 5. Therefore, we explored the interaction between them and the influence of

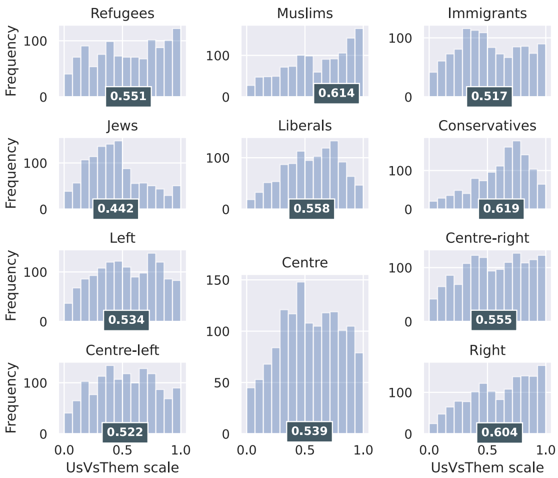

Figure 2: Comment frequency distribution on the *UsVsThem* scale per social group and news source bias. The mean for the scale is shown at the x axis.

news bias on how each group is perceived. We performed a *Tukey HSD test* to check for significance between means in the *UsVsThem* scale.

Social groups. There were differences between groups in terms of the *UsVsThem* scale when looking at the comment frequency distributions in Figure 2. For *Refugees*, the distribution was relatively flat as they received a similar amount of positive and negative attitude comments. *Immigrants* showed a similar distribution with fewer comments in the higher end, i.e. the group received less discrimination than *Refugees*. Despite the two share many inherent similarities, these differences may be explained by negative media coverage of *Refugees* portrayed as a threat and being attributed to negative attitudes. *Muslims* received a higher amount of discriminatory comments than any other group. On the other hand, *Conservatives* showed a similar mean, due to a very high amount of critical comments. *Liberals* also received a relatively high amount of critical comments. Both share moderately low tails, as they received less support and discrimination. Finally, *Jews* showed lower critical and discrimination values, with most values around *Neutral*, having the lowest mean value of all social groups. These variations translate into a significant ($p < 0.05$) difference between the means of each group, except for *Conservatives* and *Muslims*, and for *Liberals* and *Refugees*.

News source bias. In this case, the bias was not directly associated with the comment itself. However, differences in the distribution of comments and the out-group attitudes based on the original article's bias can be observed, as shown in Figure 2. Moreover, means increased from the *centre-left* to the *right* bias. Interestingly, there was no symmetry at the *centre* bias, contrary to the *Horseshoe Theory* (Hanel et al., 2019), which argues both ends of the political spectrum closely resemble one another. In terms of significant differences, all biases were significantly different from the *right* bias ($p < 0.05$), and there was a significant difference between *centre-left* and *centre-right* ($p < 0.05$). The remaining groups showed no significant difference.

Groups and news source bias. In line with the above-mentioned bias effect, there was almost always a significant difference between *right* and *centre-right* bias and the rest for each group. Only *right* bias showed a distinct high value and a negative attitude towards *Immigrants*, which even exceeds those towards *Refugees*. With the exception of the attitude towards *Conservatives*, *centre*, *centre-left* and *left* showed lower degrees of negative attitude towards any of the groups. Full results can be seen in Appendix A.4 Table 6 and Figure 10.

4.2 Emotions

Instead of using *CrowdTruth* for emotions, we considered an emotion as being present in the comment provided that at least 1/4 of annotators selected it. In case more than half of annotators marked that comment as *Neutral*, it was labelled as *Neutral*. This way, a comment can contain more than one emotion, except for *Neutral*. Unless specified otherwise, in this subsection *Neutral* refers to emotionally neutral.

In Figure 3 we present the correlations between the values for each emotion dimension and the *UsVsThem* scale across all comments, in the same fashion as Demszky et al. (2020). We show the hierarchical relations at the top, demonstrating which emotions interact more strongly with each other. The frequency of emotions in our dataset is as follows: *Anger* 1724, *Contempt* 2538, *Disgust* 1843, *Fear* 1136, *Gratitude* 70, *Guilt* 170, *Happiness* 59, *Hope* 307, *Pride* 174, *Relief* 37, *Sadness* 122, *Sympathy* 1139, *Neutral* 2094.

Emotions and the *UsVsThem* scale. We were interested in the interaction between emotions and social identity by exploring how the *UsVsThem* scale is shaped for each emotion. Not surprisingly, comments with negative emotions showed a higher value on the *UsVsThem* scale and a high correlation

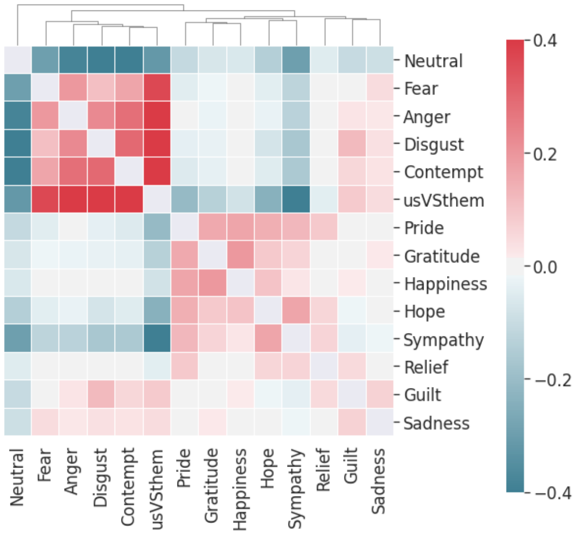

Figure 3: Correlation heat-map for different emotions.

with it, except for *Guilt* and *Sadness*. *Contempt* showed the strongest correlation, while *Anger* and *Fear* showed a higher proportion of *Discriminatory* comments. *Guilt* and *Sadness*, on the other hand, are characterised by a lower amount of comments in the *Discriminatory* range. In line with these results, the *UsVsThem* scale had a negative correlation with *Sympathy* and *Neutral* comments, and while *Sympathy* was the most frequent positive emotion, other emotions displayed a very similar relation to the *UsVsThem* scale. These results are visualised in Figure 3 including the *UsVsThem* scale and the distributions are summarised in Figure 9 in Appendix A.4.

Emotions and groups. We used a two-sided proportion z-test to check for significant differences since emotions are discrete variables. More than 25% of comments towards *Muslims* and *Refugees* showed *Fear*, with no significant difference between the two, followed by *Immigrants* at 21.5% and other groups at less than 10%. Another notable finding is that *Contempt* (47.7%) and *Disgust* (44.4%) were significantly higher towards *Conservatives*, particularly the latter, which for other groups never exceeded 30% of comments. *Sympathy* for *Liberals* (6.5%) and *Conservatives* (6.9%) was significantly lower when compared to other groups. *Hope* was present in a significantly higher number of comments for *Liberals* (7.9%). The values for all proportions can be found in Appendix Appendix A.4 Table 7.

Emotions and bias. Not many differences between biases were found. Most salient was the *right* bias showing a higher value in all negative emotions, significantly for *Anger* (31.5%), *Contempt* (43.4%) and *Fear* (21.9%). All proportion values can be found in Appendix A.4 Table 8.

5 Modelling populist rhetoric

5.1 Main tasks

Our models' main focus was to assess to which degree a social group is viewed as an out-group and whether in a negative or discriminatory manner. Our annotation procedure provided a scale from *Supportive* to *Discriminatory* for each comment. While this scale is artificial and highly dependent on our task's context, it provides a good indication of how strongly a social group is targeted in social media comments.

Regression *UsVsThem*. In our models, we explored two different main tasks. The first task was to predict the values on the *UsVsThem* scale in a regression model. This scale provides a score for each comment, which illustrates the attitude towards a social group mentioned in the comment ranging from *Supportive* (closer to 0) to *Discriminatory* (closer to 1). Values in between depict an intermediate attitude, *Neutral* lies at $1/3$, and *Critical* at $2/3$. By predicting the score, we modelled the out-group attitude of each comment. We used 33% of the data as the test set, and 13.4% as the validation set.

Classification *UsVsThem*. Our second task was to classify each comment in a binary fashion as whether the comment shows a negative attitude towards a group, i.e., *Critical* or *Discriminatory*, or not, i.e., *Neutral* or *Supportive*. This task resulted in a relatively balanced dataset, with 56% of *Critical* or *Discriminatory* comments. We used the same splits as before.

5.2 Auxiliary tasks

Emotion detection. Interactions between populist rhetoric and emotions have been explored in political psychology through surveys and behavioural experiments (Fischer and Roseman, 2007; Tausch et al., 2011; Salmela and von Scheve, 2017b; Redlawsk et al., 2018; Rollwage et al., 2019; Nguyen, 2019; Roseman et al., 2020). This is consistent with our findings in section 4 and further motivates modelling emotions in the context of populist rhetoric. For each comment, emotions were annotated as a Boolean vector. For our task, some emotions were rarely annotated or only present alongside more frequent ones. They increased the difficulty of the task while not providing relevant information. To simplify the auxiliary task, we considered the 8 most common emotions, *Anger, Contempt, Disgust, Fear, Hope, Pride, Sympathy* and *Neutral*.

