AdapterFusion:
Non-Destructive Task Composition for Transfer Learning

Abstract

Sequential fine-tuning and multi-task learning are methods aiming to incorporate knowledge from multiple tasks; however, they suffer from catastrophic forgetting and difficulties in dataset balancing. To address these shortcomings, we propose *AdapterFusion*, a new two stage learning algorithm that leverages knowledge from multiple tasks. First, in the *knowledge extraction* stage we learn task specific parameters called *adapters*, that encapsulate the task-specific information. We then combine the adapters in a separate *knowledge composition* step. We show that by separating the two stages, i.e., knowledge extraction and knowledge composition, the classifier can effectively exploit the representations learned from multiple tasks in a non-destructive manner. We empirically evaluate AdapterFusion on 16 diverse NLU tasks, and find that it effectively combines various types of knowledge at different layers of the model. We show that our approach outperforms traditional strategies such as full fine-tuning as well as multi-task learning. Our code and adapters are available at AdapterHub.ml.

1 Introduction

The most commonly used method for solving NLU tasks is to leverage pretrained models, with the dominant architecture being a transformer (Vaswani et al., 2017), typically trained with a language modelling objective (Devlin et al., 2019; Radford et al., 2018; Liu et al., 2019b). Transfer to a task of interest is achieved by fine-tuning all the weights of the pretrained model on that *single task*, often yielding state-of-the-art results (Zhang and Yang, 2017; Ruder, 2017; Howard and Ruder, 2018; Peters et al., 2019). However, each task of interest requires all the parameters of the network to be fine-tuned, which results in a specialized model for each task.

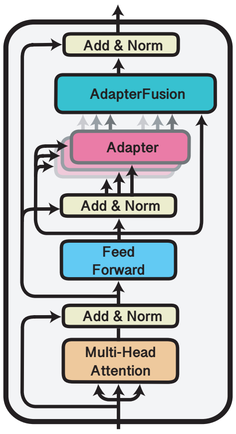

Figure 1: AdapterFusion architecture inside a transformer (Vaswani et al., 2017). The AdapterFusion component takes as input the representations of multiple adapters trained on different tasks and learns a parameterized mixer of the encoded information.

There are two approaches for sharing information across multiple tasks. The first consists of starting from the pretrained language model and sequentially fine-tuning on each of the tasks one by one (Phang et al., 2018). However, as we subsequently fine-tune the model weights on new tasks, the problem of catastrophic forgetting (McCloskey and Cohen, 1989; French, 1999) can arise, which results in loss of knowledge already learned from all previous tasks. This, together with the non-trivial decision of the order of tasks in which to fine-tune the model, hinders the effective transfer of knowledge. Multi-task learning (Caruana, 1997; Zhang and Yang, 2017; Liu et al., 2019a) is another approach for sharing information across multiple tasks. This involves fine-tuning the weights of a pretrained language model using a weighted sum of the objective function of each target task simultaneously. Using this approach, the network captures the common structure underlying all the target tasks. However, multi-task learning requires simul-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 487–503
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

taneous access to all tasks during training. Adding new tasks thus requires complete joint retraining. Further, it is difficult to balance multiple tasks and train a model that solves each task equally well. As has been shown in Lee et al. (2017), these models often overfit on low resource tasks and underfit on high resource tasks. This makes it difficult to effectively transfer knowledge across tasks with all the tasks being solved equally well (Pfeiffer et al., 2020b), thus considerably limiting the applicability of multi-task learning in many scenarios.

Recently, *adapters* (Rebuffi et al., 2017; Houlsby et al., 2019) have emerged as an alternative training strategy. Adapters do not require fine-tuning of all parameters of the pretrained model, and instead introduce a small number of task specific parameters — while keeping the underlying pretrained language model fixed. Thus, we can separately and simultaneously train adapters for multiple tasks, which all share the same underlying pretrained parameters. However, to date, there exists no method for using *multiple* adapters to maximize the transfer of knowledge across tasks without suffering from the same problems as sequential fine-tuning and multi-task learning. For instance, Stickland and Murray (2019) propose a multi-task approach for training adapters, which still suffers from the difficulty of balancing the various target tasks and requiring simultaneous access to all target tasks.

In this paper we address these limitations and propose a new variant of adapters called *AdapterFusion*. We further propose a novel two stage learning algorithm that allows us to effectively share knowledge across multiple tasks while avoiding the issues of catastrophic forgetting and balancing of different tasks. Our AdapterFusion architecture, illustrated in Figure 1, has two components. The first component is an adapter trained on a task without changing the weights of the underlying language model. The second component — our novel Fusion layer — combines the representations from several such task adapters in order to improve the performance on the target task.

Contributions Our main contributions are: (1) We introduce a novel two-stage transfer learning strategy, termed *AdapterFusion*, which combines the knowledge from multiple source tasks to perform better on a target task. (2) We empirically evaluate our proposed approach on a set of 16 diverse NLU tasks such as sentiment analysis, commonsense reasoning, paraphrase detection, and recognizing textual entailment. (3) We compare our approach with Stickland and Murray (2019) where adapters are trained for all tasks in a multi-task manner, finding that AdapterFusion is able to improve this method, even though the model has simultaneous access to all tasks during pretraining. (4) We show that our proposed approach outperforms fully fine-tuning the transformer model on a single target task. Our approach additionally outperforms adapter based models trained both in a Single-Task, as well as Multi-Task setup.

The code of this work is integrated into the AdapterHub.ml (Pfeiffer et al., 2020a).

2 Background

In this section, we formalize our goal of transfer learning (Pan and Yang, 2010; Torrey and Shavlik, 2010; Ruder, 2019), highlight its key challenges, and provide a brief overview of common methods that can be used to address them. This is followed by an introduction to *adapters* (Rebuffi et al., 2017) and a brief formalism of the two approaches to training adapters.

Task Definition. We are given a model that is pretrained on a task with training data D_0 and a loss function L_0. The weights Θ_0 of this model are learned as follows:

$$\begin{aligned} D_0 &:= \text{Large corpus of unlabelled text} \\ L_0 &:= \text{Masked language modelling loss} \\ \Theta_0 &\leftarrow \underset{\Theta}{\operatorname{argmin}}\; L_0(D_0; \Theta) \end{aligned}$$

In the remainder of this paper, we refer to this pretrained model by the tuple (D_0, L_0).

We define C as the set of N classification tasks having labelled data of varying sizes and different loss functions:

$$C = \{(D_1, L_1), \ldots, (D_N, L_N)\}$$

The aim is to be able to leverage a set of N tasks to improve on a target task m with $C_m = (D_m, L_m)$. In this work we focus on the setting where $m \in \{1, \ldots, N\}$.

Desiderata. We wish to learn a parameterization Θ_m that is defined as follows:

$$\Theta_m \leftarrow \underset{\Theta'}{\operatorname{argmin}}\; L_m(D_m; \Theta')$$

where Θ' is expected to have encapsulated relevant information from all the N tasks. The target model for task m is initialized with Θ' for which we learn the optimal parameters Θ_m through minimizing the task's loss on its training data.

2.1 Current Approaches to Transfer Learning

There are two predominant approaches to achieve sharing of information from one task to another.

2.1.1 Sequential Fine-Tuning

This involves sequentially updating all the weights of the model on each task. For a set of N tasks, the order of fine-tuning is defined and at each step the model is initialized with the parameters learned through the previous step. However, this approach does not perform well beyond two sequential tasks (Phang et al., 2018; Pruksachatkun et al., 2020) due to catastrophic forgetting.

2.1.2 Multi-Task Learning (MTL)

All tasks are trained simultaneously with the aim of learning a shared representation that will enable the model to generalize better on each task (Caruana, 1997; Collobert and Weston, 2008; Nam et al., 2014; Liu et al., 2016, 2017; Zhang and Yang, 2017; Ruder, 2017; Ruder et al., 2019; Sanh et al., 2019; Pfeiffer et al., 2020b, *inter alia*).

$$\Theta_{0\rightarrow\{1,...,N\}} \leftarrow \underset{\Theta}{\operatorname{argmin}} \left(\sum_{n=1}^{N} L_n(D_n; \Theta_0) \right)$$

Where $\Theta_{0\rightarrow\{1,...,N\}}$ indicates that we start with Θ_0 and fine-tune on a set of tasks $\{1, ..., N\}$.

However, MTL requires simultaneous access to all tasks, making it difficult to add more tasks on the fly. As the different tasks have varying sizes as well as loss functions, effectively combining them during training is very challenging and requires heuristic approaches as proposed in Stickland and Murray (2019).

2.2 Adapters

While the predominant methodology for transfer learning is to fine-tune all weights of the pretrained model, *adapters* (Houlsby et al., 2019) have recently been introduced as an alternative approach with applications in domain transfer (Rücklé et al., 2020b), machine translation (Bapna and Firat, 2019; Philip et al., 2020) transfer learning (Stickland and Murray, 2019; Wang et al., 2020; Lauscher et al., 2020), and cross-lingual transfer (Pfeiffer et al., 2020c,d; Üstün et al., 2020; Vidoni et al., 2020). Adapters share a large set of parameters Θ across all tasks and introduce a small number of task-specific parameters Φ_n. While Θ represents the weights of a pretrained model (e.g., a transformer), the parameters Φ_n, where $n \in \{1, \ldots, N\}$, are used to encode task-specific representations in intermediate layers of the shared model. Current work on adapters focuses either on training adapters for each task separately (Houlsby et al., 2019; Bapna and Firat, 2019; Pfeiffer et al., 2020a) or training them in a multi-task setting to leverage shared representations (Stickland and Murray, 2019). We discuss both variants below.

2.2.1 Single-Task Adapters (ST-A)

For each of the N tasks, the model is initialized with parameters Θ_0. In addition, a set of new and randomly initialized adapter parameters Φ_n are introduced.

The parameters Θ_0 are fixed and only the parameters Φ_n are trained. This makes it possible to efficiently parallelize the training of adapters for all N tasks, and store the corresponding knowledge in designated parts of the model. The objective for each task $n \in \{1, \ldots, N\}$ is of the form:

$$\Phi_n \leftarrow \underset{\Phi}{\operatorname{argmin}}\ L_n(D_n; \Theta_0, \Phi)$$

For common adapter architectures, Φ contains considerably fewer parameters than Θ, e.g., only 3.6% of the parameters of the pretrained model in Houlsby et al. (2019).

2.2.2 Multi-Task Adapters (MT-A)

Stickland and Murray (2019) propose to train adapters for N tasks in parallel with a multi-task objective. The underlying parameters Θ_0 are fine-tuned along with the task-specific parameters in Φ_n. The training objective can be defined as:

$$\boldsymbol{\Theta} \leftarrow \underset{\Theta, \Phi}{\operatorname{argmin}} \left(\sum_{n=1}^{N} L_n(D_n; \Theta_0, \Phi_n) \right)$$

where

$$\boldsymbol{\Theta} = \Theta_{0\rightarrow\{1,...,N\}}, \Phi_1, \ldots, \Phi_N.$$

2.2.3 Adapters in Practice

Introducing new adapter parameters in different layers of an otherwise fixed pretrained model has been shown to perform on-par with, or only slightly below, full model fine-tuning (Houlsby et al., 2019; Stickland and Murray, 2019; Pfeiffer et al., 2020a).

For NLP tasks, adapters have been introduced for the transformer architecture (Vaswani et al., 2017). At each transformer layer l, a set of adapter parameters Φ_l is introduced. The placement and architecture of adapter parameters Φ within a pretrained model is non-trivial. Houlsby et al. (2019) experiment with different architectures, finding that a two-layer feed-foward neural network with a bottleneck works well. They place two of these components within one layer, one after the multi-head attention (further referred to as *bottom*) and one after the feed-forward layers of the transformer (further referred to as *top*).[1] Bapna and Firat (2019) and Stickland and Murray (2019) only introduce one of these components at the *top* position, however, Bapna and Firat (2019) include an additional *layer norm* (Ba et al., 2016).

Adapters trained in both single-task (ST-A) or multi-task (MT-A) setups have learned the idiosyncratic knowledge of the respective tasks' training data, encapsulated in their designated parameters. This results in a compression of information, which requires less space to store task-specific knowledge. However, the distinct weights of adapters prevent a downstream task from being able to use multiple sources of extracted information. In the next section we describe our two stage algorithm which tackles the sharing of information stored in adapters trained on different tasks.

3 AdapterFusion

Adapters avoid catastrophic forgetting by introducing task-specific parameters; however, current adapter approaches do not allow sharing of information between tasks. To mitigate this we propose AdapterFusion.

3.1 Learning algorithm

In the first stage of our learning algorithm, we train either ST-A or MT-A for each of the N tasks.

In the second stage, we then combine the set of N adapters by using AdapterFusion. While fixing both the parameters Θ as well as all adapters Φ, we introduce parameters Ψ that learn to combine the N task adapters to solve the target task.

$$\Psi_m \leftarrow \underset{\Psi}{\operatorname{argmin}}\ L_m(D_m; \Theta, \Phi_1, \ldots, \Phi_N, \Psi)$$

Ψ_m are the newly learned AdapterFusion parameters for task m. Θ refers to Θ_0 in the ST-A setting or $\Theta_{0\rightarrow\{1,\ldots,N,m\}}$ in the MT-A setup. In our experiments we focus on the setting where $m \in \{1, \ldots, N\}$, which means that the training dataset of m is used twice: *once* for training the adapters Φ_m and *again* for training Fusion parameters Ψ_m, which learn to compose the information stored in the N task adapters.

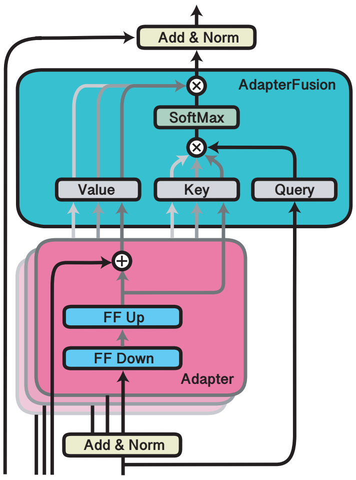

Figure 2: Our AdapterFusion architecture. This includes learnable weights *Query*, *Key*, and *Value*. *Query* takes as input the output of the pretrained transformer weights. Both *Key* and *Value* take as input the output of the respective adapters. The dot product of the *query* with all the *keys* is passed into a softmax function, which learns to weight the adapters with respect to the context.

By separating the two stages — knowledge extraction in the adapters, and knowledge composition with AdapterFusion — we address the issues of catastrophic forgetting, interference between tasks and training instabilities.

3.2 Components

AdapterFusion learns to compose the N task adapters Φ_n and the shared pretrained model Θ, by introducing a new set of weights Ψ. These parameters learn to combine the adapters as a dynamic function of the target task data.

As illustrated in Figure 2, we define the AdapterFusion parameters Ψ to consist of *Key, Value* and *Query* matrices at each layer l, denoted by $\mathbf{K}_l$, $\mathbf{V}_l$ and $\mathbf{Q}_l$ respectively. At *each layer* l of the transformer and *each time-step* t, the output of the feed-forward sub-layer of layer l is taken as the query vector. The output of each adapter $\mathbf{z}_{l,t}$ is used as input to both the *value* and *key* transformations. Similar to attention (Bahdanau et al., 2015; Vaswani et al., 2017), we learn a contextual activation of

---

[1] We illustrate these placements in Appendix Figure 5 (left).

each adapter n using

$$\begin{aligned}
\mathbf{s}_{l,t} &= \text{softmax}(\mathbf{h}_{l,t}^{\top}\mathbf{Q}_l \otimes \mathbf{z}_{l,t,n}^{\top}\mathbf{K}_l), n \in \{1, ..., N\} \\
\mathbf{z}'_{l,t,n} &= \mathbf{z}_{l,t,n}^{\top}\mathbf{V}_l, n \in \{1, ..., N\} \\
\mathbf{Z}'_{l,t} &= [\mathbf{z}'_{l,t,0}, ..., \mathbf{z}'_{l,t,N}] \\
\mathbf{o}_{l,t} &= \mathbf{s}_{l,t}^{\top}\mathbf{Z}'_{l,t}
\end{aligned}$$

Where $\otimes$ represents the dot product and $[\cdot, \cdot]$ indicates the concatenation of vectors.

Given the context, AdapterFusion learns a parameterized mixer of the available trained adapters. It learns to identify and activate the most useful adapter for a given input.

4 Experiments

In this section we evaluate how effective AdapterFusion is in overcoming the issues faced by other transfer learning methods. We provide a brief description of the 16 diverse datasets that we use for our study, each of which uses accuracy as the scoring metric.

4.1 Experimental Setup

In order to investigate our model's ability to overcome catastrophic forgetting, we compare Fusion using ST-A to only the ST-A for the task. We also compare Fusion using ST-A to MT-A for the task to test whether our two-stage procedure alleviates the problems of interference between tasks. Finally, our experiments to compare MT-A with and without Fusion let us investigate the versatility of our approach. Gains in this setting would show that AdapterFusion is useful even when the base adapters have already been trained jointly.

In all experiments, we use BERT-base-uncased (Devlin et al., 2019) as the pretrained language model. We train ST-A, described in Appendix A.2 and illustrated in Figure 5, for all datasets described in §4.2. We train them with reduction factors[2] $\{2, 16, 64\}$ and learning rate 0.0001 with AdamW and a linear learning rate decay. We train for a maximum of 30 epochs with early stopping. We follow the setup used in Stickland and Murray (2019) for training the MT-A. We use the default hyperparameters[3], and train a MT-A model on all datasets simultaneously.

For AdapterFusion, we empirically find that a learning rate of $5e-5$ works well, and use this in all experiments.[4] We train for a maximum of 10 epochs with early stopping. While we initialize $\mathbf{Q}$ and $\mathbf{K}$ randomly, we initialize $\mathbf{V}$ with a diagonal of ones and the rest of the matrix with random weights having a small norm ($1e-6$). Multiplying the adapter output with this value matrix $\mathbf{V}$ initially adds small amounts of noise, but retains the overall representation. We continue to regularize the *Value* matrix using l_2-norm to avoid introducing additional capacity.

4.2 Tasks and Datasets

We briefly summarize the different types of *tasks* that we include in our experiments, and reference the related datasets accordingly. A detailed descriptions can be found in Appendix A.1.

Commonsense reasoning is used to gauge whether the model can perform basic reasoning skills: *Hellaswag* (Zellers et al., 2018, 2019), *Winogrande* (Sakaguchi et al., 2020), *CosmosQA* (Huang et al., 2019), *CSQA* (Talmor et al., 2019), *SocialIQA* (Sap et al., 2019). **Sentiment analysis** predicts whether a given text has a positive or negative sentiment: *IMDb* (Maas et al., 2011), *SST* (Socher et al., 2013). **Natural language inference** predicts whether one sentence entails, contradicts, or is neutral to another: *MNLI* (Williams et al., 2018), *SciTail* (Khot et al., 2018), *SICK* (Marelli et al., 2014), *RTE* (as combined by Wang et al. (2018)), *CB* (De Marneffe et al., 2019). **Sentence relatedness** captures whether two sentences include similar content: *MRPC* (Dolan and Brockett, 2005), *QQP*[5]. We also use an argument mining *Argument* (Stab et al., 2018) and reading comprehension *BoolQ* (Clark et al., 2019) dataset.

5 Results

We present results for all 16 datasets in Table 1. For reference, we also include the adapter architecture of Houlsby et al. (2019), ST-A$^{\text{Houlsby}}$, which has twice as many parameters compared to ST-A. To provide a fair comparison to Stickland and Murray (2019) we primarily experiment with BERT-base-uncased. We additionally validate our best model configurations — ST-A and Fusion with ST-A — with RoBERTa-base, for which we present our results in Appendix Table 4.

---

[2] A reduction factor indicates the factor by which the hidden size is reduced such that the bottle-neck size for BERT Base with factor 64 is reduced to 12 ($768/64 = 12$).

[3] We additionally test out batch sizes 16 and 32.

[4] We have experimented with learning rates $\{6e-6, 5e-5, 1e-4, 2e-4\}$

Table 1: Mean and standard deviation results (development sets) for each of the 16 datasets and the different architectural setups. The datasets are ordered by their respective training dataset size. Dashed horizontal lines separate datasizes $\{> 40k, > 10k, > 5k\}$, respectively. Each model is initialized with BERT-base (Devlin et al., 2019) weights. **Head** indicates training only a classification head on top of fixed BERT weights. For **Full** training we fine-tune all weights of BERT. Single-Task Adapters (**ST-A**) is the training of independently trained adapters for each task, using the architecture illustrated in Figure 5. Multi-Task Adapters (**MT-A**) shows results of jointly trained adapters using the default settings of Stickland and Murray (2019). **Fusion w/ ST-A** and **Fusion w/ MT-A** show the results of AdapterFusion using the respective pre-trained Adapters. **ST-A$^{\text{Houlsby}}$** shows the results of ST-Adapters with the architecture proposed by Houlsby et al. (2019). Reported results are accuracy scores.

5.1 Adapters

Training only a prediction-head on the output of a pretrained model can also be considered an adapter. This procedure, commonly referred to as training only the *Head*, performs considerably worse than fine-tuning all weights (Howard and Ruder, 2018; Peters et al., 2019). We show that the performance of only fine-tuning the *Head* compared to *Full* fine-tuning causes on average a drop of 10 points in accuracy. This demonstrates the need for more complex adaptation approaches.

In Table 1 we show the results for MT-A and ST-A with a reduction factor 16 (see the appendix Table 3 for more results) which we find has a good trade-off between the number of newly introduced parameters and the task performance. Interestingly, the ST-A have a regularization effect on some datasets, resulting in better performance on average for certain tasks, even though a much small proportion of weights is trained. On average, we improve 0.66% by training ST-A instead of the *Full* model.

For MT-A we find that there are considerable performance drops of more than 2% for *CSQA* and *MRPC*, despite the heuristic strategies for sampling from the different datasets (Stickland and Murray, 2019). This indicates that these heuristics only partially address common problems of multi-task learning such as catastrophic interference. It also shows that learning a shared representation jointly does not guarantee the best results for all tasks. On average, however, we do see a performance increase of 0.4% using MT-A over *Full* fine-tuning on each task separately, which demonstrates that there are advantages in leveraging information from other tasks with multi-task learning.

5.2 AdapterFusion

AdapterFusion aims to improve performance on a given target task m by transferring task specific knowledge from the set of all N task adapters, where $m \in \{1, \ldots, \mathrm{N}\}$. We hypothesize that if there exists at least one task that supports the target task, AdapterFusion should lead to performance gains. If no such task exists, then the performance should remain the same.

Dependence on the size of training data. In Table 1 we notice that having access to relevant tasks considerably improves the performance for the target task when using AdapterFusion. While datasets with more than 40k training instances perform well without Fusion, smaller datasets with fewer training instances benefit more from our approach. We

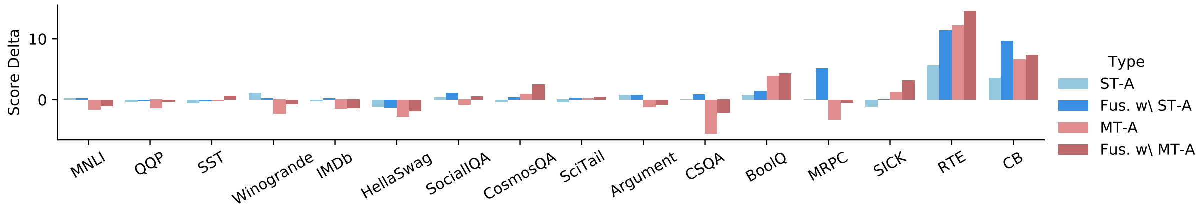

Figure 3: Relative performance difference of the two adapter architectures and the AdapterFusion models over fully fine-tuned BERT. Fusion improves over its corresponding adapters (ST-A and MT-A) for most tasks.

Table 2: Performance changes of AdapterFusion compared to ST-A and MT-A. Arrows indicate whether there has been an improvement ↗ (> 0.3), decrease ↘ (< -0.3), or whether the results have stayed the same → $[-0.3, 0.3]$.

observe particularly large performance gains for datasets with less than 5k training instances. For example, Fusion with ST-A achieves substantial improvements of 6.5 % for *RTE* and 5.64 % for *MRPC*. In addition, we also see performance gains for moderately sized datasets such as the commonsense tasks *CosmosQA* and *CSQA*. Fusion with MT-A achieves smaller improvements, as the model already includes a shared set of parameters. However, we do see performance gains for *SICK*, *SocialIQA*, *Winogrande* and *MRPC*. On average, we observe improvements of 1.27% and 1.25% when using Fusion with ST-A and MT-A, respectively.

Mitigating catastrophic interference. In order to identify whether our approach is able to mitigate problems faced by multi-task learning, we present the performance differences of adapters and AdapterFusion compared to the fully fine-tuned model in Figure 3. In Table 2, we compare AdapterFusion to ST-A and MT-A. The arrows indicate whether there is an improvement ↗, decrease ↘, or if the the results remain the same →. We compare the performance of both, Fusion with ST-A and Fusion with MT-A, to ST-A and MT-A. We summarize our four most important findings below.

(1) In the case of Fusion with ST-A, for $15/16$ tasks, the performance remains the same or improves as compared to the task's pretrained adapter. For $10/16$ tasks we see performance gains. This shows that having access to adapters from other tasks is beneficial and in the majority of cases leads to better results on the target task. **(2)** We find that for $11/16$ tasks, Fusion with ST-A improves the performance compared to MT-A. This demonstrates the ability of Fusion with ST-A to share information between tasks while avoiding the interference that multi-task training suffers from. **(3)** For only $7/16$ tasks, we see an improvement of Fusion with MT-A over the ST-A. Training of MT-A in the first stage of our algorithm suffers from all the problems of multi-task learning and results in less effective adapters than our ST-A on average. Fusion helps bridge some of this gap but is not able to mitigate the entire performance drop. **(4)** In the case of AdapterFusion with MT-A, we see that the performances on *all 16 tasks* improves or stays the same. This demonstrates that AdapterFusion can successfully combine the specific adapter weights, even if the adapters were trained in a multi-task setting, confirming that our method is versatile.

Summary. Our findings demonstrate that Fusion with ST-A is the most promising approach to sharing information across tasks. Our approach allows us to train adapters in parallel and it requires no heuristic sampling strategies to deal with imbalanced datasets. It also allows researchers to easily add more tasks as they become available, without requiring complete model retraining.

While Fusion with MT-A does provide gains over simply using MT-A, the effort required to train

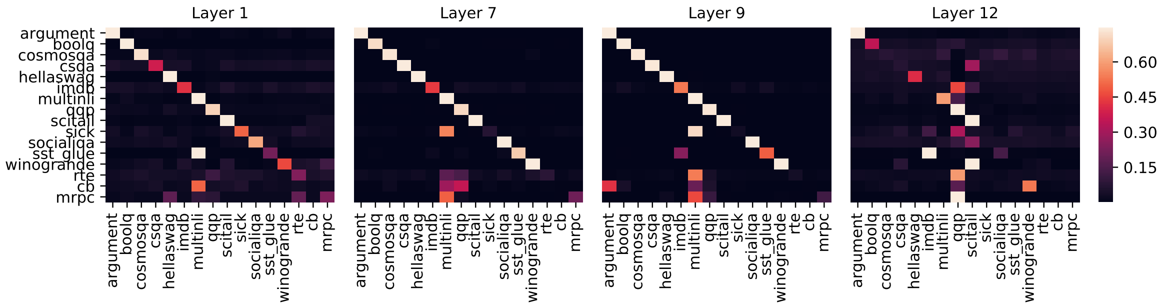

Figure 4: AdapterFusion activations of pretrained **ST-Adapters**. Rows indicate the target task m, columns indicate adapters n. We assume that the softmax activation for $\Phi_{n,l}$ is high if the information of adapter n is useful for task m. For our analysis, we calculate the softmax activation for each adapter $\Phi_{n,l}$, where $n \in \{1, \ldots, N\}$, and average over all activations within the same layer l calculated over all instances in the development set.

these in a multi-task setting followed by the Fusion step are not warranted by the limited gains in performance. On the other hand, we find that Fusion with ST-A is an efficient and versatile approach to transfer learning.

6 Analysis of Fusion Activation

We analyze the weighting patterns that are learned by AdapterFusion to better understand which tasks impact the model predictions, and whether there exist differences across BERT layers.

We plot the results for layers 1, 7, 9, and 12 and ST-A in Figure 4 (see Appendix Figure 6 for the remaining layers). We find that tasks which do not benefit from AdapterFusion tend to more strongly activate their own adapter at every layer (e.g. *Argument, HellaSwag, MNLI, QQP, SciTail*). This confirms that AdapterFusion only extracts information from adapters if they are beneficial for the target task m. We further find that *MNLI* is a useful intermediate task that benefits a large number of target tasks, e.g. *BoolQ, SICK, CSQA, SST-2, CB, MRPC, RTE*, which is in line with previous work (Phang et al., 2018; Conneau and Kiela, 2018; Reimers and Gurevych, 2019). Similarly, *QQP* is utilized by a large number of tasks, e.g. *SICK, IMDB, RTE, CB, MRPC, SST-2*. Most importantly, tasks with small datasets such as *CB, RTE,* and *MRPC* often strongly rely on adapters trained on large datasets such as *MNLI* and *QQP*.

Interestingly, we find that the activations in layer 12 are considerably more distributed across multiple tasks than adapters in earlier layers. The potential reason for this is that the last adapters are not encapsulated between frozen pretrained layers, and can thus be considered as an extension of the prediction head. The representations of the adapters in the 12th layer might thus not be as comparable, resulting in more distributed activations. This is in line with Pfeiffer et al. (2020d) who are able to improve zero-shot cross-lingual performance considerably by dropping the adapters in the last layer.

7 Contemporary Work

In contemporaneous work, other approaches for parameter efficient fine-tuning have been proposed. Guo et al. (2020) train sparse "diff" vectors which are applied on top of pretrained frozen parameter vectors. Ravfogel and Goldberg (2021) only finetune bias terms of the pretrained language models, achieving similar results as full model finetuning. Li and Liang (2021) propose prefix-tuning for natural language generation tasks. Here, continuous task-specific vectors are trained while the remaining model is kept frozen. These alternative, parameter-efficient fine-tuning strategies all encapsulate the idiosyncratic task-specific information in designated parameters, creating the potential for new composition approaches of multiple tasks.

Rücklé et al. (2020a) analyse the training and inference efficiency of adapters and AdapterFusion. For AdapterFusion, they find that adding more tasks to the set of adapters results in a linear increase of computational cost, both for training and inference. They further propose approaches to mitigate this overhead.

8 Conclusion and Outlook

8.1 Conclusion

We propose a novel approach to transfer learning called AdapterFusion which provides a simple and effective way to combine information from several tasks. By separating the extraction of knowledge from its composition, we are able to effectively avoid the common pitfalls of multi-task learning, such as catastrophic forgetting and interference between tasks. Further, AdapterFusion mitigates the problem of traditional multi-task learning in which complete re-training is required, when new tasks are added to the pool of datasets.

We have shown that AdapterFusion is compatible with adapters trained in both single-task as well as multi-task setups. AdapterFusion consistently outperforms fully fine-tuned models on the target task, demonstrating the value in having access to information from other tasks. While we observe gains using both ST-A as well as MT-A, we find that composing ST-A using AdapterFusion is the more efficient strategy, as adapters can be trained in parallel and re-used.

Finally, we analyze the weighting patterns of individual adapters in AdapterFusion which reveal that tasks with small datasets more often rely on information from tasks with large datasets, thereby achieving the largest performance gains in our experiments. We show that AdapterFusion is able to identify and select adapters that contain knowledge relevant to task of interest, while ignoring the remaining ones. This provides an implicit no-op option and makes AdapterFusion a suitable and versatile transfer learning approach for any NLU setting.

8.2 Outlook

Rücklé et al. (2020a) have studied pruning a large portion of adapters after Fusion training. Their results show that removing the less activated adapters results in almost no performance drop at inference time while considerably improving the inference speed. They also provide some initial evidence that it is possible to train Fusion with a subset of the available adapters in each minibatch, potentially enabling us to scale our approach to large adapter sets — which would otherwise be computationally infeasible. We believe that such extensions are a promising direction for future work.

Pfeiffer et al. (2020d) have achieved considerable improvements in the zero-shot cross-lingual transfer performance by dropping the adapters in the last layer. In preliminary results, we have observed similar trends with AdapterFusion when the adapters in the last layer are not used. We will investigate this further in future work.

A Appendices

A.1 Datasets

Commonsense Reasoning We work with a large number of datasets, all of which have emerged recently in this domain, ranging from sentence level and document level classification to multiple choice questions. The next sentence prediction task *HellaSWAG* (Zellers et al., 2019) is a more difficult version of the previously released *SWAG* dataset (Zellers et al., 2018). *Winogrande* (Sakaguchi et al., 2020) is a large scale and adversarially filtered (Zellers et al., 2018) adaptation of the *Winograd Schema Challenge* (Levesque, 2011). *Cosmos QA* (Huang et al., 2019) is a commonsense reading comprehension dataset which requires reasoning over larger text passages. *Social IQA* (Sap et al., 2019) is a multiple choice dataset which requires reasoning over social interactions between humans. *Commonsense QA* (Talmor et al., 2019) is a multiple choice dataset based on ConceptNet (Speer et al., 2017), which requires reasoning over general knowledge.

Sentiment Analysis We conduct experiments on two binary sentiment classification tasks on long and short text passages. *IMDb* (Maas et al., 2011) consists of long movie reviews and *SST-2* (Socher et al., 2013) consists of short movie reviews from Rotten Tomatoes[6].

Natural Language Inference (NLI) The goal is to classify whether two sentences entail, contradict, or are neutral to each other. For this we conduct experiments on *MultiNLI* (Williams et al., 2018), a multi-genre dataset, *SciTail* (Khot et al., 2018) a NLI dataset on scientific text, *SICK* (Marelli et al., 2014) a NLI dataset with relatedness scores, the composition of *Recognizing Textual Entailment (RTE)* datasets provided by Wang, Singh, Michael, Hill, Levy, and Bowman (2018), as well as the *Commitment Bank (CB)* (De Marneffe et al., 2019) three-class textual entailment dataset.

Sentence Relatedness We include two semantic relatedness datasets which capture whether or not two text samples include similar content. *Microsoft Research Paraphrase Corpus (MRPC)* (Dolan and Brockett, 2005) consists of sentence pairs which capture a paraphrase/semantic equivalence relationship. *Quora Question Pairs (QQP)* targets duplicate question detection.[7]

Misc The Argument Aspect corpus (Stab et al., 2018) is a three-way classification task to predict whether a document provides arguments *for*, *against* or *none* for a given topic (Nuclear Energy, Abortion, Gun-Control, etc). BoolQ (Clark et al., 2019) is a binary reading comprehension classification task for simple *yes, no* questions.

A.2 What Is The Best Adapter Setup?

As described in §2.2.3, the placement of adapter parameters Φ within a pretrained model is non-trivial, and thus requires extensive experiments. In order to identify the best ST-A setting, we run an exhaustive architecture search on the hyperparameters — including the position and number of adapters in each transformer layer, the position and number of pretrained or task dependent layer norms, the position of residual connections, the bottleneck reduction factors $\{2, 8, 16, 64\}$, and the non linearity $\{\text{ReLU, LeakyReLU, Swish}\}$ used within the adapter. We illustrate this in Figure 5. This grid search includes the settings introduced by Houlsby et al. (2019) and Bapna and Firat (2019). We perform this search on three diverse tasks[8] and find

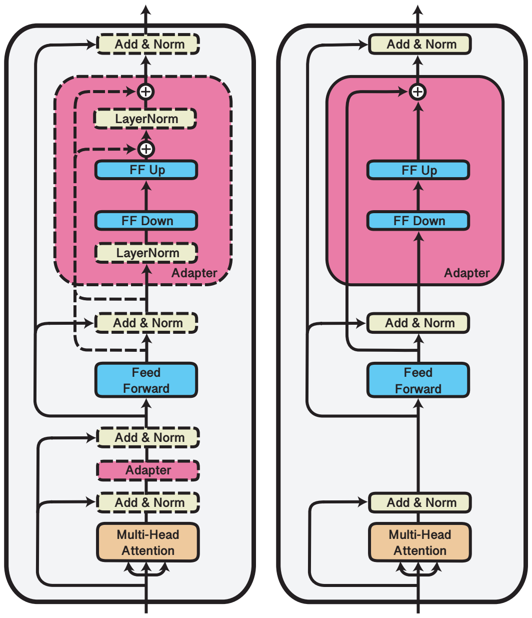

Figure 5: Different architectural components of the adapter. On the left, we show all components for which we conduct an exhaustive search (dashed lines). On the right, we show the adapter architecture that performs the best across all our tasks.

that across all three tasks, the same setup obtains best results. We present our results on the SST-2, Argument, and CSQA datasets in Figures 7, 8, and 9 respectively, at different granularity levels. We find that in contrast to Houlsby et al. (2019), but in line with Bapna and Firat (2019), a single adapter after the feed-forward layer outperforms other settings. While we find that this setting performs on-par with that of Houlsby et al. (2019), it requires only half the number of newly introduced adapters as compared to them, resulting in a more efficient setting in terms of number of operations.

For the single-task adapter setting, we thus perform all subsequent experiments with the best architecture illustrated in Figure 5 on the right and a learning rate of $1e-4$. In order to reproduce the multi-task results in Stickland and Murray (2019) and build upon them, for experiments involving multi-task training, we adopt their architecture as described in §2.2.3.

A.3 AdapterFusion Activations of all Layers

We present the cross-product of activations of AdapterFusion of all layers for BERT-Base and ST-A_{16} in Figure 6, as an extension to Figure 4.

A.4 BERT-base ST-A with Reduction Factors $\{2, 16, 64\}$

We present the ST-A results with different capacity leveraging BERT-base weights in Table 3. Reduction factors 2, 16, and 64 amount to dense adapter dimensions 384, 48, and 12 respectively.

A.5 ST-A and Fusion with ST-A Results with RoBERTa-base

In order to validate our findings of our best setup—ST-A—we re-evaluate our results leveraging RoBERTa-base weights. We present our results in Table 4. Similar to our findigs with BERT-base, especially datasets with less data profit from AdapterFusion. We find that, in contrast to BERT-base, RoBERTa-base does not perform well with high capacity adapters with reduction factor 2.

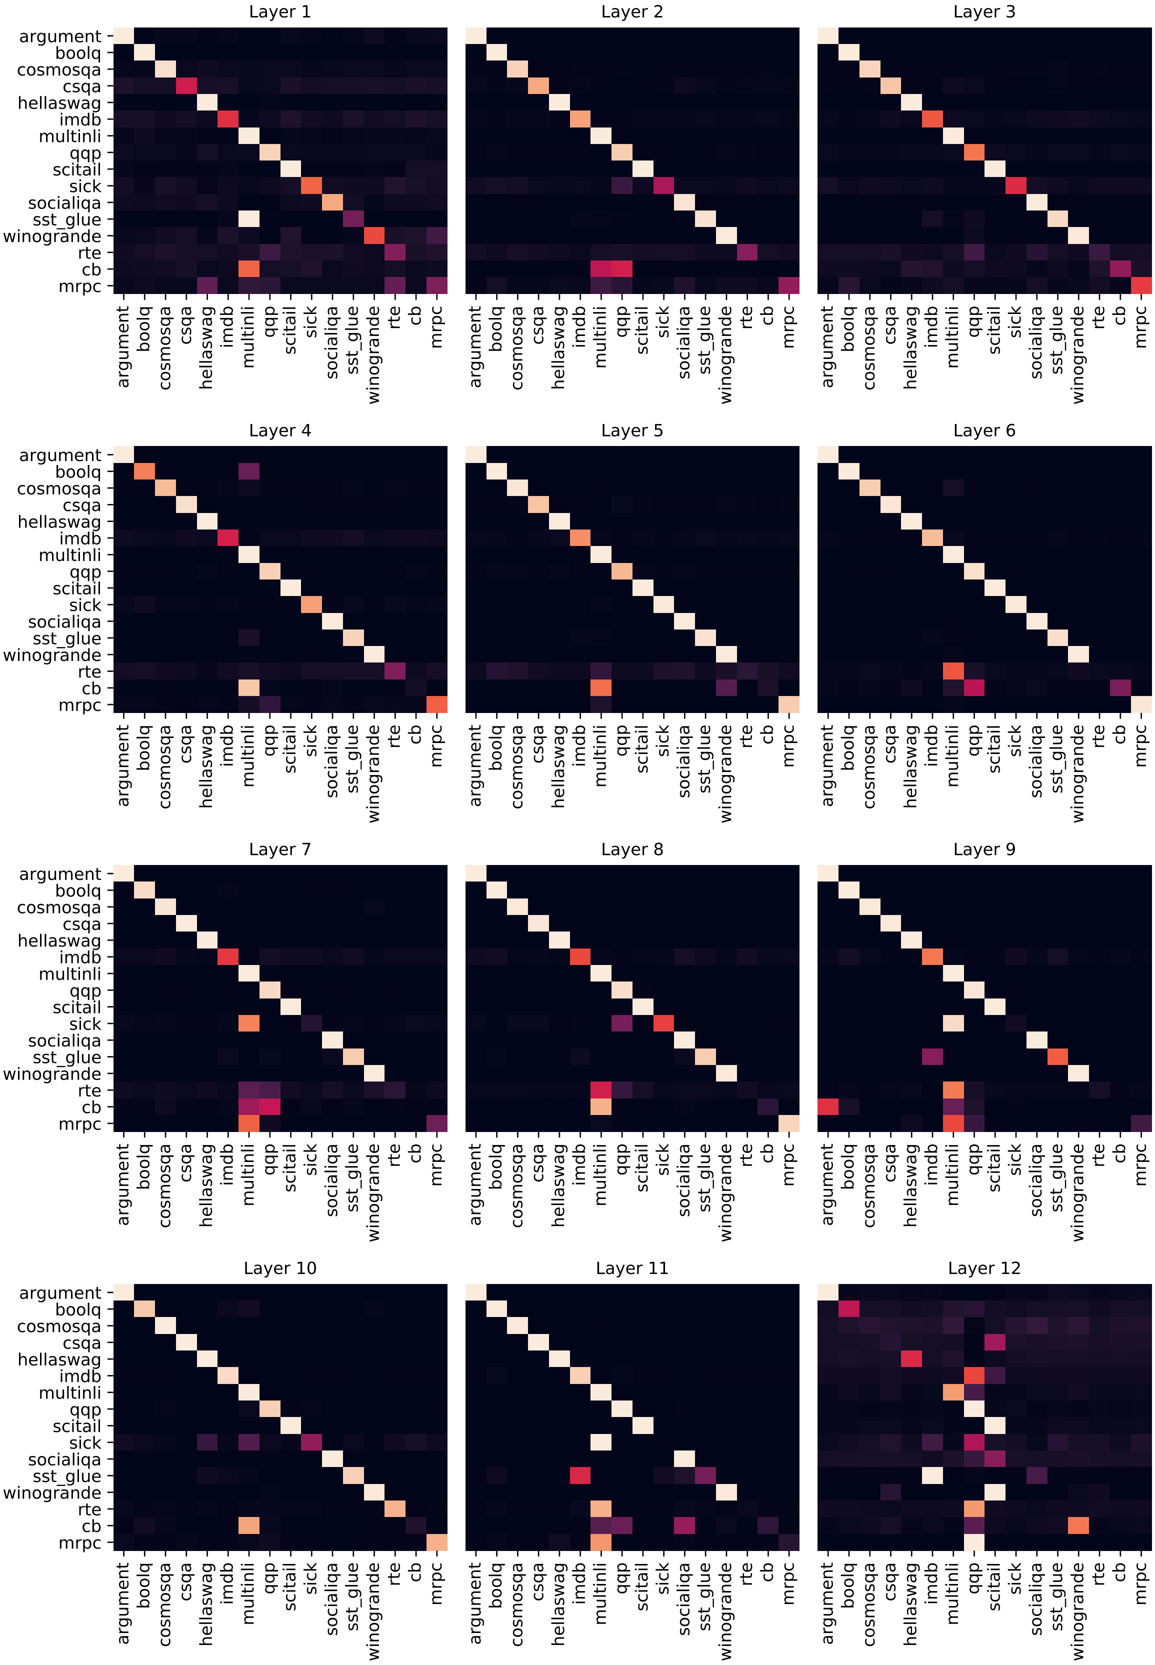

Figure 6: AdapterFusion activations in the 12 BERT-base layers. Target tasks are presented in rows, whereas the set of adapters are displayed in columns. Black squares indicate that an adapter has not been activated, whereas white cells indicate full activation.

Abstract

In this paper, we propose CHOLAN, a modular approach to target end-to-end entity linking (EL) over knowledge bases. CHOLAN consists of a pipeline of two transformer-based models integrated sequentially to accomplish the EL task. The first transformer model identifies surface forms (entity mentions) in a given text. For each mention, a second transformer model is employed to classify the target entity among a predefined candidates list. The latter transformer is fed by an enriched context captured from the sentence (i.e. local context), and entity description gained from Wikipedia. Such external contexts have not been used in state of the art EL approaches. Our empirical study was conducted on two well-known knowledge bases (i.e., Wikidata and Wikipedia). The empirical results suggest that CHOLAN outperforms state-of-the-art approaches on standard datasets such as CoNLL-AIDA, MSNBC, AQUAINT, ACE2004, and T-REx.

1 Introduction

The explicit schema, graph-based structure, and interlinking nature of information represented in publicly available knowledge graphs (KGs) e.g., DBpedia (Auer et al., 2007), Freebase (Bollacker et al., 2007), Wikidata (Vrandecic, 2012) or knowledge bases (KBs) such as Wikipedia; introduce a new landscape of features, as well as structured knowledge and embeddings. Researchers have developed several techniques to align information available in unstructured text to the concepts of these KGs (Wu et al., 2019b; Broscheit, 2019).

End-to-end Entity Linking (hereafter EL) task follows this direction; such that, given a sentence EL first identifies the entity mention in the sentence, then maps these mentions to the most likely KG/KB entities. The EL comprises of a three-step process. With respect to the given example sentence *Soccer: Late Goals Give Japan win Over Syria*, the first step called mention detection (MD) identifies the surface forms *Japan* and *Syria*. The next step is candidate generation (CG) aiming to find a list of possible entity candidates in the KG/KB for each entity mention. For example, the candidates list for entity mention *Japan* consists in part of *Japan national football team, Japan (country), Japan (Band)* and for *Syria* is *Syria (Roman province), Syria national football team, Greater Syria*. Finally, the third step deals with the entity disambiguation (ED) which employs the coreference and contextual features to discriminate the most likely entity from the candidates list e.g., *Japan national football team* and *Syria national football team* are correct entities.

Entity Linking approaches are broadly categorised into three categories. The initial attempts (Hoffart et al., 2011; Piccinno and Ferragina, 2014) solve MD and ED as independent sub-tasks of EL (i.e., a pipeline based system). However, these approaches exhibit a behaviour where errors propagate from MD to ED hence might downgrade the overall performance of the system. The second category has emerged in an attempt to mitigate these errors, where researchers focused on jointly modelling MD and ED, emphasising the importance of the mutual dependency of the two sub-tasks (Kolitsas et al., 2018). These two EL

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 504–514
April 19 - 23, 2021.

approaches depend on an intermediate candidate generation step and rely on a pre-computed list of entity candidates. For example, (Kolitsas et al., 2018) propose a joint MD and ED model and inherits the candidate list from (Ganea and Hofmann, 2017). The third approach combines the three sub-steps in a joint model and illustrates that each of those tasks is interdependent (Durrett and Klein, 2014; Broscheit, 2019).

The recent EL approaches focus on jointly modelling two or three subtasks (Sevgili et al., 2020). Furthermore, the NLP research community has extensively used transformers in end-to-end models for entity linking (Broscheit 2019, Peters et al. 2019, and Févry et al. 2020). Nevertheless, these works report less performance than (Kolitsas et al., 2018), which is a bi-LSTM based model. The observations regarding the limited performance of transformer-based models for the EL motivate our work, and in this paper, our focus is to understand the bottlenecks in the entity linking process. We argue that the less studied task in literature, i.e., candidate generation, has an essential role in the EL models' performance, which has not been a focus in the recently proposed transformer-based entity linking models.

In this paper, we **hypothesise** that the transformer models, though trained on a large corpus, may require additional task-specific contexts. Furthermore, inducing the context at the entity disambiguation step may positively impact the overall performance, which has not been utilised in the state of the art methods due to monolithic implementations (Kolitsas et al., 2018; Peters et al., 2019; Broscheit, 2019; Févry et al., 2020). Subsequently, we deviate from the joint modelling of two or three subtasks of the EL and revert to the methodology opted by earlier EL systems in 2011 (Hoffart et al., 2011), i.e. treat each subtask independently. As such, we study the research question: **RQ**: *what is the impact of each sub-task (aka component) on the overall outcome of the transformer-based entity linking approach?* We propose an intuitive novel approach named CHOLAN, comprising a modular architecture of two transformer models to solve MD and ED independently. In the first step, CHOLAN employs BERT (Devlin et al., 2019) model to identify mentions of the entities in an input sentence. The second step involves expanding each mention with a list of KB entity candidates. Finally, the entity mention, sentence (local context), an entity candidate, and entity Wikipedia description (entity context) are fed as input sequences in the second BERT based model to predict the correct KB entity (cf. Figure 1). We train MD and ED steps independently during training, and while testing, we run the CHOLAN pipeline end-to-end for predicting the KB entity. The following are the novel features of CHOLAN:

- The core focus of the approach is to flexibly induce external context and candidate lists in a transformer-based model to improve the EL performance. CHOLAN is independent of a particular candidate list and additional background context. We study four different configurations of CHOLAN to demonstrate the impact of candidate generation step and background knowledge (i.e. entity and sentential context) induced in the model. CHOLAN achieves a new state of the art performance on several datasets: T-REx (ElSahar et al., 2018) for Wikidata; AIDA-B, MSBC, AQUAINT, and ACE2004 for Wikipedia (Hoffart et al., 2011; Guo and Barbosa, 2018).
- CHOLAN is the first approach which is empirically demonstrated to be transferable across KBs having completely different underlying structure and schema i.e., on semi-structured Wikipedia and fully structured Wikidata.

The implementation is publicly available[1]. The paper is structured as follows: next section summarises the related work. Section 3 describes the problem statement and approach. Section 4 explains the experimental settings followed by results in 5. We conclude in Section 6.

2 Related Work

Mention Detection (MD): The first attempt to organise a named entity recognition (NER) task traced back to 1996 (Grishman and Sundheim, 1996). Since then, numerous attempts have been made ranging from conditional random fields (CRFs) with features constructed from dictionaries (Rocktäschel et al., 2013) or feature-inferring neural networks (Collobert and Weston, 2008).

---

[1] `https://github.com/ManojPrabhakar/CHOLAN`

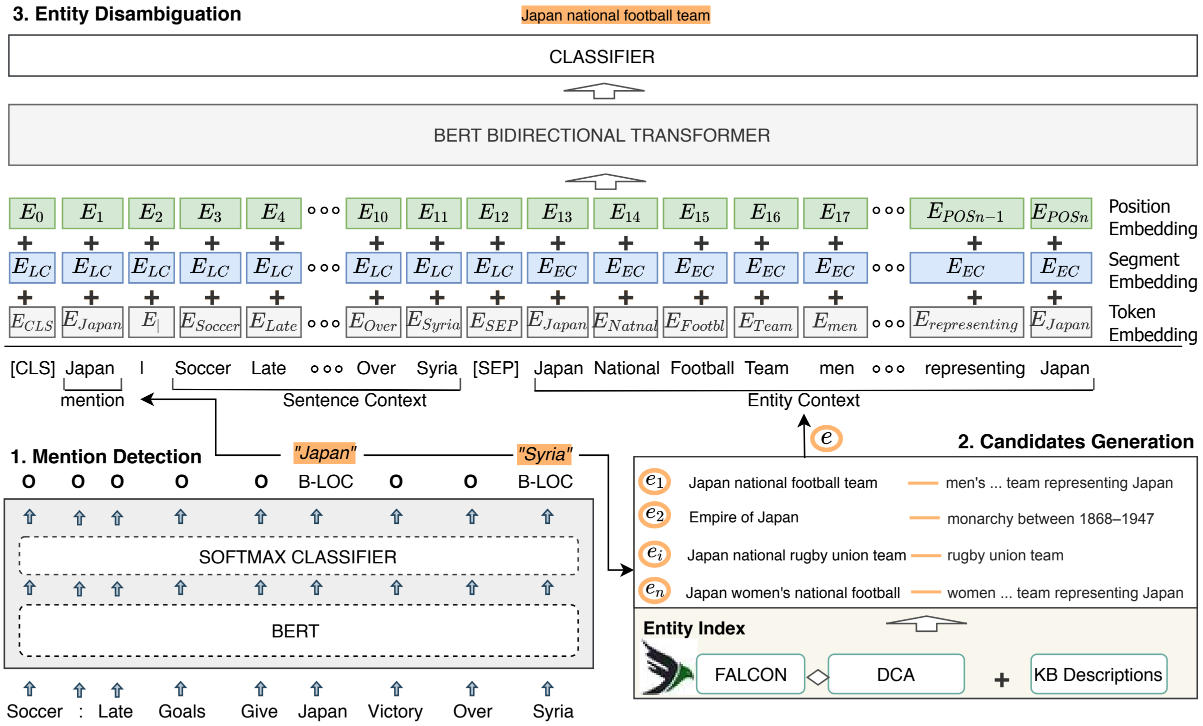

Figure 1: CHOLAN has three building blocks: i) BERT-based Mention Detection that identifies entity mentions in the text ii) Candidate Generation that retrieves a set of entities for the mention iii) Entity Disambiguation: employs BERT transformer model powered by background knowledge from KB and local sentential context.

Recently, contextual embedding based models achieve state of the art for NER/MD task (Akbik et al., 2018; Devlin et al., 2019). We point to the survey by Yadav and Bethard (2018) for details about NER. Few early EL models have performed MD task independently (Ceccarelli et al., 2013; Cornolti et al., 2016).

Candidate Generation (CG): There are four prominent approaches for candidate generation. First is a direct matching of entity mentions with a pre-computed candidate set (Zwicklbauer et al., 2016). The second approach is the dictionary lookup, where a dictionary of the associated aliases of entity mentions is compiled from several knowledge base sources (e.g. Wikipedia, Wordnet) (Sevgili et al., 2020; Fang et al., 2019; Cao et al., 2017). The third approach is to generate entity candidates using empirical probabilistic entity-map $p(e|m)$. The $p(e|m)$ is a pre-calculated prior probability of correspondence between positive mentions and entities. A widely used entity map was built by (Ganea and Hofmann, 2017) from Wikipedia hyperlinks, Crosswikis (Spitkovsky and Chang, 2012) and YAGO (Hoffart et al., 2011) dictionaries. End-to-end EL approaches such as (Kolitsas et al., 2018; Cao et al., 2018) relies on the entity map built by Ganea and Hofmann. The next approach for generating the candidates is proposed by (Sakor et al., 2019). Authors build a local KG by expanding entity mentions using Wikidata and DBpedia entity labels and associated aliases. The local KG can be queried using BM25 ranking algorithm (Logeswaran et al., 2019). The modular architecture of CHOLAN gives us the flexibility to experiment with several ways of generating entity candidates. Hence, we reused candidate list proposed by (Ganea and Hofmann, 2017) and built a new CG approach based on (Sakor et al., 2019).

End to End EL: Few EL approaches accomplish MD and ED tasks jointly. (Nguyen et al., 2016) propose joint recognition and disambiguation of named-entity mentions using a graphical model and show that it improves EL. The work in (Kolitsas et al., 2018) also proposes a joint model for MD and ED. Authors use a bi-LSTM based model for mention detection and computes the similarity between the entity mention embedding and set of predefined entity candidates. The work in (Broscheit, 2019) employs BERT to jointly model three subtasks of the EL. Author employ an entity vocabulary of 700K top most frequent entities to train the model. Work in (Févry et al., 2020) uses a Transformer architecture with large scale pre-training from Wikipedia links for EL. For CG, authors train the model to predict BIO-tagged mention boundaries to disambiguate among all entities. For Wikidata KG, Opentapioca is an entity linking approach which relies on a heuristic-based model for disambiguation of the mentions in a text to the Wikidata entities (Delpeuch, 2020). Arjun (Mulang et al., 2020) is the most similar to our approach CHOLAN and trains two independent neural models for MD and ED. It generates candidates on the fly using a Wikidata entity alias map. Arjun does not induce any context in the model.

3 Problem Statement and Approach

We formally define EL task as follows: given an input sequence of words W = $\{w_1, w_2, w_3, \ldots, w_n\}$, and a set of entities denoted by $\mathcal{E}$ from a KG/KB. The EL task aligns the text into a subset of entities represented as $\Theta : W \rightarrow \mathcal{E}'$ where $\mathcal{E}' \subset \mathcal{E}$. We formulate the EL task as a three step process in which the first step is the mention detection (MD). The MD is a function $\theta_1 : W \rightarrow \mathcal{M}$, where the set of mentions is denoted by $\mathcal{M} = (m_1, m_2, ..., m_k)$ $(k \leq n)$ and each mention m_x is a sequence of words starting from i to end position j: $m_x^{(i,j)} = (w_i, w_{i+1}, ..., w_j)$ $(0 < i, j \leq n)$. The next task is candidate generation where for each mention m_x a set of candidates $C(m_x)$= $\{e_1^x, ..., e_n^x | e_i^x \in \mathcal{E}\}$ is derived. Finally, the entity disambiguation (ED) task aims to map each mention $m_x \in \mathcal{M}$ to the most likely entity from its list of candidates. In our case, we model the ED task as a classification task and augment the input with extra signals as context. For every candidate entity $c_i \in C(m_x)$, the model estimates a probability p_i, thus the most likely entity is the one with the highest probability as $\gamma = \arg\max_{p_i}\{\mathcal{P}(p_i \mid m_x, c_i^x, W, C)\}$ where W and C are the input representations respectively for the given sentence (local context) and the context derived from KG/KB. As such the probability of score p_i is conditioned not only on m_x and c_i^x but also on W and C as contextual parameters.

3.1 CHOLAN Approach

The CHOLAN architecture comprises of three main modules as illustrated in Figure 1.

3.1.1 Mention Detection (MD)

We adapt the vanilla BERT (Devlin et al., 2019) model for the task of entity mention detection in an unstructured text. For each input sentence, we append the special tokens [CLS] and [SEP] to the beginning and end of the sentence, respectively. This is then used as input to the model which learns a representation of the tokens in the sentence. We then introduce a (logistic regression based) classification layer on top of the BERT model to determine named entity tags for each token following the BIO format (Sang and Meulder, 2003). Our BERT† model is initialised using publicly available weights from the pretrained BERT$_{BASE}$ model and is fine-tuned to the specific dataset for detecting a mention m_i. Please note that BERT$_{BASE}$ model is the latest approach which successfully outperformed in various NLP tasks, including MD. Thus, we reuse this model for the completion of our approach.

$$m_i = BERT^\dagger(w_i) \tag{1}$$

3.1.2 Candidate Generation (CG)

One of the critical focus of CHOLAN is to understand the bottleneck at the CG step. Hence, we reuse the DCA candidate list and propose a novel candidate list to understand the candidate generation impact on overall EL performance.

DCA Candidates: (Yang et al., 2019) adapts the probabilistic entity-map $p(e|m)$ created by (Ganea and Hofmann, 2017) (cf. section 2) to calculate the prior probabilities of candidate entities for a given mention. In the probabilistic entity-map, each entity mention has 30 potential entity candidates. Yang and colleagues also provide associated Wikipedia description of each entity. In CHOLAN, we *reuse* candidate set $C(m)$ provided by (Yang et al., 2019) and further consider associated Wikipedia entity descriptions.

Falcon Candidates: (Sakor et al., 2019) created a local index of KG items from Wikidata entities expanded with entity aliases. For example, in Wikidata the entity Q33[2] has the label "Finland". Sakor and colleagues expanded the entity label with other aliases from Wikidata such as “Finlande”, “Finnia”, “Land of Thousand Lakes”, “Suomi”, and “Suomen tasavalta”. We adopt this local KG index to generate entity candidates per entity mention in the employed datasets. The local KG has a querying mechanism using BM25† algorithm (cf. equation (2)) and ranked by the calculated score. We build a predefined candidate set using the top 30 Wikidata entity candidates in

---

[2] `https://www.wikidata.org/wiki/Q33`

$C\_Falcon(m)$ for each entity mention. We enrich the candidates set obtained from Wikidata by the correspondence from Wikipedia. We also add the first paragraph of Wikipedia as entity descriptions (only if Wikidata entity has corresponding Wikipedia page) to the hyperlinks. By selecting two different candidate list, our idea is to understand the impact of candidate generation step on end-to-end entity linking performance.

$$e_i = BM25^{\dagger}(m_i) \tag{2}$$

3.1.3 Entity Disambiguation (ED)

In order to use the power of the transformers, we propose "WikiBERT" to perform the ED task. In WikiBERT, our novel methodological contribution is the induction of local sentential context and global entity context at the ED step in a transformer model, which has not been used in the recent EL models. WikiBERT is derived from the vanilla BERT$_{BASE}$ model and fine-tuned on the two EL datasets (CoNLL-AIDA and T-REx). We view the ED task as sequence classification task. The input to our model is a combination of two sequences. The first sequence S_1 concatenates the entity mention $m \in \mathcal{M}$ and sentence $\mathcal{W}$ where the sentence acts as a local context. The second sequence S_2 is a concatenation of entity candidate $e \in C(m)/C\_Falcon(m)$(obtained from Equation 2) and its corresponding Wikipedia description (entity context ct_i). The two sequences are paired together with special start and separator tokens: ([CLS] S_1 [SEP] S_2 [SEP]). The sequences are fed into the model which in turn learns the input representations according to the architecture of BERT (Devlin et al., 2019). Any given token (local context word, entity mention, or entity context words) is a summation of the three embeddings :

i. *Token embedding*: refers to the embedding of the corresponding token. We make note here on specific tokens that comprises the input representations for our model more specialised as compared to other fine-tuning tasks. The entity mention tokens appended at the beginning of S_1 and separated from the sentence context tokens by a single vertical token bar |, likewise, for the entity context sequence S_2, we prepend the entity title tokens from the KB before adding the descriptions.

ii. *Segment embedding*: each of the sequences receive a single representation such that the segment embedding for the local context E_{LC} refers to the representation for S_1 whereas E_{EC} is the representation of S_2

iii. *Position embedding*: represents the position of the token in an input sequence. A token appearing at the i-th position in the input sequence is represented with E_i

To train the model, we use the negative sampling approach similar to Yamada and Shindo (2019). The candidate list is generated for each identified mention. The desired entity candidate item is labelled as one, and the rest of the incorrect candidate items (from candidate list) are labelled as zero for a given mention. This process iterates over all the identified mentions using Equation 1.

The training process fine-tunes BERT using the contextual input from sentence and Wikipedia resulting into the WikiBERT model (Equation (3)). The model predicts the relatedness of the two sequences by classifying it as either positive or negative.

$$e_i = WikiBERT(m_i, e_i, ct_i) \tag{3}$$

4 Experimental Setup

4.1 Datasets

For Wikidata EL, we rely on T-REx dataset (ElSahar et al., 2018). We adapt the subset of T-REx used by Mulang et al. (2020) for a fair evaluation setting. The dataset contains 983,257 sentences (786,605 in training and 196,652 in the test set) accommodating 3,133,778 instances of surface forms which are linked to 85,628 distinct Wikidata entities. T-REx does not have a separate validation set to fine-tune the hyperparameters. Therefore, we further divide the train set into a 90:10 ratio for training and validation.

For EL over Wikipedia, we adapt standard dataset CoNLL-AIDA proposed by (Hoffart et al., 2011) for the training. The dataset contains 18,448 linked mentions in 946 documents, a test set of 4,485 mentions in 231 documents, and a validation set of 4,791 mentions in 216 documents. For testing, we use AIDA-B (test) dataset from (Hoffart et al., 2011) and MSNBC, AQUAINT, ACE2004 datasets from (Guo and Barbosa, 2018).

4.2 Models for Comparison

4.2.1 Baselines over Wikidata

We now briefly explain Wikidata baselines.

1. OpenTapioca (Delpeuch, 2020): is a heuristic-based end-to-end approach that depends on topic similarity and mapping coherence for linking

Wikidata entity in an input text.
2. Arjun (Mulang et al., 2020): is a pipeline of two attentive neural networks employed for MD and ED. Arjun is the SotA, and we take baseline values from Arjun's paper.

4.2.2 Baselines over Wikipedia

1. (Hoffart et al., 2011): build a weighted graph of entity mentions and candidate entities. Then, the model computes a dense subgraph that predicts the best joint mention-entity mapping.
2. DBpedia Spotlight (Mendes et al., 2011) proposes a probabilistic model and relies on the context of the text to link the entities.
3. KEA (Steinmetz and Sack, 2013) employs a linguistic pipeline coupled with metadata generated from several Web sources. The candidates are ranked using a heuristic approach.
4. Babelfy (Moro et al., 2014) is a graph-based approach that uses loose identification of candidate meanings coupled with the densest subgraph heuristic to link the entities.
5. Piccinno and Ferragina (2014): to solve entity linking, authors focus on mentions recognition and annotations pruning to propose a voting algorithm for entity candidates using PageRank.
6. Kolitsas et al. (2018) train MD and ED task jointly using word and character-level embeddings. The model reuses candidate set from (Ganea and Hofmann, 2017) and generates a global voting score to rank the entity candidates.
7. Peters et al. (2019) induce multiple KBs into a large pretrained BERT model with a knowledge attention mechanism.
8. Broscheit (2019) trains MD, CG, ED task jointly using a BERT-based model. Besides, an entity vocabulary containing 700K most frequent entities in English Wikipedia was utilised.
9. Févry et al. (2020) consider large scale pretraining from Wikipedia links as the context for a transformer model to predict KB entities.
In Wikipedia-based experiments, we report values from (Févry et al., 2020) and (Kolitsas et al., 2018) for AIDA-B test set. On MSNBC (MSB), AQUAINT (AQ), and ACE2004 (ACE) test datasets, only (Kolitsas et al., 2018), DBpedia Spotlight (Mendes et al., 2011), KEA (Steinmetz and Sack, 2013), and Babelfy (Moro et al., 2014) report the values and we compare against them.

Hyper-parameters	**Value**
Epochs	4
Batch size	8
Learning rate	$2e^{-5}$
Learning rate decay	linear
Adam β_1	0.9
Adam β_2	0.999
dropout	0.1
Loss Function	Cross-Entropy
Classifier	Softmax

Table 1: Hyper-parameters during fine-tuning.

4.3 CHOLAN Configurations

We configure CHOLAN model applying various candidate generation approaches detailed below.
CHOLAN-Wikidata: we train the model using T-REx dataset and employ $C\_Falcon(m)$ candidate set. The ED model (WikiBERT) is fed with the sentential context but not with entity description as not all Wikidata entities have a corresponding Wikipedia entity.
CHOLAN-Wiki+FC: is trained on CoNLL-AIDA (Hoffart et al., 2011). For CG step, we employ Falcon candidate set $C\_Falcon(m)$. Here, the ED model (WikiBERT) is only fed with the sentential context.
CHOLAN-Wiki+DCA: We train the MD and ED models on CoNLL-AIDA. The CG step involves DCA candidate set $C(m)$. During ED step (WikiBERT), Wikipedia descriptions associated with each entity is fed along with sentential context.
CHOLAN: inherits **CHOLAN-Wiki+FC** but in addition, Wikipedia entity description is induced into the ED model (WikiBERT).

4.4 Metrics and Hyper-parameters

On Wikidata-based experiments, we employ standard metrics of accuracy i.e., precision (P), recall (R), and F-score (F) same as (Mulang et al., 2020). For Wikipedia-based datasets, we use Micro-F1 score in strong matching setting (Kolitsas et al., 2018). The strong matching needs exactly predicting the gold mention (i.e. target entity mention) boundaries and its corresponding entity annotation in the KB. To compare the recalls of two CG approaches, we report the performance on gold recall. Gold recall is the percentage of entity mentions for which the candidate set contain the ground truth entity (Yao et al., 2019).
We have implemented all our models in PyTorch[3]

---

[3] `https://pytorch.org/`

and optimized using Adam (Kingma and Ba, 2015). We used the pre-trained BERT models from the Transformers library (Wolf et al., 2019). We ran all the experiments on a single GeForce GTX 1080 Ti GPU with 11GB size. Table 1 outlines the hyper-parameters used in the fine-tuning on both the datasets. We followed the standard settings suggested by (Devlin et al., 2019). The average run time is 9.31 hours/epoch for CHOLAN and without description, it was 7.23 hours/epoch.

5 Results

We study the following research question:*what is the impact of each sub-task (aka component) on the overall outcome of the transformer-based entity linking approach?* We further investigate a sub-research question: how do the external context and the candidate generation step impact the overall performance of CHOLAN? Our every experiment systematically studies the research questions in different settings.

Model	**P**	**R**	**F**
Delpeuch 2020	40.7	**82.9**	57.9
Mulang et al. 2020	71.4	71.2	71.3
CHOLAN-Wikidata	**75**	76	**75.4**

Table 2: Comparison on T-REx test set for Wikidata EL. Best values in bold.

5.1 Results on Wikidata dataset

Table 2 summarises CHOLAN performance on T-REx dataset. CHOLAN-Wikidata configuration outperforms the baselines. We dig deeper into our reported values. We observe that for MD task, our F-score is 94.3 (compared to 77 F-score of Arjun (Mulang et al., 2020)). However, the gold recall for CG step is 81.2. We generate the entity candidates using an information retrieval approach (BM25† algorithm) to get the top 30 candidates based on the confidence score. The Wikidata KG is challenging, and many labels share the same name. It contributes to a large loss in the F-score for the CG step. For instance, the entity mention "National Highway" matches exactly with four Wikidata ID labels while 2,055 other entities contain the full mention in their labels. Please note that we did not perform retraining of (Kolitsas et al., 2018) (SOTA on Wikipedia EL) on the T-REx dataset since we determined that the model is tightly coupled and relies on pre-computed Wikipedia candidate list from (Ganea and Hofmann, 2017).

5.1.1 Ablation Study on Wikidata

We study the impact of local context on the performance of CHOLAN. Therefore, we exclude the sentence as input in the ED step at training and testing time. Hence, the inputs to the ED model are only entity mention and the entity candidates gained from the CG step. We observe that the performance drops when the local sentential context is not fed (cf. Table 3). It justifies our choice to feed the model by the sentence during the ED task.

Model	**P**	**R**	**F**
CHOLAN-Wikidata	**75**	**76**	**75.4**
CHOLAN-Wikidata (WLC†)	72	73.5	72.7

Table 3: The ablation study on T-REx test set for Wikidata EL. Best values in bold. WLC† denotes model without local context. When the local sentential context is excluded from ED, the performance drops.

5.2 Results on Wikipedia datasets

Table 4 reports the performance of CHOLAN's configurations on AIDA-B test set. The first configuration is "CHOLAN-Wiki+ FC" in which MD and ED models are trained using CoNLL-AIDA. We notice a clear jump in the performance. We then replaced the Falcon candidate list $C\_Falcon(m)$ with DCA candidates $C(m)$ resulting into "CHOLAN-Wiki+ DCA". In DCA candidates, the description of entities is attached. The performance is increased when an additional background knowledge as an entity description is fed. Our next configuration is CHOLAN where we attached Wikipedia entity descriptions in Falcon candidate list $C\_Falcon(m)$ (as a modification of "CHOLAN-Wiki+ FC"). This setting outperforms all the existing baselines and previous CHOLAN configurations. Our experiments illustrate the impact of CG step and background knowledge on end-to-end EL performance. The improvement of CHOLAN continues to the other three test datasets where the jump is significantly higher compared to the baselines (cf. Table 5). Reported values in Table 5 also approves transferability of CHOLAN when we apply cross-domain experiments.

5.2.1 Ablation Study on Wikipedia

We conducted three ablation studies to understand the behaviour of CHOLAN's configurations over Wikipedia datasets. The first study

Model	Micro F1
Hoffart et al. 2011	72.8
Mendes et al. 2011	57.8
Steinmetz and Sack 2013	42.3
Moro et al. 2014	48.5
Piccinno and Ferragina 2014	73
Kolitsas et al. 2018	82.4
Peters et al. 2019	73.7
Broscheit 2019	79.3
Févry et al. 2020	76.7
CHOLAN-Wiki+ FC	75.1
CHOLAN-Wiki+ DCA	77.5
CHOLAN	**83.1**

Table 4: Comparison on *AIDA-B*. Best value in bold and previous SOTA value is underlined.

Model	MSB	AQ	ACE
Mendes et al. 2011	40.6	45.2	60.5
Steinmetz and Sack 2013	30.9	35.9	40.3
Moro et al. 2014	39.7	35.8	17.8
Kolitsas et al. 2018	72.4	40.4	68.3
CHOLAN-Wiki+ FC	77.8	70	85.7
CHOLAN-Wiki+ DCA	78.3	75.9	71.3
CHOLAN	**83.4**	**76.8**	**86.8**

Table 5: The micro F1 scores are listed from the comparative study over three datasets (out of domain). The model is trained over CoNLL-AIDA dataset. Best value in bold and previous SOTA value is underlined.

is to calculate the Gold recall values for various datasets. CHOLAN uses the candidates from $C\_Falcon(m)$ candidate set for each entity mention. While generating the candidate set from local KG of (Sakor et al., 2019) we observe a drop in the Gold recall as reported in Table 6. CG plays a crucial role in trading off precision and recall. We conclude that more robust CG approaches likely impact overall performance. The second ablation study is about to calculate the performance of our configurations for ED step, i.e., running WikiBERT in isolation. Here, we assume that all entities are truly recognised; thus, our focus of the study is the ED model. We report the impact of various candidate generation approaches on the ED model in Table 7. The significant jump in the performance from ”CHOLAN-Wiki+FC Vs CHOLAN” contributes to the additional background knowledge provided in CHOLAN as entity candidate descriptions. The third ablation study tests the impact of sentential context fed into two configurations on a Wikipedia dataset. Table 8 reports the achieved performance after excluding sentence as the additional context. Obviously, the performance decreases. The model shows similar behaviour on T-REx in Table 3. These observations confirm our hypothesis as the ED model is enhanced using additional contexts.

Model	AIDA-B	MSB	AQ	ACE
Falcon Candidates	94	93.8	85.3	97.3
DCA Candidates	98.3	98.5	94.2	90.6

Table 6: Gold Recall for Candidate Generation techniques over Wikipedia test datasets.

Model	Micro F1

CHOLAN-Wiki+ FC	78.4
CHOLAN-Wiki+ DCA	79.1
CHOLAN	**85.7**

Table 7: Comparison on *AIDA-B* for ED. Best score in bold and previous SOTA value is underlined.

Model	Micro F1
CHOLAN-Wiki+ DCA	77.5
CHOLAN-Wiki+ DCA (WLC†)	71.2
CHOLAN	**83.1**
CHOLAN (WLC†)	79.6

Table 8: Ablation study on *AIDA-B*. We observe that when local sentential context is removed from ED step, the performance drops. Best values in bold. WLC† denotes model without local context.

6 Conclusions

In the last two years, the NLP research community has extensively tried transformer-based models for the EL task. However, the performance remained lower than Kolitsas et al. (2018). This paper combines the traditional software engineering principle of modular architecture with the context-induced transformers to effectively solve the EL task. Our reason to deviate from an end-to-end architecture was to provide full flexibility to our system in terms of candidate generation list, underlying KG, and induction of the context at the ED step. We attribute CHOLAN's outperformance to the following reasons: 1) the modular architecture, which brings flexibility and interoperability as CHOLAN can treat each task independently. Kolitsas et al. (2018) reports that shifting towards joint modelling of MD and ED tasks helps mitigate error propagation from MD to ED. However, the performance of BERT$_{BASE}$ for the MD task is significantly high (92.3 on AIDA-B and 94.3 F1-

score on T-REX calculated by us) remarkably reducing the errors in MD. CHOLAN leverages this capability in the MD subtask, placing more focus on CG and ED tasks. 2) The flexibility in architecture further permits us to induce sentence and entity descriptions as additional contexts. Furthermore, using candidate list in plug and play manner has resulted in a significant increase in the performance. In earlier transformer approaches, the implementation is monolithic and context is not utilised. There are scopes for improvement in our approach. Wu et al. (2019a) introduces a novel CG method that retrieves candidates in a dense space defined by a bi-encoder and can be used as alternate CG approach. We aim for scaling CHOLAN to multilingual entity linking as a viable next step.

Abstract

Collaborative grounding is a fundamental aspect of human-human dialog which allows people to negotiate meaning. In this paper we argue that it is missing from current deep learning approaches to dialog and interactive systems. Our central point is that making mistakes and being able to recover from them collaboratively is a key ingredient in grounding meaning. We illustrate the pitfalls of being unable to ground collaboratively, discuss what can be learned from the language acquisition and dialog systems literature, and reflect on how to move forward.

1 Introduction

Collaborative grounding is shaped by *constraints* that are not explicit in successful dialog turns. These constraints combine information from world *causal relations*, the *task* under discussion, the *communicative intents* of the dialog partners, and much else besides. They are used to *negotiate meaning*, to decide which beliefs to add to the shared *common ground*, which is constructed using the *joint attention* of the dialog partners to things either real or imagined. Once beliefs are grounded, they cannot be magically ungrounded without further negotiation, for the dialog partners are *committed* to them. But it's tricky:

> *Human-analogous natural language understanding (NLU) is a grand challenge of artificial intelligence, which involves mastery of the structure and use of language and the ability to ground it in the world.* (*Bender and Koller, 2020*)

What does "the ability to ground it in the world" involve? Implicit constraints that shape grounding become explicit when communication starts to break. We claim that *making mistakes* and being able to recover from them *collaboratively* is a key ingredient of the ability to ground.

We proceed as follows. We first discuss obstacles to current research on dialog and interactive systems (Section 2) and then present working definitions of *collaborative grounding* and related concepts (Section 3). Section 4 plays with scenarios illustrating the pitfalls of being unable to ground collaboratively; we then turn to the language acquisition literature for insight into how humans do it (Section 5) and to the dialog systems literature to discuss what is known (Section 6). In Section 7, we reflect on the progress made and make recommendations, while in Section 8 we note possible objections to our account and conclude.

2 Motivation

Dialog and interactive systems is one of the most popular research areas in computational linguistics nowadays. But — unlike machine translation and information retrieval — deep learning approaches to it have had little impact on products that people use daily.[1] In 1991, cognitive scientist Brennan asked: *Why is it that natural language has yet to become a widely used modality of human/computer interaction?* (Brennan, 1991), and in 2020 the AI researchers de Vries, Bahdanau and Manning (de Vries et al., 2020) asked the same question yet again. In 1990, research on dialog systems used symbolic approaches; today neural generative models are favoured. Methods have changed, but the question remains the same.

Neural generative models offer flexibility, can be easily adapted to new domains, and require minimal domain engineering. But though they generate fluent responses (Serban et al., 2016), the result is often boring and repetitive ("I don't know") or they contradict themselves, or wander away from the

---

[1] Almost all commercial dialog systems currently available seem to be based on pre-deep learning pipeline architectures (Takanobu et al., 2020) in spite of efforts such as the Alexa Prize (Ram et al., 2018; Gabriel et al., 2020).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 515–531
April 19 - 23, 2021.

topic of conversation (Li et al., 2016). De Vries et al (2020) note that neural generative models assume that the required data is available and appropriate. They say: *Ideally, the data used for training and evaluating should reflect the intents and linguistic phenomena found in real-world applications and be of reasonable size to accommodate modern data-intensive methods.* They remark that data quality and quantity are hard to reconcile, and that the community has prioritized quantity over quality; thus dialog systems are inadequate because datasets are poor. But ineffective use of dialog history seems to play a role too. Sankar et al (2019) study model sensitivity to artificially introduced context perturbations at test time. Working with multi-turn dialog datasets, they found that commonly used neural dialog architectures, like recurrent and transformer-based seq2seq models, are rarely sensitive to perturbations such as missing or reordered utterances, and word shuffling.

The ineffective use of dialog history often goes unnoticed because of the evaluation practices that are common nowadays. Automatic metrics such as BLUE, ROUGE, and so on, do not correlate well with human judgement, either for semantic preserving natural language generation or for dialog (Mathur et al., 2020). For human evaluation, it is not enough to show a few turns to the annotators (Liu et al., 2016). This does not measure how well the system is able to recover from its own mistakes; a human-in-the-loop evaluation that judges the overall interaction is needed for that (Walker et al., 1997).

Graphical user interfaces (GUIs), on the other hand, tend to get things right. We agree with Brennan (1998) that GUIs are more successful in everyday use than dialog systems (DSs) because GUIs enable collaborative grounding effectively while deep learning approaches to DSs do not.

3 What is collaborative grounding?

In this section we provide working definitions of collaborative grounding and other key concepts. To get the ball rolling, we take the *common ground* to be the commitments that the dialog partners have (explicitly or implicitly) agreed upon.

Collaborative grounding not symbol grounding *Collaborative grounding* is the process of seeking and providing incremental evidence of mutual understanding through dialog; we view the ongoing exchange of speaker and hearer roles as fundamental to conversation (Benotti, 2010; Benotti and Blackburn, 2014). When the speaker believes that the dialog is on track, *positive evidence* of understanding is provided in different forms (depending on the communication channel) such as explicit acknowledgements and eye contact. *Negative evidence* of understanding signals that something needs to be negotiated before the dialog partners can commit — and negative evidence is ubiquitous:

Conversations with other people are rarely fluent and without mishap, and people do not expect them to be. (Brennan, 1991)

Mishaps lead to the need for *repair*. Repair is fundamental to *conversational analysis* (Schegloff et al., 1977; Schegloff, 2007), the linguistic study of language-driven social interactions. Together with the more psychologically oriented work of Clark and his colleagues (Clark and Wilkes-Gibbs, 1986; Clark, 1996), conversational analysis, is a key inspiration for the lines of research that we review in this paper.

We consider collaborative grounding to be distinct from symbol grounding (Harnad, 1990) though they interact in interesting ways (Larsson, 2018). *Symbol grounding* (or perceptual grounding, or language grounded in vision) is the set of capabilities that link symbols with perceptions; it is an important research area (Roy, 2005) in which accurate connections between systems' linguistic representations and sensor data are often viewed as proof that a system means what it says. These connections are important for meaning, but we agree with De Vault et al. (2006) that *perceptual grounding is neither necessary nor sufficient to justify the attribution of linguistic meaning*. Human perception and memory are neither accurate nor stable, and different people have different abilities and limitations. Human meaning attributions do not rely on the accurate perceptions and perfect memory sought by symbol grounding, but on a *collaborative negotiation process* in which language speakers coordinate their perceptual memories and linguistic usage with other members of their communities. If a dialog system *commits* itself to negotiate its meanings collaboratively when perception and memory falter, then we claim that this gives grounds for assigning linguistic meaning to it. See Section 4 and A for examples.

Collaborative grounding: basic mechanisms When people talk to each other, they tailor their utterances to their partners. People can talk with friends, strangers, disembodied voices on the telephone, readers who will come along after they are gone, foreigners, children, and even dogs. Flexibility in tailoring utterances for a particular addressee has been documented even among the very young; five year olds have been observed to use more simple language and a different pitch range when talking to three year olds than they do talking to adults (Golinkoff, 1986). People adapt by initially estimating the common ground they share with a particular partner, by monitoring the positive and negative evidences of understanding (aka *grounding acts*) and by adapting their initial common ground estimate accordingly.

Alikhani and Stone (2020) explain that dialog systems can participate in collaborative grounding by ensuring they get attention and feedback from their users and tracking user state. Such *pragmatic mechanisms* have been explored, including those for dealing with problems related to joint attention (Koller et al., 2012; Koleva et al., 2015; Tan et al., 2020), engagement (Bohus and Horvitz, 2014; Foster et al., 2017), turn taking and incremental interpretation (Schlangen and Skantze, 2009; Selfridge et al., 2012; DeVault and Traum, 2013; Eshghi et al., 2015) corrections and clarifications (Villalba et al., 2017; Ginzburg and Fernández, 2010) and dialog management (DeVault and Stone, 2009; Selfridge et al., 2012). These mechanisms have been studied for different kinds of applications (Denis, 2010; Dzikovska et al., 2010, 2012). In Section 6 we discuss this research tradition; we believe it can provide top-down research guidance for research on dialog systems that commit to what they say.

Collaborative grounding: exposing limitations As we said at the start, collaborative grounding is shaped by constraints that may not be explicit in successful dialog turns. Dialog partners use constraints to negotiate meaning, adding beliefs to the common ground through their joint attention to a real or imagined world. Further negotiation is required to unground a belief; unilateral belief withdrawal leads to a sense of commitment being brushed aside.

A dialog system is an unusual kind of linguistic partner. A user must figure out what its *limitations* are and then design her utterances with them in mind. Limitations may arise due to gaps in grammatical coverage, an unexpectedly narrow domain vocabulary, or a lack of *common sense*; by common sense we here mean the basic knowledge and competencies required for successful navigation through a world full of objects, time, money, politeness, animals, people, and so on. One much-studied component of commonsense involves *causality* (Pearl, 2009) and the *frame problem* (Shanahan, 2016), the ability to figure out what changes and what does not change due to various kinds of (inter)action. Our point, however, is *not* that dialog systems need all these components of commonsense — it is rather that they need enough *interpersonal* common sense to not try and hide their inadequacies!

Often, however, these limitations are deliberately well hidden by the designers — who thereby unintentionally inhibit users from employing the powerful meaning-negotiation strategies available in a human-human dialog. Dialog systems may generate words they cannot understand, thus building false expectations of common ground in their dialog partner. Humans cannot adapt and ground collaboratively if a dialog system fails to *expose its own limitations*. In the next section we explore examples of such failures.

4 Test scenarios

This section uses playful scenarios to illustrate the implications of not learning to do collaborative grounding appropriately. We start with a text adventure scenario, then consider a multimodal scenario followed by a BlenderBot example, and conclude by contrasting these with the collaborative grounding typical of GUIs.

4.1 Dungeon intelligence

Consider the following interaction with the text game adventure AI Dungeon[2] powered by GPT-2 (Radford et al., 2019). The Webtext dataset used to train GPT-2 contains web content from Reddit links that have been rated as trustable by some Reddit users, probably including blogs, online news, and other discourse data.

In the example, when we detect a problem, we prompt Dungeon AI (DAI) with a negative grounding act (for example, *but before you only had seven, how many are there really?*). This makes the inconsistency with the previous turns explicit; in effect, we offer to negotiate. But the model blithely ig-

---

[2] https://play.aidungeon.io/ accessed on 19/08/2020

nores the negative evidence and talks about something else:

DAI: You are wearing nondescript clothing, and you manage to escape without being recognized. You open the purse and find seven gold coins, which is good since you only planned to steal a little.
Human: How many coins are there in the purse?
DAI: You count the coins and find that you have eighty one coins, which is good since you planned to steal just a little. You think to yourself "I should be able to afford a room tonight."
Human: But before you only had seven, how many are there really?
DAI: You head to the first inn you see, which seems to be a place where merchants stay. The desk clerk is a young woman who is probably only just thirteen or fourteen.

We posed this question several times but the model never tried to negotiate the inconsistency (for example, by replying: *there are 81 coins, I saw only some of them before*). In A there is a continuation of this dialog, illustrating other kinds of inconsistency and lack of collaborative grounding.

Bender and Koller (2020) argue that language models like GPT-2 are unable to ground language in the world: because they are only exposed to form, it is unreasonable to expect them to negotiate meaning. Others propose to tackle all kinds of grounding experimentally, by collecting datasets grounded in various modalities, developing models that learn from them, and using leaderboards (Linzen, 2020) and checklists (Ribeiro et al., 2020) to measure how effectively the model generalizations aligns with those of humans. So let's turn to a multimodal task: visual dialog.

4.2 Visual dialog

Visual dialogs have long been a test-bed for natural language understanding. They played a prominent role in early work on natural language understanding (Winograd, 1972) and are now the focus of an active community investigating the interplay between computer vision and computational linguistics (Baldridge et al., 2018; Shekhar et al., 2019). Important progress has been obtained thanks to the recent release of datasets like VisDial (Das et al., 2017) and GuessWhat?! (de Vries et al., 2017); the former contains chit-chat conversations about an image whereas the latter is a visual game, hence its dialogs are goal oriented.

As we see in Figure 1, GuessWhat?! is a cooperative game: two players attempt to identify an object in an image. The *Questioner* has to guess the referent by asking yes/no questions; the *Oracle* knows the referent object and provides the answers. In the figure, the referent is the second woman from right to left of the group of four women in the back.

The Oracle model that includes the dialog history as an input (de Vries et al., 2017), correctly answers 9 out of 10 questions for the dialog in Figure 1; it only fails on question number 9, incorrectly answering "no". But question 9 does not look particularly hard; why does it create a problem? *Because it trades on the common ground built by the previous dialog turns.* Humans use common ground here, as shallower methods fail (the referent is not salient in the image). Indeed — except for one turn — Figure 1 is just visual question answering; the system fails on precisely the question that *cannot* be correctly answered without using the common ground built by the previous turns. Is this error only due to the rarity of such dialog turns (as (Agarwal et al., 2020) argue), something which might be fixed by better datasets?

The answer may be "no". Collaborative grounding in visual dialog has *two* characteristics that make it difficult for current machine learning methods: it is not only that turns requiring common ground may be infrequent in these datasets, in addition — as in our example — they may not be lexicalized. Common ground dependency is easier to spot when it is lexicalized with explicit pronouns (e.g. 'them' in "is it one of them?" in position 7). If the question "is it the second one?" had been asked in position 2, the model's answer "no" would have been correct, as "second" would then refer to the second (highly salient) man in the row. But in position 9 the correct answer is "yes" due to the common ground built by turns 6 to 8. Common ground dependence may be less lexicalized in visual dialog as the visual modality tends to favor visual saliency to resolve ambiguities.

As we said in Section 3, common ground is the set of commitments that the dialog partners have agreed upon, while collaborative grounding is the process by which such commitments are made. Common ground dependence, as illustrated in turn 9 in Figure 1, may not be as frequent and as lexicalized in multimodal datasets as current data hungry models need (Agarwal et al., 2020; de Vries et al., 2020). But better datasets alone will not solve the

1. It is a person?	yes
2. It is a male?	no
3. Is it a female?	yes
4. Is she in the red dress?	no
5. She is in black?	yes
6. In the back from right to left you see four women?	yes
7. Is it one of them?	yes
8. Right to left, is it the first one, gray sweater?	no
9. Is it the second one?	yes
10. Does she look to have panty hose on?	yes

Figure 1: Human-human dialog on the Guesswhat?! referential task extracted from (de Vries et al., 2017). The example illustrates the linguistic variability present in this task.

problem: we need models that are trying to do collaborative grounding. That is, we need models that are not only led by the lexical cues in the dialog but also by pragmatic mechanisms reflected by timely exchanges between speaker and hearer. So let us turn to a model that has been exposed to such pragmatic mechanisms in its data.

4.3 BlenderBot

Facebook AI has built and open-sourced BlenderBot, which they call the largest-ever open-domain chatbot. It outperforms systems such as Google's Meena (Adiwardana et al., 2020) in terms of engagement and also feels more human, according to human evaluators (Smith et al., 2020). BlenderBot attempts to combine different conversational skills including empathy, knowledge, and personality together in one system. The trained models are available for research (Smith et al., 2020) in different sizes and with different hardware requirements. The largest model has 9.4 Billion parameters, the middle sized version has 2.7 Billion.

Unlike the GPT-2 model we discussed earlier which is mostly trained on discourse data, BlenderBot is pre-trained with a large dataset of multi-party conversations extracted from the Reddit Pushshift dataset (Baumgartner et al., 2020). The dataset consists of free-form exchanges between multiple speakers and hearers where collaborative grounding is occurring. Thus the data on which BlenderBot models are pre-trained includes positive and negative evidence of understanding. BlenderBot models are then fine-tuned on dialogs that have been crowdsourced to exhibit empathy, knowledge about some particular topic, a consistent persona, and on a crowdsourced dataset that blends these abilities together (Smith et al., 2020).

The following interaction was generated using the middle sized model trained on Reddit Pushshift through July 2019 (Smith et al., 2020); we call the model BB2.7B.[3]

Human: Do you know Blender?
BB2.7B: Yes, I've used it a little bit. I am not very good at it, though.
Human: But I don't mean the 3D software.
BB2.7B: Oh, I see. Yeah, I know a little bit about it. What do you like to do with it?
Human: I mean Blender, the chatbot. Have you used it?
BB2.7B: Oh, yes, I have used it. I like to use it to make 3D models.[4]

This fragment explores BlenderBot reaction to negative evidence (*but I don't mean the 3D software*). It does not ignore it, as the Dungeon AI based on GPT-2 does. Indeed it replies with a coherent follow up and it includes a sentence that seems intended to acknowledge the misunderstanding (*Oh, I see*). However, the rest of the dialog shows that in spite of recognizing the structure of negative evidence, BlenderBot is unable to integrate negative grounding into the conversation consistently.

4.4 Graphical user interfaces

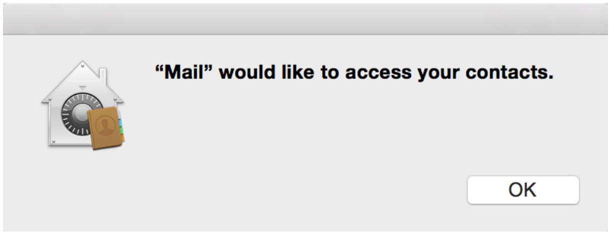
GUIs exploit graphical elements that mimic physical objects: we can point, drag and toss them in the trash bin. GUIs respond by updating immediately, thus the relationship between the user's action and the graphical result is utterly clear. Even though GUIs are primarily graphical, they are also conversational and implement pragmatic mechanisms;

---

[3] The model is available at https://parl.ai/projects/recipes/

[4] See https://www.youtube.com/watch?v=-op_yOXBNEY for the full dialog.

indeed, their response is as timely and relevant as backchannels in human conversation (acknowledgments, nods, eye contact; see (Gravano and Hirschberg, 2011)). As they enable direct manipulation, they trivially solve the linguistic reference problem. They model common ground by tracking what is visible to the user. They model joint attention graphically through focus. And they do not suffer from the frame problem: consistency is carefully preserved in GUI design (Brennan, 1998); if you move something, it will stay there until somebody moves it back. They ask for both positive (e.g. ok) and negative (e.g. cancel) evidence for understanding. GUIs are good at exposing their own limitations and most users are good at adapting to them — some even overadapt and blame themselves for misunderstandings. For example, take the dialog box window in Figure 2. The system wants positive grounding evidence from the user but (confusingly) it does not offer the choice of giving negative grounding evidence (the conventional negative grounding label for buttons in GUIs is "cancel").



"Mail" would like to access your contacts.

Figure 2: Sample dialog box not allowing negative evidence of grounding: there is no cancel button.