Group identification. In the work of Burnap and Williams (2016), types of hate speech were differentiated based on race, religion, etc., and models were trained specifically on those categories. In ElSherief et al. (2018), data-driven analysis of online hate speech explored in profundity the differences between *directed* and *generalised* hate speech, and Silva et al. (2016) analysed the different targets of hate online. In our case, the *Us vs. Them* rhetoric metric showed significant differences for each group as we have seen in the previous section. Therefore, we hypothesised that the information bias (Caruana, 1993) the group identification task provides will help understand the *Us vs. Them* rhetoric aimed at the different social groups, which motivated its role as an auxiliary task.

5.3 Model architecture

We used the *Robustly Optimized BERT Pretraining Approach* (RoBERTa) (Liu et al., 2019) in its BASE variant as provided by Wolf et al. (2019).

Multi-task learning. In all setups, tasks shared the first eleven *transformer* layers of *RoBERTa*. The final 12th layer was task-specific, followed by a classification layer that used the hidden representation of the <s> token, to output a prediction. We used scheduled learning, where the losses of each task are weighted and changed during training. We also experimented with a three-task MTL model where the two auxiliary tasks are learned simultaneously.

We assigned three different loss weights associated with each task, λ_m for the main task, either regression or binary classification; λ_e for emotion detection; λ_g for group identification. For MTL with one auxiliary task, $\lambda_m + \lambda_e = \lambda_m + \lambda_g = 2$, while for the three-task MTL: $\lambda_m + \lambda_e + \lambda_g = 3$.

Regression *UsVsThem*. We used *Mean Squared Error* loss with a sigmoid activation function for the main task. For emotion identification as the auxiliary task, we used *Binary Cross-Entropy* loss, and for the group identification, we used *Cross-Entropy* loss, both with sigmoid activation. For all MTL models, there was a warm-up period of ω epochs, after which the weight is changed to $\lambda_g = 10^{-2}$ and $\lambda_e = 10^{-5}$, and $\lambda_e = \lambda_g = 10^{-5}$ for the three-task setting.

Classification *UsVsThem*. We used *Cross-Entropy* loss with a sigmoid activation function for the main task. The remaining tasks were kept the same as with the Regression case above. For all MTL models, there was a warm-up period of ω epochs, after which the weight was changed to $\lambda_g = 10^{-2}$ and $\lambda_e = 10^{-2}$, and $\lambda_e = \lambda_g = 10^{-5}$ for the three-task setting.

5.4 Experimental setup

Regression *UsVsThem*. We report model performance in terms of Pearson correlation coefficient (R). We found the optimal STL hyperparameters using the validation set: a learning rate of $3e-05$, a lineal warm-up period of 2 epochs and dropout of 0.15. The batch size used was 128. These hyperparameters were kept constant across our experiments for the regression *UsVsThem* task. For the emotion detection MTL setup, $\lambda_e = 0.15$ and $\omega = 8$. For the groups MTL, $\lambda_g = 0.15$ and $\omega = 5$. For the three-task MTL model we obtained optimal validation performance by setting $\omega = 8$ and both $\lambda_g = \lambda_e = 0.073$, which was the equivalent of $\lambda_g = \lambda_e = 0.05$ for the two-task MTL.

Classification *UsVsThem*. Similarly, we ran a grid-search to find the best hyperparameters for the classification setup. For the STL model, we obtained a learning rate of $5e-05$, a warm-up of 2 epochs and an extra dropout of 0.2. For emotions-MTL, $\lambda_e = 0.2$ and $\omega = 8$. For the groups-related MTL, $\lambda_g = 0.25$ and $\omega = 5$. For the three-task MTL, $\lambda_e = 0.95$, $\lambda_g = 0.25$, and $\omega = 8$. For both regression and classification, we report performance averaged over 10 different seeds.

5.5 Results

Results are presented in Table 1. We find that MTL outperforms STL in both versions of our task.

Regression *UsVsThem*. The STL baseline showed a 0.545 Pearson R to the gold score. When emotion identification was used as an auxiliary task, the performance increased by almost one point, to 0.553. The groups MTL setup showed a higher increase, up to 0.557. Both improvements

	STL	MTL, Emotion	MTL, Group	MTL, Emotion & Group
Pearson R	0.545 ± 0.005	$\mathbf{0.553 \pm 0.009}$	$\mathbf{0.557 \pm 0.012}$	$\underline{\mathbf{0.570 \pm 0.009}}$
Accuracy	0.705 ± 0.006	0.710 ± 0.009	0.711 ± 0.007	$\mathbf{0.717 \pm 0.004}$

Table 1: Results for the *Us vs. Them* rhetoric as regression and classification tasks. Significance compared to STL is bolded ($p < 0.05$). Significance compared to two-task MTL is underlined ($p < 0.05$). Average over 10 seeds.

were significant compared to the STL model, using the Williams test (Williams, 1959). Perhaps all the more interesting is that the three-task MTL model achieved the highest performance, even without its hyperparameters being specifically tuned as with the other setups. It resulted in a Pearson R of 0.570, i.e. over 2 points performance increase over STL, a statistically significant improvement over both STL and the remaining two MTL approaches.

Classification *UsVsThem*. Although not shown in the table, the accuracy baseline for a majority class classifier would be 0.550. All models highly surpassed that, with the real baseline set by the STL setup achieving a 0.705 accuracy. Results for the MTL approaches were similar to what we observed in the regression task. Emotion-MTL increased performance by half a point, to 0.710, as did group-MTL, with 0.711. The best performing model was again the three-task MTL, at 0.717, yielding a statistically significant improvement over STL, using the permutation test.

5.6 Analysis

Qualitative and error analysis. We selected comments with higher values on the scale where MTL improved the STL baseline predictions for the regression task. Comments with high emotion valence were better predicted by models that included emotion identification. Comments that had group-specific rhetoric with references to (derogatory) terms such as ‘illegal aliens’ were better predicted by models that incorporated group identification (see the first example in Table 2).

The standard deviation of the difference between the STL and the three-task predictions was just 0.055. This means that MTL helped capture nuanced information that improved prediction; however, comments with high squared error for STL still showed similar behaviour for MTL models. This aspect is shown in Appendix A.5 Figure 11. All models’ squared error showed a pair-wise Pearson correlation higher than 0.92. This observation prompted us to investigate comments with a high squared error. We identified three different sources. (1) **Comments with emotionally charged language**, slurs, or insults, which may often be associated with a more negative attitude towards a group, were mispredicted due to not being negative towards such group or being used ironically or satirically. (see second example in Table 2). (2) **Reference to multiple groups**: we removed comments that included keywords from similar groups, however it was impossible to account for all the terms that may refer to other groups. Hence, there are comments for which the prediction seems to be about a target different than the one at annotation time (see the third example in Table 2). More examples can be found in Appendix A.5 Table 9. (3) **Annotation error** is expected in any crowd-sourced annotation. While these were not as frequent as to pose a problem during training, they did occur as incorrect model predictions that can mistakenly decrease performance.

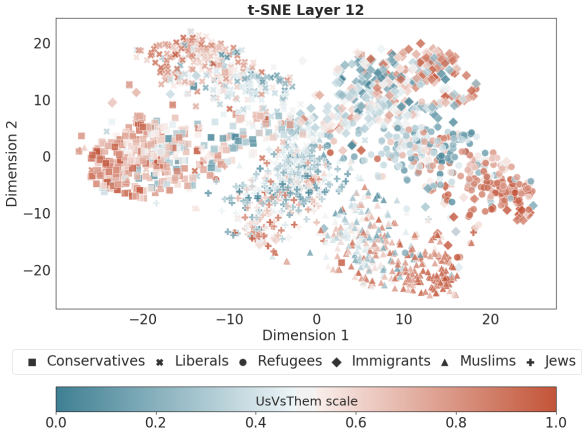

Figure 4: Three-task MTL main task specific layer.

Analysis of model representations. Our qualitative analysis showed that auxiliary tasks had a positive effect on predictions. Still, it cannot explain how the model changes its underlying structure and Reddit comments’ encoding. We explored how auxiliary tasks affected how the network encodes information through its layers to get a better understanding. We used *t-Distributed Stochastic Neighbour Embedding* (t-SNE) (van der Maaten and Hinton, 2008), a stochastic technique for dimension-

n	**Reddit Comment**
1	Does anyone else think it's absurd that we have Muslims serving in our congress? Literal foreign agents acting as if they hold the interests of the country and its people at heart? They never talk about the will of the people. It's always some bullshit about how white men (who founded and built this country) are evil and we need to let in more 3rd worlders who want to bomb and kill us. This is literal clown world tier nonsense.
2	You proud of yourselves, making 3 year olds represent themselves in immigration court? You fucking proud of that insanity? All for the sake of keeping out a gang that has already been in America for a long time, meanwhile regular home grown white kids are murdering dozens of their own classmates but goddam, at least they we're legal, amirite
3	Conservatives have every right to revolt. If we don't get our way we will destroy the country. I hope the left keeps pushing us to provoke a civil war. Or maybe Commiefornia should secede. Maybe that's the best thing that can happen, a complete break up. That way we can have our ethnostate, and the left can have their degenerate cesspool without us paying taxes for it. The US is dead anyway. It's time to burn this diverse shithole to the ground. It will be the ultimate proof that diversity doesn't work.

	Label	**MTL, E. & G.**	**MTL, Emo.**	**MTL, Groups**	**STL**	**Group**	**Emotions**

3	0.071	0.729	0.773	0.747	0.8	Conservatives	Hope & Pride

Table 2: Examples of predictions for comments. Predictions are averages over 10 seeds for each model.

ality reduction focused on high dimensional data visualisation. We used it to visualise the hidden representations of the test set comments in-between *transformer* layers across the network. We present the results for both STL and the three-task MTL in Appendix A.5 Figures 12 and 13, where for both the first layers showed some structure not related to the tasks at hand. As we were using pre-trained weights from *RoBERTa*, this could be explained by the first layers modelling lower-level language characteristics as shown empirically in Tenney et al. (2019), where probing mechanisms indicate early layers being more relevant for tasks such as *POS tagging*. For STL, the last layers showed the *UsVsThem* scale continuously in the y axis. Once we introduced the auxiliary tasks of group identification and emotion classification differences in the last layers were exacerbated. For three-task MTL the last layers showed clusters for each social group, and related groups were closer together, such as *Refugees* and *Immigrants*, or *Liberals* and *Conservatives*. We also observe a radial distribution with highly emotional comments further away from the centre. Comments with very distant values on the scale (*Discriminatory* and *Supportive*) were closer together than with those in the mid-range (*Neutral* and *Critical*) as seen in Figure 4 and Appendix A.5 Figure 15. While paradoxical, our interpretation is that the model leverages the valence of emotion, where *Discriminatory* and *Supportive* comments are more loaded with emotion. This leads to a better performance of MTL compared to STL. This idea is supported by the distribution of emotions on the last layer, where emotionally neutral comments are closer to the centre of the plot, while more emotionally charged comments radially increase, visualised in Appendix A.5 Figure 14. In Appendix A.5 Figures 16 and 17 we present the emotion distribution for the group and emotion-specific layers, respectively.

6 Conclusions

We presented a new, large-scale dataset of populist rhetoric and the first series of computational models on this phenomenon. We have shown that joint modelling of emotion and populist attitudes towards social groups enhances performance over the single-task model, further corroborating previous research findings in various social sciences. Future work may deploy social information (e.g., Twitter) or explore the interactions of populist attitudes and the political bias of news articles as provided in our *Us Vs. Them* dataset.

A Supplemental material

A.1 Data collection

	Time ranges	Events
Conservatives	2016/09/15 - 2016/12/15 2018/09/15 - 2018/12/15	Election periods
Liberals	2016/09/15 - 2016/12/15 2018/09/15 - 2018/12/15	Election periods
Muslims	2016/11/01 - 2017/11/30 2018/04/01 - 2018/05/01 2019/03/01 - 2019/06/01	Trump Muslim ban, Mosque attacks.
Immigrants	2016/11/01 - 2017/11/30 2017/01/15 - 2017/03/15 2018/06/17 - 2018/07/01 2018/10/01 - 2019/02/01	Migrant caravans, Children at the US border
Jews	2018/10/20 - 2018/11/25	Christchurch shooting

Table 3: Events and periods used for each group. If comments were not sufficient, they were sampled randomly from other time ranges. Refugees did not have enough overall comments to be filtered by time range.

	News Title	Comment
Refugees	refugee, asylum seeker	refugee, asylum seeker, undocumented, colonization
Immigration	-migra-, undocumented, colonization	-migra-, undocumented, colonization
Muslims	muslim, arab, muhammad, muhammed, islam, hijab, sharia	muslim, arab, muhammad, muhammed, islam, hijab, sharia
Jews	-jew(i/s)-, heeb- , sikey-, -zionis-, -semit-	-jew(i/s)-, heeb- , sikey-, -zionis-, -semit-
Liberals	antifa, libtard, communist, socialist, leftist, liberal, democrat	antifa, libtard, communist, socialist, leftist, liberal, democrat
Conservatives	altright, alt-right, cuckservative, trumpster, conservative, republican	altright, alt-right, cuckservative, trumpster, conservative, republican

Table 4: Keywords used in our data filtering process. The use of more emotionally laden terms is justified by their low occurrence compared to more common terms just to ensure a more diverse dataset.

A.2 Description of the annotation options

Discriminatory or Alienating. Annotators were asked to mark this in case the comment was either, (A) alienating or portraying a social group as negative, (B) a threat, danger or peril to society, (C) trying to ridicule it and attack that group as lesser or worthless.

Critical but not Discriminatory. In case the comment was critical, but not to the extent of the first option, annotators were asked to mark this option.

Supportive or Favorable. This answer refers to comments expressing support towards that group, by defending it or praising it.

Neutral. This option was offered in case none of the above applied, either because the group was only mentioned but the comment was not addressed at them, or there was no opinion whatsoever expressed towards the group, such as expressing purely factual information.

Annotators were first asked to select whether the comment showed a 'Positive', 'Negative' or 'Neutral' sentiment towards the specified group. With this approach, we intended to simplify the task and guide annotators, which then were offered to choose from 6 positive or 6 negative emotions according to sentiment they initially chose. In case annotators selected Neutral no further options were provided. The descriptions for each emotion were:

Positive emotions: **Gratitude** *Someone is doing/causing something good or lovely.*
Happiness/Joy[5] *Something good is happening. Something amusing or funny is happening.*
Hope *Something good/better might happen (sooner or later).*
Pride *Someone is taking credit for a good achievement.*
Relief *Something bad has changed for the better.*
Sympathy *Someone shows support or devotion.*

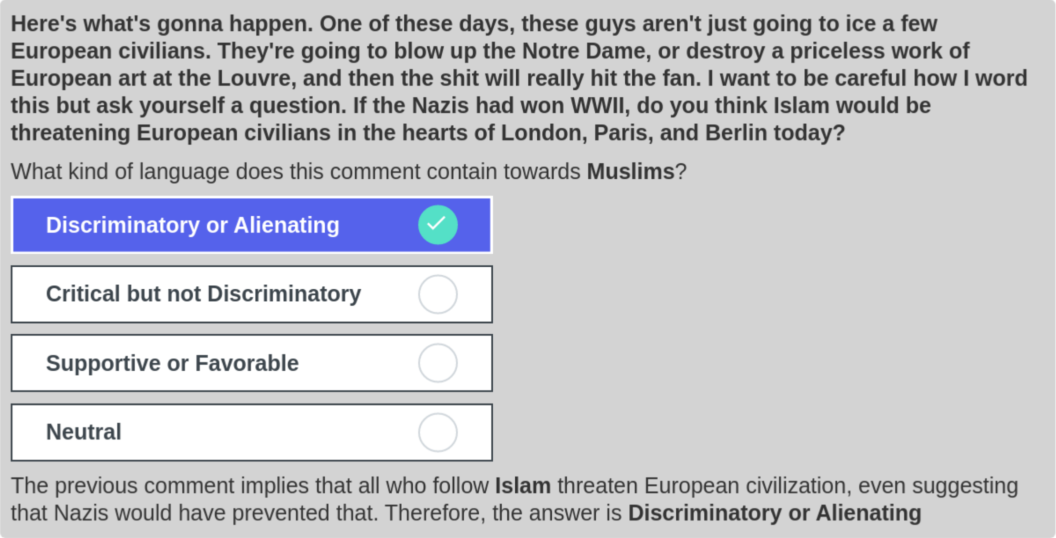
Negative emotions: **Anger.** *Someone is causing harm or a negative/undeserved outcome, while this could have been avoided.*
Someone is acting in an unjustified manner towards people.
Someone is blocking the goals of people.
Anxiety/Fear *Something negative might/could happen (sooner or later), which threatens the well-being of people.*
Contempt *Someone is inferior (for example, immoral, lazy or greedy).*
Someone is incompetent (for example, weak or stupid).
Sadness *Something bad or sad has happened.*
Someone has experienced a loss (for example, death or loss of possessions).
Moral Disgust[6] *Someone behaves in an offensive way (for example, corrupt, dishonest, ruthless, or unscrupulous behavior).*
Guilt/Shame[7] *Someone sees him-/herself as responsible for causing a harmful/ immoral/ shameful/ embarrassing outcome to people.*

---

[5] Referred to as Happiness for simplicity

[6] Referred to as Disgust for simplicity

[7] Referred to as Guilt for simplicity



Here's what's gonna happen. One of these days, these guys aren't just going to ice a few European civilians. They're going to blow up the Notre Dame, or destroy a priceless work of European art at the Louvre, and then the shit will really hit the fan. I want to be careful how I word this but ask yourself a question. If the Nazis had won WWII, do you think Islam would be threatening European civilians in the hearts of London, Paris, and Berlin today?