5 Human language acquisition

Clark (2001) presents evidence that collaborative grounding underpins the process of first language acquisition in babies. She argues that collaborative grounding offers a way of placing a new piece of the language at the center of *joint attention* of the language learner and her caregiver. In particular, it is through such pragmatic mechanisms that:

> *(a) children solve the general mapping problem between form and meaning when offered new words; (b) they take up conventional terms for unfamiliar objects and events, and see how they relate to familiar terms; (c) they take up information about what they should have said when they have produced an erroneous utterance when offered reformulations. (Clark, 2001)*

Babies around one year old have been shown to perform *negative grounding acts* in order to *repair* a request that they made (e.g. "doll!") whose *intention* (e.g. "getting the doll") was *misunderstood* by an adult. Babies tend to do the repair act even when the request is satisfied by other means (maybe the frustrated adult gave the baby all the toys including the doll — yet the baby takes the doll and repeats "doll!"). In other words, they care that their intention is understood, not only satisfied (Ackermann et al., 2014; Tomasello et al., 2005). Tomasello et al argue that this is a basic ability, one required for the development of language and cognitive capabilities like belief attribution. Golinkoff describes this ability as follows:

> *Importantly, from their earliest forays into linguistic communication, infants engage in a "negotiation of meaning" in which they request clarification from the adult and produce communicative repairs for the adult when needed [...] Infants can and will persevere in the face of failure by altering their signals in creative non stereotypical ways. (Golinkoff, 1986)*

Developmental psychologists have documented repeatedly that children with autism have difficulties signaling non-comprehension and making appropriate repairs to their own linguistic messages (Katherin et al., 1990). Deaf and hearing children have been found to employ different repair strategies. Deaf children were also more likely to revise utterances; hearing children more likely to provide cue repairs. When facing communication breakdown, both deaf and hearing children persisted effectively in clarifying utterances (Ciocci SR, 1998).

Allwood and colleagues have documented that grounding acts have a central role not only for first language acquisition but also for second languages (Allwood et al., 1991; Allwood, 1993, 1997; Allwood and Ahlsen, 1999).

6 Previous work, key insights

In this section we focus on previous work (and key insights) on collaborative grounding from research on human dialog analysis and dialog systems. We won't cover work from robotics and symbol grounding; for that see e.g. (Roy and Reiter, 2005; Bohus and Rudnicky, 2009; Bohus et al., 2012; Larsson, 2018).

Long before the deep learning era, dialog system researchers were aware that constructing common ground *collaboratively* is a key task. A notable pioneer was Traum (1991; 2003) with his focus on dialog turns whose conversational role is to provide positive and negative evidence of grounding as tools for negotiating meaning. The interaction between dialog system and human computer interaction research was fruitful back then, but the tools available today for dealing with language variability (Mrksic et al., 2017) were not yet developed so systems were brittle (Allen et al., 2001).

DeVault and Stone (2009) showed that using predefined semantic tags (e.g. colors of objects) falls short for human dialog; people tend to invent new tags collaboratively as needed (e.g. using *greenish blue* to distinguish one object from a bluer one). This example could be described as "zooming into" the details of the available distinctions, but "zooming out" can occur when limitations are revealed. Saying *I am color blind* will (hopefully) shift the dialog away from reliance on color terms.

Rieser et al. (2010; 2011) and Georgila et al. (2005) propose using Wizard of Oz data instead of naturally occurring human-human dialog for training; this puts the spotlight on the necessary constraints and primes dialog systems with explicit grounding subdialogs for overcoming limitations, instead of restricting attention to the limitations of the channel through which the human crowdsourcers interact. This enables data to be collected that makes explicit strategies for negotiating meaning, and could allow systems to learn particular collaborative grounding skills relevant for the dialog system task.

The surface form of explicit negotiations of meaning in dialog are frequently non-sentential utterances (Fernandez, 2006; Fernández et al., 2007). These include prototypical positive and negative evidence of grounding such as acknowledgements and clarification requests (Stoyanchev et al., 2013; Benotti and Blackburn, 2017), but also less-well-known forms such as self-corrections, rejections, modifiers and plain old questions and answers (Purver, 2004; Purver et al., 2018). Such work makes it evident that non-sentential utterances are not errors of performance and do not need "fixing" into sentential utterances. Ginzburg and Fernandez (2010) contributed detailed formalizations of how different evidences of grounding modified the public common ground and the private commitments of each dialog participant. A simple observation in (Ginzburg, 2012) does a big job in illustrating how different written discourse and dialog can be: it is often said that the most common word in written discourse is *'the'* while the most frequent word in naturally occurring conversations in the British National Corpus (Clear, 1993) is *'yes'*. This makes it evident that the contexts available to the dialog partners in the aftermath of an utterance are *not* identical. Positive acknowledgements (like *'yes'*) signal that the participants are synchronized and that collaborative grounding is proceeding smoothly (Denis et al., 2007).

In Section 3 we said that the ongoing exchange of speaker and hearer roles is fundamental to conversation. Schlangen and others have shown in detail how the ongoing exchange of these roles is so natural that we complete and correct each others sentences in *incremental* approaches to dialog (Schlangen and Skantze, 2009; DeVault et al., 2009; Baumann and Schlangen, 2012; DeVault and Traum, 2013; Kennington and Schlangen, 2017).

Hough and Schlangen (2017) argue that embodied dialog systems must ground the degree of uncertainty they have; that is they must *expose their limitations* as we argued in Section 3 and as GUI systems routinely do. They show that humans can reliably understand the level of uncertainty that a robot has and act accordingly. No complex natural language generation abilities are needed for this; negative grounding can be realized by perceivable hesitations in a physical act done by the robot.

Koller and colleagues explain how the joint attention of the conversational participants can be considered and manipulated in order to correct the common ground. In particular, they show how listener attention can be manipulated when there is co-presence through speech and gaze (Koller et al., 2012; Koleva et al., 2015) and through emphasis in the text ("press the RED button") when co-presence is not possible (Villalba et al., 2017).

In sum, *the possibility of making mistakes and collaboratively recovering from them is one of the key pragmatic mechanisms for grounding meaning*. Much is already understood about this process, and in Section 7 we recommend using this work to motivate top down advances in dialog and interactive systems that would complement the bottom up approaches described in Section 2.

7 Moving forward

In *What Computers Can't Do* (1972), Dreyfus drew on the ideas of philosophers like Merleau-

Ponty (Merleau-Ponty, 1962) and Heidegger (Heidegger, 1993) to criticize symbolic AI. Dreyfus emphasized the embodied capability of *knowing how*, rather than the abstract propositional *knowing that* typical of symbolic AI; he did not anticipate that AI would find plausible methods (deep neural nets, embodied robotics, distributional semantics) for exploring knowing how.

Dreyfus' criticisms may seem obvious in retrospect, but it is useful to recall another philosopher that he cited. In *Philosophical Investigations*, Ludwig Wittgenstein (1953) critiqued earlier approaches to language and meaning (including his own) for failing to take the collaborative aspect of language into account.

Wittgenstein's later work foregrounds the importance of *social interaction*. In Sections 3 and 4 we remarked that collaborative grounding is more than symbolic/perceptual grounding, and claimed that the crucial missing component is provided by social interaction. In Section 5 we saw that human children are born into is a complex world of agents, relationships, affect and much else beside. Moreover (as the child soon learns) it is a world in which interesting others collaborate with the help of a malleable system called language. This system is capable of expressing multiple types of meaning — symbolic, scientific, social — which Wittgenstein summed up anthropologically: language was a form of life (*Lebensform*).

Wittgenstein's ideas are inspiring, but we don't need to look so far back: the work we reviewed in Sections 5 and 6 shows that social aspects of language use are central to the roots of meaning, and cannot be an afterthought in dialog models. This leads to our recommendations.

Appreciate socially grounded dialog datasets Dialog datasets are scarce as most naturally created dialog corpora cannot be shared due to privacy issues. Matters are different in written discourse, which has made great progress thanks to vast corpora from news services, Wikipedia and the like. We agree with de Vries et al (2020) that more effort should be put into designing what they call *ecologically valid* datasets for dialog. We agree that datasets should avoid four common issues: synthetic language, artificial tasks, not working with prospective users, and single-turn interfaces. We add two items to this wish-list: (1) dialog grounded in at least one modality and (2) dialog grounded in a (symmetric or asymmetric) social collaboration.

Regarding (1), there is much work that has been done on data collection in the visual (i.e. seeing) modality (Baldridge et al., 2018) and more recently in the kinaesthetic (i.e. moving) modality (Weihs et al., 2020). The work we reviewed in Section 6 is a good starting point for designing tasks that also consider (2) for various modalities: auditory (hearing) (Schlangen and Skantze, 2009), tactile (touching) (Hough and Schlangen, 2017), kinaesthetic (moving) (Foster et al., 2014), and visual (seeing) (Koleva et al., 2015). Dialogs grounded in social collaboration can be symmetric or asymmetric. In symmetric dialogs, the dialog roles are socially exchangeable (e.g. (Ilinykh et al., 2019; Haber et al., 2019)). In asymmetric dialogs the roles of the dialog partners are different due to expertise, social power or for some other reason. Typical examples include instruction dialog (Anderson et al., 1991) and medical or technical support (Janarthanam and Lemon, 2009).

Our final recommendation regarding datasets is to let humans collaborate freely during the first round of data collection but then to collect more restricted datasets on the same task once the limitations of the model are clear. That is: let people adapt to its limitations and collect further data that reflects the collaborative adaptation mechanisms.

Use datasets better Better data alone may not be enough; we need to consider models that explicitly tackle collaborative grounding. Examples of such work that builds on fundamental research (like that reviewed in Section 6) already exists. Consider, for example, the following exchange extracted from a human-human dataset (Andreas et al., 2020) collected through a Wizard of Oz methodology:

User: What time is my planning meeting?
Agent: You meet with Grace at noon.
User: Sorry, I meant all-hands.
Agent: Your all-hands meeting is at 2:30 pm.

The fragment contains the negative grounding act *Sorry, I meant all-hands*; which requires access to the user's previous utterance to obtain the revised intention: *What time on Tuesday is my all-hands meeting?*. Promising results have been obtained using hybrid learned-symbolic dialog systems that explicitly model the intention by grounding it into an application domain. For example (Andreas et al., 2020) represent intentions (including grounding acts) as programs that modify the common ground; (El Asri et al., 2017) track the common ground using frames, (Lison and Kennington, 2016) do so using Bayesian networks, and (Ultes et al., 2018) using entities. Such approaches have been rather marginalized in favor of more shallow ones.

Interact with models in order to test them Asking someone "do you need history to answer this question?" is not the same as answering it correctly without history. Most human evaluation of dialog systems are about self perception, not about actually performing an action. As is done in Human Computer Interaction, let people interact with models and then rate them; do not just offer pairs of turns. Dialog is *not* the concatenation of pairs of dialog turns, as noted by (Walker et al., 1997; Schlangen and Skantze, 2009; Ginzburg, 2012; Agarwal et al., 2020) and others (see Section 6).

Focus on error recovery, not error avoidance. Explore your dataset thinking about the *constraints* present in the dialog system you are building: Can they be learned from the data that you have? What are the limitations that you know your system will have? How can you expose these limitations to the dialog partner so that she can adapt to them? Will a Wizard of Oz setup in which a human simulates the system limitations help here?

The metric for evaluating a dialog system should not (only) be accuracy on some static dataset, but also: *how many mistakes you cannot recover from when interacting with a potentially adversarial human being*. Other areas of NLP are already using such evaluations (Nie et al., 2020).

Design with collaborative grounding in mind Many deep learning dialog systems differ from simple question answering approaches in recording the dialog history up to some limit, usually dictated by the number of tokens that can be reasonably encoded as model input (e.g. (Agarwal et al., 2020; Smith et al., 2020)). Which leads to a question: if collaborative grounding occurs in the conversations on which these models are trained, what exactly is missing in (say) BlenderBot, which was trained on Reddit conversations and has a dialog memory of at least a few turns? Is it that current training approaches do not capture this skill? For example could it be that the pre-trained model could exhibit such a skill but that fine-tuning to given tasks (on datasets where collaborative grounding does not occur) wipes it out? Or is it that something more is needed? We believe that attention needs to be paid to the collaborative grounding mechanisms reviewed in Section 6.

Don't leave the social aspects till last Bisk et al (2020) give a detailed description of milestones that must be passed to achieve what they call *truly contextual language understanding*. They argue that we are currently close to the written word milestone, the next milestone being perception, the following one embodiment, with the final one being the social. This may be motivated by the fact that humans evolved through perception and embodiment before developing language.

However language is not just about words and their semantics; it is primarily about people, their intentions and their interactions. We urge the community *not* to leave the social aspects of language for the future but to (re)consider existing work on collaborative grounding (Sections 3 and 6) and language acquisition (Section 5). We need to face up to language as *lebensform* right from the start.

8 Conclusion

Possible objections range from the practical (*new datasets are expensive; old datasets are too small for deep learning*) through the theoretical (*much coherent dialog does not require conversational history, task-oriented dialog may requires collaborative grounding but chit chat does not*) to the technical (*grounding acts cannot be identified automatically; deep learning models can learn to do some collaborative grounding without explicitly representing grounding intentions*). But lack of space precludes further discussion, so with these noted, we conclude by restating our basic point.

The idea that simply training models on large amounts of successful dialog as is currently done will lead to human-analogous collaborative grounding seems dubious. As we have described and illustrated, human grounding has to do not only with successful exchanges and positive grounding, but also with negative grounding. Negative grounding includes pragmatic mechanisms by which we negotiate what we actually mean. It is about errors and corrections, about exposing limitations. Until we figure out how to train these, our dialog models will lack a crucial capability: commitment to their own meanings.

Acknowledgments

We thank the anonymous reviewers and area chair for their detailed reviews and insightful comments.

A More examples from the test scenarios

In this section we present more examples that illustrate the basic points made in the test scenarios presented in Section 4 of the paper.

A.1 Dungeon Intelligence

This is a continuation of the dialog with the Dungeon AI (DAI) game (mode fantasy, character wizard) presented in Section 4. The example in the main paper illustrated numeric inconsistency. In this extended example we illustrate also gender inconsistency (the clerk is first a girl and then a man) and then causal inconsistency (after the food is brought the clerk says they do not serve food, but finally food is available).

DAI: You are wearing nondescript clothing, and you manage to escape without being recognized. You open the purse and find seven gold coins, which is good since you only planned to steal a little.
Me: How many coins are there in the purse?
DAI: You count the coins and find that you have eighty one coins, which is good since you planned to steal just a little. You think to yourself "I should be able to afford a room tonight."
Me: but before you only had seven, how many are there really?
DAI: You head to the first inn you see, which seems to be a place where merchants stay. The desk clerk is a young woman who is probably only just thirteen or fourteen.
Me: I count the coins again
DAI: You count the coins and there are exactly 32 coins there. Hmm, makes it easy to know how much to give to beggars.
Me: I am hungry, I buy a burger.
DAI: You walk over to the counter and order a Whopper with cheese.
Me: I look at your burger.
DAI: It looks like meat. "A burger of goat meat and a mug of ale please." The man nods and quickly brings you the food. "Thanks."
Me: I am surprised, I thought the clerk was a girl.
DAI: "Sorry kid, I don't serve food."
Me: I am confused, I ask "Do you serve food or not?"
DAI: "Sure, if you have the coin." He gives you the food. The food is delicious. You haven't eaten anything so good in a while.

As mentioned in Section 4, it is unsurprising that language models trained only on form are unable to perform collaborative grounding. So in the next subsection we further explore a widespread dataset (de Vries et al., 2017) to look for evidence of collaborative grounding in a multimodal task.

A.2 Visual dialog

Figure 3a, 3b and 3c are random dialogs extracted for the Guesswhat?! dataset (de Vries et al., 2017). In all dialogs, the meaning of the question is correctly interpretable without the previous dialog. In Figure 3a it seems that question 7 *On the left side?* is dependent of the previous turn, and means *On the left side of the boy in the backwards baseball cap?*. However it can be answered correctly with an absolute interpretation without context such as *On the left side of the picture?*. Similarly, in Figure 3b it seems that question 7 *Is it touching the right edge?* should be interpreted as *Is the carrot touching the right edge?*. However, it can correctly answered in a context independent fashion interpreting it as *Is it something touching the right edge?*. Finally, in Figure 3c even the elliptical question 6 *Partially visible?* can be answered correctly without considering the previous turns of the dialog.

The ellipsis can be resolved by changing the question to *It is the one partially visible?*. Even though the "partially visible" criterion hold of more than one potential referent, it is only necessary to know it is true for the target to answer it correctly.

From the Oracle perspective, the whole interaction can be solved without access to the dialog

Question	Answer
1. Is it alive?	yes
2. Is it the baseball player?	no
3. Is it a fan?	yes
4. Is he standing?	no
5. In he wearing a backwards baseball cap?	no
6. Next to the boy in the backwards baseball cap?	yes
7. On the left side?	yes

(a) Question 7 can be interpreted with respect to question 6 as *"on the left side of the boy with the backwards baseball cup"*.

Question	Answer
1. Is it the plate?	no
2. Is it food?	yes
3. Is it a little piece of food?	yes
4. Is it carrot?	yes
5. Is it on the left side?	no
6. Is it on the far right?	yes
7. Is it touching the right edge?	yes

(b) Question 7 could be enriched to *"is it the little piece of carrot touching the right edge"*, considering to questions 3 and 4.

Question	Answer
1. Is it a person?	yes
2. Are they wearing blue?	yes
3. Are they one of the three in the front?	yes
4. Is it a man?	no
5. A woman wearing shorts?	yes
6. Partially visible?	yes

(c) Question 6 could be enriched by the previous dialog as *"is it a partially visible woman in blue wearing shorts"*.

Figure 3: Sample image and dialog from the GuessWhat?! dataset (de Vries et al., 2017). The green mask marks the dialog referent. Questions seem dialog dependent but they can be answered correctly in isolation.

history. There is no need for the Oracle to engage in collaborative grounding for these dialogs.

A.3 Graphical User Interfaces

In this section we illustrate another parallelism between a bad graphical user interface (GUI) and a bad dialog system. A dialog systems that does not expose its limitations and acts as if it was able to detect more intentions that it can actually do, may be compared to a GUI that offers too many options as illustrated in Figure 4.

Both of these interfaces, the graphical and the conversational, overwhelm the user with options, many of which may turn out to be useless. Moreover, a GUI that uses icons that are unfamiliar to the target user, or are hard to recognize, suffers from the same problems as a conversational system trained with a different language variety or expertise than that of the user. This last problem can be overcome through collaborative grounding. In particular, if users need to use this GUI, they can ground the meaning of the strange icons through interaction — all the needed information will exposed by the GUI. We illustrate both points in Figure 4, a GUI cluttered with strange icons.

B Examples of collaborative grounding

Building datasets is expensive. In this section we briefly describe dialog datasets already built that include collaborative grounding phenomena. An

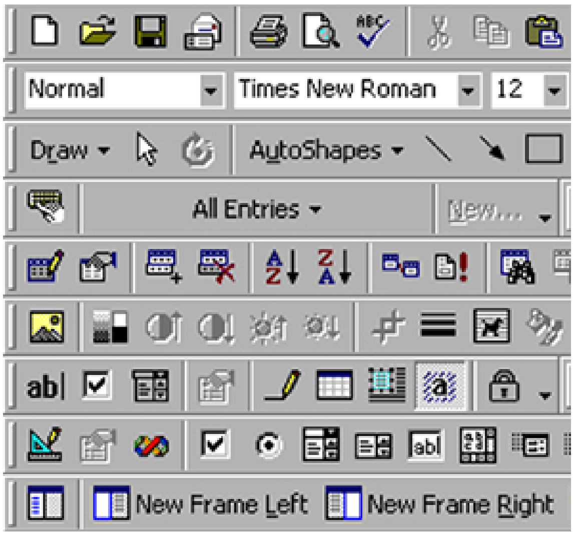

Figure 4: A cluttered GUI that contains icons which are not meaningful for the user

interesting direction of future research would be to analyze and quantify the collaborative grounding acts in these 2 datasets in the spirit of (Fernandez, 2006; Fernández et al., 2007) and other work reviewed in Section 6 of the paper.

The following is an example from (Clark and Wilkes-Gibbs, 1986) with a trial noun phrase collaboratively grounded between S and J. This dataset motivated the creation of larger datasets on the same task (Shore et al., 2018).

S: The small blue cap we talked about before?
J: The one with yellow dots?
S: Yeah

The following example from the Photobook dataset (Haber et al., 2019) starts with a trial noun phrase from A who referred to a TV as a computer, which is collaboratively grounded between A and B. The authors propose to integrate grounding acts to a model based on reference chains.

A: Man with dog on lap looking at his computer?
B: I don't have that, but could it be a TV in yours? Mine has a man sitting with his dog watching TV.
A: yes, TV - sorry!
B: Okay.

This example shows two dialog participants collaboratively grounding their position in a map in the MeetUp corpus (Ilinykh et al., 2019). The map contains pictures of the different rooms the participants can be in. They coordinate the position by describing the rooms. The task is designed to be symmetric, so both participants can contribute equally. Other datasets with a symmetric task are Mutual Friends (He et al., 2017) and Light (Urbanek et al., 2019) and others (Cho and May, 2020).

B: I think I am in a basement
B: i think i might be too
A: maybe not though
A: wood panel?
A: two doors?
B: there's a tan couch, and a tan loveseat/chair brown coffee table. bar. tv
B: nope, different room
A: ok i am not there

The following dialog fragment was collected between crowdsourcers acting as a tourist and a guide (de Vries et al., 2018). By looking at a map the guide had to accomplish the goal of guiding the tourist to a given location in a city. The tourist had access to a navigation street view and provided feedback to the guide about what he did and saw. The task is designed to be asymmetric so collaboration is limited to the roles each participant plays. The guide can make mistakes because the map information is incomplete. The tourist takes a more active role when the guide makes a mistake as illustrated below.

Guide: Ok, turn left then go straight up that road
Guide: There should be shops on two of the corners but you need to go to the corner without a shop.
Tourist: on my left is Radio city Music hall
Tourist: I can't go straight any further.
Guide: ok. turn so that the theater is on your right.
Guide: then go straight
Tourist: That would be going back the way I came
Guide: yeah. I was looking at the wrong bank

Other datasets collected for asymmetric tasks are (Eric et al., 2017; Kottur et al., 2019; Alamri et al., 2019; Kim et al., 2019; Narayan-Chen et al., 2019; Kontogiorgos et al., 2020). All these datasets show collaborative grounding phenomena and are promising contributions for the development of models that can learn to collaboratively ground meaning.

Does He Wink or Does He Nod? A Challenging Benchmark for Evaluating Word Understanding of Language Models

Lutfi Kerem Senel and **Hinrich Schütze**
Center for Information and Language Processing (CIS), LMU Munich, Germany
`lksenel@gmail.com`, `inquiries@cislmu.org`

Abstract

Recent progress in pretraining language models on large corpora has resulted in large performance gains on many NLP tasks. These large models acquire linguistic knowledge during pretraining, which helps to improve performance on downstream tasks via fine-tuning. To assess what kind of knowledge is acquired, language models are commonly probed by querying them with 'fill in the blank' style cloze questions. Existing probing datasets mainly focus on knowledge about *relations between* words and entities. We introduce WDLMPro (Word Definition Language Model Probing) to *evaluate word understanding directly* using dictionary definitions of words. In our experiments, three popular pretrained language models struggle to match words and their definitions. This indicates that they understand many words poorly and that our new probing task is a difficult challenge that could help guide research on LMs in the future.

1 Introduction

Natural language processing (NLP) has advanced drastically in the last decade with the design of larger and more sophisticated models, availability of larger corpora and increasing computational power. Pretrained word embeddings (Mikolov et al., 2013; Pennington et al., 2014) popularized the use of distributed word representations, which became a fundamental building block for NLP systems. Peters et al. (2018a) introduced LSTM-based deep contextual representations and obtained large performance gains by fine-tuning on tasks after unsupervised pretraining (Radford et al., 2018; Howard and Ruder, 2018). More recently, the attention based transformer architecture was shown to use context more effectively (Vaswani et al., 2017) and several subsequent models achieved state of the art results in many NLP tasks by combining the transformer architecture with unsupervised pretraining and task specific fine-tuning (Devlin et al., 2019; Liu et al., 2019). Radford et al. (2019) showed that language models can be applied to a variety of tasks without task specific fine tuning. This is demonstrated on a much larger scale by Brown et al. (2020).

Deep models improve performance. However, what they actually learn about language and word meaning is still to a large extent unclear due to their uninterpretable nature. For static word embeddings, researchers used word similarity (Hill et al., 2015) and word analogy (Gladkova et al., 2016) tests to shed light on what information is captured in these dense vector spaces. For language models, a great amount of linguistic knowledge is stored in the model parameters (Peters et al., 2018b). Several studies proposed using 'fill in the blank' type cloze statements to test knowledge learned by these models during unsupervised pretraining. Petroni et al. (2019) proposed the LAMA (LAnguage Model Analysis) probe to test the factual and common sense knowledge stored in language models. Similarly, Schick and Schütze (2020) introduced WNLaMPro (WordNet Language Model Probing) to assess the ability of language models to understand words based on their frequency. In WNLaMPro, cloze style questions are generated based on antonym, hypernym and cohyponym relations among words extracted from WordNet.

The existing probing datasets mainly focus on investigating the knowledge about *relations between* words or entities. However, a more direct way of testing whether a language model understands the meaning of a word is to use its dictionary definition. If a pretrained language model truly understands the meaning of a word, then it should be able to match it with its dictionary definition. Based on this motivation, we introduce the *Word Definition*

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 532–538

synset	definition
a_cappella_singing.n.01	*singing without instrumental accompaniment*
caroling.n.01	singing joyful religious songs (especially at Christmas)
crooning.n.01	singing in a soft low tone
singalong.n.01	informal group singing of popular songs
bel_canto.n.01	a style of operatic singing

Table 1: Five candidates from $\mathcal{G}(t)$ for t= *a_cappella_singing.n.01* and their definitions

	Noun	Verb
# of Synset Groups	51260	8487
Average # of Candidates	50.2	47.7
min / max # of Candidates	5 / 404	5 / 593

Table 2: WDLMPro statistics

Language Model Probing (WDLMPro) dataset;[1] it is a challenging benchmark for testing NLP models for their ability to understand words. WDLMPro is essentially a set of thousands of synset groups; each synset group consists of a target word (with its definition) and its taxonomic sisters (with their definitions). Using taxonomic sisters, rather than random word groups, makes the task more challenging for statistical models that are based on the distributional hypothesis since these words have similar distributional characteristics (Lenci, 2008). We evaluate two masked language models, BERT and RoBERTa, and the auto-regressive model GPT-2 on WDLMPro using two different probing tests: (i) match definition to word (D2W) (ii) match word to definition (W2D). We also provide a baseline using static fastText embeddings (Mikolov et al., 2018). We find that all three language models perform clearly better than the baseline. Nevertheless, they have great difficulty matching words and their definitions, implying a poor understanding of word meaning. This is an important result that could help guide research on LMs in the future.

2 WDLMPro

In this section, we introduce WDLMPro (Word Definition Language Model Probing), a dataset to test how well NLP models can match nouns and verbs with their definitions. We view this as a test of how well the models understand lexical meaning.

2.1 Dataset

WordNet (Miller, 1995) is the basis for constructing WDLMPro. A WordNet *synset* contains a set of synonyms along with a short definition of the synset. Different senses of polysemous words are represented in different synsets providing disambiguation. WordNet connects synsets with each other via semantic relations.

Based on a *target synset* t and the semantic relation hyponymy $<$, we construct a *synset group* $\mathcal{G}$ for the target as follows.

$$\mathcal{G}(t) = \{x | \exists y : t < y \land x < y\}$$

that is, G contains all synsets that are “sister hyponyms” to t with respect to a hypernym of t. $\mathcal{G}(t)$, along with the definitions of the synsets in $\mathcal{G}(t)$, will be used to set up the WDLMPro tasks that require matching of words and definitions. We discard groups $\mathcal{G}(t)$ that have a size of less than 5.

In this study, we focus on nouns and verbs, i.e., we create synset groups $\mathcal{G}$ for the nouns and verbs in WordNet. Table 1 displays five members from $\mathcal{G}(t)$ and their definitions for the target *a_cappella_singing.n.01* (see appx. for the target *beckon.v.01*.) Table 2 shows statistics of the dataset.

2.2 Probing Tests

We define two probing tests that are converses of each other:

- **Match definition to word (D2W).** Given a definition and a set of words, the task is to find the word that the definition defines.
- **Match word to definition (W2D).** Given a word and a set of definitions, the task is to find the definition that defines the word.

Each synset group $\mathcal{G}(t)$ gives rise to one instance of D2W by providing the definition of t, and all words in $\mathcal{G}(t)$. The word from $\mathcal{G}(t)$ that matches the definition has then to be identified. (Note that t is a member of $\mathcal{G}(t)$.) Similarly, each synset group $\mathcal{G}(t)$ gives rise to one instance of W2D by providing t and the definitions of all words in $\mathcal{G}(t)$. The correct definition of t has then to be identified among all definition candidates. Note that WordNet definitions by construction do not contain the word

---

[1] WDLAMPro and evaluation scripts are available at https://www.cis.lmu.de/definition_benchmark/WDLAMPro.zip

	Masked Language Model (MLM)
Noun	_ is `<DEF>`
	_ means `<DEF>`
	_ is defined as `<DEF>`
Verb	definition of _ is to `<DEF>`
	to `<DEF>` is the definition of _
	Autoregressive Language Model (ALM)
Noun	`<DEF>` is the definition of _
Verb	to `<DEF>` is the definition of _

Table 3: Patterns used for querying language models for nouns and verbs. `<DEF>` refers to the definition, _ is the mask or missing word that the language model has to predict.

to be defined. So there are no instances where the two tasks are trivial.

2.2.1 Application to language models

In principle, any NLP model can be tested on D2W and W2D. In this paper, we are particularly interested in testing language models. To this end, we convert the data to a format that is suitable for language models, i.e., to cloze-style questions as shown in Table 3. The basic quantity that allows us to assess the compatibility of a word t and a definition is the probability of t being generated for "_" when the definition is substituted for <DEF>.

More precisely, we compute the probability that the string representation of t is being generated. We will denote the string representation of synset t by $\boldsymbol{t}$. We obtain the string representation by removing the word type and sense information from the name of the synset and replacing underscores with white space. For example, synset *warm_up.v.04* is represented by the string "warm up".

Table 3 shows that we define different templates for masked and autoregressive language models. For the masked language models, we average the prediction scores across patterns before ranking the candidates.

2.3 Baselines

For a masked language model (MLM) M, the probability of a candidate $c \in \mathcal{G}(t)$ on W2D is calculated as:

$$P_M^{\text{W2D}}(c|t) = \prod_{i=1}^{|\boldsymbol{t}|} P(\boldsymbol{t}^i | Q(c, |\boldsymbol{t}|))$$

where $\boldsymbol{t} = [\boldsymbol{t}^1, \boldsymbol{t}^2, ..., \boldsymbol{t}^{|\boldsymbol{t}|}]$ is the tokenization produced by M. $Q(c, |\boldsymbol{t}|)$ is the input query created from one of the patterns (Table 3) with _ replaced with $|\boldsymbol{t}|$ consecutive mask tokens. For an autoregressive language model (ALM) A, we decompose $P(\boldsymbol{t}^i | Q(c), \boldsymbol{t})$ in the standard way:

$$P_A^{\text{W2D}} = \prod_{i=1}^{|\boldsymbol{t}|} P(\boldsymbol{t}^i | Q(c), \boldsymbol{t}^1, ..., \boldsymbol{t}^{i-1})$$

For D2W, we need to compare, given a definition, the probabilities of different candidate words that are generally of different lengths. To ensure a fair comparison, we follow Xiong et al. (2020). For MLMs, we match the number of mask tokens in an input query to the token count of each candidate. The final score is the average log-probability of the masked tokens:

$$P_M^{\text{D2W}}(c|t) = \frac{1}{|\boldsymbol{c}|} \sum_{i=1}^{|\boldsymbol{c}|} \log P(\boldsymbol{c}^i | Q(t, |\boldsymbol{c}|))$$

For ALMs, we use the probability of the first token:

$$P_A^{\text{D2W}}(c|t) = P(\boldsymbol{c}^1 | Q(t))$$

Considering further tokens does not make sense since they are often easily predictable from the first token.

We apply our probing test to two different pretrained MLMs (BERT and RoBERTa) and one ALM (GPT-2). To investigate the effect of model size on the performance, we experiment with both base and large versions of BERT and RoBERTa along with all four sizes of GPT-2 (small, medium, large, xl). For RoBERTa, we capitalize the first letter of the candidate noun since pretrained RoBERTa models are case sensitive and expect a capital letter at the beginning of a sentence.[2]

In addition to the deep contextual language models, we also provide fastText static word embeddings[3] (Mikolov et al., 2018) as a baseline.[4] For fastText embeddings, we tokenize the candidates and their definitions using the NLTK tokenizer and represent them with their average vector. We rank candidates based on their cosine similarity to the target embedding.

---

[2] Not using capitalization resulted in poor performance for single token target words for D2W.

[3] We use the crawl-300d-2M-subword model from https://fasttext.cc/docs/en/english-vectors.html

[4] A reviewer suggests that it would also be interesting to investigate the performance of supervised approaches, e.g., ranking models. Our main focus here is the lexical knowledge acquired in pretraining, so we leave this for future work.

2.4 Measures

We use two measures: precision at 1 (P@1) and a rank score (RS), both based on a ranked results list, either of words or of definitions. P@1 is the percentage of top-ranked items that is correct. We define RS as follows:

$$\mathrm{RS}(L, k) = \frac{L - k}{L - 1}$$

where $L = |\mathcal{G}(t)|$ is the number of candidates and k is the rank of the correct item, $1 \leq k \leq L$. Table 2 shows that the size of $\mathcal{G}(t)$ is highly variable; in contrast to P@1, RS is less affected by this and the random baseline (cf. Tables 4 and 5) is always 0.5.

3 Results

Tables 4 and 5 present W2D and D2W results for BERT, RoBERTa and GPT-2 along with fastText and random baselines. Language models perform clearly better than both baselines. Larger models perform generally better than smaller ones and RoBERTa consistently outperforms BERT. This might be an indication for the correlation between performance on WDLAMPro and downstream performance. However, further investigation is necessary to show the correlation more clearly. For W2D, best performance is achieved by GPT-2$_{xl}$ for nouns (47.3 P@1, 0.81 RS) and by RoBERTa large for verbs (50.8 P@1, 0.84 RS). Performance on D2W is much lower than for W2D for all models. For nouns, RoBERTa large and GPT-2$_{xl}$ perform similarly (28.8 and 29.8 P@1, 0.70 and 0.73 RS) while RoBERTa large achieves the best results for verbs (38.6 P@1, 0.80 RS). Poor performance on D2W compared to W2D might be due to language models' ability to distinguish different definitions better than individual words since definitions are more informative than individual words. Overall GPT-2 models perform better than masked language models (with the exception of Roberta large for verbs), despite using a single pattern as opposed to the multiple patterns used by masked language models. This might indicate that the ALM objective is better at learning word meaning than the MLM objective.

To investigate the effect of frequency, we stratify words into *rare* (fewer than 10 occurrences), *medium* (10 to 99 occurrences) and *frequent* (100 or more occurrences), based on occurrences in WWC[5] (Westbury Wikipedia Corpus, Shaoul (2010)), where we use WWC frequency as a substitute for the models' training corpora. We focus on nouns since most verbs in our dataset are relatively frequent. Table 7 shows that, for W2D, all models have a poor understanding of the meaning of rare and medium words. (See appx. for D2W results.) Even for frequent words, P@1 is never above 55.

Model	**Noun**		**Verb**	
	P@1	RS	P@1	RS

Random	7.6	0.50	8.0	0.50

Table 5: P@1 and rank score (RS) on D2W

We additionally break down the results based on the depth of the synsets in the WordNet hierarchy. Specifically, we investigate the performance of the GPT-2$_{xl}$ model on W2D for WordNet nouns, where we take the depth of a synset group as the length of the shortest path from the target synset to the root synset (i.e., *entity.n.01*). Table 6 shows that performance drops steadily as we go deeper in the hierarchy. Lower levels of the WordNet hierarchy contain many scientific terms and names of (sub)species such as types of cattle (e.g., *cattalo*, *hereford*, *galloway*). These results suggest that even very large LMs lack the knowledge necessary to distinguish these terms.

---

[5] Targets that have more than 3 tokens (based on NLTK tokenization) are taken as rare without counting.

Depth	# synsets	# cand.	RS	P@1
3–5	2106	110	0.94	62.9
6–8	25,232	53	0.83	49.0
9–11	18,521	45	0.81	46.6
12–14	4473	19	0.74	37.4
15–19	928	13	0.67	31.5

Random	6.6	7.0	8.2	7.6

Table 7: P@1 scores on W2D for nouns of different frequency ranges

Analysis. The correct definition of the medium frequency verb ‘beckon’ is ‘signal with the hands or nod’. GPT-2$_{xl}$ predicts ‘signal by winking’. The correct definition of the frequent noun ‘roleplaying’ is ‘acting a particular role (as in psychotherapy)’ GPT-2$_{xl}$ predicts ‘acting the part of a character on stage’. So GPT-2$_{xl}$ understands that beckoning is signaling and that roleplaying is acting, but it has not learned to distinguish between different types of signaling and acting. This points to an important future goal for LMs: they should be developed to gain an understanding of words that goes beyond the current superficial state of the art.

Human performance on WDLAMPro. It is beyond the scope of this paper to evaluate human performance on the entirety of WDLAMPro. However, we provide a comparison with human performance on a small subset to provide an intuition about the difficulty of the task. For each of the two tasks, 20 synset groups that have a maximum of 10 candidates are randomly sampled from WDLAMPro. Then two native English speakers are asked to rank the candidates. Table 8 displays the average performance of the human participants and the language models on this subset. For both tasks, performance of the best model is comparable to the average human performance.

Model	W2D		D2W

Human	62.5	0.88	57.5	0.77

Table 8: LM and human performance on 20 random samples of WDLAMPro.

Human performance is the upper bound for many NLP tasks. We believe that this is not the case for WDLAMPro: arguably, we should aim for models with an excellent understanding of the meanings of words even if it is better than average human understanding. Knowledge based tasks are an analogous case: we should strive for models that know as many facts as possible even if that performance is above average human performance.

4 Conclusion

We introduced WDLMPro, a probing test that helps analyze how well a model understands word meaning. WDLMPro is complementary to existing probing tests that are about *relations* between words or entities. We evaluated three popular pretrained language models on the W2D (word to definition) and D2W (definition to word) tasks. Our findings show that, despite their remarkable performance on many downstream tasks, these models struggle to match a word and its true definition, suggesting an insufficient understanding of word meaning. Relatively poor performance of these powerful models on WDLMPro can be seen as evidence for the limitations of purely distributional systems and the need for incorporating external knowledge. WDLMPro provides an important evaluation benchmark, encouraging design and training of models with precise word understanding.

Joint Coreference Resolution and Character Linking for Multiparty Conversation

Jiaxin Bai[1], **Hongming Zhang**[1], **Yangqiu Song**[1], **and Kun Xu**[2]

Abstract

Character linking, the task of linking mentioned people in conversations to the real world, is crucial for understanding the conversations. For the efficiency of communication, humans often choose to use pronouns (e.g., "she") or normal phrases (e.g., "that girl") rather than named entities (e.g., "Rachel") in the spoken language, which makes linking those mentions to real people a much more challenging than a regular entity linking task. To address this challenge, we propose to incorporate the richer context from the coreference relations among different mentions to help the linking. On the other hand, considering that finding coreference clusters itself is not a trivial task and could benefit from the global character information, we propose to jointly solve these two tasks. Specifically, we propose C^2, the joint learning model of **C**oreference resolution and **C**haracter linking. The experimental results demonstrate that C^2 can significantly outperform previous works on both tasks. Further analyses are conducted to analyze the contribution of all modules in the proposed model and the effect of all hyper-parameters.

1 Introduction

Understanding conversations has long been one of the ultimate goals of the natural language processing community, and a critical step towards that is grounding all mentioned people to the real world. If we can achieve that, we can leverage our knowledge about these people (e.g., things that happened to them before) to better understand the conversation. On the other hand, we can also aggregate the conversation information back to our understanding about these people, which can be used for understanding future conversations that involve the same people. To simulate the real conversations and investigate the possibility for models to ground mentioned people, the character linking task was proposed (Chen and Choi, 2016). Specifically, it uses the transcripts of TV shows (i.e., *Friends*) as the conversations and asks the models to ground all person mentions to characters.

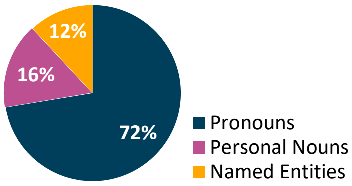

Figure 1: The composition of the mentions in conversations for character grounding. Over 88% of the mentions are not named entities, which brings exceptional challenges when linking those to character entities.

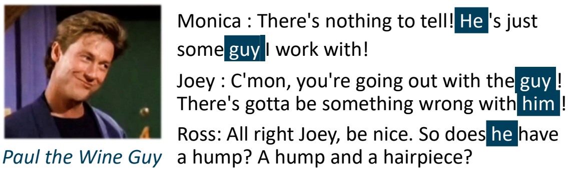
Even though the character linking task can be viewed as a special case of the entity linking task, it is more challenging than the ordinary entity linking task for various reasons. First, the ordinary entity linking task often aims at linking named entities to external knowledge bases such as Wikipedia, where rich information (e.g., definitions) are available. However, for the character linking task, we do not have the support of such rich knowledge base and all we have are the names of these characters and simple properties (e.g., gender) about these characters. Second, the mentions in the ordinary entity linking are mostly concepts and entities, but not pronouns. However, as shown in Figure 1, 88% of the character mentions are pronouns (e.g., "he") or personal nouns (e.g., "that guy") while only 12% are named entities.

Considering that pronouns have relatively weak semantics by themselves, to effectively ground mentions to the correct characters, we need to fully utilize the context information of the whole conversation rather than just the local context they appear in. One potential solution is using the coreference relations among different mentions as the bridge to

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 539–548
April 19 - 23, 2021.



Monica : There's nothing to tell! He 's just some guy I work with!

Joey : C'mon, you're going out with the guy ! There's gotta be something wrong with him !

Ross: All right Joey, be nice. So does he have a hump? A hump and a hairpiece?

Figure 2: Coreference clusters can help to connect the whole conversation to provide a richer context for each mention such that we can better link them to *Paul*. Meanwhile, the character *Pual* can also provide global information to help resolve the coreference.

connect the richer context. One example is shown in Figure 2. It is difficult to directly link the highlighted mentions to the character *Paul* based on their local context because the local context of each mention can only provide a single piece of information about its referent, e.g., "person is a male" or "the person works with Monica." Given the coreference cluster, the mentions refer to the same person, and the pieces of information are put together to jointly determining the referent. As a result, it is easier for a model to do character linking with resolved coreference. Similar observations are also made in (Chen et al., 2017).

At the same time, we also noticed that coreference resolution, especially those involving pronouns, is also not trivial. As shown by the recent literature on the coreference resolution task (Lee et al., 2018; Kantor and Globerson, 2019), the task is still challenging for current models and the key challenge is how to utilize the global information about entities. And that is exactly what the character linking model can provide. For example, in Figure 2, it is difficult for a coreference model to correctly resolve the last mention *he* in the utterance given by *Ross* based on its local context, because another major male character (*Joey*) joins the conversation, which can distract and mislead the coreference model. However, if the model knows the mention *he* links to the character *Paul* and *Paul* works with *Monica*, it is easier to resolve *he* to some *guy* that Monica works with.

Motivated by these observations, we propose to jointly train the **C**oreference resolution and **C**haracter linking tasks and name the joint model as C^2. C^2 adopts a transformer-based text encoder and includes a mention-level self-attention (MLSA) module that enables the model to do mention-level contextualization. Meanwhile, a joint loss function is designed and utilized so that both tasks can be jointly optimized. The experimental results demonstrate that C^2 outperforms all previous work significantly on both tasks. Specifically, compared with the previous work (Zhou and Choi, 2018), C^2 improves the performance by 15% and 26% on the coreference resolution and character linking tasks[1] respectively comparing to the previous state-of-the-art model ACNN (Zhou and Choi, 2018) . Further hyper-parameter and ablation studies testify the effectiveness of different components of C^2 and the effect of all hyper-parameters. Our code is available at `https://github.com/HKUST-KnowComp/C2`.

2 Problem Formulations and Notations

We first introduce the coreference resolution and character linking tasks as well as used notations. Given a conversation, which contains multiple utterances and n character mentions $c_1, c_2, ..., c_n$, and a pre-defined character set $\mathcal{Z}$, which contains m characters $z_1, z_2, ..., z_m$. The coreference resolution task is grouping all mentions to clusters such that all mentions in the same cluster refer to the same character. The character linking task is linking each mention to its corresponding character.

3 Model

In this section, we introduce the proposed C^2 framework, which is illustrated in Figure 3. With the conversation and all mentions as input, we first encode them with a shared mention representation encoder module, which includes a pre-trained transformer text encoder and a mention-level self-attention (MLSA) module. After that, we make predictions for both tasks via two separate modules. In the end, a joint loss function is devised so that the model can be effectively trained on both tasks simultaneously. Details are as follows.

3.1 Mention Representation

We use pre-trained language models (Devlin et al., 2018; Joshi et al., 2019a) to obtain the contextualized representations for mentions. As speaker information is critical for the conversation understanding, we also include that information by appending speaker embeddings to each mention. As

---

[1] The performance on the coreference resolution is evaluated based on the average F1 score of B3, CEAF$_{\phi}$4, and BLANC. The performance on the character linking task is evaluated by the average F1 score of the micro and macro F1.

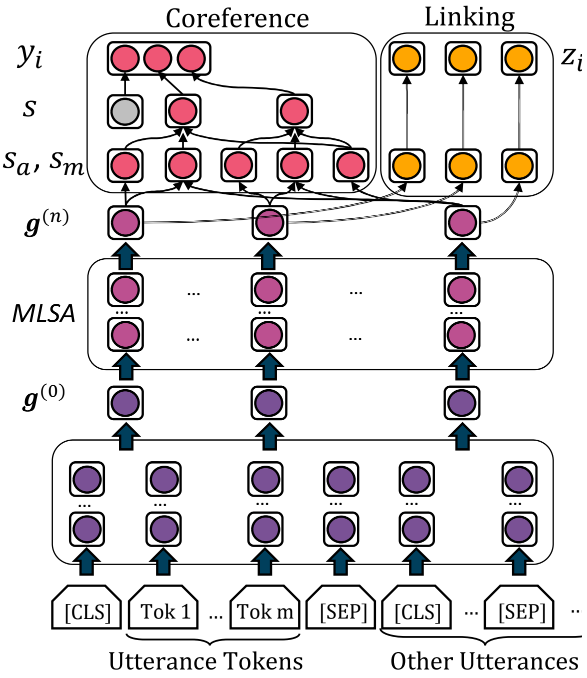


Figure 3: The coreference module and the linking module share the same mention representation $g^{(n)}$ as inputs. The mention representation $g^{(i)}$ are iteratively refined through the mention-level self-attention layers. The initial mention representations $g^{(0)}$ are the sum of text span representations from a pre-trained text encoder and corresponding speaker embeddings.

a result, the initial representation of mention i is:

$$g_i^{(0)} = t_{start_i} + t_{end_i} + e_{speaker_i}, \qquad (1)$$

where t_{start_i} and t_{end_i} are the contextualized representation of the beginning and the end tokens of mention i, and the $e_{speaker_i}$ is the speaker embedding for the current speaker. Here, we omit the embeddings of inner tokens because their semantics has been effectively encoded via the language model. The speaker embeddings are randomly initialized before training.

Sometimes the local context of a mention is not enough to make reasonable predictions, and it is observed that the co-occurred mentions can provide document-level context information. To refine the mention representations given the presence of other mentions in the document, we introduce the Mention-Level Self-Attention (MLSA) layer, which has n layers of transformer encoder structure (Vaswani et al., 2017) and is denoted as T. Formally, this iterative mention refinement process can be described by

$$g_1^{(i+1)}, ..., g_k^{(i+1)} = T(g_1^{(i)}, ..., g_k^{(i)}), \qquad (2)$$

where k indicates the number of mentions in a document, and the $g^{(i)}$ means the mention representation from the i-th layer of MLSA.

3.2 Coreference Resolution

Following the previous work (Joshi et al., 2019a), we model the coreference resolution task as an antecedent finding problem. For each mention, we aim at finding one of the previous mentions that refer to the same person. If no such previous mention exists, it should be linked to the dummy mention ε. Thus the goal of a coreference model is to learn a distribution, $P(y_i)$ over each antecedent for each mention i:

$$P(y_i) = \frac{e^{s(i,y_i)}}{\Sigma_{y' \in \mathcal{Y}(i)} e^{s(i,y')}}, \qquad (3)$$

where $s(i, j)$ is the score for the antecedent assignment of mention i to j. The score $s(i, j)$ contains two parts: (1) the plausibility score of the mentions $s_a(i, j)$; (2) the mention score measuring the plausibility of being a proper mention $s_m(i)$. Formally, the $s(i, j)$ can be expressed by

$$s(i,j) = s_m(i) + s_m(j) + s_a(i,j), \qquad (4)$$

$$s_m(i) = FFNN_m(g_i^{(n)}), \qquad (5)$$

$$s_a(i,j) = FFNN_a([g_i^{(n)}, g_j^{(n)}]), \qquad (6)$$

where $g^{(n)}$ stands for the last layer mention representation resulted from the MLSA and $FFNN$ indicates the feed-forward neural network.

3.3 Character Linking

The character linking is formulated as a multi-class classification problem, following previous work (Zhou and Choi, 2018). Given the mention representations $g^{(n)}$, the linking can be done with a simple feed-forward network, denoted as $FFNN(\cdot)$. Specifically, the probability of character entity z_i is linked with a given mention i can be calculated by:

$$Q(z_i) = Softmax(FFNN_l(g_i^{(n)}))_{z_i}, \qquad (7)$$

where the notation $(.)_z$ represents the z-th composition of a given vector.

3.4 Joint Learning

To jointly optimize both coreference resolution and entity linking, we design a joint loss of both tasks. For coreference resolution, given the gold clusters, we minimize the negative log-likelihood of

DATASET	EPISODES	SCENES	UTTERANCES	SPEAKERS	MENTIONS	ENTITIES
TRN	76	987	18,789	265	36,385	628
DEV	8	122	2,142	48	3,932	102
TST	13	192	3,597	91	7,050	165
TOTAL	97	1,301	24,528	331	47,367	781

Table 1: The detailed information about the datasets. For each season, the episode 1 to 19 are used for training, the episode 20 to 21 for development, and the remaining for testing.

the possibility that each mention is linked to a gold antecedent. Then the coreference loss L_c becomes

$$L_c = -\sum_{i=1}^{N} \log \sum_{y \in \mathcal{Y}(i) \cap GOLD(i)} P(y), \quad (8)$$

where the $GOLD(i)$ denotes the gold coreference cluster that mention i belongs to. Similarly, for character linking, we minimize the negative log-likelihood of the joint probability for each mention being linked to the correct referent character:

$$L_l = -\sum_{i=1}^{N} \log Q(z_i). \quad (9)$$

Finally, the joint loss can be the arithmetic average of the coreference loss and linking loss:

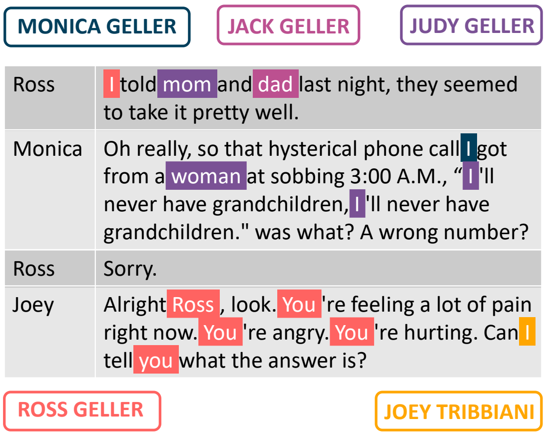
$$L = \frac{1}{2}(L_l + L_c). \quad (10)$$

4 Experiments

In this section, we introduce the experimental details to demonstrate the effectiveness of C^2.

4.1 Data Description

We use the latest released character identification V2.0[2] as the experimental dataset, and we follow the standard training, developing, and testing separation provided by the dataset. In the dataset, all mentions are annotated with their referent global entities. For example, in Figure 4, the mention *I* is assigned to *ROSS*, and the mentions *mom* and *dad* are assigned to *JUDY* and *JACK* respectively in the first utterance given by *Ross*. The gold coreference clusters are derived by grouping the mentions assigned to the same character entity. Statistically, the dataset includes four seasons of the TV show *Friends*, which contain 97 episodes, 1,301 scenes, and 24,528 utterances. In total, there are 47,367 mentions, which are assigned to 781 unique characters. The detailed statistics are shown in Table 1.



Ross	I told mom and dad last night, they seemed to take it pretty well.
Monica	Oh really, so that hysterical phone call I got from a woman at sobbing 3:00 A.M., “ I 'll never have grandchildren, I 'll never have grandchildren." was what? A wrong number?
Ross	Sorry.
Joey	Alright Ross , look. You 're feeling a lot of pain right now. You 're angry. You 're hurting. Can I tell you what the answer is?

Figure 4: The example annotations for character identification. The arrows in the figure are pointing from the character mentions to their referent character entities.

4.2 Baseline Methods

The effectiveness of the joint learning model is evaluated on both the coreference resolution and character linking tasks. To fairly compare with existing models, only the singular mentions are used following the singular-only setting (S-only) in the previous work (Zhou and Choi, 2018).

For the **coreference resolution** task, we compare with the following methods.

- ACNN: A CNN-based model (Zhou and Choi, 2018) coreference resolution model that can also produce the mention and mention-cluster embeddings at the same time.

- C2F: The end-to-end coarse-to-fine coreference model (Joshi et al., 2019b) with BERT (Devlin et al., 2018) or SpanBERT (Joshi et al., 2019a) as the encoder.

- CorefQA: An approach that reformulates the coreference resolution problem as a question answering problem (Wu et al., 2020) and being able to be benefited from fine-tuned question-answer text encoders.

Table 2: Experimental results on the coreference resolution task. The results are presented in a 2-digit decimal following previous work. Standard deviations of the average F1 scores are shown in brackets.

For the **character linking** task, we also include ACNN as a baseline method. Considering existing general entity linking models (Kolitsas et al., 2018; van Hulst et al., 2020; Raiman and Raiman, 2018; Onando Mulang et al., 2020) cannot be applied to the character linking problem because they are not designed to handle pronouns, we propose another text-span classification model with transformer encoder as another strong baseline for the character linking task.

- ACNN: A model that uses the mention and mention-cluster embeddings as input to do character linking (Zhou and Choi, 2018).
- BERT/SpanBERT: A text-span classification model consists of a transformer text encoder followed by a feed-forward network.

4.3 Evaluation Metrics

We follow the previous work (Zhou and Choi, 2018) for the evaluation metrics. Specifically, for coreference resolution, three evaluation metrics, B^3, $CEAF_{\phi 4}$, and BLANC, are used. The metrics are all proposed by the CoNNL'12 shared task (Pradhan et al., 2012) to evaluate the output coreference cluster against the gold clusters. We follow Zhou and Choi (2018) to use BLANC (Recasens and Hovy, 2011) to replace MUC (Vilain et al., 1995) because BLANC takes singletons into consideration but MUC does not. As for the character linking task, we use the Micro and Macro F1 scores to evaluate the multi-class classification performance.

4.4 Implementation Details

In our experiments, we consider four different pretrained language encoders: BERT-Base, BERT-Large, SpanBERT-Base, and SpanBERT-Large, and we use $n = 2$ layers of the mention-level self-attention (MLSA). The feed-forward networks are implemented by two fully connected layers with ReLU activations. Following the previous work, (Zhou and Choi, 2018), the scene-level setting is used, where, each scene is regarded as a document for coreference resolution and linking. During the training, each mini-batch consists of segments obtained from a single document. The joint learning model is optimized with the Adam optimizer (Kingma and Ba, 2015) with an initial learning rate of 3e-5, and a warming-up rate of 10%. The model is set to be trained for 100 epochs with an early stop. All the experiments are repeated three times, and the average results are reported.

5 Results and Analysis

In this section, we discuss the experimental results and present a detailed analysis.

5.1 Coreference Resolution Results

The performances of coreference resolution models are shown in Table 2. C^2 with SpanBERT-large achieves the best performance on all evaluation metrics. Comparing to the baseline ACNN model, which uses hand-crafted features, C^2 uses a transformer to better encode the contextual information. Besides that, even though ACNN formulates the coreference resolution and character linking tasks in a pipe-line and uses the coreference resolution result to help character linking, the character linking result cannot be used to help to resolve coreference clusters. As a comparison, we treat both tasks jointly such that they can help each other.

Currently, CorefQA is the best-performing general coreference resolution model on the OntoNotes dataset (Pradhan et al., 2012). However, its performance is limited on the conversation dataset due to

MODEL	RO	RA	CH	MO	JO	PH	EM	RI	MICRO	MACRO
ACNN	78.3	86.5	78.8	81.7	78.3	88.8	69.2	**83.9**	73.7 (0.6)	59.6 (2.3)
BERT-BASE	87.4	89.9	86.6	88.2	87.1	91.1	94.3	62.4	84.0 (0.1)	77.3 (0.2)
BERT-LARGE	88.2	89.9	87.9	88.8	87.7	93.1	93.5	68.0	84.8 (0.2)	79.1 (0.2)
SPANBERT-BASE	87.6	91.8	86.7	88.2	86.8	92.6	94.6	73.3	84.2 (0.1)	77.3 (0.2)
SPANBERT-LARGE	90.9	92.8	88.3	90.3	90.2	94.3	94.6	71.7	85.5 (0.1)	79.8 (0.2)
C^2 (BERT-BASE)	86.5	87.8	85.6	86.8	88.1	92.4	93.0	66.0	84.0 (0.1)	78.6 (0.2)
C^2 (BERT-LARGE)	85.9	90.0	87.3	86.9	87.2	93.0	**96.1**	66.0	84.9 (0.1)	79.5 (0.2)
C^2(SPANBERT-BASE)	89.8	91.3	90.5	90.9	87.8	93.2	93.4	71.3	85.7 (0.1)	81.0 (0.1)
C^2 (SPANBERT-LARGE)	**91.2**	**94.1**	**91.1**	**92.5**	**90.4**	**94.4**	89.2	77.1	**87.0** (0.1)	**81.1** (0.1)

Table 3: Experimental results per character on the character linking. The results are presented in a 1-digit decimal following previous work. Standard deviations of the Micro and Macro F1 scores are shown in brackets. The names in the table are written in two-letter acronyms. Ro: Ross, Ra: Rachel, Ch: Chandler, Mo: Monica, Jo: Joey, Ph: Phoebe, Em: Emily, Ri: Richard

two reasons. First, different from the experimental setting of OntoNotes, the mentions in our experiment setting are gold mentions. Consequently, the flexible span predicting strategy of CorefQA loses its advantages because of the absence of the mention proposal stage. Second, the CorefQA leverages the fine-tuning on other question answering (QA) datasets and it is possible that the used QA dataset (i.e., SQuAD-2.0 (Rajpurkar et al., 2018)) is more similar to OntoNotes rather than the used multiparty conversation dataset, which is typically much more informal. As a result, the effect of such fine-tuning process only works on OntoNotes.

The coarse-to-fine (C2F) model (Joshi et al., 2019b) with a transformer encoder was the previous state-of-the-art model on OntoNotes. Referring to Table 2, given the same text encoder, the proposed C^2 model can constantly outperform the C2F model. These results further demonstrate that with the help of the proposed joint learning framework, the out-of-context character information can help achieve better mention representations so that the coreference models can resolve them more easily.

5.2 Character Linking Results

As shown in Table 3, the proposed joint learning model also achieves the best performance on the character linking task and there are mainly two reasons for that. First, the contextualized mention representations obtained from pre-trained language encoders can better encode the context information than those representations used in ACNN. Second, with the help of coreference clusters, richer context about the whole conversation is encoded for each mention. For example, when using the same pre-trained language model as the encoder, C^2 can always outperform the baseline classification model. These empirical results confirm that, though the BERT and SpanBERT can produce very good vector representation for the mentions based on the local context, the coreference clusters can still provide useful document-level contextual information for linking them to a global character entity.

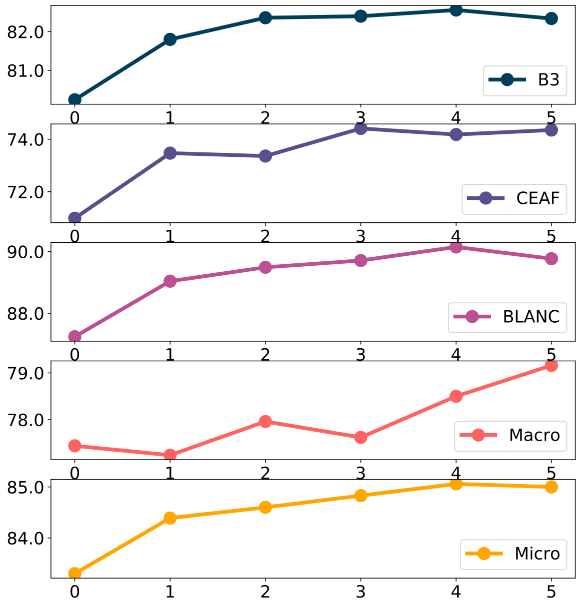

Figure 5: The x-axis is the number of MLSA layers used in the C^2. The y-axes are the F1 scores on each metric for their corresponding tasks. The curves have general trends of going up, which indicates that the model performs better when there are more layers.

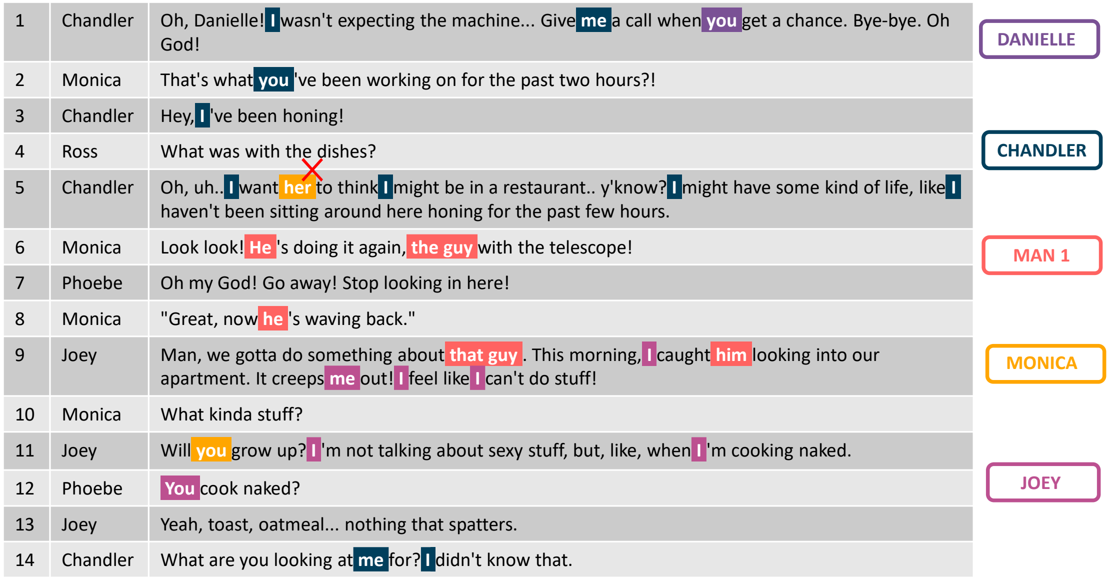
5.3 The Number of MLSA Layers

Another contribution of the proposed C^2 model is the proposed mention-level self-attention (MLSA) module, which helps iteratively refine the mention representations according to the other mentions co-occurred within the same document. In this section, to show its effect and the influence of iteration layers, we tried different layers and show their per-



1	Chandler	Oh, Danielle! I wasn't expecting the machine... Give me a call when you get a chance. Bye-bye. Oh God!
2	Monica	That's what you 've been working on for the past two hours?!
3	Chandler	Hey, I 've been honing!
4	Ross	What was with the dishes?
5	Chandler	Oh, uh.. I want her to think I might be in a restaurant.. y'know? I might have some kind of life, like I haven't been sitting around here honing for the past few hours.
6	Monica	Look look! He 's doing it again, the guy with the telescope!
7	Phoebe	Oh my God! Go away! Stop looking in here!
8	Monica	"Great, now he 's waving back."
9	Joey	Man, we gotta do something about that guy . This morning, I caught him looking into our apartment. It creeps me out! I feel like I can't do stuff!
10	Monica	What kinda stuff?
11	Joey	Will you grow up? I 'm not talking about sexy stuff, but, like, when I 'm cooking naked.
12	Phoebe	You cook naked?
13	Joey	Yeah, toast, oatmeal... nothing that spatters.
14	Chandler	What are you looking at me for? I didn't know that.

Figure 6: Case study. All mentions that are linked to the same character and in the same coreference cluster are highlighted with the same color. The misclassified mention is marked with the red cross.

	Coreference F1			Linking F1	
Model	B3	CEAFϕ4	BLANC	Micro	Macro
C^2	**85.54**	**77.48**	**92,17**	**87.05**	**81.09**
- MLSA	83.57	75.32	90.51	86.26	80.32
- Linking	83.50	76.10	90.08	-	-
- Coref.	-	-	-	86.94	79.58

Table 4: Three ablation studies are conducted concerning the MLSA layers, the coreference resolution module, and the character linking module.

formances on the test set in Figure 5. We conducted the experiments with the SpanBERT-Base encoder and all other hyper-parameters are the same. The x-axis is the number of layers, and the y-axes are F1 scores of B3, CEAF, and BLANC for coreference resolution, the Macro and Micro F1 scores for character linking. From the results, we can see that with the increase of layer number from zero to five, the F1 scores on both tasks gradually increase. This trend demonstrates that the model can perform better on both tasks when there are more layers. Meanwhile, the marginal performance improvement of the MLSA layer is decreasing. This indicates that adding too many layers of MLSA may not further help improve the performance because enough context has been included. Considering the balance between performance and computational efficiency, we chose the iteration layers to be two in our current model based on similar observations made on the development set.

5.4 Ablation Study

In this section, we present the ablation study to clearly show the effect of different modules in the proposed framework C^2 in Table 4. First, we try to remove the mention-level self-attention (MLSA) from our joint learning model and a clear performance drop is observed on both tasks. Specifically, the performance on coreference resolution is reduced by 1.21 on the average F1, and meanwhile, the macro-F1 and micro-F1 scores on character linking decreased by 0.77 and 0.79 respectively. The reduction reveals that the MLSA indeed helps achieve better mention representations with the help from co-occurred mentions. Second, we try to remove the coreference resolution and character linking modules. When the character linking module is removed, it is observed that the performance on coreference resolution decreased by 1.94 on the averaged F1 score. When the coreference module is removed, the performance of C^2 on character linking dropped by 0.83 on the average of Micro and Macro F1 scores. These results prove that the modeling of coreference resolution and character linking can indeed help each other and improve the performance significantly, and the proposed joint learning framework can help to achieve that goal.

5.5 Case Study

Besides the quantitative evaluation, in this section, we present the case study to qualitatively evaluate the strengths and weaknesses of the proposed C^2 model. As shown in Figure 6, we randomly select an example from the development set to show the prediction results of the proposed model on both tasks. To illustrate the coreference resolution and character linking results from the C^2 model, the mentions from the same coreference cluster are highlighted with the same color. Also, we use the same color to indicate to which character the mentions are referring. Meanwhile, the falsely predicted result is marked with a red cross.

5.5.1 Strengths

For this example, the results on both tasks are consistent. The mentions that are linked to the same character entity are in the same coreference group and vice versa. Based on this observation and previous experimental results, it is more convincing that the proposed model can effectively solve the two problems at the same time. Besides that, we also notice that the model does not overfit the popular characters. It can correctly solve all the mentions referring to not only main characters, and also for the characters that only appear several times such as *MAN 1*. Last but not least, the proposed model can correctly resolve the mention to the correct antecedent even though there is a long distance between them in the conversation. For example, the mention *me* in utterance 14 can be correctly assigned to the mention *you* in utterance 2, though there are 11 utterances in between. It shows that by putting two tasks together, the proposed model can better utilize the whole conversation context. The only error made by the model is incorrectly classifying a mention and at the same time putting it into a wrong coreference cluster.

5.5.2 Weaknesses

By analyzing the error case, it is noticed that the model may have trouble in handling the mentions that require common sense knowledge. Humans can successfully resolve the mention *her* to Danielle because they know Danielle is on the other side of the telephone, but Monica is in the house. As a result, Chandler can only deceive Danielle but not Monica. But the current model, which only relies on the context, cannot tell the difference.

5.6 Error Analysis

We use the example in Figure 6 to emphasize the error analysis that compares the performance of our model and the baseline models. The details are as follows. In this example, the only mistake made by our model is related to common-sense knowledge, and the baseline models are also not able to make a correct prediction.

For coreference resolution, 3 out of 25 mentions are put into a wrong cluster by the c2f baseline model. The baseline model failed to do long-distance antecedent assignments (e.g., the "me" in utterance 14). Meanwhile, our model is better in this case because it successfully predicts the antecedent of the mention "me", even though its corresponding antecedent is far away in utterance 2. This example demonstrates the advantage that our joint model can use global information obtained from character linking to better resolve the co-referents that are far away from each other.

For character linking, 2 out of 25 mentions are linked to the wrong characters by the baseline model. It is observed that the baseline model cannot consistently make correct linking predictions to less-appeared characters, for example, the "He" in utterance 6. In this case, our model performs better mainly because it can use the information gathered from the nearby co-referents to adjust its linking prediction, as its nearby co-referents are correctly linked to corresponding entities.

6 Related Works

Coreference resolution is the task of grouping mentions to clusters such that all the mentions in the same cluster refer to the same real-world entity (Pradhan et al., 2012; Zhang et al., 2019a,b; Yu et al., 2019). With the help of higher-order coreference resolution mechanism (Lee et al., 2018) and strong pre-trained language models (e.g., SpanBERT (Joshi et al., 2019b)), the end-to-end based coreference resolution systems have been achieving impressive performance on the standard evaluation dataset (Pradhan et al., 2012). Recently, motivated by the success of the transfer learning, Wu et al. (2020) propose to model the coreference resolution task as a question answering problem. Through the careful fine-tuning on a high-quality QA dataset (i.e., SQUAD-2.0 (Rajpurkar et al., 2018)), it achieves the state-of-the-art performance on the standard evaluation benchmark. However, as disclosed by Zhang et al. (2020), current systems are still not perfect. For example, they still cannot effectively handle pronouns, especially those in informal language usage scenarios like conversations. In this paper, we propose to leverage the out-of-context character information to help resolve the coreference relations with a joint learning model, which has been proven effective in the experiments.

As a traditional NLP task, entity linking (Mihalcea and Csomai, 2007; Ji et al., 2015; Kolitsas et al., 2018; Raiman and Raiman, 2018; Onando Mulang et al., 2020; van Hulst et al., 2020) aims at linking mentions in context to entities in the real world (typically in the format of knowledge graph). Typically, the mentions are named entities and the main challenge is the disambiguation. However, as a special case of the entity linking, the character linking task has its challenge that the majority of the mentions are pronouns. In the experiments, we have demonstrated that when the local context is not enough, the richer context information provided by the coreference clusters could be very helpful for linking mentions to the correct characters.

In the NLP community, people have long been thinking that the coreference resolution task and entity linking should be able to help each other. For example, Ratinov and Roth (2012) show how to use knowledge from named-entity linking to improve the coreference resolution, but do not consider doing it in a joint learning approach. After that, Hajishirzi et al. (2013) demonstrate that the coreference resolution and entity linking are complementary in terms of reducing the errors in both tasks. Motivated by these observations, a joint model for coreference, typing, and linking is proposed (Durrett and Klein, 2014) to improve the performance on three tasks at the same time. Compared with previous works, the main contributions of this paper are two-fold: (1) we tackle the challenging character linking problem; (2) we design a novel mention representation encoding method, which has been shown effective on both the coreference resolution and character linking tasks.

7 Conclusion

In this paper, we propose to solve the coreference resolution and character linking tasks jointly. The experimental results show that the proposed model C^2 performs better than all previous models on both tasks. Detailed analysis is also conducted to show the contribution of different modules and the effect of the hyper-parameter.

Improving Factual Consistency Between a Response and Persona Facts

Mohsen Mesgar **Edwin Simpson*** **Iryna Gurevych**

Department of Computer Science, Technical University of Darmstadt
https://www.ukp.tu-darmstadt.de

Abstract

Neural models for response generation produce responses that are semantically plausible but not necessarily factually consistent with facts describing the speaker's persona. These models are trained with fully supervised learning where the objective function barely captures factual consistency. We propose to fine-tune these models by reinforcement learning and an efficient reward function that explicitly captures the consistency between a response and persona facts as well as semantic plausibility[1]. Our automatic and human evaluations on the PersonaChat corpus confirm that our approach increases the rate of responses that are factually consistent with persona facts over its supervised counterpart while retaining the language quality of responses.

1 Introduction

Response generation models should ideally generate an appropriate *response* to a given context consisting of utterances previously exchanged between dialogue partners and facts describing the speakers' persona. These models have applications in developing dialogue systems as user interfaces for digital assistants (Bobrow et al., 1977) and also in asynchronous interactions in social media in which speakers define themselves by their profiles.

In this work, we focus on the aspects of persona that can be captured by a set of factual statements, a.k.a., profiles. Table 1 illustrates the persona of the speaker who should respond to the given message. The first response is *topically coherent with the message* and also *linguistically fluent* (or in general, *semantically plausible*) but *factually inconsistent*, unlike the second response, with the second fact in the speaker's persona. We aim to improve the response quality in terms of its factual consistency with facts about the given speaker's persona while retaining its semantic plausibility.

Persona

fact 1: i hate my job
fact 2: i ' m 40 years old
fact 3: i work as a car salesman
fact 4: my wife spends all my money
fact 5: i am planning on getting a divorce

Dialogue History

message: hi , want to be friends?

Generated Responses:

inconsistent: i ' d love to be friends . i ' m 50 years old
consistent: sure , i am 40 , i can tell you about myself

Table 1: A speaker's persona, dialogue history, one inconsistent, and one consistent possible response.

Recent approaches to this problem (Zhang et al., 2018; Dinan et al., 2019; Wolf et al., 2019) generate a response conditioned on persona facts and dialogue history and then use human-generated responses as demonstrations to train their models by fully supervised learning (SL). While this strategy has led to markedly improved performance, there is still a misalignment between this training objective – maximizing the likelihood of human-written responses – and what users care about – generating semantically plausible and factually consistent outputs as determined by humans. This misalignment has several reasons: the maximum likelihood objective considers no distinction between primary errors (e.g. inconsistent responses) and unimportant errors (e.g. selecting the precise word from a set of synonyms); models are incentivized to place probability mass on all human-generated responses, including those that are low-quality; and distributional shift during sampling can degrade performance. Optimizing for targeted quality factors is a principled approach to overcome these problems

(e.g., Gao et al. (2019) optimize text summarization systems for quality factors relevant to that task).

Our goal is to advance methods for training response generation models on objectives that closely capture the behavior users care about. We first define a reward function to explicitly assesses the quality of a generated response according to *factual consistency with persona facts*, *topical coherence with dialogue history*, and *language fluency*. We then train a policy via reinforcement learning (RL) to maximize the score given by our reward function; the policy generates a token of response at each "time step", and is updated using the Actor-Critic learning approach (Mnih et al., 2016) based on the "reward" our reward function gives to the entire generated response.

We evaluate our approach on PersonaChat (Zhang et al., 2018), a benchmark corpus of English dialogues designed to evaluate the factual consistency between a response and persona facts. We assess the language quality and the factual consistency of responses our RL-based model generates using automatic metrics and human evaluations . Our core contributions are twofold:

- We propose to fine-tune a transformer-based response generation model by an RL method including an efficient reward function that ensures factual consistency with persona facts as well as semantic plausibility of a response.

- We use automatic and human evaluations to show that our RL-based method generates a response that is factually consistent with persona facts more frequently than its SL-based counterpart (Wolf et al., 2019).

The method we present in this paper is motivated in part by long-term concerns about the misalignment of NLP systems with what humans want them to do. When misaligned response generation models generate facts inconsistent with background knowledge like persona facts, their mistakes are relatively low-risk and easy to catch. However, as these systems become more popular to solve essential tasks, their mistakes will likely become more subtle, making this an important area for further research.

2 Method

Let $d = (u_1, ..., u_{T-1})$ be the exchanged utterances between dialogue partners until turn $T-1$, and $p = \{f_1, ..., f_{|p|}\}$ be a persona expressed by a set of facts (i.e. short sentences) about the speaker who should generate a response. Our goal is to generate a response $r = (t_1, ..., t_M)$ consisting of M tokens so that r is consistent with the facts in persona p, topically coherent with u_{T-1}, and linguistically fluent.

2.1 TransferTransfo-SL

We use the *TransferTransfo* (Wolf et al., 2019) dialogue model which is pre-trained and then fine-tuned with fully supervised learning (SL). TransferTransfo is a multi-layer transformer (Vaswani et al., 2017) based on the Generative Pre-trained Transformer (GPT) (Radford et al., 2018). Each transformer layer uses constrained self-attention where every token can only attend to its left context. Generation was performed using beam search with sampling, and an n-gram filtering is used to ensure the model does not directly copy from the persona facts nor former utterances. This model significantly improves over the traditional seq-to-seq, memory-based, and information-retrieval baselines in terms of (1) topical coherence of the response, (2) consistency with a predefined persona, and (3) grammaticality and fluency as evaluated by the automatic metrics in the ConvAI2 competition (Dinan et al., 2019). Since this agent uses transformers, it copes with different lengths of dialogue history.

The transformer layers' parameters in this model are transferred from the pre-trained GPT and then are fine-tuned in a supervised scenario to optimize the losses for the response classification and response generation tasks. The former loss measures if the model distinguishes a correct response appended to the input sequence from a set of randomly sampled distractors, which are randomly selected. The latter one is the language modeling loss that measures how well the model can generate a response similar to the human-generated response. The generative loss is estimated as follows: the self-attention model's final hidden state is fed into an output softmax over the vocabulary to obtain the next response token probabilities. These probabilities are then scored using a negative log-likelihood loss, where the gold next tokens are taken as labels.

2.2 TransferTransfo-RL

Besides the remarkable improvement achieved by TransferTransfo-SL, its generated responses are not necessarily factually consistent with persona

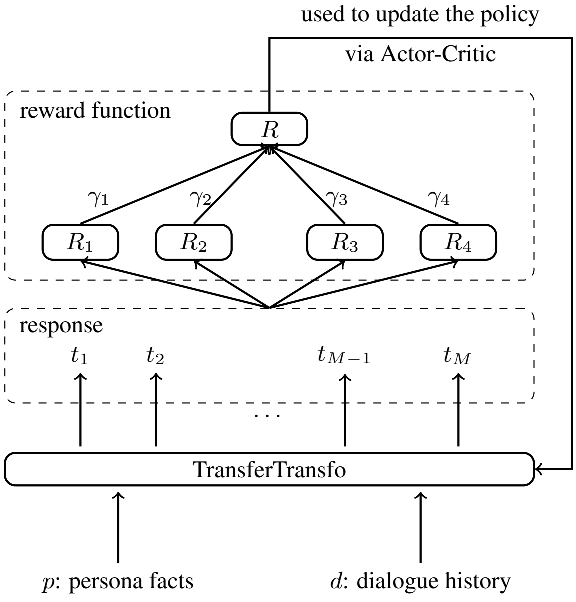

Figure 1: An abstract view of our RL approach.

facts. For example, the inconsistent response in Table 1 is generated by this system. We propose to fine-tune the parameters of this model using reinforcement learning (RL). The TransferTransfo model generates a response token-by-token for a given persona and dialogue history. After generating the last token, i.e. '`<EOS>`', or reaching the maximum length allowed for a response, a reward model assesses the quality of the response (Figure 1). The reward value is used to fine-tune the parameters of TransferTranfo towards the policy that generates a response that is factually consistent with persona facts and also semantically plausible.

Action We consider generating each token of a response as an action performed by the TransferTransfo model:

$$\mathcal{P}_\theta\left(r|s\right) = \mathcal{P}_\theta(t_1|s)\prod_{k=2}^{M}\mathcal{P}_\theta(t_k|t_{1..k-1},s)\ , \quad (1)$$

where t_k is the kth token in response r and $t_{1..k-1}$ indicates the sequence of tokens generated prior to token k. For the sake of brevity, we use the notation s to refer to (p,d). The function $\mathcal{P}_\theta(r|s)$ is the policy with the parameters θ of TransferTransfo.

Reward function A response generation system should ideally generate a response that is factually consistent with the persona facts, topically coherent with the former interactions, and linguistically fluent. Thus, we propose a compound reward consisting of four sub-rewards: R_1 ensures factual consistency with the persona facts. R_2 accounts for topical coherence with the former utterance. R_3 and R_4 reinforce fluency. We use a weighted sum of these sub-rewards as the training signal:

$$R = \gamma_1 R_1 + \gamma_2 R_2 + \gamma_3 R_3 + \gamma_4 R_4\ , \quad (2)$$

where $\gamma_1 + \gamma_2 + \gamma_3 + \gamma_4 = 1$. These weights can be tuned as described below to prevent biasing the policy toward a particular sub-reward.

Persona consistency sub-reward ($\mathbf{R_1}$) Recent studies (Welleck et al., 2019; Dziri et al., 2019) show that consistency with factual information, such as persona facts, can be characterized as a natural language inference (NLI) problem, where entailment labels can be taken as consistent labels and contradiction labels as inconsistent labels. Building on this, we use an NLI model to design this sub-reward. We define our NLI model using BERT as a bidirectional contextualized encoder:

$$\begin{aligned} & h^{\texttt{[cls]}}, - = \texttt{BERT}(\texttt{[cls]}\,f_i\,\texttt{[SEP]}\,r)\ , \\ & [s_e, s_c, s_n] = \texttt{MLP}(h^{\texttt{[cls]}})\ , \qquad (3) \\ & \left[\mathcal{P}_e^{\text{NLI}}, \mathcal{P}_c^{\text{NLI}}, \mathcal{P}_n^{\text{NLI}}\right] = \texttt{Softmax}([s_e, s_c, s_n])\ , \end{aligned}$$

where f_i is a fact in the given persona, r is the generated response, `[SEP]` is the separator token, and $h^{\texttt{[cls]}}$ is provided by BERT to classify semantic relationships between input sentences (Devlin et al., 2019). `MLP` is a linear layer that maps $h^{\texttt{[cls]}}$ to the scores s_e, s_c and s_n, for the *entailment*, *contradiction*, and *neutral* classes, respectively. $\mathcal{P}_e^{\text{NLI}}$, $\mathcal{P}_c^{\text{NLI}}$ and $\mathcal{P}_n^{\text{NLI}}$ denote the respective class probabilities.

We train our NLI model to predict the NLI classes of pairs of utterances and persona facts (§3.3). We then use this trained model as R_1 to penalize the agent if its generated response contradicts one of the facts in the persona, and encourages the agent if its response entails a fact:

$$R_1 = \frac{1}{|p|}\sum_{f_i \in p}\mathcal{P}_e^{\text{NLI}}(f_i, r) - \frac{\beta}{|p|}\sum_{f_i \in p}\mathcal{P}_c^{\text{NLI}}(f_i, r)\ , \quad (4)$$

where $\mathcal{P}_e^{\text{NLI}}$ and $\mathcal{P}_c^{\text{NLI}}$ are the entailment and contradiction probabilities of the relationship between f_i and r. Scalar $\beta \geq 1$ is a marginal penalty for contradiction over entailment: responses that lack entailment may acceptably be neutral, while contradictory responses are a serious consistency error.

The sub-reward for the factual consistency with persona facts is not sufficient to generate a semantically plausible response. The agent can maximize this sub-reward merely by repeating the persona's facts and ignoring topical coherence (for an example, see Appendix A). To prevent such behavior, we assess the topical coherence and grammatical fluency of a response by the following sub-rewards.

Topical coherence sub-reward ($\mathbf{R_2}$) Topical coherence is a crucial property of high-quality dialogues (See et al., 2019; Mesgar et al., 2020). We capture the topical coherence of response r to the last utterance u_{T-1} in dialogue history by representing them using an average pooling layer over their token representations obtained by BERT. Inspired by Baheti et al. (2018) and See et al. (2019), we use *cosine similarity* between $\vec{r}$ and $\vec{u}_{T-1}$ as a proxy for topical coherence:

$$R_2 = \cos(\vec{r}, \vec{u}_{T-1}) \ . \tag{5}$$

Fluency sub-rewards ($\mathbf{R_3}$ and $\mathbf{R_4}$) The above sub-rewards do not assess if the response content expressed is linguistically fluent. As also suggested in prior work (Yarats and Lewis, 2018; Zhao et al., 2019; Bao et al., 2019), applying RL for specific metrics might bring in adverse impacts on linguistic quality. As such, we add sub-rewards R_3 and R_4 to promote linguistic quality. R_3 employs a language model (LM) fine-tuned on a set of utterances (§3.4) to evaluate the language quality of response. To do so, we use the Negative Log-Likelihood (NLL) loss obtained by this LM:

$$R_3 = \frac{\alpha - \texttt{NLL}(r)}{\alpha}, \tag{6}$$

where parameter α is used to map any value of NLL that is greater than α to α so that the output of R_3 will be between 0 and 1. To retain the language quality of responses similar to those of TransferTransfo, we set α to the maximum NLL value that this LM returns for responses generated by the TransferTransfo model on a development set. R_3 is not biased to the length of a response as NLL is already normalized by response length.

Repeated tokens in a response *significantly and negatively* influence the quality of the response (See et al., 2019). R_4 specifically discourages the generation of 1-gram tokens that appear in a response more than one time in a row:

$$R_4 = 1 - \frac{\text{\#repeated-tokens-in-response}}{\text{\#tokens-in-response}}. \tag{7}$$

Weight optimization In combination, these sub-rewards reinforce factual consistency with persona facts, topical coherence, and language fluency. We use their linear combination as a reward R to prevent our policy from becoming overly biased towards any of the sub-rewards. For instance, while generic responses, such as *"I don't know"*, have high fluency, they are discouraged by the persona-consistency sub-reward as they cannot be entailed from any persona fact. However, the weights must be tuned to ensure a suitable balance between the sub-rewards. We apply grid search over the weights and choose the values that yield a policy with the best performance on a validation set (§3.2).

2.3 Training

The goal of RL is to learn a policy, $\mathcal{P}_\theta$, for generating a response that maximizes the expected reward:

$$\mathcal{L} = \mathbb{E}_{\substack{s \in D \\ r \sim \mathcal{P}_\theta(.|s)}} [R(r, s)] \ , \tag{8}$$

where R is the reward function (Equation 2) and $s = (p, d)$ is the given persona and dialogue history that our policy has generated response r for. Function $\mathcal{L}$ is optimized by a stochastic gradient method, where its gradient is (Mnih et al., 2016):

$$\frac{\partial \mathcal{L}}{\partial \theta} = \mathbb{E}_{\substack{s \in D \\ r \sim \mathcal{P}_\theta(.|s)}} \left[R(r, s) \frac{\partial \log \mathcal{P}_\theta(r|s)}{\partial \theta} \right]. \tag{9}$$

To avoid the high-variance issue, we adopt the *actor-critic* method (Mnih et al., 2016) to fine-tune the policy function directly for our quality goals. This approach reduces the variance in the estimated gradient by sampling a single response $r \sim \mathcal{P}_\theta(.|s)$ and computing the difference between its reward $R(r, s)$ and the reward predicted by a critic, $\eta(t_{1..k}, s)$, for the tokens up to position k in response r. The gradient in Equation 9 is then approximated as follows:

$$\frac{\partial \mathcal{L}}{\partial \theta} \approx \sum_k (R(r, s) - \eta(t_{1..k}, s)) \frac{\partial}{\partial \theta} \log \mathcal{P}_\theta(t_k|s) \ . \tag{10}$$

The critic function is $\eta = w^T h_k$, where w is its trainable parameters and h_k is the vector returned by the TransferTransfo model (our agent) at position k. We update the critic's parameters after each update of the policy's parameters by minimizing the squared error between its estimated rewards and the value our reward model assigns to the response:

$$\mathcal{L}_\eta = \mathbb{E}_{\substack{s \in D \\ r \sim P_\theta(.|s)}} \sum_k [\eta(t_{1..k}, s) - R(r, s)]^2. \tag{11}$$

	Train	Validation
Num. of dialogues	17,878	1,000
Num. of utterances	262,876	15,602
Num. of personas	955	200

Table 2: Statistics of PersonaChat as used in the ConvAI2 competition and our experiments.

3 Experiments

We measure to what extent our RL-based fine-tuning (§2) improves the factual consistency of generated responses while retaining their semantic plausibility. We first introduce the corpus used in our experiments (§3.1). We then evaluate the TransferTransfo-SL and TransferTransfo-RL systems by automatic and human evaluations (§3.2). We finally analyze the models we employ to estimate the factual consistency (§3.3) and language fluency (§3.4) sub-rewards.

3.1 PersonaChat Corpus

We use datasets built on the PersonaChat corpus (Zhang et al., 2018), which consists of dialogues, in English, with 6 to 8 turns between randomly paired human crowd-workers. The workers were assigned short text facts representing personas and instructed to talk to their dialogue partner *naturally to discover each other's persona*. We chose this corpus because of its focus on promoting natural conversations while grounding conversations in the persona facts. Each persona consists of 4 or 5 facts, and on average is assigned to 8.3 unique dialogues. We train and evaluate the aforementioned systems on the standard splits of the version of this corpus made available in ParlAI[2] for the ConvAI2 challenge (Dinan et al., 2019) (Table 2). As the test set is hidden, we evaluate the systems on the validation set. To create a training and evaluation sample consisting of a persona and a dialogue history (Table 1), each dialogue is split at each dialogue turn.

3.2 Response Generation

We study to what extent our RL approach generates a response that is factually consistent with given persona facts and semantically plausible. We use TranserTransfo, which performed best in automatic evaluation and second-best in human evaluation among 26 participants in the ConvAI2 competition, as a response generation model.

Settings Following the training setup used by Wolf et al. (2019), we fine-tune TransferTransfo on all training samples in PersonaChat and stop the fine-tuning after three epochs. We refer to this fine-tuned model as TransferTransfo-SL. For TransferTransfo-RL, we continue to fine-tune the TransferTransfo model with our RL approach on 90% of the training set for one epoch, where after each policy update, the critic's parameters are updated for 5 times. For R_1, we use the BERT model trained on Dialogue NLI (§3.3) with $\beta = 2$ and for R_3 we use Dialogue LM (§3.4) with $\alpha = 4$. The maximum response length is 20. The input texts are tokenized according to the GPT byte pair encoding (BPE) but the reward is computed on a completely decoded response text. We use the remaining 10% of the training set to choose the sub-reward weights (Equation 2) based on token-level F1-score, which indicates how well the system's responses match the content of human-generated responses (examined weights and their F1-scores are in Appendix B), resulting in $\gamma_1 = 0.4$, $\gamma_2 = 0.16$, $\gamma_3 = 0.22$ and $\gamma_4 = 0.22$. The high weight of the persona consistency sub-reward (γ_1) is compatible with the goal of dialogues in PersonaChat, which is to reveal the persona of dialogue partners. The weights are also consistent with See et al. (2019): fluency factors (γ_3 and γ_4) are more crucial than cosine-relatedness (γ_2) for responses in this corpus.

3.2.1 Automatic Evaluation

We evaluate these systems on the PersonaChat validation set as used in ConvAI2. We report PPL, F1, and BLEU to assess generated responses according to reference responses. We evaluate the factual consistency of a response and the given persona facts using our NLI model (§3.4). It assigns inference relations between a generated response and each fact in the given persona. Given N fact-response pairs in the whole evaluation set, this metric is:

$$\text{PC} = 100\frac{N_e - N_c}{N}\ , \qquad (12)$$

where N_e and N_c are the numbers of entailment and contradiction labels, respectively.

Results The TransferTransfo-RL outperforms its supervised counterparts on all metrics except PPL (Table 3). The improvements on F1 and BLEU indicate that responses generated by TransferTransfo-RL are more similar to reference responses generated by humans and are not biased

---

[2] `https://github.com/facebookresearch/ParlAI/tree/master/projects/personachat`

Method	PPL	F1	BLEU	PC
TransferTransfo-SL	21.31	17.06	0.065	09.32
TransferTransfo-RL	22.64	**17.78**	**0.067**	**13.06**

Table 3: Automatic evaluations of responses generated by TransferTransfo-SL and TransferTransfo-RL.

toward simply repeating persona facts or previous utterances. It also shows that responses are as informative as human-provided ones. Our RL method decreases the average word repetition rate (Equation 7) from 9% with TransferTransfo-SL to 7%, increasing the language fluency of responses. So far, we observe that the RL method could retain and even improve the semantic plausibility of a response.

Regarding the factual consistency between a response and given persona facts, TransferTransfo-RL scores significantly higher for the PC metric. This indicates that the number of evaluation samples for which TransferTransfo-RL generates a response consistent with given persona facts is significantly higher than what TransferTransfo-SL does. Looking at PC in detail (Table 4, top), TransferTransfo-RL increases the frequency of cases whose generated responses are entailed from (or consistent with) persona facts by 3.41% over TransferTransfo-SL, while reducing contradictions (or inconsistency) by 0.07% and neutral by 3.61%; showing that fine-tuning with RL improves the policy for generating a response that is factually consistent with persona facts. While our combined reward function achieves good all-round performance, ablation experiments (Appendix A and B) show that each sub-reward is effective and necessary to capture consistency with persona facts, topical coherence, and language fluency.

3.2.2 Human Evaluation

We also conduct a human evaluation between TransferTransfo-RL and TransferTransfo-SL. We randomly select *100 samples*, each of which consists of a dialogue history, a persona, and the responses generated by the examined systems. We ask *seven human judges* (two native and five fluent English speakers) to assign a *consistency label* from {*consistent, neutral, contradicting*} to the response concerning the facts in the persona (instructions in Appendix D). We also ask the human judges to rate the *semantic plausibility* of each response with an ordinal score ranging from 1 (worst) to 5 (best), encompassing *coherence*, *grammatical correctness*, and *low repetitiveness*.

	Consistent	Contradicting	Neutral
Automatic Evaluation			
TransferTransfo-SL	11.14	01.82	87.04
TransferTransfo-RL	**14.81**	**01.75**	**83.43**
Δ	3.41 ↑	0.07 ↓	3.61 ↓
Human Evaluation			
TransferTransfo-SL	43.71	17.71	38.58
TransferTransfo-RL	**52.71**	**14.00**	**33.29**
Δ	9.00 ↑	3.71 ↓	5.29 ↓

Table 4: Frequencies (%) of consistency labels. Automatic evaluation uses our NLI model to assign labels for the whole evaluation set. For human evaluation, judges labeled 100 samples. Δ is the improvement of TransferTransfo-RL over TransferTransfo-SL.

Method	Average Semantic Plausibility
TransferTransfo-SL	3.33
TransferTransfo-RL	**3.50**

Table 5: Human evaluation: semantic plausibility.

Results Table 4 (bottom) shows the average percentage of consistency labels human judges assign to responses generated by TransferTransfo-RL and TransferTransfo-SL. The number of samples for which TransferTransfo-SL generates a consistent response increases by 9% using our RL fine-tuning approach while contradictions (or inconsistencies) decrease by 3.71%, confirming that human judges more frequently find responses generated by TransferTransfo-RL factually consistent with persona facts than those of TransferTransfo-SL. The number of neutral responses also decreases, suggesting fewer generic responses, as neutral responses tend to be generic (Welleck et al., 2019).

Overall, Table 4 shows a similar trend between the human and the automatic evaluations, confirming the findings of the automatic evaluation. Unlike the human evaluation, our automatic evaluation shows that the models generate a neutral response for most cases. The NLI model assesses more responses to be neutral than humans do – humans can reason about entailment relations using their common senses, while the NLI model does not identify any relation. Further analysis (Appendix E) shows that for over half of the cases for which TransferTransfo-SL generates a contradicting (inconsistent) response, our TransferTransfo-RL generates a consistent response, indicating that the idea of using RL to fine-tune a pre-trained agent improves its capability in generating a factually consistent response with persona facts.