What kind of language does this comment contain towards **Muslims**?

- **Discriminatory or Alienating** ●
- **Critical but not Discriminatory** ○
- **Supportive or Favorable** ○
- **Neutral** ○

The previous comment implies that all who follow **Islam** threaten European civilization, even suggesting that Nazis would have prevented that. Therefore, the answer is **Discriminatory or Alienating**

Figure 5: Example of the first question as reference presented to MTurk annotators.

Which **primary** emotion does the text show towards **Muslims**?

- **Positive** ○
- **Negative** ●

Please select at least one type of type of **Negative** emotion the text primarily contains towards **Muslims**. You may select up to two emotions if the text contains them.

- **Anger** ○
  Someone is causing harm or a negative/undeserved outcome, while this could have been avoided.
  Someone is acting in an unjustified manner towards people.
  Someone is blocking the goals of people.
- **Anxiety/Fear** ●
  Something negative might/could happen (sooner or later), which threatens the well-being of people.
- **Contempt** ○
  Someone is inferior (for example, immoral, lazy or greedy).
  Someone is incompetent (for example, weak or stupid).
- **Moral Disgust** ○
  Someone behaves in an offensive way (for example, corrupt, dishonest, ruthless, or unscrupulous behavior).
- **Guilt/Shame** ○
  Someone sees him-/herself as responsible for causing a harmful/immoral/shameful/embarrassing outcome to people.
- **Sadness** ○
  Something bad or sad has happened.
  Someone has experienced a loss (for example, death or loss of possessions).

- **Neutral** ○

The exemplary comment describes **Muslims** and **Islam** as a threat that will "blow out the Notre Dame or destroy...", therefore it sees it as dangerous and posing a threat.

Figure 6: Example of the second question as reference presented to MTurk annotators.

A.3 Reliability

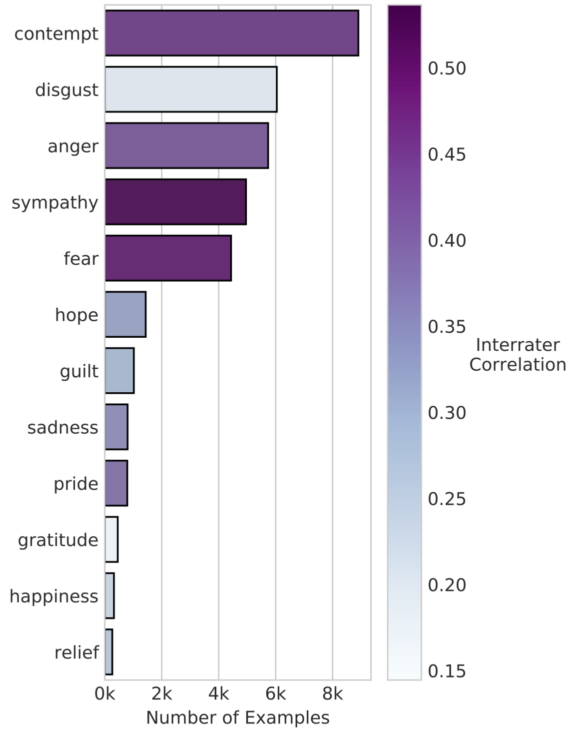


Figure 7: Number of annotations per emotions and the inter-rater correlation.

We also applied the algorithm called *Leave-One-Rater-Out* PPCA Cowen et al. (2019), using Bonferroni correction on p-values. *Principal Preserved Component Analysis* (PPCA) finds principal components which instead of preserving variance within a single dataset as conducted in PCA, preserve the cross-covariance between two different datasets, in our case being a comparison between annotations by one rater and a random set of other raters. In this manner, we can assess the degree of agreement and whether all component dimensions are significant, indicating significant emotion dimensions to be preserved. In our setup, the largest p-value for a dimension was $1.2e-03$, with all other dimensions showing much smaller values. This supports the idea that our emotion dimensions are significant, in order to be kept.

A.4 Data analysis

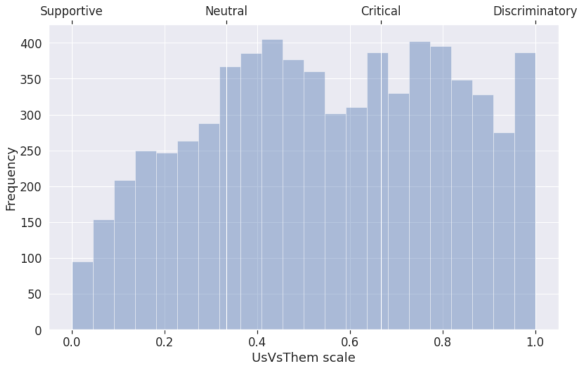

Figure 8: Distribution for the *UsVsThem* scale. Values closer to 0 are more supportive towards the target group, while higher values indicate a higher degree of criticism or eventually discrimination.

Predictor	Sum of Squares	*df*	Mean Square	*F*	*p*	partial η^2
(Intercept)	2582.47	1	2582.47	46×10^3	0.000

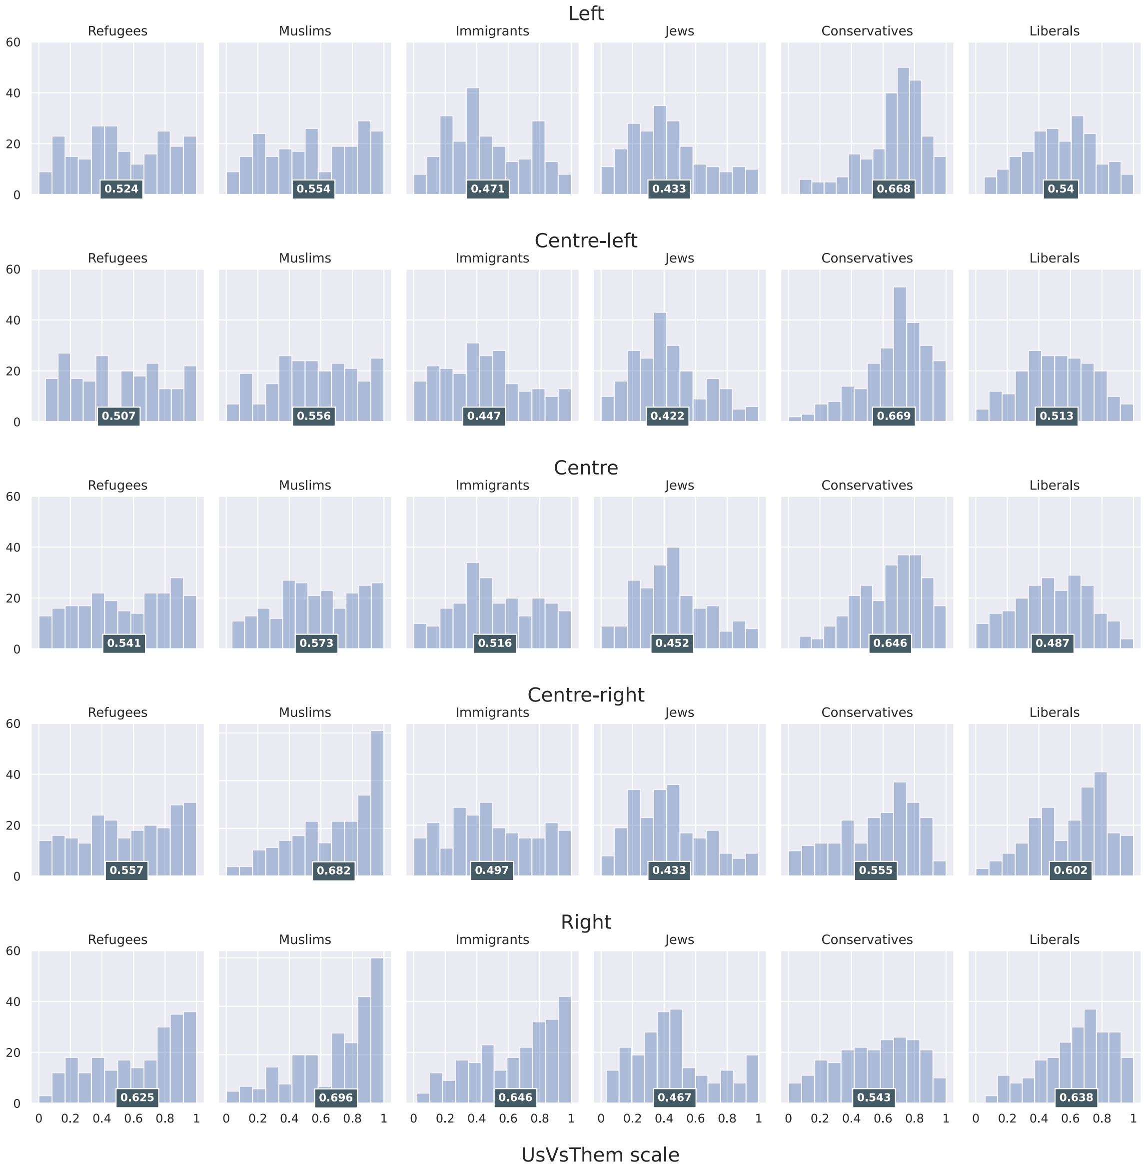

Figure 10: Distribution for the *UsVsThem* scale per social group and bias. The mean for the scale is shown at the x axis.

A.5 Analysis

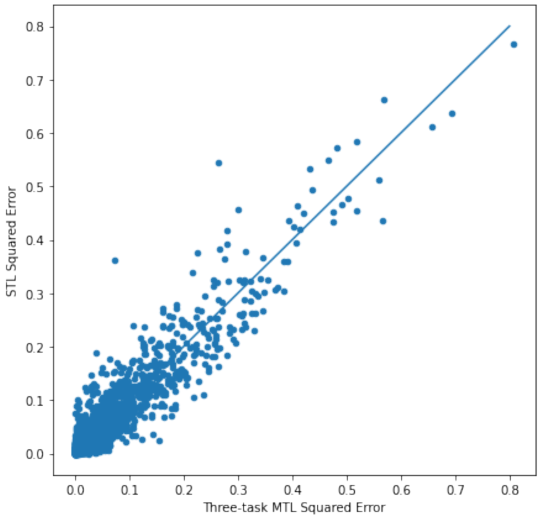

Figure 11: Squared error for STL and three-task MTL

n	**Reddit Comment**
1	I can't believe this bullshit. It's literally come down to picking between letting refugees sleep in your bed and fuck your wife and daughter or you're a racist hate monger. Literally no point on the spectrum exists between the two ends.

Label	**MTL, E. & G.**	**MTL, E.**	**MTL, G.**	**STL**	**Group**	**Emotions**
0.920	0.646	0.752	0.376	0.655	Refugees	Anger & Fear

n	**Reddit Comment**
2	As a legal immigrant, the newfound term 'undocumented immigrant' annoys the heck out of me. They're illegal aliens. Stop trying to sugarcoat it. It took me years to move here legally, and I resent those who chose to do it illegally. The process is long but it is fair. Come in through the front door, not the backdoor.

Label	**MTL, E. & G.**	**MTL, E.**	**MTL, G.**	**STL**	**Group**	**Emotions**
0.746	0.661	0.530	0.577	0.436	Immigrants	Anger & Disgust

n	**Reddit Comment**
3	By every moral or ethical standard, it is your duty to refuse orders to "defend" the US from these migrants. History will look kindly upon you if you do. There are thousands, if not millions, of us who will support your decision to lay your weapons down.

Label	**MTL, E. & G.**	**MTL, E.**	**MTL, G.**	**STL**	**Group**	**Emotions**
0.17	0.923	0.856	0.884	0.83	Immigrants	Sympathy & Hope

n	**Reddit Comment**
4	I was about to be shocked, until i thought about the god damn state of the world, the western world is at the moment at almost the same state, where at least a large minority wish the same thing of the Muslims. That and god damn people THERE IS MILLIONS OF MUSLIMS NOT EVERYONE THINKS THIS WAY!

Label	**MTL, E. & G.**	**MTL, E.**	**MTL, G.**	**STL**	**Group**	**Emotions**
0.099	0.847	0.833	0.882	0.815	Muslims	Sympathy

n	**Reddit Comment**
5	The Democrats are the ones preventing people? That's funny. Who are the lawmakers in the state legislatures that are constantly scheming up roundabout ways to defund planned parenthood and completely outlaw abortion access, despite a large majority of Americans supporting at least some degree of abortion? Hint: they're not Dems.

Label	**MTL, E. & G.**	**MTL, Emo.**	**MTL, Groups**	**STL**	**Group**	**Emotions**
0.059	0.78	0.75	0.766	0.734	Liberals	Sympathy

Table 9: 1 and 2 are examples of predictions for comments with high values on the *UsVsThem* scale where MTL models showed an improvement over STL, 3 and 4 are examples of ambiguous and challenging comments and 5 is an example with mentions to more than one group with high error predictions. Predictions are averages of all 10 seeds predictions for each model.

Abstract

We present a novel dataset and model for a multilingual setting to approach the task of Joint Entity and Relation Extraction. The SMiLER dataset consists of 1.1 M annotated sentences, representing 36 relations, and 14 languages. To the best of our knowledge, this is currently both the largest and the most comprehensive dataset of this type. We introduce HERBERTa, a pipeline that combines two independent BERT models: one for sequence classification, and the other for entity tagging. The model achieves micro F_1 81.49 for English on this dataset, which is close to the current SOTA on CoNLL, SpERT.

1 Introduction

The majority of the – constantly growing – amount of openly accessible knowledge is locked in unstructured text, and hence inefficiently utilized by any systems. The NLP tasks related to this problem include Information Extraction, Relation Extraction, Named Entity Retrieval, as well as Joint Entity and Relation Extraction.

Our contribution is twofold. First, we present SMiLER (Samsung MultiLingual Entity and Relation Extraction dataset): an open-domain corpus of annotated sentences, created for the Joint Entity and Relation Extraction task. With 1.1 M sentences, 36 relation types, and 14 languages, SMiLER seems to be both the largest and the most diversified corpus for the task in existence, to the best of our knowledge. The corpus was semi-automatically created from Wikipedia and DBpedia, and partly checked by linguists.

Our second contribution is HERBERTa – Hybrid Entity and Relation extraction BERT for a multilingual setting that consists of two independently pretrained BERT models (Devlin et al., 2018). The first one classifies the input sequence as belonging to one of our 36 relations (including *no_relation*). Its output – the relation – is then fed to the second BERT, together with the same input sequence. The second model performs entity tagging and outputs two spans for the two entities selected from the input sequence. Our model is close to SpERT (Eberts and Ulges, 2019), the current state-of-the-art for Joint Entity and Relation Extraction, achieving micro F_1 81.49 for English on the presented dataset.

The SMiLER corpus and the source code is available at https://github.com/samsungnlp/smiler/.

2 Related Work

Available Datasets The datasets that are commonly used for the task of Joint Entity and Relation Extraction are still insufficient in size and diversification; furthermore, they are all monolingual English corpora. For instance, CONLL04 (Roth and Yih, 2004) has only 1.7k annotated sentences and 5 relations. ADE (Gurulingappa et al., 2012) is larger, with almost 21k sentences, but it distinguishes only 2 relations (plus no_relation). Yet another such dataset, SciERC (Luan et al., 2018), contains 500 annotated abstracts and 7 relations; however, all of the relations belong to the scientific domain.

We believe that presenting a new, large and diversified dataset will be a valuable contribution to the joint task of Entity and Relation Extraction – both for English and for the multilingual setting.

Information Extraction Information extraction systems collect knowledge that is locked in unstructured text, such as in our Wikipedia articles. A nota-

ble example is the Never-Ending Language Learner (NELL), which was reading the Web for almost 10 years, 2010-2019 (Mitchell et al., 2018). This semi-supervised system was retrained continuously, with the use of the current knowledge, to collect new instances of a pre-defined set of entity types and relations, which also constitutes the final goal of our system. Another well-known knowledge base is Knowledge Vault (Dong et al., 2014). The system extracts information from the Internet (text, tabular data, page structure, human annotations) and combines it with information from Freebase (Bollacker et al., 2008). A probabilistic inference system computes calibrated probabilities of fact correctness.

Instead of utilizing pre-defined entity and relation types, some systems use syntactic analysis: ReVerb (Fader et al., 2011), MinIE (Gashteovski et al., 2017). Another approach is to create a taxonomy with just one relation: isA, as in Probase (Wu et al., 2012).

Relation Extraction Current models (HEBERTa included) for Relation Extraction are based on BERT (Devlin et al., 2018), a multi-layer bidirectional Transformer encoder (Vaswani et al., 2017). Its main contribution is pre-training deep bidirectional representations from unlabeled text by joint conditioning on both left and right context, in all the layers.