In terms of semantic plausibility (topically coherent and linguistically fluent), Table 5 shows that the human judges find responses generated by TransferTransfo-RL are on par with those of TransferTransfo-SL, showing the effectiveness of our topical coherence and fluency sub-rewards.

3.3 Persona-Consistency Sub-reward Validation

As discussed in §2, assessing factual consistency with persona facts can be characterized as an NLI problem. In this experiment, we investigate the choice of the NLI model for this sub-reward by comparing our BERT-based NLI model (§2) with recent NLI models on the *Dialogue NLI* dataset (Welleck et al., 2019). This dataset, which is designed for evaluating factual NLI in dialogues, consists of a set of fact-utterance, fact-fact, and utterance-utterance pairs extracted from the PersonaChat corpus. Each pair is accompanied by a *human-annotated NLI label*, i.e., entailment (or consistent), contradiction (or inconsistent), and neutral. Two examples of the fact-utterance pair from this dataset are: *"My dad is a priest."* **contradicts** *"Since my dad is a mechanic we had mostly car books."*; and *"I like playing basketball"* **entails** *"I prefer basketball. Team sports are fun."*. This dataset contains 310,110 training, 16,500 validation and 16,500 test pairs. Besides the standard test set, which was annotated by *one crowdworker*, there is *Test Gold* containing 12,376 of test pairs, which were annotated by *three crowdworkers* (Welleck et al., 2019).

We compare our BERT-based NLI model with (1) **Majority**, which returns the majority class; (2) **ESIM** Enhanced Sequential Inference Model (Chen et al., 2017), an LSTM-based model with inter-sentence attentions. ESIM is the state of the art on the Dialogue NLI dataset. We use *bert-base-uncased* (Devlin et al., 2019) to encode utterances and facts. We fine-tune the whole model during training. We set the maximum input length to 128, the learning rate to 5×10^{-5}, and the training- and evaluation-batch sizes to 32 and 8, respectively. We compare the NLI models using *accuracy* (Welleck et al., 2019).

Results Table 6 shows that the BERT-based NLI model outperforms ESIM, suggesting that our model better captures the factual relationships between an utterance and a persona fact. Welleck et al. (2019) previously demonstrated that the performance of ESIM is sufficient to check the factual consistency between a response and persona facts; as our model outperforms ESIM, we chose our NLI model for the consistency sub-reward R_1. Indeed, a more accurate NLI model reduces the noise in the reward function and consequently the errors our system makes.

Model	Validation	Test	Test Gold
Majority	33.33	34.54	34.96
ESIM	86.31	88.20	92.45
Our NLI model	**86.84**	**89.50**	**93.60**

Table 6: Accuracy of candidate NLI models for R_1 on the Dialogue NLI dataset.

Model	PPL
Non-Dialogue LM	108.29
Dialogue LM	**10.01**

Table 7: The perplexity (PPL) of the language model (Dialogue LM) used for the fluency sub-reward $R_{3.1}$.

3.4 Response Fluency Sub-reward Validation

Sub-reward R_3 requires a language model to measure the language quality of a response. In this experiment, we investigate if fine-tuning a pre-trained, non-dialogue language model on dialogue utterances makes it suitable for this goal. To do so, we compare (1) **Non-Dialogue LM**, which is the GPT language model with no fine-tuning; and (2) **Dialogue LM**, which is the GPT language model fine-tuned on utterances from PersonaChat. We fine-tune the GPT language model (Radford et al., 2018) for three epochs on 90% of utterances ($\approx$236,588) from the PersonaChat training set. We evaluate the language model on the remaining 10% ($\approx$26,288) of utterances, so the PersonaChat validation dialogues remain unseen for evaluating our dialogue systems. Training- and validation-batch sizes are 8 and 16, respectively. Learning rate is 6.25×10^{-5}, and *perplexity (PPL)* is the evaluation metric.

Results Dialogue LM substantially improves perplexity over Non-Dialogue LM (Table 7). This shows that the fine-tuned language model better captures the linguistic properties of dialogue utterances, yielding a more suitable language model for the fluency sub-reward R_3. See et al. (2019) validated the benefits of cosine similarity for estimating the coherence (R_2) and word repetition (R_4) for language quality.

4 Discussions

Case analysis We presented one example of an evaluation sample in Table 1, in which the inconsistent response is generated by TransferTransfo-SL and the consistent one by TransferTransfo-RL. Since TransferTransfo-SL is fine-tuned only with reference responses and does not have any training signal for factual consistency, we speculate that variants of *"I'm 50 years old"* occur in the training set leading the agent to produce a response that is inconsistent with the persona fact *"I'm 40 years old"*. In contrast, TransferTransfo-RL generates a consistent response which is also topically coherent with the given question and linguistically fluent. The above sample is an example of "attribute" consistency, where the response should express an attribute of the speaker. Table 8 shows some other evaluation samples. The top sample shows that TransferTransfo-RL can deal with "have" consistency. Our system correctly recognizes the number of dogs the speaker has and grounds its response on this fact. The evaluation sample in the middle row of Table 8 shows that our RL-based model can also deal with "like-to-do" consistency.

Although TransferTransfo-RL outperforms TransferTransfo-SL in generating different types of consistent responses (such as 'attribute", "have", and "like-to-do"), they both struggle with generating consistent responses for evaluation samples in which understanding of persona facts and dialogue history requires common sense knowledge. As an example, consider the second evaluation sample shown in Table 8. TransferTransfo-SL generates the response "*I'm not married yet*" which contradicts the first fact of the given persona "*My husband is adopted.*"; it seems the model does not have enough knowledge to capture the semantic relationship between "*my husband*" and "*marriage*". The bottom evaluation sample in Table 8 demonstrates the lack of common sense knowledge for TransferTransfo-RL as well. The response "*I like to go to church to sing with wife*" contradicts the fact "*My wife left me and took my children*" in the given dialogue history.

Limitations One limitation of our work is to narrow a speaker's persona to a set of facts expressed as short sentences. Persona has other aspects, such as speaking styles, which need a separate study. Nevertheless, the research question and experiments presented in this work demonstrate the benefits of RL methods for fine-tuning transformer-based models, which are already pretrained, to obtain a policy more aligned with target quality factors. Other aspects of the persona can also be involved in the reward function, given that our method potentially reduces the need for the high-quality demonstration responses generated by humans for supervised fine-tuning.

Future directions In this paper, we demonstrate the effectiveness of RL over SL for fine-tuning pretrained neural models (like GPT) for generating responses that fulfill quality goals such as factual consistency with given persona facts and semantic plausibility in a single round of dialogue. Therefore, the next step might be adopting our reward function to generate factually-consistent responses while retaining the diversity of responses through multiple rounds of dialogue.

5 Related Work

There are two types of approach to persona consistency. The first category includes systems that learn speaker-level embeddings from responses produced by a particular speaker (Li et al., 2016a; Madotto et al., 2019). These systems depend on the availability of suitable responses performed by the speaker whose persona we wish to imitate. If those responses do not reveal the persona information, dialogue systems cannot learn the persona. Moreover, these systems cannot be adapted to new personas at deployment time since the persona embeddings must be learned from training data. So our approach is complementary to them and not directly comparable.

The second category includes systems that rely on a set of facts about a persona. For example, Zhang et al. (2018) propose a key-value memory neural model for this task. This model is outperformed by TransferTransfo (Wolf et al., 2019), which is used in our experiments. Welleck et al. (2019) rank a given set of utterances using an NLI model to select a persona-consistent response. In contrast, we use NLI to train a generative model. Song et al. (2020) propose an NLI-based reward for persona consistency that calculates a score using only the persona facts with the highest entailment and contradiction probabilities, rather than the whole persona. Their approach does not reward topical coherence, which we found crucial

Persona	Dialogue History	TransferTransfo-SL	TransferTransfo-RL
fact 1: i go to the gym regularly . *fact 2*: i like doing the treadmill and rowing machine . *fact 3*: i ' ve short hair . *fact 4*: two dogs live with me . *fact 5*: eating is something i do when i am bored .	*message*: hello , how are you ? *response*: hello , i am feeling fit since i visited the gym today ! how are you ? that ' s absolutely great just fantastic after rowing and running on the treadmill , i ' m pretty hungry . do you work out ? *message*: yes after i cook all my chef food	i do a lot of cardio . i ' m really short , so i am always looking to	i love to cook , i have 2 dogs .

for relieving effects of the persona-consistency subreward on the quality of response.

Persona consistency was also a quality target in the ConvAI2 dialogue generation competition (Dinan et al., 2019). The winner of the human evaluation part of ConvAI2 is the “Lost in Conversation” system (Dinan et al., 2019), which is also a transformer-based model trained by SL on two extra datasets besides PersonaChat. In our paper, we used TransferTransfo trained only on PersonaChat. Our experiments showed that our idea of using RL for fine-tuning neural agents improves factual consistency between a response and persona facts by accounting for it in its reward function.

RL has been extensively used for training task-oriented dialogue systems (e.g., Nogueira and Cho (2017); Liu et al. (2018)). Unlike task-oriented scenarios, where a reward can measure if a task is fulfilled or not, incorporating persona facts lacks a straight-forward measurable outcome. Li et al. (2016b) use RL for generating open-domain dialogue using REINFORCE (instead of Actor-Critic) and an RNN-based model. This agent has no notion of factual consistency with facts about a persona, so is not comparable with our system.

6 Conclusions

We proposed to fine-tune response generation models by RL to improve on the quality goals that matter, e.g., factual consistency between a response and persona facts while retaining semantic plausibility. We adopted the actor-critic method for fine-tuning a pre-trained transformer-based model by defining an efficient and effective reward function measuring persona consistency, topical coherence, and language fluency. Automatic and human evaluations on PersonaChat demonstrate that compared to just using supervised learning, further fine-tuning with RL yields responses that are more frequently factually consistent with persona facts while still semantically plausible.

A Using Only the Persona-Consistency Sub-reward R_1

By using the persona-consistency sub-reward as the only reward function, the policy learns only to generate responses that state information about the persona facts and ignores the topical coherence with its former utterance.

Persona

fact 1: i prefer vinyl records to any other music format.
fact 2: i fix airplanes for a living.
fact 3: i drive junk cars that no one else wants.
fact 4: i think if i work hard enough i can fix the world.

Dialogue

message: hi how are you doing?
response: i am fine. i am a mechanic, so i fix airplanes. i fix them.
message: do you have any hobbies?
response: i enjoy listening to vinyl records. i also fix planes. i also fix them. i also fix
message: sounds cool.
response: i also fix airplanes. i also fix airplanes. i also fix them. i also fix them.

Table 9: Response generated by the TransferTransfo model where it is fine-tuned by only the persona-consistency sub-reward ($R = R_1$).

Table 9 illustrates an example dialogue that is conducted with an agent trained with only the persona consistency sub-reward ($R = R_1$). The agent always repeats, *"i fix airplanes. i fix them."*, no matter what the input message is about. This problem not only produces topically irrelevant responses but also makes the agent look nagging and self-centered in a conversation.

Persona

fact 1: i like hunting.
...

Dialogue

message: hi how are you doing?
response: hunting hunting hunting hunting hunting hunting
message: do you have any hobbies?
response: hunting hunting hunting hunting hunting hunting

Table 10: Another example dialogue with an agent that is trained by only the persona-consistency sub-reward ($R = R_1$).

Table 10 illustrates another example dialogue with the agent where it is trained only by persona-consistency sub-reward. The agent keeps repeating *"hunting"* from the persona to maximize its reward. The NLI model used for R_1 evaluates the inference relation between a response and a persona and does not capture the topical coherence of the response with its former utterance and language fluency of the response. It is therefore necessary to use R_1 in combination with topical coherence (R_2) and language fluency sub-rewards (R_3 and R_4), as we propose in our reward function.

B Weight Optimization and Reward Ablation

We examine various weight sets $(\gamma_1, \gamma_2, \gamma_3, \gamma_4)$ to balance the contribution of sub-rewards in the complete reward function on the held out set (10% of the PersonaChat training set). Table 11 shows those weights. The balanced weights give the highest F1 score, suggesting that a combination of sub-rewards leads to responses that are more similar to the human responses.

0.00	0.00	1.00	0.00	12.77	**04.76**	12.21	00.46	**99.35**	00.20	51.49
0.00	0.00	0.00	1.00	17.91	21.35	**01.62**	03.53	95.90	00.57	50.13
0.40	0.16	0.22	0.22	**20.75**	12.36	09.61	14.14	84.54	01.32	56.50

Table 12: Performance metrics on our validation set (10% of the PersonaChat training set) when training is performed with each individual sub-reward and our chosen weighted sum of sub-rewards.

the persona facts, $\gamma_3 = 1$ minimizes perplexity, and $\gamma_4 = 1$ gives lowest repetition. Besides F1 score, the balanced weights give good performance across perplexity, repetition, and persona consistency. The setups with fewer neutral responses also tend to have more responses that contradict the persona facts, e.g., for $\gamma_1 = 1$. Neutral responses are a trivial way to avoid contradictory responses and the setup with the least contradictions, $\gamma_3 = 1$, has almost no responses that are consistent with the persona facts. The better overall persona consistency is reflected in the highest PC score for $\gamma_1 = 1$ and next highest for the balanced weights, which trades of PC for less repetition, lower perplexity and a higher F1 score.

C REINFORCE vs Actor-Critic

Figures 2 and 3 show the trend of changes in our reward function during training by REINFORCE and Actor-Critic, respectively. All parameters are the same for the two experiments. We observe that the actor-critic approach converges faster and also is less noisy (has a lower variance) than REINFORCE.

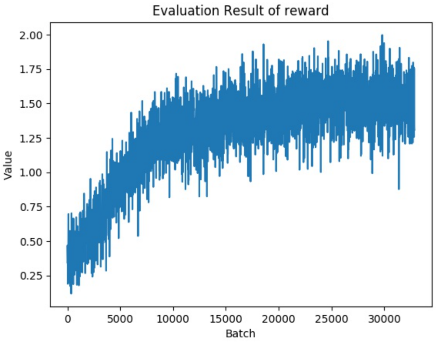

Figure 2: The reward curve during training by REINFORCE.

D Human Evaluation

For each sample, we show to each participant a set of persona facts, a dialogue history, and the response generated by one of TransferTransfo-SL and TransferTransfo-RL. We instruct our participants to assess semantic plausibility according to the following objective definition: *"grammatical correctness, lowest repetitiveness, and coherence"*. The plausibility rates are integer values between 1 and 5, where 5 is most plausible.

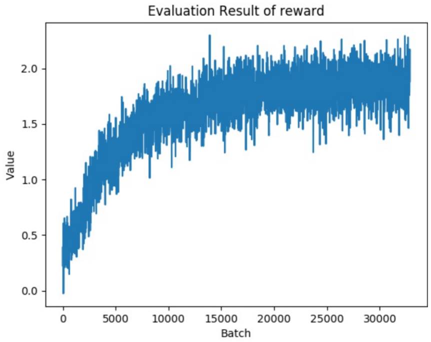

Figure 3: The reward curve during training by Actor-Critic.

To measure persona consistency, we instruct participants as follows:

An answer is considered consistent if:

- It contradicts with neither the dialogue history nor the persona facts;
- It is relevant to any of the given persona facts.

An answer is considered neutral if:

- It contradicts with neither the dialogue history nor the persona facts;
- It is **not** relevant to any of the given persona facts.

E Human Evaluation: Confusion Matrix

Table 13 presents the distributions of consistency labels for TransferTransfo-RL's responses given the consistency labels for TransferTransfo-SL's responses. For the majority of cases whose

		TransferTransfo-RL label		
		Consistent	Neutral	Contradicting
Transfer	Consistent	57.46	27.73	14.82
Transfo	Neutral	46.87	44.99	08.14
-SL	Contradicting	52.48	22.05	25.47

Table 13: Each row corresponds to the cases in the human evaluation for which TransferTransfo-SL received a particular consistency label. The values in each row show the percentages of consistency labels for TransferTransfo-RL for the same data points.

TransferTransfo-SL's responses are contradictory or neutral, TransferTransfo-RL generates consistent responses, showing improved factual consistency with persona facts. However, TransferTransfo-RL generates contradictory responses for some cases whose TransferTransfo-SL responses are consistent with their personas. This may be due to errors in the NLI model's predictions of entailment, hence a more accurate NLI model may improve the quality of the reward function and consequently the consistency of responses. Alternatively, these contradictory responses may receive high rewards from the topic consistency and fluency sub-rewards, which could override R_1.

PolyLM: Learning about Polysemy through Language Modeling

Abstract

To avoid the "meaning conflation deficiency" of word embeddings, a number of models have aimed to embed individual word *senses*. These methods at one time performed well on tasks such as word sense induction (WSI), but they have since been overtaken by task-specific techniques which exploit contextualized embeddings. However, sense embeddings and contextualization need not be mutually exclusive. We introduce PolyLM, a method which formulates the task of learning sense embeddings as a language modeling problem, allowing contextualization techniques to be applied. PolyLM is based on two underlying assumptions about word senses: firstly, that the probability of a word occurring in a given context is equal to the sum of the probabilities of its individual senses occurring; and secondly, that for a given occurrence of a word, one of its senses tends to be much more plausible in the context than the others. We evaluate PolyLM on WSI, showing that it performs considerably better than previous sense embedding techniques, and matches the current state-of-the-art specialized WSI method despite having six times fewer parameters. Code and pre-trained models are available at `https://github.com/AlanAnsell/PolyLM`.

1 Introduction

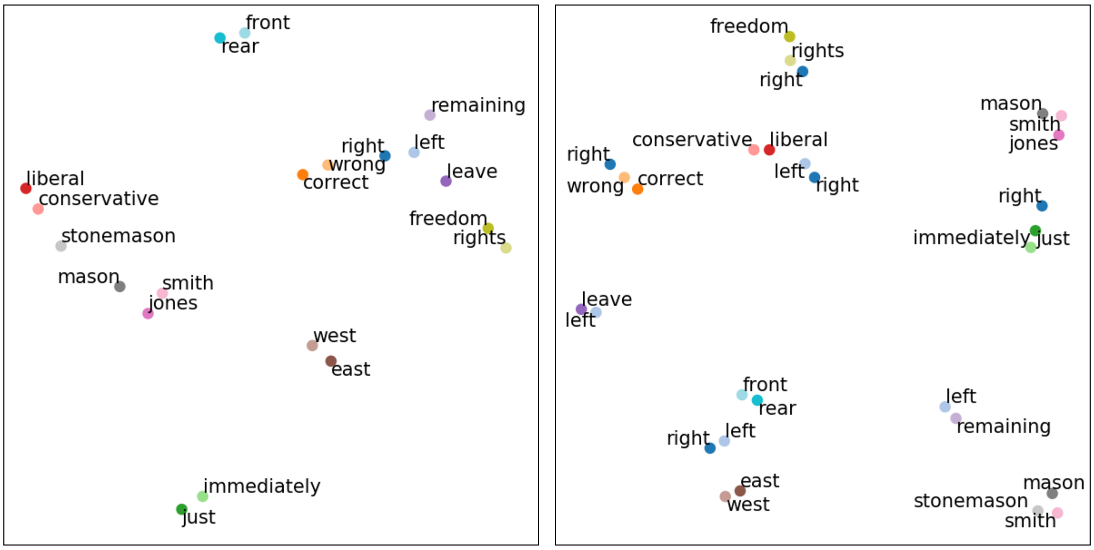
Much work in NLP has been dedicated to vector representations of words, but it has been recognized since as early as (Schütze, 1998) that such representations fail to capture the polysemous nature of many words, conflating their multiple senses into a single point in semantic space. There have been several attempts at embedding individual word senses to avoid this issue, termed the "meaning conflation deficiency" by Camacho-Collados and Pilehvar (2018) in their survey on the area.

We propose PolyLM, an unsupervised sense embedding model which is effective and easy to apply to downstream tasks. PolyLM can be thought of as both a (masked) language model and a *sense* model, as it calculates a probability distribution both over words and word senses at masked positions. The formulation is derived from two observations about word senses: firstly, that the probability of a word occurring in a given context is equal to the sum of the probabilities of its individual senses occurring; and secondly, that for a given occurrence of a word, one of its senses tends to be much more plausible in the context than the others.

There are several reasons for the interest in sense representations. The first is the downsides associated with the meaning conflation deficiency. Word embedding models can have difficulty distinguishing which sense of an ambiguous word applies in a given context (Yaghoobzadeh and Schütze, 2016). Additionally, homonymy and polysemy cause distortion in word embeddings: for instance, we would find the unrelated words *left* and *wrong* unreasonably close in the vector space due to their similarity to two different senses of the word *right*, an effect noted by Neelakantan et al. (2014) and illustrated in Figure 1. Intuitively we would expect that sense embedding models could gain superior semantic understanding by avoiding these problems.

In addition to well-established applications for sense representations such as word sense disambiguation (WSD) and induction (WSI), another interesting use case is the automatic construction of lexical resources (Neale, 2018). While there are existing human-curated word sense inventories for English such as such as WordNet (Miller, 1995), these are expensive to create and are unavailable for most languages. Panchenko (2016) showed that sense embeddings learned using the model of Bartunov et al. (2016) could be linked with word senses contained in BabelNet (Navigli and Ponzetto, 2012) with a reasonable degree of precision, although the mapping struggled with recall. PolyLM represents a significant advance over Bartunov et al.'s in terms of WSI performance, so

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 563–574
April 19 - 23, 2021.



(a) Word embeddings

(b) Sense embeddings

Figure 1: An illustration of the meaning conflation deficiency, showing selected word and sense embeddings learned by PolyLM visualized using t-SNE (Maaten and Hinton, 2008) and adjustText (Flyamer, 2017). Sense embeddings were learned by training PolyLM$_{\text{SMALL}}$ with the standard 8 senses per word; word embeddings were learned by training PolyLM$_{\text{SMALL}}$, but with a single sense per word. Note that both models were trained on unlemmatized data, unlike those used in the WSI experiments. The occurrence of closely related polysemous words nearby in the word embedding space (i.e. *left* and *right*) causes unrelated words to be closer together (e.g. *left* and *wrong*) and related words to be further apart (e.g. *right* and *east*) than they otherwise would be. The use of sense embeddings avoids such distortion. PolyLM is capable of detecting comparatively rare word senses, such as the political senses of *left* and *right*, and the use of *smith* and *mason* to refer to tradespeople.

it seems reasonable to imagine that this approach to lexical resource construction might now be more feasible.

The emergence of contextualized models such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019) has had a tremendous impact on the area of semantic representation. Rather than representing words using a single embedding, or even a set of sense embeddings, these models allow words to be represented using an infinite set of possible embeddings depending on the context. This approach has been very effective across NLP and many state-of-the-art systems incorporate contextualized models, including systems for WSD and WSI. The success of contextualized models raises the question of whether there is still value in learning discrete sense representations.

However, contextualized models still rely on word embeddings, and are therefore subject to the meaning conflation deficiency. Furthermore it could be argued that it is inefficient to have the same representation size for all words regardless of how diverse their range of senses is. Another drawback is that before they can be applied to word sense-related tasks, an adaptation step such as clustering to induce discrete senses or fine-tuning is generally required, which is often expensive in terms of both research and compute time.

The contributions of this paper can be summarized as follows:

- We propose PolyLM, an end-to-end, unsupervised neural sense embedding model derived from two simple assumptions about word senses. We demonstrate that PolyLM learns senses which correspond well to human notions by showing that it performs well at WSI.
- PolyLM is flexible in that it can use any "contextualizer" (a useful term coined by Liu et al. (2019)), so it will remain relevant as contextualization techniques improve.
- We reduce the effect of the meaning conflation deficiency by disambiguating word senses at the input with a neural "disambiguation layer." We show that good performance on WSI can be achieved using the output of this layer alone, suggesting that it could be a useful component in many neural networks for language understanding.

2 Related Work

One of the first works in unsupervised learning of sense representations was by Schütze (1998), who proposed a two-step process, where vector representations are first derived for each context containing an ambiguous word, and these are then clustered into a pre-defined number of groups. Huang et al. (2012) added a third step, where after sense-labeling each word according to its context cluster, sense representations are learned through neural language modeling.

A number of later approaches employed a joint training approach, where sense labeling and sense representation learning happen in parallel. Neelakantan et al. (2014), Li and Jurafsky (2015) and Bartunov et al. (2016) each proposed multi-sense variants of the Skip-Gram model (Mikolov et al., 2013). Various approaches were tried for determining the number of senses per word: for instance, Li and Jurafsky and Bartunov et al. used Chinese Restaurant Processes and Dirichlet Processes respectively to automatically learn an appropriate number of senses for each word.

Many joint training approaches have the disadvantage that they create ambiguity in the context representation by representing context words with word embeddings in order to avoid considering the exponential number of possible sense labelings for the context. Qiu et al. (2016) and Lee and Chen (2017) propose purely sense-based approaches which can sense-label the input efficiently.

Arora et al. (2018) took a novel approach to the problem of learning word senses, demonstrating that the embedding learned by traditional techniques for an ambiguous word tends to be very close to a linear combination of the hypothetical vectors corresponding to its individual senses. They proposed a method for recovering the underlying sense vectors and coefficients, and evaluated their system on WSI.

Since the emergence of contextualized models, there have been a number of other systems which have exploited their powerful semantic representations for specific tasks such as word sense disambiguation (Huang et al., 2019; Vial et al., 2019) and induction (Amrami and Goldberg, 2018, 2019), however none of these methods creates explicit sense embeddings.

3 PolyLM

3.1 Overview

Consider a typical neural language model. Each word w in a vocabulary V is assigned a single embedding, resulting in an embedding matrix $M \in \mathbb{R}^{|V|\times d}$, where d is the embedding dimensionality. The probability of w occurring in a context c is estimated as

$$\mathbb{P}(w \mid c) = \big[\text{softmax}\big(M\boldsymbol{y}(c) + \boldsymbol{a}\big)\big]_w, \quad (1)$$

where $\boldsymbol{y}(c) \in \mathbb{R}^d$ is a vector representation of c and $\boldsymbol{a} \in \mathbb{R}^{|V|}$ is a trainable bias vector. In BERT (Devlin et al., 2019) for instance, $\boldsymbol{y}(c)$ corresponds to the final output of multiple Transformer encoder layers (Vaswani et al., 2017).

Now suppose that for each $w \in V$, there is a corresponding set S_w of *sememes*, or senses which w can have. For instance, intuitively we might have $S_{\text{rock}} = \{\text{rock:stone, rock:musical genre, rock:shake}\}$. We assume that the S_w are disjoint, i.e. $S_w \cap S_{w'} = \emptyset$ whenever $w \neq w'$, and we define the full sense inventory $S = \bigcup_{w\in V} S_w$.

Context induces specific senses for the words it contains. Thus a passage of text can be thought of as a sequence of sememes as well as a sequence of words. The first observation underlying PolyLM is that the probability of a word w occurring in a context c is equal to the sum of the probabilities of w's component sememes occurring in the context, i.e.

$$\mathbb{P}(w \mid c) = \sum_{s\in S_w} \mathbb{P}(s \mid c). \quad (2)$$

We wish to learn representations for individual senses, and so we assign an embedding to each sememe in our sense inventory, resulting in a matrix E with dimension $|S| \times d$ and bias vector $\boldsymbol{b}$ of dimension $|S|$. Note that this assumes that we know the number of senses of each word *a priori*, an assumption whose consequences we discuss later. Following Eq. 1, we define the vector $\boldsymbol{p}(c) \in \mathbb{R}^{|S|}$ of sememe probabilities in a context c as

$$\boldsymbol{p}(c) = \text{softmax}\big(E\boldsymbol{x}(c) + \boldsymbol{b}\big). \quad (3)$$

Considering Eq. 2, we have

$$\mathbb{P}(w \mid c) = \sum_{s\in S_w} p(c)_s, \quad (4)$$

allowing us to formulate the problem of learning sense representations with a language modeling objective.

PolyLM is constructed from three components: the input layer, which represents the input tokens as aggregates of their sense embeddings, the disambiguation layer, which attempts to determine the contextually appropriate sense embeddings for the input, and the prediction layer, which implements the language modeling objective.

We adopt the masked language modeling (MLM) task used for training BERT. When training, we select a subset $T \subset \{1, 2, ..., n\}$ of the tokens in the input sequence as targets for prediction, and produce a masked version $c' = w'_1, w'_2, ..., w'_n$ of the original sequence $c = w_1, w_2, ..., w_n$ as follows: 15% of tokens are chosen at random as targets, of which 80% are replaced with a special [MASK] token, 10% are replaced with a random token, and 10% are left unchanged.

3.2 Input Layer

We define a contextualizer to be a function which maps a sequence of input representations $\boldsymbol{x}_1, \boldsymbol{x}_2, ..., \boldsymbol{x}_n \in \mathbb{R}^d$ to a corresponding sequence of output representations $\boldsymbol{y}_1, \boldsymbol{y}_2, ..., \boldsymbol{y}_n \in \mathbb{R}^d$. Recurrent Neural Networks and Transformer architectures are both commonly used as contextualizers for language modeling. Typically the input representations are drawn from an embedding matrix $I \in \mathbb{R}^{|V| \times d}$. It has become common (e.g. BERT) to set I equal to O, the embedding matrix used at the language modeling output, as recommended by Press and Wolf (2017), and thus have a single embedding matrix E.

The issue of input representation poses a problem for our model. Our output embeddings $E \in \mathbb{R}^{|S| \times d}$ correspond to sememes. We cannot straightforwardly tie our input and output embeddings as Press and Wolf suggest, because we receive words rather than sememes as input. We solve this problem by setting the input representation of a word to be a convex combination of the representations of its sememes, i.e.

$$\boldsymbol{x}(w) = \sum_{s \in S_w} \lambda_{ws} \boldsymbol{e}_s, \qquad (5)$$

where $\boldsymbol{e}_s$ is the row of E corresponding to sememe s, and $\boldsymbol{\lambda}_w$ is a learnable weight vector with the properties that $\sum_{s \in S_w} \lambda_{ws} = 1$ and $\boldsymbol{\lambda}_w \geq \boldsymbol{0}$ (in practice, $\boldsymbol{\lambda}_w$ is the softmax of an underlying, unconstrained variable vector).

3.3 Disambiguation Layer

The disambiguation layer attempts to infer the contextually appropriate sememe embeddings for the input based on the conflated representations from the input layer.

Representations $\boldsymbol{x}(w'_1), \boldsymbol{x}(w'_2), ..., \boldsymbol{x}(w'_n)$ of c', calculated according to Eq. 5, are fed into a contextualizer instance C^D, which outputs representations $\boldsymbol{y}_1^D(c'), \boldsymbol{y}_2^D(c'), ..., \boldsymbol{y}_n^D(c')$. We use these representations to calculate a probability distribution over each sense of the tokens in the input:

$$\boldsymbol{q}_i^D(c') = \text{softmax}\big(E^{(w'_i)} \boldsymbol{y}_i^D(c') + \boldsymbol{b}^{(w'_i)}\big), \qquad (6)$$

where $E^{(w'_i)}$ is a submatrix of E containing only the rows corresponding to senses of token w'_i, and similarly $\boldsymbol{b}^{(w'_i)}$ is a subvector of a learnable bias vector $\boldsymbol{b} \in \mathbb{R}^{|S|}$. In other terms,

$$q_{is}^D(c') = \frac{e^{\boldsymbol{e}_s^\top \boldsymbol{y}_i^D(c') + b_s}}{\sum_{s' \in S_{w'_i}} e^{\boldsymbol{e}_{s'}^\top \boldsymbol{y}_i^D(c') + b_{s'}}}, \qquad (7)$$

where $s \in S_{w'_i}$. $q_{is}^D(c')$ corresponds to the probability that the ith token in sequence c' has sense s.

The disambiguated representation of a token could simply be its highest-probability sememe embedding in the context, but to allow gradients to flow through the disambiguation layer, we take the sum of the sememe embeddings weighted by their probabilities:

$$\boldsymbol{x}_i^P(c') = \sum_{s \in S_{w'_i}} q_{is}^D(c') \boldsymbol{e}_s. \qquad (8)$$

3.4 Prediction Layer

The prediction layer maps a sequence of disambiguated input representations onto a corresponding set of output representations, and from each output representation estimates the probability of every sememe in the sense inventory occurring at the corresponding position of the sequence.

Disambiguated representations $\boldsymbol{x}_1^P(c'), \boldsymbol{x}_2^P(c'), ..., \boldsymbol{x}_n^P(c')$ are fed into another contextualizer instance C^P, which returns output representations $\boldsymbol{y}_1^P(c'), \boldsymbol{y}_2^P(c'), ..., \boldsymbol{y}_n^P(c')$. These are used to calculate a probability distribution over the entire sense inventory, as prescribed by Eq. 3:

$$\boldsymbol{p}_i(c') = \text{softmax}(E \boldsymbol{y}_i^P(c') + \boldsymbol{b}). \qquad (9)$$

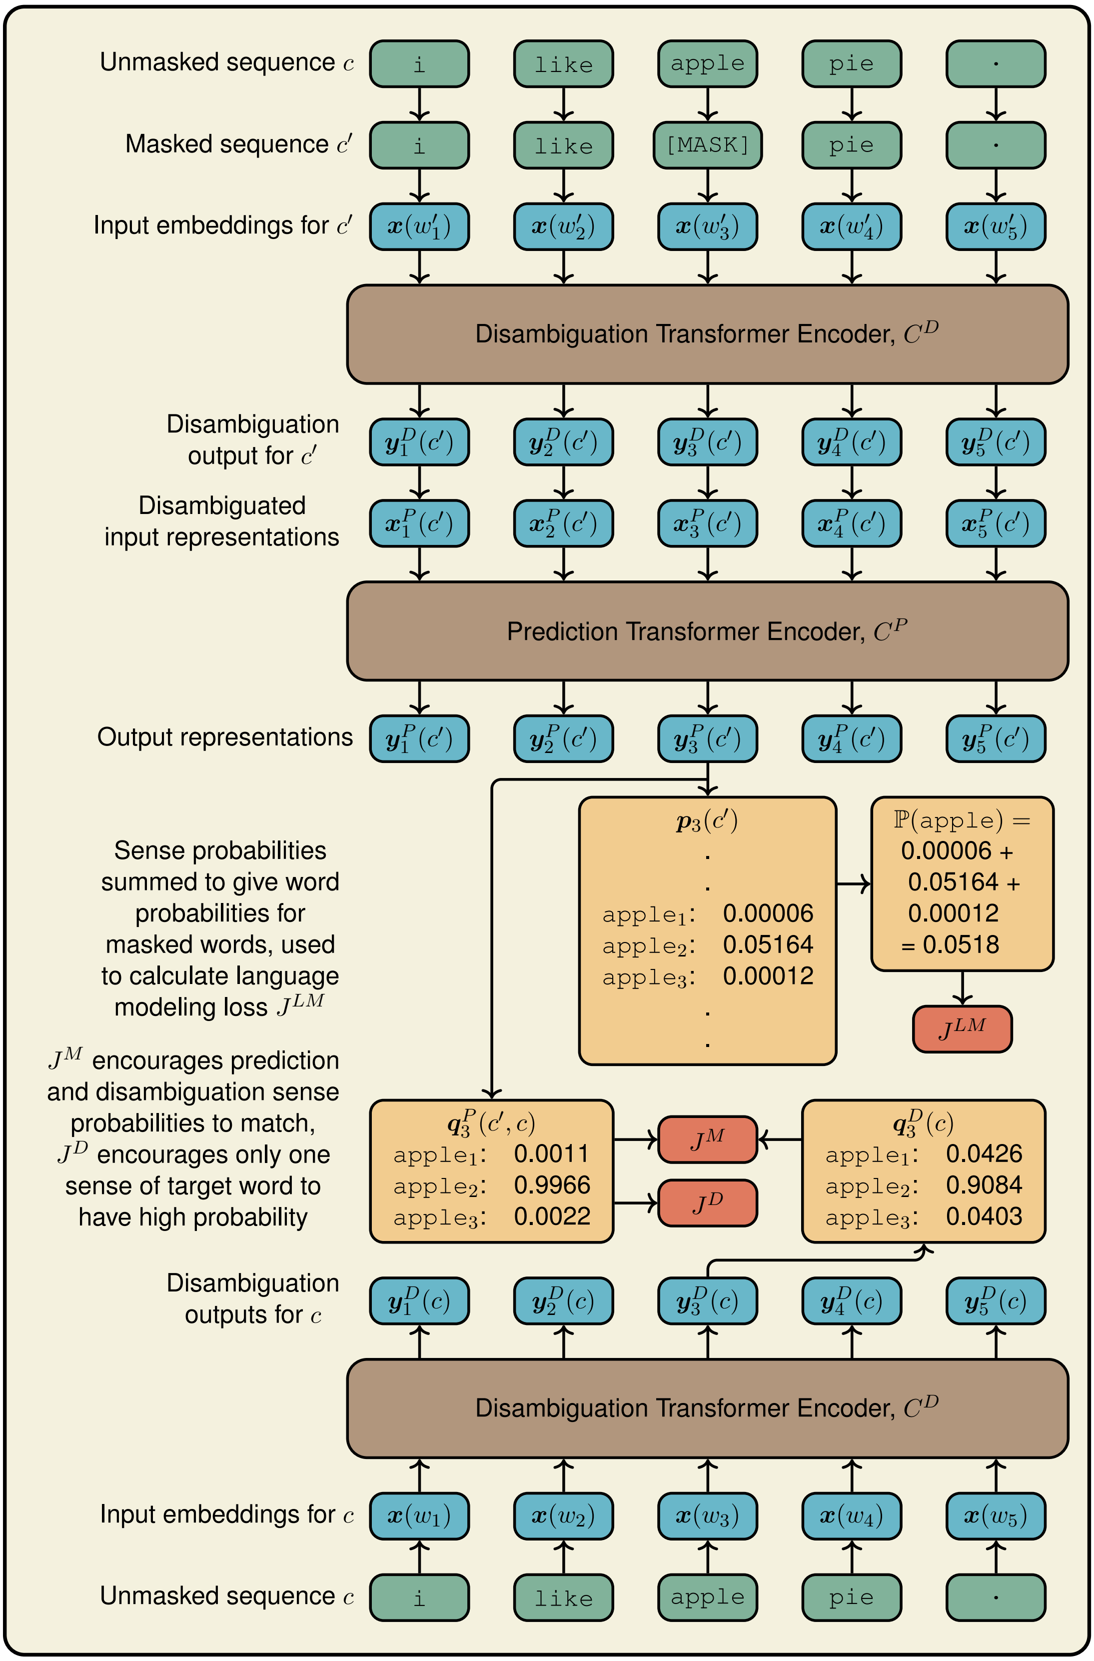


Figure 2: Architecture diagram for PolyLM when training, illustrated on the sentence “I like apple pie.”, where the word “apple” is chosen as a target and masked (note that “apple” is ambiguous when tokens are lower-cased, as it may refer to a fruit or a technology company). At inference time, the bottom components (up to and including $\boldsymbol{q}^D(c)$) do not need to be evaluated, and the sequence may not be masked at the input.

We define an additional set of probabilities $\boldsymbol{q}^P$ analogous to $\boldsymbol{q}^D$ defined in Eq. 6:

$$\boldsymbol{q}_i^P(c', c) = \operatorname{softmax}\big(E^{(w_i)}\boldsymbol{y}_i^P(c') + \boldsymbol{b}^{(w_i)}\big). \tag{10}$$

$\boldsymbol{q}_i^P$ takes both c' and the unmasked sequence c as arguments because we are interested in the sense probabilities of the words w_i that actually occurred. $\boldsymbol{q}_i^P$ will be used later for defining the loss function and is useful for downstream tasks.

3.5 Loss Function

We seek to minimize a loss function J with three components, each of which is explained below:

$$\begin{aligned} J(c, c', T) = J^{LM}(c, c', T) &+ \\ J^D(c, c', T) &+ \\ J^M(c, c', T)& \end{aligned} \tag{11}$$

3.5.1 Language Modeling Loss

The language modeling loss J^{LM} is defined as the mean negative log likelihood of the target tokens occurring:

$$\begin{aligned} &J^{LM}(c, c', T) \\ &= \frac{-1}{|T|}\sum_{i\in T}\log\hat{\mathbb{P}}(w_i \mid c') \qquad (12) \\ &= \frac{-1}{|T|}\sum_{i\in T}\log\sum_{s\in S_{w_i}}\hat{\mathbb{P}}(\text{sememe } i \text{ is } s \mid c') \qquad (13) \\ &= \frac{-1}{|T|}\sum_{i\in T}\log\sum_{s\in S_{w_i}}p_{is}(c'), \qquad (14) \end{aligned}$$

where $\boldsymbol{p}_i$ is as defined in Eq. 9.

3.5.2 Distinctness Loss

Recall that we assume in advance a number of senses for each word. In practice we guess a relatively high number to avoid missing senses. When we overestimate the number of senses, we find that two different sense embeddings for a word converge to essentially the same meaning. The aim of the distinctness loss is to ensure that each sense has a distinct meaning, and to "kill off" superfluous senses by causing them to have very low probability in all contexts.

The second key observation of PolyLM is that if the sememes corresponding to a word w are distinct, then in contexts where w occurs, we would expect one of these sememes to have a high estimated probability of occurring, and the rest to have a low probability. The distinctness loss, given by,

$$J^D(c, c', T) = \frac{-1}{r|T|}\sum_{i\in T}\log\sum_{s\in S_{w_i}}\big(q_{is}^P(c', c)\big)^r, \tag{15}$$

with hyperparameter $r > 1$, encourages this separation to occur. A full justification is given in Appendix A.

3.5.3 Match Loss

Without extra supervision, the disambiguation layer tends to very quickly allocate almost all of the probability mass for a word to a single one of its senses. This appears to be due to a "rich get richer" effect in Eq. 8, where the sense embedding with the highest weight has larger gradients associated with it.

A more reliable source of sense probabilities is the output of the prediction layer, as this is more closely associated with the ground truth. Therefore we encourage the disambiguation sense probabilities $\boldsymbol{q}^D$ to be similar to the prediction sense probabilities $\boldsymbol{q}^P$ by adding a sense probability "match loss," which is proportional to the cosine similarity between $\boldsymbol{q}^D$ and $\boldsymbol{q}^P$.

Because $\boldsymbol{q}_i^D(c')$ is meaningless when token i is replaced with [MASK], when calculating the match loss we evaluate the disambiguation layer on the unmasked sequence (shown with bottom-up arrows in Figure 2), obtaining $\boldsymbol{q}_i^D(c)$. The match loss is defined as

$$J^M(c, c', T) = \frac{-\lambda^M}{|T|}\sum_{i\in T}\frac{\boldsymbol{q}_i^D \cdot \boldsymbol{q}_i^P}{\|\boldsymbol{q}_i^D\|\|\boldsymbol{q}_i^P\|}, \tag{16}$$

where $\boldsymbol{q}_i^D$ and $\boldsymbol{q}_i^P$ are shorthand for $\boldsymbol{q}_i^D(c)$ and $\boldsymbol{q}_i^P(c', c)$ respectively, and λ^M is a hyperparameter.

As we wish the disambiguation layer to learn from the prediction layer rather than the other way around, we do not allow gradients from the match loss to propagate through $\boldsymbol{q}_i^P$.

3.6 Details and Parameters

3.6.1 Preprocessing

To avoid the issue of how to represent a word's sense when it is broken into sub-word level tokens, our vocabulary consists of whole-word tokens. However the WSI tasks on which we evaluate our model operate on the lemma level, so we lemmatize our training corpus as described in Appendix B. The vocabulary consists of the ~86K tokens appearing more than 500 times in our training corpus, which like BERT's consists of English Wikipedia + BookCorpus (Zhu et al., 2015). All tokens are lower-cased.

3.6.2 Contextualizers

One of the advantages of PolyLM is that it can be used with any type of contextualizer - note however that we must train our contextualizers together with the rest of the model rather than using pretrained contextualizer instances, because their word embedding matrix would not match our sense embedding matrix. In this paper we present results where the disambiguation and prediction contextualizers C^D and C^P use BERT's implementation of the Transformer encoder architecture.

3.6.3 Parameters

To keep the total number of embeddings reasonable, we allow only the ~10,000 tokens which occur more than 20,000 times in the training corpus, or appear as focuses in the evaluation datasets, to have multiple senses. Specifically, we assign these tokens a fixed number of $k = 8$ embeddings, and other tokens a single embedding. Since according to Zipf's law (Zipf, 1950), it is the most frequent words which tend to have the most senses, we expect not to miss too many senses by assuming that infrequent words are monosemous. We leave the investigation of more sophisticated methods for pre-allocating or dynamically updating the number of senses for each token for future work.

We train two PolyLM models of different sizes, PolyLM$_{\text{SMALL}}$ and PolyLM$_{\text{BASE}}$. Due to the prohibitive computational cost of training a model of BERT$_{\text{LARGE}}$'s size, we use significantly smaller dimensions, as shown in Table 1.

Models were trained over 6,000,000 batches consisting of 32 sequences of length 128 using the Adam optimizer (Kingma and Ba, 2014). The learning rate was increased linearly from 0 to 3e-5 over the first 10,000 batches, and then reduced linearly back to zero over the remaining batches. The hyperparameters λ^M and r specific to PolyLM's loss function were first increased linearly and then left constant, λ^M from 0 to 0.1 over the first 1,000,000 batches, and r from 1.0 to 1.5 over the first 2,000,000 batches.

It is important for r to be gradually increased in this manner because if r is large initially, then the effect of the distinctness loss reduces the diversity of the senses learned. On the other hand, increasing r too slowly seems to be detrimental to the senses' distinctness.

4 Experiments

Word sense induction (WSI) is the task of inferring the senses of a word in an unsupervised manner. This is precisely the aim of our method, and so is an ideal test task. We evaluate PolyLM on two WSI datasets, SemEval-2010 Task 14 (Manandhar et al., 2010) and SemEval-2013 Task 13 (Jurgens and Klapaftis, 2013). Both datasets consist of passages containing one of a set of polysemous focus words. The occurrences of the focus words in the test set have been sense-labeled by human annotators according to a reference sense inventory.

In the SemEval-2010 dataset, each instance is labeled with a single sense, whereas in the SemEval-2013 dataset an instance may be labeled with several relevant senses, each with a corresponding weight denoting its degree of applicability in the context.

Performance on SemEval-2010 is measured using paired F-Score (F-S) and V-Measure (V-M), and on SemEval-2013 using Fuzzy B-Cubed (FBC) and Fuzzy Normalized Mutual Information (FNMI). Overall performance on each task (**AVG**) is typically defined as the geometric mean of its two sub-metrics.

Currently, the best performing system on both datasets is that of Amrami and Goldberg (2019). Their system uses the idea of *substitute vectors*, first devised by Başkaya et al. (2013). For each instance, a set of most likely words that could have occurred instead of the focus word is obtained from the output of a language model. These sets are then clustered, and each cluster is taken to correspond to a different sense of the focus word. Amrami and Goldberg use BERT$_{\text{LARGE}}$ as their language model.

PolyLM can be used for WSI without any further training. For the SemEval-2010 dataset, each instance c is labeled with the sense of the focus word w_i which has the highest predicted probability, i.e. $\text{argmax}_{s \in S_{w_i}} \boldsymbol{q}^P_{is}(c', c)$, where c' is formed from c by replacing w_i with [MASK]. For SemEval-2013, we consider a sense applicable if it has a predicted probability $q^P_{is}(c', c) > p^{\text{thresh}}$, and the weight assigned to each applicable sense is its probability $q^P_{is}(c', c)$. We arbitrarily set p^{thresh} to 0.2.

Model	d	**Filter size**	**No. attn. heads**	**No. layers**	**Seq. len.**	**Vocab size**	**No. embeddings**	**Total params**
PolyLM$_{\text{SMALL}}$	128	512	8	4 (C^D), 8 (C^P)	128	86K	157K	24M
PolyLM$_{\text{BASE}}$	256	1024	8	4 (C^D), 12 (C^P)	128	86K	157K	54M
BERT$_{\text{LARGE}}$	1024	4096	16	24	512	30K	30K	340M

Disambiguation layer only	63.6	29.3	43.2	62.7	15.7	31.4

Table 3: PolyLM ablation study.

Results are shown in Table 2. Both PolyLM models comprehensively outperform previous sense embedding methods. PolyLM$_{\text{BASE}}$ and Amrami and Goldberg's system slightly outperform each other on one dataset each, suggesting similar overall proficiency at WSI. However it is worth noting that the BERT$_{\text{LARGE}}$ language model used by Amrami and Goldberg has more than six times as many parameters as PolyLM$_{\text{BASE}}$ and is much more computationally expensive to train and run.

PolyLM scales well for the sizes tested, with PolyLM$_{\text{BASE}}$ outperforming PolyLM$_{\text{SMALL}}$ by 3.2 and 4.1 points in **AVG** score on the two datasets with a 2.25x increase in the number of parameters. Even if further increases in model dimensions yielded much smaller improvements in performance, it seems likely that a PolyLM model of BERT$_{\text{LARGE}}$'s 340 million parameter size would achieve results significantly better than those of Amrami and Goldberg (2019).

4.1 Ablation Study

We test three alternative configurations against PolyLM$_{\text{SMALL}}$: one where the distinctness loss term is removed from the objective ("no distinctness loss"), one where the disambiguation layer is removed ("no disambiguation layer"), and one where the disambiguation sense probabilities $\boldsymbol{q}^D$ are used in place of $\boldsymbol{q}^P$ when performing WSI ("disambiguation layer only"). Note that the first two configurations require new models to be trained, whereas the last simply uses PolyLM$_{\text{SMALL}}$ in a different way. Results are shown in Table 3.

The use of the distinctness loss has a big impact on model performance, while the disambiguation layer is somewhat less important but still useful. The model still performs surprisingly well when the disambiguation rather than the prediction sense probabilities are used; these are the output of only four Transformer layers and hence are much cheaper to compute. This suggests that it might be practical to add the disambiguation layer at the input of various neural NLP models to improve their understanding of polysemy.

5 Conclusions

PolyLM is a novel model of polysemy based on two assumptions about word senses: firstly, that the probability of a word occurring in a context is equal to the sum of its individual senses occurring, as expressed by the language modeling loss; and secondly, that generally only one sense of a word ought to have a high probability of occurring in a given context, as expressed by the distinctness loss. PolyLM does indeed learn word senses which correspond well to human notions, as demonstrated by its performance on word sense induction, which matches that of the previous state-of-the-art system despite having 6 times fewer parameters. It can be easily applied to many word-sense related tasks, as it generates a probability distribution over the senses of each word in the input text. It is not specific to any one contextualizer and so can be improved as contextualizers improve.

A Justification of the Distinctness Loss

Consider the derivative of the language modeling loss for one particular target position $i \in T$ with respect to the pre-softmax scores $\boldsymbol{e}_k^\top \boldsymbol{y}_i^P + b_k$ of the target word w_i's sense embeddings $k \in S_{w_i}$. For brevity, we define $y_k = \boldsymbol{e}_k^\top \boldsymbol{y}_i^P + b_k$.

$$
\begin{aligned}
&-\frac{\partial}{\partial y_k} J^{LM}(c, c', \{i\}) \\
&= \frac{\partial}{\partial y_k} \log \sum_{s \in S_{w_i}} \left[\mathrm{softmax}(E\boldsymbol{y}_i^P + \boldsymbol{b})\right]_s \\
&= \frac{\partial}{\partial y_k} \log \sum_{s \in S_{w_i}} \frac{e^{y_s}}{\sum_{s' \in S} e^{y_{s'}}} \\
&= \frac{\partial}{\partial y_k} \log \frac{\sum_{s \in S_{w_i}} e^{y_s}}{\sum_{s \in S_{w_i}} e^{y_s} + \sum_{s \in S \setminus S_{w_i}} e^{y_s}} \\
&= \frac{\partial}{\partial y_k} \log \frac{\sum_{s \in S_{w_i}} e^{y_s}}{\sum_{s \in S_{w_i}} e^{y_s} + C},
\end{aligned}
$$

where $C = \sum_{s \in S \setminus S_{w_i}} e^{y_s}$,

$$
\begin{aligned}
&= \frac{\partial}{\partial y_k} \left(\log \sum_{s \in S_{w_i}} e^{y_s} - \log \left(\sum_{s \in S_{w_i}} e^{y_s} + C \right) \right) \\
&= \frac{\frac{\partial}{\partial y_k} \sum_{s \in S_{w_i}} e^{y_s}}{\sum_{s \in S_{w_i}} e^{y_s}} - \frac{\frac{\partial}{\partial y_k} (\sum_{s \in S_{w_i}} e^{y_s} + C)}{\sum_{s \in S_{w_i}} e^{y_s} + C} \\
&= \frac{e^{y_k}}{\sum_{s \in S_{w_i}} e^{y_s}} - \frac{e^{y_k}}{\sum_{s \in S_{w_i}} e^{y_s} + C} \\
&= \frac{e^{y_k}}{\sum_{s \in S_{w_i}} e^{y_s}} - \frac{e^{y_k}}{\sum_{s \in S} e^{y_s}} \\
&= q_{ik}^P(c', c) - p_{ik}(c).
\end{aligned}
$$

Since $q_{ik}^P > p_{ik}$, $\frac{\partial}{\partial y_k} J^{LM}(c, c', \{i\})$ will always be negative, meaning that every sense embedding for the target word will always move towards the contextualized representation $\boldsymbol{y}_i^P$. This is undesirable, because it means that even senses which are irrelevant in a context will receive a positive update.

Now consider the derivatives of the distinctness loss:

$$
\begin{aligned}
&-\frac{\partial}{\partial x_y} J^D(c, c', \{i\}) \\
&= \frac{\partial}{\partial y_k} \frac{1}{r} \log \sum_{s \in S_{w_i}} \left(q_{is}^P(c', c)\right)^r \\
&= \frac{1}{r} \frac{\partial}{\partial y_k} \log \sum_{s \in S_{w_i}} \left(\frac{e^{y_s}}{\sum_{s' \in S_{w_i}} e^{y_{s'}}} \right)^r \\
&= \frac{1}{r} \frac{\partial}{\partial y_k} \log \sum_{s \in S_{w_i}} \frac{e^{r y_s}}{(\sum_{s' \in S_{w_i}} e^{y_{s'}})^r} \\
&= \frac{1}{r} \frac{\partial}{\partial y_k} \log \frac{\sum_{s \in S_{w_i}} e^{r y_s}}{(\sum_{s \in S_{w_i}} e^{y_s})^r} \\
&= \frac{1}{r} \frac{\partial}{\partial y_k} \left(\log \sum_{s \in S_{w_i}} e^{r y_s} - \log \left(\sum_{s \in S_{w_i}} e^{y_s} \right)^r \right) \\
&= \frac{1}{r} \left(\frac{\frac{\partial}{\partial y_k} \sum_{s \in S_{w_i}} e^{r y_s}}{\sum_{s \in S_{w_i}} e^{r y_s}} - \frac{r \frac{\partial}{\partial y_k} \sum_{s \in S_{w_i}} e^{y_s}}{\sum_{s \in S_{w_i}} e^{y_s}} \right) \\
&= \frac{1}{r} \left(\frac{r e^{r y_k}}{\sum_{s \in S_{w_i}} e^{r y_s}} - \frac{r e^{y_k}}{\sum_{s \in S_{w_i}} e^{y_s}} \right) \\
&= \frac{e^{r y_k}}{\sum_{s \in S_{w_i}} e^{r y_s}} - q_{ik}^P(c', c).
\end{aligned}
$$

When $r > 1$, $\frac{e^{r y_k}}{\sum_{s \in S_{w_i}} e^{r y_s}}$ is a "sharpened" version of $q_{ik}^P(c', c)$: it is larger than q_{ik}^P when q_{ik}^P is large, and smaller when q_{ik}^P is small.

Now we have

$$
\begin{aligned}
&-\frac{\partial}{\partial y_k} \left(J^{LM}(c, c', \{i\}) + J^D(c, c', \{i\}) \right) \\
&= -\frac{\partial}{\partial y_k} J^{LM}(c, c', \{i\}) - \frac{\partial}{\partial y_k} J^D(c, c', \{i\}) \\
&= q_{ik}^P(c', c) - p_{ik}(c) + \frac{e^{r y_k}}{\sum_{s \in S_{w_i}} e^{r y_s}} - q_{ik}^P(c', c) \\
&= \frac{e^{r y_k}}{\sum_{s \in S_{w_i}} e^{r y_s}} - p_{ik}(c) \\
&= q_{ik}^{\text{sharp}}(c', c) - p_{ik}(c).
\end{aligned}
$$

Thus the addition of the distinctness loss results in even stronger reinforcement for senses which are highly applicable in the context, and even weaker (possibly negative) reinforcement for senses which are inapplicable. This encourages only one sense of a word to have high probability in a given context, as desired.

B Lemmatization

The training corpus and all text used for evaluation are lemmatized as follows: first, we perform part-of-speech (POS) tagging using Stanford CoreNLP's POS tagger (Manning et al., 2014). Any token with a tag associated with inflectional morphology in English (NNS, JJR, JJS, RBR, RBS, VBD, VBG, VBP, VBZ or VNB) is split into two separate tokens, its lemmatized form and a special token. There is a unique special token for each of the above tags except the pairs JJR and RBR (comparative adjectives and adverbs) and JJS and RBS (superlative adjective and adverbs), which share [COMP] and [SUP] tokens respectively.

Predicting Treatment Outcome from Patient Texts: The Case of Internet-Based Cognitive Behavioural Therapy

Abstract

We investigate the feasibility of applying standard text categorisation methods to patient text in order to predict treatment outcome in Internet-based cognitive behavioural therapy. The data set is unique in its detail and size for regular care for depression, social anxiety, and panic disorder. Our results indicate that there is a signal in the depression data, albeit a weak one. We also perform terminological and sentiment analysis, which confirm those results.

1 Introduction

The Internet Psychiatry Clinic in Stockholm offers Internet-based Cognitive Behavioral Therapy (ICBT) for depression, social anxiety, and panic disorder with documented significant treatment effects (Titov, 2018). The treatment is delivered on a secure online platform that enables patients to submit answers to weekly questionnaires of primary symptoms, depression, and suicidal ideation, as well as interactive worksheets. Because patients normally are not in contact with the psychologists away from keyboard during treatment, the infrastructure platform logs a large amount of data for each patient, yielding a unique data set. Because Sweden was the first country to introduce this kind of ICBT, the clinical experience is considerable (Hedman et al., 2012), and experimental research of the kind reported in this paper rests on well-established procedures for sensemaking of machine learning at the clinic (Boman and Sanches, 2015). The overarching problem is how to be able to offer accelerated care, via identification of those predicted not to succeed with treatment, or at least not with enough decrease in symptoms, and giving these people more attention, as early as possible.

We here investigate the possibility of predicting outcome based *only* on patient texts, in various points in treatment. We formulate this as a unimodal binary text categorisation problem, where the categories are simplified to either success or failure. In this initial feasibility study, we evaluate the performance of a number of text categorisation methods for predicting treatment outcome. Even if our methodology is mostly exploratory, we also relate terminological and sentiment analysis of patients' text to the treatment outcome.

2 Related work

NLP has previously been used for predicting the outcome of psychiatric treatment in a number of encouraging studies. Stylometric analysis on patients' texts from the data set under study indicates variation through time in the sentiment sign (positive or negative) in patient text messages (Boman et al., 2019). Althoff et al. (2016) suggest that more references to the future, references to other individuals, and positive conversation perspective are all positively related to the success of counseling conversations. Cohan et al. (2018) construct a

mental health-related corpus with Reddit posts and analyse users' language to identify self-reported diagnoses of nine different mental health conditions, including depression. Pestian et al. (2010) propose a classification model based on linguistic features, including part-of-speech tags and emotional concepts among others, that under some circumstances outperforms mental health professionals on identifying fake suicide notes. Gkotsis et al. (2016) study the usefulness of negation and affirmation in mental health records with the word *suicide* itself, while Song et al. (2020) identify statements related to suicidal behaviour in electronic health records, using a deep neural network. Trotzek et al. (2018) address the problem of early detection of depression using an ensemble of a Convolutional Neural Network and a classifier based on user-level linguistic metadata.

3 Data Set

The total data covers $6,821$ patients enrolled in a 12-week treatment for three different psychological disorders: Major Depressive Disorder (hereafter referred to as MDD, or depression), social anxiety, or panic disorder. Each treatment consists of weekly exercises, referred to as *homework reports*. For predicting treatment outcome, we focus on the depression treatment programme, which consists of 10 homework reports distributed over the 12 weeks. The homework contains questions about the progress made by the patient during treatment, such as "What is the most important thing you bring from module 1?" The questions can be both closed questions, where the patient selects pre-defined answers from a list, and open-ended questions, where the patient is invited to type in free text. The depression data covers $3,179$ patients. We remove patients who completed less than five homework reports (out of ten), patients without treatment outcome (who did not fill out the self-assessment at the end of the treatment), and empty texts. The resulting filtered data set contains $16,379$ texts from homework reports completed by $1,986$ patients. Each text is a concatenation of all answers written by a patient in one single weekly homework.

We also use patients' texts from the other treatments in order to enhance the domain pre-training for the embeddings. This data covers all $6,821$ patients participating in any of the three treatments, including $180,017$ free texts answers from the homework reports and $146,398$ direct messages, totalling almost 29 million $(28,993,089)$ tokens.

As target scores for predicting treatment outcome for the depression patients, we use the self-assessment MADRS-SR method (Fantino and Moore, 2009), which consists of ten questions scored between zero and six, and amounting to each patient having done between five and ten modules, yielding a total score from zero to 54. Therapists commonly use the cut-off score of 10 to partially define successful treatment. All diagnosed patients started the treatment above this score, and the treatment is defined as successful if the score drops below 10 at the end of the treatment (*remission*) (Hawley et al., 2002). When patients show a symptom reduction of at least 50%, this is defined as a *response*, and the treatment is also considered successful, even if the final score is above the cut-off value. In other cases, the treatment is considered a failure. Regarding the choice of 50% cut-off for the definition of the responder patients, it is supported by previous work (Karin et al., 2018), while the same value has been previously used by clinical researchers (Forsell et al., 2019). All patients are labelled as being subject to a treatment success or a treatment failure, as shown in Table 1.

Table 1: Patient labels in the prediction data set, based on the treatment outcome.

Outcome	Cases	Label	Total
Response	164	Success	1,075
Remission	111		
Response and remission	800		
No response, no remission	911	Failure	911

4 Methodology

We formulate the task of predicting outcome as a simple binary text classification problem, where the classes are either *success* or *failure*. Our goal is to assist clinicians in defining the best possible adaptive treatment strategy. Therefore, the class definitions used here are inherited from the treatment model employed at the clinic. We compare four different text representations: TF-IDF (Jones, 1972),[1] Word2Vec (Mikolov et al., 2013), FastText (Bojanowski et al., 2017), and Doc2Vec (Le and Mikolov, 2014), all of which are fed into a simple linear classifier trained with binary cross entropy loss using PyTorch.[2] All word embeddings are pro-

---

[1] `https://scikit-learn.org`

[2] `https://pytorch.org/`

duced with the Gensim implementation [3] and are pre-trained on patients' texts from all three treatments, as described in Section 3.

We use a naïve classification model that generates stratified predictions based on the class distributions as the baseline. The training set includes $1,588$ patients, with 860 labelled as success and 728 as failure, from the depression programme who have completed at least five weeks of homework reporting. All models are trained with 3-fold cross validation and early stopping, to avoid overfitting. After training, we evaluate each model on the test set, which consists of 398 patients (215 labelled as success and 183 as failure). Model performance is measured using the F1 score metric.

5 Results

The results from the classification experiment are presented in Table 2. The classification model based on TF-IDF consistently improves on the baseline, for all three values of the parameter #Homework reports. On the other hand, the models based on Word2Vec, FastText and Doc2Vec marginally reach this goal. Between all combinations of embeddings and number of homework reports considered, the TF-IDF model using one or three homework reports is the best performing model. Word2Vec exhibits better performance than FastText and Doc2Vec when the number of homework reports used is set to 3. Particularly remarkable is the relative F1 score difference between TF-IDF (number of homework reports equal to 1 or 3) and the rest of the models. This difference indicates the appropriateness of Bag-of-Words models in this experimental setup, compared to text representation methods that leverage semantic information. Interestingly, model performance does not always improve when more homework reports are considered. One possible explanation is that the resulting patient representation has less predictive power when more patient's text is considered, given the relatively small size of the training set. However, further research is necessary to confirm this.

Table 3 shows the test F1 score of the best performing model, which is TF-IDF, for each subgroup of the *success* class and all three values of the parameter #Homework reports. As defined in Section 3, the *success* class consists of patients that are *responders* or *remitters* or both *responders* and *remitters* (*responders+remitters*). It is observed that the F1 score calculated for the group of *remitters* is consistently lower than the ones achieved in the other two groups. This suggests that the model might benefit from a different classification setup, where *remitters* are considered as a separate class. Such analysis is left for future work.

As indicated by the classification results, simple lexical representations perform best in our experimental setup. A concrete follow-up question then becomes: Which vocabulary terms have a strong positive or negative correlation with the success class? To answer the question, we perform a linear regression analysis on the complete set of $1,986$ TF-IDF patient embeddings from our prediction data set, using the first three homework sets, and then compute the dot product between each word in the patient vocabulary and the regression coefficient. Vocabulary words with positive value of dot product contribute positively to the prediction of the success class and *vice versa*. Examples of terms with high positive or negative correlation with the success class are presented in Table 4.

There seems to be a vague relation between terminology and treatment outcome, which corroborates previous work by Althoff et al. (2016) that reports positive correlation between positively signed written language and successful counseling conversations. We therefore perform sentiment analysis on the complete list of homework reports written by $2,611$ depression patients, with at least one homework report completed. Since we are interested in the overall progression of sentiment in patients' answers, we are not constrained to include only patients with a specified number of homework reports completed. We train a Multinomial Naïve Bayes classifier for predicting the sentiment class (positive, neutral or negative) on the SenSALDO Swedish sentiment lexicon.[4] All words are represented with TF-IDF embeddings. The sentiment classifier is then used to identify the sentiment class of all words in the vocabulary, excluding stopwords and words with document frequency lower than 0.2. For each patient and concatenated set of homework reports, the number of word occurrences per sentiment class is calculated. We group the patients by the label outcome and compute the average relative frequency of the number of positive words divided by the number of negative words for each homework report and group. The progression of

the average relative frequency of words with positive sentiment throughout the homework reports is presented in Figure 1.

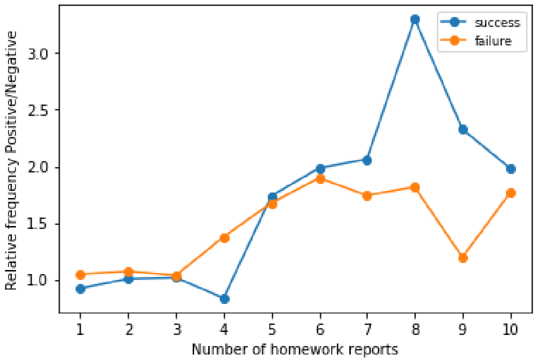

Figure 1: Average relative frequency of words with positive sentiment for all depression patients grouped by the outcome label.

Similar to (Althoff et al., 2016), we observe that more positive sentiment in the homework answers is related to successful treatment outcome. This reflects the treatment progress for patients that in the end are classified as successful. Specifically, homework report 8 had questions concerned with the overall opinion of the treatment, and the usefulness of the tools that the patients had been using. The large differences observed at homework report 8 confirm our intuition that patients showing substantial progress during the treatment, would evaluate its usefulness in more positive terms. Whereas the analysis presented in (Althoff et al., 2016) concerns open-ended counseling conversations, our data set contains patients' answers to targeted questions with positive or negative underlying sentiment. Two indicative questions are *"What's the most important thing you have learned from the past week?"* and *"Tell us about the activities you had planned for this week that you followed through. How was it?"*. The variation in sentiment in homework questions is reflected in the saturation of the relative frequency throughout the progression of homework reports.

6 Discussion

The results demonstrate that the task of predicting treatment outcome based on patient text is very difficult. It is interesting to note that embedding-based representations in some cases fail to perform better than random guessing, which we partly attribute to the comparably small amounts of training data for both domain adaptation and classification, and partly to the fact that such models tend to conflate paradigmatically similar terms, which in this application can signal very different treatment effects. This is demonstrated by terminological and sentiment analysis, which indicate a small but noticeable difference in vocabulary between successful and not successful patients. One hypothesis may be that antonyms are predictive of different outcomes, but have similar representations in the word embeddings, which makes it difficult for a simple linear classifier to separate them. The Bag of Words does not have this problem, which may be the reason it performs better in this specific application.

The selection of patients with a minimum predefined number of homework reports completed for the classification experiments serves the purpose of identifying the best prediction point in the home-

Positive words	forward, away, day, thoughts, initiative, act, wanted, feeling, together, energy, later
Negative words	sleep, rarely, unfortunately, sad, friend, rewarding, despite, life, walk, fill, different

Table 4: List of positively (up) and negatively (down) correlated words with the success class. Words have been translated to English from the original Swedish.

work completion task, but it also poses an important limitation: it reduces the variance in the outcome label. More specifically, success rate is expected to be higher among patients that have completed at least five homework reports. The more careful study of different patient subgroups, based on the number of completed homework reports, is left for future work.

Our current analysis ignores the set of homework assignment questions. Since much of the patient text in ICBT is generated on the prompt of a question, future work could study the correlation of question-answer pairs with the treatment outcome.

7 Conclusions

We have analysed the potential of using patient text from Internet-based Cognitive Behavioural Therapy as the only signal for predicting treatment outcome. When framing the problem as a binary classification task between treatment success and failure, we manage to beat stratified random guessing using a simple Bag of Words classifier. This demonstrates the feasibility of our approach. Interestingly, word embeddings fail to improve on this simple approach, and our best results are achieved using only data from the first couple of weeks of treatment. This has clinical significance because interventions during treatment are still meaningful, and could prove crucial, in the first four weeks of treatment. Additionally, we provide simple terminological and sentiment analysis, which also indicate that there is a signal in the patient text data, albeit a weak one.

The work reported on here should be seen as a feasibility study in that it shows the potential to predict treatment outcome based on patient text, even in a very small subset of the set of patients reporting and reflecting on what they do in treatment, and how treatment progresses. Our next step is to look into larger subsets than the one employed here, but that step will be taken in conjunction with moving from the well-established albeit simple methods used here to contextualised language models.

Abstract

We consider the situation in which a user has collected a small set of documents on a cohesive topic, and they want to retrieve additional documents on this topic from a large collection. Information Retrieval (IR) solutions treat the document set as a query, and look for similar documents in the collection. We propose to extend the IR approach by treating the problem as an instance of positive-unlabeled (PU) learning—i.e., learning binary classifiers from only positive (the query documents) and unlabeled (the results of the IR engine) data. Utilizing PU learning for text with big neural networks is a largely unexplored field. We discuss various challenges in applying PU learning to the setting, showing that the standard implementations of state-of-the-art PU solutions fail. We propose solutions for each of the challenges and empirically validate them with ablation tests. We demonstrate the effectiveness of the new method using a series of experiments of retrieving PubMed abstracts adhering to fine-grained topics, showing improvements over the common IR solution and other baselines.

1 Introduction

We are interested in the task of *focused document set expansion*, in which a user has identified a set of documents on a focused and cohesive topic, and they wish to find more documents about the same topic in a large collection. This problem is also known as a “More Like This” (MLT) query in web retrieval. A common way of modeling this problem is to consider the set of documents as a long *query*, with which Information Retrieval (IR) techniques can rank documents. IR literature on document similarity and ranking is vast (Faloutsos and Oard, 1995; Mitra and Chaudhuri, 2000, inter alia)—beyond the scope of this work, and largely orthogonal to it, as will be explained later.

Current methods in document set expansion for very large collections are based on word-frequency or bag-of-words document similarity metrics such as Term Frequency-Inverse Document Frequency (TF-IDF) and Okapi BM25 and its variants (Robertson and Zaragoza, 2009; Zaragoza et al., 2004), considered strong due to their robustness to extreme class imbalance, corpus variance and variable length inputs, as well as their scalability and efficiency (Mitra and Craswell, 2017). However, the performance of such solutions is limited, as the models cannot capture local or global relationships between words.

We examine methods to improve document set expansion by leveraging non-linear (neural) models under the setting of imbalanced binary text classification. To this end, we look to positive-unlabeled (PU) learning (Du Plessis et al., 2015): a binary classification setting where a classifier is trained based on only positive and unlabeled data. In the standard document expansion setting, we indeed only possess positive (the document set) and unlabeled (the very large collection) data.

PU learning has originally been employed for text classification by Liu et al. (2002); Li and Liu (2005); Li and Liu (2003) by using techniques such as EM and SVM. Since then, the setting has been well studied theoretically (Elkan and Noto, 2008; Du Plessis et al., 2015; Niu et al., 2016), and recently objective functions have been developed to facilitate training of flexible neural networks from PU data (Kiryo et al., 2017). We discuss the PU learning setting in more detail in Section 2, and relevant work on PU learning for text in Section 8.

We are, however, not interested in replacing traditional (term-frequency-based) IR solutions, but rather improve upon their results by further classifying the outputs of those models. There are

two reasons for this approach: (1) Traditional IR engines are based on word frequencies, and as a result, cannot capture features based on word order; (2) Classification by the use of neural networks does not scale well to "extreme" imbalance[1].

Following these observations, we see traditional IR engines and neural models as complementary to each other. Our proposed solution is a two-step process: First, a BM25-based, MLT IR engine retrieves relevant candidates; Then, a non-linear PU learning model is trained based on the subset of candidates. In this way, each method relieves the weakness of the other.

As already discussed above, PU learning has recently become viable for deep neural network models. As a result, we are able to leverage it to train models that are able to capture higher order features between words. However, PU learning literature focused on theoretical analysis and experiments on small models and simple—**notably, class-balanced**—benchmarks such as MNIST, CIFAR10 and 20News (Kato et al., 2019; Hsieh et al., 2018; Xu et al., 2019). PU learning has not been extensively tested for imbalanced datasets. Scaling PU solutions to high-dimensional, ambiguous and complex data is a significant challenge. One reason for this is that PU data is, by definition, difficult or sometimes impossible to be fully labeled for exhaustive, large-scale evaluation.

For the purpose of document set expansion, and in particular for fine-grained topics, gathering fully-labeled data for an accurate benchmark is also a challenge. For this reason, we propose to simulate the scenario synthetically but realistically by using the PubMed collection of bio-medical academic papers. PubMed entries are manually assigned multiple terms from Medical Subject Headings (MeSH), a large ontology of medical terms and topics. We can treat a set of MeSH terms as defining a fine-grained topic, and use the MeSH labels for deriving fully-labeled tasks (see examples of MeSH topic conjunctions in Table 1). This results in an evaluation setup which is **extensive**, allowing for a large variety of different datasets based on different bio-medical topics; **flexible**, with the ability to simulate different biases in the data gathering to account for many possible practical settings; and **accurate**, with a fully labeled test set.

The contributions of this work are thus:[2]

1. We propose a procedure for generating DSE tasks based on PubMed by using conjunctions of MeSH terms for labels. This serves as a new large-scale benchmark for evaluating (1) PU learning solutions, and (2) DSE solutions, both of which currently suffer from lack of difficult and large-scale evaluation.
2. We expand the PubMed DSE task formulation with a variant that includes biased or unbiased negative data.
3. We apply state-of-the-art PU solutions, previously only evaluated on simple benchmarks for small neural networks, to the PubMed DSE tasks, and report that they perform poorly due to various challenges: no knowledge of class prior, batch size restrictions, extremely imbalanced data (small class prior), and very limited labeled data.
4. We propose methods to deal with the above challenges, and empirically evaluate the new PU solution (which incorporates our solution) on the PubMed DSE tasks, noting a significant improvement over currently available methods.

2 Background: Positive-Unlabeled Learning

PU learning refers to learning a binary classifier from positive and unlabeled data. In this section we briefly describe notation and relevant literature.

Notation. We refer to the *positive set* as *P*, the *labeled positive set* as *LP*, the *unlabeled set* as *U*, and the *negative set* as *N*. Empirical approximations of expectations and priors are denoted $\widehat{\cdot}$.

2.1 Setting

Let $x \in \mathbb{R}^d$ and $y \in \{+1, -1\}$ be random variables jointly distributed by $p(x, y)$ where $p^+(x) := p(x \mid y = +1)$ and $p^-(x) := p(x \mid y = -1)$ are the class marginals (i.e., the positive and negative class-conditional densities), and let $g : \mathbb{R}^d \to \mathbb{R}$ and $\ell : \mathbb{R} \times \{\pm 1\} \to \mathbb{R}_+$ be an arbitrary binary

---

[1] In practice, an IR task may involve positive documents in the order of hundreds or thousands, and negative documents in the order of dozens of millions. Literature dealing with imbalanced classification traditionally discuss typical ratios of 1:50 and 1:100 (Huang et al., 2018; Dong et al., 2018). To our knowledge, the setting of extreme imbalance has not been discussed in literature.

Table 1: Experiment F1 results against the baselines of average performance across topics, as well as three example topics. See Section 6 for details. † denotes the same collection of topics. The average of 15 topics ‡ includes †. The nnPU experiments include BER optimization and proportional batching, but *without* pre-trained embeddings. All experiments use a $|U|$ size of 20,000.

decision function and a loss function of $(g(x), y)$ respectively. For the purpose of this work, we will use the common sigmoid loss, $\ell_{\text{sig}}(t, y) = \frac{1}{1+\exp(ty)}$, as we have observed the best empirical performance with this loss. We denote $\pi^+ := p(y = +1)$ and $\pi^- := p(y = -1)$ as the class prior probabilities, such that $\pi^+ + \pi^- = 1$. The methods described in this section all assume the proportion π^+ to be known.

Binary classification aims to minimize the risk:

$$R(g) := \mathbb{E}_{(x,y)\sim p(x,y)}[\ell(g(x), y)].$$

In supervised (positive and negative: *PN*) learning, both positive $P := \{x_i^P\}_{n^+} \sim p^+(x)$ and negative $N := \{x_i^N\}_{n^-} \sim p^-(x)$ samples are available. The supervised classification risk can be expressed as the partial class-specific risks:

$$R(g) = \pi^+\mathbb{E}_{x\sim p^+(x)}[\ell(g(x), +1)] + \pi^-\mathbb{E}_{x\sim p^-(x)}[\ell(g(x), -1)]. \quad (1)$$

Notice that under the zero-one loss (ℓ_{01}), the risk $R(g)$ refers to $\pi^+\frac{FN}{FN+TP} + \pi^-\frac{FP}{TN+FP}$. When training, we use ℓ_{sig} which can be regarded as a soft approximation of this formulation for back-propagation. In practice, the expectations are expressed as the average of losses and optimized in batched gradient-descent or similar methods.

2.2 Unbiased PU Learning (uPU)

We utilize the case-control variant of PU learning[3] (Ward et al., 2009). Formally, unlabeled data $U := \{x_i^U\}_{n^u} \sim p(x)$ is available instead of N, in addition to $P = \{x_i^P\}_{n^+} \sim p^+(x)$ as before.

In order to train a binary classifier from PU data, we could naively train a classifier to separate positive from unlabeled samples. This approach will result, of course, in a sub-optimal biased solution since the unlabeled dataset contains both positive and negative data. Du Plessis et al. (2015) proposed the following unbiased risk estimator to train a binary classifier from PU data.

Since

$$\pi^-\mathbb{E}_{x\sim p^-(x)}[f(x)] = \mathbb{E}_{x\sim p(x)}[f(x)] - \pi^+\mathbb{E}_{x\sim p^+(x)}[f(x)],$$

we can substitute the negative-class expectation in Equation (1):

$$\begin{aligned} R_{PU}(g) := \mathbb{E}_{(x,y)\sim p(x,y)}[\ell(g(x), y)] = \\ \pi^+\mathbb{E}_{x\sim p^+(x)}[\ell(g(x), +1)] \\ + \mathbb{E}_{x\sim p(x)}[\ell(g(x), -1)] \\ - \pi^+\mathbb{E}_{x\sim p^+(x)}[\ell(g(x), -1)]. \end{aligned} \quad (2)$$

By empirically approximating this risk as an average of losses over our available dataset, we arrive at an unbiased risk estimator that can be trained on PU data, referred to as the *uPU* empirical risk.

Non-negative PU (nnPU). If the loss ℓ is always positive, so should be the risk. However, Kiryo et al. (2017) noted that by using stochastic batched optimization, and specifically via very flexible models (such as neural networks), the negative portion of the uPU loss can eventually cause the loss to go negative during training. To mitigate this overfitting phenomenon, they proposed to encourage the loss to stay positive by using gradient-ascent on the negative portion (which replaces the negative-class risk of the classification risk) when it becomes negative. This method is referred to as *nnPU*.

---

[3] In case-control PU learning, the positive and unlabeled data are collected separately. There are other variants which assume different distributions on the data.

3 The PubMed Set Expansion Task

In this section we discuss the method of generating an extensive benchmark for evaluating solutions of MLT document set expansion.

We are inspired by the following scenario: A user has a set of documents which all pertain to a latent topic, and is interested in retrieving more documents about that topic from a large collection. While traditional term-frequency-based IR solutions scale well to extremely large collections of documents, they are imprecise, and contain a significant amount of noise. Therefore, an additional step based on PU learning can be utilized to classify the output of the IR model, and improve the results.

We are interested in gathering a task for evaluation of the second step. In other words, given an existing black-box IR solution, we would like to use it to produce a dataset for training and evaluation of models which should improve upon the black-box IR solution's performance.

Due to the varied nature of the setting, it is impractical to acquire full supervision for a large number of topics. Therefore, we propose to generate synthetic tasks inspired by the real use-case application.

3.1 Task Generation Method

We generate the document-set expansion tasks by leveraging the expansive PubMed Database: A collection of 29 million bio-medical academic papers. Each document is labeled with MeSH tags, denoting the subject of the document. A conjunction of MeSH terms defines a fine-grained topic, which we use to simulate a user's information intent (example conjunctions in Table 1).

The method of generating one task is then:

1. *Input*: $T \leftarrow$ set of MeSH terms (the retrieval topic); $n^+ \leftarrow$ number of labeled positive data; IR, $\theta_T \leftarrow$ a black-box MLT IR engine, along with query parameters.

2. LP $\leftarrow n^+$ randomly selected papers that are labeled with T.

3. $U \leftarrow \text{IR}(\text{LP}; \theta_T)$.

For the tasks generated and utilized in this paper, we have chosen MeSH sets manually, and $n^+ \in \{20, 50\}$ (for the training set). For the MLT IR engine we have used the Elasticsearch[4] implementation of BM25. The top-$\{10000, 20000\}$ scoring documents are retrieved. We make use of the abstracts of the PubMed papers only. See Appendix A for exact details of our method, as well as a comparison to an alternative method for generating *censoring PU* (explained in the appendix) tasks.[5]

We note that although in essence document set expansion involves using U for both training and evaluation (*transductive case*), we are interested in the case where the PU model is able to generalize to unseen data (*inductive case*). As a result, we split the dataset $[LP; U]$ into training, validation, and test sets, where we use the validation set for hyperparameter tuning and early-stopping, and evaluate on the test set using the true labels. In other words, we assume a separate (from training) small PU set is available for validation. In our experiments, the size of the validation set is half of the size of the training set. In a deployment setting, the PU model can be used to label the training U data.

4 Experiment Details

The rest of this work will reference experiment results. Unless otherwise noted, our base architecture is a single-layer CNN (Kim, 2014). The choice of CNN, over other recurrent-based or attention-based models, is due to this architecture achieving the best performance in our experiments. Test-set performance is reported as an average over multiple MeSH topics (as many as our resources allowed). Except for the experiments that use pretrained models, the inputs are tokenized by words, and word embeddings are randomly initialized and trained with the model. More details are available in Appendix B. We stress that our intent in this work is not to report the very best scores possible, but rather to perform controlled experiments to test hypotheses. To this end, many orthogonally beneficial "tricks" in NLP literature were not utilized. Additionally, nnPU-trained models generally required more diligent hyperparameter tuning due to an additional two hyperparameters.

[5] The code for generating the tasks, and the data of our generated tasks are available online at the aforementioned repository. The uploaded dataset contains the paper abstracts. The PubMed identifiers are also available in cases where additional information about each paper, such as the full text, can be retrieved from PubMed if desired.

$\lvert LP \rvert$	Prior	Accuracy	F1
20	π^+	84.27	0.0
20	0.5	62.09	33.26
50	π^+	81.71	0.0
50	0.5	59.92	37.36

Table 2: Experiments for the PU model, trained with the nnPU loss with either the true class prior (optimizing for accuracy surrogate) or a prior of 0.5 (optimizing for BER surrogate). Reported average across 10† topics.

5 PU Learning for Document Set Expansion

In PU classification literature, traditionally small (and in many cases, linear) models have been used on relatively simple tasks, such as CIFAR-10 and 20News. However, performance of existing methods does not scale well to very high-dimensional inputs and state-of-the-art neural models for text classification; applying the PU learning methods described in Section 2 to a more practical setting results in several critical challenges that must be overcome—for example, PU learning methods often assume a known class prior, yet estimation of the class prior, particularly for text, is hard and inaccurate. In this section we discuss various challenges we have encountered in applying PU learning to the PubMed Set Expansion task, along with proposed, empirically validated solutions.

5.1 Class Imbalance and Unknown Prior (BER Optimization)

Due to the class imbalance (very small class prior), the classification risk encourages the model to be biased towards negative-class prediction (by prioritizing accuracy) in lieu of a model that achieves worse accuracy but better F1. Thus, optimizing for a metric that is similar to F1 or AUC is preferable.

Under a known class prior π^+ assumption, Sakai et al. (2018) derived a PU risk estimator for optimizing AUC directly. However, π^+ cannot be assumed to be known in practice. Furthermore, the high dimensionality and lack of cluster assumption in the input of our task makes estimation difficult and noisy (Menon et al., 2015; Ramaswamy et al., 2016; Jain et al., 2016; du Plessis et al., 2017).

Following this line of thought, we propose a simple solution to both problems: by assuming a prior of $\widehat{\pi}^+ = 0.5$ in the uPU loss regardless of the value of the true prior, we are able to optimize a surrogate loss for the Balanced Error (BER) metric[6] (Brodersen et al., 2010). Effectively, the uPU loss we are optimizing is:

$$\begin{aligned} R_{PU}(g) = \\ \frac{1}{2}\mathbb{E}_{x\sim p^+(x)}[\ell(g(x),+1) - \ell(g(x),-1)] \\ + \mathbb{E}_{x\sim p(x)}[\ell(g(x),-1)]. \quad (3) \end{aligned}$$

When using the zero-one loss (ℓ_{01}), the binary classification risk is equivalent to BER, while BER minimization is equivalent to AUC maximization: $AUC = \frac{3}{2} - 2BER$ (Menon et al., 2015). Since back-propagation requires a surrogate loss in place of ℓ_{01}, such as ℓ_{sig}, the BER and AUC metrics are not inversely equivalent; However, we've found BER optimization to perform well in practice.

Results. Table 2 shows a performance comparison in which the models trained using a prior of 0.5 achieved stronger F1 performance despite weaker accuracy.

5.2 Small Batch Size (Proportional Batching)

The large memory requirements of state of the art neural models such as Transformer (Vaswani et al., 2017) and BERT (Devlin et al., 2018), as discussed in the next subsection, coupled with the need to run on GPU, restrict the batch sizes that can be used.

This presents a challenge: When the loss function is composed of losses for multiple classes, when using stochastic batched optimization, each batch should contain a proportionate amount of data of each class relative to the entire dataset. When the classes are greatly imbalanced, this imposes a lower-bound on the batch size when the batch contains one positive example or more. For example, for a dataset which contains 50 positive and 10,000 unlabeled samples, each batch which contains a positive sample must have 200 unlabeled samples. In practice, we were limited to the vicinity of 20 samples per batch when training large Transformer models.

Using a smaller batch-size than the lower-bound (in the case of the example, 20 as opposed to 201)

---

[6] Given a decision function g:

$$BER(g) = \frac{1}{2}(\frac{FP}{TN+FP} + \frac{FN}{FN+TP})$$

$$R(g;\ell_{01}) = \pi^- \frac{FP}{TN+FP} + \pi^+ \frac{FN}{FN+TP}$$

implies that the vast majority of batches will not have labeled positive samples. This result damages performance in multiple ways. First, the model may overfit to the unlabeled data: Since unlabeled examples are treated as discounted negative examples by the uPU loss, the model will be encouraged to predict the negative class due to an abundance of batches that contain only the "negative" (in truth unlabeled) class. Additionally, early-stopping may be compromised due to the significantly smaller loss in batches that contain only unlabeled data.

To solve these problems, we propose to increase the sampling frequency of the positive class *inversely* to its frequency in the dataset. In practice, this solution simply enforces each batch to have a *rounded-up* proportion of its samples for each class. In the example above, every batch with 20 samples will have 1 positive and 19 unlabeled samples. As we "run out" of positive samples before unlabeled samples, we define an epoch as the a single loop through the positive set.

The implication of increasing the sampling frequency is essentially that the positive component of the uPU loss receives a stronger weight. In our running example, the sampling frequency was increased $\times 10$. For a sampling frequency increase by an order of α, the uPU loss becomes:

$$\grave{R}_{PU}(g) = \alpha\pi^{+}\mathbb{E}_{x\sim p^{+}(x)}[\ell(g(x),+1) - \ell(g(x),-1)] + \mathbb{E}_{x\sim p(x)}[\ell(g(x),-1)]. \quad (4)$$

This, intuitively, counter-acts the overfitting problem caused the abundance of stochastic update steps of entirely unlabeled-class batches. The issue of unstable validation uPU loss is solved as well, since every batch must contain both positive and unlabeled samples, by a ratio that is consistent between the training and validation sets (and thus the validation uPU loss remains a reliable validation metric).

The issue of overfitting in this case is derived from a more general problem: Overfitting to the "bigger" class in stochastic optimization of extremely imbalanced data, when the loss can be decomposed into multiple components for each of the classes (as is the case for cross-entropy loss, as well). For this reason, our solution improves ordinary imbalanced classification under batch size restrictions, as well.

Results. Table 3 shows the effect of the increased sampling frequency method in ordinary imbalanced binary classification, as well as in nnPU training. In the small batch size experiments, the method causes an increase in recall, showing that the model is less inclined towards the "bigger" (in our case, the negative) class. *The results apply in both the PN and PU settings, showing that proportional batching can be beneficial to any imbalanced classification task under batch size restrictions.*

Setting	Class Ratio	Batch Size	Proportional Batching	F1
PN	(P:N) 15:85	512		32.55
		16		5.55
		16	✓	41.61
PU	(LP:U) 2:100	512		22.77
		16		0.0
		16	✓	22.35

Table 3: Evaluation for the sampling frequency increase method for mitigating overfitting to the bigger class in imbalanced classification with small batch size. Results show that proportional batching dramatically improves results under batch size constraints for both ordinary supervision (PN) and PU settings.

5.3 Limited Data

A defining challenge of document set expansion tasks, when observed through the lens of imbalanced classification, is the very small class prior and small amount of labeled positive data. Although BER optimization mitigates the issue of the class imbalance, the issue of very little labeled data remains. To this end, we investigate pretraining as a solution.

We utilize SciBERT (Beltagy et al., 2019) for pretrained contextual embeddings in the PubMed domain. For PubMed abstracts that go above the 512 word-piece limit of SciBERT, we utilize a sliding-window approach that averages all embeddings for a word-piece that appeared in multiple windows.

Results. Utilizing SciBERT embeddings has yielded an increase of F1 performance from 25.75 to 29.96 as an average of five topics.

6 Effectiveness of PU Learning

In this section we evaluate the viability of our proposed solution. All experiments in this section use *BER optimization* and *proportional batching* (Section 5), but no pre-trained embeddings. We refer to our proposed method as **BM25+nnPU** where the IR solution BM25 selects the unlabeled dataset for the PU solution, a CNN model with the nnPU loss.

As an anchor for comparison, we use the following *reference*: **Upper-bound**: An identical model, trained on the same training data with full supervision using the true labels. This reference can be regarded as the upper-bound performance in the ideal case.

We directly compare against the current commonly-used and best-performing solution as **IR (BM25)**[7]: The top-k documents of the IR engine's output, for $k \in \{i\}_{i=|LP|}^{5000}$, are selected as positive documents, while the rest are treated as negative. F1 mean and standard deviation are reported across k. **This strong baseline serves as a reference to the state-of-the-art.**

We additionally compare against standard DSE baselines **All + (all positive)**: Classifying all samples as the positive class; and **Naive**: Supervised learning between the labeled positive set (as P) and the unlabeled set (as N).

Finally, we compare against two additional baselines with the aim of validating the beneficial synergy between the IR step and the PU step. In the **Rand+PU** baseline, we replace the IR step with a random selection of U data. In the **BM25+COPK** baseline, we replace the PU step with a *Constrained K-means Clustering* (Wagstaff et al., 2001) solution, where we perform k-means clustering, $k = 2$, under the constraint that all LP examples must be in the same cluster. To represent examples in embedding space for k-means, we encode the text with SciBERT. Additional details of constrained clustering as a replacement to PU learning are discussed in Appendix C.

The IR baseline is the main alternative to our approach. The all-positive and naive baselines are very simplistic "lower-bound" models to be compared against, while the other two-step baselines evaluate the IR or PU steps separately, providing further justification to using the IR and PU solutions together.

Experiments in Table 1 show a significant increase in F1 performance as an average across many topics, against all baselines.

An interesting experiment in Figure 1 shows the performance of the IR and PU models normalized by the performance of the upper-bound, as a function of the amount of labeled data. The reported values are the distance of F1 scores between each respective model with the upper-bound, normalized by the sum of scores. The figure shows that as more labeled data is added, the PU model (in truth IR+PU) increases in performance at a rate that is higher than the performance increase of the upper-bound. In comparison, the IR model improvement stays relatively constant beyond 300 labeled samples, while the upper-bound continues to increase, causing the disparity between them to grow. This experiment shows that the **IR+PU system scales well with increase in *LP* data, increasing performance at a stronger pace than the fully-supervised reference**, while the IR solution scales poorly.

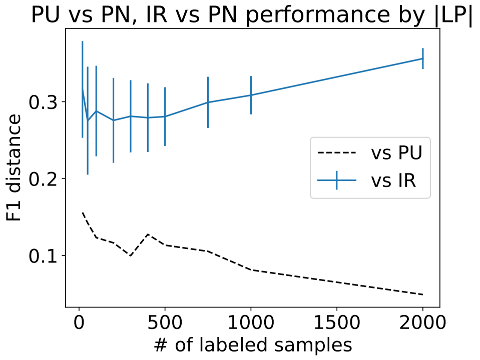

Figure 1: The F1 *absolute difference*, normalized by the sum of the two F1 scores, between the upper-bound and nnPU as a function of the amount of labeled positive samples, as well as between the IR top-k baseline (mean and standard deviation) and the upper-bound. Numbers are the average of five topics.

7 Using Negative Data

The document set expansion scenario may allow for cases where a limited amount of negative data can be collected. For example, the user may possess some number of relevant negative documents which were acquired alongside the positive documents, prior to training; alternatively, the user may label some documents from the model's output as they appear. Therefore, it is of interest to augment the task with biased labeled negative data—i.e., negative documents which were not sampled from the true negative distribution, but were selected with some bias, such as their length, popularity (for example, the number of citations), or their placement within the IR engine's rankings. We consider a bias from document character length, randomly sampling abstracts that are below a certain amount of characters. Alternative bias methods are dis-

---

[7] We note that the comparison here should be made to the *specific IR engine* which resulted in the dataset of the PU model, as the PU model benefits greatly from better performance in the IR engine.