The current state-of-the-art in Relation Extraction are REDN (on SemEval-2010 Task 8, NYT, and WebNLG) (Li and Tian, 2020) and Matching the Blanks (on FewRel) (Soares et al., 2019). REDN extracts the token embeddings (BERT) from two different layers to represent the head and tail entities separately, in order to enhance learning reversible relations. Next, it calculates a parameterized asymmetric kernel inner product matrix between all the head and tail embeddings of each token in a sequence. On the other hand, the model constructed by Soares et al. (2019) combines BERT with extensions of Harris' distributional hypothesis to relations, to build task-agnostic relation representations solely from entity-linked text.

Joint Entity and Relation Extraction A more robust approach to Relation Extraction is to combine it with Entity Extraction. Three such joint solutions have achieved the current state-of-the-art: SciBERT (on SciERC) (Beltagy et al., 2019), SpERT (for RE on CONLL04) (Eberts and Ulges, 2019), and End2End Joint NER & RE (for NER on CONLL04) (Giorgi et al., 2019).

SciBERT leverages unsupervised pretraining on a multi-domain corpus of scientific publications, as this domain differs significantly from the general domain used by the original BERT. The second model, SpERT, is an attention model for Span-Based Joint Entity and Relation Extraction. It is trained using within-sentence negative samples, which are extracted in a single BERT pass. Finally, End2End Joint NER & RE combines BERT with biaffine attention.

Distant Supervision *Distant supervision* proposed by Mintz et al. (2009) for Relation Extraction task is a training paradigm, based on the assumption that if there is a relation between entities, then every sentence containing them may also express that relation. In the experiments, multiple sentences containing the entities were used to create their feature vectors. Thus, this approach allows a prediction of the relation between two entities, but does not identify sentences containing useful and correct cues for this relation in the corpus.

Data collection for SMiLER was based on the same assumption, but thanks to the subset of manually validated examples, the dataset could be used as the sole source of supervision during training, where the algorithm was supervised by the database.

Multilingual BERT M-BERT (Pires et al., 2019) is a model that is particularly relevant to our multilingual approach, and one that we tested repeatedly. This is a single language model, pre-trained from monolingual corpora in 104 languages, which performs zero-shot cross-lingual model transfer. Task-specific annotations in one language are used to fine-tune the model for evaluation in another language. Such transfer is possible even to languages in different scripts, such as English and Korean.

M-BERT has become the basis for building other multilingual models, as well as monolingual ones for languages other than English. We have experimented with three such models: German BERT, Italian BERT, and KoBERT for Korean (see section 4 for details).

3 Data

Our SMiLER corpus consists of 1.1 M annotated Wikipedia sentences, and was created specifically for the task of Entity and Relation Extraction. It

	EN-full	EN-mid	EN-small	KO	IT	FR	DE	PT	NL	PL	ES	AR	RU	SV	FA	UK	Total
sentences	748k	269k	35k	20k	76k	62k	53k	45k	40k	17k	12k	9k	7k	5k	3k	1k	1.1M
relations	36	36	32	28	22	22	22	22	22	22	22	9	8	22	8	7	36

Table 1: SMiLER: number of sentences and relations for each language. EN-mid includes EN-small, and EN-full includes EN-mid.

consists of annotated sentences in 14 languages, with each language representing a subset of 36 relations. As far as we know, this is both the biggest and the most comprehensive corpus for these NLP tasks. Table 1 provides the number of sentences and relations for each language, while Table 2 shows a few examples from the corpus.

The relations belong to 9 rough domains: Person (e.g. has-child, has-occupation), Organization (e.g. org-has-member, headquarters), Location (e.g. loc-leader, has-tourist-attraction), Animal (e.g. has-lifespan, eats), Art (e.g. starring, has-author), Device (e.g. invented-by), Event (event-year), Measurement (e.g. has-length), and no_relation. The no_relation sentences do not contain any of the 35 "positive" relations.

Figure 1 shows the number of sentences for each relation, for each language.

Relation	Sentence
has-child	[**Bill**]$_{e1}$ married Hillary on October 11, 1975, and their only child, [**Chelsea**]$_{e2}$, was born on February 27, 1980.
head-quarters	[**AMC Airlines**]$_{e1}$ è una compagnia aerea egiziana con sede al [**Cairo**]$_{e2}$, esegue voli charter da Sharm el-Sheikh, Hurghada, Il Cairo verso le maggiori capitali europee dal maggio 2006.
movie-has-director	[**Lili**]$_{e1}$ ist ein US-amerikanischer Spielfilm des Regisseurs [**Charles Walters**]$_{e2}$ aus dem Jahr 1953.

Table 2: Examples from the SMiLER corpus.

3.1 Dataset Building

To collect the English dataset, we queried DBpedia for (entity$_1$, entity$_2$, relation) triples. The articles about entity$_1$ that would also contain entity$_2$ were obtained from a Wikipedia dump. They were parsed and automatically selected. The complete English dataset is referred to as EN-full in the following discussion.

During this process it is possible that the same sentence will appear multiple times containing:

1. different entity annotations for the same relation, or
2. different entity annotations for another relation.

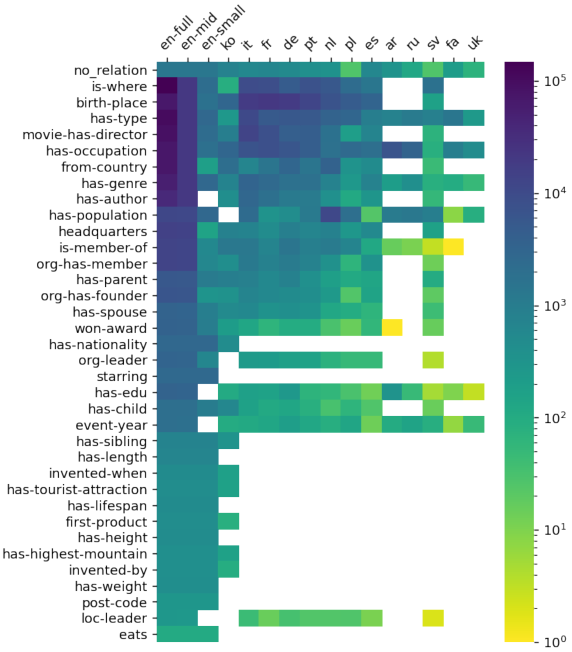

Figure 1: SMiLER: the number of sentences for each relation and for each language.

The first case is unlikely, because sentences are taken from the Wikipedia article of the "main" entity. The second case is possible, though.

Theoretically, it is possible to write grammatical rules in order to do a "cross-match" for augmenting a number of annotated sentences, and it has been done previously (e.g. Wu et al. (2012)). The reason why we did not use grammatical rules is that we wanted to scale the approach to multiple (and diverse) languages and the rules that could help with this task are not universal.

A part of EN-full was manually validated by linguists. The linguistic validation was more in-depth for English than for other languages, as for English the task was to correct the entity annotation whenever possible. Hence, passable annotations were corrected for English, while they were simply assessed as correct for the other languages. Overall, the linguists assessed 58.2% of the sample as fully correct, corrected the annotations in further 18.4%, and assessed the remaining 23.4% as incorrect. The correct 58.2% plus the corrected 18.4% of the sample together form the EN-small dataset.

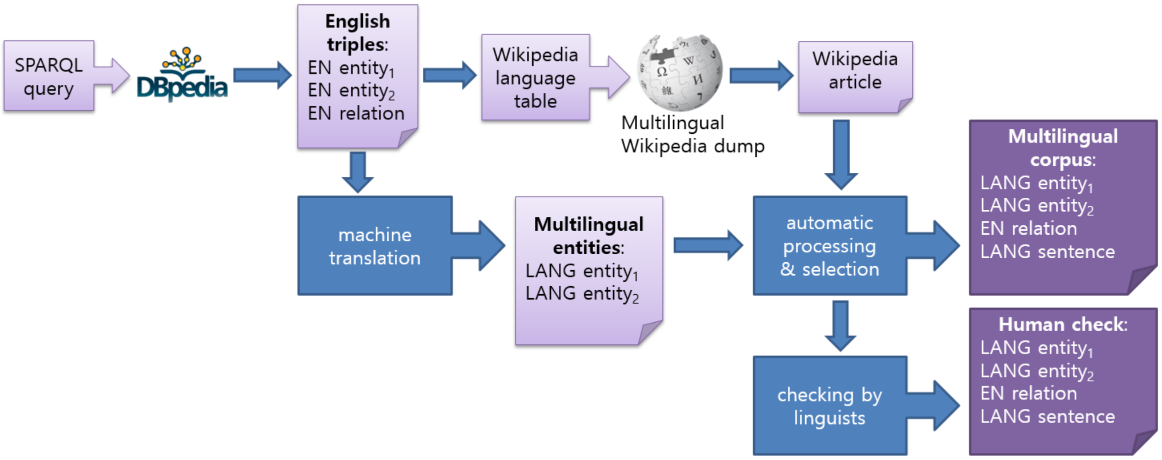

Figure 2: The process of creating the multilingual parts of SMiLER.

The corpus-building process was adapted for the other languages. First, the entities (as well as the entire no_relation sentences) were translated from English. The translation was carried out by an in-house multilingual system similar to (Przybysz et al., 2017; Williams et al., 2018; Wetesko et al., 2019). After translating the entities, the relevant article was copied from the Wikipedia dump in the other language. Finally, samples from the corpus were checked by linguists. Figure 2 illustrates the process.

The no_relation sentences in English have been selected by linguists from Wikipedia articles. The sentences contained entities that were in a relation in another sentence in the data set but were not in a relation in the selected sentence. Since the process is so strict, the translation to other languages was done automatically. All no_relation sentences needed to be hand-checked, because they could contain some hidden relations, and for this reason preparing original sentences for all the languages would take too much time. This is not the case for the 'positive' relations; e.g. if 'Bill' is the father of 'Chelsea', then a sentence containing both 'Bill' and 'Chelsea' – and coming from a Wikipedia article on Bill Clinton – would probably also express the relation has-child. However, if a sentence contains 'Bill', but not 'Chelsea', it could still express another of the "positive" relations.

We also tried other automated approaches for finding no_relation sentences. For example, given a Wikipedia article with a relation found, we could find other sentences with the same entities and assume all of them are no_relation sentences. Unfortunately this approach caused too much noise and was not used in the end.

The linguists verified a random sample of 50 sentences for 16 largest relations + no_relation for each of the following languages: IT, FR, DE, PT, ES, KO. The results are shown in Table 3. The overall percentage of correctness reached 79-80%, which is very high, considering the level of automation involved in the process. The selected random sample was small, because the verification needed to be cost- and time-effective. Still, the results were thoroughly checked and they were largely consistent.

	IT	FR	DE	PT	ES	KO	Overall
positive relations (scraped)	79	70	76	84	84	78	79
no_relation (translated)	88	94	86	86	74	53	80

Table 3: The percentage of correct sentences for selected languages in SMiLER.

The most common errors found by the linguists belong to three groups: (1) unexpected DBpedia query results, (2) wrong sentence parsing (deleting the second half of the sentence or including HTML), (3) selecting random sentences, which either do not express the relation, or have the entities marked in wrong places. Other typical errors are related to missing translations of some English words and *no_relation* sentences that contain one of the 35 positive relations. Table 4 shows one example of each error.

3.2 Datasets for the Model

For each language in our multilingual dataset, we automatically extracted 2% of the sentences to create a dev set and another 2% for a test set. This corpus split maintained the distribution of the rela-

Relation	Error	Sentence with an error
has-type	unexpected type "cardinal" obtained from DBpedia	[**Gerhard Ludwig Müller**]$_{e1}$ (Finthen, 31 dicembre 1947) è un [**cardinale**]$_{e2}$, arcivescovo cattolico e teologo tedesco, prefetto emerito della Congregazione per la dottrina della fede dal 1º luglio 2017.
headquarters	random sentences and deleted words	Temple des Martyrs à [**Taipei**]$_{e2}$. Les [**Forces armées de la république de Chine**]$_{e1}$ sont constituées d'une force d'active d'environ et de .
has-type	HTML included	vignette|gauche|250px|La salle de concerts de Raanana [**Ra'anana**]$_{e1}$ est une [**ville**]$_{e2}$ israélienne d'environ habitants au nord-est de Tel Aviv, dans le sud de la région de Sharon.
no_relation	untranslated "ranks"	[**iSuppli**]$_{e1}$ ranks [**Kingston**]$_{e2}$ como el fabricante de módulos de memoria número uno del mundo para el mercado de memoria de terceros por el décimo año consecutivo.
no_relation	sentence contains relation has-genre	Nach der Registrierung seines aktuellen YouTube-Kanals 2010 veröffentlichte [**Kjellberg**]$_{e1}$ vor allem [**Let's Play**]$_{e2}$ Videos von Horror- und Action-Videospielen.

Table 4: Most common error types found by linguists.

tions in the original data, whenever possible. For the languages where the label distribution was impossible to preserve, the number of relations in the test set may be smaller than in the train set.[1]

For English, we used a single test set for both EN-mid and EN-small. The only difference was in the number of labels: EN-mid (both train and dev) had 36 labels, while EN-small (albo both train and dev) – 32 (see Table 1).

For training the models, we created several combinations of languages, in order to examine the effect of adding/removing languages from the training set. We experimented with the following combinations:

1. **EURO**: IT, FR, PT, DE, ES, EN
2. **SVO**: **EURO**, RU, SV, NL, PL, UK
3. **ALL**: **SVO**, AR, KO, FA
4. Each individual language combined with EN (e.g. IT+EN)
5. Each language alone (e.g. IT)

Pires et al. (2019) showed that the language structure had an impact on the performance of the model. Therefore, we treat Korean, Farsi and Arabic as a special case because they are non-SVO languages (Korean and Farsi are SOV, while Arabic is VSO).[2]

4 Model

Our architecture HERBERTa (Figure 3) uses two pre-trained BERT models. It solves the problem of Entity and Relation Extraction with the use of an unconventional pipeline. In the first step it is trained for Relation Extraction, while the entities are retrieved in the second stage.

The first model is BERT, fine-tuned for the Sequence Classification task. Its input is a tokenized sequence, while its output consists of a sequence output and a pooled output that represents the overall sentence context (from the [CLS] token). The latter is passed to a softmax for classifying the relation.

The second model is our implementation of BERT for Entity Tagging. It is based on BERT for Question Answering, and its inputs are:

- the same tokenized sequence as the one used for Relation Extraction,
- the relation outputted in the first step – encoded as a BERT [unused] token.

As a result, the input sequence is as follows: [CLS] [relation] [SEP] [E0] [E1] ... [En] [SEP]. The output of the model is a set of four indices that correspond to the spans of the two entities having the relation.

At inference time, the model will return the start and end of the two entities separately and this is used to mark the entities. Using our model, it is also possible to select N best predictions (one prediction = one entity pair) for the same relation. This has not been used for the result of the paper because we wanted to find a single best entity pair for each sentence.

---

[1] Train/test set number of relations for the languages in which the numbers differ: ES (train: 21, test: 16), RU (train: 8, test: 7), SV (train: 22, test: 14), FA (train: 8, test: 4), AR (train: 9, test: 7), NL (train: 22, test: 21), PL (train: 21, test: 20), UK (train: 7, test: 6), KO (train: 28, test: 26).

[2] SVO, SOV, and VSO stand for the relative position of the Subject, Verb, and Object in the typical affirmative sentence.

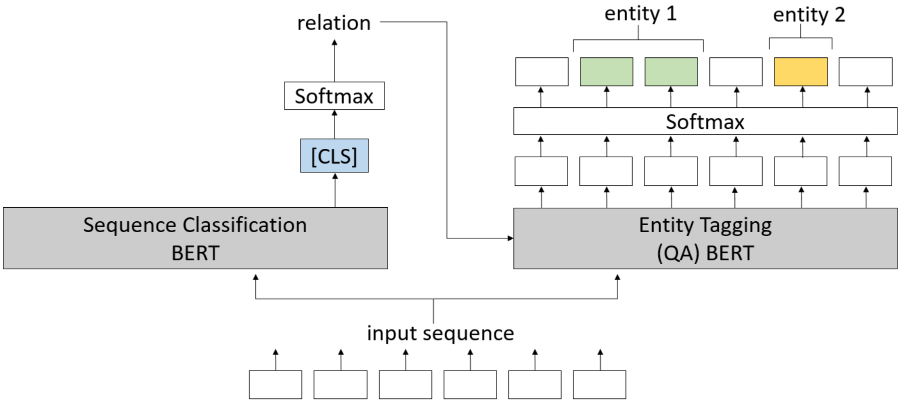

Figure 3: Model architecture.

We used the following types of BERT, depending on the language(s):

- bert-base-cased (Devlin et al., 2018),
- bert-base-multilingual-cased (Pires et al., 2019),
- bert-base-german-cased from the HuggingFace Transformer library (Wolf et al., 2019),
- bert-base-korean-cased – the monologg/kobert model from HuggingFace,
- bert-base-italian-cased – the dbmdz/bert-base-italian-cased model from HuggingFace.

Below we call our model LANG(B) if it is a fine-tuning of bert-base, e.g. DE(B) is the bert-base-german model fine-tuned on the German corpus. We call our model just LANG if it is a fine-tuning of bert-base-multilingual, e.g. DE-EN is the English and German model trained using bert-base-multilingual. The English dataset has two versions: EN (EN-mid) and EN_S (EN-small). We did not use EN-full for the training.