Setting	Precision	Recall	F1
PU	29.35	71.83	40.78
PN (unbiased N)	33.83	70.40	42.14
PN (biased N)	19.34	90.62	31.29

Table 4: Experiments for five topics. All experiments used $|LP| = 50$, $|N| = 50$ for training and $|LP| = 25$, $|N| = 25$ for validation (as well as U in the PU setting).

Setting	Model	(a) Unbiased N F1	(b) Biased N F1
PNU	Ensemble (PN+PU 1+1)	42.31	37.63
PNU	Multi-task	41.50	41.48
PU	Ensemble (3)	41.25	

Table 5: Average performance of the same five topics as in Table 4. All experiments used $|LP| = 50$, $|N| = 50$ for training and $|LP| = 25$, $|N| = 25$ for validation (as well as U). Bias selection for N was performed by character length. "Multi-task" refers to Equation (5).

cussed in Appendix A.

PNU Learning. When it is possible to obtain negative data in limited capacity, it can be incorporated in training. When the negative data is sampled simply from $p^-(x)$, i.e., it is *unbiased* negative data, it is possible to use *PNU classification* (Sakai et al., 2017), which is a linear combination of $R(g)$ and $R_{PU}(g)$:

$$R_{PNU}(g) := \gamma R(g) + (1-\gamma) R_{PU}(g). \quad (5)$$

We note that to our knowledge, PNU learning has not yet been successfully applied to deep models prior to this work. We apply the same solution to the case of biased negative samples. Our PNU experiments include Proportional Batching to overcome the extreme class imbalance.

Results. Tables 4 and 5 summarize the results of PNU learning for the biased and unbiased settings. We observe that performance improves with unbiased negative samples, but does not improve with negative documents selected with bias to shorter documents. In the unbiased case, a simple ensemble of PN and PU models out-performs PNU learning, and we verify that the ensembling is not the sole cause of the performance increase by noting that the PN and PU ensemble out-performs a 3-model PU ensemble. In the biased case, the performance of the PN model is severely lower than the PU model, and in this case indeed the PNU model slightly out-performs the PN and PU ensemble.

8 Related Work

Linear PU models have been extensively used for text classification (Liu et al., 2004; Yu et al., 2005; Cong et al., 2004; Li and Liu, 2005) by using EM and SVM algorithms. Particularly, the 20News corpus has been often leveraged to build PU tasks for evaluation of those models (Lee and Liu, 2003; Li et al., 2007). Li et al. (2010b) have evaluated EM-based PU models against distributional similarity for entity set expansion. Li et al. (2010a) proposed that PU learning may out-perform PN when only the negative data's distribution significantly differs between training and deployment.

du Plessis et al. (2017); Kato et al. (2018) describe methods of estimating the class prior from PU data under some distributional assumptions. Hsieh et al. (2018) introduced *PUbN* as another PU-based loss for learning with biased negatives. PUbN involves two steps, where the marginal probability of a sample to be labeled (positive/negative) is estimated using a neural model, and then used. In our experiments, PUbN has consistently overfit to the majority baseline. We suspect that this is a result from noisy estimation of the labeling probability due to the difficulty of the task.

9 Conclusion

We propose a two-stage solution to document set expansion—the task of retrieving documents from a large collection based on a small set of documents pertaining to a latent fine-grained topic—as a method of improving and expanding upon current IR solutions, by training a PU model on the output of a black-box IR engine. In order to accurately evaluate this method, we synthetically generated tasks by leveraging PubMed MeSH term conjunctions to denote latent topics. Finally, we discuss challenges in applying PU learning to this task, namely an unknown class prior, extremely imbalanced data and batch size restrictions, propose solutions (one of which—"Proportional Batching"—applies in the general scope of PN imbalanced classification, as we empirically validate), and provide empirical evaluation against multiple baselines which showcase the effectiveness of the approach.

Future Work. Stronger class prior estimation, through additional task assumptions, may facilitate direct AUC optimization. Additionally, methods of increasing precision may be considered (such as data augmentation or adversarial training).

A PubMed Set Expansion Task Generation

In this section we discuss details of the PubMed Set Expansion task generation process.

Parameters. For this work, we have indexed the January 2019 version of PubMed in an Elasticsearch ver-6.5.4 index. We discard all papers in PubMed that do not have MeSH terms or abstracts (of which there are few). The title and abstract of each paper are tokenized using the Elasticsearch English tokenizer, with term vectors. The title receives a 2.0 score boost during retrieval. For retrieval, we use the Elasticsearch "More Like This" query with the default implementation of BM25, and a "minimum should match" parameter of 20%, indicating that papers that do not share a 20% overlap of terms with the query are dropped. This parameter was controlled in the interest of efficiency, as the query is otherwise very slow.

Table 6 contains statistics about sample topics.

Topic	$\lvert LP\rvert$	$\lvert U\rvert$	Precision	Recall
Liver + Rats, Inbred Strains + Rats	20	10,000	17.45	15.59
	50	10,000	16.55	14.82
Adult + Middle-Aged + HIV Infections	20	20,000	18.33	20.06
	50	20,000	25.42	27.85

Table 6: Dataset sizes for two example PubMed Set Expansion tasks based on the given topics, each composed of three MeSH terms. The reported sizes are for the training set. Precision denotes the proportion of P samples in U, and recall denotes the proportion of retrieved P samples from all positive documents in PubMed.

Censoring PU learning. An alternative, easier, scenario for the Document Set Expansion task involves the case where the LP data was sampled and labeled from the U distribution, termed *censoring PU learning*. To model this case, the task can be generated in the following way:

1. *Input*: $T \leftarrow$ set of MeSH terms (the retrieval topic); $n^+ \leftarrow$ number of labeled positive data; $IR, \theta_T \leftarrow$ a black-box MLT IR engine, along with query parameters.
2. $P \leftarrow$ All papers that are labeled with T.
3. $N \leftarrow IR(P; \theta_T)$
4. $LP \leftarrow n^+$ randomly selected papers in P.
5. $U \leftarrow [P - LP; N]$

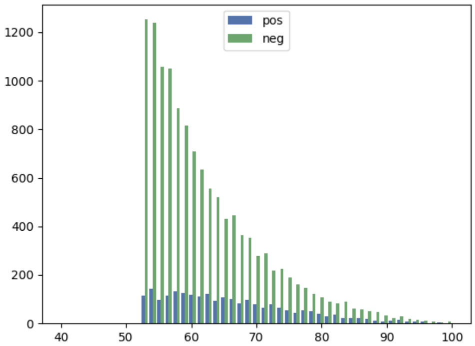

Figure 2: Two histograms of U positive and negative documents respectively by their BM25 score. The horizontal axis denotes buckets of BM25 scores, and the vertical axis is the amount of samples in that bucket.

Experimentally, the F1 performance of all the models (PU and PN) was greatly increased for this setting, in comparison to the case-control tasks described in the main work. All methods discussed in this work apply to the censoring setting, as it is a special case of case-control.

Bias. It is possible to simulate bias in the sampling of documents according to many heuristics and assumptions. For example, it may be assumed that the user is more likely to label documents that are shorter, or documents that are more famous (as indicated by amount of citations in PubMed). Additional possible conditions include the ranking of the IR engine in two possible ways: 1. The user may submit labels after the IR query while viewing the results. In this case, the user is more likely to label documents that are ranked higher; 2. In the case of an IR engine modeled by bag-of-words (such as BM25), documents that rank lower can be assumed to possess less relevant vocabulary overlap with the positive class, such that they may be easier to label at a glance. Figure 2 shows a typical distribution of class according to the rank of BM25 for a sample task of PubMed Set Expansion.

B Experiment Details

The experiments were implemented in PyTorch version 1.0.1.post2, AllenNLP version 0.8.3-unreleased. The neural models used a CNN encoder with max-pooling, with 100 filters for the title and 200 filters for the abstract, split evenly between window sizes of 3 and 5. The choice of CNN (over other recurrent-based or attention-based models) is due to this architecture achieving the best performance in practice. For the SciBERT contextual embeddings, SciBERT-base was used. The learning rate for the model with no pretraining used is 0.001, while the learning rate for the SciBERT model is 0.00005. The nnPU parameters β, γ were set to 0 and tuned over the validation set loss, respectively. In all cases of nnPU training we used the biggest batch-size possible, which was 1000 for the CNN model with no pretraining, and between 16 to 25 for the SciBERT model. In the case of the SciBERT model, we've ignored training and validation samples longer than 600 words, tokenized by the AllenNLP default implementation of `WordTokenizer`, to avoid long outliers which greatly limit the batch size. This was not performed on the test set to maintain an unbiased comparison.

B.1 Experiment Topics

The topics were chosen by a policy of related triplets, such that they could conceivably (though loosely) be relevant searches in practice, by sampling and filtering from MeSH triplets that they occur together in PubMed on an order of hundreds, thousands or tens of thousands. The topics were chosen *without* knowledge of any experiment results related to them, such that they were not picked to achieve a particular outcome.

C Constrained Clustering for PU Learning

Unfortunately, we are not aware of many competitive alternative solutions to nnPU that interface with only positive and unlabeled data. One such a solution is *constrained clustering*, or clustering under constraints of prior knowledge on which examples should belong in the same cluster, or which examples should not belong in the same cluster.

Constrained clustering can be reduced to a PU problem in the following way: Given LP and U data, we perform clustering under constraints that all of the examples in LP must belong in the same cluster. If N data is available, we may constrain all N data to be in the same cluster, as well, and that LP and N examples may not be in the same cluster. If the algorithm allows a parameterization of the number of clusters, such as COP-Kmeans (Wagstaff et al., 2001), we may specify this number to be 2. Otherwise, all clusters that do not contain the LP examples can be selected as clusters of N, and the cluster that contains the LP examples shall be selected as P.

In this way, we achieve a reduction from the constrained clustering problem to a PU problem, allowing it to serve as a replacement to nnPU. While we are not aware of other work which made this reduction or comparison between constrained clustering and PU learning, in our experiments we note that nnPU has achieved stronger performance and scalability in large data.

The Role of Syntactic Planning in Compositional Image Captioning

Emanuele Bugliarello and **Desmond Elliott**
Department of Computer Science
University of Copenhagen
`{emanuele,de}@di.ku.dk`

Abstract

Image captioning has focused on generalizing to images drawn from the same distribution as the training set, and not to the more challenging problem of generalizing to different distributions of images. Recently, Nikolaus et al. (2019) introduced a dataset to assess compositional generalization in image captioning, where models are evaluated on their ability to describe images with unseen adjective–noun and noun–verb compositions. In this work, we investigate different methods to improve compositional generalization by planning the syntactic structure of a caption. Our experiments show that jointly modeling tokens and syntactic tags enhances generalization in both RNN- and Transformer-based models, while also improving performance on standard metrics.

1 Introduction

Image captioning is a core task in multimodal NLP, where the aim is to automatically describe the content of an image in natural language. To succeed in this task, a model first needs to recognize and understand the properties of the image. Then, it needs to generate well-formed sentences, requiring both a syntactic and a semantic knowledge of the language (Hossain et al., 2019). Deep learning techniques are the standard approach to tackling this problem: images are represented by visual features extracted from Convolutional Neural Networks (*e.g.* He et al. 2016), and sentences are generated by conditioning Recurrent Neural Networks (*e.g.* Hochreiter and Schmidhuber 1997), or Transformers (Vaswani et al., 2017) on the extracted visual features.

While deep neural networks achieve impressive performance in a variety of applications, including image captioning, their ability to demonstrate compositionality, defined as the algebraic potential to understand and produce novel combinations from known components (Loula et al., 2018), has been questioned. Semantic compositionality of language in neural networks has attracted interest in the community (Irsoy and Cardie, 2014; Lake and Baroni, 2018; Baroni, 2019) as compositionality is conjectured to be a core feature not only of language but also of human thought (Fodor and Lepore, 2002).

In image captioning, improving compositional generalization is a fundamental step towards generalizable systems that can be employed in daily life. To this end, Nikolaus et al. (2019) recently introduced a compositional generalization dataset where models need to describe images that depict unseen compositions of primitive concepts. For example, models are trained to describe images with "white" entities and all types of "dog" concepts but never the adjective–noun composition of "white dog." In their dataset, models are evaluated on their ability to caption images depicting the unseen composition of held out concepts. Their study suggests that RNN-based captioning models do not compositionally generalize, and that this is primarily attributable to the language generation component.

In this paper, we study the potential for syntax to improve compositional generalization in image captioning by combining syntactic planning and language generation in a single model. Our study is inspired by the traditional Natural Language Generation (NLG) framework (Reiter and Dale, 1997), where NLG is split into three distinct steps: text planning, sentence planning, and linguistic realization. While state-of-the-art captioning models typically proceed directly from visual features to sentence generation, we hypothesize that a model that plans the structure of a sentence as an intermediate step will improve compositional generalization. A model with a planning step can learn the high-level structure of sentences, making it less prone to overfitting the training data.

Specifically, we explore three methods for integrating syntactic planning into captioning in our

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 593–607
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

experiments: (a) pre-generation of syntactic tags from the image, (b) interleaved generation of syntactic tags and words (Nădejde et al., 2017), and (c) multi-task learning with a shared encoder that predicts syntactic tags or words (Currey and Heafield, 2019). We do so while also empirically investigating four different levels of syntactic granularity.

The main findings of our experiments are that:

- jointly modeling syntactic tags and tokens leads to improvements in Transformer-based (Cornia et al., 2020) and RNN-based (Anderson et al., 2018) image captioning models;
- although the effectiveness of each syntactic tag set varies across our explored approaches, the widely-used *chunking* tag set never outperforms syntactic tags with finer granularity;
- compositional generalization is affected by directly mapping from image representation to tokens because performance can be improved by interleaving a dummy tag with no meaning;
- interleaving syntactic tags with tokens leads to a loss in performance for retrieval systems.

Finally, we also propose an attention-driven image–sentence ranking model, which makes it possible to adaptively combine syntax within the re-scoring approach of Nikolaus et al. (2019) to further improve compositional generalization in image captioning.

2 Planning Image Captions

Natural language generation has traditionally been framed in terms of six basic sub-tasks: content determination, discourse planning, sentence aggregation, lexicalization, referring expression generation and linguistic realization (Reiter and Dale, 1997). Within this framework, a three-stage pipeline has emerged (Reiter, 1994):

- **Text Planning:** combining content determination and discourse planning.
- **Sentence Planning:** combining sentence aggregation, lexicalization and referring expression generation to determine the structure of the selected input to be included in the output.
- **Linguistic Realization:** this stage involves syntactic, morphological and orthographic processing to produce the final sentence.

Early methods for image captioning drew inspiration from this framework; for example, the MIDGE system (Mitchell et al., 2012) features explicit steps for content determination, given detected objects, and sentence aggregation based on local and full phrase-structure tree construction, and TREETALK composes tree fragments using integer linear programming (Kuznetsova et al., 2014). More recently, Wang et al. (2017) propose a two-stage algorithm where the skeleton sentence of the caption (main objects and their relationships) is first generated, and then the attributes for each object are generated if they are worth mentioning. In contrast, the majority of neural network models are based on the encoder-decoder framework (Sutskever et al., 2014) of learning a direct mapping from different granularities of visual representations (Vinyals et al., 2015; Xu et al., 2015; Anderson et al., 2018) to language model decoders based on RNNs (Vinyals et al., 2015) or Transformers (Guo et al., 2020; Cornia et al., 2020).

2.1 Motivation

In this paper, we explore whether image captioning models can be improved by explicitly modeling sentence planning as an intermediate step between content determination and linguistic realization. In particular, we study the use of syntactic tags in enriching the sentence planning step to improve compositional generalization. In the compositional image captioning task, models are tasked with describing images that depict unseen combinations of adjective–noun and noun–verb constructions (see Nikolaus et al. 2019 for a more detailed description of this task). Nikolaus et al. (2019) presented a model that improves generalization with a jointly trained discriminative re-ranker, whereas here, we investigate the role of sentence planning via syntax.

From a psycholinguistic perspective (Griffin and Bock, 2000; Coco and Keller, 2012), there is evidence that humans make plans about how to describe the visual world: they first decide what to talk about (analogous to content determination), then they decide what they will say (a sentence planning phase), and finally, they produce an utterance (linguistic realization). We hypothesize that, analogously to humans, neural network decoders will also find it useful to make such sentence plans.

From a machine learning perspective, the use of syntactic structure can mitigate the bias introduced by the maximum likelihood training of neural network image captioning models. Recall that in the context of image captioning, the optimization objective consists of maximizing the likelihood:

$$\mathcal{L} = \prod_{t=1}^{T} \mathbb{P}(y_t | y_{<t}, v), \qquad (1)$$

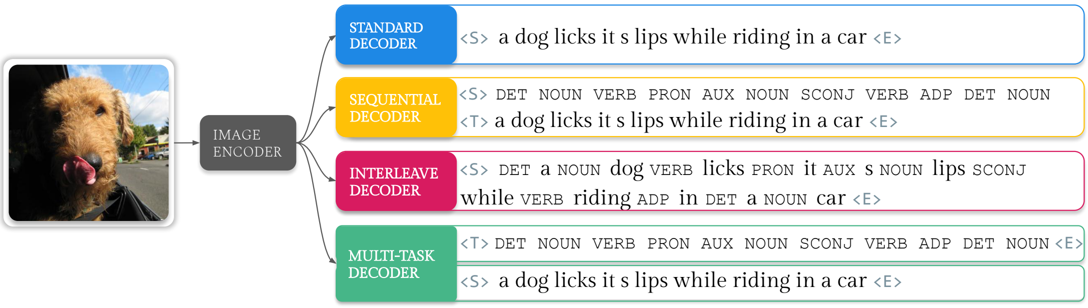

Figure 1: Approaches to syntactically plan image captioning (with POS tags). STANDARD captioning systems directly generate a sequence of surface forms (i.e. words). SEQUENTIAL generates a sequence of syntactic tags, followed by a sequence of surface forms. INTERLEAVE alternates syntactic tags and surface forms. MULTI-TASK generates either a sequence of syntactic tags or a sequence of surface forms from a shared decoder.

where v denotes the visual features (either a single vector or a set of vectors extracted from an image).

In a standard generation task, a model learns to predict the next token based on what it has observed so far. This is especially limiting when it is evaluated on unseen combinations of adjective–noun and noun–verb constructions in the compositional generalization task (i.e. data points that fall outside the training distribution). In fact, models are not explicitly asked to learn *word classes* nor how to connect them to form novel combinations. Whereas, if a system also models syntax, it can assign higher probability to “white dog” if it expects to generate a sequence with an adjective followed by a noun.

2.2 Planning Approaches

We investigate three approaches to jointly modeling tokens and syntactic tags: syntax-driven sequential caption planning (SEQUENTIAL), syntax-interleaved caption generation (INTERLEAVE), and syntax and caption generation via multi-task learning (MULTI-TASK). See Figure 1 for an overview.

SEQUENTIAL: Our first approach closely follows the traditional NLG pipeline and it is related to the *text planning* stage defined above, although limited to sentence-level rather than to a full discourse. Here, a model plans, through syntactic tags, the order of the information to be presented. Specifically, the model is required to generate a sequence whose first T outputs represent the underlying syntactic structure of the sentence before subsequently generating the corresponding T surface forms.

INTERLEAVE: Our second approach consists of interleaving syntactic tags and tokens during generation, which means a syntactic tag and its realization are next to each other, removing the pressure for a model to successfully track long-range dependencies between tags and tokens. Moreover, this allows for a more flexible planning, where the model can adapt the sentence structure based on the previously generated tags and tokens. In particular, a model can break bi-gram dependencies and learn narrower distributions over the next word based on the current syntactic tag. For instance, if we consider part-of-speech tags, the model learns that only a subset of the vocabulary corresponds to nouns, and another subset to adjectives, and so on.

MULTI-TASK: Our last approach is based on multi-task learning, where a model produces either a sequence of tokens (main task) or syntactic tags (secondary task). We draw on the simple and effective approach of Currey and Heafield (2019), proposed for neural machine translation (NMT). In the NMT framework, the source sentence was prepended a task-specific tag, which led the decoder to either predict the translation of the source sentence or the syntactic tags of the source sentence. We adapt this to image captioning by setting the first token to either a start-of-syntax token (`<T>`) or start-of-sentence token (`<S>`) and then generating tags or tokens, respectively. Compared to the other approaches, MULTI-TASK allows the model to learn both types of forms at the same position. While this approach does not double sequence length, it doubles the number of sequences per training epoch.

2.3 Syntactic Granularity

In addition to the three approaches of realizing sentence planning, we investigate the effects of different syntactic tags from a coarse to fine granularity. We experiment with the following tags:

- **CHUNK:** Also known as *shallow parsing*, chunks are syntactic tags that model phrasal structure in a sentence, such as noun phrases (NP) and verb phrases (VP).

- **POS:** Part-of-speech tags are specific lexical categories to which words are assigned, based on their syntactic context and role, such as nouns (N) and adjectives (ADJ).
- **DEP:** Dependency-based grammars model the structure as well as the semantic dependencies and relationships between words in a sentence. In this study, we consider the dependency labels assigned to each word, such as adjectival modifiers (amod), which denote any adjective that modifies the meaning of a noun.
- **CCG:** Combinatory categorial grammar (Steedman and Baldridge, 2006) is based on combinatory logic and provides a transparent interface between surface syntax and the underlying semantic representation. For example, the syntactic category assigned to "sees" is "(S\NP)/NP", denoting it as a transitive verb that will be followed by a noun phrase.

We also study the merit of breaking bi-gram dependencies for the INTERLEAVE approach by tagging each word with a synthetic tag <IDLE>. We hypothesize this approach would not give any benefits in any metric, as attention-based models can simply learn to ignore these pseudo-tags.

3 Experimental Setup

Data We use training and evaluation sets such that paradigmatic gaps exist in the training set. That is, for a concept pair $\{c_i, c_j\}$, the validation $\mathcal{D}_{val}$ and test $\mathcal{D}_{test}$ sets only contain images in which at least one of the captions contains the pair of concepts, while the complementary set – where concepts c_i and c_j can only be observed independently – is used for training $\mathcal{D}_{train}$. Following Nikolaus et al. (2019), we select the same 24 adjective–noun and verb–noun concept pairs, and split the English COCO dataset (Lin et al., 2014) into four sets, each containing six held out concept pairs.

Pre-processing We first lower-case and strip away punctuation from the captions. We then use StanfordNLP (Qi et al., 2018) to tokenize and lemmatize the captions, and to extract universal POS tags and syntactic dependency relations. For IOB-based chunking, we train a classifier-based tagger on *CoNLL2000* data (Tjong Kim Sang and Buchholz, 2000) using NLTK (Bird et al., 2009). Finally, we use the A* CCG parsing model by Yoshikawa et al. (2017) with ELMo embeddings (Peters et al., 2018) to extract CCG tags. Visual features are extracted from 36 regions of interest in each image using Bottom-Up attention (Anderson et al., 2018) trained on Visual Genome (Krishna et al., 2017).

Evaluation Following Nikolaus et al. (2019), we evaluate compositional generalization with Recall@K. Given K generated captions for each of the M images in an evaluation set, $\{\langle s_1^1, \ldots, s_K^1 \rangle, \ldots, \langle s_1^M, \ldots, s_K^M \rangle\}$, the recall of the concept pairs is given by:

$$\text{Recall@K} = \frac{|\{\langle s_k^m \rangle | \exists k : s_k^m \in \mathcal{C}\}|}{M}, \quad (2)$$

where s_k^m denotes the k-th generated caption for image m and $\mathcal{C}$ is the set of captions which contain the expected concept pair and in which the adjective or the verb is a dependent of the noun.

In addition, we use `pycocoeval` to score models on the common image captioning metrics: METEOR (M; Denkowski and Lavie 2014), SPICE (S; Anderson et al. 2016), CIDEr (C; Vedantam et al. 2015), and BLEU (B; Papineni et al. 2002); and the recent multi-reference BERTScore (BS; Yi et al. 2020). In particular, we report the average recall across all concept pairs, the average across the four splits for each score in `pycocoeval`, and the average across all captions for BERTScore.

Models We evaluate three models:

- **BUTD**: Bottom-Up and Top-Down attention (Anderson et al., 2018), a strong and widely-employed RNN-based captioning system.
- **BUTR**: Bottom-Up and Top-Down attention with Ranking (Nikolaus et al., 2019), an RNN-based, multi-task model trained for image captioning and image–sentence ranking that achieves state-of-the-art performance in the compositional generalization task.[1]
- **$\mathcal{M}^2$-TRM**: Meshed-Memory Transformer (Cornia et al., 2020), a recently proposed Transformer-based architecture that achieves state-of-the-art performance in image captioning on the COCO dataset.

Implementation details We follow Nikolaus et al. (2019) and Cornia et al. (2020) to train their systems. Model selection is performed using early stopping, which is determined when the BLEU score of the generated captions in the validation set

---

[1] We denote as BUTR the model that uses the re-ranking module (BUTR+RR in Nikolaus et al. 2019) as it was shown to be essential to improve compositional generalization.

	Model	R@5	M	S	C	B	BS

Table 1: Average validation results for our approaches to integrating syntactic planning into image captioning evaluated across four types of syntactic forms.

does not increase for five consecutive epochs.[2] We use the default hyperparameters and do not fine-tune them when tasking the models with syntax generation. For full experimental details, refer to App. A. Our code and data are publicly available.[3]

4 Syntax Awareness

In Table 1, we first report the performance of BUTD when jointly modeling different types of syntactic tags and each approach to sentence planning.

Syntax helps compositional image captioning Table 1 clearly shows that, regardless of the level of granularity, syntactic planning enhances compositional generalization in image captioning (R@5). Moreover, CHUNK – one of the most widely-used tag sets for syntax-aware image captioning (*e.g.* Kuznetsova et al. 2012; Yang and Liu 2020) – is outperformed by tag sets with finer granularity (e.g. DEP) in *every* approach, motivating further research into incorporating them in image captioning.

Looking at the results for the SEQUENTIAL approach, we see that, with the exception of POS tags, syntactic planning increases the ability of the model to recall novel concept pairs, with gains of at least +1.1 R@5 points. We then hypothesize that syntax-based sequential planning is effective if the tags convey information about words in relation to each other, e.g. CCG tags as opposed to POS tags.

When the model INTERLEAVEs syntactic tags and words, there is an improvement of at least +1.0 R@5, except for CHUNK. Moreover, POS tags lead to the highest gain of +2.3 R@5.

Finally, the MULTI-TASK approach also leads to significant gains in compositional generalization, with DEP (original setup of Currey and Heafield 2019) giving the highest R@5, corroborating the effectiveness of our porting into image captioning.

Generalization across categories We further investigate the role of syntactic planning for the different unseen composition categories defined by Nikolaus et al. (2019). Figure 2 illustrates how our different combinations of approaches and syntactic tags deal with color and size, type of the objects (animate and inanimate) and type of the verbs (transitive and intransitive). We see that DEP tags consistently improve upon BUTD for color and size concept pairs, regardless of the planning approach, making them a robust tag set for future research. INTERLEAVE+POS also leads to gains for all color and size categories, with up to +10 R@5 for colors of inanimate objects. Conversely, all the variants perform worse than the baseline for the sizes of animate objects. However, this drop is not substantial because BUTD already performs poorly.

Towards neural NLG pipelines While the SEQUENTIAL approach closely follows the traditional NLG pipeline, it consistently degrades performance in standard metrics for image captioning. On the other hand, both INTERLEAVE and MULTI-TASK lead to higher performance in compositional generalization and other metrics. In particular, when BUTD is trained to predict either words or CCG tags in the MULTI-TASK approach, the generated captions achieve the highest average scores, including a substantial gain of +2.9 CIDEr points. These results indicate that neural models require novel ways of sentence planning; and that effectively doing so *consistently* leads to the same or better performance in every considered metric.

Grounding the need for planning Overall, Table 1 provides empirical support that an explicit planning step improves compositional generalization in image captioning. In fact, even breaking bi-grams with the <IDLE> tag in the INTERLEAVE approach improves performance: the standard approach of directly mapping image representations to tokens is sub-optimal because the model learns to generate *n*-grams seen during training.

---

[2] Whenever present, syntactic tags are stripped away when computing evaluation metrics such as BLEU scores.

Table 2: Average validation results when interleaving syntactic and lexical forms in BUTR and our variants.

Given its superior performance in the recall of novel compositions of concepts, we adopt INTERLEAVE+POS throughout the remainder of this paper to jointly model syntactic tags and words. For clarity of exposition, we refer to this approach as POS.

4.1 Adaptive Re-Ranking for Syntax

Recall that the best-performing model for compositional image captioning re-ranks its generated captions given the image (BUTR; Nikolaus et al. 2019). Here, we study how to combine the benefits of syntactic planning and their re-ranking approach.

The BUTD model, investigated above, is a two-layer LSTM (Hochreiter and Schmidhuber, 1997) in which the first LSTM encodes the sequence of words, and the second LSTM integrates visual features through an attention mechanism to generate the output sequence (Anderson et al., 2018). The state-of-the-art BUTR model extends this with an image–sentence ranking network that projects images and captions into a joint visual-semantic embedding. The sentence representation used by the ranking network is a learned projection of the final hidden state of the first LSTM: $\mathbf{s} = \mathbf{W}\mathbf{h}_T^l$.

Ranking performance Table 2 shows that the image–sentence retrieval performance of BUTR decreases when interleaving POS tags with words. Given the previous formulation of BUTR and its connection to BUTD, we conclude that jointly modeling syntactic tags and words leads to decreased performance in the generation and ranking tasks.

Adaptively attending to tags We explore two approaches to combining the improvements of interleaved syntactic tagging with ranking:

- *mean*: The model creates a mean representation over the hidden states of the first LSTM.
- *weight*: The model forms a weighted pooling of the hidden states of the first LSTM layer, whose weights are learned through a linear layer. This is a simple form of attention mechanism and it is equivalent to the one used

Model	R@5	M	S	C	B	BS
BUTD	9.5	25.2	18.6	92.7	32.3	41.7
+POS	11.8	25.4	18.8	94.4	32.7	41.7
BUTR$_{weight}$	14.9	26.4	20.2	88.8	28.5	43.2
+POS	**16.4**	26.4	20.0	89.8	29.1	43.1
$\mathcal{M}^2$-TRM	10.6	27.9	21.6	**114.0**	**37.2**	44.4
+POS	13.2	**28.0**	**21.7**	113.8	35.4	**44.9**

Model	R@5	M	S	C	B	BS
BUTD	9.2	25.4	18.6	94.4	32.4	41.8
+POS	11.1	25.4	18.7	96.3	32.9	41.8
BUTR$_{weight}$	13.5	26.4	20.1	91.0	28.6	43.3
+POS	**15.4**	26.3	20.0	91.0	28.7	43.2
$\mathcal{M}^2$-TRM	10.1	27.8	21.5	**115.7**	**36.5**	44.5
+POS	12.1	**28.0**	**21.6**	**115.7**	35.0	**44.9**

Table 3: Average validation (left) and test (right) results when interleaving syntactic (POS) and lexical forms.

by Nikolaus et al. (2019) to represent image features in the shared embedding space:

$$\begin{aligned} \omega_t &= \mathbf{W}_\alpha \mathbf{h}_t^l, \\ \boldsymbol{\alpha} &= \text{softmax}\left(\omega\right), \\ \mathbf{s} &= \mathbf{W} \sum_{t=1}^{T} \alpha_t \mathbf{h}_t^l. \end{aligned} \tag{3}$$

Table 2 shows that the weighting mechanism in the ranking model effectively disentangles syntactic tags and tokens, resulting in $+1.5$ RECALL points over BUTR, with small improvements to the other metrics. Compared to BUTR, BUTR$_{weight}$ also improves the retrieval performance of the ranking module. Adding POS tags still decreases retrieval performance but, compared to BUTR+POS, the difference is now halved for text retrieval and only 0.7 points for image retrieval. Overall, our BUTR$_{weight}$ is a more general and robust approach to jointly training a captioning system and a discriminative image–sentence ranker.

5 Results and Discussion

We now report the final performance of three image captioning models that integrate the syntactic planning (INTERLEAVE+POS) with word generation.

Model-agnostic improvements We start by investigating whether the compositionality given by syntactic planning generalizes across architectures. Table 3 reports average validation and test scores for the BUTD, BUTR$_{weight}$ and $\mathcal{M}^2$-TRM models. We find that interleaving POS tags and tokens consistently leads to $+2$ RECALL points in each model without affecting the performance on other metrics, with the exception of decreased BLEU score of $\mathcal{M}^2$-TRM. In this case, $\mathcal{M}^2$-TRM +POS generates captions that are abnormally truncated, ending with bi-grams such as "of a," "on a" and "to a".[4] Furthermore, we can clearly see that despite $\mathcal{M}^2$-TRM outperforming the RNN-based models in every standard metric, it is only +1 RECALL point better than BUTD at compositional generalization. Hence, syntactic planning is an effective strategy to compositional generalization, *regardless* of the language model used.

Model	Color		Size		Verb	
	A	I	A	I	T	I
BUTD	6.9	10.4	**0.9**	0.2	21.8	16.7
+POS	7.8	20.2	0.4	0.3	24.1	18.2
BUTR$_{weight}$	15.0	24.9	0.8	1.6	26.2	20.8
+POS	**16.2**	**30.4**	**0.9**	**2.5**	26.8	**21.9**
$\mathcal{M}^2$-TRM	5.2	11.9	0.2	0.2	29.1	16.6
+POS	7.9	17.9	0.1	0.2	**32.3**	20.6

Table 4: Average validation R@5 scores for different categories of held out pairs. Color and size adjectives are split into **A**nimate or **I**nanimate objects; Verbs are split into **T**ransitive and **I**ntransitive verbs.

Generalization across categories Table 4 lists the R@5 scores for different categories of held out pairs. Differently from the results reported by Nikolaus et al. (2019), we find the performance of BUTD for noun–verb concept pairs to be much higher thanks to a larger beam size (equal to the one used for BUTR in our experiments). Moreover, the performance from interleaving POS across different categories of held out pairs shows that improvements are consistent across categories and models, with the exception of size modifiers of animate objects, where all models perform poorly. This was also found by Nikolaus et al. (2019) and it is likely due to the need for real-world knowledge (i.e. does this image depict a "big dog" compared to *all other* "dogs"?). For a full breakdown of the R@5 generalization performance for each held out pair by each model, see Table 9 in App. B.

---

[4] This is known as reward hacking (Amodei et al., 2016) which arises in models with a reinforcement learning-based optimization phase. Investigating whether proposed approaches to mitigate this problem (Liu et al., 2017; Li et al., 2019, *inter alia*) are also effective in our setup is left as future work.

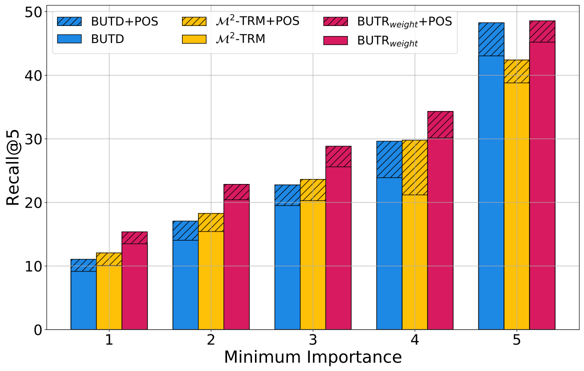

Figure 3: Average test R@5 as a function of the minimum importance of a concept pair for each model.

Performance by minimum importance Given that annotators of the COCO dataset were given a relatively open task to describe images, captioning systems should exhibit higher recall of concept pairs when more annotators use them in the descriptions. As shown in Figure 3, this behavior is seen in each model, with increasing gains given by jointly modeling lexical and syntactic forms. In particular, we observe that the $\mathcal{M}^2$-TRM model recalls fewer pairs than BUTD when they are considered more relevant (more annotators use them in describing an image), and that interleaving POS tags partially solves its limitations. Moreover, as agreement among annotators increases, we also see that BUTD+POS is as effective as BUTR$_{weight}$, corroborating the effectiveness of our model-agnostic approach against a more complex, multi-task model.

Captions diversity Table 5 reports the average scores for caption diversity (van Miltenburg et al., 2018) in the validation data. Comparing BUTD (RNN-based) and $\mathcal{M}^2$-TRM (Transformer-based) models, we see that the output vocabulary of the $\mathcal{M}^2$-TRM-based model spans many more word types, resulting in +11% novel captions. However, $\mathcal{M}^2$-TRM has lower mean segmented type-token ratios (TTRs), contrasting the conclusion of van Miltenburg et al. (2018) that the number of novel descriptions is strongly correlated with the TTR (while this correlation is maintained with the number word types). The models that jointly model syntactic tags and tokens lead to a higher number of types in both models and a substantial +8% in novel captions for $\mathcal{M}^2$-TRM, without affecting other metrics. Clearly, BUTR$_{weight}$ leads to longer sentences, more types, higher TTRs and the highest percentage of novel captions. We can also see that BUTR$_{weight}$ achieves the highest coverage (defined as the percentage of learnable words it can recall), while $\mathcal{M}^2$-TRM has the highest local recall score, being able to better recall the content words that are important to describe a given image.

Model	**ASL**	**Types**	**TTR$_1$**	**TTR$_2$**	**%Novel**	**Cov**	**Loc$_5$**
BUTD	8.6	463	0.16	0.37	69.2	0.12	0.74
+POS	8.6	466	0.16	0.37	70.3	0.12	0.75
BUTR$_{weight}$	**10.3**	**783**	**0.20**	**0.49**	**97.2**	**0.20**	0.78
+POS	**10.3**	778	**0.20**	**0.49**	96.7	**0.20**	0.78
$\mathcal{M}^2$-TRM	9.1	580	0.14	0.33	80.1	0.15	**0.83**
+POS	9.5	601	0.13	0.33	88.4	0.15	**0.83**

Table 5: Average validation set scores for diversity metrics as defined in van Miltenburg et al. (2018).

Accuracy of syntactic forms We verify that the models can correctly predict syntactic tags, regardless of their granularity and the approach used to jointly modeling them with tokens. Indeed, the accuracy of the generated syntactic tags, measured as the ratio of *sequences* matching the annotations from StanfordNLP, by BUTD is high, ranging between 95% and 99%. See App. B for details.

Qualitative examples Figure 4 shows generated captions. Compared to standard BUTD, all syntax-aware approaches allow the model to recall more unseen concept pairs, while also improving the overall quality of the captions. In addition, when looking at the captions generated by all three models, both with and without interleaving POS tags, we find the integration of syntactic tags to clearly **improve the quality** of the generated caption. See Figure 5 in App. B for more examples.

6 Related Work

Compositional image captioning Nikolaus et al. (2019) studies compositional generalization in image captioning with combinations of unseen adjective–noun and verb–noun pairs, whose constituents are observed at training time but not their combination, thus introducing a *paradigmatic gap* in the training data. Nikolaus et al. (2019) showed how to improve compositional generalization by jointly training an image–sentence ranking model with a captioning model. Other work has also investigated generalization to unseen combinations of visual concepts as a classification task (Misra et al., 2017; Kato et al., 2018), triplet prediction (Atzmon et al., 2016), or unseen objects (Lu et al., 2018). Here, we improve generalization by jointly modeling syntactic tags and tokens, and we show

BUTD: there is a woman that is on the floor
BUTD + SEQUENTIAL: a woman doing a trick on a bicycle
BUTD + INTERLEAVE: a woman riding a bike on a wooden floor
BUTD + MULTI-TASK: a woman riding a bike on a wooden surface

BUTD: a woman with a child sitting on a bench
BUTD + POS: **a girl that is standing** on a skateboard

BUTR$_{weight}$: a girl and child playing with a toy in a backyard
BUTR$_{weight}$ + POS: **a girl doing a trick on a skateboard** on a brick walkway

$\mathcal{M}^2$-TRM: a girl doing a trick on a skateboard with
$\mathcal{M}^2$-TRM + POS: a little girl **standing on a skateboard** in the

Figure 4: **Top:** Captions generated by BUTD with different approaches to integrating syntactic tags (based on best R@5). **Bottom:** Captions generated by BUTD, BUTR$_{weight}$, and $\mathcal{M}^2$-TRM, and each model when interleaving POS tags. Syntax-aware approaches generate **higher quality** captions with more unseen concept pairs.

how to combine this with the improvements gained from a jointly-trained ranking model.

Joint syntactic and semantic representations While little work has investigated the interaction of jointly modeling semantics and various syntactic forms in captioning models, a few studies have exploited syntax in image and video captioning. Zhao et al. (2018) propose a multi-task system to jointly train the task of image captioning with two additional tasks: multi-object classification and syntax generation. The same LSTM decoder is used to generate captions *and* CCG tags by mapping the hidden representations to either word or tag vocabularies through two different output layers. Dai et al. (2018) propose a two-stage sequential pipeline where a sequence of noun-phrases is first selected from a fixed pool, which are then patched together via predetermined connecting phrases. This method, however, is unlikely to realize any benefits for compositional generalization because it uses the top-50 noun-phrases and $1,000$ connecting phrases from the training set. Our INTERLEAVE approach can be used to address these limitations in their "phrase pool" and "connecting" modules to produce unseen compositions. Deshpande et al. (2019) rely on sequences of POS tags to produce diverse captions. Similarly to our SEQUENTIAL approach, their model first predicts a sequence of POS tags conditioned on the input image. However, the authors limit the POS sequences to $1,024$ templates obtained through quantization of the training set. During inference, the model samples k POS tag sequences and uses them to condition a greedy decoder for captions generation. Hou et al. (2019) take yet another approach to jointly learn POS tags and surface forms in the framework of video captioning. They introduce a model that resembles our INTERLEAVE approach but with two main differences: (i) the t-th tag is not conditioned on previous tags, and (ii) the t-th word is only conditioned on the t-th tag and the video.

7 Conclusion

We investigated a variety of approaches along with the use of syntactic tag sets to achieve compositional generalization in image captioning via sentence planning. Our results support the claim that combining syntactic planning and language generation *consistently* improves the generalization capability of RNN- and Transformer-based image captioning models, especially for inanimate color–noun combinations. While this approach penalizes image–sentence ranking models, we showed that this can be overcome with an adaptive mechanism, resulting in state-of-the-art performance on the compositional generalization task. We believe our results will lead to further exploration of syntax-aware captioning models given their potential to better generalize, both in terms of under-researched syntactic granularity (e.g. CCG) and more expressive alternatives to modeling syntactic structure. Another direction for future work is to focus on size–noun compositions, which rely on the successful integration of real-world knowledge.

A Experimental Setup

Data In order to evaluate the compositional generalization of a model, we use training and evaluation sets such that paradigmatic gaps are observed in the training set. That is, for a concept pair $\{c_i, c_j\}$, the validation $\mathcal{D}_{val}$ and test $\mathcal{D}_{test}$ sets only contain images in which at least one of the captions contains the pair of concepts, while the complementary set – where concepts c_i and c_j can only be observed independently – is used for training $\mathcal{D}_{train}$. Specifically, following Nikolaus et al. (2019), we select the same 24 adjective–noun and verb–noun concept pairs, and split the English COCO dataset (Lin et al., 2014) into four sets, each containing six held out concept pairs (training and validation instances are drawn from `train2014`, while test instances from `val2014`). Table 6 lists the sizes (in number of images) of each split.[5] For more details, we refer the reader to Nikolaus et al. (2019).

Training details Following Nikolaus et al. (2019) and Cornia et al. (2020), each system is trained with teacher forcing. Model selection is performed using early stopping, which is determined when the BLEU score of the generated captions in the validation set does not increase for five consecutive epochs.[6] All models are trained using the Adam optimizer (Kingma and Ba, 2014): BUTD and BUTR use an initial learning rate of $1e-4$, $\beta_1 = 0.9$ and $\beta_2 = 0.999$, and gradients are clipped when they exceed 10.0. For the GradNorm optimizer (Chen et al., 2018) used in BUTR, the initial learning rate is 0.01 and the asymmetry is 2.5, although we find it beneficial to tune the latter when generating syntax.[7] Moreover, we find that taking the absolute value of the GradNorm weights for each loss in the renormalization step (given that our loss functions are by definition positive) leads to more stable multi-task training. $\mathcal{M}^2$-TRM first uses an initial learning rate of 1, $\beta_1 = 0.9$ and $\beta_2 = 0.98$, with a warm-up equal to $10,000$ iterations (Vaswani et al., 2017), and it is then fixed to $5e-6$ during CIDEr-D optimization. A batch size of 50 is used when training $\mathcal{M}^2$-TRM, while BUTD and BUTR are trained with batch sizes of 100. When adding syntactic forms, due to memory limitations, a batch size of 50 is always used (see Table 7 for a comparison of the planning approaches). All models are trained on one NVIDIA TitanX GPU in a shared cluster. See Table 8 for running times on the second held out dataset.

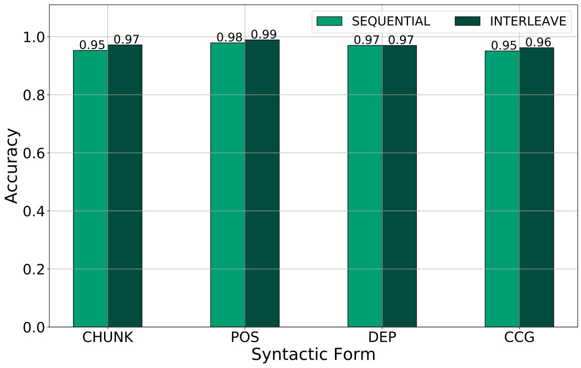

Figure 6: Validation accuracy of syntactic tags generated by BUTD using SEQUENTIAL and INTERLEAVE.

Inference At evaluation time, a maximum caption length of 20 is used when generating lexical forms only, and of 40 when also syntactic tags are generated. Notably, we use the default hyperparameters provided by the respective authors and do not fine-tune them when tasking the models with syntax generation. Differently from Nikolaus et al. (2019), rather than using a beam of 100 for BUTR only, we let all systems generate captions using such beam size as we found it to significantly improve compositional generalization of BUTD in our validation sets.[8]

B Further Analysis

Accuracy of syntactic forms We verify that a model can correctly predict syntactic forms, regardless of their granularity and the approach used to jointly modeling them with lexical forms. Figure 6 shows that, indeed, the accuracy of the generated syntactic tags, measured as the ratio of *sequences* matching the annotations from StanfordNLP, by BUTD is high, ranging between 95% and 99%. Note that we only evaluate accuracy of the SEQUENTIAL and INTERLEAVE approaches as there is no close relationship between syntactic and lexical sequences in the MULTI-TASK approach.

Qualitative examples Figure 5 shows more generated captions for images in the validation sets.

---

[5] Note that the size of each set is slightly different from the one in Nikolaus et al. (2019) as they used different tools for tokenizing and parsing, while we use a single framework to maximize its performance when parsing the captions (used to identify concept pair candidates).

[6] When present, syntactic forms are stripped away when computing evaluation metrics such as BLEU scores.

[7] Searched over the minimal grid: $\alpha \in \{1.5, 2.0, 2.5, 4.0\}$.

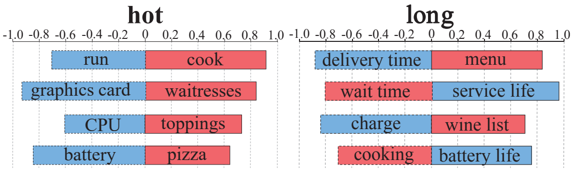
Abstract

Modelling a word's polarity in different contexts is a key task in sentiment analysis. Previous works mainly focus on domain dependencies, and assume words' sentiments are invariant within a specific domain. In this paper, we relax this assumption by binding a word's sentiment to its collocation words instead of domain labels. This finer view of sentiment contexts is particularly useful for identifying commonsense sentiments expressed in neutral words such as "big" and "long". Given a target (e.g., an aspect), we propose an effective "perturb-and-see" method to extract sentiment words modifying it from large-scale datasets. The reliability of the obtained target-aware sentiment lexicons is extensively evaluated both manually and automatically. We also show that a simple application of the lexicon is able to achieve highly competitive performances on the unsupervised opinion relation extraction task.

1 Introduction

Sentiments of words can be subtle. We are used to using the same word to express different emotions in different contexts. "Hot", for example, suggests a negative sentiment when commenting a computer hardware and a positive sentiment when commenting a pizza, even itself alone is identified without any general orientation. In these situations, it is the composition of a word, contexts, and commonsense carries an opinion. Automatically detecting such context dependent sentiments would strengthen both our understanding of implicit opinions in languages and improve existing sentiment analyses models, which is the main topic of this work.

To handle shifts of word sentiment, prior works studied how to adapt existing sentiment lexicons to new domains (Hamilton et al., 2016; Xing et al., 2019). By modeling differences and similarities of text topics, they can detect new sentiments of words as the domain changes. The basic assumption of those domain-level sentiment lexicons is that a word keeps a consistent sentiment within a domain. This assumption, however, might be strong for fine-granularity analyses of text sentiments: words (especially, neural words such as "long", "fast") could exhibit different orientations even in the same domain (Figure 1).



(a) (b)

Figure 1: Visualization of real-world commonsense sentiment of "hot" and "long" extracted by our framework. Red and blue indicate the targets in restaurant and electronic domains, respectively.

To collect more detailed information of a sentiment, another branch of works (aspect-based sentiment analysis (Pontiki et al., 2014; Zhou et al., 2020a,b), opinion relation extraction (Sun et al., 2017)) attempt find answers of "who express what opinion on which target" for opinion bearing texts. Existing solutions heavily rely on manual annotations and linguistic rules, which are either hard to scale-up or hard to be complete.

In this work, we study the task of extracting *target-aware* sentiment lexicons. An entry of such lexicon is a pair of a sentiment word and a target word, and their collocation expresses a sentiment. It improves existing domain-dependent lexicons by being more concrete and accurate on describing opinions. Departing from approaches adopted in existing aspect-based analyses, we aim to build context-aware lexicons by minimizing the requirement of annotations (e.g., only document-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 608–618
April 19 - 23, 2021.

level sentiment labels) and errors from handcrafted patterns. Our method starts from a target word (e.g., an aspect in product reviews), and extract sentiment words from its local context. The main strategy is to perturb context words and see how the sentiment of the target word changes: words with high influence on the target's sentiment hold high probability of forming a collocation with the target. We accomplish this by observing the behaviour of a well-trained document-level sentiment classifier when we change the contexts of the target word. Two types of perturbations are examined, *discrete perturbation* which only requires a black-box classifier, and *continuous perturbation* which asks for network gradients. We collect evidences of each candidate pair on large datesets to ensure the reliability of the final lexicon. Finally, the polarities of a lexicon entry can also be obtained by querying the sentiment classifier.

On two online product review domains (electronic and restaurant), we evaluate the extracted target-aware lexicon both manually and automatically. Quantitative and qualitative results show that the lexicons are reasonable to reflect common sentiment usage in each domain. As an application, we apply the lexicons to the task of unsupervised opinion relation extraction. The model performs significantly better than the baseline extractor, and even competitive with a recent supervised model on restaurant reviews. We summarize main contributions as follows,

- We propose to extend general purpose opinion lexicons with target constraints which provides a finer view on word-level sentiments.
- We develop a scalable approach to automatically mine target-aware sentiment lexicon from texts without extensive annotations and elaborated linguistic rules.
- Besides manual evaluations, we propose an automatic way to evaluate the extracted lexicon with downstream tasks.
- We are able to achieve significant improvements on unsupervised opinion relation extraction task with the help of the new lexicons.

2 Definitions and the Task

Let d be a document with sentences $s_1, s_2, \ldots, s_{|d|}$ and $y \in Y$ be the sentiment label of d. [1] Given a corpus $\mathcal{D} = \{(d_i, y_i)\}_{i=1}^{|\mathcal{D}|}$ and a target word t (e.g., screen, pizza), [2] our task is to extract *target-aware opinion words* of t only using document-level sentiment labels. Precisely, we aim to output a set of triples $(t, o, \mathbf{p})$, where o is an opinion word commonly used to comment target t and $\mathbf{p} \in \mathbf{R}^{|Y|}$ is the distribution of its sentiment orientation.

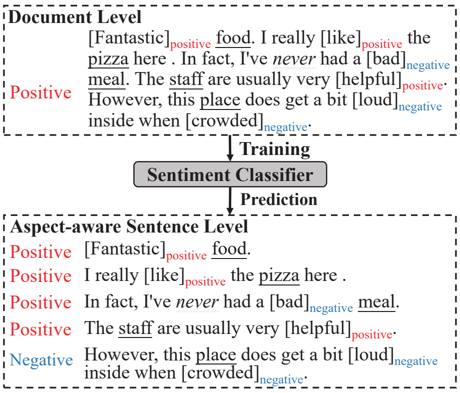


Figure 2: The process of distant supervision.

We develop the lexicon extractor in three steps. First, we build an approximate target-level sentiment classifier (Section 3) using document-level sentiment labels. Second, for each sentence s containing target t, we calculate how important a word $w \in s$ is on helping the classifier correctly predicting s's polarity (Section 4.1 and 4.2). We aggregate scores of w over all its occurrences to get its confidence of being an opinion word of t. Finally, we derive the polarity of w by querying the classifier with template sentences (Section 5).

3 Approximating Target-oriented Opinion

To identify target-aware opinion words, our key approach is to inspect how the opinion of a target changes when its context words change. Hence, it is crucial to know the polarity of a target in documents. However, annotations in D are document-level: for a document, its sentiment label expresses overall sentiments for all targets in the document, rather than a specific one. For example, the restaurant review in Figure 2 talks about 5 targets, each of them is commented by different opinion words with different polarities. In one of our datasets, 93% of documents contain multiple sentences (6 in average), and more than 82% contain multiple targets (7 in average). Therefore, directly using

---

[1] We use the 5-level label set $Y = \{1, 2, 3, 4, 5\}$ (the larger a number, the more positive it represents).

[2] Here we mainly focus on online reviews, but the methods could be applied to other sentiment-bearing texts.

document-level sentiment labels could be inappropriate for target-level analyses. On the other hand, it is quite expensive to annotate target-level sentiments, and existing datasets are far from enough for a robust commonsense opinion extractor.

To deal with this problem, we borrow the idea of distant supervision (Mintz et al., 2009): if a document is labelled as positive, at least one sentence (target) in it is positive. By seeing a large amount of positive documents, a classifier may be able to generalize patterns of their positive sentences, thus may help finding sentence-level (target-level) opinions. Here we simply build a document-level sentiment classifier, and apply it on sentences to get pseudo target-level sentiment labels (for simplicity, we assume one sentence contains one target). Advanced distant supervision models could also be applied, but we find this simple method preforms quite well in our experiments.

To build the sentiment classifier, we fine-tune BERT (Devlin et al., 2019) on $\mathcal{D}$ to encode domain specific semantics and augment it with a sentiment prediction task to encode sentiment information. For a document d, we feed its word sequence into BERT and obtain a vector representation $\mathbf{d} = \mathrm{BERT}(d)$, then we apply a $\mathrm{softmax}$ operator on $\mathbf{d}$ to get the probability of its sentiment $P(y|d)$,

$$P(y|d) = \mathrm{softmax}(W_c\mathbf{d} + b_c), \tag{1}$$

where W_c, b_c are new parameters for the sentiment classification task. The loss function is the cross-entropy between the predicted probability and the true label,

$$L = -\frac{1}{|\mathcal{D}|}\sum_{i=1}^{|\mathcal{D}|} \log P(y_i|d_i). \tag{2}$$

For each sentence s containing t, we apply above classifier to predict pseudo sentiment label y_p of s. In the following sections, we will rely on the set $S_t = \{(s, y_p)|t \in S\}$ to extract target-aware opinion words of t.

4 Importance Scores

We propose two score functions for measuring a context word w's influence on the target-oriented sentiment: one is *discrete perturbation* which only requires outputs of the sentiment classifier, another is *continuous perturbation* which needs network gradients. They are also called model-free and model-based methods, respectively. Both of them are simple and easy to compute given the trained model, and thus suitable for large-scale collective analyses.

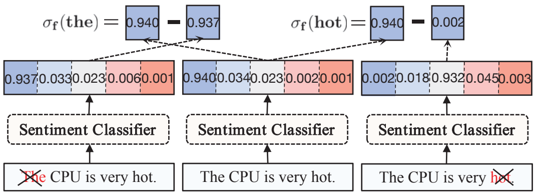

Figure 3: The possibility of the sentence is super negative changed from 0.940 to 0.002 when the word "hot" is deleted.

4.1 Discrete Perturbation

A well-trained sentiment classifier should correctly capture correlations between sentence words and sentence polarities. Intuitively, an opinion word (of the target) would have high influence on the sentiment distribution $P(y_p|s)$. For example, in Figure 3, "hot" is more informative than "The" for predicting the sentence's negative label.

In order to see whether a word w affects $P(y_p|s)$, we perturb the sentence s by removing w from it (denoted by s_{-w}) and examine the output differences,

$$\sigma_f(w, s) = P(y_p|s) - P(y_p|s_{-w}).$$

The larger $\sigma_f(w, s)$ is, the more $P(y_p|s_{-w})$ changes, and the more important w for getting the right sentiment label. We will use $\sigma_f(w, s)$ as an indicator of target-aware opinion words, and aggregate them on $\mathcal{D}$. Let $S_t^w \subseteq S_t$ be the set of sentences which t and w co-occur, we average $\sigma_f(w, s)$ on S_t^w to get the model-free importance score $\sigma_f(w)$,

$$\sigma_f(w) = \log P(w|t)\frac{1}{|S_t^w|}\sum_{s \in S_t^w} \sigma_f(w, s). \tag{3}$$

In order to reduce the affect of noise and rare language usage, we take co-occurrence statistic into account: a target-aware opinion word should co-occur with the target often. Therefore, the average score is empirically scaled with their co-occurrence probability $P(w|t) = \frac{|S_t^w|}{|D|}$.

The score $\sigma_f(w)$ is model-free in the sense that we don't need to know details of the sentiment classifier and only inquire the difference of outputs when the input sentence is perturbed. Hence, though we use the BERT-based classifier here, we can use any other off-the-shelf sentiment classifiers (e.g., pre-trained models with different training objectives, multi-task learned classifiers, etc.) to further enrich (or constrain) the score.

4.2 Continuous Perturbation

Besides the discrete perturbation setting, we could also utilize the full classification model to identify target-aware opinion words. In this continuous perturbation setting, we ask the same question of how the sentiment prediction will change when we perturb sentence words. However, instead of perturbing them discretely (i.e., removing a word), we can perform continuous perturbations on word vectors (Goodfellow et al., 2015).

Let $L(y_p, s, \mathbf{w}) = -\log P(y_p|s)$ be the loss on sentence s and $\mathbf{w}$ is the word vector of w. If we slightly perturb $\mathbf{w}$ to $\mathbf{w}'$ with $\|\mathbf{w}' - \mathbf{w}\| \leq \varepsilon$, we can bound the absolute change of the loss function using the first-order approximation of $L(y_p, s, \mathbf{w})$,

$$\begin{aligned}
&|L(y_p, s, \mathbf{w}') - L(y_p, s, \mathbf{w})| \\
&\approx |\nabla_{\mathbf{w}} L(y_p, s, \mathbf{w})^T (\mathbf{w}' - \mathbf{w})| \\
&\leq \|\nabla_{\mathbf{w}} L(y_p, s, \mathbf{w})\| \|\mathbf{w}' - \mathbf{w}\| \\
&\leq \varepsilon \|\nabla_{\mathbf{w}} L(y_p, s, \mathbf{w})\|.
\end{aligned}$$

The magnitude of the gradient's norm $\|\nabla_{\mathbf{w}} L(y_p, s, \mathbf{w})\|$ could be a sign of how sensitive the sentiment label is with respect to w: to get the right prediction we will prefer not to perturb those words with large gradient norms. Therefore, a large gradient norm may also indicate an opinion words of the target. Define

$$\sigma_b(w, s) = \frac{1}{g^* - g_*} \left(\|\nabla_{\mathbf{w}} L(y_p, s, \mathbf{w})\| - g_* \right),$$

where $g^* = \max_{s \in S_t^w} \|\nabla_{\mathbf{w}} L(y_p, s, \mathbf{w})\|$, $g_* = \min_{s \in S_t^w} \|\nabla_{\mathbf{w}} L(y_p, s, \mathbf{w})\|$ are the maximum and minimum gradient norm in S_t^w, which help normalizing $\sigma_b(w, s)$ into $[0, 1]$.

Similar to Equation 3, we collect all $\sigma_b(w, s)$ in S_t^w and scale their average with co-occurrence probability. The model-based score of w is defined as,

$$\sigma_b(w) = \log P(w|t) \frac{1}{|S_t^w|} \sum_{s \in S_t^w} \sigma_b(w, s). \qquad (4)$$

Finally, the computation of both discrete perturbation and continuous perturbation could be done efficiently using auto-gradient tools. The discrete perturbation setting requires a forward process of the network, while the continuous perturbation setting needs an additional backward computation. We also note that the "perturb-and-see" strategy behind both scores characterizes the relation between opinion words and the target only through the sentiment label, which is an indirect way. As a consequence, though the scores could recognize "big" implies a negative opinion on "battery", it could also identify "not" in "the battery is not big" as an important word for the positive opinion. In practice, we could filter out such cases by rules, but how to explicitly handle semantic composition in importance scores would be an important future work.

5 Polarity Inference

Given the importance scores of words with respect to t, we can rank them accordingly and take the top-k words as t's opinion lexicon. As the final step, we are left to determine the polarity of an opinion word o. We accomplish this by building template sentences which try to carry the semantic like "what opinion on which target". We call these sentences *template* which will be use to probe the sentiment classifier's knowledge on (t, o)'s polarity.

Formally, define $\mathcal{T}$ to be a set of templates, each template $\tau \in \mathcal{T}$ takes an opinion word and a target as input, outputs a natural language sentence $\tau(t, o)$. Here, we use the following two templates,

- $\tau(t, o) =$ "The t is o." (e.g., $\tau(\text{battery}, \text{big}) =$ "The battery is big.").

- $\tau(t, o) =$ "o t." (e.g., $\tau(\text{battery}, \text{big}) =$ "big battery.").

By feeding $\tau(t, o)$ into the sentiment classifier, we obtain $P(y_p|\tau(t, o))$, and the polarity distribution $\mathbf{p}$ of (t, o) is averaged over all templates,

$$\mathbf{p} = \frac{1}{|\mathcal{T}|} \sum_{t \in \mathcal{T}} P(y|\tau(t, o)) \qquad (5)$$

6 Experimental Results and Analyses

We wish to evaluate the merit of our target-aware sentiment lexicon in this section. We first introduce the experimental setup in Section 6.1. Then, we design detail experiments to answer the following key questions.

	Electronic						Restaurant					
	P@5		P@10		P@20		P@5		P@10		P@20	
	$\mathcal{L}$	$\mathcal{L}_c$	$\mathcal{L}$	$\mathcal{L}_c$	$\mathcal{L}$	$\mathcal{L}_c$	$\mathcal{L}$	$\mathcal{L}_c$	$\mathcal{L}$	$\mathcal{L}_c$	$\mathcal{L}$	$\mathcal{L}_c$
PMI	0.292	0.176	0.284	0.190	0.287	0.178	0.260	0.132	0.260	0.138	0.273	0.149

Table 1: The results of human evaluation on $\mathcal{L}$ and $\mathcal{L}_c$ over electronic and restaurant. DP and CP mean discrete perturbation and continuous perturbation, respectively.

- **Q1 Can we trust our target-aware sentiment lexicon?** To evaluate the quality of the extracted lexicon, we test the performance with both manual evaluation (Section 6.2) and automatic downstream task (Section 6.3).

- **Q2 Useful or not?** As an application, we apply our lexicon into unsupervised opinion extraction task in Section 6.4.

- **Q3 Do we really understand our model?** In Section 6.5, to investigate the insight of commonsense sentiment mined from the texts, we visualize several real-world examples.

6.1 Experimental Setup

We conduct experiments to validate the effectiveness of our approach on two widely different domains: electronic and restaurant, taken from Amazon dataset[3] and Yelp Challenge 2015[4]. We obtain the target set from SemEval'14, SemEval'15, and SemEval'16 for convenience [5].

The extracted target-aware sentiment lexicon ($\mathcal{L}$) can be divided into target-aware general sentiment lexicon ($\mathcal{L}_g$) and commonsense sentiment lexicon ($\mathcal{L}_c$). $\mathcal{L}_g$ means the opinion words in $\mathcal{L}$ that are in general lexicon and $\mathcal{L}_c$ means the opinion words in $\mathcal{L}$ that are not in general lexicon. Here, we use the general lexicon from (Hu and Liu, 2004) to filter the general sentiment words and obtain the commonsense lexicon. This general lexicon contains around 6800 positive and negative opinion words or sentiment words for the English language.

We adopt $\mathrm{BERT}_{\mathrm{base}}$ as the basis for all experiments. Adam (Kingma and Ba, 2015) is adopted as the optimizer with learning rate 5e-5 for fine-tuning and sentiment classification.

6.2 Human Evaluation

To evaluate the quality of the target-aware sentiment lexicon, we test its performance through human evaluation. For quantitative evaluation, we sample 50 targets with top-20 opinion words in each domain to investigate the performance of $\mathcal{L}$ and $\mathcal{L}_c$. Finally, we obtain 3122 and 2877 (t, o) pairs after filtering repetitive pairs for electronic and restaurant, respectively. We ask ten annotators to label them to make sure each pair is marked with three times. Then, we obtain the label through voting. We calculate the Krippendorff's alpha coefficient (Krippendorff, 2011) to measure the inter-annotator agreement of the manual annotation. The value is 0.850 and 0.702 for restaurant and electronic, which indicates the high agreement of the labeled data.

Table 1 reports the results of the human evaluation. The pointwise mutual information (PMI) measure (Hamilton et al., 2016; Church and Hanks, 1990) is adopted as the baseline to compare with, which applied to each target t w.r.t. each word w. We adopt the precision of top-k (e.g., 5, 10, and 20) to measure the performance of the methods across both $\mathcal{L}$ and $\mathcal{L}_c$. From this table, we observe that: **First**, both our discrete perturbation and continuous perturbation algorithms perform much better than PMI. Additionally, in the restaurant domain, our model obtains more than 90% precision for $\mathcal{L}$. These indicate the great effectiveness of capturing target-aware sentiment words and commonsense sentiment words. **Second**, the discrete perturbation method often has higher precision than continuous perturbation method, but the combination of them (Discrete+Continuous Perturbation) [6] obtains the best results in most cases. It suggests that the discrete perturbation and the continuous perturbation settings may focus on different types of opinion words.

---

[4] https://www.yelp.com/dataset/challenge

[5] Here we use the targets from existing datasets, but the targets could be extracted automatically through existing work (Poria et al., 2014) or be inputted by users.

[6] Here we simply calculate the average score of them, but different weights can be used.

	Electronic	Restaurant
Original	93.82	91.64
Random-based Deleting	90.49	88.13
Lexicon-based Deleting	$84.77^{\dagger\ddagger}$	$80.67^{\dagger\ddagger}$

Table 2: The results of downstream task: sentiment analysis via **Strategy 1**. The marker † and ‡ refer to p-values < 0.05 when "original" and "random-based deleting" compare with "lexicon-based deleting".

6.3 Downstream Tasks

Besides human evaluation, we also automatically evaluate our commonsense sentiment lexicon $\mathcal{L}_c$ with downstream tasks. Here we examine document-level sentiment analysis. In particular, for each domain, we sample 3500 documents which do not contain any general sentiment lexicon words but have obvious opinion orientations on electronic and restaurant ("Original"). Then we perform sentiment classification on the dataset with $\mathcal{L}_c$ using two strategies.

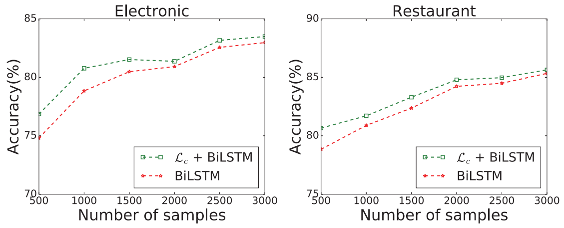
Strategy 1 For each sample in "Original", we remove opinion words which appear in our $\mathcal{L}_c$, and test the performance of sentiment classification using a well-trained sentiment classifier (Section 3). Note that we only use the top-100 opinion words to make sure only fewer than five words are being deleted. To show the effectiveness of our lexicon, we compare our model with removing words randomly with the same rate (Table 2). We find that removing the words in $\mathcal{L}_c$ performs significantly worse than both the original and random removing. It indicates that our method can capture the commonsense opinion words effectively.

Strategy 2 We apply our commonsense lexicon as extra knowledge to enhance a sentiment classification model. Here, we study the standard BiLSTM-based classifier: a BiLSTM is used to encode sentences, the last hidden vector of a sentence is adopt for classification. To inject our extracted lexicon $(t, o, \mathbf{p})$, we concatenate $\mathbf{p}$ to the input of BiLSTM if t and o occur. We sample 1000 and 500 instances from previous 3500 samples as the training and test set. To validate the effectiveness of each model components, we also show ablation test results. Table 3 shows the results. We have the following observations.

- Our commonsense lexicon $\mathcal{L}_c$ can significantly improve the performance of sentiment classification. $\mathcal{L}_c$ + BiLSTM outperforms basic BiLSTM, while the model with PMI is even worse than BiLSTM. We also find the results of the discrete perturbation and continuous perturbation method are similar, and both of them can improve the results of sentiment classification.

	Electronic	Restaurant
BiLSTM	78.84	80.89
$\mathcal{L}_c$ + BiLSTM	$80.77^{\triangle}$	$81.71^{\triangle}$
$\mathcal{L}_c$ + BiLSTM - $\mathbf{p}$	79.56	81.11
$\mathcal{L}_c$ + BiLSTM (PMI)	78.75	80.63
$\mathcal{L}_c$ + BiLSTM (w/o DP)	80.11	81.45
$\mathcal{L}_c$ + BiLSTM (w/o CP)	80.01	81.50
$\mathcal{L}_c$ + BiLSTM (w/o DS)	79.57	80.94

Table 3: The results of sentiment analysis via **Strategy 2**. The marker $^{\triangle}$ refers to p-values < 0.05 comparing with "BiLSTM". DP and CP mean discrete perturbation and continuous perturbation, respectively. DS represents distant supervision.



(a) (b)

Figure 4: The results of sentiment analysis with different sample number.

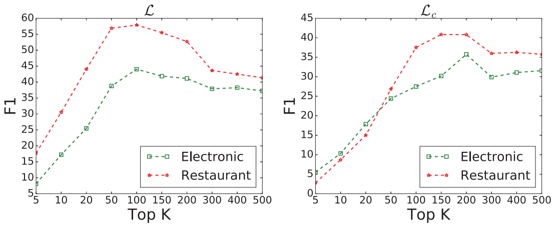
- $\mathcal{L}_c$ + BiLSTM performs better than the corresponding model without distant supervision, which indicates our distant supervision can capture the target information effectively. To further verify the effectiveness of distant supervision, we also randomly select 200 samples from the set S_t and evaluate them with three annotators by voting. The accuracy is 80.5% and 82% for 5-class classification over electronic and restaurant domains. Additionally, there are 71% and 65% of the samples have different polarities with their document-level label, and the accuracy of these samples is 80.99% and 81.54% in electronic and restaurant domains. These indicate our distant supervision can learn the target-oriented sentiment effectively.

- Compared with $\mathcal{L}_c$ + BiLSTM - $\mathbf{p}$ (which takes whether a word is an opinion word as feature), $\mathcal{L}_c$ + BiLSTM obtains better results. It suggest that polarity inference might be reasonable to infer the polarities of (t, o) pairs.

Additionally, to investigate the influence of sample numbers, we draw the results with different sample numbers in Figure 4. We can find that the

	Electronic			Restaurant		
	P	R	F1	P	R	F1
Rule-based	50.13	33.86	40.42	58.14	42.71	47.39
Ours	46.12	42.13	44.04	53.93	62.47	57.89
LSTM	55.71	57.53	56.52	57.46	64.96	60.87

Table 4: The results of opinion extraction. Note that LSTM is a supervised method.



(a) (b)

Figure 5: The results of unsupervised opinion extraction with different top-k via $\mathcal{L}$ and $\mathcal{L}_c$.

fewer samples, the more improvement by our commonsense lexicon.

6.4 Application (Unsupervised Opinion Extraction)

To answer **Q2**, we apply our lexicon into unsupervised opinion relation extraction. We test our lexicon on two datasets[7]: electronic and restaurant, which are released by (Fan et al., 2019), who labeled the opinion words towards the given target.

To investigate the performance of the target-aware sentiment lexicon $\mathcal{L}$, we perform unsupervised opinion extraction on the whole dataset. Table 4 reports the experimental results. We compare our method with two methods: 1) rule-based method (Hu and Liu, 2004) use the distance and POS tags to determine the opinion words; 2) supervised LSTM was proposed by (Liu et al., 2015). We use the results reported in (Fan et al., 2019) here. From this table, we observe: **First**, our $\mathcal{L}$ performs significantly better than the rule-based method even without using any rules or human annotations. **Second**, our unsupervised method is comparable with the supervised method (e.g., LSTM) in Restaurant. Additionally, we explore the influence of top-k in Figure 5 (a). We can find that top-100 is recommended for $\mathcal{L}$ in our experiments.

To verify our method can extract commonsense opinion words accurately, we also evaluate our $\mathcal{L}_c$ on the samples without general words. From Figure 5 (b), we can find that $\mathcal{L}_c$ achieves 40% F1 on the restaurant domain. Considering that we don't include any general sentiment words, we think the result is quite promising.

6.5 Case Studies

To investigate the insight of commonsense sentiment mined from texts, we show several real-world examples in electronic and restaurant in this section. We present some interesting discoveries through in-depth analysis as follows.

We explore the sentiment polarity of different targets with the same opinion word here. As shown in Figure 1, we draw the targets w.r.t. opinion words "hot" and "long". We obtain the following interesting findings. **First**, our model can detect the commonsense sentiment in the corpus effectively. For example, our model can find that "hot" is a common-used collocation for "pizza", "CPU", and "battery", and it expresses a positive sentiment for "pizza", while it represents a negative sentiment for "CPU" and "battery". **Second**, domain-dependent sentiment words and their orientations are insufficient, and both the target and the opinion words are essential. For example, "long" has a positive polarity for "battery life" and negative sentiment for "charge" even both "battery life" and "charge" are in the electronic domain.

The opinion words most related to the given target (top-10) in $\mathcal{L}$ and $\mathcal{L}_c$ are shown in Table 5. From this table, we obtain the following discoveries. **First**, our method captures not only the general opinion words but also the commonsense opinion words. **Second**, as mentioned in Section 4.2, though the scores could recognize "fast" expresses a positive opinion on "response", it also identifies the words are important for sentiment but not opinion words, such as "no", "not" and "never". In practice, we could filter out such cases by rules, but how to explicitly handle semantic composition in importance scores would be an important future work.

From Table 5, we observe that $\mathcal{L}$ and $\mathcal{L}_c$ for different targets are quite different. To investigate whether the common-used opinion words for different targets are different, we measure it by,

$$\text{div} = \frac{1}{|T|(|T|-1)} \sum_{\substack{i,j=0 \\ i \neq j}}^{|T|} 1 - \frac{|\mathcal{L}^{t_i} \cap \mathcal{L}^{t_j}|}{|\mathcal{L}^{t_i} \cup \mathcal{L}^{t_j}|} \qquad (6)$$

where T is the set of targets in our dataset, t_k is the k-th target in T and $\mathcal{L}^{t_k}$ means the sentiment lexicon of t_k. The value of div is 0.65 and 0.90 (0.89

and 0.96) for $\mathcal{L}$ and $\mathcal{L}_c$ over restaurant (electronic). All these indicate that commonsense lexicon $\mathcal{L}_c$ is more diverse than general lexicon $\mathcal{L}_g$ over different targets. In addition, the commonly used general opinion words and commonsense sentiment words are different for different targets.

7 Related Work

Domain adaptation has been studied for a long time in the field of sentiment analysis (Wu et al., 2017; Choi and Cardie, 2009; Cambria et al., 2018; Zhou et al., 2020c). We mainly summarize the related work about lexicon domain adaptation that aims to build a domain-specific sentiment lexicon (Ofek et al., 2016; Vo and Zhang, 2016; Hamilton et al., 2016). In (Hamilton et al., 2016), authors inferred the orientation of words from general opinion words by building a graph for each domain. Xing et al. (2019) judged the word polarity via a document-level sentiment classifier. However, it is time-consuming for they have to retrain the model for each word after changing the polarity randomly. Moreover, these existing methods mainly focus on the domain-level, while the sentiment polarities of some words depend on their opinion targets (Liu and Zhang, 2012). It is essential to predict the sentiment in target-level by integrating both target and opinion words.

The most related work to us is (Zhao et al., 2012). Zhao et al. (2012) focused on inferring the polarity of a binary tuple of a polarity word and a target via search engine, while target-aware opinion words extraction is not fully explored. To take the target into account, Wu et al. (2019) proposed to construct a target-specific sentiment lexicon. However, both NLP preprocessing pipelines (e.g., parsing, POS tagging) and linguistic rules are integrated into their algorithm. Different from them, we first extract the target-aware commonsense opinion words via pre-trained models, which learned rich commonsense knowledge hidden in human languages. Then, we predict the sentiment polarity of target and opinion word pair through a probing strategy. We focus on building context-aware lexicons by minimizing the requirement of annotations and handcrafted external resources.

To take the target into account, Wu et al. (2019) proposed to construct a target-specific sentiment lexicon. However, both NLP preprocessing pipelines (e.g., parsing, POS tagging) and linguistic rules are integrated into their algorithm. Available resources like general sentiment lexicon and thesaurus are also made used. Since it is not easy to apply on different domains, we develop a framework to automatically mine aspect-aware commonsense sentiment from texts without extensive annotations and elaborated linguistic rules.

Pre-trained models (e.g., ELMo (Peters et al., 2018), GPT (Radford et al., 2019), BERT (Devlin et al., 2019)) have achieved great success in NLP recently. By exploring a large number of open domain texts, pre-trained models are able to encode rich semantic information hidden in human languages and thus provide new powerful tools for knowledge mining and extraction (Davison et al., 2019; Petroni et al., 2019). Since the commonsense opinions are closely related to human commonsense and background knowledge, we adopt pre-trained language models to mine the commonsense sentiment from texts automatically.

Gradient-based methods (Goodfellow et al., 2015) have been widely applied into computer version and NLP (Zeiler and Fergus, 2014; Liang et al., 2018). The gradient-based approach is also used to understand the decisions of the text classification models from the token level (Li et al., 2016; Alikaniotis et al., 2016). In addition, Rei et al. (2018)

adopted gradient-based approach to detect the important tokens in the sentence via the sentence-level label. In this paper, we design a continuous perturbation algorithm to discover the target-aware opinion words using the gradient.

8 Conclusion

In this paper, we propose a framework for automatic target-aware sentiment mining from texts without manual annotations or linguistic rules. We evaluate the proposed framework on two large-scale online review domains: restaurant and electronic with both manual checking and automatic downstream tasks. We also achieve significant improvements by applying the opinion lexicon to the task of unsupervised opinion relation extraction. To investigate the insight of commonsense sentiment mined from the texts, we visualize several real-world examples and analyze them in-depth. The extensive experimental results demonstrate the excellent performance in building a target-aware sentiment lexicon.

Abstract

Quality estimation aims to measure the quality of translated content without access to a reference translation. This is crucial for machine translation systems in real-world scenarios where high-quality translation is needed. While many approaches exist for quality estimation, they are based on supervised machine learning requiring costly human labelled data. As an alternative, we propose a technique that does not rely on examples from human-annotators and instead uses synthetic training data. We train off-the-shelf architectures for supervised quality estimation on our synthetic data and show that the resulting models achieve comparable performance to models trained on human-annotated data, both for sentence and word-level prediction.

1 Introduction

The adoption of Machine Translation (MT) has been increasing in areas ranging from government and finance, to even social media due to the substantial improvements achieved from Neural Machine Translation (NMT). However, even with improved performance, translation quality is not consistent across language pairs, domains, and sentences. This can be detrimental to end-user's trust and can cause unintended consequences arising from poor translations. Thus, having metrics to assess the quality of translated content is crucial to ensure that only high-quality translations are provided to end-users or downstream tasks. Quality Estimation (QE) metrics aim to predict translation quality without access to reference translations (Blatz et al., 2004; Specia et al., 2009, 2013).

State-of-the-art QE techniques have leveraged MT systems and language-specific human annotations as supervision, including direct assessment and post-editing (Kepler et al., 2019a; Fonseca et al., 2019; Sun et al., 2020). However, these annotations are costly and time-consuming, particularly for word-level QE, where each token needs a label.

Some unsupervised approaches take inspiration from statistical MT (Popović, 2012; Moreau and Vogel, 2012; Etchegoyhen et al., 2018) or apply uncertainty quantification (Fomicheva et al., 2020) for QE. However, their performance is inferior to that of supervised models. In related areas such as automatic post-editing, parallel data has been used to create synthetic post-editing data (Negri et al., 2018), however this technique only compares machine-translated sentences to references. Our approach augments MT errors with additional errors via masked language model rewriting.

We leverage noisy, mined comparable sentences obtained by weakly-supervised techniques (El-Kishky et al., 2020b). These noisy bitexts have been mined from a variety of domains such as Wikipedia (Schwenk et al., 2019a) and large web-crawls (Schwenk et al., 2019b; El-Kishky et al., 2020a; El-Kishky and Guzmán, 2020) and have been shown to be an invaluable source of training data for NMT models. Using this data is crucial to avoid data leakage between a trained NMT model and the data we use to create synthetic QE data. For each source-target sentence pair from the mined data, we apply an MT system to generate a candidate translation of the source sentence. Additionally we rewrite each target reference sentence using a masked language model to introduce errors. These two approaches generate two alternative "translations" of the source sentence. We then produce pseudo-labels for each token in these translations by edit distance alignment to the original reference sentence. This results in each translated word being pseudo-labelled as correct or incorrect, which is our synthetic QE training data. Analogously, sentence-level training data is derived as the proportion of incorrect words per sentence.

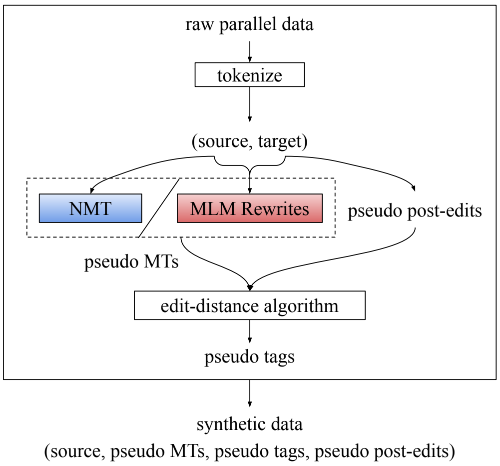

Figure 1: The pipeline to synthesize data for QE from comparable mined data.

Our **main contributions** are: (i) We explore a simple technique to effectively generate synthetic data for QE that allows for both word-level and sentence-level estimation (ii) we demonstrate that our technique performs comparably to off-the-shelf models trained on human-annotated data.

2 QE Task Description

Word-level QE has been mainly framed as the task of predicting which words in the translation need to be post-edited. As such, word-level QE aims to assign a tag for each word and gap between words in a machine-generated translation as *correct*, i.e., the word does not need editing, or *incorrect*, i.e., the words should be substituted, deleted, or inserted (tags for gaps) (Specia et al., 2020).

For word-level, we denote the tag of each word in a translation as $m_t \in \{\texttt{OK}, \texttt{BAD}\}$, where $t \in [1, T]$ and T is the length of the translation. Also, we denote the tag of each gap between two words (including the beginning and the end) as $g_t \in \{\texttt{OK}, \texttt{BAD}\}$, where $t \in [1, T+1]$.

In traditional QE, data is collected by first translating source sentences using an MT model. Second, experts post-edit these translations. Third, the post-edits and machine translations are aligned in such a way that induces the minimum edit distance between the tokens of each. Finally, each m_t is labelled as `BAD` if it should be deleted or substituted and each g_t is labelled as `BAD` if at least a word should be inserted there. Sentence-level QE labels can be generated by computing the Human-targeted Translation Error Rate (HTER) (Snover and Brent, 2001; Snover et al., 2006), which is the minimum ratio of edit operations needed to fix the translation to the number of its tokens. We explore the possibility to skip the costly human post-editing process by proposing a data synthesis pipeline, which we then test on human labelled data.

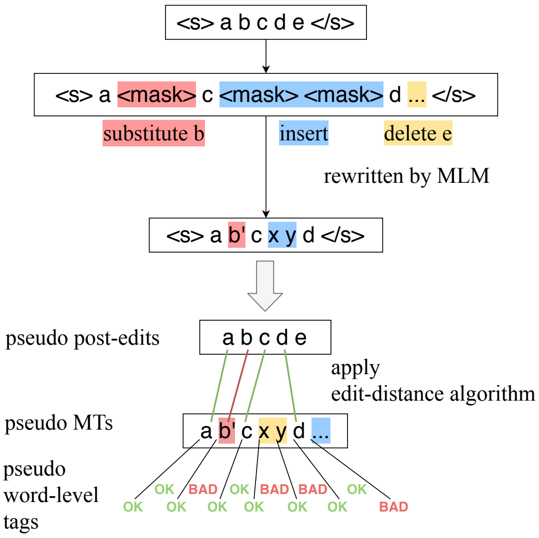

Figure 2: The rewriting process by text-infilling using a masked language model.

3 Approach to Data Synthesis

As depicted in Figure 1, we synthesize data from mined Wikipedia datasets, where each example consists of a *(source, target)* sentence pair.

We create candidate translations of source sentences in two ways: For the first approach, we apply the *NMT* model to translate each source sentence. For the second approach, we rewrite each reference target sentence using a masked language model (MLM), as shown in the *MLM Rewrites* block in Figure 1. The two approaches create two forms of translations. Then, by treating target sentences as if they were post-edited data (*pseudo post-edits*), we identify errors in each candidate translation by looking at the insertions, deletions, and substitutions between the references and generated translations.

Neural Machine Translation. For the first approach to generating synthetic data, we use a pre-trained NMT model to create translations. The NMT model is the same model that was used to generate translations in the supervised data; the architecture is a standard transformer as used in (Vaswani et al., 2017; Ott et al., 2019). The process of creating synthetic QE data first involves translating each source sentence using this model and taking the output as a translation which will

Data	English-German			English-Chinese		
	size	MT bad (%)	Gap bad (%)	size	MT bad (%)	Gap bad (%)
Human annotation	7K	27.8	4.7	7K	54.2	8.4
NMT	459K	38.2	5.7	189K	49.5	6.8
MLM (word-QE)	459K	40.7	2.9	189K	53.9	8.6
MLM (sent-QE)	459K	43.1	3.3	189K	49.9	2.7

Table 1: Statistics of annotated and synthetic (NMT and MLM) data.

later be used to generate the synthetic labels. When decoding, we apply a beam of 5 following the NMT models available in Fomicheva et al. (2020) to generate a candidate translation. Next, we take the mined reference target sentence and treat it as a pseudo post-editing of the machine translation.

We then compute the edit distance between MTs and pseudo post-edits. The resulted edit operations are the pseudo tags, which consist of word tags m_t and gap tags g_t. This process is illustrated in Algorithm 1.

Algorithm 1: DataSynthesis-NMT

```
Input: pairs (source, target) from mined data,
       pretrained NMT model
Output: (MTs, pseudo tags)
for each pair (source, target) do
    MTs = NMT(source)
    $\{m_t\}_{t=1}^{T}$, $\{g_t\}_{t=1}^{T+1}$ = edit_distance(MTs, target)
    pseudo tags = ($\{m_t\}_{t=1}^{T}$, $\{g_t\}_{t=1}^{T+1}$)
    return (MTs, pseudo tags)
```

Rewriting by Masked Language Model (MLM). Our second approach to creating synthetic QE training data is to introduce errors by rewriting target sentences. We inject these errors by performing *text-infilling* (Zhu et al., 2019; Lewis et al., 2019). As displayed in Figure 2, we perform text-infilling by applying three operations: (1) randomly substituting a proportion of tokens with a `<mask>` token, (2) deleting consecutive tokens, and (3) inserting additional consecutive `<mask>` tokens. We determine the lengths of consecutive deletions and insertions by drawing them from a Poisson distribution with mean $\lambda = 1$ shifted by 1 to avoid zero-length insertions or deletions. We then use a pre-trained masked language model (MLM) supplied with the source sentence as input to infill the masked reference sentence. We select multilingual BERT (Devlin et al., 2019) as it is pre-trained on Wikipedia which is in-domain to our test set. We present the target-rewriting approach in detail in Algorithm 2.

In Section 4, we will investigate the performance of QE models trained on NMT-based synthetic data, rewriter-based synthetic data, and a two-model ensemble where each model is trained on a different form of synthetic data.

Algorithm 2: DataSynthesis-Rewriting

```
Input: pairs $(S, W)$:=(source, target) from mined
       data, pretrained MLM
Input: $P_s$, $P_d$, $P_i$ as the probabilities of substitution,
       deletion, and insertion
Output: (pseudo MTs, pseudo tags)
for each pair $(S, W)$ do
    $W'$ = randomly mask tokens in $W$ by $P_s$
    $D$ = randomly mark deletion in $W'$ by $P_d$
    $W'$ = randomly delete a text span from marks $D$
      in $W'$ (length~ $Poisson(\lambda = 1) + 1$)
    $I$ = randomly mark insertion in $W'$ by $P_i$
    $W'$ = randomly insert contiguous masks from
      marks $I$ in $W'$ (length~ $Poisson(\lambda = 1) + 1$)
    rewrites = MLM_fills_in_masks($S$, $W'$)
    $\{m_t\}_{t=1}^{T}$, $\{g_t\}_{t=1}^{T}$ = edit_distance(rewrites, $W$)
    pseudo tags = ($\{m_t\}_{t=1}^{T}$, $\{g_t\}_{t=1}^{T+1}$)
    return (rewrites, pseudo tags)
```

4 Experiments and Results

We focus on data released by the WMT20 shared task on QE for predicting post-editing effort, which includes English-to-German (En-De) and English-to-Chinese (En-Zh) word-level data and their sentence-level HTER (Specia et al., 2020).[1] As the human-annotated data is sampled from Wikipedia, we choose to synthesize data from WikiMatrix (Schwenk et al., 2019a), which consists of mined Wikipedia parallel data from which we sample pairs with a LASER (Artetxe and Schwenk, 2019) margin score threshold of 1.06 to ensure high-quality pairs. We note that the original QE data is not a subset of WikiMatrix. The German and Chinese text were tokenized using the Moses[2] and Jieba[3] tokenizers, respectively. We list the statistics of the filtered Wikimatrix data as well as our resulting synthetic data in Table 1.

For the off-the-shelf QE model, we choose the

Table 3: Results of sentence-level HTER QE trained on human-annotated and synthetic data. For Pearson, positive improvement is better while for MAE & RMSE negative is better. We report improvement comparing models trained with human-annotation vs our combined NMT+MLM synthetic data.

multi-task predictor-estimator model (Kim et al., 2017) implemented by OpenKiwi v0.1.3 (Kepler et al., 2019b). This was the top-performing architecture for QE at WMT19 (Kepler et al., 2019a; Fonseca et al., 2019). We train the predictor on parallel MT data provided by the WMT20 QE shared task. The predictor reads in words' contextualized word representations, the estimator passes these features through a 2-layer 125-dimension bidirectional LSTM (biLSTM) and then feeds the outputs into 1-layer linear word-level classifier. The first output of the biLSTM is also fed into a multi-layer perceptron to predict a sentence-level score. For multi-task learning, we train the model with both word- and sentence-level data.

For a fair comparison, we take the pre-trained predictor provided by the WMT20 QE shared task, fine-tune the whole model on the human annotated data, and compare results to those when fine-tuned on our synthetic data. We test by comparing model predictions and held-out human-annotated QE at word and sentence-level. At the word level, we measure QE performance with Matthew's Correlation Coefficient (MCC) (Matthews, 1975) (main metric), as well as F1 scores for BAD and OK tags. At the sentence-level, we measure the sentence-level Pearson's correlation (Benesty et al., 2009), mean absolute error (MAE) and Root-mean-square deviation (RMSE).

As shown in Table 2, for word-level QE,[4] the model trained on synthetic data generated from NMT translations performs comparably to the same model trained on the original 7k human-annotated post-edits. This suggests that having human annotators post-edit each translation to create training data may be unnecessary and using reference sentences is good enough. The model trained on the MLM rewriting synthetic data generally under-performs compared to NMT generated data on MCC. However, we note that it performs better on F1 on OK tags. Therefore, we also ensemble the two models trained on each set of synthetic data through a linear combination. This yields comparable or better performance than the model trained on human-annotated data according to the main metric, MCC.

In Table 3, we compare the models trained on human-annotated data to our synthetic data for predicting sentence-level HTER scores. Again our synthetic data from NMT-generated translations outperforms MLM-rewriting data. Both underperform models trained on human-annotated data, but when combined they significantly improve and even outperform human-annotated for En-Zh. This once again suggests that the two forms of synthetic data are complementary and provide valuable signals for QE.

---

Table 4: Ablation study of synthetic data amounts.

5 Discussion

In this section, we further analyze how the quantity of synthetic data impacts performance, and what types of errors are represented in each of the MLM and NMT portions of the synthetic data.

5.1 Amount of Synthetic Data

As previously observed, the amount of synthetic data is orders of magnitude larger than the amount of human-annotated data. It begs the question: How much benefit do we get from smaller amounts of synthetic data? To analyze how the quantity of synthetic data affects QE performance, we conduct an ablation study of word-level QE.[5] As shown in Table 4, using only about half of the synthetic data generated (200k for En-De and 100k for En-Zh) is comparable to using the full generated set. While this suggests an upper-bound in performance to training on synthetic data. The ablation also suggests that this synthetic process can yield good performance with even a small amount of synthetic data.

5.2 Error Analysis

In addition to the performance, we posit that there are essential differences between MLM and NMT synthetic data. To test that, bilingual volunteers qualitatively analyzed the types of mistakes from MLM rewrites vs traditional NMT translations. The major reported differences in error types are:

1. Deletions from NMT translations appear more natural and do not destroy the sentence fluency. However, deletions in MLM rewrites are more destructive (e.g., “new york restaurants” vs “new restaurants” The semantics is changed).

2. Most incorrect insertions or deletions from NMT translations are due to re-ordering words. (e.g., “on 2020 in california” vs “in california on 2020”) However insertions with MLM-rewrites introduces seemingly random words.

3. NMT translations often have semantically distant word substitutions. However, MLM-rewrites tend to substitute similar words (e.g., “strong tea” vs “powerful tea”).

In summary, NMT translations and MLM-rewrites appear to generate different types of errors – the former leads to more subtle errors while the latter often introduces more catastrophic errors. Since a high-quality QE model should be able to detect both types of errors, ensembling the models trained on these two forms of synthetic data indeed is expected to outperform using only one form of synthetic data.

6 Conclusions and Future Work

In this work we devise a technique for building word and sentence-level QE models by creating synthetic training data. By training an off-the-shelf model on our synthetic data, we achieve performance comparable to and often better than training on human-annotated data. This technique for data synthesis can be invaluable if human annotation is difficult to come-by, for example when dealing with low-resource scenarios.

This work can be extended in various ways. While we investigate the scenario of utilizing solely synthetic data, further work can study the effects of augmenting human-labeled data with synthetic data. Further work can analyze the efficacy of this technique into low-resource language pairs where such human-annotation is difficult to obtain. Additionally, instead of a simple MLM re-writer, adversarial training to generate and detect errors could provide more realistic synthetic data.

How Fast can BERT Learn Simple Natural Language Inference?

Yi-Chung Lin and **Keh-Yih Su**
Institute of Information Science
Academia Sinica, Taiwan
`{lyc,kysu}@iis.sinica.edu.tw`

Abstract

This paper empirically studies whether BERT can really learn to conduct natural language inference (NLI) without utilizing hidden dataset bias; and how efficiently it can learn if it could. This is done via creating a simple entailment judgment case which involves only binary predicates in plain English. The results show that the learning process of BERT is very slow. However, the efficiency of learning can be greatly improved (data reduction by a factor of 1,500) if task-related features are added. This suggests that domain knowledge greatly helps when conducting NLI with neural networks.

1 Introduction

Entailment judgment (Dagan et al., 2006; Marelli et al., 2014a) is a common test for *natural language inference* (NLI) (Camburu et al., 2018; Conneau et al., 2018) as it possesses the simplest form in related tasks such as question and answering (Bowman and Zhu, 2019). Also, SNLI dataset (Bowman et al., 2015) is frequently adopted for NLI evaluation because it is the first corpus to show the power of neural networks for the task that specifically targets NLI.

Recently, BERT (Devlin et al., 2019), XLNet (Yang et al., 2019), and RoBERTa (Liu et al., 2019) have all shown excellent performances on SNLI, surpassing even human performance (Gong et al., 2017). However, Tsuchiya (2018) and Gururangan et al. (2018) show that SNLI contains *hidden bias*. Also, deep neural networks (DNNs) have been shown to predominantly capture the *statistical irregularities* that go unnoticed by humans (Poliak et al., 2018); this surprisingly yields 69% accuracy on SNLI without being provided the associated *premise* (i.e., the required *supporting evidence*). Furthermore, some studies (Naik et al., 2018; McCoy et al., 2019; Jiang and Marneffe, 2019) have shown that BERT mainly conducts NLI with surface clues/patterns, but not those clues actually adopted by humans.

To the best of our knowledge, none of previous studies carefully removes the dataset bias, and then investigates how efficiently that BERT could learn NLI if the surface clues are *completely* removed. In this paper, we empirically study whether BERT is capable of learning NLI without surface clues/bias appearing in the dataset; and if it is, whether it can learn NLI efficiently. We carefully created absolutely unbiased datasets, in which the premises and hypotheses simply describe the relative position of two objects in plain English. That is, given a premise "*John is on the left side of Mary*" (abbreviated as a predicate "left(John, Mary)" from now on), the hypotheses predicates "left(John, Mary)", "left(Mary, John)" and "left(John, Helen)" should be labeled as *entailment*, *contradictory* and *neutral* respectively. Our experiment results show BERT is very slow in learning this simple NLI.

We then further study if the learning efficiency can be improved with domain knowledge (Gülçehre and Bengio, 2016). Inspired by Chen et al. (2017), we think whether two entities are *exactly the same* is quite crucial in making the above NLI. So, the task-related features, such as whether the first/second argument of the premise predicate exactly matches that of hypothesis, are fed into BERT. The obtained results show that such task-related features are able to greatly benefit BERT (reducing the data needed by a factor of 1,500), which is important as it is difficult to acquire enough data in many real-world applications.

Our main contributions are: (1) We are the first to quantitatively study how efficiently BERT can learn to conduct NLI without available surface clues/bias. (2) We design experiments to completely eliminate hidden bias while evaluating

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 626–633
April 19 - 23, 2021.

the inference capability of BERT. (3) We show that adding task-related features greatly enhances the learning efficiency of BERT.

2 Teaching BERT Binary Predicates

The sentence "*John is on the left side of Mary*" describes a positional relation between two people. For conciseness, it will be denoted by a binary predicate "left(John,Mary)" from now on, where "left" is the predicate name, "John" is the first argument and "Mary" is the second argument. We seek to determine how much data are required to teach BERT to truly understand this simple binary predicate (i.e., premise) and correctly judge that the hypothesis "left(Mary,John)" is contradictory and that the hypothesis "left(John,Helen)" is neutral. Besides, we also seek to determine whether BERT is also able to learn the antonymous predicate "right(·,·)", and judge that the hypothesis "right(Mary,John)" is entailed by the above premise.

2.1 Entity Names and Datasets

The arguments of the above binary predicates "left(·,·)" and "right(·,·)" actually can be the names of any objects. However, in this paper, we simply trained BERT with *personal names*. To avoid dividing a personal name into sub-words, we collected 1,696 male and female first names which appear in the vocabulary of the pre-trained "BERT-Base, Uncased" model (Devlin et al., 2019). These names were randomly partitioned into three sets: $\boldsymbol{\eta}_\mathbf{T}$, $\boldsymbol{\eta}_\mathbf{V}$ and $\boldsymbol{\eta}_\mathbf{E}$. The subscripts **T**, **V** and **E** indicate these name sets will be used for **T**raining, **V**alidation and **E**valuation respectively. Sets $\boldsymbol{\eta}_\mathbf{T}$ and $\boldsymbol{\eta}_\mathbf{V}$, which consist of 1,356 and 170 names respectively, are used to generate the training and validation datasets for fine-tuning BERT; and Set $\boldsymbol{\eta}_\mathbf{E}$, consisting of 170 names, is used to generate a dataset for evaluating the performance of BERT in understanding the predicates with personal names.

Furthermore, we also seek to ascertain whether the BERT model trained by the predicates with personal names also understands the predicates with names of other object types. Therefore, in addition to personal names, we also collected 30 common fruit and vegetable names to create an additional set $\mathbf{f}_\mathbf{E}$, which will be used to generate another dataset for performance evaluation.

We conduct a number of experiments on *recognizing textual entailment* (RTE) (Dagan et al., 2006; Marelli et al., 2014a) to study the learning curves of BERT in understanding binary predicates. In each experiment, four datasets—**Name-T**, **Name-V**, **Name-E** and **Fruit-E**—are created by filling experiment-specific templates with names randomly chosen from $\boldsymbol{\eta}_\mathbf{T}$, $\boldsymbol{\eta}_\mathbf{V}$, $\boldsymbol{\eta}_\mathbf{E}$ and $\mathbf{f}_\mathbf{E}$ respectively. The training set **Name-T** and the validation set **Name-V** are used to fine-tune the BERT model. The other two sets (**Name-E** and **Fruit-E**) are test sets. They are used to assess the performances of the BERT model. Each dataset is generated via iteratively and sequentially adding one entailment example, one contradictory example, and one neutral example until it reaches the desired size. Thus a dataset of a size 100 will consist of 34 entailment examples, 33 contradictory examples, and 33 neutral examples. The experiment-specific templates are described in the following sections.

2.2 One Simple Binary Predicate

We first conducted *EXP-SP* (SP: **S**imple **P**redicate) experiment to show if BERT can be taught to understand the simple binary predicate "left(·,·)". In this experiment, a template has the form "*premise* [s] *hypothesis*", where "[s]" is a separator token between the premise and the hypothesis. The templates are partitioned into entailment, contradictory, and neutral template sets. The entailment template set has only one template "left(x,y) [s] left(x,y)", where "left(x,y)" represents the token sequence "x is on the left side of y" and the variables x and y indicate the names to be filled in. Likewise, the contradictory template set has only one template "left(x,y) [s] left(y,x)". However, the neutral template set consists of four templates:

"left(x,y) [s] left(x,z)",
"left(x,y) [s] left(z,x)",
"left(x,y) [s] left(y,z)",
"left(x,y) [s] left(z,y)",

where the variable z indicates a name to be filled in. Names and templates were randomly selected during dataset creation. For example, when generating a neutral example for **Name-T**, we randomly chose one template from the neutral template set and randomly chose three distinct names (for variables x,y,z) from name set $\boldsymbol{\eta}_\mathbf{T}$. Obviously, the generated datasets do not have any hidden bias, as all examples share the same token sequence except the argument tokens which are randomly chosen. Therefore, no annotation

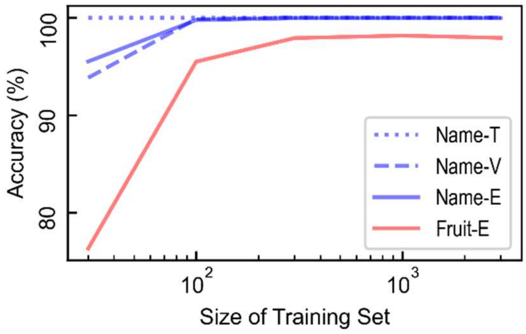

Figure 1: RTE performances of EXP-SP.

artifacts (Gururangan et al., 2018) in the data can provide hints for predicting final inference answers.

To quantitatively study the learning efficiency, we generated various **Name-T** sets with different sizes to study how much data would be required to teach BERT to understand the simple binary predicate "left(·,·)". We set **Name-V**, **Name-E**, and **Fruit-E** to 1,000 examples each. The solid lines in Figure 1 show that the accuracies of BERT on both test sets (i.e., **Name-E** and **Fruit-E**) increase when the training set size increases. However, even if we train BERT with 3,000 examples, it still cannot achieve 100% accuracy on the test sets. In fact, all sentences in this experiment have the form "*x is on the left side of y*", where x and y are object names. Therefore, only 6 different words could appear in the context of object names. In other words, given 3,000 examples, BERT still cannot fully understand the meaning of the context "*is on the left side of*".

Furthermore, training BERT to reach over 99% accuracy on **Name-E** requires 100 training examples. However, even given 30 times the training data, BERT is still unable to achieve 99% accuracy on **Fruit-E**. That is, BERT is not able to well generalize what it has learned from the examples with person names to the examples with fruit and vegetable names.

2.3 One Antonymous Predicate

Antonyms are frequently used in natural language and play an important role in natural language inference. Given the premise "*John is on the left side of Mary*", we can easily infer that the hypothesis "*Mary is on the right side of John*" is entailed by the premise, and that the hypothesis "*John is on the right side of Mary*" contradicts to the premise. This inference is easy for humans; but is it also easy for BERT? Therefore, we conducted another test named *EXP-AP* (AP: **A**ntonymous **P**redicate), a more complicated RTE experiment in which we added the antonymous predicate "right(·,·)".

In this experiment, the entailment template set consists of the following four templates:

$$\text{"left}(x,y)\text{ [s] left}(x,y)\text{"},$$
$$\text{"left}(x,y)\text{ [s] right}(y,x)\text{"},$$
$$\text{"right}(x,y)\text{ [s] right}(x,y)\text{"},$$
$$\text{"right}(x,y)\text{ [s] left}(y,x)\text{"}.$$

The contradictory template set consists of the following four templates:

$$\text{"left}(x,y)\text{ [s] left}(y,x)\text{"},$$
$$\text{"left}(x,y)\text{ [s] right}(x,y)\text{"},$$
$$\text{"right}(x,y)\text{ [s] right}(y,x)\text{"},$$
$$\text{"right}(x,y)\text{ [s] left}(x,y)\text{"}.$$

Likewise, the neutral template set consists of 16 templates. In brief, adding one antonymous predicate "right(·,·)" enlarges the number of all possible templates for dataset generation from 6 to 24.

The solid lines in Figure 2 are the accuracies on the test sets **Name-E** and **Fruit-E** in EXP-AP. For ease of comparison, we also plot the EXP-SP counterpart accuracies with dotted lines. Although EXP-AP uses only four times as many templates as EXP-SP uses, we must provide more than 30 times the training data (from 100 to 3,000) for BERT to reach 99% accuracy on **Name-E**. That is, by adding a single antonymous predicate, the RTE task of EXP-AP becomes 30 times harder than that of EXP-SP. It seems teaching BERT to "almost understand" two simple binary predicates requires more than 3,000 examples. This result could be also interpreted in another view. In the EXP-AP, the context of object names in each sentence is either "*is on the left side of*" or "*is on the right side of*". BERT requires 3,000 examples to learn the meanings of the 7 different words that appear in these two contexts. This represents a quite inefficient learning curve.

3 Incorporating Human Knowledge

The previous section showed that many training examples are needed to teach BERT for understanding two binary predicates "left(·,·)" and "right(·,·)" in a simple RTE task. It thus naturally leads to a conjecture that training BERT to understand more complicated predicates would very likely require infeasible amount of training

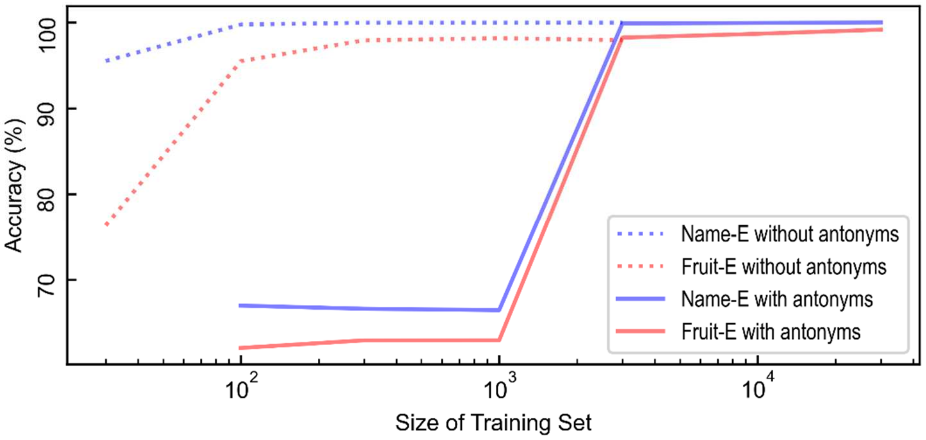

Figure 2: RTE performances of EXP-SP (dotted lines) and EXP-AP (solid lines).

data. One possible solution is to improve the learning curve of BERT by feeding it useful/obvious features that have been identified in human/domain knowledge.

3.1 Simple Features (SF)

Accordingly, we conducted an experiment *EXP-SF*, in which we appended features to the input tokens of EXP-AP to improve the learning curve. In this experiment, a template has the form “*premise* [s] *hypothesis* [s] *features*”. Obviously, humans directly compare the predicate name and the predicate arguments in the premise against their counterparts in the hypothesis. Perhaps this knowledge about which two fields should be compared would be helpful when training BERT on the EXP-AP task. Let N_{P} and N_{H} indicate the predicate names in the premise and the hypothesis respectively; also, let $A_{i,\mathrm{P}}$ and $A_{i,\mathrm{H}}$ indicate the i-th predicate arguments in the premise and the hypothesis respectively. In EXP-SF, every example in the datasets of EXP-AP will be augmented by the following three indicator features:

$$f_1 = I(N_{\mathrm{P}} = N_{\mathrm{H}}),$$
$$f_2 = I\big(A_{1,\mathrm{P}} = A_{1,\mathrm{H}}\big),$$
$$f_3 = I\big(A_{2,\mathrm{P}} = A_{2,\mathrm{H}}\big).$$

Here the indicator function $I(x)$ returns the word “*true*” if x is true and “*false*” if it is not. EXP-SF templates thus could be directly transformed from the corresponding EXP-AP templates. To illustrate this transformation, we show an entailment template, a contradictory template and a neutral template in EXP-SF as follows:

“left(x, y) [s] right(y, x) [s] false false false”,
“left(x, y) [s] left(y, x) [s] true false false”,
“left(x, y) [s] right(x, z) [s] false true false”.

The dashed lines in Figure 3 are the accuracies on the test sets **Name-E** and **Fruit-E** in EXP-SF. For ease of comparison, we also plot the counterpart accuracies of the baseline (i.e., EXP-AP) with dotted lines. The fact that the dashed lines lie far on the left side of the dotted lines indicates that much fewer training examples are required to train BERT after adding these three simple features [1]. This represents a greatly improved learning curve. Specifically, given merely 100 EXP-SF examples, BERT achieves over 99% accuracy on **Name-E**; in contrast, BERT requires 3,000 examples to surpass 99% accuracy on **Name-E** in EXP-AP. This represents a greatly improved learning curve.

3.2 Discriminant Features (DF)

In the previous experiment EXP-SF, features f_2 and f_3 do not precisely indicate the situation in which the arguments in the premise match the arguments in the hypothesis after swapping. For example, for both “left(x, y) [s] left(y, x)” and “left(x, y) [s] left(z, x)”, features f_2 and f_3 are all *false* in EXP-SF. However, the former is a contradictory case and the latter is a neutral case. We thus conducted the last experiment named *EXP-DF*, in which we replaced f_2 and f_3 with a

---

[1] Note that it does not matter which words were chosen to represent the values of features. We had randomly selected *fortification* and *mississippi* from BERT’s vocabulary to replace the words *true* and *false*. The experimental results were similar to those in Figure 3. In other words, the initial embeddings of the feature values are not crucial.

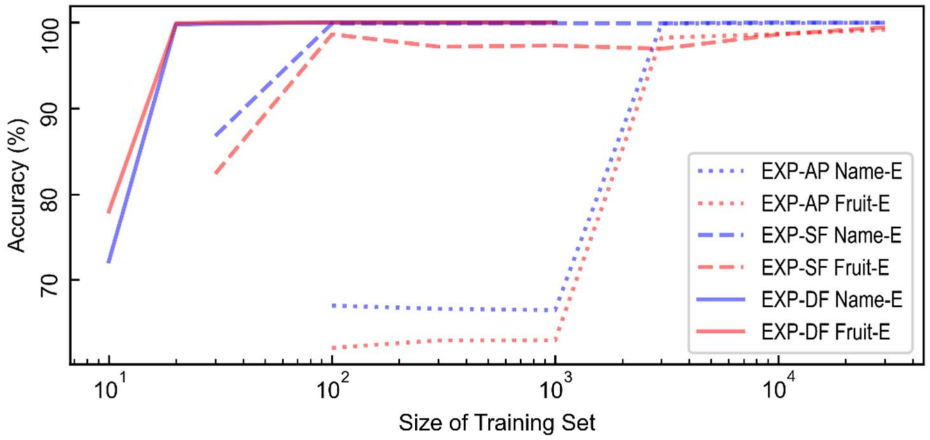

Figure 3: RTE performances of EXP-AP (dotted lines), EXP-SF (dashed lines) and EXP-DF (solid lines). More detailed data values are listed in Appendix.

new discriminant feature f_2'. Words *true*, *false* and *fuzzy* were used to indicate the three possible values of this new feature as follows:

$$f_2' = \begin{cases} true, & A_{1,\mathrm{P}} = A_{1,\mathrm{H}} \land A_{2,\mathrm{P}} = A_{2,\mathrm{H}}; \\ false, & A_{1,\mathrm{P}} = A_{2,\mathrm{H}} \land A_{2,\mathrm{P}} = A_{1,\mathrm{H}}; \\ fuzzy, & \text{otherwise.} \end{cases}$$

The solid lines in Figure 3 show that the learning curve of BERT is further improved after adopting this discriminant feature. Given only 20 EXP-DF examples, BERT achieves 99.9% accuracy on **Fruit-E**. However, in EXP-AP, 1,500 times amount of data (i.e., 30,000 examples) is needed for reaching 99.1% accuracy on **Fruit-E**.

4 Related Work

Dagan et al. (2006) first initiated the task of recognizing textual entailment about fifteen years ago. This task continued until 2011 (Bentivogli et al., 2011). Afterwards, conducting inference with BERT was studied in (Clark et al., 2019; Zellers et al., 2019; Tenney et al., 2019; Aken et al., 2019; Coenen et al., 2019; Michel et al., 2019).

On the other hand, various corpora have been created for conducting NLI for different purposes: SICK (Marelli et al., 2014b), SNLI (Bowman et al., 2015), MNLI (Willams et al., 2018), MPE (Lai et al., 2017), JOCI (Zhang et al., 2017), XNLI (Conneau et al., 2018), and SciTail (Khot et al., 2018). Corpora such as HOTPOTQA (Yang et al., 2018), Breaking-NLI (Glockner et al., 2018), CommonSense QA (Talmor et al., 2019), DROP (Dua et al., 2019) and ROPES (Lin et al., 2019) have also been created recently to evaluate more diverse and difficult NLI cases. However, all those corpora are not created for keeping the data absolutely unbiased. We believe using bias-free simple binary predicates would be more suitable to assess the true inference capability of BERT (or even other DNNs).

Recently, Ribeiro et al. (2020) proposed a new evaluation methodology, named CheckList, to check general linguistic capabilities of a given NLI model. They generated a large number of diverse test cases to identify the critical failures hidden behind state-of-art models. In contrast, our work mainly targeted the learning efficiency of BERT on various unbiased datasets. Besides, we also studied how adding useful domain-specific features would affect the learning curve of BERT.

5 Conclusion

This paper is the first quantitative study on whether BERT could really learn to conduct NLI without implicitly utilizing hidden dataset bias, and how quickly it does so if it could. We conduct experiments to evaluate the capability of BERT on making inference without hidden bias, and show that BERT learns NLI inefficiently even for a simple case. We further add task-related features to greatly enhance BERT's learning efficiency. As a result, it suggests that domain knowledge may be essential in conducting NLI with neural networks (at least for BERT).

Appendix

To reduce the performance assessment error, each accuracy reported in this paper is the mean of accuracies obtained from multiple simulations. Each simulation uses a unique random seed to fine-tune the BERT model. The accuracies plotted in the figures for EXP-AP, EXP-SF and EXP-DF are listed in the following table, where μ denotes the accuracy mean and σ denotes the standard deviation of μ.

Training Set Size	Test Set Accuracy (%)			
	Name-E		**Fruit-E**	
	μ	σ	μ	σ

GRIT: Generative Role-filler Transformers for Document-level Event Entity Extraction

Xinya Du **Alexander M. Rush** **Claire Cardie**
Department of Computer Science

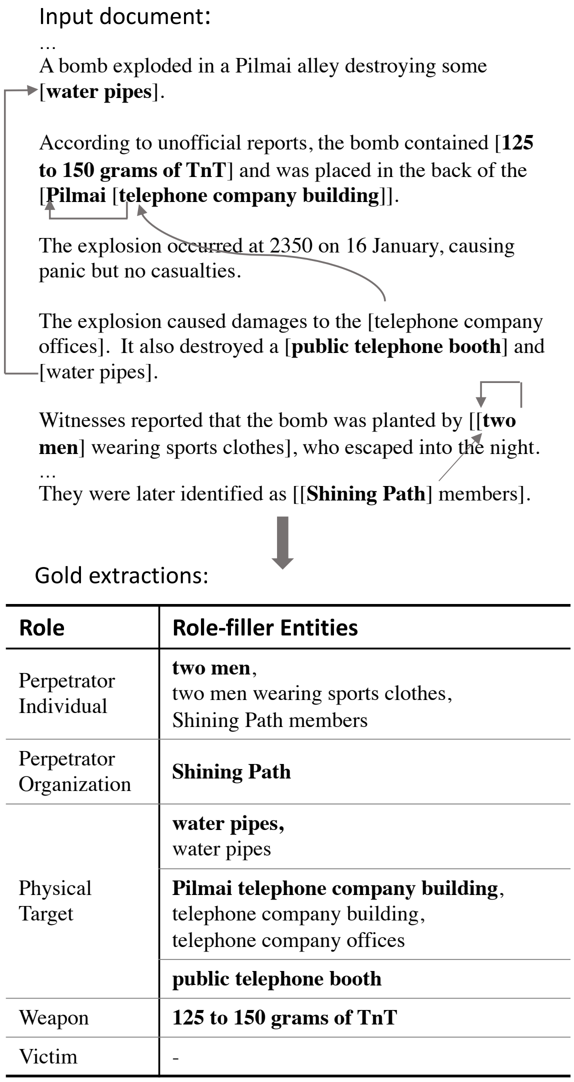
arush@cornell.edu

Abstract

We revisit the classic problem of document-level role-filler entity extraction (REE) for template filling. We argue that sentence-level approaches are ill-suited to the task and introduce a generative transformer-based encoder-decoder framework (GRIT) that is designed to model context at the document level: it can make extraction decisions across sentence boundaries; is *implicitly* aware of noun phrase coreference structure, and has the capacity to respect cross-role dependencies in the template structure. We evaluate our approach on the MUC-4 dataset, and show that our model performs substantially better than prior work. We also show that our modeling choices contribute to model performance, e.g., by implicitly capturing linguistic knowledge such as recognizing coreferent entity mentions.

1 Introduction

Document-level template filling (Sundheim, 1991, 1993; Grishman and Sundheim, 1996) is a classic problem in information extraction (IE) and NLP (Jurafsky and Martin, 2014). It is of great importance for automating many real-world tasks, such as event extraction from newswire (Sundheim, 1991). The complete task is generally tackled in two steps. The first step detects events in the article and assigns templates to each of them (template recognition); the second step performs role-filler entity extraction (REE) for filling in the templates. In this work we focus on the **role-filler entity extraction (REE)** sub-task of template filling (Figure 1).[1] The input text describes a bombing event; the goal is to identify the entities that fill any of the roles associated with the event (e.g., the perpetrator, their organization, the weapon) by extracting a descriptive "mention" of it – a string from the document.



Input document:

...
A bomb exploded in a Pilmai alley destroying some [**water pipes**].

According to unofficial reports, the bomb contained [**125 to 150 grams of TnT**] and was placed in the back of the [**Pilmai** [**telephone company building**]].

The explosion occurred at 2350 on 16 January, causing panic but no casualties.

The explosion caused damages to the [telephone company offices]. It also destroyed a [**public telephone booth**] and [water pipes].

Witnesses reported that the bomb was planted by [[**two men**] wearing sports clothes], who escaped into the night.
...
They were later identified as [[**Shining Path**] members].

Gold extractions:

Role	Role-filler Entities
Perpetrator Individual	**two men**, two men wearing sports clothes, Shining Path members
Perpetrator Organization	**Shining Path**
Physical Target	**water pipes,** water pipes
	Pilmai telephone company building, telephone company building, telephone company offices
	public telephone booth
Weapon	**125 to 150 grams of TnT**
Victim	-

Figure 1: Role-filler entity extraction (REE). The first mention of each role-filler entity is bold in the table and document. The arrows denote coreferent mentions.

In contrast to sentence-level event extraction (see, e.g., the ACE evaluation (Linguistic Data Consortium, 2005)), document-level REE introduces

---

[1] In this work, we assume there is one generic template for the entire document (Huang and Riloff, 2011, 2012).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 634–644
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

several complications. First, **role-filler entities must be extracted even if they never appear in the same sentence as an event trigger**. In Figure 1, for example, the WEAPON and the first mention of the telephone company building (TARGET) appear in a sentence that does not explicitly mention the explosion of the bomb. In addition, **REE is ultimately an entity-based task** — exactly one descriptive mention for each role-filler should be extracted even when the entity is referenced multiple times in connection with the event. The final output for the bombing example should, therefore, include just one of the "water pipes" references, and one of the three alternative descriptions of the PERPIND and the second TARGET, the telephone company building. As a result of these complications, end-to-end sentence-level event extraction models (Chen et al., 2015; Lample et al., 2016), which dominate the literature, are ill-suited for the REE task, which calls for models that encode information and track entities across a longer context.

Fortunately, neural models for event extraction that have the ability to model longer contexts have been developed. Du and Cardie (2020), for example, extend standard contextualized representations (Devlin et al., 2019) to produce a document-level sequence tagging model for event argument extraction. Both approaches show improvements in performance over sentence-level models on event extraction. Regrettably, these approaches (as well as most sentence-level methods) handle each candidate role-filler prediction in isolation. Consequently, they cannot easily **model the coreference structure required to limit spurious role-filler mention extractions**. Nor can they easily **exploit semantic dependencies between closely related roles** like the PERPIND and the PERPORG, which can share a portion of the same entity span. "Shining Path members", for instance, describes the PERPIND in Figure 1, and its sub-phrase, "Shining Path", describes the associated PERPORG.

Contributions In this work we revisit the classic but recently under-studied problem of document-level role-filler entity extraction problem and introduce a novel end-to-end generative transformer model — the "**G**enerative **R**ole-f**i**ller **T**ransformer" (**GRIT**) (Figure 2).

- Designed to model context at the document level, GRIT (1) has the ability to make extraction decisions across sentence boundaries; (2) is implicitly aware of noun phrase coreference structure; and (3) has the capacity to respect cross-role dependencies. More specifically, GRIT is built upon the pre-trained transformer model (BERT): we add a pointer selection module in the decoder to permit access to the entire input document, and a generative head to model document-level extraction decisions. In spite of the added extraction capability, GRIT requires no additional parameters beyond those in the pre-trained BERT.

- To measure the model's ability to both extract entities for each role, and implicitly recognize coreferent relations between entity mentions, we design a metric (CEAF-REE) based on a maximum bipartite matching algorithm, drawing insights from the CEAF (Luo, 2005) coreference resolution measure.

- We evaluate GRIT on the MUC-4 (1992) REE task (Section 3). Empirically, our model outperforms substantially strong baseline models. We also demonstrate that GRIT is better than existing document-level event extraction approaches at capturing linguistic properties critical for the task, including coreference between entity mentions and cross-role extraction dependencies.[2]

2 Related Work

Sentence-level Event Extraction Most work in event extraction has focused on the ACE sentence-level event task (Walker et al., 2006), which requires the detection of an event trigger and extraction of its arguments from within a single sentence. Previous state-of-the-art methods include Li et al. (2013) and Li et al. (2015), which explored a variety of hand-designed features. More recently, neural network based models such as recurrent neural networks (Nguyen et al., 2016; Feng et al., 2018), convolutional neural networks (Nguyen and Grishman, 2015; Chen et al., 2015) and attention mechanisms (Liu et al., 2017, 2018) have also been shown to help improve performance. Beyond the task-specific features learned by the deep neural models, Zhang et al. (2019) and Wadden et al. (2019) also utilize pre-trained contextualized representations.

Only a few models have gone beyond individual sentences to make decisions. Ji and Grishman (2008) and Liao and Grishman (2010) utilize event type co-occurrence patterns to propagate

---

[2] Our code for the evaluation script and models is at `https://github.com/xinyadu/grit_doc_event_entity` for reproduction purposes.

event classification decisions. Yang and Mitchell (2016) propose to learn within-event (sentence) structures for jointly extracting events and entities within a document context. Similarly, from a methodological perspective, our GRIT model also learns structured information, but it learns the dependencies between role-filler entity mentions and between different roles. Duan et al. (2017) and Zhao et al. (2018) leverage document embeddings as additional features to aid event detection. Although the approaches above make decisions with cross-sentence information, their extractions are still done the sentence level.

Document-level IE Document-level event role-filler *mention* extraction has been explored in recent work, using hand-designed features for both local and additional context (Patwardhan and Riloff, 2009; Huang and Riloff, 2011, 2012), and with end-to-end sequence tagging based models with contextualized pre-trained representations (Du and Cardie, 2020). These efforts are the most related to our work. The key difference is that our work focuses on a more challenging, and more realistic, setting: extracting **role-filler entities** rather than lists of role-filler mentions that are not grouped according to their associated entity. Also on a related note, Chambers and Jurafsky (2011), Chambers (2013), and Liu et al. (2019) work on *unsupervised* event schema induction and open-domain event extraction from documents. The main idea is to group entities corresponding to the same role into an event template.

Recently, there has also been increasing interest in cross-sentence/document-level relation extraction (RE). In the scientific domain, Peng et al. (2017); Wang and Poon (2018); Jia et al. (2019) study N-ary cross-sentence RE using distant supervision annotations. Luan et al. (2018) introduce SciERC dataset and their model rely on multi-task learning to share representations between entity span extraction and relations. Yao et al. (2019) construct an RE dataset of cross-sentence relations on Wikipedia paragraphs. Ebner et al. (2020) introduce RAMS dataset for multi-sentence argument *mention* linking, while we focus on entity-level extraction in our work. Different from work on joint modeling (Miwa and Bansal, 2016) and multi-task learning (Luan et al., 2019) setting for extracting entities and relations, through the generative modeling setup, our GRIT model *implicitly* captures (non-)coreference relations between noun phrases, without relying on the cross-sentence coreference and relation annotations during training.

Neural Generative Models with a Shared Module for Encoder and Decoder Our GRIT model uses one shared transformer module for both the encoder and decoder, which is simple and effective. For the machine translation task, He et al. (2018) propose a model which shares the parameters of each layer between the encoder and decoder to regularize and coordinate the learning. Dong et al. (2019) presents a new unified pre-trained language model that can be fine-tuned for both NLU and NLG tasks. Similar to our work, they also introduce different masking strategies for different kinds of tasks (see Section5).

3 The Role-filler Entity Extraction Task and Evaluation Metric

We base the REE task on the original MUC[3] formulation (Sundheim, 1991), but simplify it as done in prior research (Huang and Riloff, 2012; Du and Cardie, 2020). In particular, we assume that one generic template should be produced for each document: for documents that recount more than one event, the extracted role-filler entities for each are merged into a single event template. Second, we focus on entity-based roles with string-based fillers[4].

- Each *event* consists of the set of roles that describe it (shown in Figure 1). The MUC-4 dataset that we use consists of ∼1k terrorism events.
- Each *role* is filled with one or more entities. There are five such roles for MUC-4: perpetrator individuals (PERPIND), perpetrator organizations (PERPORG), physical targets (TARGET), victims (VICTIM) and weapons (WEAPON). These event roles represent the agents, patients, and instruments associated with terrorism events (Huang and Riloff, 2012).
- Each *role-filler entity* is denoted by a single descriptive *mention*, a span of text from the input document. Because multiple such mentions for each entity may appear in the input, the gold-standard template lists all alternatives (shown in Figure 1), but systems are required to produce just one.

---

[3] The Message Understanding Conferences were a series of U.S. government-organized IE evaluations.

[4] Other types of role fillers include normalized dates and times, and categorical "set" fills. We do not attempt to handle these in the current work.

Evaluation Metric The metric for past work on document-level role-filler *mentions* extraction (Patwardhan and Riloff, 2009; Huang and Riloff, 2011; Du and Cardie, 2020) calculates mention-level precision across all alternative mentions for each role-filler entity. Thus it is not suited for our problem setting, where entity-level precision is needed, where spurious entity extractions will get punished (e.g., recognizing "telephone company building" and "telephone company offices" as two entities will result in lower precision).

Drawing insights from the entity-based CEAF metric (Luo, 2005) from the coreference resolution literature, we design a metric (**CEAF-REE**) for measuring models' performance on this document-level **role-filler entity extraction** task. It is based on maximum bipartite matching algorithm (Kuhn, 1955; Munkres, 1957). The general idea is that, for each role, the metric is computed by aligning gold and predicted entities with the constraint that a predicted (gold) entity is aligned with at most one gold (predicted) entity. Thus, the system that does not recognize the coreferent mentions and use them for separate entities will be penalized in precision score. For the example in Figure 1, if the system extracts "Pilmai telephone company building" and "telephone company offices" as two distinct TARGETs, the precision will drop. We include more details for our CEAF-TF metric in the appendix.

4 REE as Sequence Generation

We treat document-level REE as a sequence-to-sequence task (Sutskever et al., 2014) in order to better model the cross-role dependencies and cross-sentence noun phrase coreference structure. We first transform the task definition into a source and target sequence.

As shown in Figure 2, the *source sequence* simply consists of the tokens of the original document prepended with a "classification" token (i.e., [CLS] in BERT), and appended with a separator token (i.e., [SEP] in BERT). The *target sequence* is the concatenation of target extractions for each role, separated by the separator token. For each role, the target extraction consists of the first mention's beginning (b) and end (e) tokens:

$$\begin{gathered} \text{<S>}\ e^{(1)}_{1_b}, e^{(1)}_{1_e}, \ldots\ \text{[SEP]} \\ e^{(2)}_{1_b}, e^{(2)}_{1_e}, \ldots\ \text{[SEP]} \\ e^{(3)}_{1_b}, e^{(3)}_{1_e}, e^{(3)}_{2_b}, e^{(3)}_{2_e}, \ldots\ \text{[SEP]} \\ \ldots \end{gathered}$$

Note that we list the roles in a fixed order for all examples. So for the example used in Figure 2, $e^{(1)}_{1_b}$, $e^{(1)}_{1_e}$ would be "two" and "men" respectively; and $e^{(3)}_{1_b}$, $e^{(3)}_{1_e}$ would be "water" and "pipes" respectively. Henceforth, we denote the resulting sequence of source tokens as $x_0, x_1, ..., x_m$ and the sequence of target tokens as $y_0, y_1, ..., y_n$.

5 Model: Generative Role-filler Transformer (GRIT)

Our model is shown in Figure 2. It consists of two parts: the encoder (left) for the source tokens; and the decoder (right) for the target tokens. Instead of using a sequence-to-sequence learning architecture with separate modules (Sutskever et al., 2014; Bahdanau et al., 2015), we use a single pretrained transformer model (Devlin et al., 2019) for both parts, and introduce no additional fine-tuned parameters.

Pointer Embeddings The first change to the model is to ensure that the decoder is aware of where its previous predictions come from in the source document, an approach we call "pointer embeddings". Similar to BERT, the input to the model consists of the sum of token, position and segment embeddings. However, for the position we use the corresponding source token's position. For example, for the word "two", the target tokens would have the identical position embedding of the word "two" in the source document. Interestingly, we do not use any explicit target position embeddings, but instead separate each role with a [SEP] token. Empirically, we find that the model is able to use these separators to learn which role to fill and which mentions have filled previous roles.

Our encoder's embedding layer uses standard BERT embedding layer, which applied to the source document tokens. To denote boundary between source and target tokens, we use sequence A (first sequence) segment embeddings for the source tokens, we use sequence B (second sequence) segment embeddings for the target tokens.

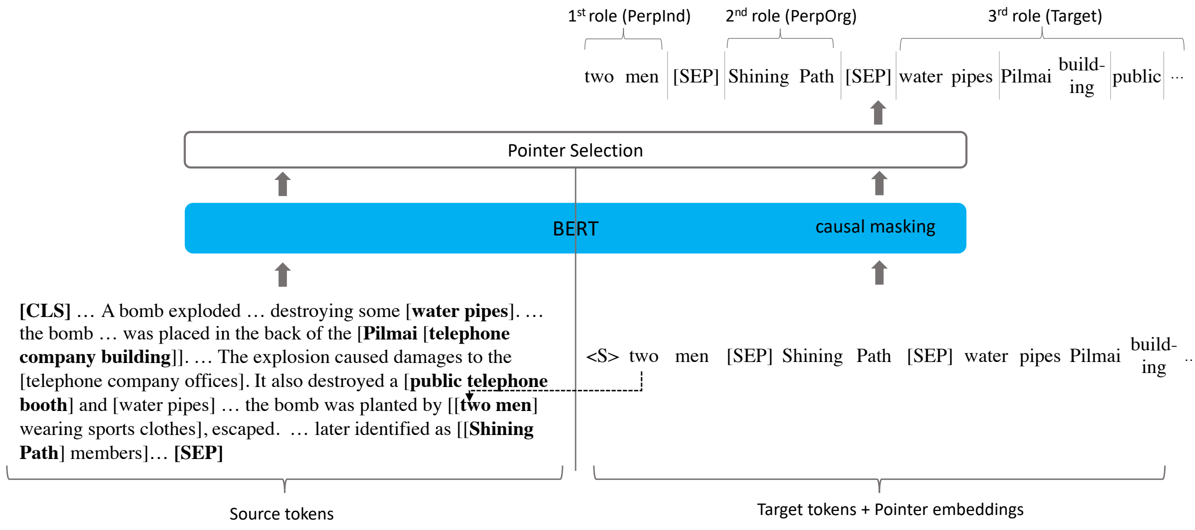


Figure 2: GRIT: generative transformer model for document-level event role-filler entity extraction. (Noun phrase bracketing and **bold** in the source tokens are provided for readability purposes and are not part of the source sequence.)

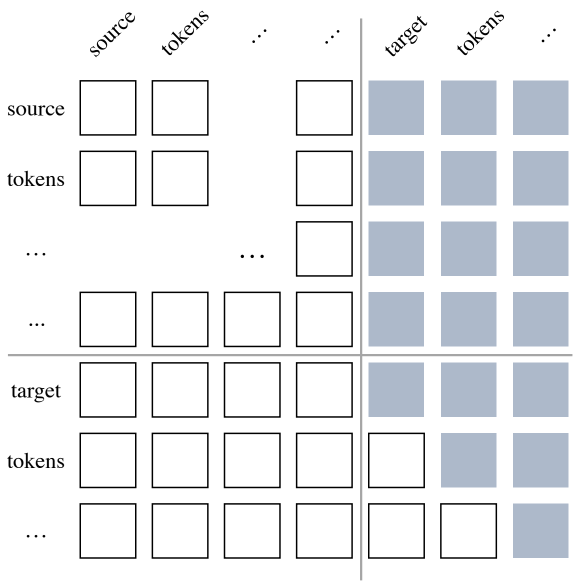

Figure 3: Partially causal masking strategy ($\mathbf{M}$). (White cell: unmasked; Grey cell: masked).

We pass the source document tokens through the encoder's embedding layer, to obtain their embeddings $\mathbf{x}_0, \mathbf{x}_1, ..., \mathbf{x}_m$. We pass the target tokens $y_0, y_1, ..., y_n$ through the decoder's embedding layer, to obtain $\mathbf{y}_0, \mathbf{y}_1, ..., \mathbf{y}_n$.

BERT as Encoder / Decoder We utilize one BERT model as both the source and target embeddings. To distinguish the encoder / decoder representations, we provide a partial causal attention mask on the decoder side.

In Figure 3, we provide an illustration for the attention masks – 2-dimensional matrix denoted as $\mathbf{m}$. For the source tokens, the mask allows full source self-attention, but mask out all target tokens. For $i \in \{0, 1, ..., m\}$,

$$\mathbf{M}_{i,j} = \begin{cases} 1, & \text{if } 0 \leq j \leq m \\ 0, & \text{otherwise} \end{cases}$$

For the target tokens, to guarantee that the decoder is autoregressive (the current token should not attend to future tokens), we use a causal masking strategy. Assuming we concatenate the target to the source tokens (the joint sequence mentioned below), for $i \in \{m + 1, ..., n\}$,

$$\mathbf{M}_{i,j} = \begin{cases} 1, & \text{if } 0 \leq j \leq m \\ 1, & \text{if } j > m \text{ and } j \leq i \\ 0, & \text{otherwise} \end{cases}$$

The joint sequence of source tokens' embeddings ($\mathbf{x}_0, \mathbf{x}_1, ..., \mathbf{x}_m$) and target tokens' embeddings ($\mathbf{y}_0, \mathbf{y}_1, ..., \mathbf{y}_n$) are passed through BERT to obtain their contextualized representations,

$$\begin{aligned} &\hat{\mathbf{x}}_0, \hat{\mathbf{x}}_1, ..., \hat{\mathbf{x}}_m, \hat{\mathbf{y}}_0 ..., \hat{\mathbf{y}}_n \\ &= \mathtt{BERT}(\mathbf{x}_0, \mathbf{x}_1, ..., \mathbf{x}_m, \mathbf{y}_0, ..., \mathbf{y}_n) \end{aligned}$$

Pointer Decoding For the final layer, we replace word prediction with a simple pointer selection mechanism. For target time step t ($0 \leq t \leq n$), we first calculate the dot-product between $\hat{\mathbf{y}}_t$ and $\hat{\mathbf{x}}_0, \hat{\mathbf{x}}_1, ..., \hat{\mathbf{x}}_m$,

$$z_0, z_1, ..., z_m = \hat{\mathbf{y}}_t \cdot \hat{\mathbf{x}}_0, \hat{\mathbf{y}}_t \cdot \hat{\mathbf{x}}_1, ..., \hat{\mathbf{y}}_t \cdot \hat{\mathbf{x}}_m$$

Then we apply softmax to $z_0, z_1, ..., z_m$ to obtain the probabilities of pointing to each source token,

$$p_0, p_1, ..., p_m = \text{softmax}(z_0, z_1, ..., z_m)$$

Test prediction is done with greedy decoding. At each time step t, argmax is applied to find the source token which has the highest probability. The predicted token is added to the target sequence for the next time step $t + 1$ with its pointer embedding. We stop decoding when the fifth [SEP] token is predicted, which represents the end of extractions for the last role.

In addition, we add the following decoding constraints,

- Tune probability of generating [SEP]. By doing this, we encourage the model to point to other source tokens and thus extract more entities for each role, which will help increase the recall. (We set the hyperparameter of downweigh to 0.01, i.e., for the [SEP] token $p = 0.01 * p$.)
- Ensure that the token position increase from start token to end token. When decoding tokens for each role, we know that mention spans should obey this property. Thus we eliminate those invalid choices during decoding.

6 Experimental Setup

We conduct evaluations on the MUC-4 dataset (1992), and compare to recent competitive end-to-end models (Wadden et al., 2019; Du and Cardie, 2020) in IE (Section 7). Besides the normal evaluation, we are also interested in how well our GRIT model captures coreference linguistic knowledge, and comparison with the prior models. In Section 8, we present relevant evaluations on the subset of test documents.

Dataset and Evaluation Metric The MUC-4 dataset consists of 1,700 documents with associated templates. Similar to (Huang and Riloff, 2012; Du and Cardie, 2020), we use the 1300 documents for training, 200 documents (`TST1+TST2`) as the development set and 200 documents (`TST3+TST4`) as the test set. Each document in the dataset contains on average 403.27 tokens, 7.12 paragraphs. In Table 1, we include descriptions for each role in the template.

We use the first appearing mention of the role-filler entity as the training signal (thus do not use the other alternative mentions during training).

Roles	Descriptions
PERPIND	A person responsible for the incident.
PERPORG	An organization responsible for the incident.
TARGET	A thing (inanimate object) that was attacked.
VICTIM	The name of a person who was the obvious or apparent target of the attack or who became a victim of the attack.
WEAPON	A device used by the perpetrator(s) in carrying.

Table 1: Natural Language Descriptions for Each Role.

We use CEAF-REE which is covered in Section 3 as the evaluation metric. The results are reported as Precision (P), Recall (R) and F-measure (F1) score for the micro-average for all the event roles (Table 4). We also report the per-role results to have a fine-grained understanding of the numbers (Table 2).

Baselines We compare to recent strong models for (document-level) information/event extraction. CohesionExtract (Huang and Riloff, 2012) is a bottom-up approach for event extraction that first aggressively identifies candidate role-fillers, and prune the candidates located in event-irrelevant sentences.[5] Du and Cardie (2020) propose *neural sequence tagging (NST)* models with contextualized representations for document-level role filler mentions extraction. We train this model with BIO tagging scheme to identify the first mention for each role-filler entity and its type (i.e., B-PerpInd, I-PerpInd for perpetrator individual). DYGIE++ (Wadden et al., 2019) is a span-enumeration based extraction model for entity, relation, and event extraction. The model (1) enumerates all the possible spans in the document; (2) concatenates the representations of the span's beginning & end token and use it as its representation, and pass it through a classifier layer to predict whether the span represents certain role-filler entity and what the role is. Both the NST and DYGIE++ are end-to-end and fine-tuned BERT (Devlin et al., 2019) contextualized representations with task-specific data. We train them to identify the first mention for each role-filler entity (to ensure fair comparison with our proposed model). Unsupervised event schema induction based approaches (Chambers and Jurafsky, 2011; Chambers, 2013; Cheung et al., 2013) are also able

---

[5] Instead of using feature-engineering based sentence classification to identify event-relevant sentences, we re-implement the sentence classifier with BiLSTM-based neural sequence model.

	PerpInd	PerpOrg	Target	Victim	Weapon
NST (Du and Cardie, 2020)	48.39 / 32.61 / 38.96	60.00 / 43.90 / 50.70	54.96 / 52.94 / **53.93**	62.50 / 63.16 / 62.83	61.67 / 61.67 / **61.67**
DyGIE++ (Wadden et al., 2019)	59.49 / 34.06 / 43.32	56.00 / 34.15 / 42.42	53.49 / 50.74 / 52.08	60.00 / 66.32 / 63.00	57.14 / 53.33 / 55.17
GRIT	65.48 / 39.86 / **49.55**	66.04 / 42.68 / **51.85**	55.05 / 44.12 / 48.98	76.32 / 61.05 / **67.84**	61.82 / 56.67 / 59.13

Table 2: Per-role performance scored by CEAF-REE (reported as P/R/F1, highest F1 for each role are boldfaced).

	$k = 1$	$1 < k \leq 1.25$	$1.25 < k \leq 1.5$	$1.5 < k \leq 1.75$	$k > 1.75$
NST (Du and Cardie, 2020)	63.83 / 51.72 / 57.14	57.45 / 38.57 / 46.15	60.32 / 49.03 / 54.09	64.81 / 50.00 / 56.45	66.67 / 51.90 / 58.36
DyGIE++ (Wadden et al., 2019)	**72.50** / 50.00 / 59.18	70.00 / 40.00 / 50.91	60.48 / 48.39 / 53.76	52.94 / 38.57 / 44.63	66.96 / 48.73 / 56.41
GRIT	65.85 / 46.55 / 54.55	**74.42** / 45.71 / 56.64	**73.20** / 45.81 / 56.35	**67.44** / 41.43 / 51.33	**69.75** / 52.53 / 59.93

Table 3: Evaluations on the subsets of documents with increasing number of mentions per role-filler entity. k denotes the average # mentions per role-filler entity. Results for each column are reported as Precision / Recall / F1. The highest precisions are boldfaced for each bucket.

Models	P	R	F1
CohesionExtract (Huang and Riloff, 2012)	58.38	39.53	47.14
NST (Du and Cardie, 2020)	56.82	**48.92**	52.58
DyGIE++ (Wadden et al., 2019)	57.04	46.77	51.40
GRIT	**64.19****	47.36	**54.50***

Table 4: Micro-average results (the highest number of each column is boldfaced). Significance is indicated with $^{**}(p < 0.01)$,$^{*}(p < 0.1)$ – all tests are computed using the paired bootstrap procedure (Berg-Kirkpatrick et al., 2012).

to model the coreference relations and entities at document-level, but have been proved to perform substantially worse than supervised models (Patwardhan and Riloff, 2009; Huang and Riloff, 2012). Thus we do not compare with them. We also experimented with a variant of our GRIT model – instead of always pointing to the same [SEP] in the source tokens to finish extracting the role-filler entities for a role, we use five different [SEP] tokens. During decoding, the model points to the corresponding [SEP] as the end of extraction for that role. This variant does not improve over the current best results and we omit reporting its performance.

7 Results

In Table 4, we report the micro-average performance on the test set. We observe that our GRIT model substantially outperforms the baseline extraction models in precision and F1, with an over 5% improvement in precision over DyGIE++.

Table 2 compares the models' performance scores on each role (PerpInd, PerpOrg, Target, Victim, Weapon). We see that, (1) our model achieves the best precision across the roles; (2) for the roles that come with entities containing more human names (e.g., PerpInd and Victim), our model substantially outperforms the baselines; (3) for the role PerpOrg, our model scores better precision but lower recall than neural sequence tagging, which results in a slightly better F1 score; (4) for the roles Target and Weapon, our model is more conservative (lower recall) and achieves lower F1. One possibility is that for role like Target, on average there are more entities (though with only one mention each), and it's harder for our model to decode as many Target entities correct in a generative way.

8 Discussion

How well do the models capture coreference relations between mentions? We also conduct targeted evaluations on subsets of test documents whose gold extractions come with coreferent mentions. From left to right in Table 3, we report results on the subsets of documents with increasing number (k) of possible (coreferent) mentions per role-filler entity. We find that: (1) On the subset of documents with only one mention for each role-filler entity ($k = 1$), our model has no significant advantage over DyGIE++ and the sequence tagging based model; (2) But as k increases, the advantage of our GRIT substantially increases – with an over 10% gap in precision when $1 < k \leq 1.5$, and a near 5% gap in precision when $k > 1.5$.

From the qualitative example (document excerpt and the extractions in Figure 4), we also observe our model recognizes the coreference relation between candidate role-filler entity mentions, while the baselines do not, which shows that our model is better at capturing the (non-)coreference relations between role-filler entity mentions. It also proves the advantage of a generative model in this setting.

[P1]... a bomb exploded at the front door of the [home of a peruvian army general], causing damages but no casualties. ... **[P2]** The terrorist attack was ..., by ... who hurled a bomb at the [home of general enrique franco], in the San ... **[P3]** The bomb seriously damaged the [general's [vehicle]], ... and those of [neighboring [houses]].

	Target
Gold Role-filler Entities	• home of peruvian army general, home of general enrique franco • vehicle, general's vehicle • houses, neighboring houses
NST	• home of peruvian army general • home of general enrique franco
DyGIE++	• home of peruvian army general • home of general enrique franco • houses
GRIT	• home of peruvian army general • houses

Figure 4: Our model implicitly captures coreference relations between mentions.

How well do models capture dependencies between different roles? To study this phenomenon, we consider nested role-filler entity mentions in the documents. In the example of Figure 1, "shining path" is a role-filler entity mention for PerpOrg nested in "two *shining path* members" (a role-filler entity mention for PerpInd). The nesting happens more often between more related roles (e.g., PerpInd and PerpOrg) – we find that 33 out of the 200 test documents' gold extractions contain nested role-filler entity mentions between the two roles.

In Table 5, we present the CEAF-REE scores for role PerpOrg on the subset of documents with nested roles. As we hypothesized beforehand, GRIT is able to learn the dependency between different roles and can learn to avoid missing relevant role-filler entities for later roles. The results provide empirical evidence: by learning the dependency between PerpInd and PerpOrg, GRIT improves the relative recall score on the subset of documents as compared to DyGIE++. On all the 200 test documents, our model is $\sim 2\%$ below DyGIE++ in recall; while on the 33 docs, our model scores much higher than DyGIE++ in recall.

	PerpOrg (all docs)	PerpOrg (33/200)
	P / R / F1	P / R / F1
NST	56.00 / 34.15 / 42.42	80.00 / 44.44 / 57.14
DyGIE++	60.00 / **43.90** / 50.70	61.54 / 35.56 / 45.07
GRIT	66.04 / 42.68 / 51.85	80.77 / **46.67** / 59.15

Table 5: Evaluation on the subset of documents that have nested role-filler entity mentions between role PerpInd and PerpOrg (highest recalls boldfaced).

...[[[**guerrillas**] of the [**FARC**] and the [**popular liberation army**]] (EPL)] attacked four towns in northern Colombia, leaving 17 guerrillas and 2 soldiers dead and 3 bridges partially destroyed. ...

	PerpInd	PerpOrg
Gold Role-filler Entities	• guerrillas, guerrillas of FARC and popular liberation army (EPL)	• EPL, popular liberation army • FARC
NST & DyGIE++	• guerrillas	-
GRIT	• guerrillas	• FARC • popular liberation army

Figure 5: Our model captures dependencies between different roles.

For the document in the example of Figure 5, our model correctly extracts the two role-filler entities for PerpOrg: "FARC" and "popular liberation army", which are closely related to the PerpInd entity "guerrilla". While DyGIE++ and NST both miss the entities for PerpOrg.

Decoding Ablation Study In the table below, we present ablation results based on the decoding constraints. These illustrate the influence of the decoding constraints on the our model's performance. The two constraints both significantly improve model predictions. Without downweighing the probability of pointing to [SEP], the precision increases but recall and F1 significantly drops.

	P	R	F1	Δ (F1)
GRIT	64.19	47.36	54.50	
− [SEP] downweigh	67.43	40.12	50.31	-4.19
− constraint on pointer offset	62.90	45.79	53.00	-1.50

Table 6: Decoding Ablation Study

Additional Parameters and Training Cost Finally we consider additional parameters and training time of the models: As we introduced previously, the baseline models DYGIE++ and NST both require an additional classifier layer on top of BERT's hidden state (of size H) for making the predictions. While our GRIT model does not require adding any new parameters. As for the training time, training the DYGIE++ model takes over 10 times longer time than NST and our model. This time comes from the DYGIE++ model requirement of enumerating all possible spans (to a certain length constraint) in the document and calculating the loss with their labels.

	additional params	training cost
DYGIE++	$2H(\#\text{roles} + 1)$	~20h
NST	$H(2\#\text{roles} + 1)$	~1h
GRIT	0	<40min

Table 7: Additional Parameters and Training Cost.

9 Conclusion

We revisit the classic and challenging problem of document-level role-filler entity extraction (REE), and find that there is still room for improvement. We introduce an effective end-to-end transformer based generative model, which learns the document representation and encodes the dependency between role-filler entities and between event roles. It outperforms the baselines on the task and better captures the coreference linguistic phenomena. In the future, it would be interesting to investigate how to enable the model to also do template recognition.

Abstract

Much research effort has been put to multilingual knowledge graph (KG) embedding methods to address the entity alignment task, which seeks to match entities in different language-specific KGs that refer to the same real-world object. Such methods are often hindered by the insufficiency of seed alignment provided between KGs. Therefore, we propose an incidentally supervised model, JEANS, which jointly represents multilingual KGs and text corpora in a shared embedding scheme, and seeks to improve entity alignment with incidental supervision signals from text. JEANS first deploys an entity grounding process to combine each KG with the monolingual text corpus. Then, two learning processes are conducted: (i) an *embedding learning process* to encode the KG and text of each language in one embedding space, and (ii) a self-learning based *alignment learning process* to iteratively induce the matching of entities and that of lexemes between embeddings. Experiments on benchmark datasets show that JEANS leads to promising improvement on entity alignment with incidental supervision, and significantly outperforms state-of-the-art methods that solely rely on internal information of KGs.[1]

1 Introduction

A multilingual knowledge base (KB) such as DBpedia (Lehmann et al., 2015), ConceptNet (Speer et al., 2017) and Yago (Mahdisoltani et al., 2015) stores multiple language-specific knowledge graphs (KGs) that express relations of many concepts and real-world entities. As each KG thereof is either extracted independently from monolingual corpora (Lehmann et al., 2015; Mahdisoltani et al., 2015) or contributed by speakers of the language (Speer et al., 2017; Mitchell et al., 2018), it is common for different KGs to constitute complementary knowledge (Bleiholder and Naumann, 2009; Bryl and Bizer, 2014). Hence, aligning and synchronizing language-specific KGs support AI systems with more comprehensive commonsense reasoning (Lin et al., 2019; Li et al., 2019b; Yeo et al., 2018), and benefit various knowledge-driven NLP tasks, including machine translation (Moussallem et al., 2018), narrative prediction (Chen et al., 2019) and dialogue agents (Sun et al., 2019a).

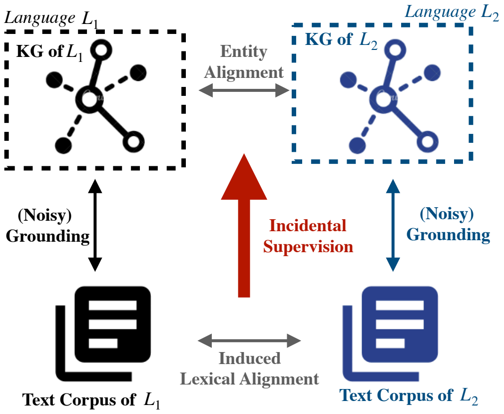

Figure 1: The learning framework of JEANS.

Learning to align multilingual KGs is a nontrivial task, as KGs with distinct surface forms, heterogeneous schemata and inconsistent structures easily cause traditional symbolic methods to fall short (Suchanek et al., 2011; Wijaya et al., 2013; Jiménez-Ruiz et al., 2012). Recently, much attention has been paid to methods based on multilingual KG embeddings (Chen et al., 2017a,b, 2018; Sun et al., 2017, 2018, 2019b; Zhang et al., 2019). Those methods seek to separately encode the structure of each language-specific KG in an embedding space. Then, based on some seed entity alignment, the entity counterparts in different KGs can be easily matched via distances or transformations of embedding vectors. The principle is

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 645–658
April 19 - 23, 2021.

that entities with relevant neighborhood information can be characterized with similar embedding representations. Such representations particularly are tolerant to the aforementioned heterogeneity of surface forms and schemata in language-specific KGs (Chen et al., 2017a; Sun et al., 2018, 2020a).

While multilingual KG embeddings provide a general and tractable way to align KGs, it still remains challenging for related methods to precisely infer the cross-lingual correspondence of entities. The challenge is that the seed entity alignment, which serves as the essential training data to learn the connection between language-specific KG embeddings, is often limitedly provided in KBs (Chen et al., 2018; Sun et al., 2018). Hence, the lack of supervision often hinders the precision of inferred entity counterparts, and affects even more significantly when KGs scale up and become inconsistent in contents and density (Pujara et al., 2017). Several methods also gain auxiliary supervision from profile information of entities, including descriptions (Chen et al., 2018; Yang et al., 2019; Zhang et al., 2019) and numerical attributes (Sun et al., 2017; Trsedya et al., 2019). However, such profile information is not available in many KGs (Speer et al., 2017; Mitchell et al., 2018; Bond and Foster, 2013), therefore causing these methods to be not generally applicable.

Unlike existing models that rely on internal information of KGs, we seek to create embeddings that incorporate both KGs and freely available text corpora, and exploit incidental supervision signals (Roth, 2017) from text corpora to enhance the alignment learning on KGs (Figure 1). In this paper, we propose a novel embedding model `JEANS` (**J**oint **E**mbedding Based Entity **A**lignment with **IN**cidental **S**upervision; 👖). Particularly, `JEANS` first performs a *grounding process* (Gupta et al., 2017; Upadhyay et al., 2018) to link entity mentions in each monolingual text corpus to the KG of the same language. Based on the KGs and grounded text in a pair of languages, `JEANS` conducts two learning processes, i.e. *embedding learning* and *alignment learning*. The embedding learning process distributes entities, relations and lexemes of each language in its embedding space, in which a KG embedding model and a language model for that language are jointly trained. This process seeks to leverage text contexts to help capture the proximity of entities. On top of that, alignment learning captures cross-lingual correspondence for entities and lexemes in a self-learning manner (Artetxe et al., 2018). Starting from a small amount of seed entity alignment, this process iteratively induces a transformation between language-specific embedding spaces, and infers more alignment of entity and lexemes at each iteration to improve the learning at the next one. Moreover, we also employ the closed-form Procrustes solution (Conneau et al., 2018) to strengthen alignment induction within each iteration. Experimental results on two benchmarks confirm the effectiveness of `JEANS` in leveraging incidental supervision, leading to significant improvement to entity alignment and drastically outperforming existing methods.

2 Related Work

We discuss relevant works in four topics. Each of them has a large body of work which we can only provide as a highly selected summary.

Entity alignment. Entity alignment in KBs has been a long-standing problem (Shvaiko and Euzenat, 2011). Aside from earlier approaches based on symbolic or schematic similarity of entities (Suchanek et al., 2011; Wijaya et al., 2013; Jiménez-Ruiz et al., 2012), more recent research addresses this task with multilingual KG embeddings. A representative method of such is MTransE (Chen et al., 2017a). MTransE jointly learns two model components. There are a translational embedding model (Bordes et al., 2013) that distributes the facts in language-specific KGs into separate embeddings, and a transformation-based alignment model that maps between entity counterparts across embedding spaces.

Following the general principle of MTransE, later approaches are developed through the following three lines. One is to incorporate various *embedding learning techniques* for KGs. Besides translational techniques, some models employ alternative *relation modeling* techniques to encode relation facts, such as circular correlation (Nickel et al., 2016), Hadamard product (Hao et al., 2019) and recurrent skipping networks (Guo et al., 2019). Others encode entities with *neighborhood aggregation* techniques, including GCN (Wang et al., 2018; Yang et al., 2019; Cao et al., 2019; Xu et al., 2019; Wu et al., 2019b), RGCN (Wu et al., 2019a) and GAT (Zhu et al., 2019). Their benefits are mainly to produce entity representations capturing high-order proximity, so as to better suit the alignment task. A few works follow the second line to enhance the *alignment learning* with semi-supervised learning techniques. Representative ones include co-training (Chen et al., 2018), optimal transport (Pei et al., 2019b) and bootstrapping (Sun et al., 2018), which improve the preciseness of alignment captured with limited supervision. The third line of research seeks to obtain additional supervision from entity profiles, including descriptions (Chen et al., 2018; Yang et al., 2019), attributes (Sun et al., 2017; Trsedya et al., 2019; Pei et al., 2019a; Yang et al., 2020) and KG schemata (Zhang et al., 2019). While those alternative views of entities can effectively bridge the embeddings, the limitation of such methods lies in the unavailability of those views in many KGs (Speer et al., 2017; Mitchell et al., 2018; Bond and Foster, 2013). A survey on the entity alignment problem by Sun et al. (2020b) has provided a more comprehensive summarization of recent advances in these lines.

Our method is mainly related to the third line of research. While instead of leveraging specific intra-KB information, our method introduces supervision signals from text contexts that are freely accessible to almost any KBs with the aid of grounding techniques. Meanwhile, our paper also follows the second line to improve alignment learning techniques, and couples two mainstream techniques for embedding learning.

Joint embeddings of entities and text. Fewer efforts have been put to jointly characterize entities and text as embeddings. Wang et al. (2014b) propose to connect a translational embedding of Freebase (Bollacker et al., 2008) to a English word embedding based on Wikipedia anchors, therefore providing a joint embedding to enhance link prediction in the KG. Zhong et al. (2015) generalize the approach by Wang et al. (2014b) with distant supervision based on entity descriptions and text corpora. Toutanova et al. (2015) extract dependency paths from sentences and jointly embed them with a KG using DistMult (Yang et al., 2015) to support the relation extraction task. Several other approaches focus on jointly embedding words, entities (Yamada et al., 2017; Newman-Griffis et al., 2018; Cao et al., 2017; Almasian et al., 2019) and entity types (Gupta et al., 2017) appearing in the same textual contexts without considering relational structure of a KG. These approaches are employed in monolingual NLP tasks including entity linking (Gupta et al., 2017; Cao et al., 2017), entity abstraction (Newman-Griffis et al., 2018) and factoid QA (Yamada et al., 2017). As they focus on a monolingual and supervised scenario, they are essentially different from our goal to help cross-lingual KG alignment with incidental supervision from unparalleled corpora.

Multilingual word embeddings. Our model component of alignment induction from text is closely connected to multilingual word embeddings. Earlier approaches in this line, regardless of being supervised or weakly supervised, based on seed lexicon (Zou et al., 2013) or parallel corpora (Gouws et al., 2015), are systematically summarized in a recent survey (2017). While a number of methods in this line can be employed in our model to gain addition supervision for entity alignment, we choose to use a combination of Procrustes solution (Conneau et al., 2018) with self-learning to offer precise inference of cross-lingual alignment based on limited seed alignment. Note that recent contextualized embeddings such M-BERT (Pires et al., 2019) and XLM-R (Conneau et al., 2020) do not directly suit our problem setting, since contextualization could cause ambiguity to entity representations, therefore impairing the alignment of entities across embedding spaces.

Incidental supervision. Incidental supervision is a recently introduced learning strategy (Roth, 2017), which seeks to retrieve supervision signals from data that are not labeled for the target task. This strategy has been applied to tasks including SRL (He et al., 2020), controversy prediction (Rethmeier et al., 2018) and dataless classification (Song and Roth, 2015). To the best of our knowledge, the proposed method here is the first of its kind that incorporates incidental supervision in embedding learning or alignment.

3 Method

We hereby begin introducing our method with the formalization of learning resources.

In a KB, $\mathcal{L}$ denotes the set of languages, and $\mathcal{L}^2$ unordered language pairs. G_L is the language-specific KG of language $L \in \mathcal{L}$. E_L and R_L respectively denote the corresponding vocabularies of entities and relations. $T = (h, r, t)$ denotes a triple in G_L such that $h, t \in E_L$ and $r \in R_L$. Boldfaced $\mathbf{h}$, $\mathbf{r}$, $\mathbf{t}$ represent the embedding vectors of head h, relation r, and tail t respectively. For a language pair $(L_1, L_2) \in \mathcal{L}^2$, $I_E(L_1, L_2)$ denotes a set of entity alignments between L_1 and L_2, such that $e_1 \in E_{L_1}$ and $e_2 \in E_{L_2}$ for each entity pair $(e_1, e_2) \in I_E(L_1, L_2)$. Following the convention of previous work (Chen et al., 2018; Sun et al., 2018; Yang et al., 2019), we assume the entity pairs to have a 1-to-1 mapping and it is specified in $I_E(L_1, L_2)$. This assumption is congruent to the design of mainstream KBs (Lehmann et al., 2015; Mahdisoltani et al., 2015) where disambiguation of entities is granted. Besides the definition of multilingual KGs, we use D_L to denote the text corpus of language L. D_L is a set of documents $\{d_L\}$, where each document $d_L = [w_1, w_2, ..., w_l]$ is a sequence of tokens from the monolingual lexicon W_L. Each token w_i thereof is originally a lexeme, but may also be an entity surface form after the ground process, and we also use boldfaced $\mathbf{w}_i$ to denote its vector. $I_W(L_1, L_2)$ denotes the seed lexicon between (L_1, L_2), such that $w_1 \in W_{L_1}$ and $w_2 \in W_{L_2}$ for each lexeme pair $(w_1, w_2) \in I_W(L_1, L_2)$. Note that I_W only include the alignment between lexemes, and may optionally serve as external supervision data. To be consistent with previous problem settings of entity alignment (Chen et al., 2017a; Sun et al., 2018; Yang et al., 2019), I_W is not necessarily provided to training, but is defined to be compatible with the scenarios where it is available.

`JEANS` addresses entity alignment in three consecutive processes. (i) A *grounding process* first link entities of each KG to possible mentions of them in the corresponding monolingual corpus, therefore connecting entities and text tokens of the same language into a shared vocabulary. (ii) An *embedding learning* process characterizes the KG and text of each language into a separate embedding space. In this process, we couple both the translational technique (Bordes et al., 2013; Chen et al., 2017a, 2018) and the neighborhood aggregation technique (Wang et al., 2018; Yang et al., 2019), which are two representative techniques to characterize a KG. Simultaneously, the monolingual text tokens are encoded with a skip-gram language model (Mikolov et al., 2013). (iii) On top of the embeddings, starting from a small amount of seed entity alignment and *optional* seed lexicon, the *alignment learning* process iteratively infers more alignment both on KGs and text using self-learning and Procrustes solution (Schönemann, 1966). The processes of `JEANS`'s learning is consistent to Figure 1. The rest of this section introduces the technical details of each process.

3.1 (Noisy) Entity Grounding

The goal of the grounding process is to combine vocabularies of the KG and the text corpus in each language. This serves as the premise for the embedding learning process to produce a shared representation scheme for entities, relations and lexemes, therefore allowing the alignment learning process to leverage supervision signals for both entities and lexemes. It is noteworthy that, the purpose of entity grounding here is to combine the two data modalities. Hence, we only expect this process to discover enough entity contexts and offer a higher coverage on entity vocabularies, while being tolerant to possible noise in entity recognition and linking. Particularly, we consider two grounding techniques, one using a pre-trained entity discovery and linking (EDL) model, the other based on simple surface form matching (SFM).

Pre-trained EDL model. One technique is to use off-the-shelf EDL models (Khashabi et al., 2018; Manning et al., 2014). A typical model of such sequentially handles the steps of NER to detect entity mentions, and link each mention to candidate entities from the KG based on symbolic and contextual similarity. Many EDL models are easily trainable on large text corpora with anchors, and offer promising performance of grounding and disambiguation on multiple languages (Sil et al., 2018). In this paper, we do not go into details to the design of EDL models. Interested readers are referred to the aforementioned literature.

Surface form matching. Suppose a pre-trained EDL model is not available, then a simpler way of combining data is to match KG surface forms with text. This can be efficiently done by building a Completion Trie (Hsu and Ottaviano, 2013) for multi-token surface forms, and conducting a longest prefix matching (Dharmapurikar et al., 2006) between surface forms and sub-sequences of text tokens. While this simple technique does not necessarily disambiguate entity mentions, experiments find it sufficient to combine the two modalities and allow supervision signals from induced lexical alignment to propagate to entities.

Once the entity vocabulary E_L and the lexicon W_L of a language are combined, we assume that entity mentions in D_L are properly tokenized as grounded surface forms in $E_L \cap W_L$. Specifically, we now use x to denote a token in the grounded corpus D_L that can either be an entity e or a lexeme w. Given the combined learning resources for each language, we next describe the processes of embedding learning and alignment learning.

3.2 Embedding Learning

The embedding learning process is responsible for capturing the combined KG and text corpus of each language in a shared embedding space $\mathbb{R}^k$. In this process, `JEANS` jointly learns two model components to respectively encode units of the KG and the text, among which the overlaps $E_L \cap W_L$ use shared representations. We hereby describe these two model components in detail.

3.2.1 KG Embedding

As discussed in §2, previous approaches respectively leverage two forms of embedding learning techniques: (i) *relation modeling* (Chen et al., 2017a; Sun et al., 2018) such as vector translations, circular correlation and Hadamard product seeks to capture relations as an arithmetic operation in the vector space; (ii) *neighborhood aggregation* (Wang et al., 2018; Yang et al., 2019; Cao et al., 2019) employs graph neural networks (GNN) to encode neighborhood contexts for better seizing the proximity of entities.

The KG embedding model proposed in this work couples both forms of techniques. This aims at seizing both relations and entity proximity, two factors that are both beneficial to produce transferable entity embeddings. To achieve this goal, the encoder first stacks n layers of GCN (Kipf and Welling, 2016) on the KG. Formally, the l-th layer representation $\mathbf{E}^{(l)}$ is computed as

$$\mathbf{E}^{(l)} = \phi\left(D^{-\frac{1}{2}}\tilde{A}D^{-\frac{1}{2}}\mathbf{E}^{(l-1)}\mathbf{M}^{(l-1)}\right),$$

where D is the diagonal degree matrix D of the KG, $\tilde{A} = A + I$ is the sum of the adjacency matrix A and an identity I, and $\mathbf{M}^{(l-1)}$ is a trainable weight matrix. The raw features of entities $\mathbf{E}^{(0)}$ can be either entity attributes or randomly initialized. The last layer outputs are regarded as entity embedding representations, i.e. $\mathbf{E} = \mathbf{E}^{(n)}$.

We use $\mathbf{E}_L$ to denote the entity representations of language L, then the following log-softmax loss is optimized to perform relational modeling with translation vectors in the embedding space of L:

$$S_L^K = -\sum_{T \in G_L} \log \frac{\exp\left(b - f_r(h,t)\right)}{\sum_{\hat{T} \notin G_L} \exp\left(b - f_r(\hat{h},\hat{t})\right)},$$

where $f_r(h,t) = \|\mathbf{h} + \mathbf{r} - \mathbf{t}\|$ is the plausibility measure of a triple (Bordes et al., 2013), $\hat{T} = (\hat{h}, r, \hat{t})$ is a Bernoulli negative-sampled triple (Wang et al., 2014a) created by substituting either head or tail entities h or t in $T = (h, r, t)$. b is a positive bias to adjust the scale of the plausibility measure. All the entity representations optimized in S_L^K are from $\mathbf{E}_L$. Note that the reason for us to choose the translational technique over other relation modeling techniques is due to this technique being more robust in cases where KG structures are sparser (Pujara et al., 2017).

3.2.2 Text Embedding

In addition to the KG embedding, the text embedding seeks to leverage the contextual information of free text to help the embedding better capture the proximity of entities This model employs the continuous skip-gram language model, which is inline with a number of word embedding methods (Mikolov et al., 2013; Bojanowski et al., 2017; Conneau et al., 2018), and is realized by optimizing the following log-softmax loss:

$$S_L^T = -\sum_{x \in E_L \cup W_L} \sum_{x_c \in C_{x,D_L}} \log \frac{\exp\left(d(x, x_c)\right)}{\sum_{x_n} \exp\left(d(x, x_n)\right)}.$$

The text context C_{x,D_L} thereof is the set of tokens that surround a token x in the entity-grounded corpus D_L, d denotes the l_2 distance, and x_n denotes a randomly sampled token in $E_L \cup W_L$.

3.2.3 Embedding Learning Objective

For each language $L \in \mathcal{L}$, the goal of embedding learning is to optimize the joint loss

$$S_L^E = S_L^K + S_L^T.$$

As mentioned, the grounded entity surface forms in $E_L \cap W_L$ use shared representations in both model components, hence are optimized with both S_L^K and S_L^T. The rest lexeme, relation and entity representations are optimized alternately by either component. In both model components, the number of negative samples of triples and tokens are both adjustable hyperparameters.

It is noteworthy that, both model components may choose alternative techniques, including other

KG encoders such as GAT (Veličković et al., 2018), multi-channel GCN (Cao et al., 2019) and gated GNN (Sun et al., 2020a), and text embeddings such as GloVe (Pennington et al., 2014). As experimenting with different embedding techniques is not a main contribution of this work, we leave them as future work. Specifically, contextualized text representations (Peters et al., 2018; Devlin et al., 2019) cannot directly apply, as contextualization will cause ambiguity to token representations that hinder the match of embeddings.

3.3 Alignment Learning

Once the KG and text units of each language are captured in a shared embedding, the alignment learning process therefore bridges the alignment between each pair of embeddings. This process seeks to exploit additional alignment labels from text embeddings, and use those to help the alignment of entities. Different from the majority of methods in §2 that jointly learn embeddings and alignment, the alignment learning process in `JEANS` is a retrofitting process (Shi et al., 2019; Faruqui et al., 2015). Hence, the embedding of each language is fixed and does not require duplicate training for different language pairs (Chen et al., 2017a; Sun et al., 2017).

Given a pair of languages $(L_i, L_j) \in \mathcal{L}^2$, the objective of alignment learning is to induce a transformation $\mathbf{M}_{ij} \in \mathbb{R}^{k \times k}$ between the two embedding spaces. The following loss is minimized

$$S^A_{L_i,L_j} = \sum_{(x_i,x_j)\in I(L_i,L_j)} \|\mathbf{M}_{ij}\mathbf{x}_i - \mathbf{x}_j\|_2 \,,$$

in which $I(L_i, L_j) = I_E(L_i, L_j) \cup I_W(L_i, L_j)$, and the word seed lexicon I_W is considered additional supervision data that are optionally provided. Each $\mathbf{x}_i$ ($\mathbf{x}_j$) denotes a fixed representation of either an entity or a lexeme of L_i (L_j).

Starting from a small amount of seed alignment in $I(L_i, L_j)$, `JEANS` conducts an iterative self-learning process to exploit more alignment labels for both entities and lexemes to improve the learning of $\mathbf{M}_{ij}$. In each iteration, we follow Conneau et al. (2018) to induce a Procrustes solution for $\mathbf{M}_{ij}$. To propose new alignment labels, the self-learning technique in `JEANS` deploys a mutual nearest neighbor (NN) constraint, which requires a suggested pair of matched items to appear in the NN of each other. More specifically, define $\mathcal{N}^K_{L_i}(\mathbf{x})$ as the K-NN of vector $\mathbf{x}$ in the embedding space of L_i, this constraint requires a proposed match (x_i, x_j) to be inserted into I only if $\mathbf{M}_{ij}\mathbf{x}_i$ is in $\mathcal{N}^1_{L_j}(\mathbf{x}_j)$, and $\mathbf{x}_j$ mutually appears in $\mathcal{N}^1_{L_j}(\mathbf{M}_{ij}\mathbf{x}_i)$. Besides, we also require (x_i, x_j) to be of the same type, i.e. both being entities or being lexemes. Particularly, we only select entities that have not been aligned in I to form the newly-proposed (x_i, x_j). This respects the 1-to-1 matching constraint of entities being defined at the beginning of this section, and effectively reduces the candidate space after each iteration of self-learning. Meanwhile, 1-to-1 matching is not required for lexemes. To mitigate hubness, we also follow Conneau et al. (2018) to employ the Cross-domain Similarity Local Scaling (CSLS) measure.

After the iteration, the newly proposed alignment labels are inserted to I to enhance the learning at the next iteration. The iterative self-learning is stopped once the number of proposed entity alignment in an iteration is below certain quantity (e.g. 1% of $|E_{L_i}|$). With more and more matched entities and lexemes being exploited within each iteration, a better $\mathbf{M}_{ij}$ is induced, whereas the lexical alignment naturally serve as incidental supervision signals for entity alignment.

After the alignment learning process, given a query $(e_i, ?e_j)$ to find the counterpart entity of $e_i \in E_{L_i}$ from E_{L_j}, the answer e_j is predicted as the 1-NN entity after applying $\mathbf{M}_{ij}$ to transform $\mathbf{e}_i$, denoted $\{e_j\} = \mathcal{N}^1_{E_{L_i}}(\mathbf{M}_{ij}\mathbf{e}_i)$. The inference phase by default also adopts CSLS as the distance measure, which is consistent with the default setting of recent works (Sun et al., 2019b, 2020a).

4 Experiment

In this section, we evaluate `JEANS` on two benchmark datasets for cross-lingual entity alignment, and compare against a wide selection of recent baseline methods. We also provide detailed ablation study on model components of `JEANS`.

4.1 Experimental Settings

Datasets. Experiments are conducted on DBP15k (Sun et al., 2017) and WK3l60k (Chen et al., 2018) that are widely used benchmarks on the studied task. DBP15k contains four language-specific KGs that are respectively extracted from English (En), Chinese (Zh), French (Fr) and Japanese (Ja) DBpedia (Lehmann et al.,

Table 1: Entity alignment results. Baselines are separated in accord with the three groups described in Section 4.1. † indicates results obtained from (Sun et al., 2020a), and ‡ indicates those from (Pei et al., 2019b). Results of KECG, GCN-JE, MMR, HMAN, KDCoE and NAEA are from original papers. Hyphens denote not available. MRR were not reported by GCN-JE, MMR and HMAN. Top results (incl. w/ and w/o seed lexicon) are boldfaced. Note that results by GCN-JE, GMN and HMAN are reported only for the versions where the extra cross-lingual alignment information (such as machine translation) is removed, so as to conduct fair comparison with all the rest models that are trained using only the alignment labels in the benchmark training sets.

2015), each of which contains around 65k-106k entities. Three sets of 15k alignment labels are constructed to align entities between each of the other three languages and English. WK3l60k contains larger KGs with around 57k to 65k entities in En, Fr and German (De) KGs, and around 55k reference entity alignment for En-Fr and En-De settings. Dataset statistics are given in Appendix §A.2 (Chen et al., 2021).

We also use the text of Wikipedia dumps (dated Jan 01, 2019) in the five participating languages in training. For Chinese and Japanese corpora thereof, we obtain the segmented versions respectively from PKUSEG (Luo et al., 2019) and MeCab (Kudo, 2006).

Baseline methods. We compare with a wide selection of recent approaches for entity alignment on multilingual KGs. The baseline methods include (i) those employing different structure embedding techniques, namely MTransE (Chen et al., 2017a), GCN-Align (Wang et al., 2018), AlignE (Sun et al., 2018), GCN-JE (Wu et al., 2019b), KECG (Li et al., 2019a), MuGCN (Cao et al., 2019), RotatE (Sun et al., 2019c), RSN (Guo et al., 2019) and AliNet (Sun et al., 2020a); (ii) methods that incorporate auxiliary information of entities, namely JAPE (Sun et al., 2017), SEA (Pei et al., 2019a), GMN (Xu et al., 2019) and HMAN (Yang et al., 2019); (iii) semi-supervised alignment learning methods, including BootEA (Sun et al., 2018), KDCoE (Chen et al., 2018), MMR (Shi and Xiao, 2019), NAEA (Zhu et al., 2019) and OTEA (Pei et al., 2019b). Descriptions of these methods are given in Appendix §A.1 (Chen et al., 2021).

Note that some works have allowed to incorporate extra cross-lingual signals such as machine translation in training, or using pre-aligned word embeddings to delimit candidate spaces (Wu et al., 2019a,b; Xu et al., 2019). For example, Wu et al. (2019a,b) used Google Translate to translate surface forms of entities in all other languages to English, and initialize the entity embeddings in their model with pre-trained word embedding of translated entity names. Results for these models are reported for the versions where the extra cross-lingual alignment information is removed so as to conduct fair comparison with all the rest models that are trained from scratch and using the same alignment labels in the benchmark datasets. This also necessarily prevents potential leakage of testing data to training (Liu et al., 2020), considering that training a comprehensive NMT system may have subsumed many of the testing data in the entity alignment benchmarks.

Evaluation protocols. The use of the datasets are consistent with previous studies of the baseline methods. On each language pair in DBP15k, around 30% of seed alignment is used for training, the rest for testing. On WK3l60k, 20% of seed alignment on En-Fr and En-De settings is respectively used for training. Following the convention, we calculate several ranking metrics on test cases, including the accuracy $H@1$, the proportion of cases that are ranked no larger than p $H@p$, and mean reciprocal rank MRR. Note that to align with the results in previous studies (Sun et al., 2020a; Pei et al., 2019b), p is set to 10 on DBP15k and 5 on WK3l60k. All metrics are preferred higher to indicate better performance.

Model Configurations. We use AMSGrad (Reddi et al., 2018) to optimize the training losses of the embedding learning process, for which we set the learning rate α to 0.001, the exponential decay rates β_1 and β_2 to 0.9 and 0.999, and batch sizes to 512 for both S_L^K and S_L^T. Trainable parameters are initialized using Xavier initialization (Glorot and Bengio, 2010). The dimension k is set to 300, which is often used for bilingual word embedding models trained on Wikipedia corpora (Conneau et al., 2018; Gouws et al., 2015), considering that the vocabulary sizes and training data density here are relatively close to those models. The number of GCN layers is set to 2. We set negative sample sizes of triples and text contexts to 5, the text context width to be 10 and the bias b in S_L^K to be 2. More implementation details are in Appendix §A.3 (Chen et al., 2021). Specifically, we evaluate variants of `JEANS` by adjusting two technical details. First, for the grounding process, aside from the simple surface form matching (marked with SFM), we also explore with the off-the-shelf Wikification-based EDL model (Upadhyay et al., 2018, marked with EDL). A grounding performance estimation is given in §4.4. In addition, we consider both CSLS and l_2 in inference.

4.2 Results

We report the entity alignment results in Table 1.

Considering the baseline results on DBP15k, we can see that the simplest variant of `JEANS` using SFM-based grounding has consistently outperformed all baselines on three cross-lingual settings. Particularly, it leads to 17.0-17.4% of absolute improvement in $H@1$ over the best structure-based baseline, 14.0-22.3% over the best entity profile based one, and 6.30-9.30% over the best semi-supervised one. This shows that while `JEANS` preserves the key merit of a semi-supervised entity alignment method, and effectively enhances the alignment of KGs by exploiting incidental supervision signals from unaligned text corpora. Considering different grounding techniques, we observe that SFM variants often perform closely to EDL ones. This indicates that simple SFM is enough to combine KG and text corpora for `JEANS`'s embedding learning without EDL-related resources. The results on Wk3l60k generally exhibit similar observations. In comparison to KDCoE that leverages strong but expensive supervision data of entity descriptions in co-training, `JEANS` offers comparable performance based on very accessible resources.

Setting	DBP15k$_{En-Fr}$			DBP15k$_{En-Ja}$		
Metrics	$H@1$	$H@10$	MRR	$H@1$	$H@10$	MRR
`JEANS`-SFM	0.766	0.939	0.814	0.723	0.913	0.793
—w/o Self-learning	0.628	0.845	0.720	0.622	0.835	0.728
—w/o GCN	0.742	0.913	0.809	0.709	0.905	0.789
—w/o Text	0.725	0.891	0.786	0.681	0.857	0.761
—w/o KG	0.699	0.872	0.771	0.635	0.819	0.706
—w/o CSLS	0.697	0.905	0.762	0.687	0.893	0.768
—w/ seed lexicons	0.788	0.947	0.848	0.738	0.931	0.803

Table 2: The ablation study results for components of `JEANS` based on DBP15k$_{En-Fr}$ and DBP15k$_{En-Ja}$. Note that the additional seed lexicon is not used in the main experiment, and is not obligatory. The last row in this table is only to show the effectiveness of leveraging available supervision data on lexemes.

Language	SFM		EDL	
Estimation	Coverage	Avg match	Coverage	Avg match
En	0.982	1,268	0.933	1,367
Fr	0.987	295	0.926	929
Zh	0.855	141	0.774	348
Ja	0.982	159	0.797	881
De	0.981	297	0.951	1,092

Table 3: Estimated vocabulary coverage and average match per entity on each of the five language-specific Wikipedia corpora.

In general, the experiments here show that `JEANS` promisingly improves SOTA performance for entity alignment, with only the need for unparalleled free text and no need for additional labels.

4.3 Ablation Study

In Table 2 we report an ablation study for `JEANS`-SFM based on DBP15k, so as to understand the importance of each incorporated technique.

From the results, we observe that self-learning is the most important factor. The removal of it can lead to a drop of 10.1-13.8% in $H@1$, as well as drastic drop of other metrics. This also explains why semi-supervised baselines (group 3) typically perform better than others. However, even with self-learning, the removal of text can lead to $H@1$ drop of 2.4% on En-Fr and 4.2% on En-Ja. This shows that context information `JEANS` retrieves from free text effectively infers the match of entities. On the other hand, the structure encoding of KGs is more important than textual contexts, as it causes higher performance drops of 6.7-8.8% in $H@1$ by removing KGs. Note that the model without KG learns entity embeddings solely based on free text. Its results show that context information from text alone can provide a strong starting point from which incorporating KGs can further enhance its performance. Employing GCN leads to relatively slight performance gain, as joint learning the relation model and the language model can satisfyingly capture entity proximity. Changing the distance metric to l_2 also leads to 3.6-6.9% of decrease in $H@1$. This shows CSLS's ability to handle hubness and isolation is also important for similarity inference in the dense embedding space for the metric words and entities. Hence, this metric is also recommended by recent work (Sun et al., 2020a, 2019b; Zhang et al., 2019). In addition, if we introduce additional 5k seed lexicon (with only word alignment information, not including any entity alignment) provided by Conneau et al. (2018) for each language pair, it leads to additional improvement of 1.5-2.2% in $H@1$. This shows that `JEANS` effectively leverages available supervision data on lexemes to further enhance entity alignment, although it is not obligatory.

4.4 Grounding Performance Estimation

Due to the lack of ground truths on unlabeled text, it is hard to estimate the precision of entity grounding by the two types of (noisy) grounding techniques. However, as the requirement of the grounding process is to simply connect two data modalities for training the embeddings, we may encourage a technique that handles enough entity mentions and offer a higher coverage on entity vocabularies. Accordingly, the estimations of these two factors for the two techniques are reported in Table 3. As we can observe that, without considering disambiguation, SFM can overall cover higher proportions of the entity vocabularies, while pretrained EDL generally discovers more entity mentions for each entity. However, both techniques are sufficient to support the noisy grounding process and combine two data modalities for embedding learning and alignment induction.

5 Conclusion

This paper introduces `JEANS` for entity alignment. Different from previous methods that leverage only internal information of KGs, `JEANS` extends the learning on any text corpora that may contain the KG entities. For each language, a noisy grounding process first connects both data modalities, followed by an embedding learning process coupling GCN with relational modeling, and an self-learning based alignment process. Without introducing additional labeled data, `JEANS` offers significantly improved performance over SOTA models on benchmarks. Hence, it shows the effectiveness and feasibility of exploiting incidental supervision from free text for entity alignment.

For future work, aside from experimenting with other embedding learning techniques for KGs and text, we plan to extend `JEANS` to learn associations on KGs with different specificity (Hao et al., 2019). We also seek to extend the representation scheme in hyperbolic spaces (Nickel and Kiela, 2017; Chen and Quirk, 2019) along with the incorporation of hyperbolic lexical embedding techniques (Tifrea et al., 2018), aiming at better capturing the associations for hierarchical ontologies.

Acknowledgement

We appreciate the anonymous reviewers for their insightful comments and suggestions. Also, we would like thank Jennifer Sheffield, Yi Zhang and other members of the UPenn Cognitive Computation Group for giving suggestions that improved the manuscript.

Abstract

This paper studies the problem of generating likely queries for multimodal documents with images. Our application scenario is enabling efficient "first-stage retrieval" of relevant documents, by attaching generated queries to documents before indexing. We can then index this expanded text to efficiently narrow down to candidate matches using inverted index, so that expensive reranking can follow. Our evaluation results show that our proposed multimodal representation meaningfully improves relevance ranking. More importantly, our framework can achieve the state of the art in the first-stage retrieval scenarios.

1 Introduction

As more documents on the web are generated and consumed by mobile devices with cameras, documents are often multimodal, containing information in both text and image modalities. This poses a new challenge of finding relevance documents across modalities. More formally, the relevance of document, consisting of text t and image i, to the given query keywords q, should be modeled as a trimodal function $f(q, t, i)$, rather than a simple lexical match between q and t (or, **BM25** baseline) assuming the semantics of image i is fully represented by the surrounding text (or, **paired-text** assumption).

Prior research observes that paired-text assumption is often violated (Henning and Ewerth, 2017) – for example, some semantics can be better captured in image modality, and may not (or, cannot) be described in text. Meanwhile, BM25 baseline (Robertson et al., 1994) would fail to serve queries for such semantics.

To overcome this limitation of BM25, one may model relevance from query as a trimodal function $f(q, t, i)$ (Nian et al., 2017; Kordan and Kotov, 2018) instead, but they require runtime invocation of f for the given query q with all potential document matches. This incurs a prohibitive runtime overhead, unacceptable for search engines finding results online. A common practice is to use a cheap BM25 ranking as a "first-stage retrieval", efficiently supported by inverted index, to quickly narrow down to a few candidate documents, then evaluate $f(q, t, i)$. However, due to simple nature of BM25 using exact term matching, a document will be missed, if the query term is absent in t, even though it semantically matches image or another term in the text.

Our contribution is to keep first-stage retrieval as efficient as BM25, but enable multimodal semantic matching, using Query Generation **(QG)** before indexing. More specifically, we generate a likely query q from a joint modeling of t and i, to create an expanded text $t' = q \cup t$ such that (q, t') pair has more lexical overlaps, or better paired than (q, t), for first-phase retrieval. Specifically, we train a sequence-to-sequence model, such that given the representation of multimodal document, this model generates possible queries that users may ask to retrieve such document. This is analogous to doc2query (Nogueira et al., 2019) approach used for first-stage retrieval of textual relevance ranking, though this model, dealing with text modality only, cannot apply to our problem of retrieving multimodal documents.

For such multimodal representation for **QG**, a naive baseline is bimodal representation shown in Figure 1a: We may assume (t, i), even when lexical overlaps are low, is semantically paired in the embedding space. Note this is a relaxed version of paired-text assumption. Given this relaxed assumption, common architecture of bimodal representa-

(*a*) (*b*)

Figure 1: (a) bimodal and (b) trimodal representation for QG, query is used for disentangling shared and private space and relaxing paired-text assumption of bimodal representation.

tion for QG consists of the encoders for image i and text t. Each generates vector representation, which is later fused into a multimodal space, then decoded into a textual caption. Specifically, we consider two strong baselines: (a) cross-modal representation, pretrained from a large-scale paired corpus of image and caption, such as LXMERT (Tan and Bansal, 2019), ViLBERT (Lu et al., 2019), and VisualBERT (Li et al., 2019), finetuned for our task, and (b) memory network structure (Park et al., 2017). Based on these baselines, we design Bimodal QG combining the advantages of the two as a strong baseline. Then, we extend into Trimodal QG leveraging text, image and query (q, t, i).

Alternatively, we may further relax paired-text assumption and propose Trimodal QG in Figure 1b: (t, i) can be partially paired, where some semantics is conveyed in one modality. To deal with that challenge, the query given at training, helps "disentangle" shared and private semantics as additional loss terms. Another role of query is improving image representation, to de-emphasize semantics not discussed in either text or query.

In summary, our contributions are as follows:

- We study QG for multimodal documents, as an enabler for efficient first-stage ranking.
- We build a multi-task model, for query generation and representation learning, to generate effective queries for offline indexing.
- We improve the QG model by considering query as third modality in order to work well without paired-text assumption.
- We validated that our model outperforms all baselines in both public dataset and real-life web search query logs and quality annotation for multimodal documents.

2 Related Work

Our work is closely related to the following three areas of research.

2.1 Web search with images

Most efficient way to treat multimodal document ranking has been making paired-text assumption (Coelho et al., 2004; Azilawati and Meriam, 2008), such that simply matching q with t is sufficient. Our work is as efficient, by incurring no additional runtime overhead, but does not make such assumption. Alternatively, Rodríguez-Vaamonde et al. (2015) adds a reranking phase, checking if the images are relevant to the query, supervised by whether the given image is correlated with clicks.