4.1 Training Procedure

The two models presented in Section 4 are trained independently, each one with a different loss function. The first model uses standard cross-entropy as its loss for relation classification. The loss function for the second model is:

$$\mathcal{L} = \frac{1}{4}(\mathcal{L}^{1,start} + \mathcal{L}^{1,end} + \mathcal{L}^{2,start} + \mathcal{L}^{2,end}) \quad (1)$$

Where $\mathcal{L}^{j,start}$ is the cross-entropy loss for the prediction of j-th entity first token index and $\mathcal{L}^{j,end}$ is the cross-entropy of the predictions of its last token index.

The result of the first model becomes the input to the second one, during inference. We conclude that this works well because the performance of the relation classification model is very high (please refer to Table 5 and the Relation column).

The number of epochs is established using an early stopping mechanism. On average, each model (Relation Classifier and Entity Tagger) is trained for around 6 epochs for models with EN-mid set and 3-4 epochs for others. We fine-tune the whole BERT.

The model with all languages (ALL_EN) runs on 6 GPU GeForce RTX 2080 (8GB) for 31h.

5 Results

For evaluating the models, we use the micro F_1 score on the entities and relations together, ignoring no_relation. Below, this measure is referred to as Combined. When comparing with the state-of-the-art, we also show the relation-only micro F_1, as well as the entity-only micro F_1 (for a single entity and for the pair of entities). We use such metrics because they are typically calculated for these tasks; see for instance Eberts and Ulges (2019).

5.1 Comparison with the State-of-the-Art

Given that our dataset is new, there is no state-of-the-art for it. Nevertheless, we decided to compare the results of HERBERTa with SpERT (Eberts and Ulges, 2019), the currently best model on CoNLL (Roth and Yih, 2004). Table 5 presents the results that we obtained by training SpERT on our Wikipedia EN-mid (denoted as EN(SpERT)) and EN-small (denoted as EN_S(SpERT)). Additionally, Table 5 also shows the results of our model trained on the same datasets. In terms of combined F_1, HERBERTa is close, the difference being about 0.2

percentage point with SpERT, the current SOTA on CONLL.

Model	Relation	Entities (Pair)	Combined
EN_S(SpERT)	N/A	80.71	59.24
EN(SpERT)	N/A	**92.89**	**81.71**
EN_S(B)	80.94	61.94	58.31
EN(B)	**94.94**	82.55	81.49
ALL-EN_S	81.64	57.46	53.76
ALL-EN	93.85	78.26	76.97

Table 5: Micro F_1 results on the Wikipedia EN-mid dataset. Combined – both the relation and the entity pair are correct.

5.2 Language and Model Comparison

Single Language As the first step, we trained HERBERTa for each language separately. The results (F_1 measure) are presented in Figure 4 (left). Our models trained with the use of multilingual BERT are named after language, e.g. IT, FR, PT. Our non-multilingual BERT models are called LANG plus (B), e.g. IT(B), DE(B).

We obtained the best result for EN(B). BERT trained on EN-small (EN_S(B)) achieved lower results, 81 vs. 58, because EN-small contains over 7 times fewer sentences. If we compare this with the other languages, the relationship between F_1 and the logarithm of the number of sentences holds in general. That is, the higher number of sentences, the higher F_1 (see Figure 5). EN-small (35k sentences, F_1=58) falls between NL (40k sentences, F_1=60) and PL (17k sentences, F_1=50). RU (7k) and UK (1k, the smallest set) achieve F_1=29 and 10 respectively.

Surprisingly, FA (3k) and SV (5k) – despite small sets – yield F_1=65 and 58 respectively; as a result, they are the outliers in Figure 5. AR (9k) achieves a higher F_1 score than ES (12k); however, the difference is just 2 percentage points. FA, AR (and KO) have different word orders than all the other languages, which might be one of the reasons why they achieve high F_1 despite small datasets. Another reason might be their small number of relations. The high result for SV, which is SVO, could be explained by a smaller number of relations in the test set than in the train set. UK and RU, in spite of their small number of relations, obtain the lowest results, because they have small datasets. Furthermore, contrary to SV, UK and RU have rich inflection which might also be the case.

Comparing the results of our models trained with multilingual BERT versus non-multilingual BERT, we observe that all three possibilities are present in the pairs we checked. For DE we get the same results F_1=58, for IT the non-multilingual BERT gives lower results 64 vs. 66, while for KO the non-multilingual BERT achieves significantly higher results, 51 vs. 42.

Multilingual In the second step, we added models trained with the multilingual BERT for several languages simultaneously, e.g. ALL-EN for all the languages available in the corpus (see Figure 4 (left)). There are four main groups of models: (A) a model with EN-mid and all other languages, (B) models with EN-small and at least 6 languages, (C) models with EN-small and one other language, (D) other models with about 3-4 similar languages.

Comparing the models for single languages with group A and B models, we observe that the multilingual models typically yield similar or better results. The largest increase was observed for UK: F_1=10 on its own and even 26 in ALL-EN_S. We tried to group similar languages RU, PL, and UK to boost UK. However, we obtained just F_1=20 for UK, which is still significantly higher compared to the UK single language model, but lower compared to UK-EN and UK-EN_S.

One exception is EN-mid, which works significantly better in the single model (81 vs. 77); for EN-small, the difference is less pronounced (58 vs. 54-57). Another exception is KO, for which the single KO(B) model obtains 51 vs. multilingual 43-47. However, if we compare the multilingual KO, F_1=42, then the multilanguage models increase the results. Finally, the model that groups IT, FR, PT, and ES achieves similar results to ALL-EN_S.

Relations Figure 4 (right) shows F_1 for relations. The results differ widely between the languages and the relations. For instance, for EN some relations achieve F_1=100 (e.g. has-lifespan, eats), while one relation gets just F_1=22 (from-country). However, the same relation achieves F_1=73 for PL and even 0 for SV. We conclude that the results depend on the number of training examples for each relation.

Entity$_1$ vs Entity$_2$ Figure 6 demonstrates a significant difference in results between the two entities in the sentence. We obtain far higher results for entity$_1$ (left) than for entity$_2$ (right). This is because entity$_1$ usually occurs at the beginning of the sentence, while the position of entity$_2$ is not so deterministic.

Figure 4: Left: F_1 (label and both entities correct) for all languages and models. Right: F_1 (label correct) for all languages and labels, averaged over the models available for each language.

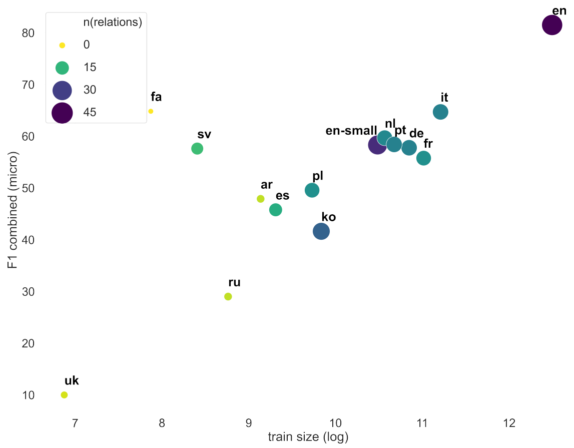

Figure 5: F_1 Combined for single language models versus the number of sentences in the train set. Dot size is proportional to the number of relations in the test set.

It is important to note though that typically sentences begin with their linguistic subject. As a result, for the sentence 'Bill has a child called Chelsea.', the relation has-child is far more plausible than has-parent, even though both are logically correct. For this reason, the fact that entity$_1$ has a more deterministic behavior is not a problem.

6 Conclusions

We have described our approach to solving the task of multilingual Joint Entity and Relation Extraction, by training our novel, HERBERTa model on SMiLER – our large, comprehensive dataset. The model combines two independent BERT models: one for Sequence Classification, and the other for Entity Tagging. Regarding F1 measure our model is close to SpERT (the current state-of-the-art for CONLL04), the difference being 0.2 percentage point. What is more, the SMiLER dataset appears to be currently the largest (1.1 M annotated sentences) dataset for this task, as well as the most comprehensive one (14 languages, 36 relation types).

We observe that our multilingual models achieve higher or similar results, compared to the models trained for each language separately. Languages with less data can benefit the most from such multilingual models. The victim here is English, as it seems to be a giver of F1 to other languages, especially when the number of sentences for this language is significantly higher than for other languages. On the one hand, due to the large amount of data for English, a model is well trained for patterns existing in this language and thus other languages with less data can benefit from it (because of some similarities between languages). Therefore, we observe increased results for less resourced languages. On the other hand, a model tries to accommodate the nuances of the less resourced languages. Their features are noticeable for the model, which reduces the dominant role of English.

As we can see from the results, each non-English language follows a slightly different (error) path.