Our distinction: We do not build on paired-text assumption, and can be viewed as generating a better-paired document by adding likely queries.

2.2 Image captioning

Another closely related work is the task of generating textual captions to the given query. As overviewed in Section 1, state-of-the-art models include bimodal joint representation of image i and text t (Kiros et al., 2014b; You et al., 2016; Park et al., 2017). Alternatively, such joint models can also be transferred from pretrained models, such as LXMERT (Tan and Bansal, 2019), ViLBERT (Lu et al., 2019), and VisualBERT (Li et al., 2019). Section 3 will compare and contrast these two approaches, and discuss why these models are

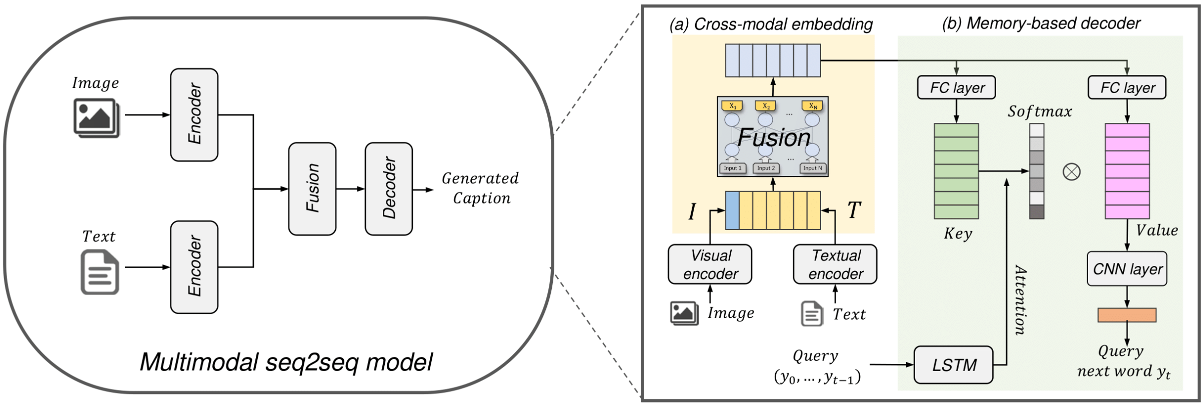

Figure 2: Proposed bimodal QG baseline, combining (a) cross-modal and (b) memory-based state-of-the-arts

limited for our task setting. (Jeon et al., 2003) is a non-neural model trained to annotate images with textual description, though requiring expensive supervision of segmented image with term.

Our distinction: We propose and validate trimodal joint representation for higher-quality captioning. Meanwhile, we do not require segment-level annotation, though our query-guided trimodal image representation naturally emphasizes important segments.

2.3 QG for first-stage retrieval

QG for first-stage text retrieval was pioneered by doc2query (Nogueira et al., 2019), generating likely queries for the document for indexing purposes in text modality. Our work can be viewed as query generation for multimodal documents: For each document, the task is to predict a set of likely queries. We train a sequence-to-sequence transformer using a data set of (query, relevant document) pairs. Alternatively, inverted index can be built for a latent term (Zamani et al., 2018), though it cannot be human-interpreted or reweighed. In contrast, we focus on inverted index on actual terms, as it is human interpretable and combines more naturally with legacy tf-idf ranker and reweighting module.

Our distinction: We validate the effectiveness of trimodal QG over bimodal state-of-the-art methods.

3 Bimodal Baselines: LXMERT and Memory-Based Generator

This section compares and contrasts two bimodal baselines: LXMERT [1] and Memory-Based Generator encode text t and image i into vector representations (Section 3.1), then the two are aggregated into a multimodal representation (Section 3.2), such that this vector can feed a decoder to generate a text sequence (Section 3.3). Specifically, we build **Bimodal QG** baseline, combining LXMERT representation and Memory-Based Generator decoding. Figure 2 shows overall architecture of our Bimodal QG baseline.

3.1 Text and image encoder

LXMERT and Memory-Based Generator generate text and image vectors, using transformer and memory network structure respectively. Both can be explained as **key** memory, aggregating **value** memory representation with proper self-attention, denoted as key and val, respectively, following the conventions of prior literature (Sukhbaatar et al., 2015).

Formally, we encode textual context words $C = \{w_1, w_2, ..., w_j\}$ obtained by concatenating the $n-$dimensional word embedding ($w \in R^n$) of the

---

[1] Out of cross-modal representations discussed in Section 1, we empirically found LXMERT performs the best in our problem setting and thus adopt it as a baseline.

top-j words with the highest TF-IDF weights [2].

$$\begin{aligned} T_i^{key} &= \text{ReLU}(W_1 w_i + b_1), \;\; i \in [1, j] \\ T_i^{val} &= \text{ReLU}(W_2 w_i + b_2), \;\; i \in [1, j] \\ T^{key} &= [T_1^{key}; ...; T_j^{key}] \\ T^{val} &= [T_1^{val}; ...; T_j^{val}] \end{aligned}$$

where W_1, $W_2 \in R^{m \times n}$, $b_1, b_2 \in R^m$ are trainable linear transformation parameters where m is the dimension of memory. When parameter, such as T or I, is denoted without superscript (key or val), it refers both key and val vectors.

Similarly, an image input $U \in R^{2048}$ is generated from pool5 feature vector of Resnet-101 CNN encoder, which is similarly embedded into:

$$\begin{aligned} I^{key} &= \text{ReLU}(W_3 U + b_3) \\ I^{val} &= \text{ReLU}(W_4 U + b_4) \end{aligned}$$

where $W_3, W_4 \in R^{m \times 2048}$ and $b_3, b_4 \in R^m$ are trainable matrices for tuning on given dataset. Final image embedding is generated with key and value vector, following the convention of attention network (Kiros et al., 2014a). Note only the representation of text and image is used at this point, and using query representation will be discussed in Section 4. Also, LXMERT extract image features by using Faster-RCNN (Ren et al., 2015) and transformer structure, which is pre-trained on large dataset combined by MSCOCO (Lin et al., 2014) and Visual Genome (Krishna et al., 2016). Therefore, both methods can be applicable on general images.

3.2 Multimodal fusion

The goal of multimodal fusion module in Figure 2 is to get text and image representations as input, and create a joint representation as output. When paired-text assumption holds (Figure 1a), this can be achieved by simply concatenating or adding two input modalities, and the future layers will be tuned for a proper alignment of the two. However, such concatenation is less effective when paired-text assumption does not hold as in Figure 1b.

One solution is transfer learning from pretrained joint representation model trained from a large-scale paired resources, such as LXMERT (Tan and Bansal, 2019). LXMERT is a transformer-based architecture for cross-modal representation learning, for predicting masked words from the text modality, and vice versa. This auxiliary task, known as masked cross-modality language model, helps building connections across modalities. In our problem setting, this option can be considered for public English dataset, as pre-trained LXMERT with a large scale paired training resources is readily available to generate a joint representation M_{lxm}, to replace simple concatenated fusion embedding M_{fusion} ($[I; T]$).

3.3 Bimodal QG: Joint text decoding for query generation

We now observe the two baselines: LXMERT, focuses on the problem of joint representation, but does not consider a decoder of generating a query sequence from such representation (Figure 2a). Meanwhile, Memory-Based Generator has the advantage of tightly coupling the key-value encoder and CNN decoder, by concatenating the representations of all modalities, co-attended based on the query keywords generated thus far, as illustrated in Figure 2b. This multimodal vector is calculated in each time step and used to decode the next word, which is an effective decoder design adopted for our model:

$$M_{total} = [I; T; Q]$$

With this joint representation, query generation is predicting the output probability of the next word among all vocabularies, by a convolution neural network, denoted as CNN in Figure 2.

For combining with the strength of LXMERT, we can simply replace the cross modal embedding vector in Figure 2 by M_{lxm} for bimodal QG. Alternatively, for ablation purpose, M_{lxm} can directly decoded without memory-based decoder, which we denote as LXMERT QG. Our final loss of bimodal captioning is a seq2seq loss.

$$L_{seq} = -\sum_{t=0}^{l} log(P(y_t | y_{<t}, I, T))$$

where t is the time step and l is the length of caption.

4 Trimodal QG: Query-aware representation

Our proposed bimodal QG partially contributes to relax paired-text assumption, but neither image

---

[2] C can be a subset of arbitrary size from t, which we empirically tune to $j = 30$.

and text representation is aware of queries. We argue that, queries carry rich semantics and contribute significantly to to relax paired-text assumption, specified as two key contributions C1 and C2 below.

- C1: We use query to improve image and text representation to disentangle into shared/private semantics where q matches the shared semantics.
- C2: As query generation is better trained when t and i are paired, we revise image representation to enhance pairedness with given query.

Motivated, we propose two new loss functions L_1 and L_2, addressing C1 and C2 respectively.

4.1 Query-aware relevance

For addressing **C1**, we model "private" parts of image and text, denoted as P_i and P_t, to relax the paired-text assumption. Our goal is to build joint representation S, aligning only the shared part of image and text, with query q.

$$S = W_5[I^{key}; T^{key}] + b_5$$
$$P_i = W_6 I^{key} + b_6$$
$$P_t = W_7 T^{key} + b_7$$

where $W_5, W_6, W_7 \in R^{m\times 2m}$ and $b_5, b_6, b_7 \in R^m$ are trainable parameters. I^{key} and T^{key} are the image and text input vectors, respectively. These inputs are concatenated into $[I^{key}, T^{key}]$ and multiplied by W_5 so that the combined modality can be projected into same semantic space with private vectors P_i and P_t.

To ensure this joint representation to project closely to the representation of query, query embedding vector Q_v is generated by LSTM with generated query $y_0, ..., y_{t-1}$:

$$Q_v = \mathrm{LSTM}(Q)$$

with the objective loss to keep private vectors away from query, and shared close to query:

$$L_1^{img} = \max\{0, r - (\mathrm{sim}(Q_v, S) - \mathrm{sim}(Q_v, P_i))\}$$
$$L_1^{text} = \max\{0, r - (\mathrm{sim}(Q_v, S) - \mathrm{sim}(Q_v, P_t))\}$$
$$L_1 = L_1^{img} + L_1^{text}$$

where r is the margin parameter. This margin enables our model to relax the decision function in LXMERT, predicting whether t and i are paired, as a binary classification. Unlike such binary prediction, computing zero or one score for partially paired pair (Figure 1b), the above two losses compute a scalar score and make a soft decision based on similarity. The query-aware relevance loss L_1 is defined by combining the two losses for each modality.

4.2 Query-aware alignment

For **C2**, we revise image representation to highlight query-related semantics, to make it semantically pair better with text representation. To reflect a (possibly nonlinear) relation with the query and the image, a fully connected neural network is applied to each modality before gating. Formally, query-aware image embedding V_p is described below:

$$A_q = \sigma(w_8 Q_v + b_8)$$
$$V_p = (w_9 I^{key} + b_9) \odot A_q$$

where Q_v is the query embedding, A_q is the attention derived from query with sigmoid σ, $\odot$ means element-wise multiplication and $w_9 \in R^{m\times m}$ and $b_9 \in R^m$ are trainable parameters. $w_8 \in R^{m\times m}$ and $b_8 \in R^m$ are learned with m-dimension query embedding. We apply the fully connected layer (first term before element-wise multiplication) to project image near query embedding.

We apply query-aware image representation to the multimodal space learning:

$$L_2 = \max\{0, r - (\mathrm{sim}(V_p, T_+^{key}) - \mathrm{sim}(V_p, T_-^{key}))\}$$

where r is the margin and $+$ means positive text where text belongs into same document with given image and $-$ means negative text from different document.

Finally, we combine the two loss functions as a final query-aware loss L_q:

$$L_q = L_1 + L_2$$

Our final loss of trimodality captioning is the sum of seq2seq loss and query aware alignment loss:

$$L_{final} = L_{seq} + L_q$$

	R@1	R@10	R@30
BM25	0.166	0.672	0.809
LXMERT QG	0.175	0.684	0.813
Bimodal QG	0.207	0.718	0.816
Ours (Trimodal QG)	**0.213**	**0.723**	**0.823**

Table 1: Public dataset results for first-stage retrieval

5 Experiment

The goal of our evaluations is to validate the effectiveness of our approach in public dataset and real-world Web search queries and settings. In particular, we have two research questions:

- **RQ1** Would QG task benefit from LXMERT model? How does our approach compare with BM25 or Bimodal for first-stage retrieval?
- **RQ2** Would our approach improve real-life Web search queries?

We use public dataset for RQ1 and real-life queries and quality annotation for ad-hoc web search task from NAVER for RQ2.

5.1 RQ1: Public reproducible scenarios

5.1.1 Dataset

As there is no public dataset with query workloads and multimodal documents, we repurpose a public dataset of instructional videos (Kim et al., 2020) by transforming videos into multimodal documents, which consists of 2000 query-video pairs, where each video is a recipe instruction from YouCook2 dataset[3]. We first sample an image corresponding to each sentence in the transcript, by capturing a center frame. As this may create too many (image,sentence) pairs, we propose to cluster into more natural boundaries using temporal and semantic aspects: A pair of successive frames, each with textual transcript and a set of objects [4], will be merged if more than $clip\%$ objects overlap, which is empirically tuned for each experiment. When $clip\%$ is set to 100%, it is our initial setting without merging, and this can be tuned to better fit the target scenario. Figure 3 shows the example of video clipping, where associated frames are merged into multimodal paragraphs with images and transcripts. The lengths of extracted multimodal paragraphs are from 1 to 20 according to video. Therefore it can correspond to short to long length of actual documents.

5.1.2 Experiment settings

To preprocess text and image input data, we use NLTK text tokenizer (Sukhbaatar et al., 2015) and Resnet-101 CNN respectively. When learning a query generator, the dimensionality of image and word embedding vector is set to 2048 (by following the size of pool5 vector of ResNet) and 100 respectively. The dimensionality of memory m and query embedding are empirically determined to 256. Mini-batch stochastic gradient descent method is used to learn our query generator. Specifically, we used Adam optimizer (Kingma and Ba, 2014) with the default setting. The initial learning rate is set as 0.001 and is divided by 1.2 at every five epoch until it reaches 30 epochs. The number of generated query is up to 8.

In this study, we follow a standard two-stage document retrieval scenario: First, top 30 candidate documents are ranked and selected from the index using a first-stage ranker, namely BM25, LXMERT, Bimodal, and Trimodal in Table 1. Then, the second-stage ranker follows, which is generally more sophisticated and expensive, such as BERT-based ranker (Nogueira et al., 2019). However, we stress that our work is orthogonal to second-stage ranker and focus on first-stage results.

5.1.3 Results

First-stage ranking results on this public English dataset are shown in Table 1. In this dataset, evaluation metrics is limited to R@K, due to binary nature of relevance annotation: the ratio of ground truth videos that appear in our top-K results, when $K = 30$ is returning all results. In real-life evaluation in the next section, graded relevance annotations will be collected to evaluate rank accuracy. BM25 in the table uses raw BM25 score on text t itself. The other QG models (LXMERT QG, Bimodal QG, and Trimodal QG) are implemented as BM25 scoring on expanded text t' with queries, generated from each QG model respectively. In all evaluations, relevance scores on t and t' are aggregated with linear weighting, which we empirically tune $\lambda = 0.9$ for t' (and $1 - \lambda$ for t). In all metrics, Bimodal and Trimodal outperform BM25 ranking, validating our hypothesis that considering image for joint document representation is effective.

Based on this result, our evaluations from this point on focus on evaluating Trimodal, with real-

(a) Raw video (b) Multimodal document

Figure 3: An example of video clipping to show how we transform a video into a multimodal document. Each multimodal document is clustered into paragraphs, with images and transcripts, shown as red boxes.

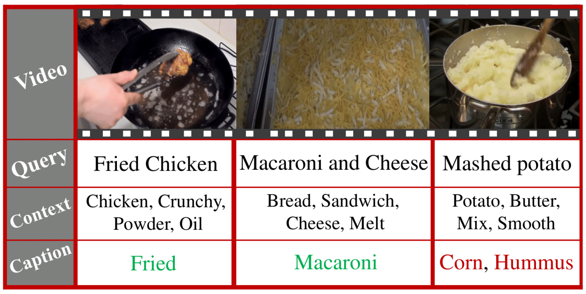

Figure 4: Qualitative examples demonstrating caption generation of our model on public dataset. Successful cases are highlighted by green. Failure case is highlighted by red.

life settings, allowing multilinguality, graded relevance annotation, and a realistic ranker.

5.1.4 Qualitative results

The example images, contexts, and captions are presented in Figure 4. It shows an improvement on search by generating queries for multimodal documents. An example of correctly generating query is shown in the first and second image of Figure 4. The images and contexts are highly related to the name of cooking, but it does not exist in the context where the words are selected by applying TF-IDF to transcript. In this case, our model could make a considerable contribution to search performance by directly generating the query itself like “fried” and “macaroni”. The failure case is shown in the third image of Figure 4. The recipe for hummus and mashed potato both have a mashing step and similar-looking ingredient. If the cooking method and the appearance, color, and texture of the ingredients are similar, the model has a probability of generating other queries. As shown above, our model does great for generating query words to support first-level retrieval.

5.2 RQ2: Real-world ad-hoc web search scenarios

5.2.1 Dataset

The source dataset used in our experiments is the evaluation set of the web search ranking task from the real-life commercial search engine. This dataset contains about 28,000 queries, for each of which 60 document URLs from search engine results are found. In real-time commercial dataset, annotating the relevance of all query-document pairs is impractical. Instead, we pooled top 60 documents, as used widely in IR evaluation to reduce annotation efforts, where only top ranked documents from a small set of retrieval runs are manually assessed for relevance to investigate the impact of first-stage retrieval. These documents are labeled by expert query annotators into one of five graded relevance score, ranging from 1 (poor) to 5 (excellent), or left unlabelled. Since unlabelled documents were randomly sampled from low ranks of search results, we treat all unlabelled documents as irrelevant ones (score 1). Additionally each query is classified into domains by NAVER.we evaluate real world dataset in such experiment setting.

5.2.2 Experiment settings

Out of all domain areas, we observe five main categories where the image information is expected to complement missing information from text–namely, Fashion, Place, Entertainment, Commerce, and Food/Recipe. We select query-document pairs annotated as described above for these categories. More specifically, Table 2 shows the selected categories and the number of queries in each category.

As a realistic ranker, we replace BM25 and train LambdaMart, as implemented in LightGBM (Ke et al., 2017; Meng et al., 2016), which is gradient boosting framework developed by Microsoft that uses tree based learning algorithms. The ranking model is trained and tested separately for each

Category	# of queries
Fashion	119
Entertainment	347
Food/Recipe	205
Place	971
Commerce	1665

Table 2: Statistics of categories selected from real-life data

category. For evaluation metrics, we follow the convention of prior work, to use NDCG@1, 5, 10, evaluated using a 5-fold cross-validation. A detailed description of the text features and image feature used to learn the ranking model is as follows.

To handle Korean text, we replace a tokenizer from KoNLPy [5]. Except this, all other experiment settings, including configurations to learn our query generator, remain unchanged from previous experiments.

BM25F score of query-document
BM25 score of query-document title
BM25 score of query-highlighted text
Exact matching of query-document
Query proximity score on document
Query proximity score on document title
Covered query term ratio of document title
Covered query term ratio of front section
Covered query term ratio of highlighted text

Table 3: Descriptions of real-life text features selected

Each document in real-life search engine is represented by hundreds of pre-computed features. Among them, we select nine widely used features related to textual similarity between a query and document. The selected features are shown in Table 3. Those features are used for the text baseline in Table 4.

5.2.3 Results

Table 4 reports accuracy gains in the five selected categories. For the four of five categories, our proposed approach achieved up to 10.8% gain on NDCG@1.

The category seeing the highest gain has been Food/Recipe, where images can be informative and complement textual instructions in this domain, as consistently observed empirically.

On the other hand, Commerce domain, though we expected showing the image of actual goods would complement text information, was the worst performing category. Our analysis shows that expert annotation was biased to highly rated official sites, while the same item can be sold in millions of sites with lower authority. Meanwhile, our models focusing on document relevance only, following the convention of ad-hoc retrieval scenarios, could not distinguish such difference.

Table 5 shows the search performance of each category when a document is ranked using only trimodal-aware image feature. The best search performance category is the Food/Recipe, which had the highest performance gain in Table 4, and the other categories show a similar performance. The score of ranking model using only image feature can achieve performance about 62% of that of using all features, with respect to NDCG@5.

Table 6 reports the accuracy gains of all categories over strong baselines. Only our trimodal query generation shows positive results on all domains. This demonstrates that our proposed query-aware trimodal loss contributes to capturing the query-relevant semantic of images.

6 Conclusion

We study the problem of representing a multimodal document to be indexable for efficient first-stage. Our contribution is posing the problem as trimodal QG to augment the given text, by proposing a trimodal joint representation of image, text, and query without paired-text assumption. We validate our approach over both public dataset and real-life web search data collected from commercial search engines.

Abstract

Non-neural approaches to argument mining (AM) are often pipelined and require heavy feature-engineering. In this paper, we propose a neural end-to-end approach to AM which is based on dependency parsing, in contrast to the current state-of-the-art which relies on relation extraction. Our biaffine AM dependency parser significantly outperforms the state-of-the-art, performing at $F_1 = 73.5\%$ for component identification and $F_1 = 46.4\%$ for relation identification. One of the advantages of treating AM as biaffine dependency parsing is the simple neural architecture that results. The idea of treating AM as dependency parsing is not new, but has previously been abandoned as it was lagging far behind the state-of-the-art. In a thorough analysis, we investigate the factors that contribute to the success of our model: the biaffine model itself, our representation for the dependency structure of arguments, different encoders in the biaffine model, and syntactic information additionally fed to the model. Our work demonstrates that dependency parsing for AM, an overlooked idea from the past, deserves more attention in the future.

1 Introduction

People often hold different opinions about the same thing. One very common way to express one's opinions is to construct an argument (Mercier and Sperber, 2011; Van Eemeren and Henkemans, 2016). To help people efficiently understand different opinions and their reasoning embedded in arguments, it is necessary to develop systems that can automatically analyse structures of arguments. An emerging research field called Argumentation Mining or Argument Mining (AM) (Peldszus and Stede, 2013; Green et al., 2014) addresses this problem.

To analyse the structure of arguments, AM typically proposes four subtasks: 1) *component segmentation*, *i.e.*, cutting a raw sequence into text spans that are either argumentative or non-argumentative segments (only argumentative segments are called argument components); 2) *component classification*, *i.e.*, labelling each argument components with a tag in a pre-defined scheme, (*e.g.*, "PREMISE" or "CLAIM"); 3) *relation detection*, *i.e.*, deciding if two argument components are directly related; and 4) *relation classification*, *i.e.*, categorizing a detected relation into a class in a pre-defined scheme, (*e.g.*, "ATTACK" or "SUPPORT") (Persing and Ng, 2016; Eger et al., 2017; Habernal and Gurevych, 2017; Stab and Gurevych, 2017; Lawrence and Reed, 2020). The first two subtasks are often referred together as *component identification*, and the last two as *relation identification*. An example of the argument structure is illustrated in Figure 1. We see that the "rain" component acts as the premise, supporting the claim of "beautiful".

Some of the AM approaches that try to solve all four subtasks use a pipelined architecture. Independent models are first trained for each subtask; the final results are then achieved by using model ensemble methods such as Integer Linear Programming (Persing and Ng, 2016; Stab and Gurevych, 2017). Like many other pipelined approaches, they often suffer from error propagation. Moreover, many of those models are rule-based or feature-based (Persing and Ng, 2016; Stab and Gurevych, 2017), which require extensive manual efforts and are not flexible or robust in cross-domain scenarios.

As a result, neural end-to-end approaches are desirable for AM. However, it is difficult to jointly model all AM subtasks within one single neural network, because component segmentation and

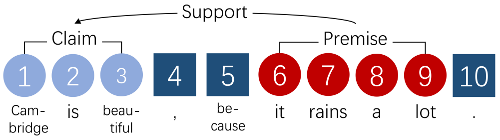

Figure 1: An example argument structure for "*Cambridge is beautiful, because it rains a lot.*"

April 19 - 23, 2021. ©2021 Association for Computational Linguistics

classification are usually approached at the token-level, but relation detection and classification at the segment-level. Therefore, many researchers try to solve only some of them with neural approaches. For example, Morio and Fujita (2019) focus only on component segmentation and classification; Niculae et al. (2017) and Morio et al. (2020) both ignore the component segmentation task, feeding manually segmented text as input into their models.

As far as we know, Eger et al. (2017) present the first study on neural end-to-end AM that addresses all subtasks in one model. They make a comprehensive comparison of methods, among which a model originally proposed for extracting entities and relations (LSTM-ER) achieves the best performance on a popular AM benchmark (Stab and Gurevych, 2017), far outperforming one that uses a dependency parsing (DP) approach.

In this paper, we propose another neural end-to-end approach for the full AM task, called Biaffine Dependency Parsing for Argument Mining (BiPAM). In our approach, AM is formalised as a DP problem, which we model with a modified biaffine neural network (Dozat and Manning, 2018), using our own dependency representation for arguments. Our representation, like the one in Eger et al. (2017), also unifies all AM subtasks under a token-level framework, so that they can be modelled with one single neural network. The biaffine parser in our approach mainly consists of a neural encoder to extract contextualized features of each token in a sequence, and a biaffine classifier that decides which relation holds between any two tokens, and returns a directed acyclic graph (DAG) expressing this information.

Compared with the DP approach in Eger et al. (2017), our model performs at a much higher performance rate. We argue that this is mainly due to the fact that our biaffine model is more powerful in modelling AM-style dependency structures, and also due to other factors such as our dependency representation, which seems closer aligned with linguistic intuitions. Eger et al. (2017) may have discredited the DP approach altogether due to its unsatisfactory results in their setting, but our work reaffirms its potential for AM, given a more powerful parser and a better dependency representation.

Experiments show that our approach also outperforms the best-performing approach (LSTM-ER) in Eger et al. (2017) and thus achieves a new state-of-the-art. Compared with LSTM-ER, our biaffine parser is conceptually and structurally simpler, and our approach is more general because the output of our biaffine parser is a DAG instead of a tree; this is required by several argument schemes which go beyond trees (Park and Cardie, 2018; Lawrence and Reed, 2020).

Our main contributions are as follows:

- We are the first to apply the biaffine parser to AM in an end-to-end approach addressing all four subtasks in one model. Our proposed biaffine argument parser is applicable to non-tree as well as tree-based argument schemes.
- As well as being a theoretically more clean-cut model, our proposed model also significantly outperforms the state-of-the-art approach by 3.3% in F_1 for component identification and 1.3% for relation identification.
- We also present a novel representation for dependency structures of arguments, which is empirically more efficient than Eger et al. (2017).

2 Related Work

Our work is closely related to existing approaches framing AM as DP and to research on neural end-to-end AM.

The essential aim of AM is to analyse the structure of arguments. Most argument schemes (Toulmin, 2003; Peldszus and Stede, 2013; Habernal and Gurevych, 2017; Visser et al., 2019) represent argument structures as trees or DAGs. Similar structures also exist in syntactic and semantic parsing, and can be efficiently analysed with existing dependency parsers (Dozat and Manning, 2017, 2018; Qi et al., 2018). However, unlike syntactic or semantic parsing, dependency structures in AM operate at the segment-level, not the token-level. To apply existing DP techniques to AM, one can either ignore the component segmentation task, only working on already segmented text, or one can convert segment-level dependencies to token-level dependencies.

Morio et al. (2020) take the first approach. In their work, the input is manually segmented, with argumentative and non-argumentative segments already given. They use task-specific BiLSTMs to encode those segments, and a biaffine dependency parser (Dozat and Manning, 2018) with minor alternation to classify argument components and their

(a) (b)

Figure 2: (a) Eger et al. (2017)'s representation, and (b) our representation, for "*Just because it killed much marine life, tourism has threatened nature.*"

relations. They report satisfactory results for component classification and relation identification on the Cornell eRulemaking Corpus (CDCP) (Niculae et al., 2017; Park and Cardie, 2018).

In contrast, Eger et al. (2017) take the second approach, taking raw text as input so that the component segmentation task is addressed. They design a dependency representation for argument structures, in which dependencies are represented at the token-level, with all edges pointing from parent to child[1]. They have evaluated feature-based parsers (McDonald et al., 2005; Bohnet and Nivre, 2012) and neural parsers (Dyer et al., 2015; Kiperwasser and Goldberg, 2016), both of which show unsatisfactory performance. As a result, they discarded DP as inferior.

Our work is similar to Morio et al. (2020) in that we also use a modified biaffine dependency parser to model dependencies in argument structures, but similar to Eger et al. (2017) in that we model AM as a full task starting from tokens, not segments.

Besides DP, Eger et al. (2017) also study other approaches to neural end-to-end AM, including sequence tagging (Ma and Hovy, 2016), multi-task tagging (Søgaard and Goldberg, 2016), and relation extraction (Miwa and Bansal, 2016). Among them, the LSTM-ER model for relation extraction performs the best. However, it requires an additional syntactic parser to produce syntactic dependency trees for the model input. Moreover, the tree-structured LSTM module used to encode those syntactic dependency trees is both conceptually and structurally complicated. In contrast, our proposed approach does not require such syntactic information to break the state-of-the-art (although we will show that it can be enhanced if this information is provided), and the architecture of our biaffine dependency parser is both simpler and more general than that of the LSTM-ER.

3 Proposed Approach

We propose to formalise AM as DP, using a modified biaffine dependency parser, which outputs dependency graphs. To make this work, we first design a dependency representation for arguments which unifies all subtasks of AM under a token-level framework.

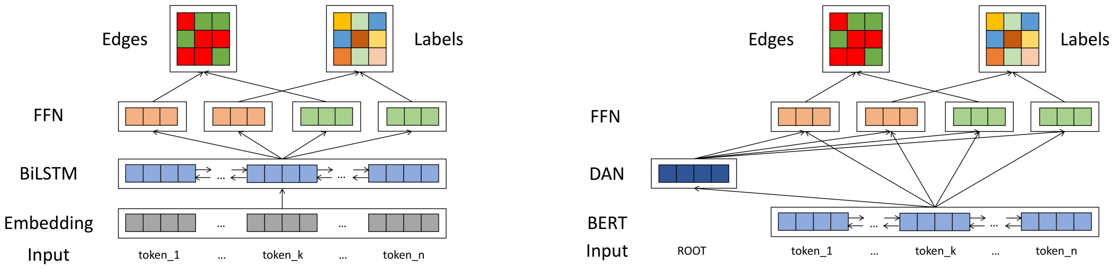
3.1 Dependency Representation for Arguments

Our dependency representation for the structure of arguments contains information about segment boundaries, and about types of relations that could potentially hold between segments, as illustrated in Figure 2(b). The relevant properties of our representation are as follows:

- Information on segment boundaries and segment labels is shown as within-segment labelled edges. Within a segment (*e.g.*, $token[3, ..., 7]$), whether argumentative or non-argumentative, each token, except the last one, is parented by its succeeding token. Labels of within-segment edges are in the form of "($segment\_label \in [component\_label, \mathrm{N}]$, APP)", in which $component\_label = \{\mathrm{MC, C, P...}\}$. "APP" here means "append", and "N" means "non-argumentative segment".
- Information on relations and relation labels is shown as inter-segment labelled edges. If a relation exists between two components, it is expressed as a labelled edge between the last token of the parent, pointing to the last token of the child (*e.g.*, the "SUPPORT" edge from $token[12]$ to $token[7]$). The last token in a non-argumentative segment does not have any parent node.

---

[1] Note the difference in arrow conventions between AM and standard DP. Figure 2 shows dependencies pointing from head to dependent, as is common in DP. In contrast, in AM, relations are shown in the opposite direction (*i.e.*, pointing from parent to child), as shown in Figure 2(a). In the rest of this paper, A→B means A pointing to B in terms of argument schemes, while A⇐B means B pointing to A in terms of dependency representations.



(a) (b)

Figure 3: (a) the biaffine parser in Dozat and Manning (2018), and (b) our modified biaffine parser.

- A pseudo-token *ROOT* is added to the beginning of each argument. This *ROOT* token can be used to represent the topic or the gist of the entire argument, making it possible to model the relationship between components and the topic or the gist. *ROOT* is always acting as a parent to the highest-level component(s).
- Each token is allowed to have zero, one, or more parents, resulting in a dependency graph.

In contrast, Eger et al. (2017) use a representation where each token in a segment is parented by the first token in its parent. But this contradicts general linguistic intuitions, whereby tokens within a segment should be closely related to their surrounding tokens, as is the case in our representation. As a result, we might expect that our representation is better able to model within-segment and long-distance inter-segment dependencies. There are also differences between how we and Eger et al. conceptualize the root node of the argument. They use the terminating token in an argument as root, with all non-argumentative tokens parented by it; in their case this is always a punctuation mark. We think this conceptualisation of the root node is troublesome for two reasons. First, there is no reason why all non-argumentative segments should be related to the terminating token. Second, for arbitrary annotation schemes, the terminating token could be a part of a component. When this happens, all non-argumentative tokens will be parented by the last component in an argument, which goes against linguistic intuitions. In contrast, our representation uses the pseudo-node *ROOT* to avoid this, which is outside all textual segments, and non-argumentative segments never have any inter-segment relations in our representation. In addition, Eger et al. (2017) use the BIO scheme to encode segment boundaries, which results in a larger prediction space than ours, because we can encode the same information topologically[2], making our representation potentially computationally more efficient.

3.2 Modified Biaffine Parser

To our knowledge, the state-of-the-art dependency parser is the one in Dozat and Manning (2018). It consists of a BiLSTM to encoder input text, and a deep biaffine attention module to score each possible head-dependent pair, as shown in Figure 3(a).

The structure of our biaffine parser, as shown in Figure 3(b), closely follows that of Dozat and Manning (2018). We have replaced the Embedding layer and the BiLSTM layer with a pre-trained BERT encoder (Devlin et al., 2019), so that the parser can benefit from rich unsupervised data. Given a text sequence $S = s_1 s_2 ... s_n$, its encoded representation $r_{\text{-}S} \in \mathbb{R}^{n \times d_{enc}}$ is calculated as in Eq. (1), where BERT means the BERT encoder.

$$r_{\text{-}S} = \mathrm{BERT}(s_1 s_2 ... s_n) \tag{1}$$

$$r_{\text{-}ROOT} = \mathrm{FFN}(\mathrm{mean}(r_{\text{-}S}), \mathrm{axis}{=}0) \tag{2}$$

$$R = [r_{\text{-}S}; r_{\text{-}ROOT}], \mathrm{axis}{=}0 \tag{3}$$

$$H^{\mathrm{edge\_parent}} = \mathrm{FFN}^{\mathrm{edge\_parent}}(R) \tag{4}$$

$$H^{\mathrm{label\_parent}} = \mathrm{FFN}^{\mathrm{label\_parent}}(R) \tag{5}$$

$$H^{\mathrm{edge\_child}} = \mathrm{FFN}^{\mathrm{edge\_child}}(R) \tag{6}$$

$$H^{\mathrm{label\_child}} = \mathrm{FFN}^{\mathrm{label\_child}}(R) \tag{7}$$

$$\mathrm{Biaff}(x, y) = x^{\top} \mathrm{U} y + \mathrm{W}(x \oplus y) + b \tag{8}$$

$$sc^{\mathrm{edge}} = \mathrm{Biaff}^{\mathrm{edge}}(H^{\mathrm{edge\_parent}}, H^{\mathrm{edge\_child}}) \tag{9}$$

$$sc^{\mathrm{label}} = \mathrm{Biaff}^{\mathrm{label}}(H^{\mathrm{label\_parent}}, H^{\mathrm{label\_child}}) \tag{10}$$

$$y_{i,j}^{\prime\mathrm{edge}} = \{sc_{i,j}^{\mathrm{edge}} \geq 0\} \tag{11}$$

$$y_{i,j}^{\prime\mathrm{label}} = argmax\ sc_{i,j}^{\mathrm{label}} \tag{12}$$

$$\mathscr{L} = (1 - \lambda)\mathscr{L}^{\mathrm{edge}} + \lambda\mathscr{L}^{\mathrm{label}}, \lambda \in (0, 1) \tag{13}$$

Eq. (2) shows how $r_{\text{-}ROOT} \in \mathbb{R}^{1 \times d_{enc}}$, the representation of *ROOT*, is calculated using a

---

[2] Segment boundaries in our system can be recognised by parenthood or by label – when a label does not contain "APP", a segment boundary has occurred.

deep averaging network (DAN) (Iyyer et al., 2015). $ROOT$ does not go through the BERT encoder like other tokens, because it is considered to represent the gist of the whole argument for the dataset in our experiments. FFN means a feedforward network.

In Eq. (3), $R \in \mathbb{R}^{(n+1)\times d_{enc}}$, the $ROOT$-inclusive representation of S, is derived as the concatenation of $r_{\text{-}ROOT}$ and $r_{\text{-}S}$.

In Eq. (4, 5, 6, 7), four representations are created for R respectively, including two parent-wise representations and two child-wise representations for edge and label prediction, as in Dozat and Manning (2018).

Eq. (8) shows the biaffine classifier in Dozat and Manning (2018), with U, W and b being trainable variables. Using this classifier, edges and their labels are predicted respectively as in Eq. (9, 10, 11, 12). Like Dozat and Manning (2018), the edge-classifier is trained with sigmoid cross-entropy, and the label-classifier with softmax cross-entropy. The total loss is calculated as in Eq. (13). During training, losses are back-propagated to the label-classifier only through edges in the gold standard.

Dropout (Srivastava et al., 2014) is applied for each layer in the proposed model.

4 Experiments

We conduct experiments on a benchmark for AM to evaluate the performance of our model.

4.1 Dataset

The dataset we use in our experiments is a benchmark constructed by Stab and Gurevych (2017), which is also used in Eger et al. (2017). This dataset consists of 402 persuasive essays randomly selected from an online forum (322 for training and 80 for testing). Statistics for this dataset are shown in Table 1.

The argument scheme adopted for this dataset is illustrated in Figure 4. In this dataset, there are four kinds of components. A *major claim* (MAJORCLAIM) is the overall stance of the author, which can be regarded as the overall gist of the whole essay. A *claim* (CLAIM) is a statement that is either *for* (FOR) or *against* (AGAINST) one or more major claims. A *premise* (PREMISE) is the lowest-level component that either *supports* (SUPPORT) or *attacks* (ATTACK) a claim or another premise.

		All	Per Essay
Size	Sentence	7,116	18
	Token	147,271	366
	Paragraph	1,833	5
Components	MAJORCLAIM	751	2
	CLAIM	1,506	4
	PREMISE	3,832	10
	Total	6,089	15
Relation	FOR	2,345	6
	AGAINST	496	1
	SUPPORT	3,613	9
	ATTACK	219	1

Table 1: Statistics of the entire Stab and Gurevych (2017) dataset (test+train).

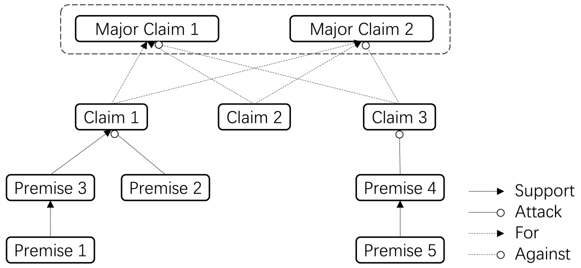


Figure 4: The argument scheme adopted in the Stab and Gurevych (2017) dataset.

Some special characteristics of this dataset are as follows:

- Each essay contains one or more major claims. All major claims within an essay are considered to be equivalent in meaning, and are treated as an equivalence class. In the case of multiple major claims, the structure of the argument is no longer a tree (it is reconstructed as a tree by regarding multiple major claims as one single node in Eger et al. (2017)).
- A claim is allowed to have no supporting or attacking premise.
- Premise→Claim and Premise→Premise pairs are always within-paragraph. Only Claim→MajorClaim pairs are allowed to cut across paragraphs.

Since most relations are within-paragraph for this dataset, our proposed model operates at the paragraph-level. According to our dependency representation, we need a pseudo-token $ROOT$ for each paragraph. If there is one or more major claims in a paragraph, $ROOT$ takes them all as children. Otherwise, $ROOT$ takes all claims in that paragraph as children.

4.2 Competing Models

We choose two models in Eger et al. (2017) for comparison: 1) LSTM-Parser, the best-performing DP model, and 2) LSTM-ER, the overall best-performing model. We use our reimplementation of these models and observe results close to those reported in Eger et al. (2017). Both models are trained at the paragraph-level, with the default hyperparameter configuration provided in the source code. The same pre-trained GloVe embeddings (Pennington et al., 2014) are used as in Eger et al. (2017)[3]. We use the Stanford syntactic dependency parser (Chen and Manning, 2014) to produce syntactic trees required by the LSTM-ER model.

4.3 Training

We create a development set by choosing 30 essays randomly from the training set, which we use for tuning the interpolation factor λ ($\lambda = 0.05$) in Eq. (13) and dropout rate ($dropout = 0.1$), as well as for the early stopping mechanism. We choose the pre-trained BERT model by OpenAI from Devlin et al. (2019) as the encoder. We abandoned another pre-trained encoder GPT2 (Radford et al., 2019) because it performed slightly below BERT. The hidden size of FFNs and biaffine classifiers is set to 600, in line with Dozat and Manning (2018). We use the Adam optimizer (Kingma and Ba, 2014) ($\beta_1 = 0.95, \beta_1 = 0.98, \epsilon = 1e^{-9}$), and adopt the strategy in Vaswani et al. (2017) for the learning rate, with warm up steps set to 1000.

Each model in our experiments, except LSTM-ER and LSTM-Parser (and their related models), which we run only once[4], is trained ten times with different random initialisations. Results are reported in terms of average performance with standard deviations.

4.4 Final Graph Generation

First, several post-processing techniques are applied to make the parser output compatible with the AM dataset (similar techniques are also applied in Eger et al. (2017)), in the following order.

1. The parser sometimes recognises a segment as (mainly) belonging to one label, but interrupts it with a small number of non-fitting labels. We assume the label intended is the majority label and therefore assign it to the segment, if at least 3/5 of the edges share that same majority label in a sequence of consecutive tokens which are linked together.
2. For the remaining inter-segment edges, only valid edges are kept, namely Claim⇐MajorClaim, Premise⇐Claim, and Premise⇐Premise.
3. If two remaining segments are linked by multiple edges, all edges except the one with the highest probability are deleted.
4. If a remaining segment has multiple inter-segment edges, only Claim⇐MajorClaim edges are kept (as only claims can have multiple parents, which have to be major claims).

Component	Model$_a$	Model$_b$
g_1	TP	FN
g_2	FN	FP
...	...	...
g_m	TP	TP
p_1	FP	TN
p_2	FP	FP
...	...	...
p_n	TN	FP

Table 2: Result table for paired permutation tests.

Since our model operates at the paragraph-level rather than the essay-level, we need to combine the sub-graph produced with each paragraph. In the Stab and Gurevych (2017) dataset, only Claim→MajorClaim pairs can connect all sub-graphs in an entire essay. As a result, for each Claim→*ROOT* or Claim→MajorClaim pair, we first eliminate it, and then redirect that claim to all major claims, keeping the original edge label. By doing so, a final graph for the argument structure of the entire essay can be generated.

4.5 Evaluation

Similar to most work in AM, we adopt the evaluation metric in Persing and Ng (2016) to evaluate the performance of AM models. The F_1 scores for component and relation identification are calculated as $F = \frac{2\text{TP}}{2\text{TP}+\text{FP}+\text{FN}}$, in which TP is a true positive, FP false positive, and FN false negative.

We also design a method to apply paired Monte Carlo permutation tests (Dwass, 1957; Nichols and Holmes, 2002) to the results of two AM models. In our situation, results are measured by F_1 scores based on components, but a paired permutation test cannot be straightforwardly applied, because in general the number of components returned by the models is not the same. To address this, a result table is first constructed, as illustrated in Table 2. The set of items consists of the union of : 1) all gold standard components $\{g_1, g_2, ..., g_m\}$, and 2) all predicted components $\{p_1, p_2, ..., p_m\}$ by both models (those that are not duplicates, *i.e.*already contained in the gold standard). The treatment of

---

[3] This pre-trained GloVe embeddings are used for all LSTM encoders in our experiments.

[4] This is due to excessively long training time.

Model	Component	Relation
LSTM-Parser	58.4 (58.9)	34.9 (35.6)
LSTM-ER	70.2 (70.8)	45.1 (45.5)
BiPAM	72.9 ± 0.7	45.9 ± 0.5

Table 3: F_1 scores for competing models and our BiPAM model, with published results for competing models (the best instead of average results) in brackets.

gold standard components is standard for such tests (*i.e.*, TP, FN, FP are possible labels), but the predicted components are added by us, and can only be labelled as TN or FP. As these components are not in the gold standard, each time a model proposes such a component, it will be punished by receiving an FP. A predicted component p_i counts as a true negative (TN) for Model$_a$ if p_i has been predicted by Model$_b$ but not Model$_a$. Permutations are generated by swapping labels in the second and third columns for combinations of randomly selected rows. The two-tailed p-value is then calculated as in Eq. (14, 15), in which F_a means the real F_1 score for Model$_a$, and $F_a'^i$ means the F_1 score for Model$_a$ in the i-th permutation. N is the number of sampled permutations. When a model is trained with multiple initialisations, the one performing closest to the average is used for permutation tests.

$$diff_i = \begin{cases} 1 & , |F_a - F_b| < |F_a'^i - F_b'^i| \\ 0 & , |F_a - F_b| \geq |F_a'^i - F_b'^i| \end{cases} \quad (14)$$

$$p\text{−value} = \frac{1 + \sum_{i=1}^{N} diff_i}{1 + N} \quad (15)$$

5 Results and Discussion

The overall results of our experiments are shown in Table 3. For both component and relation identification, our model BiPAM significantly ($p < 0.01$) outperforms the state-of-the-art model LSTM-ER (72.9% vs. 70.2% and 45.9% vs. 45.1%), and also significantly outperforms LSTM-Parser by a large margin.

We can see from these results that the DP approach for AM is able to achieve the best results currently known on this dataset. This is interesting, as the current state-of-the-art, LSTM-ER, uses a far more complex neural architecture than our BiPAM.

The equivalent model to our BiPAM in Eger et al. (2017), LSTM-Parser, is outperformed by BiPAM by a large margin. We believe this is due to two factors: a biaffine parser is far more suitable for AM than an LSTM parser, and our dependency representation is superior to Eger et al. (2017)'s. We will now investigate the influence of these two factors. As we have already shown that our version of this approach beats the state-of-the-art, we will consider only those models which treat AM as DP.

Model	Component	Relation
LSTM-Eger (LSTM-Parser)	58.4	34.9
LSTM-ours	67.9	36.0
Biaff-Eger	65.7 ± 0.5	38.4 ± 0.5
Biaff-ours (BiPAM)	72.9 ± 0.7	45.9 ± 0.5

Table 4: F_1 scores for models with different combinations of parsers and representations.

5.1 Ablation Study

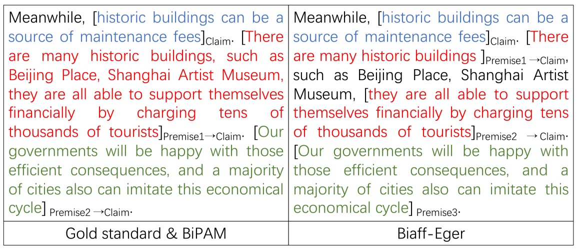
To understand why our proposed model performs better than LSTM-Parser in Eger et al. (2017), we conduct ablation experiments to assess the influence of our modified biaffine dependency parser and our representation for the dependency structure of arguments.

Besides LSTM-Parser and BiPAM (renamed as LSTM-Eger and Biaff-ours in Table 4), we also experiment with two other combinations of parsers and representations: 1) LSTM-ours, replacing Eger et al. (2017)'s representation in LSTM-Parser with ours; and 2) Biaff-Eger, replacing our representation in BiPAM with Eger et al. (2017)'s. Results of these cross-comparisons are shown in Table 4.

As far as parsers are concerned, our modified biaffine parser with either representation (Biaff-Eger and Biaff-ours) performs significantly ($p < 0.01$) better than its counterpart (LSTM-Eger and LSTM-ours). This suggests that our modified biaffine parser is better at capturing dependencies than the LSTM parser in Eger et al. (2017).

As for representations, either parser with our representation (LSTM-ours and Biaff-ours) significantly ($p < 0.01$) outperforms its counterpart (LSTM-Eger and Biaff-Eger). This demonstrates that our representation is superior.

The example text in Figure 5 is a paragraph in the test data that illustrates this fact. Our BiPAM model correctly predicts all components in it, as well as all the relations. In contrast, in the prediction of Biaff-Eger, the parenthetical phrase "such as Beijing Place[sic], Shanghai Artist Museum," in the relatively long component Premise2, is incorrectly recognized as non-argumentative. Biaff-Eger also fails to predict the relation between Premise3 and Claim, which is probably because these two components are located far from each other at opposite ends of the paragraph, making it difficult to detect the relations between and the first token in



Gold standard & BiPAM	Biaff-Eger
Meanwhile, [historic buildings can be a source of maintenance fees]$_{\text{Claim}}$. [There are many historic buildings, such as Beijing Place, Shanghai Artist Museum, they are all able to support themselves financially by charging tens of thousands of tourists]$_{\text{Premise1}\rightarrow\text{Claim}}$. [Our governments will be happy with those efficient consequences, and a majority of cities also can imitate this economical cycle] $_{\text{Premise2}\rightarrow\text{Claim}}$.	Meanwhile, [historic buildings can be a source of maintenance fees]$_{\text{Claim}}$. [There are many historic buildings]$_{\text{Premise1}\rightarrow\text{Claim}}$, such as Beijing Place, Shanghai Artist Museum, [they are all able to support themselves financially by charging tens of thousands of tourists]$_{\text{Premise2}\rightarrow\text{Claim}}$. [Our governments will be happy with those efficient consequences, and a majority of cities also can imitate this economical cycle] $_{\text{Premise3}}$.

Figure 5: Argument structures of an example paragraph predicted by BiPAM and by Biaff-Eger.

Model	Component	Relation
BiPAM	72.9 ± 0.7	45.9 ± 0.5
BiPAM-LSTM	71.4 ± 0.7	43.1 ± 0.7

Table 5: F_1 scores for BiPAM and BiPAM-LSTM.

Claim and tokens in Premise3.

We also want to understand the influence of the pre-trained BERT encoder in the biaffine parser. When we built BiPAM, we modified the original biaffine parser (Dozat and Manning, 2018) by replacing its Embedding layer and BiLSTM layer, with a pre-trained BERT encoder. It is possible that our performance improvements are at least partially due to this. We therefore test against a biaffine model without this replacement[5], named BiPAM-LSTM in Table 5. Results show that replacing the pre-trained BERT encoder with the original Embedding layer and BiLSTM layer significantly ($p < 0.01$) lowers the performance. This is easy to understand since the pre-trained BERT encoder has benefited from an tremendous amount of additional unsupervised data[6].

5.2 Enhancement with Syntactic Information

We believe that a part of the success of LSTM-ER in Eger et al. (2017) might be credited to the fact that the model is also given syntactic information in its input, in addition to the raw text. We borrow this idea to test whether BiPAM might get a performance boost in a similar way.

To do so, we use the Stanford syntactic dependency parser to produce syntactic trees. The pseudo-token *ROOT* is headed by the real root node in the syntactic tree, with an edge labelled as "ROOT". For each input token, we record its syntactic information in a triple as [head, location of head, label of in-coming edge]. The syntactic information triples are encoded as follows: 1) head tokens are encoded by an FFN with pre-trained GloVe embeddings; 2) head locations are encoded using the positional encoding method proposed in Vaswani et al. (2017); and 3) edge labels are passed to an FFN using one-hot encoding. For each token, the encoded representation of its syntactic information triple is concatenated to its encoded representation by BERT, and the entire representation is then fed into the following layers in BiPAM.

Model	Component	Relation
BiPAM	72.9 ± 0.7	45.9 ± 0.5
BiPAM-syn	73.5 ± 0.7	46.4 ± 0.6

Table 6: F_1 scores for BiPAM and BiPAM enhanced with syntactic information.

Results in Table 6 show that introducing syntactic information to the input can significantly ($p < 0.01$) boost the performance of the original BiPAM, outperforming LSTM-ER by 3.3% for component identification and 1.3% for relation identification. These results represent our best and final system.

6 Conclusion

In this paper, we solve argument mining (AM) as a neural end-to-end dependency parsing (DP) problem. As a non-pipelined approach, our solution is free from error propagation. We have demonstrated that the biaffine dependency parser from Dozat and Manning (2018) can act as a powerful AM parser, under the right circumstances. We use BERT as the encoder, feed syntactic information into the model in addition to raw text, and propose a novel, efficient and linguistically plausible representation for the dependency structure of arguments. Our model significantly outperforms current state-of-the-art in neural end-to-end AM, performing at $F_1 = 73.5\%$ for component identification and 46.4% for relation identification. Our research suggests that DP, which has been prematurely abandoned in the past, is actually a very promising approach for AM. Through an ablation study, we find that both the modified biaffine parser and the dependency representation contribute to the performance improvement of BiPAM.

---

[5] With this model, there is one change we cannot avoid, and this is that we have to keep the DAN layer for *ROOT*, which does not go through the encoder.

[6] One could also argue that the right way to address the in-domain vs. out-of-domain problem is to train the BERT encoder from scratch using our in-domain training data. We do not perform these experiments, because due to the small data size, it is almost certain that BERT would be over-fitted.

Abstract

Fake news articles often stir the readers' attention by means of emotional appeals that arouse their feelings. Unlike in short news texts, authors of longer articles can exploit such affective factors to manipulate readers by adding exaggerations or fabricating events, in order to affect the readers' emotions. To capture this, we propose in this paper to model the flow of affective information in fake news articles using a neural architecture. The proposed model, FakeFlow, learns this flow by combining topic and affective information extracted from text. We evaluate the model's performance with several experiments on four real-world datasets. The results show that FakeFlow achieves superior results when compared against state-of-the-art methods, thus confirming the importance of capturing the flow of the affective information in news articles.

1 Introduction

In today's information landscape, fake news are used to manipulate public opinion (Zhou and Zafarani, 2018) by reshaping readers' opinions regarding some issues. In order to achieve this goal, authors of fake news' narratives need to capture the interest of the reader. Thus, they are putting efforts to make their news articles look more objective and realistic. This is usually done by adding misleading terms or events that can have a negative or positive impact on the readers' emotions.

Short text false information, e.g., fake claims or misleading headlines, might be less harmful than news articles. They may have some eye-catching terms that aim to manipulate the readers' emotions (Chakraborty et al., 2016). In many cases, the identification of this kind of exaggeration in short statements can unmask the fabrication. On the other hand, in fake news articles the authors exploit the length of the news to conceal their fabricated story. This fact exposes the readers to be emotionally manipulated while reading longer texts that have several imprecise or fabricated plots. The flow of information has been investigated for different tasks: Reagan et al. (2016) studied the emotional arcs in stories in order to understand complex emotional trajectories; Maharjan et al. (2018) model the flow of emotions over a book and quantify its usefulness for predicting success in books; Kar et al. (2018) explore the problem of creating tags for movies from plot synopses using emotions.

Unlike previous works (Rashkin et al., 2017; Shu et al., 2018; Castelo et al., 2019; Ghanem et al., 2020) that discarded the chronological order of events in news articles, in this work we propose a model that takes into account the affective changes in texts to detect fake news. We hypothesize that fake news has a different distribution of affective information across the text compared to real news, e.g. more fear emotion in the first part of the article or more overall offensive terms, etc. Therefore, modeling the flow of such information may help discriminating fake from real news. Our model consists of two main sub-modules, topic-based and affective information detection. We combine these two sub-modules since a news article's topic may have a correlation with its affective information. For example, a fake news article about Islam or Black people is likely to provoke fear and express negative sentiment while another fake news that is in favor of a particular politician might try to evoke more positive emotions and also express some exaggerations.

The contributions of our work are as follows:

- We design a model that detects fake news articles by taking into account the flow of affective information[1].

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 679–689
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

- Extensive experiments on four standard datasets demonstrate the effectiveness of our model over state-of-the-art alternatives.
- We build a novel fake news dataset, called MultiSourceFake, that is collected from a large set of websites and annotated on the basis of the joint agreement of a set of news sources.

2 Related Work

Previous work on fake news detection is mainly divided into two main lines, namely with a focus on social media (Zubiaga et al., 2015; Aker et al., 2017; Ghanem et al., 2019) or online news articles (Tausczik and Pennebaker, 2010; Horne and Adali, 2017; Rashkin et al., 2017; Barrón-Cedeno et al., 2019). In this work we focus on the latter one. Fact-checking (Karadzhov et al., 2017; Zlatkova et al., 2019; Shu et al., 2019a) is another closely related research topic. However, fact-checking targets only short texts (that is, claims) and focuses on using external resources (e.g. Web, knowledge sources) to verify the factuality of the news. The focus in previous work on fake news detection is mainly on proposing new feature sets. Horne and Adali (2017) present a set of content-based features, including readability (number of unique words, SMOG readability measure, etc.), stylistic (frequency of part-of-speech tags, number of stop words, etc.) and psycholinguistic features (i.e., several categories from the LIWC dictionary (Tausczik and Pennebaker, 2010)). When these features are fed into a Support Vector Machine (SVM) classifier and applied, for instance, to the task of distinguishing satire from real news, they obtain high accuracies. Using the same features for the task of fake news detection, however, results in somewhat lower scores. Pérez-Rosas et al. (2018) propose a model (FakeNewsDetector) that uses a feature set consisting of unigrams and bigrams, psycholinguistic, readability, punctuation and dependency-based syntactic features, and they evaluate the performance of their model in a cross-domain experiment. Rashkin et al. (2017) use a model based on ngram features with a MaxEntropy classifier and apply it to a dataset with different types of fake news articles (e.g., satire, hoax, propaganda, etc.). Similar to the previous work, the authors evaluate their system's performance on in-domain and out-of-domain test sets, respectively. News, and in particular fake news, are dynamic in nature and change constantly. In order to approach the dynamic nature of news, Castelo et al. (2019) propose a topic-agnostic model (TopicAgnostic) that is based on morphological (count of part-of-speech tags), psycholinguistic (personal concerns, affection, and perception categories from the LIWC dictionary), readability (Gunning Fog metric, etc.) and Web-Markup features to capture patterns of the Web pages' layout (frequency of advertisements, presence of an author name, etc.). All of the morphological, psycholinguistic and readability features in the TopicAgnostic model were extracted from headlines and texts of the news articles. The approach obtains a better performance than FakeNewsDetector on three different datasets using a SVM classifier. FakeNewsTracker (Shu et al., 2019b) is a deep neural network-based model that consists of two branches: one encodes news article texts and the other encodes social media engagements (e.g., tweets and their replies). A similar model called Emotionally Infused Network (EIN) is proposed in Ghanem et al. (2020). EIN encodes the text of the article and their affective content, based on several dictionaries, and then combines the two vector representations. The authors evaluate their model on a multi-class false information dataset and show the effectiveness of using emotion features extracted from the text. Despite the large variety of features and models that have been explored in previous work, none of these works considers the sequence of affective information in text; instead, they feed the entire news articles as one segment into their models. In contrast, the aim of our work is to evaluate this source of information, using a neural architecture.

3 The FakeFlow Model

Given an input document, the FakeFlow model first divides it into N segments. Then it uses both word embeddings and other affective features such as *emotions, hyperbolic words*, etc. in a way to catch the flow of emotions in the document. The model learns to pay attention to the flow of affective information throughout the document, in order to detect whether it is fake or real.

Figure 1 shows the architecture of the FakeFlow model. The neural architecture has two main modules: The first module uses a Convolutional Neural Network (CNN) to extract topic-based information from articles (left branch). The second module models the flow of the affective information within the articles via Bidirectional Gated Recurrent Units (Bi-GRUs) (right branch).

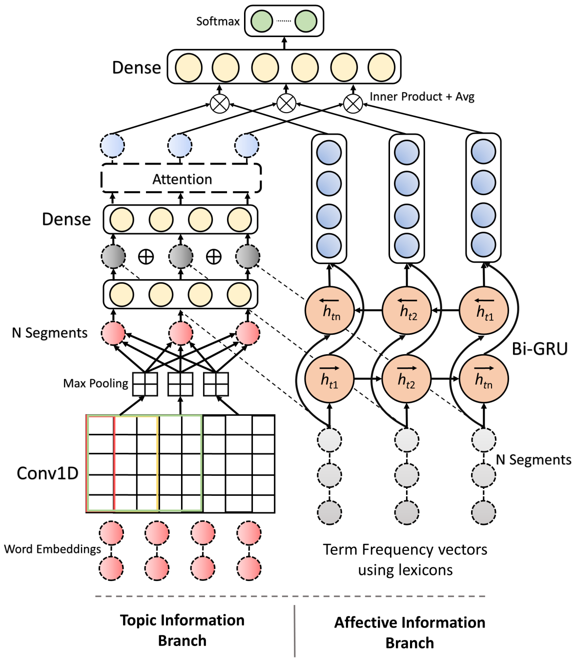

Figure 1: The architecture of the FakeFlow model.

3.1 Topic-based Information

Given a segment $n \in N$ of words, the model first embeds words to vectors through an embedding matrix. Then it uses a CNN that applies convolution processes and max pooling to get an abstractive representation of the input segment. This representation highlights important words, in which the topic information of the segment is summarized. Then it applies a fully connected layer on the output segments to get a smaller representation (v_{topic}) for later concatenation with the representation of affective information:

$$v_{topic} = f(W_a\, cnn_v + b_a)$$

where W_a and b_a are the corresponding weight matrix and bias terms, and f is an activation function such as ReLU, tanh, etc.

Key to FakeFlow is its ability to capture the relevance of the affective information with respect to the topics. For this, we concatenate the topic summarized vector v_{topic} with the representation vector v_{affect}, aimed at capturing the affective information extracted from each segment (Section 3.2).

$$v_{concat} = v_{topic} \oplus v_{affect}$$

To merge the different representations and capture their joint interaction in each segment, the model processes the produced concatenated vector v_{concat} with another fully connected layer:

$$v_{fc} = f(W_c\, v_{concat} + b_c)$$

In order to create an attention-focused representation of the segments to highlight important ones and to provide the model with the ability to weight segments differently according to the similarity of neighboring segments, the model applies a context-aware self-attention mechanism (Zheng et al., 2018) on v_{fc}. This is a crucial step, as the importance of a segment at timestep t is related to the other segments since they share the same context in the news article. Moreover, applying the attention layer can help us understand which features are most relevant by showing to which words the network attends to during learning. The output of the attention layer is an attention matrix l_t with scores for each token at each timestep.

3.2 Affective Flow of Information

To model the affective information flow in the news articles, we choose the following lexical features, under the assumption that they have a different distribution across the articles' segments. We use a term frequency representation weighted by the articles' length to extract the following features from each segment n:

- *Emotions*: We use emotions as features to detect their change among articles' segments. For that we use the NRC emotions lexicon (Mohammad and Turney, 2010) that contains ∼14K words labeled using the eight Plutchik's emotions (*8 Features*).

- *Sentiment*: We extract the sentiment from the text, *positive* and *negative*, again using the NRC lexicon (Mohammad and Turney, 2010) (*2 Features*).

- *Morality*: We consider cue words from the Moral Foundations Dictionary[2] (Graham et al., 2009) where words are assigned to one (or more) of the following categories: *care, harm, fairness, unfairness (cheating), loyalty, betrayal, authority, subversion, sanctity* and *degradation* (*10 Features*).

- *Imageability*: We use a list of words rated by their degree of abstractness and imageability[3]. These words have been extracted from the MRC psycholinguistic database (Wilson, 1988) and then using a supervised learning algorithm, the

---

[2] https://moralfoundations.org/other-materials/

[3] https://github.com/ytsvetko/metaphor/tree/master/resources/imageability

words have been annotated by the degrees of abstractness and imageability. The list contains 4,295 and 1,156 words rated by their degree of abstractness and imageability, respectively (*2 Features*).

- *Hyperbolic*: We use a list of ∼350 hyperbolic words (Chakraborty et al., 2016), i.e., words with high positive or negative sentiment (e.g., terrifying, breathtakingly, soul-stirring, etc.). The authors extracted these eye-catching words from clickbaits news headlines (*1 Feature*).

To model the flow of the above features, we represent each segment of an article by a vector v_{affect} capturing all 23 features listed above. Then we feed the document's vectors to a Bi-GRU network to summarize the contextual flow of the features from both directions[4] to obtain v_{flow}.

Given the segments' flow representation (v_{flow}) of an article and their relevance to the topics (l_t), FakeFlow applies a dot product operation and then averages the output matrix across the segments to get a compact representation $v_{compact}$, which is then fed into a fully connected layer:

$$v_{final} = f(W_d \, v_{compact} + b_d)$$

Finally, to generate the overall factuality label of an article, a softmax layer is applied to the output of the fully connected layer.

4 Fake News Datasets

Despite the recent efforts for debunking online fake news, there is a dearth of publicly available datasets. Most of the available datasets are small in size (e.g., the Politifact[5] dataset in (Shu et al., 2018) has ∼700 available articles, the Celebrity dataset in (Pérez-Rosas et al., 2018) has ∼500 articles, etc.), their test parts have not been manually annotated, or have been collected from a very small number of news sources. Nonetheless, we evaluate FakeFlow on three different available datasets to demonstrate its performance. In addition, we create our own dataset. Table 1 gives an overview of the datasets that we used in our work.

MultiSourceFake: We rely on different resources for creating the training and test portions of the dataset, so as to provide a challenging benchmark.

For the training part, we use *OpenSources.co* (OS), *MediaBiasFactCheck.com* (MBFC), and PolitiFact[6] news websites' lists. OS list contains 560 domains, MBFC list has 548 domains, and the PolitiFact list has 227 domains. These lists have been annotated by professional journalists. The lists contain domains of online news websites annotated based on the content type (as in the OS news list: *satire, reliable*, etc.; and in the PolitiFact news list: *imposter, parody, fake news*, etc.) or from a factuality perspective (as in the MBFC news list: low, medium, and high factuality). From the OS list, we select domains that are in one of the following categories: *fake, bias, reliable, hate, satire,* or *conspiracy*. We consider domains under the *reliable* category as real news sources, and the rest as fake. The PolitiFact list is different from the OS list since it has only labels for domains that are either fake or with mixed content. We discard the mixed ones[7] and map the remaining ones to the fake news label. Finally, we select from the MBFC list those domains that are annotated either as high or low factual news and we map them to real and fake labels, respectively. Out of these three final lists, we select only those domains for our dataset that are annotated in all lists in a consistent way; for example, we discard those domains that are annotated as real in the OS list but their label in the MBFC list is fake (low factuality). The final list contains 85 news websites. We now proceed by projecting the domain-level ground truth onto the content of those domains and randomly sample articles, with a maximum of 100 news articles per domain.[8]

For the test part, we use the *leadstories.com* fact checking website for which professional journalists annotated online news articles on the article level as fake or real. We do not follow the way we annotate the training part since the projection of the domain-level ground truth inevitably introduces noise. The journalists that annotated *leadstories.com* assigned a set of labels to the fake news articles like, e.g., *false, no evidence, satire, misleading*, etc.; we map them all to the *fake* label. In addition, we discard all articles that are multimedia-based. After collecting the news articles, we postprocess them by discarding very short articles (less than 30 words). The test part includes 689 fake news articles. We complement the set with a sample of 1,000 real

---

[4] During prototyping, GRU produced better overall results than LSTM.

[5] https://www.politifact.com/

[6] https://www.politifact.com/article/2017/apr/20/politifacts-guide-fake-news-websites-and-what-they/

[7] The discarded label is "Some fake stories".

[8] Some of the websites included less than 100 news articles.

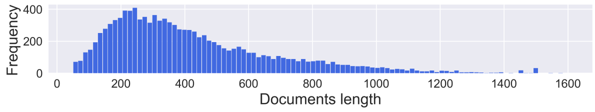

Figure 2: The distribution of the documents' length in the MultiSourceFake dataset.

Name	Total	Training	Test
MultiSourceFake	11,397	9,708	1,689
TruthShades	23,000	16,000	4,000 - 3,000
PoliticalNews	14,240	11,392	2,848
FakeNewsNet	20,208	16,156	4,039

Table 1: Number of articles in the datasets.

news articles from the training part. The overall dataset consists of 5,994 real and 5,403 fake news articles. The average document length (number of words) in the MultiSourceFake dataset is 422 words, and the 95th percentile value is 942. Figure 2 shows the distribution of the documents' length in the dataset.

TruthShades: This dataset has been proposed in Rashkin et al. (2017). The dataset was crawled from a set of domains that are annotated by professional journalists as either *propaganda, hoax, satire*, or *real*. The dataset has been built from the English Gigaword corpus for real news, and other seven unreliable domains that annotated in one of the three previous false information labels.

PoliticalNews: Due to the fact that: "a classifier trained using content from articles published at a given time is likely to become ineffective in the future" (Castelo et al., 2019), the authors of this work collected a dataset by crawling news websites in between the years 2013 to 2018 in order to evaluate their model's performance on different years.

FakeNewsNet: is a fake news repository that consists of two comprehensive datasets, one collected using claims from PolitiFact and the other from the GossipCop fact checking website. Given the large number of true and false claims from these two fact checking websites, Shu et al. (2018) built news datasets that contain visual and textual news articles content and social media information by searching Twitter for users who shared news. Out of the whole collected information, we use only the textual information of news articles, which is the part we are interested in.

5 Experiments

Experimental setup. We split the articles' text into N segments and set the maximum length of segments to 800 words, applying zero padding to the ones shorter than 800 words. Concerning the FakeFlow hyper-parameters, we tune various parameters (*dropout, the size of the dense layers, activation functions, CNN filter sizes and their numbers, pooling size, size of the GRU layer, and the optimization function*) (see Appendix A for the search space) using early stopping on the validation set. In addition to these hyper-parameters, we also use the validation set to pick the best number of segments (N). Regarding the MultiSourceFake dataset, we use 20% of the training part for validation. We represent words using pre-trained word2vec *Google-News-300* embeddings[9]. For evaluation, we follow the setup from related work. We report accuracy and weighted precision, recall and F1 score, and macro F1 for some datasets where the classes are imbalanced.

Baselines. To evaluate the performance of our model, we use a combination of fake news detection models and deep neural network architectures:

- **CNN, LSTM**: We use CNN and LSTM models and validate their performance when treating each document as one fragment. We experiment with different hyper-parameters and report results for the ones that performed best on the validation set.
- **HAN**: The authors of (Yang et al., 2016) proposed a Hierarchical Attention Networks (HAN) model for long document classification. The proposed model consists of two levels of attention mechanisms, i.e., word and sentence attention. The model splits each document into sentences and learns sentence representations from words.
- **BERT**: is a text representation model that showed superior performance on multiple natural language processing (NLP) benchmarks (Devlin et al., 2019). We use the pre-trained *bert-base-uncased* version which has 12-layers and yields output embeddings with a dimension of size 768. We feed the hidden representation of the special [CLS] token, that BERT uses to summarize the full input sentence, to a softmax layer. Experimentally, we found that fine-tuning BERT

---

[9] https://code.google.com/archive/p/word2vec/

layers gives a higher performance. It is worth mentioning that BERT input length is limited to 512 word pieces (sub-words level) (Devlin et al., 2019), thus, we discard the rest of the text in long news articles.

- **Fake News Detection Models**: We compare our model to several fake news detection models. We use Horne and Adali (2017) model, FakeNewsDetector (Pérez-Rosas et al., 2018), Rashkin et al. (2017) model, and EIN (Ghanem et al., 2020).[10]
- **Longformer**: Giving that Transformer-based models (i.e. BERT) are unable to process long sequences, we use Longformer (Beltagy et al., 2020), which is a SOTA model for long document tasks. In our experiments, we set the max sequence length to 1500 to handle documents that have more than 512 tokens in the MultiSourceFake dataset (see Figure 2). Also, we found that fine-tuning the Longformer model gives better results and a much faster convergence.

6 Results and Analysis

Table 2 presents the results of our proposed model and the baselines on the MultiSourceFake dataset. Our best result was achieved by using 10 as the number of segments (N, as found on the validation data). In Figure 3 we show the model's performance for segments of different length.[11] In general, the results show that models that are based on either word ngrams or word embeddings are performing better than other models that use handcrafted features, e.g. Horne and Adali (2017). Also, despite the huge amount of data used to train the BERT model, the results show that BERT performs worse than *FakeFlow* and also fails to outperform some of the other models. We speculate that this is due to the fact that the input length in BERT is limited to 512 words, as we mentioned previously, and a large portion of the news articles in the MultiSourceFake dataset has a length greater than 512 words. The results of the Longformer model confirm our claim regarding the documents' length and show a significantly higher F1 score than the BERT model. This emphasizes that despite the strong performance of BERT on multiple NLP benchmarks, it is unable to handle long text documents, in contrast, e.g., to vanilla text categorization (Adhikari et al., 2019). In addition, Longformer's results show a higher F1 score than the FakeFlow model, yet, the difference is statically insignificant.

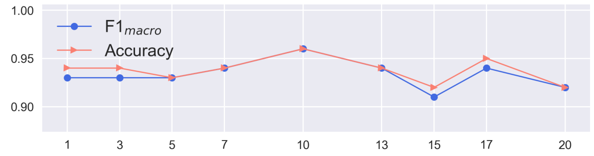

Figure 3: The accuracy and F1 results of the FakeFlow model using different N (number of segments).

Model	Acc.	Prec.	Rec.	$\mathbf{F1}_{macro}$
Majority Class	0.59	0.35	0.59	0.37
Horne and Adali (2017)	0.80	0.75	0.78	0.80
FakeNewsDetector	0.86	0.86	0.86	0.86
LSTM	0.91	0.86	0.91	0.90
CNN	0.91	0.89	0.89	0.91
Rashkin et al. (2017)	0.92	0.92	0.92	0.92
BERT	0.93	0.93	0.94	0.93‡
EIN	0.93	0.94	0.93	0.93‡
HAN	0.94	0.94	0.94	0.93‡
Longformer	0.97	0.97	0.97	**0.97**†
FakeFlow	0.96	0.93	0.97	0.96
FakeFlow – Topic only	0.91	0.89	0.90	0.90
FakeFlow – Affective only	0.61	0.38	0.60	0.40

Table 2: Results on the MultiSourceFake dataset. (‡) indicates a statistically significant improvement of *FakeFlow* over the referred model using McNemar test; (†) indicates no statistically significant improvement over *FakeFlow*.

To isolate the contribution of topical vs. affective information we run two simplified versions of our architecture, each consisting of the networks to capture topical and affective information only. The results show that the flow of the affect information has a weak performance when used alone; this emphasizes that affective information of a news article is a meaningful, yet complementary source of information.

Performance on Multiple Datasets. In Table 3 we compare the performance of the FakeFlow model to SOTA results on the other datasets we introduced in Section 4. The TruthShades dataset has two test sets, in-domain and out-of-domain. In the in-domain configuration, training and test articles come from the same sources, and from different sources in out-of-domain configuration. The results demonstrate that FakeFlow achieves a better

---

[10] We only compare TopicAgnostic on the dataset the authors proposed (PoliticalNews).

[11] In the case of N=1 in Figure 3, we set the maximum segment length to 1500 words instead of 800 to not lose parts of the longer articles.

TruthShades	Acc.	Prec.	Rec.	$\mathrm{F1}_{macro}$
Out-of-domain				
Rashkin et al. (2017)	0.67	0.70	0.67	0.65
FakeFlow	0.68	0.69	0.68	**0.68**
In-domain				
Rashkin et al. (2017)	0.91	0.91	0.91	0.91
FakeFlow	0.96	0.96	0.96	**0.96**

PoliticalNews	Acc.	Prec.	Rec.	$\mathrm{F1}_{weighted}$
TopicAgnostic	0.87	0.87	0.87	0.87
FakeFlow	0.88	0.88	0.88	**0.88**

FakeNewsNet	Acc.	Prec.	Rec.	$\mathrm{F1}_{weighted}$
FakeNewsTracker	0.80	0.82	0.75	0.79
One-Hot LR	0.82	0.90	0.72	0.80
FakeFlow	0.86	0.86	0.86	**0.85**

Table 3: Results on multiple datasets. We compare the FakeFlow model to SOTA models on each dataset.

F1 on both test sets. In a similar way, the results on the PoliticalNews dataset show that FakeFlow also outperforms the TopicAgnostic model, although the gap in results is not very large. Finally, regarding the FakeNewsNet dataset, it looks that the deep learning-based model (FakeNewsTracker) does not achieve a good performance comparing to the other proposed baseline by the authors, which is a Logistic Regression (LR) classifier with one-hot vectors of the news articles' text. Furthermore, it seems that a simple word-based model works better than a more sophisticated model that incorporates social media and context information. The FakeFlow model, on the other hand, achieves a better result, outperforming both the FakeNewsTracker and the LR baseline.

Topic-Aware Model. Constantly, new events are covered by news agencies. These events are different from the old ones in terms of discourse and topic. Therefore, a fake news detector trained on news articles from years back is unable to detect recent news. In this experiment, we are evaluating our approach on the PoliticalNews dataset that is constructed from news distributed across different years (2013 to 2018). Following the experimental setup in (Castelo et al., 2019), we train the FakeFlow model on news from one year and test on the other years, one year at a time for testing. For example, we train the model on news from 2013 and we test on news from 2015. Note that each test set is associated with 5 results, one for each year. Figure 4 shows the average accuracy for each test set. We compare FakeFlow to the TopicAgnostic model that proved to be effective at detecting fake news from different years. It is worth mentioning that the features of the TopicAgnostic model have been extracted from both headlines and text of the news articles. However, the results show that both models have a similar performance, except for the 2013 test set where FakeFlow achieves a higher accuracy with a difference of 7%. The experiment shows that FakeFlow is capable of detecting fake news from different years, with a flat performance across the years.

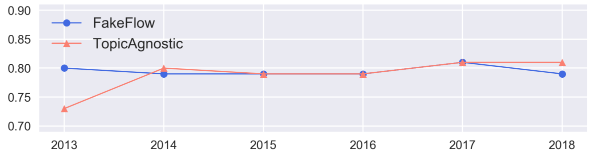

Figure 4: Topic aware experiment's results.

Attention Weights. The proposed FakeFlow model shows that taking into account the flow of affective information in fake news is an important perspective for fake news detection. We argue that being able to better understand the behaviour of the model can make it more transparent to the end-users. Figure 5 illustrates this by showing the attention weights of a fake news article across the 10 segments (left bar).[12] The figure shows that FakeFlow attends more to the beginning of the article. For better understanding, we match the affective information with the attention weights. Regarding the news text in the figure, the *emotions* features[13] show a clear example of how fake news articles try to manipulate the reader. It looks as if the existence of *fear, sadness*, and *surprise emotions* at the beginning of the article have triggered the attention on this part. Towards the end of the article, on the other hand, we can notice that such negative emotions do not exist, while *emotions* like *joy* and *anticipation* appear. This exemplifies how fake news try to attract the readers' attention in the first part of the text. Regarding the *morality* features, we only match the word "kill" with the *harm* category. Also, for the *hyperbolic* feature, we match the words "terrifying" and "powerful". In the same manner, both *morality* and *hyperbolic* features match words that occur at the beginning of the article. Lastly, for both *sentiment* and *im-*

---

[12] We averaged the attention weight matrix along the timesteps (number of segments) representations.

[13] Words with multiple colors mean that they have been annotated with multiple emotion types in the NRC lexicon.

ageability features, we are not able to find a clear interpretation in this example where many words across the segments match.

Real vs. Fake Analysis. In Table 4 we present an analysis on both real and fake news articles. The analysis gives an intuition to the reader on the distribution of the used features across the articles' segments. It shows that an emotion like *fear* has on average a higher difference between the first and the last segment in fake news than in real ones (see Figure 6 for a visualized distribution). Also, a feature like *hyperbolic* has a higher average value and lower standard deviation across all segments for fake news than real news, thus indicating that fake news have a higher amount of hyperbolic words with similarly high values.

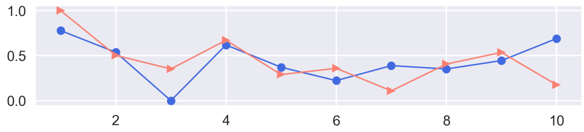

Figure 6: The flow of the *Fear* emotion in **fake** (►) and **real** (●) news articles in the MultiSourceFake dataset. Y-axis presents the average number of *Fear* emotion words in 0-1 scale; the X-axis presents the document text, divided into 10 segments.

7 Conclusion

In this paper we presented FakeFlow, a model that takes into account the flow of affective information (*emotions, sentiment, hyperbolic words*, etc.) in texts to better detect fake news articles. The model receives as input a text, segmented into smaller units, instead of processing one long fragment. This enables it to learn the flow of affective information by modeling the interaction between the topic and affective terms in the news article. We evaluated our model on four different datasets and compared it to several strong baselines. The extensive experiments show the effectiveness of FakeFlow over state-of-the-art models. Although FakeFlow was trained using a limited amount of text, the results demonstrated that it achieves results on-par with resource-hungry models (e.g. BERT and Longformer). In future work, we plan to extend our dataset and study more fine-grained news types, e.g. propaganda, from an emotional perspective. Moreover, we plan to investigate how we can replace the lexicon-based information with language-independent approaches in an attempt to make our model multilingual.

Acknowledgment

The first author would like to thank Ines Rehbein and Ana Uban for their valuable comments and suggestions. The work of the third author was partially funded by the Spanish MICINN under the research project MISMIS-FAKEnHATE on MISinformation and MIScommunication in social media: FAKE news and HATE speech (PGC2018-096212-B-C31) and by the Generalitat Valenciana under the research project DeepPattern (PROMETEO/2019/121).

A Appendices

A.1 Hyper-parameters

For FakeFlow hyper-parameters, we tune the following parameters with the their correspondent search space:

- Dropout: random selection in the range [0.1, 0.6],
- Dense layers: [8, 16, 32, 64, 128],
- Activation functions: [selu, relu, tanh, elu],
- CNN filters' sizes: [(2, 3, 4), (3, 4, 5), (4, 5, 6), (3, 5), (2, 4), (4,), (5,), (3, 5, 7), (3, 6)],
- Numbers of CNN filters: [4, 8, 16, 32, 64, 128],
- Pooling size: [2, 3],
- GRU units: [8, 16, 32, 64, 128],
- Optimization function: [adam, adadelta, rmsprop, sgd],
- For the early stopping, we set the 'patience' parameter to 4 and we set the epochs number to 50.

For the parameters selection, we use hyperopt[14] library that receives the above search space to randomly select different N combination of parameters (trials). We use a small value of N in all of our experiments to avoid overdrawn finetuning; we set N to 35.

A.2 Topic Aware experiments

In Figure 4, we present the average accuracy of our model when we train on different years and test a specific one. In the following we show the results before we averaged them.

Train \ Test	2013	2014	2015	2016	2017	2018
2013	0.00	0.82	0.74	0.76	0.78	0.74
2014	0.84	0.00	0.79	0.76	0.81	0.74
2015	0.79	0.81	0.00	0.82	0.80	0.82
2016	0.80	0.76	0.87	0.00	0.85	0.79

Abstract

Previous studies demonstrated that a dynamic phone-informed compression of the input audio is beneficial for speech translation (ST). However, they required a dedicated model for phone recognition and did not test this solution for direct ST, in which a single model translates the input audio into the target language without intermediate representations. In this work, we propose the first method able to perform a dynamic compression of the input in direct ST models. In particular, we exploit the Connectionist Temporal Classification (CTC) to compress the input sequence according to its phonetic characteristics. Our experiments demonstrate that our solution brings a 1.3-1.5 BLEU improvement over a strong baseline on two language pairs (English-Italian and English-German), contextually reducing the memory footprint by more than 10%.

1 Introduction

Speech translation (ST) is the process that converts utterances in one language into text in another language. Traditional approaches to ST consist of separate modules, each dedicated to an easier subtask, which are eventually integrated in a so-called *cascade* architecture (Stentiford and Steer, 1988; Waibel et al., 1991). Usually, its main components are an automatic speech recognition (ASR) model - which generates the transcripts from the audio - and a machine translation (MT) model - which translates the transcripts into the target language. A newer approach is *direct* ST, in which a single model performs the whole task without intermediate representations (Bérard et al., 2016; Weiss et al., 2017). The main advantages of direct ST systems are: *i)* the access to information not present in the text (e.g. prosody, vocal characteristics of the speaker) during the translation phase, *ii)* a reduced latency, *iii)* a simpler and easier to manage architecture (only one model has to be maintained), which *iv)* avoids error propagation across components.

In both paradigms (cascade and direct), the audio is commonly represented as a sequence of vectors obtained with a Mel filter bank. These vectors are collected with a high frequency, typically one every 10 ms. The resulting sequences are much longer than the corresponding textual ones (usually by a factor of ~10). The sequence length is problematic both for RNN (Elman, 1990) and Transformer (Vaswani et al., 2017) architectures. Indeed, RNNs fail to represent long-range dependencies (Bengio et al., 1993) and the Transformer has a quadratic memory complexity in the input sequence length, which makes training on long sequences prohibitive due to its memory footprint. For this reason, architectures proposed for direct ST/ASR reduce the input length either with convolutional layers (Bérard et al., 2018; Di Gangi et al., 2019) or by stacking and downsampling consecutive samples (Sak et al., 2015). However, these fixed-length reductions of the input sequence assume that samples carry the same amount of information. This does not necessarily hold true, as phonetic features vary at a different speed in time and frequency in the audio signals.

Consequently, researchers have studied how to reduce the input length according to dynamic criteria based on the audio content. Salesky et al. (2019) demonstrated that a phoneme-based compression of the input frames yields significant gains compared to fixed length reduction. Phone-based and linguistically-informed compression also proved to be useful in the context of visually grounded speech (Havard et al., 2020). However, Salesky and Black (2020) questioned the approach, claiming that the addition of phone features without segmentation and compression of the input is more effective.

None of these works is a direct ST solution, as they all require a separate model for phone recog-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 690–696
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

nition and intermediate representations. So, they: *i)* are affected by *error propagation* (Salesky and Black 2020 show in fact that lower quality in phone recognition significantly degrades final ST performance), *ii)* have higher latency and *iii)* a more complex architecture. A direct model with phone-based multi-task training was introduced by Jia et al. (2019) for speech-to-speech translation, but they neither compared with a training using transcripts nor investigated dynamic compression.

In this paper, we explore the usage of phones and dynamic content-based input compression for direct ST (and ASR). Our goal is an input reduction that, limiting the amount of redundant/useless information, yields better performance and lower memory consumption at the same time. To this aim, we propose to exploit the Connectionist Temporal Classification (CTC) (Graves et al., 2006) to add phones prediction in a multi-task training and compress the sequence accordingly. To disentangle the contribution of the introduction of phone recognition and the compression based on it, we compare against similar trainings leveraging transcripts instead of phones. Our results show that phone-based multi-task training with sequence compression improves over a strong baseline by up to 1.5 BLEU points on two language pairs (English-German and English-Italian), with a memory footprint reduction of at least 10%.

2 CTC-based Sequence Compression

The CTC algorithm is usually employed for training a model to predict an output sequence of variable length that is shorter than the input one. This is the case of speech/phone recognition, as the input is a long sequence of audio samples, while the output is the sequence of uttered symbols (e.g. phones, sub-words), which is significantly shorter. In particular, for each time step, the CTC produces a probability distribution over the possible target labels augmented with a dedicated `<blank>` symbol representing the absence of a target value. These distributions are then exploited to compute the probabilities of different sequences, in which consecutive equal predictions are collapsed and `<blank>` symbols are removed. Finally, the resulting sequences are compared with the target sequence.

Adding an auxiliary CTC loss to the training of direct ST and acoustic ASR models has been shown to improve performance (Kim et al., 2017; Bahar et al., 2019). In these works, the CTC loss is computed against the transcripts on the encoder output to favour model convergence. Generally, the CTC loss can be added to the output of any encoder layer, as in Figure 1 where the hyper-parameter N_{CTC} indicates the number of the layer at which the CTC is computed. Formally, the final loss function is:

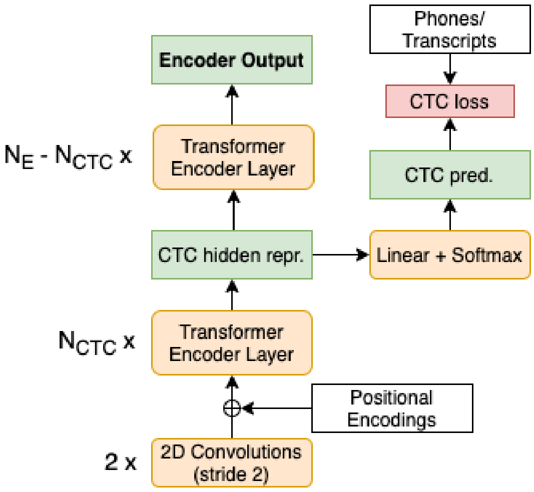

Figure 1: Encoder architecture with CTC loss.

$$\lambda = CTC(E_{\mathrm{N_{CTC}}}) + CE(D_{\mathrm{N_D}}) \qquad (1)$$

where E_{x} is the output of the x-th encoder layer, $D_{\mathrm{N_D}}$ is the decoder output, CTC is the CTC function, and CE is the label smoothed cross entropy. If N_{CTC} is equal to the number of encoder layers (N_{E}), the CTC input is the encoder output. We consider this solution as our baseline and we also test it with phones as target.

As shown in Figure 1, we use as model a Transformer, whose encoder layers are preceded by two 2D convolutional layers that reduce the input size by a factor of 4. Therefore, the CTC produces a prediction every 4 input time frames. The sequence length reduction is necessary both because it makes possible the training (otherwise out of memory errors would occur) and to have a fair comparison with modern state-of-the-art models. A logarithmic distance penalty (Di Gangi et al., 2019) is added to all the Transformer encoder layers.

Our proposed architecture is represented in Figure 2. The difference with the baseline is the introduction of an additional block (*Collapse same predictions*) that exploits the CTC predictions to compress the input elements (vectors). Hence, in this case the CTC does not only help model convergence, but it also defines variable-length segments representing the same content. So, dense audio portions can be given more importance, while re-

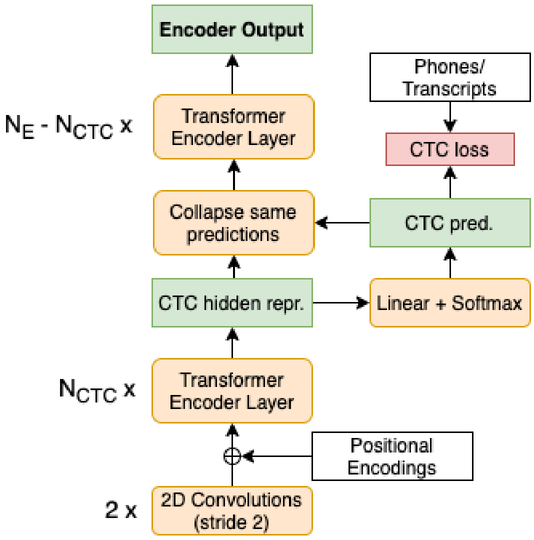

Figure 2: Encoder architecture with CTC compression.

dundant/uninformative vectors can be compressed. This allows the following encoder layers and the decoder to attend to useful information without being "distracted" by noisy elements. The architecture is a direct ST solution as there is a single model whose parameters are optimized together without intermediate representations. At inference time, the only input is the audio and the model produces the translation into the target language (contextually generating the transcripts/phones with the CTC).

We compare three techniques to compress the consecutive vectors with the same CTC prediction:

- **Average.** The vectors to be collapsed together are averaged. As there is only a linear layer between the CTC inputs and its predictions, the vectors in each group are likely to be similar, so the compression should not remove much information.

- **Weighted.** The vectors are averaged but the weight of each vector depends on the confidence (i.e. the predicted probability) of the CTC prediction. This solution is meant to give less importance to vectors whose phone/transcript is not certain.

- **Softmax.** In this case, the weight of each vector is obtained by computing the `softmax` of the CTC predicted probabilities. The idea is to propagate information (nearly) only through a single input vector (the more confident one) for each group.

3 Data

We experiment with MuST-C (Cattoni et al., 2021), a multilingual ST corpus built from TED talks. We focus on the English-Italian (465 hours) and English-German (408 hours) sections. For each set (train, validation, test), it contains the audio files, the transcripts, the translations and a YAML file with the start time and duration of the segments.

In addition, we extract the phones using Gentle.[1] Besides aligning the transcripts with the audio, Gentle returns the start and end time for each recognized word, together with the corresponding phones. For the words not recognized in the audio, Gentle does not provide the phones, so we lookup their phonetic transcription on the VoxForge[2] dictionary. For each sample in the corpus, we rely on the YAML file and the alignments generated by Gentle to get all the words (and phones) belonging to it. The phones have a suffix indicating the position in a word (at the end, at the beginning, in the middle or standalone). We also generated a version without the suffix (we refer to it as `PH W/O POS` in the rest of the paper). The resulting dictionaries contain respectively 144 and 48 symbols.

4 Experimental Settings

Our Transformer layers have 8 attention heads, 512 features for the attention and 2,048 hidden units in FFN. We set a 0.2 dropout and include *SpecAugment* (Park et al., 2019) in our trainings. We optimize label smoothed cross entropy (Szegedy et al., 2016) with 0.1 smoothing factor using Adam (Kingma and Ba, 2015) (betas *(0.9, 0.98)*). The learning rate increases linearly from 3e-4 to 5e-3 for 4,000 updates, then decays with the inverse square root. As we train on 8 GPUs with mini-batches of 8 sentences and we update the model every 8 steps, the resulting batch size is 512. The audio is pre-processed performing speaker normalization and extracting 40-channel Mel filter-bank features per frame. The text is tokenized into subwords with 1,000 BPE merge rules (Sennrich et al., 2016).

As having more encoder layers than decoder layers has been shown to be beneficial (Potapczyk and Przybysz, 2020; Gaido et al., 2020), we use 8 Transformer encoder layers and 6 decoder layers for ASR and 11 encoder and 4 decoder layers for ST unless stated otherwise. We train until the

---

[2] `http://www.voxforge.org/home`

model does not improve on the validation set for 5 epochs and we average the last 5 checkpoints. Trainings were performed on K80 GPUs and lasted ~48 hours (~50 minutes per epoch). Our implementation[3] is based on Fairseq (Ott et al., 2019).

We evaluate performance with WER for ASR and with BLEU (Papineni et al., 2002)[4] and SacreBLEU (Post, 2018)[5] for ST.

	WER (↓)	**RAM (MB)**
Baseline - 8L EN	16.0	6929 (1.00)
8L PH	**15.6**	6661 (0.96)
2L PH AVG	21.2	3375 (0.49)
4L PH AVG	17.5	4542 (0.66)
8L PH AVG	16.3	6286 (0.91)
8L PH W/O POS. AVG	16.4	6565 (0.95)
8L EN AVG	16.3	6068 (0.88)

Table 1: Results on ASR using the CTC loss with transcripts and phones as target. `AVG` indicates that sequence is compressed averaging the vectors.

5 Results

5.1 ASR

We first tested whether ASR benefits from the usage of phones and sequence compression. Table 1 shows that having phones instead of English transcripts (Baseline - 8L EN) as target of the CTC loss (`8L PH`) without compression is beneficial. When compressing the sequence, there is little difference according to the target used (`8L PH AVG`, `8L PH W/O POS. AVG`, `8L EN AVG`). However, the compression causes a 0.3-0.5 WER performance degradation and a 12-5% saving of RAM. Moving the compression to previous layers (`4L PH AVG`, `2L PH AVG`) further decreases the output quality and the RAM usage. We can conclude that compressing the input sequence harms ASR performance, but might be useful if RAM usage is critical and should be traded off with performance.

5.2 Direct ST

In early experiments, we pre-trained the first 8 layers of the ST encoder with that of the ASR model, adding three *adapter* layers (Bahar et al., 2019). We realized that ASR pre-training was not useful (probably because ASR and ST data are the same), so we report results without pre-training.

As we want to ensure that our results are not biased by a poor baseline, we compare with (Di Gangi et al., 2020), which uses the same framework and similar settings.[6] As shown in Table 2, our strong baseline (`8L EN`) outperforms (Di Gangi et al., 2020) by 2 BLEU on en-it and 1.3 BLEU on en-de.

As in ASR, replacing the transcripts with phones as target for the CTC loss (`8L PH`) further improves respectively by 0.5 and 1.2 BLEU. We first explore the introduction of the compression at different layers. Adding it to the 8th layer (`8L PH AVG`) enhances the translation quality by 0.6 (en-it) and 0.2 (en-de) BLEU, with the improvement on en-it being statistically significant over the version without CTC compression. Moving it to previous layers (`4L PH AVG`, `2L PH AVG`) causes performance drops, suggesting that many layers are needed to extract useful phonetic information.

Then, we compare the different compression policies: `AVG` outperforms (or matches) `WEIGHTED` and `SOFTMAX` on both languages. Indeed, the small weight these two methods assign to some vectors likely causes an information loss and prevents a proper gradient propagation for the corresponding input elements.

Finally, we experiment with different CTC targets, but both the phones without the position suffix (`8L PH W/O POS. AVG`) and the transcripts (`8L EN AVG`) lead to lower scores.

The different results between ASR and ST can be explained by the nature of the two tasks: extracting content knowledge is critical for ST but not for ASR, in which a compression can hide details that are not relevant to extrapolate meaning, but needed to generate precise transcripts. The RAM savings are higher than in ASR as there are 3 more layers. On the 8th layer, they range from 11% to 23% for en-it, 16% to 22% for en-de. By moving the compression to previous layers, we can trade performance for RAM requirements, saving up to 50% of the memory.

We also tested whether we can use the saved RAM to add more layers and improve the translation quality. We added 3 encoder and 2 decoder layers: this (`8L PH AVG (14+6L)`) results in

[4] To be comparable with previous works.

[5] The version signature is: `BLEU+c.mixed+#.1+s.exp+tok.13a+v.1.4.3`.

[6] We acknowledge that better results have been published in a contemporaneous paper by Inaguma et al. (2020). Besides the contemporaneity issue, our results are not comparable with theirs, as they use: *i)* a different architecture built on ESPnet-ST (a newer framework that, alone, outperforms Fairseq), *ii)* higher dimensional input features (83 vs 40 dimensions), *iii)* data augmentation, and *iv)* pre-training techniques.

Table 2: Results using the CTC loss with transcripts and phones as target. `AVG`, `WEIGHTED` and `SOFTMAX` indicate the compression method. If none is specified, no compression is performed. The symbol "*" indicates improvements that are statistically significant with respect to the baseline. "†" indicates statistically significant gains with respect to `8L PH`. Statistical significance is computed according to (Koehn, 2004) with $\alpha = 0.05$. Scores in *italic* indicate the best models among those with equal number of layers.

small gains (0.2 on en-it and 0.1 on en-de), but the additional memory required is also small (the RAM usage is still 10-16% lower than the baseline). The improvements are statistically significant with respect to the models without compression (`8L PH`) on both language pairs. When training on more data, the benefit of having deeper networks might be higher, though, and this solution allows to increase the number of layers without a prohibitive memory footprint. We leave this investigation for future works, as experiments on larger training corpora are out of the scope of this paper.

6 Conclusions

As researchers' focus is shifting from cascade to direct solutions due to the advantages of the latter, we proposed a technique of dynamic sequence-length reduction for direct ST. We showed that averaging the vectors corresponding to the same phone prediction according to the CTC improves the translation quality and reduces the memory footprint, allowing for training deeper models. Our best model outperforms a strong baseline, which uses transcripts in a multi-task training, by 1.3 (en-it) and 1.5 (en-de) BLEU, reducing memory usage by 10-16%.

Abstract

We present an open-source speech corpus for the Kazakh language. The Kazakh speech corpus (KSC) contains around 332 hours of transcribed audio comprising over 153,000 utterances spoken by participants from different regions and age groups, as well as both genders. It was carefully inspected by native Kazakh speakers to ensure high quality. The KSC is the largest publicly available database developed to advance various Kazakh speech and language processing applications. In this paper, we first describe the data collection and preprocessing procedures followed by a description of the database specifications. We also share our experience and challenges faced during the database construction, which might benefit other researchers planning to build a speech corpus for a low-resource language. To demonstrate the reliability of the database, we performed preliminary speech recognition experiments. The experimental results imply that the quality of audio and transcripts is promising (2.8% character error rate and 8.7% word error rate on the test set). To enable experiment reproducibility and ease the corpus usage, we also released an ESPnet recipe for our speech recognition models.

1 Introduction

We present an open-source Kazakh speech corpus (KSC) constructed to advance the development of speech and language processing applications for the Kazakh language. Kazakh is an agglutinative language with vowel harmony and belongs to the family of Turkic languages. During the Soviet period, the Kazakh language was overwhelmed by the Russian language, which caused a decline in Kazakh language usage (Dave, 2007). In the 1990s, it was declared an official language of Kazakhstan, and many initiatives were launched to increase the number of Kazakh speakers. Today, it is spoken by over 10 million people in Kazakhstan and by over 3 million people in other countries[1]. By introducing the KSC, we aim to accelerate the penetration of the Kazakh language into the Internet of things (IoT) technologies and to promote research in Kazakh speech processing applications.

Although several Kazakh speech corpora have been presented (Makhambetov et al., 2013; Shi et al., 2017; Mamyrbayev et al., 2019), there is no generally accepted common corpus. Most of them are either publicly unavailable or contain an insufficient amount of data to train reliable models. Especially, these databases are too small for building recent end-to-end models, which are extremely data hungry (Hannun et al., 2014). Consequently, different research groups usually conduct their experiments on internally collected data, which prevents the reproducibility and comparison of different approaches.

To address the aforementioned limitations, we created the KSC, containing around 332 hours of transcribed audio. It was crowdsourced through the Internet, where volunteers were asked to read sentences presented through a web browser. In total, we accepted over 153,000 utterances submitted from over 1,600 unique device IDs. The recordings were first checked manually, and when a sufficient amount of data was collected, were partially checked automatically using a speech recognition system. To the best of our knowledge, the KSC is the largest open-source speech corpus in Kazakh and is available for academic and commercial use upon request at this link[2] under the Creative Commons Attribution 4.0 International License[3].

April 19 - 23, 2021.

We expect that this database will be a valuable resource for research communities in both academia and industry. The primary application domains of the corpus are speech recognition, speech synthesis, and speaker recognition. To demonstrate the reliability of the database, we performed preliminary automatic speech recognition (ASR) experiments, where promising and sufficient for practical usage results were achieved. We also provide a practical guide on the development of ASR systems for the Kazakh language by sharing the reproducible recipe and pretrained models[4]. The utilization of the database for speech synthesis and speaker recognition tasks is left for future work.

The rest of the paper is organized as follows. Section 2 provides a review of related works. Section 3 presents the KSC database and explains the database construction procedures in detail. Section 4 offer a presentation of the speech recognition experiment setup and obtained results. In Section 5, the obtained results and challenges are discussed. Lastly, Section 6 concludes this paper and mentions potential future work.

2 Related Works

In the past few years, the interest in ASR has surged by its new applications in smart devices, such as voice command, voice search, message dictation, and virtual assistants (Yu and Deng, 2014). In response to this technological shift, many speech corpora have been introduced for various languages. For example, Du et al. (2018) released 1,000 hours of open-source Mandarin read speech data to bridge the gap between academia and industry. The utterances were recorded using iOS-based mobile phones and cover the following domains: voice command, smart home, autonomous driving, and so on. Similarly, Koh et al. (2019) developed a 2,000-hour read speech corpus to help speech technology developers and researchers build speech-related applications in Singapore.

Several works have presented speech databases for the Kazakh language. For example, Makhambetov et al. (2013) developed a Kazakh language corpus containing around 40 hours of transcribed read speech data recorded in a sound-proof studio. Similarly, Mamyrbayev et al. (2019) collected 76 hours of data using a professional recording booth which were further extended to 123 hours in Mamyrbayev et al. (2020). Khomitsevich et al. (2015) utilized 147 hours of bilingual Kazakh-Russian speech data to build code-switching ASR systems. Shi et al. (2017) released 78 hours of transcribed Kazakh speech data recorded by 96 students from China. The IARPA Babel project has released a Kazakh language pack[5] consisting of around 50 hours of conversational and 14 hours of scripted telephone speech. Unfortunately, the aforementioned databases are either publicly unavailable or of an insufficient size to build robust Kazakh ASR systems. Additionally, some of them are nonrepresentative–that is, they cover speakers from a narrow set of categories, such as the same region or age group. Furthermore, since most of these databases have been collected in optimal lab settings, they might be ineffective for real-world applications.

The emergence of crowdsourcing platforms and the growth in Internet connectivity has motivated researchers to employ crowdsourcing for annotated corpora construction. Different from the expert-based approaches, crowdsourcing tends to be cheaper and faster, though, additional measures should be taken to ensure the data quality (Snow et al., 2008; Novotney and Callison-Burch, 2010; Eskenazi et al., 2013). Furthermore, crowdsourcing allows to gather a variety of dialects and accents from remote geographical locations and enables the participation of people with disabilities and of an advanced age, which otherwise would be impossible or too costly (Takamichi and Saruwatari, 2018). Inspired by this, we followed the best crowdsourcing practices to construct a large-scale and open-source speech corpus for the Kazakh language, as described in the following sections.

3 The KSC Construction

The KSC project was conducted with the approval of the Institutional Research Ethics Committee of Nazarbayev University. Each reader participated voluntarily and was informed of the data collection and use protocols through an online consent form.

3.1 Text Collection and Cleaning

We first extracted Kazakh textual data from various sources such as electronic books, laws, and websites, including Wikipedia, news portals, and blogs. For each website, we designed a specialized

---

[4] `https://github.com/IS2AI/ISSAI_SAIDA_Kazakh_ASR`

[5] `https://catalog.ldc.upenn.edu/LDC2018S13`

web crawler to improve the quality of the extracted text. The extracted texts were manually filtered to eliminate inappropriate content involving sensitive political issues, user privacy, violence, and so on. Additionally, we filtered out texts entirely consisting of Russian words. Texts consisting of mixed Kazakh-Russian utterances were kept, because there are many borrowed Russian words in Kazakh, and it is common practice among Kazakh speakers to code-switch between Kazakh and Russian (Khomitsevich et al., 2015). Next, we split the texts into sentences and removed sentences consisting of more than 25 words. Lastly, duplicate sentences were removed. The total number of extracted sentences was around 2.3 million.

3.2 Text Narration and Checking

To narrate the extracted sentences, we developed a web-based speech recording platform capable of running on personal computers and smartphones. The platform randomly samples a sentence from the pool of extracted texts, and presents it to a reader (see Figure 1). It also displays the recording status and statistics, such as elapsed time and the total number of read sentences. Additionally, it has the "pause" and "next" buttons to control the recording process. The readers were allowed to quit at any time. We recruited readers by advertising the project in social media, news, and open messaging communities on WhatsApp and Telegram. Readers who were at least 18 years old were included so that they could legally agree to participate in data collection. The audios were recorded in 48 kHz and 16 bits, but downsampled to 16 kHz and 16 bits for online publication. Following our experimental protocol, we did not store readers' personal information except for the geolocation coordinates, IP address, and device type.

Category	Train	Valid	Test	Total
Duration (hours)	318.4	7.1	7.1	332.6
# Utterances	147,236	3,283	3,334	153,853
# Words	1.61M	35.2k	35.8k	1.68M
# Unique Words	157,191	13,525	13,959	160,041
# Device IDs	1,554	29	29	1,612
# Speakers	-	29	29	-

Table 1: The KSC database specifications.

Several native Kazakh transcribers were hired to check the quality of recordings. The transcribers logged on to a special transcription checking platform and were provided with an audio segment and the corresponding sentence that a reader had read. The task was to check if the reader had read the sentence according to the prompt, and to transcribe any deviations or other acoustic events based on a set of transcription instructions. As an additional quality measure, we hired a linguist who was assigned to supervise the transcribers and to randomly check tasks they completed. To harmonize the transcriptions, the linguist also held the "go through errors" sessions with the transcribers.

The transcribers were instructed to reject utterances containing obvious mispronunciations or severe noises, to convert numbers into words[6], and to trim long silences at the beginning and end of the audio segments. Additionally, they were instructed to enclose partial repetitions and hesitations in parentheses, for example, '(he) hello' and '(ah)', and to indicate other non-verbal sounds produced by readers, such as sneezing and coughing, using a special '[noise]' token. Background noises were not labeled.

When the size of accepted utterances reached 100 hours, we built an ASR system to automatically check the recordings. The system accepted only recordings perfectly matching corresponding text prompts–that is, 0% character error rate (CER), whereas the remaining utterances were left to human transcribers.

3.3 Database Specifications

The KSC database specifications are provided in Table 1. We split the data into three sets of non-overlapping speakers: training, validation, and test. While the training set recordings were collected

---

[6] Note that after converting numbers into words some sentence lengths exceeded 25 words.

Category		Valid	Test
Gender (%)	Female	51.7	51.7
	Male	48.3	48.3
Age (%)	18-27	37.9	34.5
	28-37	34.5	31.0
	38-47	10.4	13.8
	48 and above	17.2	20.7
Region (%)	East	13.8	13.8
	West	20.7	17.2
	North	13.8	20.7
	South	37.9	41.4
	Center	13.8	6.9
Device (%)	Phone	62.1	79.3
	Computer	37.9	20.7
Headphone (%)	Yes	20.7	17.2
	No	79.3	82.8

Table 2: The validation and test sets speaker details.

from anonymous speakers, the validation and test sets were collected from identifiable speakers to ensure that they did not overlap with the training set, represented different age groups and regions, and were gender balanced (see Table 2). In total, around 153,000 utterances were accepted, yielding 332 hours of transcribed speech data. Note that the device IDs could not be used to represent the number of speakers in the training set as several speakers might have used the same device or the same speaker might have used different devices. Therefore, the total number of speakers in the training set is not shown in Table 1. The whole database creation process took around four months, and the database size is around 38GB.

The Kazakh writing system differs depending on the regions where the language is spoken. For example, the Cyrillic alphabet is used in Kazakhstan and Mongolia, while an Arabic-derived alphabet is used in China. In the KSC, we presented all texts using the Cyrillic alphabet consisting of 42 letters. The distribution of these letters in the KSC is given in Figure 2.

One of the important features of the proposed KSC database is that it was collected in various environment conditions (e.g. home, office, café, transport, and street), with diverse background noises through mobile devices (e.g. phones and tablets) and personal computers, with and without headphone sets, which is similar to realistic use-case scenarios. Consequently, our database enables the development and evaluation of ASR systems designed to operate in real-world voice-enabled applications, such as voice commands, voice search, message dictation, and so on.

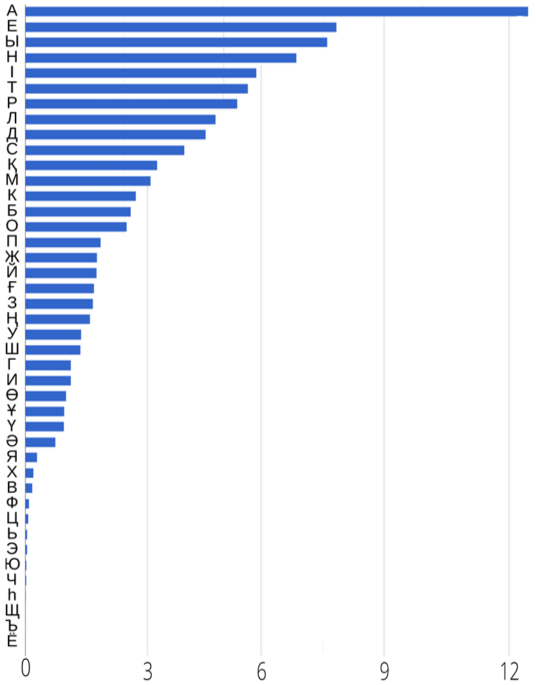

Figure 2: The distribution of letters in the KSC (%).

The KSC database consists of audio recordings, transcripts, and metadata stored in separate folders. The audio and corresponding transcription filenames are the same, except that the audio recordings are stored as WAV files, whereas the transcriptions are stored as TXT files using the UTF-8 encoding. The metadata contain the data splitting information (training, validation, and test) and the speaker's details (gender, age, region, device, and headphones) of the validation and test sets.

4 Speech Recognition Experiment

To demonstrate the utility and reliability of the KSC database, we conducted speech recognition experiments using both the traditional deep neural network-hidden Markov model (DNN-HMM) and recently proposed end-to-end (E2E) architectures. We did not compare or perform thorough architecture searches for either DNN-HMM and E2E, since this falls outside the scope of this paper.

4.1 Experimental Setup

All ASR models were trained with a single V100 GPU running on the NVIDIA DGX-2 server using the training set. All hyper-parameters were tuned using the validation set. The best-performing model was evaluated using the test set. All results are reported without lattice or n-best hypotheses rescoring, and no external data have been used.

4.1.1 The DNN-HMM ASR

The DNN-HMM ASR system was built using the Kaldi framework (Povey et al., 2011). We followed the Wall Street Journal (WSJ) recipe with the "nnet3+chain" setup and other latest Kaldi developments. The acoustic model was constructed using the factorized time-delay neural networks (TDNN-F) (Povey et al., 2018) trained with the lattice-free maximum mutual information (LF-MMI) (Povey et al., 2016) training criterion. The inputs were Mel-frequency cepstral coefficients (MFCC) features with cepstral mean and variance normalization extracted every 10 ms over a 25 ms window. In addition, we applied data augmentation using the speed perturbation (SpeedPerturb) (Ko et al., 2015) at rates of 0.9, 1.0, and 1.1 and the spectral augmentation (SpecAugment) (Park et al., 2019) techniques.

We employed a graphemic lexicon because of the strong correspondence between word spelling and pronunciation in Kazakh (e.g. "$hello \rightarrow h\ e\ l\ l\ o$"). The graphemic lexicon was constructed by extracting all words in the training set, which resulted in 157,191 unique words. During the decoding stage, we employed a 3-gram language model[7] (LM) with the Kneser-Ney smoothing built using the SRILM toolkit (Stolcke, 2002). The 3-gram LM was trained using the transcripts of the training set and the vocabulary covering all the words in the graphemic lexicon.

4.1.2 The E2E ASR

The E2E ASR systems were built using the ESPnet framework (Watanabe et al., 2018). We followed the WSJ recipe to train two different encoder-decoder architectures based on the recurrent neural networks (RNN) (Bahdanau et al., 2015) and the Transformer (Vaswani et al., 2017). Both architectures were jointly trained with the connectionist temporal classification (CTC) (Graves et al., 2006) objective function under the multi-task learning framework (Kim et al., 2017). The input speech was represented as an 80-dimensional filterbank features with pitch computed every 10 ms over a 25 ms window. For both E2E architectures, the acoustic features were first processed by few initial blocks of VGG network (Simonyan and Zisserman, 2015). Since Kazakh is a morphologically rich language, it is susceptible to severe data sparseness. To overcome this issue, we employed character-level output units in both architectures. In total, we used 45 distinct output units consisting of 42 letters from the Kazakh alphabet and 3 special tokens–that is, <*unk*>, <*space*>, and <*blank*> used in CTC.

The E2E ASR systems do not require a lexicon when modeling with grapheme-based output units (Sainath et al., 2018). The character-level LM was built using the transcripts of the training set as a two-layer RNN with 650 long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) units each. We utilized the LSTM LM during the decoding stage using the shallow fusion (Gülçehre et al., 2015) for both E2E architectures. Besides, we augment the training data using the SpeedPerturb and the SpecAugment techniques. For decoding, we set the beam size to 30 and the LSTM LM interpolation weight to 1.

E2E-RNN. The encoder module of the RNN-based E2E ASR system consists of three bi-directional LSTM layers with 1,024 units per direction per layer. The decoder module is a single uni-directional LSTM with 1,024 units. We train the model for 20 epochs using the Adadelta optimizer with the initial learning rate set to 1 and the batch size set to 30. The interpolation weight for the CTC objective was set to 0.5.

E2E-Transformer. The Transformer-based E2E ASR system consists of 12 encoder and 6 decoder blocks. We set the number of heads in the self-attention layer to 4 with 256-dimension hidden states and the feed-forward network dimensions to 2,048. We set the dropout rate and label smoothing to 0.1. The model was trained for 160 epochs using the Noam optimizer (Vaswani et al., 2017) with the initial learning rate of 10 and the warmup-steps of 25,000. The batch size was set to 96. We report results on an average model constructed using the last 10 checkpoints. The interpolation weight for the CTC objective was set to 0.3.

4.2 Experimental Results

The experimental results are presented in Table 3 in terms of both the character error rate (CER) and word error rate (WER). All the ASR models achieved competitive results on both the validation and test sets. We found that the validation set is more challenging than the test set. When compared without SpecAugment, the performance of the DNN-HMM model (ID 1) is slightly better than the E2E-RNN (ID 5), but inferior to the

---

[7] We tested different N-gram orders and found the 3-gram to perform best on our setup.

ID	Model	LM	SpeedPerturb	SpecAugment	Valid		Test	
					CER	WER	CER	WER
1	DNN-HMM	Yes	Yes	No	5.2	14.2	4.6	13.7
2		Yes	Yes	Yes	5.3	14.9	4.7	13.8
3	E2E-LSTM	No	No	No	9.9	32.0	8.7	28.8
4		Yes	No	No	7.9	20.1	7.2	18.5
5		Yes	Yes	No	5.7	15.9	5.0	14.4
6		Yes	Yes	Yes	4.6	13.1	4.0	11.7
7	E2E-Transformer	No	No	No	6.1	22.2	4.9	18.8
8		Yes	No	No	4.5	13.9	3.7	11.9
9		Yes	Yes	No	3.9	12.3	3.2	10.5
10		Yes	Yes	Yes	**3.2**	**10.0**	**2.8**	**8.7**

Table 3: The CER (%) and WER (%) performances of different ASR models built using KSC.

E2E-Transformer (ID 9). We could not achieve any improvements on the DNN-HMM model (ID 2) using the SpecAugment despite trying different hyper-parameter tuning recommendations (Zhou et al., 2020). Overall, the best CER and WER results are achieved by the E2E-Transformer (ID 10) followed by the E2E-RNN (ID 6) and then the DNN-HMM (ID 1).

We observed that the LM fusion significantly improves the performances of both E2E models. For example, 35% and 36% relative WER improvements are achieved on the test set for the RNN (from ID 3 to ID 4) and Transformer (from ID 7 to ID 8) models, respectively. Furthermore, both data augmentation techniques based on SpeedPerturb and SpecAugment are highly effective for the Kazakh E2E ASR where additional improvements are achieved. For example, when models without and with data augmentations are compared, 36% and 26% relative WER improvements are achieved on the test set for the RNN (from ID 4 to ID 6) and Transformer (from ID 8 to ID 10) models, respectively.

These experimental results successfully demonstrate the utility of the KSC database for the speech recognition task. We leave the exploration of the optimal hyper-parameter settings and detailed comparison of different ASR architectures for future work.

5 Discussion

1) Data sparsity. Kazakh language speech recognition is considered challenging due to the agglutinative nature of the language, where word structures are formed by adding derivational and inflectional affixes to stems in a specific order. As a result, the vocabulary size might considerably grow resulting in a data sparsity problem, especially for models operating in a word level, such as our DNN-HMM architecture. The potential solution is to break down words into finer-level linguistic units, such as characters or subword units (Sennrich et al., 2016). We investigated the impact of other output unit sizes on the performance of the Kazakh E2E-Transformer ASR and did not observe any considerable improvements over the character-level outputs (see Figure 3). The output units were generated using the byte pair encoding (BPE) algorithm implemented in the SentencePiece (Kudo and Richardson, 2018) tokenizer.

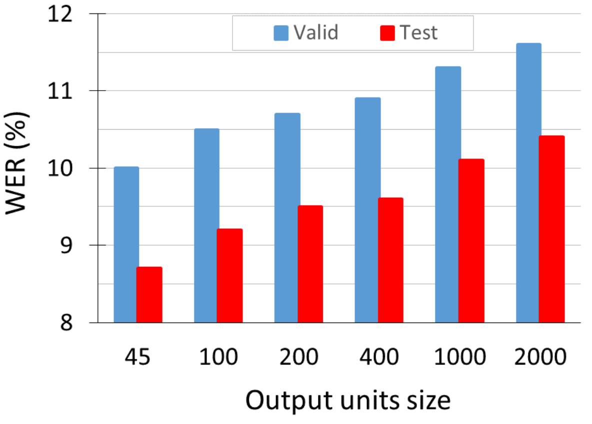

Figure 3: The impact of different output unit sizes on the E2E-Transformer ASR performance.

2) Code-switching. Another challenge is the Kazakh-Russian code-switching practice which is common in daily communication as the majority of

ID	Confusion pairs	Insertion	Deletion	Substitution
1	жоғарғы ⇒ жоғары (jogargy ⇒ jogary) “upper” or “higher” ⇒ “top” or “high”	мен (men) “I” or “with”	де (de) “too” (after a thin-vowelled word)	да (da) “too” (after a thick-voweled word)
2	өзеннің ⇒ өзенінің (uzennin ⇒ uzeninin) “of a river” ⇒ “of the river”	бұл (bul) “this” or “these”	ал (al) an imperative of “take” or “whereas”	де (de) “too” (after a thin-voweled word)
3	ас ⇒ ақ (as ⇒ aq) “meal” ⇒ “white”	бір (bir) “one"	да (da) “too” (after a thick-vowelled word)	мен (men) “I” or “with”
4	бағы ⇒ баға (bagy ⇒ baga) “the garden” ⇒ “price”	да (da) “too” (after a thick-vowelled word)	әр (ar) “every”	жылы (jyly) “the year” or "warm"
5	болу ⇒ болуы (bolu ⇒ boluy) “being” ⇒ “the being”	ақ (aq) “white”	бір (bir) “one"	бір (bir) “one”

Table 4: The top five confusion pairs (reference word ⇒ recognized word) and insertion, deletion, and substitution errors in the recognized output of the E2E-Transformer ASR.

Kazakhs are bilingual. Mostly, inter-sentential and intra-sentential types of code-switching are practiced, however, intra-word code-switching is also possible. For example, one can say “*Men magazinge bardym*” (“*I went to a store*”), where the Russian word “*magazin*” is appended by the Kazakh inflection “*-ge*” representing the preposition “*to*”. Furthermore, while the spelling of Kazakh words closely matches their pronunciation, this is not the case for Russian words, for example, the letter “*o*” is sometimes pronounced as /a/, which might confuse an ASR system. We observed that our ASR system is ineffective in code-switched utterances. Therefore, future work should focus on alleviating these errors.

3) Data efficiency. To analyze the data efficiency–that is, increase in performance due to the addition of new training data–we trained our best E2E-Transformer ASR system using different amounts of data. In particular, we first randomly sampled 40 hours of data and kept increasing their size until the entire training set was covered. The experimental results indicate that the WER performance has not converged yet and further data collection might be effective (see Figure 4). Therefore, we plan to continue the data collection process.

4) ASR output analysis. We inspected the recognized outputs of the best E2E-Transformer model to identify the most challenging characters and words. Table 4 lists the top five confusion pairs and insertion, deletion, and substitution errors. Most of them are commonly used words, such as conjunctions and numbers. In addition, we also inspected the most confused character pairs (see Figure 5). We observed that the Kazakh ASR system confuses characters with a similar pronunciation, such as “н” (/n/) and “ң” (/ŋ/), “і” (/ɪ/) and “ы” (/ə/), and so on.

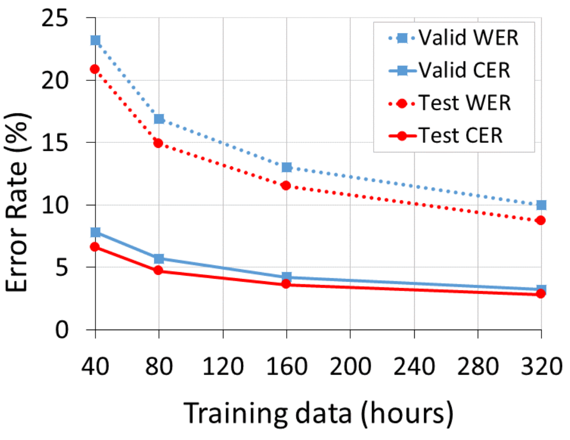

Figure 4: The data efficiency experiment.

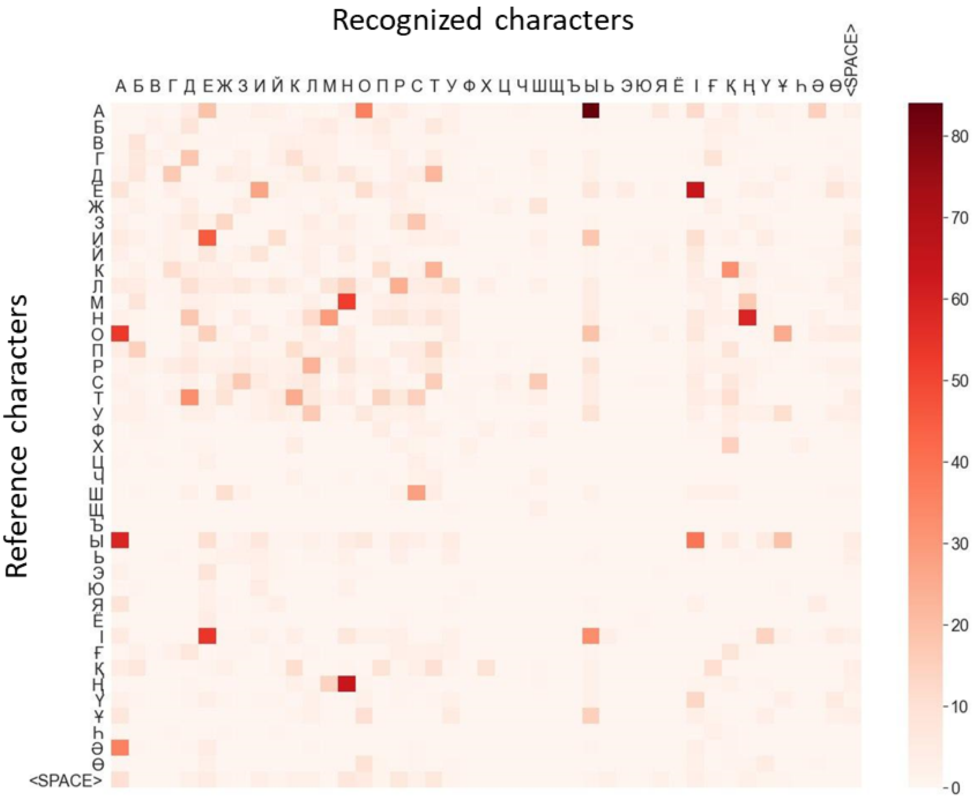

Figure 5: The character confusion matrix for the E2E-Transformer ASR.

5) Performance comparison. We cannot directly compare our results to previous works; however, our WER results are appealing. For example, Mamyrbayev et al. (2019) used 76 hours of speech data to build an DNN-HMM ASR system which achieved 32.7% WER on clean read speech. Similarly, the DNN-HMM ASR system built using 78 hours of data in (Shi et al., 2017) achieved 25.1% WER on read speech. On the other hand, Mamyrbayev et al. (2020) achieved 17.8% WER on clean read speech using the E2E ASR system trained on 126 hours of data. In comparison, our best model achieved 8.7% WER on the test set.

6) Benefit for other Turkic Languages. We also envision that the KSC can be utilized in cross-lingual transfer learning techniques (Das and Hasegawa-Johnson, 2015) to improve ASR systems for other Turkic languages, such as Kyrgyz and Tatar.

6 Conclusion

In this work, we presented the KSC database containing around 332 hours of transcribed speech data. It was developed to advance Kazakh speech processing applications, such as speech recognition, speech synthesis, and speaker recognition. We described the database construction procedures and discussed challenges that should be addressed in future work. The described methodologies might benefit other researchers planning to build a speech corpus for a low-resource language. The database is freely available for any purposes including research and commercial use. We also conducted preliminary speech recognition experiments using both traditional hybrid DNN-HMM and recently proposed E2E ASR architectures. To ease the database usage and ensure the reproducibility of experiments, we split it into three non-overlapping sets (training, validation, and test) and released our ESPnet recipe. The detailed exploration of better ASR settings, as well as the adaptation of the database to other applications, is left for future work.

Acknowledgments

We would like to thank Aigerim Boranbayeva for helping to train and monitor the transcribers. We also thank Kuralay Baimenova, Yerbol Absalyamov, Gibrat Kurmanov, and Rustem Yeshpanov for helping to attract readers and to resolve other administrative tasks.

TDMSci: A Specialized Corpus for Scientific Literature Entity Tagging of Tasks Datasets and Metrics

Yufang Hou, Charles Jochim, Martin Gleize, Francesca Bonin and Debasis Ganguly
IBM Research Europe, Ireland
`{yhou|mgleize|fbonin|debasga1}@ie.ibm.com`

Abstract

Tasks, *Datasets* and *Evaluation Metrics* are important concepts for understanding experimental scientific papers. However, most previous work on information extraction for scientific literature mainly focuses on the abstracts only, and does not treat datasets as a separate type of entity (Zadeh and Schumann, 2016; Luan et al., 2018). In this paper, we present a new corpus that contains domain expert annotations for *Task (T), Dataset (D), Metric (M)* entities on 2,000 sentences extracted from NLP papers. We report experiment results on TDM extraction using a simple data augmentation strategy and apply our tagger to around 30,000 NLP papers from the ACL Anthology. The corpus is made publicly available to the community for fostering research on scientific publication summarization (Erera et al., 2019) and knowledge discovery.

1 Introduction

The recent years have witnessed a significant growth in the number of scientific publications and benchmarks in many disciplines. As an example, in the year 2019 alone, more than 170k papers were submitted to the pre-print repository arXiv[1] and among them, close to 10k papers were classified as NLP papers (i.e., `cs.CL`). Each empirical field of science, including NLP, will benefit from the massive increase in studies, benchmarks, and evaluations, as they can provide ingredients for novel scientific advancements.

However, researchers may struggle to keep track of all studies published in a particular field, resulting in duplication of research, comparisons with old or outdated benchmarks, and lack of progress. In order to tackle this problem, recently there have been a few manual efforts to summarize the state-of-the-art on selected subfields of NLP in the form of leaderboards that extract tasks, datasets, metrics and results from papers, such as *NLP-progress*[2] or *paperswithcode*.[3] But these manual efforts are not sustainable over time for all NLP tasks.

Over the past few years, several studies and shared tasks have begun to tackle the task of entity extraction from scientific papers. Augenstein et al. (2017) formalized a task to identify three types of entities (i.e., *task, process, material*) in scientific publications (SemEval 2017 task10). Gábor et al. (2018) presented a task (SemEval 2018 task 7) on semantic relation extraction from NLP papers. They provided a dataset of 350 abstracts and reuse the entity annotations from Zadeh and Schumann (2016). Recently Luan et al. (2018) released a corpus containing 500 abstracts with six types of entity annotations. However, these corpora do not treat *Dataset* as a separate type of entity and most of them focus on the abstracts only.

In a previous study, we developed an IE system to extract $\{$*task, dataset, metric*$\}$ triples from NLP papers based on a small, manually created task/dataset/metric (TDM) taxonomy (Hou et al., 2019). In practice, we found that a TDM knowledge base is required to extract TDM information and build NLP leaderboards for a wide range of NLP papers. This can help researchers quickly understand related literature for a particular task, or to perform comparable experiments.

As a first step to build such a TDM knowledge base for the NLP domain, in this paper we present a specialized English corpus containing 2,000 sentences taken from the full text of NLP papers which have been annotated by domain experts for three main concepts: *Task* (T), *Dataset* (D) and *Metric*

(M). Based on this corpus, we develop a TDM tagger using a novel data augmentation technique. In addition, we apply this tagger to around 30,000 NLP papers from the ACL Anthology and demonstrate its value to construct an NLP TDM knowledge graph. We release our corpus at `https://github.com/IBM/science-result-extractor`.

2 Related Work

A lot of interest has been focused on information extraction from scientific literature. SemEval 2017-task 10 (Augenstein et al., 2017) proposed a new task for the identification of three types of entities (*Task, Method*, and *Material*) in a corpus of 500 paragraphs taken from open access journals. Based on Augenstein et al. (2017) and Gábor et al. (2018), Luan et al. (2018) created *SciERC*, a dataset containing 500 scientific abstracts with annotations for six types of entities and relations between them. Both SemEval 2017-task 10 and *SciERC* do not treat "*dataset*" as a separate entity type. Instead, their "*material*" category comprises a much larger set of resource types, including tools, knowledge resources, bilingual dictionaries, as well as datasets. In our work, we focus on "*datasets*" entities that researchers use to evaluate their approaches because dataset is one of the three core elements to construct leaderboards for NLP papers.

Concurrent to our work, Jain et al. (2020) develop a new corpus *SciREX* which contains 438 papers on different domains from *paperswithcode*. It includes annotations for four types of entities (i.e., *Task, Dataset, Metric, Method*) and the relations between them. The initial annotations were carried out automatically using distant signals from *paperswithcode*. Later human annotators performed necessary corrections to generate the final dataset. *SciREX* is the closest to our corpus in terms of entity annotations. In our work, we focus on TDM entities which reflect the collectively shared views in the NLP community and our corpus is annotated by five experts who all have 5-10 years NLP research experiences.

3 Corpus Creation

3.1 Annotation Scheme

We developed an annotation scheme for annotating Task, Dataset, and Evaluation Metric phrases in NLP papers. Our annotation guidelines[4] are based on the scientific term annotation scheme described in Zadeh and Schumann (2016). Different from previous corpora (Zadeh and Schumann, 2016; Luan et al., 2018), we only annotated **factual** and **content-bearing** entities. This is because we aim to build a TDM knowledge base in the future and non-factual entities (e.g., *a high-coverage sense-annotated corpus* in Example 1) do not reflect the collectively shared views of TDM entities in the NLP domain.

(1) In order to learn models for disambiguating a large set of content words, *a high-coverage sense-annotated corpus* is required.

Following the above guidelines, we also do not annotate *anonymous entities*, such as "*this task*" or "*the dataset*". These entities are anaphors and can not be used independently to refer to any specific TDM entities without contexts. In general, we choose to annotate TDM entities that normally have specific names and whose meanings usually are consistent across different papers. From this perspective, the TDM entities that we annotate are similar to named entities, which are self-sufficient to identify the referents.

3.2 Pilot Annotation Study

Data preparation. For the pilot annotation study, we choose 100 sentences from the NLP-TDMS corpus (Hou et al., 2019). The corpus contains 332 NLP papers which are annotated with triples of $\{$*Task, Dataset, Metric*$\}$ on the document level. We use string and substring match to extract a list of sentences from these papers which are likely to contain the document level *Task, Dataset, Metric* annotations. We then manually choose 100 sentences from this list following the criteria: 1) the sentence should contain the valid mention of *Task*, *Dataset*, or *Metric*; 2) the sentences should come from different papers as much as possible; and 3) there should be a balanced distribution of *task*, *dataset*, and *metric* mentions in these sentences.

Annotation agreement. Four NLP domain experts annotated the same 100 sentences for a pilot annotation study, following the annotation guidelines described above. All the annotations were conducted using BRAT (Stenetorp et al., 2012). The inter annotator agreement has been calculated with a pairwise comparison between annotators using *precision*, *recall* and *F-score* on the exact match of the annotated entities. In other words,

---

[4] Please see the appendix for the whole annotation scheme.

	Mean F-score (EM)	Fleiss' κ (Token)
Task	0.720	0.797
Dataset	0.752	0.829
Metric	0.757	0.896
Overall	0.743	0.842

Table 1: Inter-annotator agreement.

	Train	Test
# Sentences	1500	500
# Task	1219	396
# Dataset	420	192
# Metric	536	174

Table 2: Statistics of task/dataset/metric mentions in the training and testing datasets.

two entities are considered matching (true positive) if they have the same boundaries and are assigned to the same label. We also calculate Fleiss' kappa on a per token basis, comparing the agreement of annotators on each token in the corpus. Table 1 lists the mean F-score as well as the token-based Fleiss' κ value for each entity type. Overall, we achieve high reliability for all categories.

Adjudication. The final step of the pilot annotation was to reconcile disagreements among the four annotators to produce the final canonical annotation. This step also allows us to refine the annotation guidelines. Specifically, through the discussion of annotation disagreements we could identify ambiguities and omissions in the guidelines. For example, one point of ambiguity was whether a *task* must be associated with a dataset, or can we annotate higher level tasks, e.g., *sequence labeling*, which do not have a dedicated dataset but may include several tasks and datasets. This discussion also revealed the overlap in how we refer to tasks and datasets in the literature. As authors we frequently use these interchangeably, often with shared tasks, e.g., "*SemEval-07 task 17*" seems to more often refer to a dataset than a specific instance of the (Multilingual) Word Sense Disambiguation task, or the "*MultiNLI*" corpus is sometimes used as shorthand for the task. After the discussion, we agreed that we should annotate higher level tasks. In addition, we should assign labels to entities according to their actual referential meanings in contexts.

3.3 Main Annotation

After the pilot study, 1,900 additional sentences were annotated by five NLP researchers. Four annotators participated in the pilot annotation study, and all annotators joined the adjudication discussion. Note that every annotator annotate a different set of sentences. The annotator who designed the annotation scheme annotated 700 sentences, the other four annotators annotated 300 sentences each.[5]

In general, most sentences in our corpus are not from the abstracts. Note that the goal of developing our corpus is to automatically build an NLP TDM taxonomy and use them to tag NLP papers. Therefore, the inclusion of sentences from the whole paper other than the abstract section is important for our purpose. Because not all abstracts talk about all three elements. For instances, for the top ten papers listed in the {*sentiment analysis, IMDB, accuracy*} leaderboard in *paperswithcode*[6], only four abstracts mention the dataset "*IMDB*". If we only focus on the abstracts, we will miss the other six papers from the leaderboard.

4 A TDM Entity Tagger

Our final corpus *TDMSci* contains 2,000 sentences with 2,937 mentions of three entity types. We convert the original BRAT annotations to the standard CoNLL format using BIO scheme.[7] We develop a tagger to extract TDM entities based on this corpus.

4.1 Experimental Setup

To evaluate the performance of our tagger, we split *TDMSci* into training and testing sets, which contains 1,500 and 500 sentences, respectively. Table 2 shows the statistics of task/dataset/metric mentions in these two datasets. For evaluation, we report precision, recall, F-score on exact match for each entity type as well as micro-averaged precision, recall, F-score for all entities.

---

[5] Due to time constraints, we did not carry out another round of pilot study. Partially it is because we felt that the revised guidelines resulting from the discussion were sufficient for the annotators to decide ambiguous cases. So in the second stage annotators annotated disjoint sets of sentences. After this, the annotator who designed the annotation scheme went through the whole corpus again to verify the annotations.

[6] https://paperswithcode.com/sota/sentiment-analysis-on-imdb, search was carried out on November, 2020.

[7] Note that our BRAT annotation contains a small amount of embedded entities, e.g., *WSJ portion of Ontonotes* and *Ontonotes*. We only keep the longest span when we convert the BRAT annotations to the CoNLL format.

Table 3: Results of different models for *task/dataset/metric* entity recognition on *TDMSci* test dataset.

4.2 Models

We model the task as a sequence tagging problem. We apply a traditional CRF model (Lafferty et al., 2001) with various lexical features and a BiLSTM-CRF model for this task. To compare with the state-of-the-art entity extraction model on scientific literature, we also use *SciIE* from Luan et al. (2018) to train a *TDM* entity recognition model based on our training data. Below we describe all models in detail.

CRF. We use the Stanford CRF implementation (Finkel et al., 2005) to train a *TDM* NER tagger based on our training data. We use the following features: unigrams of the previous, current and next words, current word character n-grams, current POS tag, surrounding POS tag sequence, current word shape, surrounding word shape sequence.

CRF with gazetteers. To test whether the above CRF model can benefit from knowledge resources, we add two gazetteers to the feature set: one is a list containing around 6,000 dataset names which were crawled from LRE Map,[8] and another gazetteer comprises around 30 common evaluation metrics compiled by the authors.

SciIE. Luan et al. (2018) proposed a multi-task learning system to extract entities and relations from scientific articles. *SciIE* is based on span representations using ELMo (Peters et al., 2018) and here we adapt it for *TDM* entity extraction. Note that if *SciIE* predicts several embedded entities, we keep the one that has the highest confidence score. In practice we notice that this does not happen in our corpus.

Flair-TDM For BiLSTM-CRF model, we use the recent *Flair* framework (Akbik et al., 2018) based on the cased BERT-base embeddings (Devlin et al., 2018). We train our *Flair-TDM* model with a learning rate of 0.1, a batch size of 32, a hidden size of 768, and the maximum epochs of 150.

4.3 Data Augmentation

For TDM entity extraction, we expect that the surrounding context will play an important role. For instance, in the following sentence "we show that for X on the Y, our model outperforms the prior state-of-the-art", one can easily guess that X is a task entity while Y is a dataset entity. As a result, we propose a simple data augmentation strategy that generates the additional mask training data by replacing every token within an annotated TDM entity as `UNK`.

4.4 Results and Discussion

Table 3 shows the performance of different models for *task/dataset/metric* entity recognition on our testing dataset.

First, it seems that although adding gazetteers can help the CRF model detect *dataset* and *metric* entities better, the positive effect is limited. In general, both *SciIE* and *Flair-TDM* perform better than *CRF* models for detecting all three type of entities.

Second, augmenting the original training data with the additional masked data as described in Section 4.3 further improves the performance both for *SciIE* and *Flair-TDM*. However, this is not the case for the CRF models. We assume this is because CRF models heavily depend on the lexical features.

Finally, we randomly sampled 100 sentences from the testing dataset and compared the predicted TDM entities in *Flair-TDM* against the gold annotations. We found that most errors are from the boundary mismatch for task and dataset entities, e.g., *text summarization* vs. *abstractive text sum-*

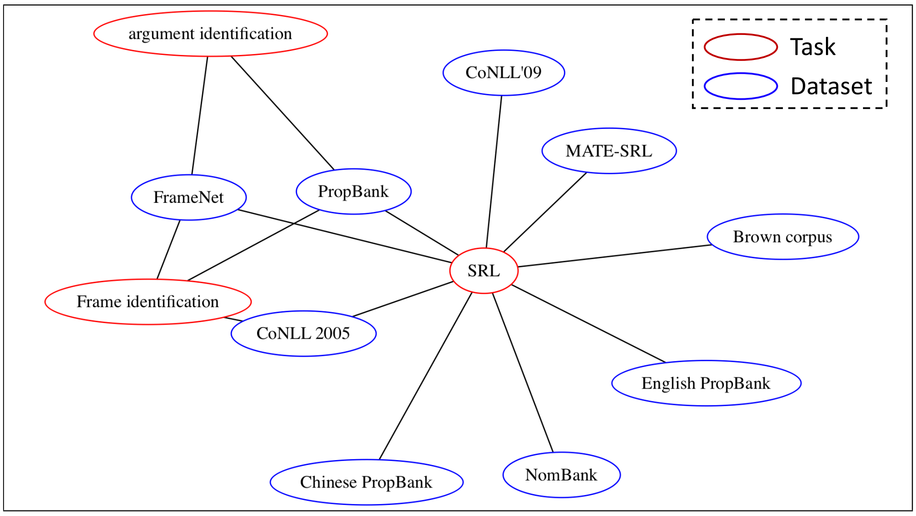

Figure 1: A subset of the *TDM* graph.

marization, or *Penn Treebank* vs. *Penn Treebank dataset*. The last error comes from the bias in the training data. A lot of researchers use "*Penn Treebank*" to refer to a dataset. So the model will learn this bias and only tag "*Penn Treebank*" as the dataset even though in a specific testing sentence, "*Penn Treebank dataset*" was used to refer to the same corpus.

In general, we think these mismatched predictions are reasonable in the sense that they capture the main semantics of the referents. Note that the numbers reported in Table 3 are based on exact match. Often, requiring exact match may be too restictive for downstreaming tasks. Therefore, we carried out an additional evaluation for the best *Flair-TDM* model using partial match from SemEval 2013-Task 9 (Segura-Bedmar et al., 2013), which gives us a micro-average F1 of 76.47 for type partial match.

5 An Initial TDM Knowledge Graph

In this section, we apply the *Flair-TDM* tagger to around 30,000 NLP papers from ACL Anthology to build an initial TDM knowledge graph.

We downloaded all NLP papers from the ACL Anthology[9] covering the period of 1974-2019. For each paper, we collect sentences from the title, the abstract/introduction/dataset/corpus/experiment sections, as well as from the table captions. We then apply the *Flair-TDM* tagger to these sentences. Based on the tagger results, we build an initial graph G using the following steps:

- add a *TDM* entity as a node into G if it appears at least five times in more than one paper;
- create a link between a *task* node and a *dataset/metric* node if they appear in the same sentence at least five times in different papers.

By applying the above simple process, we get a noisy *TDM* knowledge graph containing 180k nodes and 270k links. After checking a few dense areas, we find that our graph encodes valid knowledge about NLP task/dataset/metric. Figure 1 shows that in our graph, the task "SRL" (semantic role labelling) is connected to a few datasets such as "FrameNet", "PropBank", and "NomBank" that are standard benchmark datasets for this task.

Based on the tagged ACL Anthology and this initial noisy graph, we are exploring various methods to build a large-scale NLP TDM knowledge graph and to evaluate its accuracy/coverage in an ongoing work.

6 Conclusion

In this paper, we have presented a new corpus (*TDMSci*) annotated for three important concepts (*Task/Dataset/Metric*) that are necessary for extracting the essential information from an NLP paper. Based on this corpus, we have developed a *TDM* tagger using a simple but effective data augmentation strategy. Experiments on 30,000 NLP papers show that our corpus together with the *TDM* tagger can help to build *TDM* knowledge resources for the NLP domain.

A TDM Entity Annotation Guidelines

A.1 Introduction

This scheme describes guidelines for annotating *Task*, *Dataset*, and *Evaluation Metric* phrases in NLP papers. We have pre-processed NLP papers in PDF format and chosen sentences that are likely to contain the above-mentioned entities for annotation. These sentences may come from different sections (e.g., Abstract, Introduction, Experiment, Dataset) as well as tables (e.g., table captions).

A.2 Entity Types

We annotate the following three entity types:

- Task: A task is a problem to solve (e.g., *information extraction*, *sentiment classification*, *dialog state tracking*, *POS tagging*, *NER*).

- Dataset: A dataset is a specific corpus or language resource. Datasets are often used to develop models or run experiments for NLP tasks. A dataset normally has a short name, e.g., *IMDB*, *Gigaword*.

- Metric: An evaluation metric explains the performance of a model for a specific task, e.g., *BLEU* (for machine translation), or *accuracy* (for a range of NLP tasks).

A.3 Notes and Examples

Entity spans. Particular attention must be paid to the entity spans in order to improve agreement. The following list indicates all the annotation directions that annotators have been given regarding entity spans. Table 4 shows examples of correct span annotation.

- Following the ACL RD-TEC 2.0 annotation guideline,[10] determiners should not be part of an entity span. For example, the string 'the text8 test set', only the span 'test8' is annotated as *dataset*.

- Minimum span principle: Annotators should annotate only the minimum span necessary to represent the original meaning of task/dataset/metric. See Table 4, rows 1,2,3,4.

- Include 'corpus/dataset/benchmark' when annotating dataset if these tokens are the head-noun of the dataset entity. For example: 'ubuntu corpus', 'SemEval-2010 Task 8 dataset'.

- Exclude the head noun of 'task/problem' when annotating task (e.g., only annotation "link prediction" for "the link prediction problem") unless they are the essential part of the task itself (e.g., CoNLL-2012 shared task, SemEval-2010 relation classification task).

- Conjunction: If the conjunction NP is an ellipse, annotate the whole phrase (see Table 4, rows 6,11); otherwise, annotate the conjuncts separately (see Table 4, row 5).

- Tasks can be premodifiers (see Table 4, rows 7,8,12)

- Embedded spans: Normally TDM entities do not contain any other TDM entities. A small number of *Task* and *Dataset* entities can contain other entities (see Table 4, row 12).

Anonymous entities. Do not annotate anonymous entities, which include anaphors. The following examples are anonymous entities:

- *this task*

- *this metric*

- *the dataset*

- *a public corpus for context-sensitive response selection* in the sentence "Experimental results in a a public corpus for context-sensitive response selection demonstrate the effectiveness of the proposed multi-vew model."

Abbreviation. If both the full name and the abbreviation are present in the sentence, annotate the abbreviation with its corresponding full name together. For instance, we annotate "20-newsgroup (20NG)" as a dataset entity in Example 2.

Factual entity. Only annotate "factual, content-bearing" entities. Task, dataset, and metric entities normally have specific names and their meanings are consistent across different papers. In Example 3, "*a high-coverage sense-annotated corpus*" is not a factual entity.

Top-down Discourse Parsing via Sequence Labelling

Fajri Koto **Jey Han Lau** **Timothy Baldwin**
School of Computing and Information Systems

ffajri@student.unimelb.edu.au, jeyhan.lau@gmail.com, tbaldwin@unimelb.edu.au

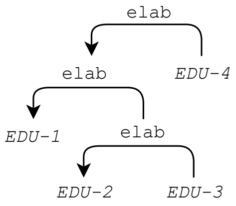
Abstract

We introduce a top-down approach to discourse parsing that is conceptually simpler than its predecessors (Kobayashi et al., 2020; Zhang et al., 2020). By framing the task as a sequence labelling problem where the goal is to iteratively segment a document into individual discourse units, we are able to eliminate the decoder and reduce the search space for splitting points. We explore both traditional recurrent models and modern pre-trained transformer models for the task, and additionally introduce a novel dynamic oracle for top-down parsing. Based on the `Full` metric, our proposed LSTM model sets a new state-of-the-art for RST parsing.[1]

1 Introduction

Discourse analysis involves the modelling of the structure of text in a document. It provides a systematic way to understand how texts are segmented hierarchically into discourse units, and the relationships between them. Unlike syntax parsing which models the relationship of words in a sentence, discourse parsing operates at the document-level, and aims to explain the flow of writing. Studies have found that discourse parsing is beneficial for downstream NLP tasks including document-level sentiment analysis (Bhatia et al., 2015) and abstractive summarization (Koto et al., 2019).

Rhetorical Structure Theory (RST; Mann and Thompson (1988)) is one of the most widely used discourse theories in NLP (Hernault et al., 2010; Feng and Hirst, 2014; Ji and Eisenstein, 2014; Li et al., 2016; Yu et al., 2018). RST organizes text spans into a tree, where the leaves represent the basic unit of discourse, known as elementary discourse units (EDUs). EDUs are typically clauses of a sentence. Non-terminal nodes in the tree represent discourse unit relations.



EDU-1: Roy E. Parrott, the company's president and chief operating officer since Sept. 1, was named to its board.
EDU-2: The appointment increased the number of directors to 10,
EDU-3: three of whom are company employees.
EDU-4: Simpson is an auto parts maker.

Figure 1: An example discourse tree, from the RST Discourse Treebank (`elab` = elaboration).

In Figure 1, we present an example RST tree with four EDUs spanning two sentences. In this discourse tree, EDUs are hierarchically connected with arrows and the discourse label `elab`. The direction of arrows indicates the nuclearity of relations, wherein a "satellite" points to its "nucleus". The satellite unit is a supporting sentence for the nucleus unit and contains less prominent information. It is standard practice that the RST tree is trained and evaluated in a right-heavy binarized manner, resulting in three forms of binary nuclearity relationships between EDUs: Nucleus–Satellite, Satellite–Nucleus, and Nucleus–Nucleus. In this work, eighteen coarse-grained relations are considered as discourse labels, consistent with earlier work (Yu et al., 2018).[2]

Work on RST parsing has been dominated by the bottom-up paradigm (Hernault et al., 2010; Feng and Hirst, 2014; Ji and Eisenstein, 2014; Braud et al., 2017; Morey et al., 2017; Yu et al., 2018). These methods produce very competitive benchmarks, but in practice it is not a straightforward

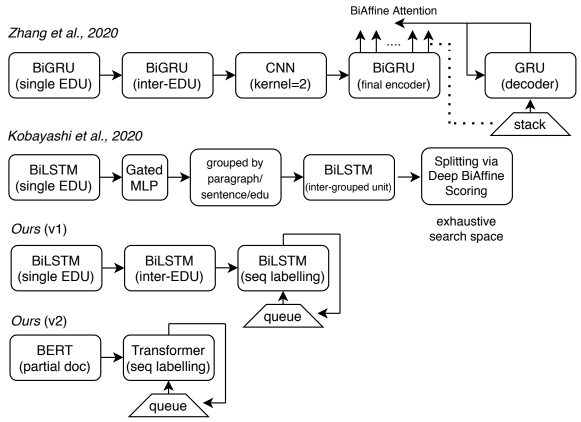

Figure 2: Comparison of our top-down models with Zhang et al. (2020) and Kobayashi et al. (2020).

approach (e.g. transition-based parser with actions prediction steps). Furthermore, bottom-up parsing limits the tree construction to local information, and macro context such as global structure/topic is prone to be under-utilized. As a result, there has recently been a move towards top-down approaches (Kobayashi et al., 2020; Zhang et al., 2020).

The general idea behind top-down parsing is to find splitting points in each iteration of tree construction. In Figure 2, we illustrate how our architecture differs from Zhang et al. (2020) and Kobayashi et al. (2020). First, Zhang et al. (2020) utilize four levels of encoder that comprise 3 Bi-GRUs and 1 CNN layer. The splitting mechanism is applied through a decoder, a stack, and bi-affine attention mechanisms. Kobayashi et al. (2020) use the gold paragraph and sentence boundaries to aggregate a representation for each unit, and generate the tree based on these granularities. Two Bi-LSTMs are used, with splitting points determined by exhaustively calculating the bi-affine score of each possible split. The use of paragraph boundaries can explicitly lower the difficulty of the task, as 77% of paragraphs in the English RST Discourse Treebank ("RST-DT") are actually text spans (Carlson et al., 2001). These boundaries are closely related to gold span boundaries in evaluation.

In this paper, we propose a conceptually simpler top-down approach for RST parsing. The core idea is to frame the problem as a sequence labelling task, where the goal is to iteratively find a segmentation boundary to split a sequence of discourse units into two sub-sequences of discourse units. This way, we are able to simplify the architecture, in eliminating the decoder as well as reducing the search space for splitting points. Specifically, we use an LSTM (Hochreiter and Schmidhuber, 1997) or pre-trained BERT (Devlin et al., 2019) as the segmenter, enhanced in a number of key ways.

Our primary contributions are as follows: (1) we propose a novel top-down approach to RST parsing based on sequence labelling; (2) we explore both traditional sequence models such as LSTMs and also modern pre-trained encoders such as BERT; (3) we demonstrate that adding a weighting mechanism during the splitting of EDU sequences improves performance; and (4) we propose a novel dynamic oracle for training top-down discourse parsers.

2 Related Work

Previous work on RST parsing has been dominated by bottom-up approaches (Hernault et al., 2010; Joty et al., 2013; Li et al., 2016; Braud et al., 2017; Wang et al., 2017). For example, Ji and Eisenstein (2014) introduce `DPLP`, a transition-based parser based on an SVM with representation learning, combined with some heuristic features. Braud et al. (2016) propose joint text segment representation learning for predicting RST discourse trees using a hierarchical Bi-LSTM. Elsewhere, Yu et al. (2018) showed that implicit syntax features extracted from a dependency parser (Dozat and Manning, 2017) are highly effective for discourse parsing.

Top-down parsing is well established for constituency parsing and language modelling (Johnson, 1995; Roark and Johnson, 1999; Roark, 2001; Frost et al., 2007), but relatively new to discourse parsing. Lin et al. (2019) propose a unified framework based on pointer networks for sentence-level discourse parsing, while Liu et al. (2019) employ hierarchical pointer network parsers.

Morey et al. (2017) found that most previous studies on parsing RST discourse tree were incorrectly benchmarked, e.g. one study uses macro-averaging while another use micro-averaging.[3] They also advocate for evaluation based on micro-averaged F-1 scores over labelled attachment decisions (a la the original Parseval).

Pre-trained language models (Radford et al., 2018; Devlin et al., 2019) have been shown to benefit a multitude of NLP tasks, including discourse analysis. For example, BERT models have been used for classifying discourse markers (Sileo et al.,

---

[3] After standardizing evaluation (based on micro-averaged F-1), they found that `DPLP` achieves the best `Full` performance, outperforming the deep learning models.

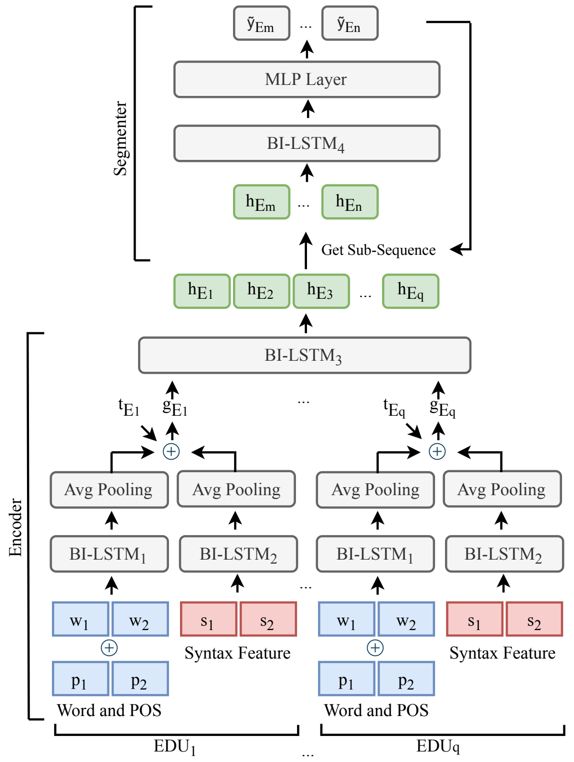

Figure 3: Architecture of the LSTM model.

2019) and discourse relations (Nie et al., 2019; Shi and Demberg, 2019). To the best of our knowledge, however, pre-trained models have not been applied in the generation of full discourse trees, which we address here by experimenting with BERT for top-down RST parsing.

3 Top-down RST Parsing

We frame RST parsing as a sequence labelling task, where given a sequence of input EDUs, the goal is to find a segmentation boundary to split the sequence into two sub-sequences. This is realized by training a sequence labelling model to predict a binary label for each EDU, and select the EDU with the highest probability to be the segmentation point. After the sequence is segmented, we repeat the same process for the two sub-sequences in a divide-and-conquer fashion, until all sequences are segmented into individual units, producing the binary RST tree (e.g. Figure 1).

3.1 LSTM Model

As illustrated in Figure 3, our LSTM parser consists of two main blocks: an encoder and a segmenter. For the encoder, we follow Yu et al. (2018) in using two LSTMs (Bi-LSTM$_1$ and Bi-LSTM$_2$) to produce EDU encodings by processing: (1) x_i, the concatenation of word embedding w_i and POS tag embedding p_i; and (2) syntax embedding s_i, the output of the MLP layer of the bi-affine dependency parser (Dozat and Manning, 2017). Similar to Yu et al. (2018), we then take the average of the output states for both LSTMs over the EDU, and concatenate it with an EDU type embedding t_{E_j} (which distinguishes the last EDU in a paragraph from other EDUs) to produce the final encoding:

$$\begin{aligned} x_i &= w_i \oplus p_i \\ \{a_1^w, .., a_p^w\} &= \text{Bi-LSTM}_1(\{x_1, .., x_p\}) \\ \{a_1^s, ..., a_p^s\} &= \text{Bi-LSTM}_2(\{s_1, .., s_p\}) \\ g_{E_j} &= \text{Avg-Pool}(\{a_1^w, .., a_p^w\}) \oplus \\ &\quad \text{Avg-Pool}(\{a_1^s, .., a_p^s\}) \oplus t_{E_j} \end{aligned} \tag{1}$$

where E_j is an EDU, p is the number of words in E_j, and $\oplus$ denotes the concatenate operation. t_{E_j} is generally an implicit paragraph boundary feature, and provides a fair benchmark with previous models. In Section 4.3, we also show results without paragraph boundary features.

As each EDU is processed independently, we use another LSTM (Bi-LSTM$_3$) to capture the inter-EDU relationship to obtain a contextualized representation h_{E_j}:

$$\{h_{E_1}, ..., h_{E_q}\} = \text{Bi-LSTM}_3(\{g_{E_1}, ..., g_{E_q}\})$$

where q is the number of EDUs in the document. Note that h_{E_j} is the final encoder output (see Figure 3) and is only computed once for each document.

The second part is the segmenter. We frame segmentation as a sequence labelling problem with $y_{E_j} \in \{0, 1\}$, where 1 denotes the splitting point, and 0 a non-splitting point. For each EDU sequence there is exactly one EDU that is labeled 1, and we start from the full EDU sequence (whole document) and iteratively perform segmentation until we are left with individual EDUs. We use a queue to store the two EDU sub-sequences as the result of the segmentation process. In total, there are $q - 1$ iterations of segmentation (recall that q is the total number of EDUs in the document).

As segmentation is done iteratively in a divide-and-conquer fashion, h_{E_j} serves as the input to the segmenter, which takes a (sub)sequence of EDUs to predict the segmentation position:

$$\begin{aligned} \{h'_{E_m}, .., h'_{E_n}\} &= \text{Bi-LSTM}_4(\{h_{E_m}, .., h_{E_n}\}) \\ \tilde{y}_{E_j} &= \sigma(\text{MLP}(h'_{E_j})) \end{aligned}$$

where m/n are the starting/ending index of the EDU sequence,[4] and $\tilde{y}_{E_j}$ gives the probability of a segmentation. From preliminary experiments we found that it's important to have this additional Bi-LSTM$_4$ to perform the EDU sub-sequence segmentation point prediction.

3.2 Transformer Model

Adapting BERT to discourse parsing is not trivial due to the limited number of input tokens it takes (typically 512 tokens), which is often too short for documents. Moreover, BERT is designed to encode sentences (and only two at maximum), where in our case we want to encode sequences of EDUs that span multiple sentences.

In our case, EDU truncation is not an option (since that would produce an incomplete RST tree), and the average number of words per document in our data is 521 (741 word pieces after BERT tokenization), which is much larger than the 512 limit. We therefore break the document into a number of partial documents, each consisting of multiple sentences that fit into the 512 token limit. This way, we allow the model to capture the fine-grained word-to-word relationships across (most) EDUs. Each partial document is then processed based on Liu and Lapata (2019) trick where we use an alternating even/odd segmentation embedding to encode all the EDUs in a document.

We illustrate this approach in Figure 4. First, all EDUs are formatted to start with [CLS] and end with [SEP], and words are tokenized using WordPiece. If the document has more than 512 tokens, we break it into multiple partial documents based on EDU boundaries, and pad accordingly (e.g. in Figure 4 we break the example document of 3 EDUs into 2 partial documents), and process each partial document independently with BERT.

We also experimented with the second alternative by encoding each EDU independently first with BERT, and use a second inter-EDU transformer to capture the relationships between EDUs. Preliminary experiments, however, suggest that this approach produces sub-optimal performance.

In Figure 4 each token is assigned three kinds of embeddings: (1) word, (2) segment, and (3) position. The input vector is computed by summing these three embeddings, and fed into BERT (initialized with `bert-base`). The output of BERT gives us a contextualized embedding for each token, and we use the [CLS] embedding as the encoding for each EDU (g_{E_j}).

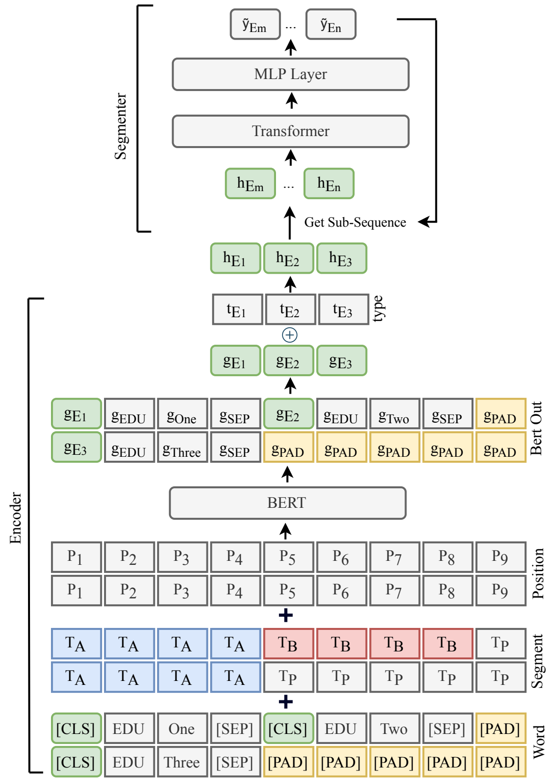

Figure 4: Architecture of the transformer model. In practice, 1 row of input can have more than two EDUs.

Unlike the LSTM model, we do not incorporate syntax embeddings into the transformer model as we found no empirical benefit (see Section 4.3). This observation is in line with other studies (e.g. Jawahar et al. (2019)) that have found BERT to implicit encode syntactic knowledge.

For the segmenter we use a second transformer (initialized with random weights) to capture the inter-EDU relationships for sub-sequences of EDUs during iterative segmentation:

$$\{h'_{E_m}, .., h'_{E_n}\} = \text{transformer}(\{h_{E_m}, .., h_{E_n}\})$$
$$\tilde{y}_{E_j} = \sigma(\text{MLP}(h'_{E_j}))$$

where $\tilde{y}_{E_j}$ gives the probability of a segmentation, and h_{E_j} is the concatenation of the output of BERT (g_{E_j}) and the EDU type embedding (t_{E_j}).

3.3 Nuclearity and Discourse Relation Prediction

In Figure 5, we give an example of the iterative segmentation process to construct the RST tree. In each iteration, we pop a sequence from the queue (initialized with the original sequence of EDUs in

---

[4] In the first iteration, $m = 1$ and $n = q$ (number of EDUs in the document).

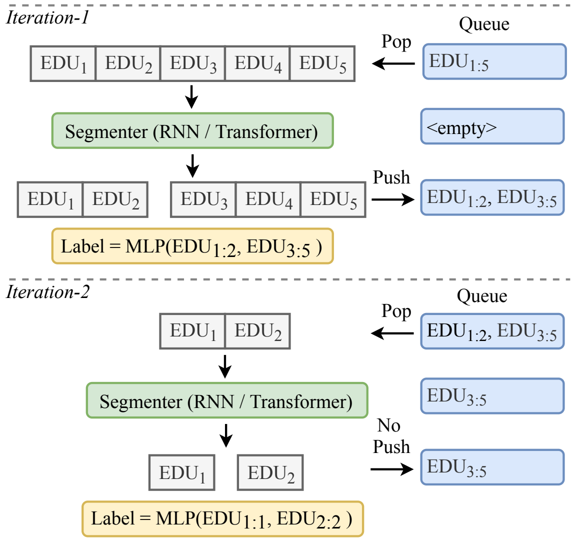

Figure 5: Nuclearity and relation prediction.

the document) and compute the segmentation label for each EDU using an LSTM (Section 3.1) or transformer (Section 3.2). After the sequence is segmented (using the ground truth label during training, or the highest-probability label at test time), we push to the queue the two sub-sequences (if they contain at least two EDUs) and repeat this process until the queue is empty.

In addition to segmentation, we also need to predict the nuclearity/satellite relationship (3 classes) and the discourse label (18 classes) for the segmented pairs. To that end, we average the EDU encodings for the segments, and feed them to a MLP layer to predict the nuclearity and discourse labels:

$$\begin{aligned} u_l &= \text{Avg-Pool}(h'_{E_m}, ..., h'_{E_{m+ind}}) \\ u_r &= \text{Avg-Pool}(h'_{E_{m+ind+1}}, ..., h'_{E_n}) \\ z_{nuc+dis} &= \text{softmax}(\text{MLP}(u_l, u_r)) \end{aligned}$$

where ind is the index of the segmentation point (given by the ground truth during training, or argmax of the segmentation probabilities $\tilde{y}_{E_j}$ at test time), and $z_{nuc+dis}$ gives the joint probability distribution over the nuclearity and discourse classes.[5]

3.4 Segmentation Loss with Penalty

One drawback of the top-down approach is that segmentation errors incurred closer to the root can be detrimental, as the error will propagate to the rest of the sub-trees. To address this, we explore scaling the segmentation loss based on the current tree depth and the number of EDUs in the input sequence. Preliminary experiments found that both approaches work, but that the latter is marginally better, and so we present results using the latter.

Formally, the modified segmentation loss of an example (document) is given as follows:

$$\begin{aligned} L(E_{m:n}) = -\sum_{i=m}^{n} \Big(& y_{E_i} \log(\tilde{y}_{E_i}) + \\ & (1 - y_{E_i}) \log(1 - \tilde{y}_{E_i}) \Big) \\ \mathcal{L}_{seg} = \frac{1}{|S|} & \sum_{(m,n)\in S} (1 + (n-m)^{\beta}) L(E_{m:n}) \end{aligned}$$

where $y_{E_i} \in \{0, 1\}$ is the ground truth segmentation label, $L(E_{m:n})$ is the cross-entropy loss for an EDU sequence, S is the set of all EDU sequences (based on ground truth segmentation), and β is a scaling hyper-parameter.

To summarize, the total training loss of our model is a (weighted) combination of segmentation loss ($\mathcal{L}_{seg}$) and nuclearity-discourse prediction loss ($\mathcal{L}_{nuc+dis}$):

$$\mathcal{L} = \lambda_1 \mathcal{L}_{seg} + \lambda_2 \mathcal{L}_{nuc+dis} \qquad (2)$$

3.5 Dynamic Oracle

The training regimen for discourse parsing creates an exposure bias, where the parser may struggle to recover when it makes a mistake at test time. Goldberg and Nivre (2012) propose a dynamic oracle for transition-based dependency parsing to tackle this. The idea is to allow the model during training to use its predictions (instead of ground truth actions), and introduce a dynamic oracle to find the next best/optimal action sequences. It does so by comparing the current state of the constructed tree and the gold-standard tree, and aims to minimize the deviation. As the model is exposed to prediction errors during training time, it has a better chance of recovering from them at test time.

We explore a similar idea, and propose a dynamic oracle for our top-down discourse parser. A crucial question to ask when designing a dynamic oracle is: *how can we compare the current state to the gold tree to obtain the next best series of actions when an error occurs during training?* In transition-based parsing, Goldberg and Nivre (2012) compute a cost/loss of each transition by

---

[5] We also experimented with predicting the nuclearity and discourse labels separately, but found joint prediction to work better in preliminary experiments.

Algorithm 1 Top-down Dynamic Oracle

```
function DynOracle($E, O, R$)
    # For training only
    # E is list of EDUs
    # O is gold order for segmentation
    # R is list of gold discourse labels based on O
    $q$ = length($E$); $queue = [E_{1:q}]$
    while $queue$ is not empty do
        $E_{m:n} = queue$.pop()
        $id_{gold}, r_{gold}$ = match($E_{m:n}, O, R$)
        $id_{pred}$ = predictSplit($E_{m:n}$)
        $r_{pred1}$ = predictLabel($E_{m:n}, id_{gold}$) # for loss
        $r_{pred2}$ = predictLabel($E_{m:n}, id_{pred}$) # ignored
        if random() $> \alpha$ then
            $L, R$ = separate($E_{m:n}, id_{gold}$)
        else
            $L, R$ = separate($E_{m:n}, id_{pred}$)
        end if
        $queue$.push($L$) if len($L$) $> 1$
        $queue$.push($R$) if len($R$) $> 1$
    end while
end function
```

counting the gold arcs that are no longer reachable based on the action taken (e.g. `SHIFT`, `REDUCE`). We apply similar reasoning when finding the next best segmentation sequence in our dynamic oracle, which we illustrate below with an example.

Say we have a document with 4 EDUs ($E_{1:4}$), and the gold tree given in Figure 6 (left). The correct sequence of segmentation is given by $O_{1:4} = [2, 1, 3, -]$, which means we should first split at E_2 (creating $E_{1:2}$ and $E_{3:4}$), and then at E_1 (creating $E_1, E_2, E_{3:4}$), and lastly at E_3, producing E_1, E_2, E_3, E_4 as the leaves with the gold tree structure. We give the last EDU E_4 a "$-$" label (i.e. $O_4 =$'$-$') because no segmentation is needed for the last EDU.

Suppose the model predicts to do the first segmentation at E_3. This produces $E_{1:3}$ and E_4. What is the best way to segment $E_{1:3}$ to produce a tree that is as close as possible to the gold tree? The canonical segmentation order $O_{1:3}$ is $[2, 1, -]$ (the label of the last EDU is replaced by '$-$'), from which we can see the next best segmentation is to segment at E_2 to create $E_{1:2}$ and E_3. Creating the canonical segmentation order O, and following it as much as possible, ensures the sub-tree that we're creating for $E_{1:3}$ mimics the structure of the gold tree.

The dynamic oracle labels nuclearity-discourse relations following the same idea. We introduce R, a list of gold nuclearity-discourse relations. For our example $R_{1:4} = [r_2, r_1, r_3, -]$ (based on the gold tree; see Figure 6 (left)). If the model decides to first segment at E_3 and creates $E_{1:3}$ and E_4, when we segment at E_2 (next best choice of segmentation), we will follow R and label the nuclearity-discourse relation with r_1. As before, following the original label list R ensures we keep the nuclearity-discourse relation as faithful as possible (Figure 6 (right bottom)).

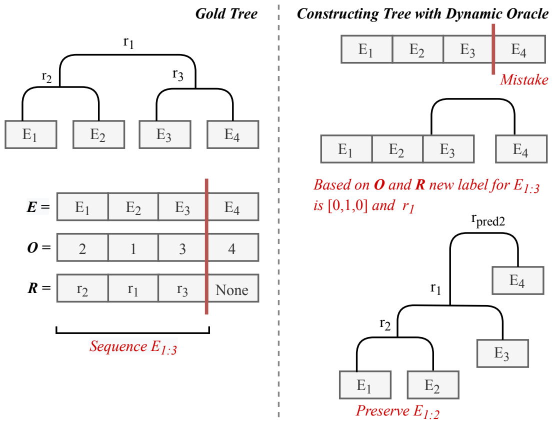

Figure 6: Dynamic oracle for top-down approach.

The dynamic oracle of our top-down parser is arguably quicker than that of a transition-based parser, as we do not need to accumulate cost for every transition taken. Instead, the dynamic oracle simply follows the gold segmentation order O to preserve as many subtrees as possible when an error occurs. We present pseudocode for the proposed dynamic oracle in Algorithm 1.

The probability of using the ground truth segmentation or predicted segmentation during training is controlled by the hyper-parameter $\alpha \in [0, 1]$ (see Algorithm 1). Intuitively, this hyper-parameter allows the model to alternate between exploring its (possibly erroneous) segmentation or learning from the ground truth segmentation. The oracle reverts to its static variant when $\alpha = 0$.

4 Experiments

4.1 Data

We use the English RST Discourse Treebank (Carlson et al., 2001) for our experiments, consistent with recent studies (Ji and Eisenstein, 2014; Li et al., 2014; Feng and Hirst, 2014; Yu et al., 2018). The dataset is based on the Wall Street Journal portion of the Penn Treebank (Marcus et al., 1993), with 347 documents for training, and the remaining 38 documents for testing. We use the same development set as Yu et al. (2018), which consists of 35 documents selected from the training set. We also use the same 18 discourse labels. Stanford

Variant	**LSTM**	**Transformer**
Vanilla	48.4±0.5	51.3±0.2
+Syntax	50.0±0.7	51.9±0.4
+Penalty	49.6±0.5	**52.1±0.4**
+Syntax+Penalty	**51.6±0.1**	51.8±0.8

Table 1: Feature addition study over the development set to find the best configuration for our models. Presented results are the mean and standard deviation of the `Full` metric (micro-averaged F-score on labelled attachment decisions) over three runs.

CoreNLP (Manning et al., 2014) is used for POS tagging.[6]

4.2 Model Configurations

We experiment with two segmentation models — LSTM (Section 3.1) and transformer (Section 3.2) — both implemented in PyTorch framework.[7] As EDUs are provided in the dataset, no automatic segmentation of EDU is required in our experiments.

For the LSTM model, the dimensionality of the Bi-LSTMs in the encoder is 256, while the segmenter (Bi-LSTM$_4$) is 128 (Figure 3). The embedding dimensions of words, POS tags, EDU type, and syntax features are 200, 200, 100, and 1,200, respectively, and we initialize words in EDU with GloVe embedding (Pennington et al., 2014).[8] For hyper-parameters, we use the following: batch size $= 4$, gradient accumulation $= 2$, learning rate $= 0.001$, dropout probability $= 0.5$, and optimizer = Adam (with epsilon of 1e-6). The loss scaling hyper-parameters (Equation (2)), are tuned based on the development set, and set to $\lambda_1 = 1.0$, and $\lambda_2 = 1.0$.

For the transformer model, the document length limit is set to 512 tokens, and longer documents are broken into smaller partial documents. As before, we truncate each EDU to the first 50 words. We initialize the transformer in the encoder with `bert-base`, and the transformer in the segmenter with random weights (Figure 4). The transformer segmenter has 2 layers with 8 heads and 2048 feed-forward hidden size. The training hyper-parameters are: initial learning rate = 5e-5, maximum epochs $= 250$, warm up $= 2000$ steps, and drop out $= 0.2$. For the λ hyper-parameters, we use the same configuration as for the LSTM model.

We tuned the segmentation loss penalty hyper-parameter β (Section 3.4) and the dynamic oracle hyper-parameter α (Section 3.5) based on the development set. Both the LSTM and transformer models use the same $\beta = 0.35$ and $\alpha = 0.65$. We activate the dynamic oracle after training for 50 epochs for both models.

In terms of evaluation, we use the standard metrics introduced by Marcu (2000): `Span`, `Nuclearity`, `Relation`, and `Full`. We report micro-averaged F-1 scores on labelled attachment decisions (original Parseval), following the recommendation of Morey et al. (2017). Additionally, we also present the evaluation with RST-Parseval procedure in Appendix A.

4.3 Results

We first perform a feature addition study over our models to find the best model configuration; results are presented in Table 1. Note that these results are computed over the *development set*, based on a static oracle.

For the vanilla models, the transformer model performs much better than the LSTM model. Adding syntax features (+Syntax) improves both models, although it's more beneficial for the LSTM. A similar trend is observed when we modify the segmentation loss to penalize the model if a segmentation error is made with more EDUs in the input sequence (+Penalty; Section 3.4): the transformer model sees an improvement of +0.8 while the LSTM model improves by +1.2. Lastly, when we combine both syntax features and the segmentation penalty, the LSTM model again shows an appreciable improvement, while the transformer model drops in performance marginally.[9] Given these results, we use both syntax features and the segmentation penalty for the LSTM model, but only the segmentation penalty for the transformer model in the remainder of our experiments.

We next benchmark our models against state-of-the-art RST parsers over the *test set*, as presented in Table 2 (original Parseval) and Table 5 (RST-Parseval as additional result). Except Yu et al. (2018), all bottom-up results are from Morey et al. (2017). We present the labelled attachment decision performance for Yu et al. (2018) by running the code of the authors for three runs and taking

Table 2: Results over the test set calculated using micro-averaged F-1 on labelled attachment decisions (original Parseval). All metrics (S: `Span`, N: `Nuclearity`, R: `Relation`, F: `Full`) are averaged over three runs. "*" denotes reported performance. "†" and "‡" denote that the model uses sentence and paragraph boundary features, respectively. In this evaluation, Kobayashi et al. (2020) does not report the original Parseval result.

the average.[10] We also present the reported scores for the other top-down RST parsers (Zhang et al., 2020; Kobayashi et al., 2020).[11] Human performance in Table 2 and Table 5 is the score of human agreement reported by Joty et al. (2015) ad Morey et al. (2017).

Overall, in Table 2 our top-down models (LSTM and transformer) outperform all bottom-up and top-down baselines across all metrics. As we saw in the feature addition study, the LSTM model outperforms the transformer model, even though the transformer uses pre-trained BERT. We hypothesize that this may be because BERT is trained over shorter texts (paragraphs or sentence pairs), while our documents are considerably longer. Also, due to memory constraints, we break long documents into partial documents (Section 3.2), limiting fine-grained word-to-word attention to only nearby EDUs.

#EDUs	**#Docs**	**#Spans**	**Type**	**S**	**N**	**R**

Table 3: Impact of the dynamic oracle over documents of differing length. Scores (micro-averaged F-1 on labelled attachment decisions) are averaged over three runs on the test set.

In Table 2, we also present results for our model without paragraph features, and compare against other models which don't use paragraph features (each marked with "‡").[12] First, we observe that our best model substantially outperforms all models with paragraph boundary features in terms of the `Full` metric. Compared to Zhang et al. (2020), our models (without this feature) achieve an improvement of $+0.1$, $+1.9$, $+3.2$, and $+3.1$ for `Span`, `Nuclearity`, `Relation`, and `Full` respectively.

5 Analysis

In Table 3 we present the impact of the dynamic oracle over documents of differing length for the LSTM model. Generally, we found that the static model performs better for shorter documents, and the dynamic oracle is more effective for longer documents. For instance, for documents with 50–100 EDUs, the dynamic oracle improves the `Span`, `Nuclearity`, and `Relation` metrics substantially. We also observe that the longer the document, the more difficult the tree prediction is. It is confirmed by the decreasing trends of all metrics for longer documents in Table 3.

In total, our best model obtains 1,698 out of 2,308 spans of original Parseval trees, and correctly predict 1,517 segmentation points (pairs). We further analyze these pairs by presenting the confusion matrices of nuclearity and relation prediction in Figure 7 and Figure 8, respectively.

First, the model tends to have more errors on `NN` (Nucleus–Nucleus) prediction where 53 span

---

[10] `https://github.com/yunan4nlp/NNDisParser`.

[11] Neither Zhang et al. (2020) nor Kobayashi et al. (2020) released their code, so we were unable to rerun their models.

[12] Yu et al. (2018) use paragraph boundary features in their original code, but do not report it in the paper.

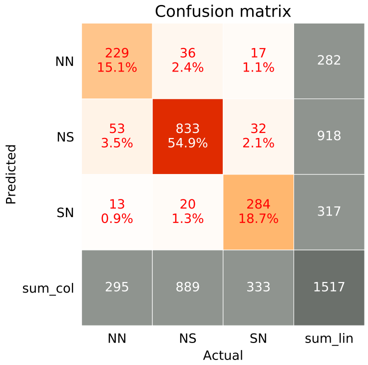

Figure 7: Confusion matrix of nuclearity prediction over the test set (`NS` = Nucleus-Satellite, `NN` = Nucleus-Nucleus, `SN` = Satellite-Nucleus).

Table 4: Examples of misclassified relations.

pairs (18% of `NN`) are classified as `NS` (Nucleus–Satellite). Class imbalance in the training set (`NN`:`NS`:`SN` = 23:61:16) is the main factor that drives the model to favor `NS` over the other classes.

In Figure 8 we present analysis over top-7 relations and a relation `other` that represents the rest of 11 classes. Similar to the nuclearity prediction, the relation class distribution is also imbalance where `elab` accounts for 37% of the examples. Some relations are related to `elab` (see Table 4 for examples), such as `back`, `cause`, and `list` which we see some false positives. This produces the low precision of `elab` (74%). Unlike `elab`, relation `attr` is also a major class (represents 14% of the training data) but its precision and recall is substantially higher, at 94% and 96% respectively, suggesting it is less ambiguous. For `other`, its recall is 45%, and most of the errors are classified as `elab` (31%).

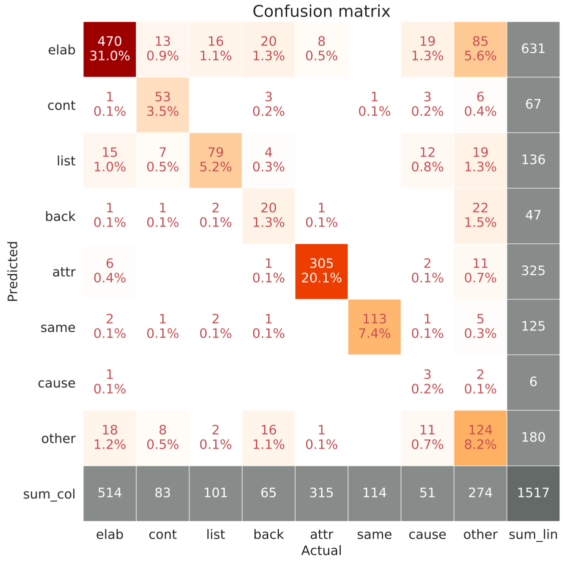

Figure 8: Confusion matrix of relation prediction over the test set with top-7 relations (`elab` = Elaboration, `cont` = Contrast, `list` = List, `back` = Background, `same` = Same, `temp` = Temporal, `eval` = Evaluation, `other` = Other 11 relations).

6 Conclusion

We introduce a top-down approach for RST parsing via sequence labelling. Our model is conceptually simpler than previous top-down discourse parsers and can leverage pre-trained language models such as BERT. We additionally propose a dynamic-oracle for our top-down parser, and demonstrate that our best model achieves a new state-of-the-art for RST parsing.

Does the Order of Training Samples Matter? Improving Neural Data-to-Text Generation with Curriculum Learning

Ernie Chang, Hui-Syuan Yeh, Vera Demberg
Dept. of Language Science and Technology, Saarland University
{cychang,yehhui,vera}@coli.uni-saarland.de

Abstract

Recent advancements in data-to-text generation largely take on the form of neural end-to-end systems. Efforts have been dedicated to improving text generation systems by changing the order of training samples in a process known as *curriculum learning*. Past research on sequence-to-sequence learning showed that *curriculum learning* helps to improve both the performance and convergence speed. In this work, we delve into the same idea surrounding the training samples consisting of structured data and text pairs, where at each update, the curriculum framework selects training samples based on the model's competence. Specifically, we experiment with various difficulty metrics and put forward a *soft edit distance metric* for ranking training samples. Our benchmarks show faster convergence speed where training time is reduced by 38.7% and performance is boosted by 4.84 BLEU.

1 Introduction

Neural data-to-text generation has been the subject of much recent research. The task aims at transforming source-side structured data into target-side natural language descriptions (Reiter and Dale, 2000; Barzilay and Lapata, 2005). The process typically involves mini-matches which are randomly sampled with a fixed size from the training set to feed into the model at each training step. In this paper, we apply curriculum learning to this process, which was explored in neural machine translation (Platanios et al., 2019; Zhou et al., 2020), and show how it can help in neural data-to-text generation.

The main idea in curriculum learning is to present the training data in a specific order, starting from *easy* examples and moving on to more *difficult* ones, as the learner becomes more *competent*. When starting out with easier instances, the risk of getting stuck in local optima early on in training is reduced, since the loss functions in neural models are typically highly non-convex (Bengio et al., 2009). This learning paradigm enables flexible batch configurations by considering the material properties as well as the state of the learner. The idea brings in two potential benefits: (1) It speeds up the convergence and reduces the computational cost. (2) It boosts the model performance, without having to change the model or add data.

With the release of large data-to-text datasets (e.g. Wikibio (Lebret et al., 2016), Totto (Parikh et al., 2020), E2E (Novikova et al., 2017)), neural data-to-text generation is now at a point where training speed and the order of samples may begin to make a real difference. We here show the efficacy of curriculum learning with a general LSTM-based sequence-to-sequence model and define *difficulty metrics* that can assess the training instances, using a sucessful *competence function* which estimates the model capability during training. Such metrics have not yet been explored in neural data-to-text generation.

In this paper, we explore the effectiveness of various difficulty metrics and propose a soft edit distance metric, which leads to substantial improvements over other metrics. Crucially, we observe that difficulty metrics that consider data-text samples jointly lead to stronger improvements than metrics that consider text or data samples alone. In summary, this work makes the following contributions towards neural data-to-text generation:

1. We show that by simply changing the order of samples during training, neural models can be improved via the use of curriculum learning.

2. We explore various *difficulty metrics* at the level of the data, text, and data-text pairs, and propose an effective novel metric.

2 Related work

The idea of teaching algorithms in a similar manner as humans, incrementally from easy concepts to more difficult ones dates back to *incremental learning*, which was discussed in light of theories of cognitive development relating to the processes of acquisition in young children (Elman, 1993; Krueger and Dayan, 2009; Plunkett and Marchman, 1993). Bengio et al. (2009) first demonstrated empirically that curriculum learning approaches can decrease training times and improve generalization; later approach address these issues by changing the mini-batch sampling strategy to also include model competence (Kocmi and Bojar, 2017; Zhou et al., 2020; Platanios et al., 2019; Liu et al., 2020; Zhang et al., 2018, 2019). While sample difficulty can be assessed for text samples and data samples or jointly, various measures have been proposed for text samples including n-gram frequency Haffari (2009); Platanios et al. (2019), token rarity, and sentence length (Liu et al., 2020; Platanios et al., 2019). Our approach considers data and text jointly, similar to edit distance metric – Levenshtein (Levenshtein, 1966) and Damerau-Levenshtein Distance (Damerau, 1964; Brill and Moore, 2000a), which was used as a content ordering metric in Wiseman et al. (2017) to measure the extent of alignment between data slots and text tokens.

3 Preliminaries of Curriculum Learning

We base our curriculum learning framework on the two standard components: (1) model competence (how capable the current model is at time t), and (2) sample difficulty, which makes independent judgement on each sample's difficulty. Specifically, we adopt the competence function $c(t)$ for a model at time t as in Platanios et al. (2019); Liu et al. (2020):

$$c_{\text{sqrt}}(t) \in (0,1] = \min\left(1, \sqrt{t\frac{1-c_0^2}{\lambda_t} + c_0^2}\right). \tag{1}$$

Where λ_t is a hyperparameter defining the length of the curriculum and is set to 2.5 as in Liu et al. (2020). $c_0 = 0.1$ as Platanios et al. (2019). Following this formulation, the number of new training examples per unit time is reduced as training progresses to give the learner sufficient time to obtain new knowledge. The sequence-to-sequence model learns using the curriculum as outlined in Algorithm 1 by primarily making batch-wise decisions about which samples to add to each batch. This decision is determined by comparing the *competence* score with the *difficulty* score as shown in Algorithm 1.

Algorithm 1: Curriculum Learning Algorithm

```
Input: Training set, $\mathcal{D} = \{s_d, s_t\}_{i=1}^{M}$, consisting of
       $M$ samples, model ($\mathcal{T}$), difficulty metric ($d$),
       and competence function ($c$).
Compute the difficulty, $d(s_i)$, for each data-text pair
    $\in \mathcal{D}$ (Section 4).
Compute the CDF score $\bar{d}(s_i)$ of $d(s_i)$, where
    $\bar{d}(s_i) \in [0,1]$ (See Figure 2).
for training step $t = 1, \ldots$ do
    Compute the model competence $c(t)$ with $\mathcal{T}$.
    Train $\mathcal{T}$ on sampled data batch, $B_t$, drawn
      uniformly from all $s_i \in \mathcal{D}$, such that
      $\bar{d}(s_i) \leq c(t)$.
    if $c(t) = 1$ then
        break.
Output: Trained model.
```

4 Difficulty Metrics

For ease of discussion, we denote sequence to be s, which can be either data or text, or their concatenation. For comparison, the difficulty metrics use the unit tokens as tokenized by SpaCy[1]. We begin with discussion on *length* and *word rarity*, which were previously applied by Kocmi and Bojar (2017); Platanios et al. (2019) on text sentences.

Length. Length-based difficulty is based on the intuition that longer sequences are harder to encode, and that early errors may propagate during the decoding process, making longer sentences also harder to generate. It is defined as:

$$d_{\text{length}}(s) = N. \tag{2}$$

Rarity. *Word rarity* of a sentence is defined as the product of the unigram probabilities (Platanios et al., 2019). This metric implicitly incorporates information about sentence length since longer sentence scores are sum of more terms and are thus likely to be larger. The difficulty metric for word rarity of a sequence s is defined as:

$$d_{\text{rarity}}(s) = -\sum_{k=1}^{N} \log p(w_k). \tag{3}$$

---

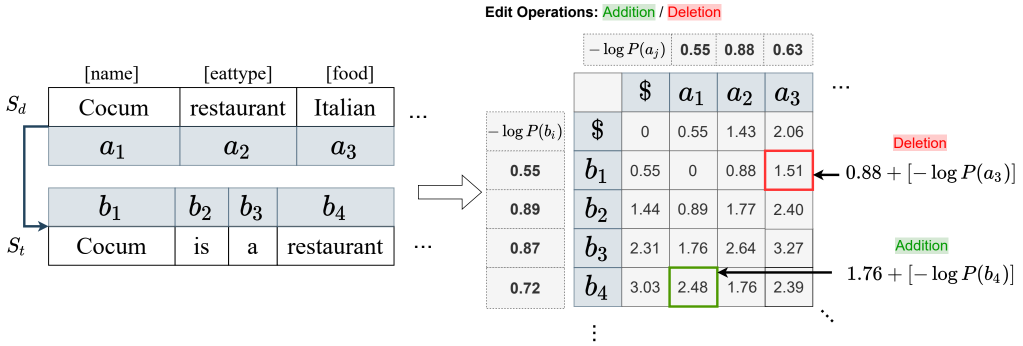

Figure 1: Depiction of the process of *soft edit distance metric* with the *Wagner-Fischer table*. Each cell in the table represents the edit distance to convert data substring's into the text substring.

Damerau-Levenshtein Distance. To consider data and text jointly, we measure the alignment between data slots and text using *the Damerau-Levenshtein Distance* (d_{dld}) (Brill and Moore, 2000a).

We calculate the minimum number of edit operations needed to transform data (s_d) into text (s_t)[2], and relies only four operations: (a) substitute a word in s_d to a different word, (b) insert a word into s_d, (c) delete a word of s_d, and (d) transpose two adjacent words of s_d. The process involves recursive calls that compute distance between substrings $s_d^i \in s_d$ and $s_t^i \in s_t$ at i^{th} comparison.

Soft Data-to-Text Edit Distance. We here present the proposed *soft edit distance (SED)*: (1) We include the basic *add* and *delete* edit operations as in the Levenshtein Distance (Levenshtein, 1966), which was used in Levenshtein Transformer (Gu et al., 2019) as the only two necessary operations for decoding sequences since it correlates well with human text writing where humans "*can revise, replace, revoke or delete any part of their generated text*". We call this variant the plain edit distance *(PED)*. (2) Next, we weight the indicator function $\mathbb{1}(s_d^i, s_t^i)$ for each edit operation with the negative logarithmic unigram probability $-\log p(w)$ for each token $w \in s^i_{\{t|d\}}$, in order to incorporate the idea of *word rarity* into the edit distance metric. For the *delete* operation, we use the $w \in s_d^i$ and for *add* operations, we use $w \in s_t^i$. This is unlike the previous proposal by Brill and Moore (2000b), in which edits are weighted by the token transition probabilities – this is not suitable for our scenario because there is no natural order of the slot sequence in data samples.

The soft distance metric d_{sed} is in principle similar to calculating the logarithmic sum as defined in the *rarity* function, but instead incrementally compares all substrings and calculates their edit distances. This way, d_{sed} includes the information on *length*, *rarity* but also combining the edit operations. We show this process in Figure 5.

Note that we can compute *length* and *rarity* on the concatenation of input data and text sequence, or as individual sequences; whereas *Damerau-Levenshtein distance* and *soft edit distance* are computed jointly on data and text.

5 Experiment Setting

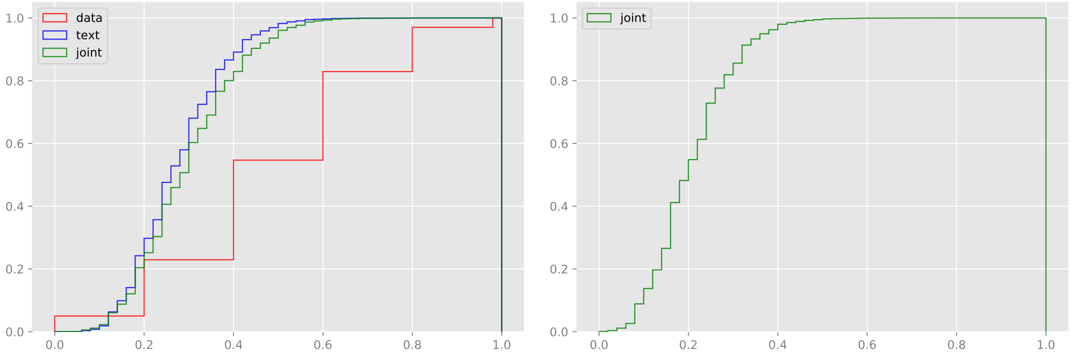
Data. We conduct experiments on the E2E (Novikova et al., 2017) and WebNLG (Colin et al., 2016) datasets. E2E is a crowd-sourced dataset containing 50k instances in the restaurant domain. The inputs are dialogue acts consisting of three to 8 slot-value pairs. WebNLG contains 25k instances describing entities belonging to 15 distinct DBpedia categories, where the data contain are up to 7 RDF triples of the form *(subject, relation, object)*.

Configurations. The LSTM-based model is implemented based on PyTorch (Paszke et al., 2019). We use 200-dimensional token embeddings and the Adam optimizer with an initial learning rate at 0.0001. Batch size is kept at 28, and we decode with beam search with size 5. The performance scores are averaged over 5 random initialization runs.

Settings. We first perform ablation studies (Table 2) on the impact of difficulty metrics on data, text or both (joint). We also analyse the average bin size for each metric – a metric that gives the same score to many instances creates large bins.

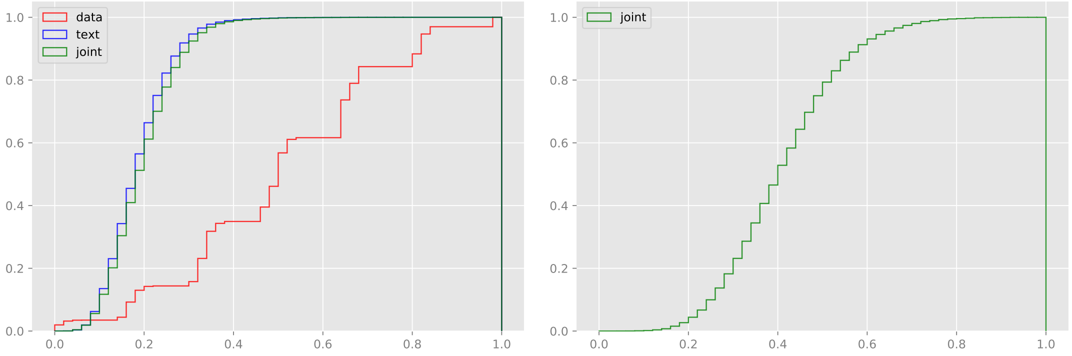
---

[2] Previous work applies *the Damerau-Levenshtein Distance* to slots in data (e.g. "[name]" in Figure 5) and extracts slots from text.



(a) *length*

(c) *Damerau-Levenshtein distance*



(b) *rarity*

(d) *soft edit distance*

Figure 2: The histogram of the cumulative density function for difficulty metrics.

This means that the order of samples within the bin will still be random. On the other hand, a metric that assigns a lot of different difficulty scores to the instances can yield a more complete ordering (and a smaller step size in moving from one level of difficulty to the next). We present the change in performance (BLEU) as the training progresses in order to compare the various difficulty metrics on both datasets (See Figure 3).

6 Results & Analysis

On Table 3, we observe that *soft edit distance* (SED) yields the best performance, outperforming a model that does not use curriculum learning by as much as 2.42 BLEU. It also outperforms all other metrics by roughly 1 BLEU. In general, we see that models perform better on *joint* and *text* than on *data*. This correlates to how a difficulty function is related to the *average bin sizes* of scores it generates. We see that for models that distinguish samples in a more defined manner, it will have a smaller average bin size where probability of having more difficult samples at every confidence threshold is lower. From this, we see that *length* and *DLD* have larger average bin sizes across its difficulty scores and this makes samples less distinguishable from one another. Thus, they result in the smallest improvement over *plain*. We show reordered samples in Table 1 for all difficulty metrics computed *jointly* on data and text. We include length (**L**), rarity (**R**), Damerau-Levenshtein Distance (**DLD**), and the proposed soft edit distance (**SED**).

On the other hand, we also justify the use of weighting for edit operation where *PED*, which is the "hard" variant of *SED* that does not weight edit operations like *SED*, is shown to be far inferior to that of *SED*. The score margin comes up to 2.81 BLEU. Moreover, we further examine the difference in sample orders and observe that *SED* yields more intuitive and better sample ordering as opposed to other metrics.

Human Evaluation. For *human evaluation*, three annotators are instructed to evaluate 100 samples from the *joint* variant to see (1) if the text is *fluent* (score 0-5 with 5 being fully fluent), (2) if it *misses* information contained in the source data and (3) if it includes *wrong* information. These scores are averaged and presented in Table 2.

Metric	Score	Data & Text
L	7	**[Data]** name[Wildwood], eatType[restaurant], familyFriendly[yes] **[Text]** Wildwood restaurant is kid-friendly.

Human	fluency	4.35	4.28	4.32	**4.60**	4.23	4.54
	miss	22	16	15	11	14	**9**
	wrong	9	5	7	10	6	**4**

Table 2: Ablation studies for the impact of difficulty metrics on data, text or both (joint) with normalized scores including length (**L**), rarity (**R**), Damerau-Levenshtein Distance (**DLD**), plain edit distance (**PED**), and the proposed soft edit distance (**SED**). **Plain** means no curriculum learning techniques are added. All scores are computed based on the E2E corpus, consisting of both performance (BLEU) and the **average bin size**. Each *bin* is defined by the number of training samples with the same difficulty scores.

On Training Speed. We define speed by the number of updates it takes to reach a performance plateau. On Figure 3, the speedup is measured by the difference between the vertical bars. It can be observed that curriculum learning reduces the training steps to converge, where it consists of up to 38.7% of the total updates for the same model without curriculum learning (on E2E). Further, we see that the use of curriculum learning yields slightly worse performance in the initial training steps, but rise to a higher score and flattens as it converges.

7 Conclusion

To conclude, we show that the sample order does indeed matter when taking into account model competence during training. Further, we demonstrate that the proposed metrics are effective in speeding up model convergence. Given that curriculum learning can be combined with pretty much any neural architecture, we recommend the use of curriculum learning for data-to-text generation. We believe this work offers insights into the annotation process of data with text labels where reduced number of labels are needed.

Abstract

We investigate how to solve the cross-corpus news recommendation for unseen users in the future. This is a problem where traditional content-based recommendation techniques often fail. Luckily, in real-world recommendation services, some publisher (e.g., Daily news) may have accumulated a large corpus with lots of consumers which can be used for a newly deployed publisher (e.g., Political news). To take advantage of the existing corpus, we propose a transfer learning model (dubbed as TrNews) for news recommendation to transfer the knowledge from a source corpus to a target corpus. To tackle the heterogeneity of different user interests and of different word distributions across corpora, we design a translator-based transfer-learning strategy to learn a representation mapping between source and target corpora. The learned translator can be used to generate representations for unseen users in the future. We show through experiments on real-world datasets that TrNews is better than various baselines in terms of four metrics. We also show that our translator is effective among existing transfer strategies.

1 Introduction

News recommendation is key to satisfying users' information need for online services. Some news articles, such as breaking news, are manually selected by publishers and displayed for all users. A huge number of news articles generated everyday make it impossible for editors and users to read through all of them, raising the issue of information overload. Online news platforms provide a service of personalized news recommendation by learning from the past reading history of users, e.g., Google (Das et al., 2007; Liu et al., 2010), Yahoo (Trevisiol et al., 2014; Okura et al., 2017), and Bing news (Lu et al., 2015; Wang et al., 2018).

When a new user uses the system (cold-start users) or a new article is just created (cold-start items), there are too few observations for them to train a reliable recommender system. Content-based techniques exploit the content information of news (e.g., words and tags) and hence new articles can be recommended to existing users (Pazzani and Billsus, 2007). Content-based recommendation, however, suffers from the issue of data sparsity since there is no reading history for them to be used to build a profile (Park and Chu, 2009).

Transfer learning is a common technique for alleviating the issues of data sparsity (Pan et al., 2010; Cantador et al., 2015; Liu et al., 2018). A user may have access to many websites such as Twitter.com and Youtube.com (Roy et al., 2012; Huang and Lin, 2016), and consume different categories of products such as movies and books (Li et al., 2009). In this case, transfer learning approaches can recommend articles to a new user in the target domain by exploiting knowledge from the relevant source domains for this new user.

A technical challenge for transfer learning approaches is that user interests are quite different across domains (corpora). For example, users do not use Twitter for the same purpose. A user may follow up on news about "Donald Trump" because she supports republican party (in the political news domain), while she may follow up account @*taylorswift13* ("Taylor Swift") because she loves music (in the entertainment news domain). Another challenge is that the word distribution and feature space are different across domains. For example, vocabularies are different for describing political news and entertainment news. An illustration is depicted in Figure 1. As a result, the user profile computed from her news history is heterogeneous across domains.

Several strategies have been proposed for heterogeneous transfer learning (Yang et al., 2009). The

transferable contextual bandit (TCB) (Liu et al., 2018) learns a translation matrix to translate target feature examples to the source feature space. This linear mapping strategy is also used in collaborative cross networks (CoNet) (Hu et al., 2018) and deep dual transfer cross domain recommendation (DDTCDR) (Li and Tuzhilin, 2020). To capture complex relations between source and target domains, some nonlinear mapping strategy is considered in the embedding and mapping cross-domain recommendation (EMCDR) (Man et al., 2017) which learns a supervised regression between source and target factors using a multilayer perceptron (MLP). Since aligned examples between source and target domains are limited, they may face the overfitting issues.

To tackle challenges of heterogeneous user interests and limited aligned data between domains, we propose a novel transfer learning model (TrNews) for cross-corpora news recommendation. TrNews builds a bridge between two base networks (one for each corpus, see Section 3.1.1) through the proposed translator-based transfer strategy. The translator in TrNews captures the relations between source and target domains by learning a nonlinear mapping between them (Section 3.2). The heterogeneity is alleviated by translating user interests across corpora. TrNews uses the translator to transfer knowledge between source and target networks. TrNews alleviates the limited data in a way of alternating training (Section 3.3). The learned translator is used to infer the representations of unseen users in the future (Section 3.4). By "translating" the source representation of a user to the target domain, TrNews offers an easy solution to create unseen users' target representations. TrNews outperforms the state-of-the-art recommendation methods on four real-world datasets in terms of four metrics (Section 4.2), while having an explanation advantage by allowing the visualization of the importance of each news article in the history to the future news (Section 4.4).

2 Related Work

Content recommendation Content-based recommendation exploits the content information about items (e.g., news title and article body (Yan et al., 2012; Xiao et al., 2019; Ma et al., 2019; Wu et al., 2020; Hu et al., 2020), tag, vlog (Gao et al., 2010)), builds a profile for each user, and then matches users to items (Lops et al., 2011; Yu et al., 2016; Wu et al., 2019b). It is effective for items with content or auxiliary information but suffers from the issues of data sparsity for users. DCT (Barjasteh et al., 2015) constructs a user-user similarity matrix from user demographic features including gender, age, occupation, and location (Park and Chu, 2009). NT-MF (Huang and Lin, 2016) constructs a user-user similarity matrix from Twitter texts. BrowseGraph (Trevisiol et al., 2014) addresses the freshly news recommendation by constructing a graph using URL links between web pages. NAC (Rafailidis and Crestani, 2019) transfers from multiple source domains through the attention mechanism. PdMS (Felício et al., 2017) assumes that there are many recommender models available to select items for a user, and introduces a multi-armed bandit for model selection. LLAE (Li et al., 2019a) needs a social network as side information for cold-start users. Different from the aforementioned works, we aim to recommending news to unseen users by transferring knowledge from a source domain to a target domain.

Transfer learning Transfer learning aims at improving the performance of a target domain by exploiting knowledge from source domains (Pan and Yang, 2009). A special setting is domain adaptation where a source domain provides labeled training examples while the target domain provides instances on which the model is meant to be deployed (Glorot et al., 2011; Li et al., 2019b). The coordinate system transfer (CST) (Pan et al., 2010) firstly learns the principle coordinate of users in the source domain, and then transfers it to the target domain in the way of warm-start initialization. This is equivalent to an identity mapping from users' source representations to their corresponding target representations. TCB (Liu et al., 2018) learns a linear mapping to translate target feature examples to the source feature space because there are many labelled data in the source domain. This linear s-

(b) Translator

Figure 2: Left: Architecture of TrNews. There is a base network for each of the two domains. The shaded area in the target network is empty for unseen users. The translator enables knowledge transfer between source and target networks. Right: The translator.

trategy is also used in CoNet (Hu et al., 2018) and DDTCDR (Li and Tuzhilin, 2020) which transforms the source representations to the target domain by a translation matrix. Nonlinear mapping strategy (Man et al., 2017; Zhu et al., 2018; Fu et al., 2019) is to learn a supervised mapping function between source and target latent factors by using neural networks. SSCDR (Kang et al., 2019) extends them to the semi-supervised mapping setting. Our translator is general to accommodate these identity, linear, and nonlinear transfer-learning strategies.

3 TrNews

3.1 Architecture

The architecture of TrNews is shown in Figure 2a, which has three parts. There are a source network for the source domain S and a target network for the target domain T, respectively. The source and target networks are both an instantiation of the base network (Section 3.1.1). The translator enables knowledge transfer between the two networks (Section 3.2). We give an overview of TrNews before introducing the base network and the translator.

Target network The information flow goes from the input, i.e., (user u, candidate news c_T) to the output, i.e., the preference score $\hat{r}_{uc_T}$, through the following three steps. First, the news encoder ψ_T computes the news representation from its content. The candidate news representation is $\psi_T(c_T) = \psi_T(d_{c_T})$ where d_{c_T} is c_T's content. The representations of historical news articles $[i]_{i=1}^{n_{uc_T}}$ of the user are $[\psi_T(d_i^{(uc_T)})]_{i=1}^{n_{uc_T}}$ where $d_i^{(uc_T)}$ is i's content and n_{uc_T} is size of the history. Second, the user encoder ϕ_T computes the user representation from her news history by: $\phi_T(u) = \phi_T\left([\psi_T(d_i^{(uc_T)})]_{i=1}^{n_{uc_T}}\right)$. Third, the neural collaborative filtering (CF) module f_T computes the preference score by: $\hat{r}_{uc_T} = f_T([\phi_T(u), \psi_T(c_T)])$. We can denote the target network by a tuple (ψ_T, ϕ_T, f_T).

Source network Similarly to the three-step computing process in target network, we compute preference score $\hat{r}_{uc_S}$ from input (u, c_S) by: $\hat{r}_{uc_S} = f_S([\phi_S(u), \psi_S(c_S)])$ with tuple (ψ_S, ϕ_S, f_S).

Translator The translator $\mathcal{F}$ learns a mapping from the user's source representation to her target representation by $\mathcal{F} : \phi_S(u) \to \phi_T(u)$.

3.1.1 Base network

There is a base network for each of the two domains. It is an attentional network which has three modules (ψ, ϕ, f): the news encoder ψ to learn news representations, the user encoder ϕ to learn user representations, and a neural collaborative filtering module f to learn user preferences from reading behaviors.

News encoder The news encoder module is to learn news representation from its content. The news encoder takes a news article c's word sequence $d_c = [w_j]_{j=1}^{n_c}$ (n_c is length of c) as the input, and outputs its representation $\psi(c) \triangleq \psi(d_c) \in \mathbb{R}^D$ where D is the dimensionality. We compute the average of c's word embeddings by: $\psi(d_c) = \frac{1}{|d_c|} \sum_{w \in d_c} e_w$, where e_w is the embedding of w.

User encoder The user encoder module is to learn the user representation from their reading history. The user encoder takes a user's reading history $[\psi(d_i^{(u)})]_{i=1}^{n_u}$ (n_u is length of u's history) as input, and outputs her representation $\phi(u) \triangleq \phi([\psi(d_i^{(u)})]_{i=1}^{n_u}) \in \mathbb{R}^D$ where D is dimensionality.

In detail, given a pair of user and candidate news (u, c), we get the user representation $\phi(u|c)$ as the weighted sum of her historical news articles' representations: $\phi(u|c) = \sum_{i=1}^{n_{uc}} \alpha_i^{(uc)} \psi(d_i^{(u)})$. The weights $\alpha_i^{(uc)}$'s are computed via attention units by: $\alpha_i^{(uc)} = a([\psi(d_i^{(u)}), \psi(d_c)])$ where a is the attention function with parameters to be learned. We use an MLP to compute it. For a specific candidate news c, we limit the history news to only those articles that are read before it. For notational simplicity, we do not explicitly specify the candidate news when referring to a user representation, i.e., $\phi(u)$ for short of $\phi(u|c)$.

Neural CF The neural collaborative filtering module is to learn preferences from user-news interactions. The module takes concatenated representations of user and news $[\phi(u), \psi(c)]$ as input, and outputs preference score $\hat{r}_{uc} = f([\phi(u), \psi(c)])$ where f is an MLP.

3.2 Translator

The target network suffers from the data sparsity issue of users who have no reading history. In this section, we propose a transfer learning component (i.e., the translator) to enable knowledge transfer for cross-domain news recommendation. The challenge is that user interests and word distributions are different across domains. For example, we compute the word clouds for two news corpora as shown in Figure 1. We can see that their word distributions are quite different and vocabularies are also different. Hence, user representations computed from their news history are heterogeneous across domains.

We build a translator, $\mathcal{F} : \phi_S(u) \to \phi_T(u)$, to learn a mapping from a user's source representation to her target representation as shown in Figure 2b. This translator captures the relationship and heterogeneity across domains. The translator learns to approximate the target representation from the source representation.

The translator takes a user's source representation $\phi_S(u)$ as the input, and maps it to a hidden representation z_u via an encoder parameterized by θ, and then gets a approximated representation $\tilde{\phi}_S(u)$ from it via a decoder parameterized by θ'. The parameters $\Theta_{\mathcal{F}} = \{\theta, \theta'\}$ of the translator are optimized to minimize the approximation error:

$$\mathcal{L}_{\mathcal{F}} = \frac{1}{|\mathcal{U}_0|} \sum_{u \in \mathcal{U}_0} ||H\tilde{\phi}_S(u) - \phi_T(u)||_2^2, \quad (1)$$

where $\mathcal{U}_0 = \mathcal{U}_S \cap \mathcal{U}_T$, and $\mathcal{U}_S$ and $\mathcal{U}_T$ are the user sets of source and target domains, respectively. H is to match the dimensions of source and target representations.

Note that, we do not minimize the approximation error between $\phi_S(u)$ and $\tilde{\phi}_S(u)$ as with the standard autoencoder because our goal is to learn a mapping from a user's source representation to her corresponding target representation. After training, the learned mapping function is then used for inferring representations of unseen users in the target domain (the inference process will be described later in Section 3.4). It fulfills knowledge transfer from the source to the target domain via a supervised learning process.

Extensions The translator can be generalized to multiple, say k, source domains. We learn k translators using the aligned examples from each of the source domain to the target domain and then we average (or concatenate) the k mapped representations as the final representation for the user. Another extension is to introduce denoising or stacking techniques into the translator framework, not just the MLP structure in (Man et al., 2017).

3.3 Model learning

We learn TrNews in two stages. First, we train the source network using source training examples D_S and train the target network using target training examples D_T, respectively. Second, we train the translator by pairs of user representations computed on-the-fly from source and target networks. We introduce these two stages in detail.

First, TrNews optimizes the parameters associated with target network $\Theta_T = \{\theta_{\phi_T}, \theta_{\psi_T}, \theta_{f_T}\}$ and source network $\Theta_S = \{\theta_{\phi_S}, \theta_{\psi_S}, \theta_{f_S}\}$ by minimizing the joint cross-entropy loss:

$$\begin{aligned} \mathcal{L} = &-\textstyle\sum_{D_T}(r_{uc_T} \log \hat{r}_{uc_T} + (1 - r_{uc_T}) \log(1 - \hat{r}_{uc_T})) \\ &-\textstyle\sum_{D_S}(r_{uc_S} \log \hat{r}_{uc_S} + (1 - r_{uc_S}) \log(1 - \hat{r}_{uc_S})), \quad (2) \end{aligned}$$

where the two terms on the right-hand side are to optimize losses over user-news examples in the target and source domains, respectively. They are related by the word embedding matrix for the union of words of the two domains. We generate D_T and D_S as follows and take the target domain as an example since the procedure is the same for the source domain. Suppose we have a whole news reading history for a user u, say $[d_1, d_2, ..., d_{n_u}]$. Then we generate the positive training examples by sliding over the history sequence: $D_T^+ = \{([d_i]_{i=1}^{c-1}, d_c) : c = 2, ..., n_u\}$. We adopt the random negative sampling technique (Pan et al., 2008) to generate the corresponding negative training examples $D_T^- = \{([d_i]_{i=1}^{c-1}, d'_c) : d'_c \notin [d_1, d_2, ..., d_{n_u}]\}$, that is, we randomly sample a news article from the corpus as a negative sample which is not in this user's reading history.

Second, TrNews optimizes the parameters associated with the translator $\Theta_{\mathcal{F}} = \{\theta, \theta'\}$ by Eq. (1). Since the aligned data is limited, we increase the training pairs by generating them on-the-fly during the training of the two networks, i.e., in an alternating way. The model learning is summarized in Algorithm 1.

Algorithm 1: Training of TrNews.

```
Input: $D_T, D_S, \mathcal{U}_0$
Output: Source & target networks, translator
for $iter = 1, 2, ..., 50$ do
    1. Train target and source networks with
       mini batch using $D_T, D_S$ respectively;
    2. for $u \in \mathcal{U}_0$ do
           (a) Generate source representations
               $\phi(u_S)$ using source network;
           (b) Generate target representations
               $\phi(u_T)$ using target network;
           (c) Train the translator using pairs
               $(\phi(u_S), \phi(u_T))$ with mini batch;
       end
    3. Compute metrics on the validation set;
       if No improvement for 10 iters then
           Early stopping;
       end
end
```

3.4 Inference for unseen users

For a new user in the target domain (not seen in the training set $\mathcal{U}_T^{train}$), we do not have any previous history to rely on in learning a user representation for her. That is, the shaded area of the target network in Figure 2a is empty for unseen users.

TrNews estimates a new user u^*'s target representation by mapping from her source representation using the learned translator $\mathcal{F}$ by:

$$\phi_T(u^*) := \mathcal{F}(\phi_S(u^*)), \ \forall u^* \in \mathcal{U}_S \wedge u^* \notin \mathcal{U}_T^{train}, \quad (3)$$

where we compute $\phi_S(u^*)$ using u's latest reading history in the source domain. Then we can predict the user preference for candidate news c^* by:

$$\hat{r}_{u^*c^*} = f_T([\phi_T(u^*), \psi_T(c^*)]). \quad (4)$$

4 Experiment

We evaluate the performance of TrNews (Section 4.2) and the effectiveness of the translator (Section 4.3) in this section.

4.1 Datasets and experimental setup

Datasets We evaluate on two real-world datasets. The first $\boldsymbol{NY}, \boldsymbol{FL}, \boldsymbol{TX}, \& \boldsymbol{CA}$ are four subdatasets extracted from a large dataset provided by an internet company Cheetah Mobile (Liu et al., 2018; Hu et al., 2019). The information contains news reading logs of users in a large geographical area collected in January of 2017, ranging from New York (NY), Florida (FL), Texas (TX), to California (CA) based on the division of user geolocation. They are treated as four rather than a single because the user set is not overlapped among them. The top two categories (political and daily) of news are used as the cross corpora. The mean length of news articles is around 12 words while the max length is around 50 words. The mean length of user history is around 45 articles while the max length is around 900 articles. The second $\boldsymbol{MIND}$ is a benchmark dataset released by Microsoft for news recommendation (Wu et al., 2020). We use the MIND-small version to investigate the knowledge transfer when news reading examples are not so large and it is publicly available https://msnews.github.io/. The title and abstract of news are used as the content. The clicked historical news articles are the positive examples for user. The top two categories (news and sports) of news are used as the cross corpora. The word clouds of the two datasets are shown in Figure 1 and the statistics are summarized in Table 1. The mean length of news articles is around 40 words while the max length is around 123 words. Besides, the mean length of user history is around 13 articles while the max length is around 246 articles.

Evaluation protocol We randomly split the whole user set into two parts, training and test sets where the ratio is 9:1. Given a user in the test set, for each news in her history, we follow the strategy in (He et al., 2017) to randomly sample a number of negative news, say 99, which are not in her reading history and then evaluate how well the recommender can rank this positive news against these negative ones. For each user in the training set, we reserve her last reading news as the valid set. We follow the typical metrics to evaluate top-K news recommendation (Peng et al., 2016; Okura et al.,

Table 2: Comparison of different recommenders.

2017; An et al., 2019) which are hit ratio (HR), normalized discounted cumulative gain (NDCG), mean reciprocal rank (MRR), and the area under the ROC curve (AUC). We report the results at cut-off $K \in \{5, 10\}$.

Implementation We use TensorFlow. The optimizer is Adam (Kingma and Ba, 2015) with learning rate 0.001. The size of mini batch is 256. The neural CF module has two hidden layers with size 80 and 40 respectively. The size of word embedding is 128. The translator has one hidden layer on the smaller datasets and two on the larger ones. The history is the latest 10 news articles.

4.2 Comparing different recommenders

In this section, we show the recommendation results by comparing TrNews with different state-of-the-art methods.

Baselines We compare with following recommendation methods which are trained on the merged source and target datasets by aligning with shared users: **POP** (Park and Chu, 2009) recommends the most popular news. **LR** (McMahan et al., 2013) is widely used in ads and recommendation. The input is the concatenation of candidate news and user's representations. **DeepFM** (Guo et al., 2017) is a deep neural network for ads and recommendation based on the wide & deep structure. We use second-order feature interactions of reading history and candidate news, and the input of deep component is the same as LR. **DIN** (Zhou et al., 2018) is a deep interest network for ads and recommendation based on the attention mechanism. We use the news content for news representations. **TANR** (Wu et al., 2019a) is a state-of-the-art deep news recommendation model using an attention network to learn the user representation. We adopt the news encoder and negative sampling the same with TrNews.

Results We have observations from results of different recommendation methods as shown in Table 2. Firstly, considering that breaking and headline news articles are usually read by every user, the POP method gets competitive performance in terms of NDCG and MRR since it ranks the popular news higher than the other news. Secondly, the neural methods are generally better than the traditional, shallow LR method in terms of NDCG, MRR, and AUC on the four subdatasets. It may be that neural networks can learn nonlinear, complex relations between the user and the candidate news to capture user interests and news semantics. Considering that the neural representations of user and candidate news are fed as the input of LR, it gets competitive performance on MIND data. Finally, the proposed TrNews model achieves the best performance with a large margin improvement over all other baselines in terms of HR, NDCG, and MRR and also with an improvement in terms of AUC. It validates the necessity of accounting for the heterogeneity of user interests and word distributions across domains. This also shows that the base network is an effective architecture for news recommendation and the translator is effective to enable the knowledge transfer from the source domain to the target domain. In more detail, it is inferior by training a global model from the mixed source and target examples and then using this global model to predict user preferences on the target domain, as baselines do. Instead, it is good by training source

Approach	Transfer strategy	Formulation
CST (Pan et al., 2010)	Identity mapping	$\phi_T(u) = \phi_S(u)$
TCB (Liu et al., 2018)	Linear mapping	$\phi_T(u) = H\phi_S(u)$
DDTCDR (Li and Tuzhilin, 2020)		H is orthogonal
EMCDR (Man et al., 2017)	Nonlinear mapping	$\phi_T(u) = \text{MLP}(\phi_S(u))$

and target networks on the source and target domains, respectively, and then learning a mapping between them, as TrNews does.

4.3 Comparing different transfer strategies

In this section, we demonstrate the effectiveness of the translator-based transfer-learning strategy.

Baselines We replace the translator of TrNews with the transfer-learning strategies of baseline methods as summarized in Table 3. All baselines are state-of-the-art recommenders and capable of recommending news to cold-start users. Note that, the compared transfer-learning methods are upgraded from their original versions. We strengthen them by using the neural attention architecture as the base component. In their original versions, CST and TCB use matrix factorization (MF) while DDTCDR and EMCDR use multilayer perceptron. The neural attention architecture has shown superior performance over MF and MLP in the literature (Zhou et al., 2018; Wu et al., 2019a). As a result, we believe that the improvement will be larger if we compare with their original versions but this is obviously unfair.

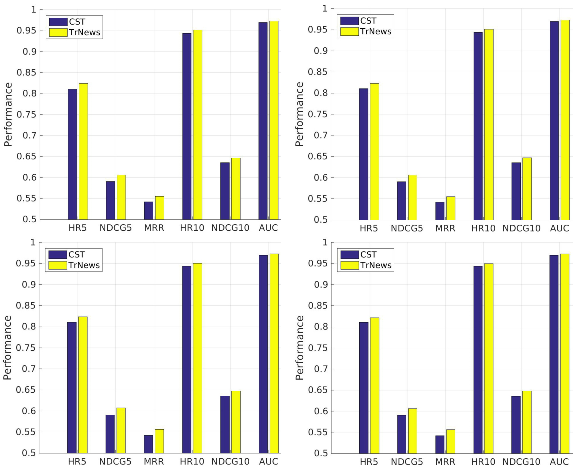

Figure 3: Impact of percentage (90%, 70%, 50%, 30%.) of shared users used to train the translator.

Results We have observations from results of different transfer learning strategies as shown in Table 4. Firstly, the transfer strategy of identity mapping (CST) is generally inferior to the linear (TCB and DDTCDR) and nonlinear (EMCDR and TrNews) strategies. CST directly transfers the source knowledge to the target domain without adaptation and hence suffers from the heterogeneity of user interests and word distributions across domains. Secondly, the nonlinear transfer strategy of EMCDR is inferior to the linear strategy of TCB in terms of MRR and AUC on the two smaller NY and FL datasets. This is probably because EMCDR increases the model complexity by introducing two large fully-connected layers in its MLP component. In contrast, our translator is based on the small-waist autoencoder-like architecture and hence can resist overfitting to some extent. Finally, our translator achieves the best performance in terms of NDCG, MRR and AUC on the two smaller NY and FL datasets, and achieves competitive performance on the two larger TX and CA datasets, and achieves the best performance in terms of HR and AUC on the MIND dataset, comparing with other four transfer methods. These results validate that our translator is a general and effective transfer-learning strategy to capture the diverse user interests accurately during the knowledge transfer for the unseen users in cross-domain news recommendation.

4.4 Analysis

Benefit of knowledge transfer We vary the percentage of shared users used to train the translator (see Eq. (1)) with $\{90\%, 70\%, 50\%, 30\%\}$. We

Sharing?	HR@5	HR@10	NDCG@5	NDCG@10	MRR	AUC
No	81.31	94.69	59.43	63.72	54.37	97.16
Yes	**82.60**	**95.15**	**60.78**	**64.83**	**55.70**	**97.28**

Table 5: Impact of sharing word embeddings between source and target domains.

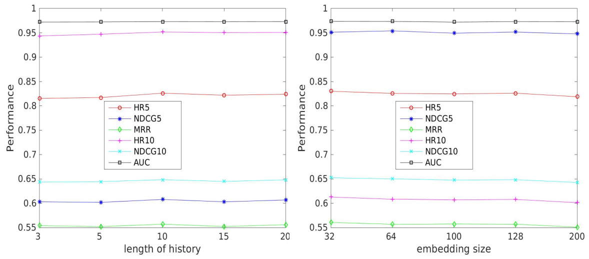
Strategy	HR@5	HR@10	NDCG@5	NDCG@10	MRR	AUC
Sepa.	82.36	94.86	60.62	64.65	55.51	97.28
Alter.	**82.60**	**95.15**	**60.78**	**64.83**	**55.70**	**97.28**

Table 6: Training TrNews with alternating (Alter.) vs separating (Sepa.) strategies.

compare with a naive transfer strategy of CST, i.e., the way of direct transfer without adaptation. The results are shown in Figure 3 on the New York dataset. We can see that it is beneficial to learn an adaptive mapping during the knowledge transfer even when limited aligned examples are available to train the translator. TrNews improves relative 0.82%, 0.77%, 0.67%, 0.64% in terms of HR@10 performance over CST by varying among $\{90\%, 70\%, 50\%, 30\%\}$ respectively. So we think that the more aligned examples the translator has, the more benefits it achieves.

Impact of sharing word embeddings We investigate the benefits of sharing word embeddings between source and target domains. There is a word embedding matrix for each of the domains and we share the columns if the corresponding words occur in both domains. Take the New York dataset as an example, the size of the intersection of their word vocabularies is 11,291 while the union is 50,263. From the results in Table 5 we can see that it is beneficial to share the word embeddings even when only 22.5% words are intersected between them.

Impact of alternating training We adopt an alternating training strategy between training the two (source & target) networks and training the translator in our experiments. In this section, we compare this alternating strategy with the separating strategy which firstly trains the two networks and then trains the translator after completing the training of the two networks. That is, the training pairs of user representations for the translator are not generated on-the-fly during the training of source and target networks but generated only once after finishing their training. From the results in Table 6, we see that the alternating strategy works slightly better. This is probably because the aligned data between domains is limited and the alternating strategy increases the size of training pairs.



(a) History length.

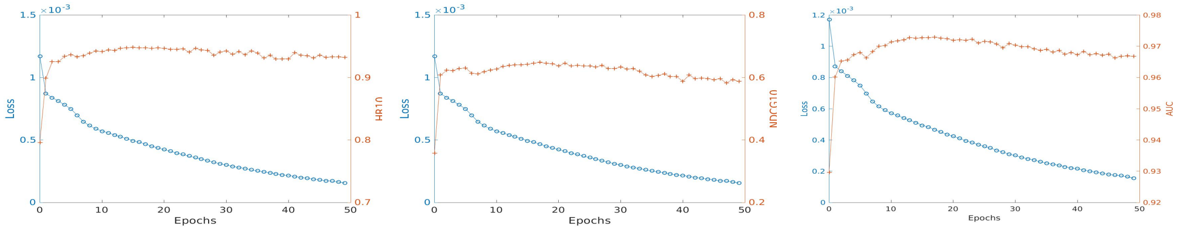
(b) Embedding size.

Figure 4: Impact of the history length (left) and embedding size (right).

Impact of two-stage learning We adopt a two-stage model learning between training the two (source & target) networks and training the translator in our experiments. In this section, we compare this two-stage learning with an end-to-end learning which jointly trains the two networks and the translator. That is, the parameters of the translator depend on the word embedding matrix and on parameters of the user encoder. From the results in Table 7, we see that the two-stage learning works slightly better. This is probably because the aligned data between domains is too limited to reliably update the parameters which do not belong to the parameters of the translator.

Impact of the length of the history Since we generate the training examples by sliding over the whole reading history for each user, the length of reading history is a key parameter to influence the performance of TrNews. We investigate how the length of the history affects the performance by varying it with $\{3, 5, 10, 15, 20\}$. The results on the New York dataset are shown in Figure 4a. We can observe that increasing the size of the sliding window is sometimes harmful to the performance, and TrNews achieves good results for length 10. This is probably because of the characteristics of news freshness and of the dynamics of user interests. That is, the latest history matters more in general. Also, increasing the length of the input makes the training time increase rapidly, which are 58, 83, 143, 174, and 215 seconds when varying with $\{3, 5, 10, 15, 20\}$ respectively.

Impact of the embedding size In this section, we evaluate how different choices of some key hyperparameter affect the performance of TrNews. Except for the parameter being analyzed, all other parameters remain the same. Since we compute the news and user representations using the content of words, the size of word embedding is a key parameter to influence representations of word-



(a) HR@10. (b) NDCG@10. (c) AUC.

Figure 5: Performance (right Y-axis in red cross) and loss (left Y-axis in blue circle) varying with training iterations.

s, uses, and news articles, and hence the performance of TrNews. We investigate how embedding size affects the performance by varying it with $\{32, 64, 100, 128, 200\}$. The results on the New York dataset are shown in Figure 4b. We can observe that increasing the embedding size is generally not harmful to the performance until 200, and TrNews achieves good results for embedding size 128. Changing it to 200 harms the performance a little bit since the model complexity also increases.

Optimization performance and loss We show the optimization performance and loss over iterations on the New York dataset in Figure 5. We can see that with more iterations, the training losses gradually decrease and the recommendation performance is improved accordingly. The most effective updates are occurred in the first 15 iterations, and performance gradually improves until 30 iterations. With more iterations, TrNews is relatively stable. For the training time, TrNews spends 143 seconds per iteration. As a reference, it is 134s for DIN and 139s for TCB, which indicates that the training cost of TrNews is efficient by comparing with baselines. Furthermore, the test time is 150s. The experimental environment is Tensorflow 1.5.0 with Python 3.6 conducted on Linux CentOS 7 where The GPU is Nvidia TITAN Xp based on CUDA V7.0.27.

Examining user profiles One advantage of TrNews is that it can explain which article in a user's history matters the most for a candidate article by using attention weights in the user encoder module. Table 8 shows an example of interactions between some user's history articles No. 0-9 and a candidate article No. 10, i.e., the user reads the candidate article after read these ten historical articles. We can see that the latest three articles matter the most since the user interests may remain the same during a short period. The oldest two articles, however, also have some impact on the candidate article, reflecting that the user interests may mix with a long-term characteristic. TrNews can capture these subtle short- and long-term user interests.

Training	HR@5	HR@10	NDCG@5	NDCG@10	MRR	AUC

5 Conclusion

We investigate the cross-domain news recommendation via transfer learning. The experiments on real-word datasets demonstrate the necessity of tackling heterogeneity of user interests and word distributions across domains. Our TrNews model and its translator component are effective to transfer knowledge from the source network to the target network. We also shows that it is beneficial to learn a mapping from the source domain to the target domain even when only a small amount of aligned examples are available. In future works, we will focus on preserving the privacy of the source domain when we transfer its knowledge.

Abstract

Thanks to the success of goal-oriented negotiation dialogue systems, studies of negotiation dialogue have gained momentum in terms of both human-human negotiation support and dialogue systems. However, the field suffers from a paucity of available negotiation corpora, which hinders further development and makes it difficult to test new methodologies in novel negotiation settings. Here, we share a human-human negotiation dialogue dataset in a job interview scenario that features increased complexities in terms of the number of possible solutions and a utility function. We test the proposed corpus using a breakdown detection task for human-human negotiation support. We also introduce a dialogue act-based breakdown detection method, focusing on dialogue flow that is applicable to various corpora. Our results show that our proposed method features comparable detection performance to text-based approaches in existing corpora and better results in the proposed dataset.

1 Introduction

Negotiation is an essential task involved in our daily life. In negotiation, people work to maximize their profits by bargaining; however, negotiation sometimes breaks down due to conflicts between people's competing interests. To help them to reach rational agreement, previous studies of multiagent systems have proposed the use of negotiating agents (Lin and Kraus, 2010; Jonker et al., 2017; Baarslag et al., 2013a). Recently, several studies have succeeded in modeling a negotiating agent in natural language that can control both text generation and reasoning in the context of goal-oriented dialogue systems, and such agents have produced better performance than human players in some cases (Lewis et al., 2017; He et al., 2018; Cheng et al., 2019). Further, support for human-human negotiation in natural language has also been tackled, involving negotiation corpora developed for goal-oriented dialogue systems, such as a Nash bargaining solution estimation (Iwasa and Fujita, 2018), real-time negotiation coaching (Zhou et al., 2019), and negotiation breakdown detection (Yamaguchi and Fujita, 2020).

Although they have recently attracted additional attention, there are only few negotiation corpora, as the most recent follow-up studies (Iwasa and Fujita, 2018; Cheng et al., 2019; Zhou et al., 2019; Yamaguchi and Fujita, 2020) have only utilized either the DEALORNODEAL (DN) (Lewis et al., 2017), CRAIGSLISTBARGAIN (CB) (He et al., 2018) datasets or both. Moreover, most existing corpora have simplified negotiation settings; for example, the DN dataset handles the negotiation of item division between humans with 22.5 possible solutions per dialogue and uses a standard linear additive utility function (Keeney and Raiffa, 1993; Raiffa et al., 2002) for scoring. The CB dataset is only concerned with price negotiation on a listed product between two human negotiators. These settings might make it easy for a machine learning (ML) model to reach optimal solution or fulfill its goal. Finally, some existing corpora (Konovalov et al., 2016; Petukhova et al., 2016; Asher et al., 2016) other than the DN and CB datasets have far smaller samples (scenarios), which makes it challenging to use them for goal-oriented dialogue systems or end-to-end human-human negotiation support. All of these factors inhibit further development in the field and its future applicability to real-world problems. Furthermore, no effective breakdown detection method for negotiation dialogues has been proposed. Negotiation features certain unique characteristics relative to other dialogues, such as offering proposals, accepting them,

and making counter-offers (Thompson et al., 2010; Traum et al., 2008). If the breakdown detection method can incorporate these characteristics, the quality of breakdown detection will be improved.

This study proposes a new negotiation corpus in a job interview setting with increased complexities relative to a range of solutions and a utility function. We enact a breakdown detection task (Yamaguchi and Fujita, 2020) across three negotiation datasets including a proposed one with a novel dialogue act-based approach that can focus on dialogue flow. This task can support human-human negotiation by alerting negotiators to potential breakdowns, which prevents the loss of time and negotiator utility. We highlight the following contributions:

1. We develop a new English negotiation corpus for a job interview setting, consisting of 2639 crowd-sourced dialogues (Section 3).

2. We propose a novel breakdown detection method that employs dialogue act-based features and a gated recurrent unit (GRU) (Chung et al., 2014)-based model (Section 5).

3. We demonstrate that the proposed method exhibits results that are comparable to models with text-based features in the existing corpora and outperforms them in the proposed corpus, which has a far smaller breakdown ratio (Section 7).

4. We conduct ablation studies and error analyses to examine how our proposed features works on a GRU-based model (Section 7).

2 Related Work

Automated Negotiation in Multiagent Systems Automated negotiation is a field of research, in which computers negotiate with each other and try to seek appropriate agreement without human intervention (Baarslag et al., 2013a). Typical applications include supply chain management (Wang et al., 2009) and smart grids (Ketter et al., 2013). As automated negotiation has gained momentum, the International Automated Negotiating Agents Competition (ANAC) (Baarslag et al., 2015; Jonker et al., 2017) has been being held annually since 2010. This event encourages the development of state-of-the-art negotiating strategies for automated negotiating agents in both agent-agent and human-agent (Mell et al., 2018) negotiations. The major difference between automated negotiation and ours is that the former supports negotiation by letting the agents negotiate instead of humans, whereas the latter seeks to support human-human negotiation in natural language only by providing feedback to negotiators with ML models.

NLP for Human-human Negotiation Support Automated negotiation has gained a great deal attention, but there have been only a few studies conducted on support for human-human negotiation in natural language: Iwasa and Fujita (2018) have proposed a GRU-based model to suggest a draft agreement that maximizes the sum of utilities based on the estimated weights of all items in the DN dataset. Zhou et al. (2019) proposed a dynamic negotiation coaching method in the setting of CB dataset that provides useful recommendations to sellers, resulting in increased profits. Our work is a follow-up study to Yamaguchi and Fujita (2020), who demonstrated that neural-network (NN)-based models trained with text-based features could capture signs of breakdowns in DN and CB datasets. Here, we show that text-based methods cannot detect breakdowns in the proposed corpus relative to our dialogue act-based approach.

Negotiation Dialogue Systems Previous efforts on building negotiation dialogue systems initially focused on modeling strategic aspects (Cuayáhuitl et al., 2015; Keizer et al., 2017; Petukhova et al., 2017), to construct an agent that could outperform human players by controlling a discrete action space. By contrast, Lewis et al. (2017) and He et al. (2018) have recently tried to simultaneously handle both text generation and reasoning by employing end-to-end neural negotiating models; moreover, Cheng et al. (2019) proposed adversarial training to improve the robustness of goal-oriented models. Although our main scope is supporting human-human negotiation, our corpus can also be used for goal-oriented dialogue systems (Lewis et al., 2017; He et al., 2018; Cheng et al., 2019) as its fundamental design is drawn from the DN dataset.

Negotiation Dialogue Datasets Several negotiation dialogue corpora, along with the DN and CB datasets, have been proposed to model strategic dialogue. Konovalov et al. (2016) built a bilateral negotiation corpus between a human and an agent in relation to terms of employment. Petukhova et al. (2016) created a corpus in which each negotiator acts as either a city councilor or a small business owner and debates new anti-smoking regulations.

Issue	Option
Salary	\$20 to \$50 per hour (integer)
Weekly day off	2 days to 5 days (integer)
⋆Position	{Engineer, Designer, Manager, Sales}
⋆Company	{Google, Apple, Facebook, Amazon}
Workplace	{Tokyo, Seoul, Beijing, Sydney}

Table 1: List of issues and options in the JI dataset: ⋆ denotes that there is an interdependent relationship between issues.

Asher et al. (2016) developed a multilateral negotiation dialogue corpus in the *Settlers of Catan* game. Our corpus and that of Konovalov et al. (2016) are similar to each other, in that both handle a job contract scenario. However, three main differences appear between the two: (1) The former handles human-human negotiation, whereas the latter deals with human-agent negotiation. (2) The former considers 11.5 times more possible solutions per dialogue than the latter. (3) The former has 2639 dialogues, and the latter has 105.

Dialogue Breakdown Detection Challenge The recently held Dialogue Breakdown Detection Challenge (DBDC) (Higashinaka et al., 2016; Hori et al., 2019) was intended to improve the coherency of a dialogue system. Given a dialogue history between a human and a system, the task is to evaluate whether a certain system response is valid. By contrast, our study focuses on predicting negotiation outcomes based on human-human negotiation to avoid negotiation breakdowns; that is, our task is different from the DBDC.

3 Job Interview Negotiation Dataset

3.1 Overview

The JOBINTERVIEW (JI) dataset is an instance of multi-issue multi-option negotiation, which includes the preferences of the negotiators, a dialogue history, proposed offers, and a settled agreement in a job interview setting. The negotiators conduct a conversation in English in the roles of recruiter or applicant and negotiate regarding the issues listed in Table 1 to maximize their scores. A dialogue sample from the JI dataset is shown in Table 2[1].

Utterance	Dialogue Act
Recruiter - Hello	`<greet>`
Worker - Hi	`<greet>`
Recruiter - I have a position open as an engineer at google. Are you interested?	`<inquire>`
Worker - Yes.	`<agree>`
Recruiter - The position is in tokyo. It pays \$35/hr and it is 4 days a week. Is this acceptable?	`<propose><inquire>`
Worker - Salary is too low.	`<disagree>`
Recruiter - OK. We could bump it to \$40/hr. Is this OK?	`<agree><propose>` `<inquire>`
Worker - How about I work in Beijing?	`<inquire>`
Recruiter - Beijing is open also.	`<inform>`
Worker - 5 days/wk.	`<propose>`
Recruiter - I cannot do 5 days a week.	`<disagree><propose>`
Worker - 4 days/wk and \$47/hr?.	`<propose><inquire>`
Recruiter - OK.	`<agree>`

Table 2: Sample dialogue between two negotiators in the JI dataset with extracted dialogue acts.

3.2 Mathematical Design

To make the negotiation competitive, we define each negotiator's preferences, and a scoring function, as in Lewis et al. (2017). In addition, we consider the interdependency (Kardan and Janzadeh, 2008; Alam et al., 2013) between a pair of issues such that the negotiators cannot easily reach an optimal agreement (Ito et al., 2006), leading them to seek a compromise solution through dialogue.

Preferences The importance of each issue and option, and bias assignment in representing interdependency between specific issues are defined as follows. Two negotiators $\boldsymbol{A} = \{a_1, a_2\}$ participate in a negotiation over the set of independent issues $\boldsymbol{I}$ and of issues $\boldsymbol{J}$ with an interdependent relationship. An issue $i \in \boldsymbol{I}$ is assigned a weight (importance) $w_i^{a_k} \in [0.1, 0.6], \sum_{i \in \boldsymbol{I}} w_i^{a_k} = 1$ per negotiator a_k with $k = 1$ or 2. An option for i, $o^i \in \boldsymbol{O}^i$, is assigned a weight $w_{o^i}^{a_k} \in [0, 1]$. While an issue included in a set of specific issues with an interdependent relationship $(j_{\text{from}}, j_{\text{to}}) \in \boldsymbol{J}$[2] has its own weight per a_k, only an option of j_{to} has a bias for that of j_{from} and j_{to}; that is, $o^{j_{\text{from}}}$ does not have a bias. The bias $b_{(o^{j_{\text{to}}}, o^{j_{\text{from}}})}^{w_{o^{j_{\text{to}}}}} \in [0, 0.5]$ represents an increase of importance for $o^{j_{\text{to}}}$ in a

---

[1] Our dataset is publicly available on GitHub: https://github.com/gucci-j/negotiation-breakdown-detection, and details on the negotiation interface and procedures are given in Appendix A.

[2] In our implementation, j_{from} is equivalent to "position," and j_{to} corresponds to "company."

	JI	DN	CB
# of dialogues	2,639	6,251	6,682
Avg turns per dialogue	12.7	4.97	7.53
Avg words per turn	6.12	8.56	13.60
Vocab size	4,476	2,631	12,139
Agreed [%]	92.9	76.2	74.9
PO solutions [%]	13.4	75.0	
PO bids for all bids [%]	0.98	18.0	
# of all bids per dialogue	9,920	22.5	
Avg score	6.4 / 10	5.7 / 10	

Table 3: Quantitative comparison of the three negotiation datasets: "PO" stands for Pareto optimal.

particular pair of options $(o^{j_\text{to}}, o^{j_\text{from}})$. Note that each weight and bias is initialized using uniform random numbers within a predefined range.

Scoring Function We define a scoring (utility) function to calculate a negotiation score. The weight of option $w_{o^{j_\text{to}}}$ is normalized after considering bias. More specifically, when an option o^{j_from} is in a draft agreement, the normalized weight of the option $w'_{o^{j_\text{to}}}$ is calculated using min-max normalization of $w_{o^{j_\text{to}}} + b^{w_{o^{j_\text{to}}}}_{(o^{j_\text{to}}, o^{j_\text{from}})}$ over $\boldsymbol{O}^{j_\text{to}}$. Thus, the scoring function is defined as follows:

$$\begin{aligned} U_{a_k}(s) = &\sum_{i \in \boldsymbol{I}} w_i^{a_k} w_{o_s^i}^{a_k} \\ &+ \sum_{(j_\text{from}, j_\text{to}) \in \boldsymbol{J}} \left(w_{j_\text{from}}^{a_k} w_{o_s^{j_\text{from}}}^{a_k} + w_{j_\text{to}}^{a_k} w'^{a_k}_{o_s^{j_\text{to}}} \right) \end{aligned}$$

where o_s^i is the option of i and is included in a draft agreement s. The function is derived from a linear additive utility function, utilized in automated bilateral negotiation (Baarslag et al., 2016) and in Lewis et al. (2017).

3.3 Data Collection

We hired workers through Amazon Mechanical Turk to collect human-human dialogues. Only those based in the USA with at least 1,000 previous HITs and an approval rating of over 95% could join our experiments. Before each session, the workers read the task description and instructions for negotiating with the opponent[1]. During a negotiation, each worker could propose a draft agreement up to three times and was asked to send six messages or more in total to submit the proposal. We paid \$0.20 per dialogue and gave a \$(score − 5)/5 bonus if the score was more than 5/10 to promote efficient negotiations.

3.4 Quantitative Comparison

Table 3 shows the quantitative comparison of three negotiation dialogue corpora. The vocabulary size is the largest in the CB dataset because it handles several categories of listed products. The JI and DN datasets focus on a single domain, and of the two, the former has the larger vocabulary size. The average number of turns per dialogue in the JI dataset is the largest of the three, though it has the smallest average number of words per turn. These statistics indicate that participants in the JI dataset likely had enough conversations to reach agreement.

Agreement Ratio The JI dataset had the highest agreement ratio of 92.9%, a sharp contrast with the values of 76.2% and 74.9% for the DN and CB datasets. This difference may be because the participants in the JI dataset could propose intermediate offers up to three times each, while those in the existing corpora could only submit one proposal per session.

Complexity of Negotiation Scenarios The JI dataset has far fewer Pareto optimal[3] solutions for agreements than the DN dataset, which can be ascribed to the following reasons: (1) the larger number of issues and options in the JI dataset, with 9920 possible solutions per dialogue, and (2) the introduction of an interdependent relationship that prevented the scoring function from following a standard linear additive utility function. As a result, participants in the JI dataset struggled to find better solutions and might have compromised with each other more often than in the DN dataset.

4 Task Description

Task We formally define the task of breakdown detection in negotiation dialogues. Let D be a negotiation dialogue between two negotiators, composed of $n \in \mathbb{N}$ turn's utterances $\{s_1, s_2, \ldots, s_n\}$, where each utterance s is a message from one of the negotiators and includes one or more sentences. Given D, the task is to label D as either a success (reaching an agreement: 0) or a breakdown (failing to find an agreement: 1).

Evaluation Metrics To evaluate the effectiveness of the different approaches, we employ area under curve (ROC-AUC) and confusion matrix (CM), both of which are based on Yamaguchi and

---

[3] When an agent's score cannot be improved without lowering the opponent's score, a solution is called Pareto optimal.

Fujita (2020). We also use average precision (AP) to consider the imbalanced nature of breakdown labels in negotiation datasets.

5 Methodology

This section introduces our breakdown detection approach using a dialogue act-based feature and ML models, including linear and NN-based models. The intuition that guides this feature is that because a breakdown dialogue should have distinct flow (e.g., many disagreements), focusing on the dialogue flow can help detect this type of breakdown.

5.1 Dialogue Act Extraction

Our dialogue acts and their extraction are based on He et al. (2018), but we made some changes in the extraction process to capture dialogue flow effectively. The process consists of two stages: (1) pattern matching and (2) filtering and alignment. The first step is almost identical to He et al. (2018), but the second is newly designed for this study.

Pattern Matching Given a dialogue turn, we extract dialogue acts according to the matching patterns (Table 4) using regular expressions[4]. If there is no matched pattern in it, an unknown tag `<unk>` is given. Note that because negotiators in the JI dataset can propose intermediate offers up to three times and because such offers are part of negotiations, we add corresponding dialogue acts whenever these offers are detected during conversations.

Filtering and Alignment He et al. (2018) only extracted one dialogue act per turn. However, because negotiators could send one or more sentences for each turn in the DN, CB, and JI datasets, there may have been two or more dialogue acts. To capture the dialogue flow in detail while matching noise due to the rule-based extraction is reduced, we filter extracted dialogue acts in a way that matches Figure 1, which only allows dialogue acts to appear in the designated order. If an illegal dialogue act follows a matched one, all remaining unmatched ones will be discarded. The constrained flow is motivated by an alternating-offer protocol (Rubinstein, 1982) utilized in automated negotiation (Baarslag et al., 2013b), where one agent proposes a draft agreement, and the other accepts it or makes a counter-offer. Although negotiation dialogues do not have a well-defined negotiation protocol, unlike the case of automated negotiation, we assume that human negotiators should follow an unwritten code to reach agreement with their opponents. Table 2 shows an example of extracted dialogue acts along with the text.

Dialogue act	Matching Pattern
`<greet>`	*hi, hello, yo, hey, hiya, howdy, how are you, good day, good afternoon, good morning*
`<disagree>`	Generic – *isn't, worse, bad, sorry, no, not, nothing, don't, can't, cannot, afraid, a lot lower/higher, too much/high/low* JI – An intermediate offer is rejected.
`<agree>`	*ok, okay, no problem, yes, great, perfect, thanks, gracias, thx, thank you, pleasure, fine, deal, cool, that works, that will work, that works, it will work, sounds good, very good, looks good, i can do*
`<inquire>`	*what, where, when, which, how's, how about, how does, do you, did you, will you, would you, could you, are you, do we, did we, could we, do i, let me know, ?*
`<propose>`	Generic – Any digits, *come down, highest, lowest, go higher/lower, i would like* DN – *ball(s), hat(s), book(s)* JI – A new intermediate offer is proposed.
`<inform>`	A previous utterance ends with `<inquire>` and its reply does not contain any other tags.

Table 4: Matching patterns for dialogue acts.

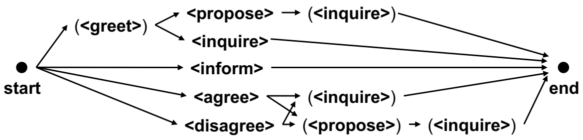

Figure 1: Constrained flow of each dialogue turn. Dialogue acts in parenthesis denote that they do not always appear in each turn.

5.2 Using Dialogue Act-based Features as Inputs for ML Models

Once we extract all features from a dialogue, we concatenate each turn with the addition of a separator tag `<sep>` to the head of each turn and an end tag `<end>` to the end of the dialogue. We then create an input vector for linear or NN-based models and use it to train the model. The input vector is produced as follows:

Linear Models We create a count vector by counting the number of each dialogue act per dialogue, including `<unk>`, `<sep>` and `<end>` tags.

---

[4] If there are two or more matched patterns for the same dialogue act, only the first matched pattern is kept.

NN-based Models We convert each extracted dialogue act into a one-hot representation $\boldsymbol{e} \in \mathbb{R}^{1\times10}$, which includes a padding tag `<pad>`. We then concatenate all one-hot representations in time series per dialogue, which generates an input matrix $\boldsymbol{E} \in \mathbb{R}^{n\times10}$, where n is the number of extracted dialogue acts, including padding.

6 Experimental Settings

6.1 Classification Models

We experiment with linear and NN-based models trained with either text-based or dialogue act-based features:

LR-BOW A logistic regression model trained with bag-of-words features weighted by TF-IDF.

GRU A GRU-based model with a linear layer on top of recurrent units. For text-based inputs, we used frozen pre-trained 300-dimensional word embeddding (GloVe) (Pennington et al., 2014). We also considered the model with a self-attention mechanism (GRU-Att) (Zhou et al., 2016).

BERT A pre-trained bidirectional encoder representations from transformers (BERT)-based model (Devlin et al., 2019) for only text-based inputs. We fine-tuned uncased $\text{BERT}_{\text{BASE}}$ and $\text{BERT}_{\text{LARGE}}$ models with one linear layer on the top of the `[CLS]` representation for binary classification.

Random A naive classifier that predicts negotiation outcomes by respecting training set's class distribution.

6.2 Data and Preprocessing

We employed three negotiation datasets compared in Table 3 for our experiments. The breakdown label of each dataset was assigned as follows. **DN**: A log has either a `<disagree>` or `<no_agreement>` tag inside an `<output>` tag. **CB**: A log does not have an offer price. **JI**: A "status" in a log is not "completed." For the CB and JI datasets, we removed short dialogues with less than three turns, as these are often labeled as breakdown and rarely include bargaining components, such as proposals. After the removal, the breakdown ratios of the CB and JI datasets were 18.9% and 4.9%. We preprocessed texts with lower-casing and inserted the `<sep>` and `<end>` tags into each dialogue, as in the dialogue act-based case. We tokenized the texts using spaCy[5]. For BERT, we used a pre-trained BERT tokenizer provided by the Transformers library (Wolf et al., 2020).

6.3 Implementation Details

We trained and tested models using stratified five-fold cross-validation. The model-specific implementation details are as follows:

Linear Model We implemented an LR-BOW model using Scikit-learn (Pedregosa et al., 2011) and trained it on Intel Core i5 (2.9 GHz - 6267U). We tested the n-gram combination of $\{(1, 1), (1, 2), (1, 3)\}$. We applied L2 regularization and weight adjustments to make the weights inversely proportional to the labels in training data.

NN-based Models We set the maximum number of epochs to 100 for GRU-based models and 20 for BERT-based models, with early stopping. We further split the training folds into training (80%) and validation subsets (20%). We used the binary cross-entropy loss and optimized the models with an Adam optimizer (Kingma and Ba, 2014). We implemented the models using PyTorch (Paszke et al., 2019) and tuned their hyperparameters based on validation F_1[6]. For BERT-based models, we utilized the implementation provided by HuggingFace (Wolf et al., 2020). We trained and tested our models with NVIDIA Tesla V100 (SXM2 - 32GB).

7 Results and Analysis

7.1 Quantitative Results

Results in Existing Corpora We can observe from Table 5 that a fine-tuned $\text{BERT}_{\text{BASE}}$ model shows the best AP for the DN and CB datasets. Moreover, NN-based models with text-based features exhibit results that are comparable to those of the best-performing models in terms of AP, in the 95% confidence interval. The proposed approach (GRU_{TAG}) also showed comparable results for either AP or CM in both datasets. Although a logistic regression model with text-based features ($\text{LR-BOW}_{\text{TEXT}}$) produced poor results in terms of AP, it showed the best results for the pair of FN and TP and that of TN and FP in the DN and CB datasets, respectively.

Results in Proposed Corpus Our GRU-based models with dialogue act-based features (GRU_{TAG} and $\text{GRU-Att}_{\text{TAG}}$) showed by far the best AP of all

Table 5: Performance comparison for three negotiation dialogue datasets: Best mean results are in **bold**. Values in parenthesis represent standard deviations over the five test folds. Values marked with * are within the 95% confidence interval of the best score for a given metric. Confusion matrices are normalized on a set each of true negative (TN) and false positive (FP), and true negative (TP) and false negative (FN).

models and better results in other metrics. For text-based models, an LR-BOW$_{\text{TEXT}}$ model showed better results in terms of AP, FN, and TP than NN-based models. While text-based GRU models could not detect signs of breakdowns at all, BERT-based models could detect them with a TP ratio of 19.8% (base) and 19.0% (large).

Discussion First, dialogue act-based features only worked with sequential models. This result is in line with our key concept of capturing negotiation flow. Because the LR-BOW$_{\text{TAG}}$ model could not consider sequential information, it could not detect breakdowns at all. Second, an LR-BOW$_{\text{TEXT}}$ model worked well in all datasets, indicating that text-based features themselves contain breakdown information. However, this approach produced more misclassification for successful dialogues in the DN and JI datasets than other models, but it

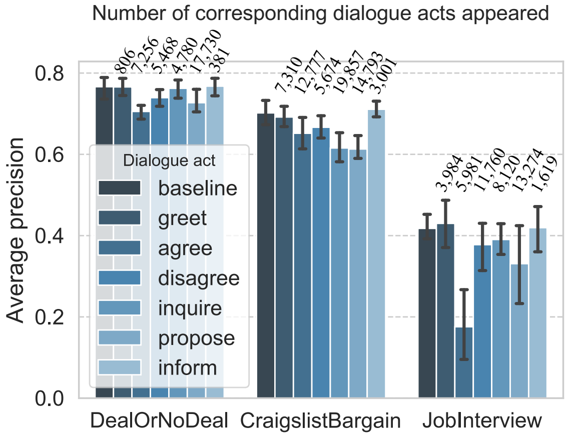

Figure 2: Classification performance comparison on five test folds when replacing a specific dialogue act with an unknown `<unk>` tag. Error bars denote the 95% confidence interval.

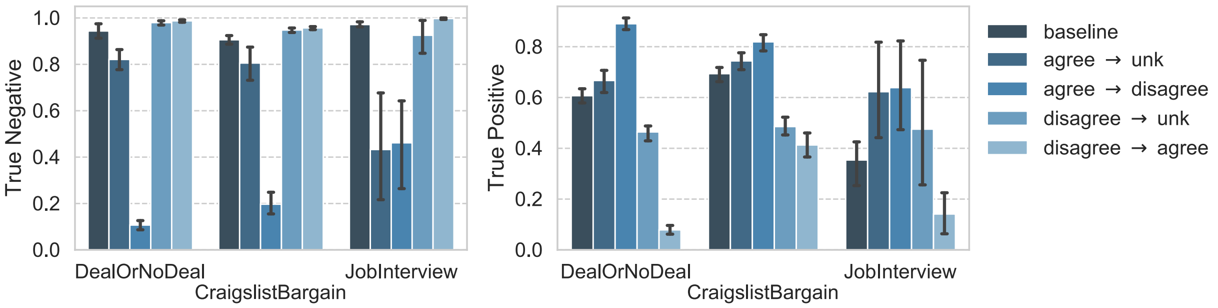

Figure 3: Performance comparison on five test folds when replacing `<agree>` and `<disagree>` tags with their counterpart or an `<unk>` tag. Error bars denote the 95% confidence interval.

could detect fewer breakdowns in the CB dataset. Because we intend to support human-human negotiation, accurate classification for both cases is vital to providing beneficial feedback to negotiators. Thus, the use of this approach is not helpful to our task. Third, NN-based models with text-based features did not perform well in the JI dataset. This was likely due to the far smaller breakdown ratio of 4.9% in the dataset compared to 23.8% and 18.9% in the DN and CB datasets. However, BERT-based models showed far better results than GRU-based ones in terms of the TP ratio. We hypothesize that BERT's rich contextualized information helped detect signs of breakdown.

7.2 Ablation Study

We conducted two ablation studies to better understand dialogue act-based input features. We first analyzed the importance of each dialogue act by replacing it with an unknown tag and tested with our best-performing model (GRU_{TAG}) over the five test folds. The `<agree>` tag was important for breakdown detection across the three corpora, despite its infrequency, especially in the DN and JI datasets (Figure 2). The frequent tag `<propose>` also played an important role in classification. By contrast, the `<disagree>` and `<inquire>` tags were not important except for the `<inquire>` tag in the CB dataset, possibly due to its highest frequency. Finally, the `<greet>` and `<inform>` tags were the least important in all datasets as these appeared less frequently and are not as closely related to breakdown as the others.

Next, we verified whether the GRU_{TAG} model captured the roles of `<agree>` and `<disagree>` tags in the breakdown detection task by replacing these tags with their counterpart or an `<unk>` tag (Figure 3). By replacing an `<agree>` tag with a `<disagree>` tag, we saw a rise in a TP ratio and a significant drop in a TN ratio compared to the baseline. When the `<disagree>` tag was replaced with an `<agree>` tag, the TN ratio slightly increased, while the TP ratio significantly decreased. These results suggest that the model properly took into account the roles of "`<agree>`" and "`<disagree>`" to some extent, and the number of such tags appeared played an important role in detecting a breakdown. While replacement with an `<unk>` tag also showed a similar trend, except with the `<disagree>` tag in the JI dataset, this was probably due to the relative increase of the counterpart.

FP (DN)	`<sep>` *i'd love to take a book and two hats off your hands* `<sep>` *hm, not many points for me but i'll agree to that.* `<end>`
	`<sep> <propose> <sep> <disagree> <end>`
FN (CB)	`<sep>` *hello, i am very interested in your car. however $12000 is out of my price range for a car that is 7 years old. i offer $6000 and i will pick up the car myself.* `<sep>` *there is no possible way i could go that low. i would take $11, 000* `<sep>` *that's fine, i will go elsewhere with my money.* `<sep>` *okay* `<end>`
	`<sep> <greet> <propose> <sep> <disagree> <propose> <sep> <agree> <sep> <agree> <end>`

Table 6: Examples of misclassified dialogues with extracted dialogue acts.

7.3 Error Analysis

Last, we conducted error analyses to examine the behavior of a GRU_{TAG} model and reveal its potential limitations. The first example is an FP sample from the DN dataset, where the model possibly focused on a `<disagree>` tag corresponding to *not*. The second one is an FN sample from the CB dataset, in which the model might have focused on repetitive `<agree>` tags. We consider that the proposed approach could not cope with euphemistic phrases because of the rule-based dialogue act extraction. Thus, annotating negotiation corpora with dialogue acts will be an important research direction for more precise detection.

8 Conclusions and Future Work

This study proposed a job interview negotiation dialogue dataset with 2639 dialogues and increased complexities compared to existing datasets to help propel development of the study of human-human negotiation support and goal-oriented dialogue systems. We also proposed a dialogue act-based breakdown detection model that can focus on negotiation flow. Our approach ($\mathrm{GRU}_{\mathrm{TAG}}$) showed comparable results when used with existing datasets and better results for the proposed dataset than models trained with text-based features. In the future, we intend to explore another application of dialogue act-based features to related tasks, such as preference estimations. We will also utilize the proposed corpus in related tasks in human-human negotiation support and goal-oriented dialogue systems.

A Job Interview Negotiation Dataset

Here, we introduce the negotiation interface and negotiation procedures. Our dataset and negotiation interface are available at `https://github.com/gucci-j/negotiation-breakdown-detection`.

A.1 Negotiation Interface

We developed an online negotiation interface for our job-interview negotiation, which implemented all mathematical settings such as preferences and a scoring function discussed in the body of the paper. Figure 4 shows the screenshot of our negotiation interface.

At the beginning of each negotiation session, the interface generates negotiators' preferences and displays them next to the corresponding issues and options so that the negotiators can easily understand which issue and option is important for them.

During the session, whenever the negotiators select a new solution, the interface calculates the score of its solution according to the scoring function described in Subsection 3.2 and displays it with the corresponding evaluation. The evaluation is based on Table 7 and intended for providing feedback to the negotiators to promote a better agreement.

At the end of the session, the interface stores the log that consists of the preferences of the participants, dialogue history, proposed offers and settled agreement in `json` format.

Score	Evaluation
< 50	Very bad
< 60	Bad
< 70	Fair
< 80	Good
< 90	Very good
≥ 90	Excellent

Table 7: Correspondence table between the score and the evaluation.

A.2 Negotiation Procedures

Before entering a negotiation session, each negotiator reads the instruction page that describes the outline of the negotiation, its procedures and some precautions (e.g., the maximum number of proposals per negotiator).

During the session, the negotiators can talk to their opponent using the left-hand side of the negotiation interface (Figure 4), while they can select an option for each issue in the right-hand side of the interface. Besides, they can also check the current score, its evaluation and estimated HIT reward for the selected options.

When the negotiators believe that they had sufficient discussion, they can propose a draft agreement by clicking the "PROPOSE" button shown in the bottom-left side of the interface. Once it is sent to the opponent, the opponent can check its details and score with the "ACCEPT" button shown on the interface. If the opponent clicks the button, the negotiation is regarded as successful. Otherwise, the negotiation continues until both the sides exceed the maximum number of propositions. If exceeding the limit, the negotiation is regarded as a breakdown, and the score of each negotiator is recorded as zero.

Hyperparameter	**Value or search space**
Maximum training epochs	100
Mini-batch size	64
Adam β_1	0.9
Adam β_2	0.999

Early stopping patience value	8
Number of GRU layers	$[1, 4]$
Number of GRU hidden units	$[64, 256]$
Bidirectional	`True` or `False`
Recurrent dropout rate	$(0.0, 1.0)$
Classifier dropout rate	$(0.0, 1.0)$

Table 8: Hyperparameters and search space for GRU-based models. If "bidirectional" is `True`, a model becomes a bidirectional GRU.

B Hyperparameter Tuning

Linear Models For the DN dataset, n-gram combination of $(1, 3)$ (uni-gram, bi-gram, and tri-gram) was chosen. For the CB dataset, that of $(1, 2)$ (uni-gram and bi-gram) was selected. For the JI dataset, that of $(1, 1)$ (uni-gram) was chosen. Since none of the models trained with dialogue act-based features did not work, these have no optimal n-gram combinations.

Neural Network-based Models We tuned the hyperparameters of all NN-based models employed in our experiments using the Optuna framework (Akiba et al., 2019). We split training folds into training (80%) and validation (20%) subsets. We tested 100 hyperparameter combinations and evaluated their performance based on F_1 in each validation subset. Tables 8 and 9 show the hyperparameters and search space for GRU and BERT-based models, respectively.

Abstract

For many new application domains for data-to-text generation, the main obstacle in training neural models consists of a lack of training data. While usually large numbers of instances are available on the data side, often only very few text samples are available. To address this problem, we here propose a novel few-shot approach for this setting. Our approach automatically augments the data available for training by (i) generating new text samples based on replacing specific values by alternative ones from the same category, (ii) generating new text samples based on GPT-2, and (iii) proposing an automatic method for pairing the new text samples with data samples. As the text augmentation can introduce noise to the training data, we use *cycle consistency* as an objective, in order to make sure that a given data sample can be correctly reconstructed after having been formulated as text (and that text samples can be reconstructed from data).

On both the E2E and WebNLG benchmarks, we show that this weakly supervised training paradigm is able to outperform fully supervised seq2seq models with less than 10% annotations. By utilizing all annotated data, our model can boost the performance of a standard seq2seq model by over 5 BLEU points, establishing a new state-of-the-art on both datasets.

1 Introduction

Neural data-to-text generation has been the subject of much recent research. The task aims at transforming *source-side* structured data into *target-side* natural language text (Reiter and Dale, 2000; Barzilay and Lapata, 2005). While neural end-to-end systems afford the advantage of easy adaptability (Lebret et al., 2016; Wiseman et al., 2017), huge amounts of data-text pairs are still necessary to perform on par with their rule-based counterparts (van der Lee et al., 2018). This makes using neural systems less appealing: oftentimes, in-domain text samples are not readily available, and there is a high cost to collecting in-domain texts which fit the data samples, and annotating these texts with the data labels – the cost for collecting this data might hence even outweigh the efforts of designing a rule-based system (Gkatzia, 2016). The goal of this work is to improve the performance of neural data-to-text models in scenarios where only very few text samples exist (we assume that these text samples are paired with corresponding data samples). We aim to answer how we can make the most of the scarce annotations, together with large amounts of unlabelled data, in order to push the limit of the neural data-to-text models. Figure 1 illustrates the scenario.

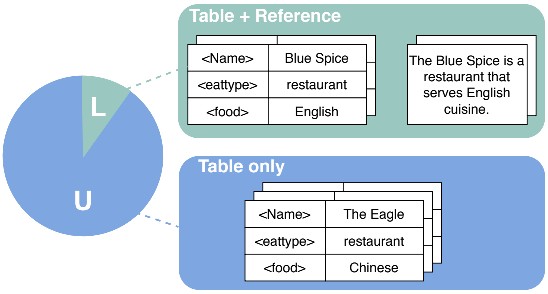

Figure 1: **Few-shot scenario**: The model is expected to learn data-to-text generation with few labeled instances (i.e. table-text pairs). The example is taken from the E2E dataset.

To address the limited-data challenge, we propose a simple yet effective way of augmenting the text side with the pretrained language model (LM) GPT-2 (Radford et al., 2019). Unlike other text augmentation work employed in data-to-text generation systems (Freitag and Roy, 2018; Agarwal et al., 2018), our proposal assumes little to no domain-dependent heuristics. It consists of two steps: (1) information augmentation by slot-value replacement and (2) LM augmentation by GPT-2

generation.

Once we have augmented the set of text samples, we are essentially in a similar setting as previously proposed semi-supervised approaches to data-to-text generation Schmitt and Schütze (2019); Qader et al. (2019); Su et al. (2020), which assume the presence of vast amounts of *unpaired* data and text instances. These approaches exploit a *cycle consistency* objective in order to learn a pairing for the data samples. The cycle consistency objective tries to make sure that data samples can be reconstructed correctly from their textual formulations, and similarly that texts can be reconstructed after having been parsed into a data representation.

As the automatically generated text samples from GPT-2 might be very noisy and not pair well with data samples, we align each augmented text sample with its most similar unlabeled data sample, as defined in their encoded vector space. This idea is inspired by recent work on representation matching in MT (Artetxe and Schwenk, 2019; Ruiter et al., 2019). To ensure good quality of the training data, only pairs above a certain similarity threshold ϵ are retained as pseudo pairs for training. The quality of the pseudo pairs will gradually improve as the encoder improves in the training process. In return, the learning of the encoder will also be facilitated with the improved quality of pseudo pairs as a virtuous cycle.

On two data-to-text benchmarks E2E (Novikova et al., 2017) and WebNLG (Gardent et al., 2017), we show that our LM-augmented weakly supervised model succeeds on outperforming fully supervised seq2seq model, though utilizing less than 10% of the data annotations. It even outperforms previous work which *additionally has access to all unpaired text samples*. When trained with full data annotations, it is able to boost the model performance by up to 5 BLEU points, establishing a new state-of-the-art on both datasets.

In summary, this work makes the following contributions:

1. We study the few-shot data-to-text scenario where, unlike previous works, no further target-side text is available.
2. We present an effective way of automatically augmenting target text by resorting to the pretrained LM GPT-2.
3. We propose utilizing the augmented text by a combination of cycle consistency and representation matching. The resulting model outperforms standard seq2seq model with less than 10% data annotations.
4. The proposed model is shown to be complementary with current seq2seq pretraining techniques, and can offer orthogonal improvements when combining both.

2 Related Work

Building neural data-to-text systems with few paired samples (but a large set of unpaired samples) has been a hot research topic recently. Most works adopt the idea of cycle consistency (Zhu et al., 2017), which has been used in many text generation tasks like machine translation (Artetxe et al., 2017; Lample et al., 2017) and style transfer (Prabhumoye et al., 2018; Subramanian et al., 2018). Schmitt and Schütze (2019); Qader et al. (2019); Su et al. (2020); Chang et al. (2020, 2021a,b) applied this idea to the task of data-to-text generation and reported promising results. Ma et al. (2019) separate the generation process into few-shot content selection and surface realization components and learn them separately. Nonetheless, all of these approaches assume the existence of *huge quantity of unpaired text samples*, which, as we mentioned, is an unrealistic assumption for the task of data-to-text generation. Freitag and Roy (2018) proposes to reconstruct usable sequences re-written from data with rules for unsupervised data-to-text generation. Unfortunately, designing these rules require efforts similar to building a template-based system. (Budzianowski and Vulić, 2019; Chen et al., 2020; Peng et al., 2020) tackle the few-shot challenge by finetuning a pretrained LM to incorporate prior knowledge from general-domain text or data-text pairs. We show that our technique is complementary with them and can offer orthogonal improvements when combining both.

3 Problem Formulation

We represent the data samples as D and the text samples as T. In our work, we do not restrict the format of the data. Each $d \in D$ can be a set of key-value pairs, as in Figure 1, or in form of RDF triples as in Gardent et al. (2017). Each text $t \in T$ consists of a sequence of words. In few-shot settings, we are assumed to have (1) k labeled pairs (D_L, T_L) and (2) large quantities of unlabeled data

D_U where $|D_U| \gg k > 0$[1]. This, we believe, is a more realistic setting as unlabeled data are usually abundant and also can be easily fabricated from predefined schemata. Notably, we assume no access to outside resources containing in-domain text. The k annotations are all we know about the text side.

4 Approach

In this section, we first explain our proposed new method for text sample augmentation, and then discuss methods to remove noise and automatically align the data by elaborating on the ideas of cycle consistency and representation matching. Finally, we summarize the approach and present the detailed algorithm.

4.1 Text Augmentation

To mitigate the paucity of the set of text samples T, we propose a pipeline approach to augment the text samples by (1) information augmentation and (2) LM augmentation.

4.1.1 Information Augmentation

We generate additional text samples by performing slot-value replacements. As many data values are exactly copied to the text samples, these copied information can be easily detected and replaced with other values (for the same slot type) to enrich the information space of the text samples. This can be considered as a simplified version of traditional methods of template mining where key words are extracted to construct templates (Kondadadi et al., 2013; Oya et al., 2014). An example is shown in Figure 2. Each text sample is augmented with 10 more distinct text samples or with all possible values being replaced.

The slot-value replacement is efficient to implement. However, it can only detect identical values and augment text with the same combinatorial patterns as the few-shot annotations. To enrich the linguistic realizations of text sentences and enable new combinations of information, we further propose a LM augmentation approach using GPT-2.

4.1.2 LM Augmentation

GPT-2 (Radford et al., 2019) is a language model pretrained on the collected WebText. It has demonstrated remarkable zero-shot multitask adaptability by simply feeding the input of each task into the LM and continuing to generate words. People have also also shown that GPT-2 is able to improve classification tasks via in-domain text augmentation (Papanikolaou and Pierleoni, 2020; Sun et al., 2020). We use a similar technique by first fine-tuning GPT-2 in the few-shot annotations (Wolf et al., 2019), and then applying it to produce synthetic text through an iterative conditional generation process: With initial seeds being samples of T_L plus new samples from information augmentation, the LM iteratively conditions on the previous output sentence to generate in-domain text[2]. Each synthetic sentence is pruned if it (1) is shorter than 5 words or (2) contains only special tokens. The iterative generation is terminated when all tokens in the initial seeds are covered or if the maximum of 100 runs is reached. All the unpruned synthetic text samples are added into the space of T to benefit the learning direction of $t \to d' \to t$ and $\tilde{t} \to t$. Figure 2 depicts the generation process of GPT-2.

In practice, obtaining clean in-domain text requires extreme efforts of designing heuristic rules. Nonetheless, the synthetic text from GPT-2 makes decent sense and can already provide useful signals to drive the learning process.

4.2 Cycle Consistency

The core idea of encouraging cycle consistency is that starting from one sample in a domain, the model first maps it into the other domain, then maps it back (He et al., 2016). The resulting sample should be identical to the original sample. Specifically, let $p_\theta(t|d)$ be the probability distribution to map a data sample d to its corresponding text t, and $p_\phi(d|t)$ be the probability distribution to map text back to data. Starting from a data sample $d \in D$, its objective is:

$$\max_{\phi} \mathbb{E}_{d\sim p(D)} \log p_\phi(d|t'); \; t' \sim p_\theta(t|d) \qquad (1)$$

which basically ensures the consistency in the direction of $d \to t' \to d$. Note that only p_ϕ is updated in this direction and p_θ serves only as as an auxiliary function to provide pseudo samples t' from d. Though it is also possible to update θ at the same time through tricks like Gumbel-softmax (Jang et al., 2016) or REINFORCE (Williams, 1992), we find it did not lead to better performance, yet complicated the training. Similar observations have

---

[1] We force $k > 0$ as we believe a reasonable generation system needs a least a few demonstrations of the annotation.

[2] We adopt the Top-k random sampling setting with $k = 2$ to encourage diversity and reduce repetition (Radford et al., 2019)

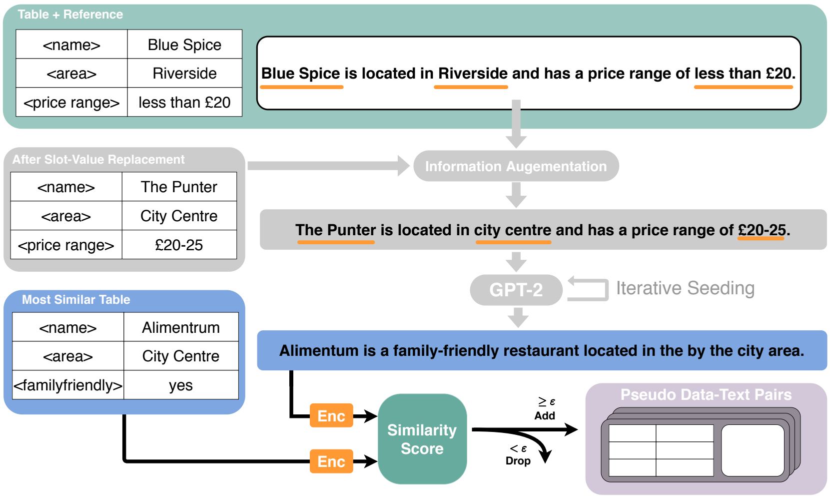

Figure 2: Depiction of *text augmentation* and *representation matching*. Each text sample first goes through information augmentation by slot-value replacement, then passed to GPT-2 with iterative conditional generation. The augmented text samples are paired with the most similar data from the corpus with a threshold cutoff.

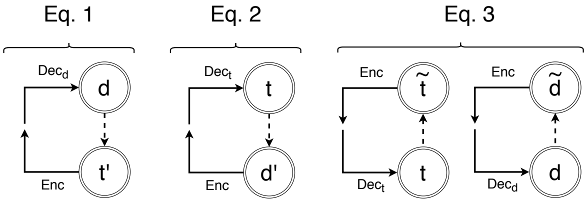

Figure 3: Four directions of cycle consistency. Gradients are backpropagated only through solid lines.

been made in Lample et al. (2018); He et al. (2020); Garcia et al. (2020).

Similarly, starting from a text $t \in T$, the objective is to ensure the consistency in the direction of $t \rightarrow d' \rightarrow t$:[3]

$$\max_{\theta} \mathbb{E}_{t\sim p(T)} \log p_\theta(t|d');\ d' \sim p_\phi(d|t) \qquad (2)$$

Finally, we further add two denoising autoencoding objectives on both the data and text sides:

$$\max_{\theta,\phi} \mathbb{E}_{d\sim p(D),t\sim p(T)} \log p_\phi(d|\tilde{d})p_\theta(t|\tilde{t}) \qquad (3)$$

where $\tilde{d}$ and $\tilde{t}$ are the corrupted versions of d and t. We use the same noise function as in Lample et al. (2018) which randomly permutes and pads a portion of the input. This can encourage the encoder to learn meaningful latent representations by reconstructing the input itself (Currey et al., 2017; Lample et al., 2018).

Figure 3 illustrates all the four directions of the cycle consistency objective.

We use one shared encoder Enc for both the data and text sides. Each data sample is flattened into a sequence by making a list of slot value pairs and fed into the same encoder. Using the same encoder for both types of input gives the model an inductive bias to project similar data/text into surrounding latent space.

We will show later that encoder sharing is essential for a good performance under the few-shot scenario. From the shared encoded space, two separate decoders Dec_d and Dec_t are used to decode d and t respectively[4].

4.3 Representation Matching

Apart from training under the cycle consistency, we further consider matching each synthetic text with its most similar data sample and treating them as supplementary training pairs. Compared with the pseudo d' obtained from back translation (Eq. 2), the matched data samples are extracted from the existing corpus D_U and thereby are guaranteed to be clean. This can provide a much more stable training signal especially at the initial training stage[5]. Previous work has used representation matching to automatically extract pseudo training pairs for machine translation (Artetxe and Schwenk, 2019; Ruiter et al., 2019). Baziotis et al. (2019); Chu and

---

[3] In the MT community, the equivalent step is usually called *back translation* (Sennrich et al., 2016; Lample et al., 2018).

[4] The shared encoding has also been shown effective in other tasks like machine translation (Lample et al., 2018) and image transition (Zhu et al., 2017). We further tried sharing the decoder as in Johnson et al. (2017) but find no improvement (see Table 2).

[5] In theory, as we can fabricate arbitrary possible data samples from the predefined schema and add to the corpus, we can always find one matched data for a text samples.

Liu (2019) also demonstrate that the representation similarity between input-output pairs can serve as a useful regularization for unsupervised text summarization. We adopt a similar idea to create pseudo pairs based on their cosine similarity in the representation space. To summarize, the process of representation matching can be described as:

$$\max_{\theta,\phi} \mathbb{E}_{t\sim p(T')} \mathbb{1}_{cos(d^*,t)>\varepsilon}\big(\log p_\theta(t|d^*) + \log p_\phi(d^*|t)\big); \quad (4)$$

$$d^* = \arg\max_{d\in D} \cos(d,t)$$

where T' is augmented text from the LM and $\mathbb{1}$ is the indicator function. We also perform mean pooling over the encoded representations before matching them. ε is a threshold. Pseudo pairs with a cosine similarity less than ε will be discarded. Ideally, as the encoder improves, the pseudo pairs created by representation matching will make more sense, which can in turn benefit the training of the encoder.

4.4 Summary

Apart from the above unsupervised objective, on the few annotated data-text pairs, we can impose the supervised objective:

$$\max_{\theta,\phi} \mathbb{E}_{d,t\sim p(D_L,T_L)} \log p_\theta(t|d) + \log p_\phi(d|t) \quad (5)$$

where (D_L, T_L) contains the k data annotations. Putting all together, we summarize it in Algorithm 1. In the training stage, we optimize the objectives of cycle consistency, representation matching and supervised learning sequentially to maintain a constant ratio of signals from all sides.

5 Experiment Setting

Data We conduct experiments on the E2E (Novikova et al., 2017) and WebNLG (Colin et al., 2016) datasets. E2E is a crowd-sourced dataset containing 50k instances in the restaurant domain. The inputs are dialogue acts consisting of three to eight slot-value pairs. WebNLG contains 25k instances describing entities belonging to fifteen distinct DBpedia categories. The inputs are up to seven RDF triples of the form *(subject, relation, object)*.

Configuration The model is implemented based on fairseq (Ott et al., 2019). We use 600-dimensional token embedding and Adam optimizer with initial learning rate at 0.0002. Batch size is kept at 48 with a dropout rate at 0.3. We employ beam search with size 3 for decoding and select models based on BLEU-4 scores on the development set. The score is averaged over 10 random initialization runs. In this work, the seq2seq models are built upon the long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997). For LSTM cells, both the encoder and decoder have 3 layers, amounting to 18M parameters for the seq2seq model (600-dimension and 1024 hidden units). Maximum sequence length is set as 100 for E2E and 200 for WebNLG (SPM-based). All encoder parameters are shared between data and text samples. All models were trained on 1 Nvidia V100 GPUs (32GB and CUDA Version 10.2) for 4k steps. The total batch size is around 48K tokens per GPU and we use the Adam optimizer ($\epsilon = 1e{-}6$, $\beta_2 = 0.98$) along with linear learning rate decay scheduling. The total number of updates is set to 8000 for all training and models are selected based on optimal validation BLEU4. At decoding time, sentences are generated using greedy decoding.

6 Results and Analysis

In this section, we present experiment results and analysis. We first compare our model with other baselines on both datasets, then perform a set of ablation studies on the E2E dataset to see the effects of each component. Finally, we analyze how text augmentation helps improves the model, include example outputs and show the human evaluation results in the end.

+ $d \rightarrow d$	53.37	**56.44**	56.09	56.11
+ Noise	54.13	**57.37**	56.59	57.04

Table 2: Ablation study for cycle consistency (10% annotations). BLEU-4 score is reported. Each line adds one condition on top of the previous one. **Supervised** is a supervised seq2seq baseline.

Comparison with Other Models In Table 1, we compare our model with (1) seq2seq baseline, (2) cycle consistency model as in Qader et al. (2019)[6] and (3) finetuned GPT-2 model as in Chen et al. (2020)[7]. For all models, we try running with 10% and 100% annotations to see how they perform under different data sizes. Our model is implemented both with LSTM encoder-decoders, same as the seq2seq baseline for a fair comparison. Note that Qader et al. (2019) further *utilized all the ground-truth unpaired text samples*, while the other models run only on the few-shot annotations. We also include the results of **SLUG** (Juraska et al., 2018) and **MELBOURNE** (Gardent et al., 2017), the overall winner on automatic metrics in the E2E and WebNLG challenge respectively(both seq2seq-based). SLUG uses a heuristic slot aligner based on a set of handcrafted rules and combines a complex pipeline of data augmentation, selection, model ensemble and reranker.

The results show that our proposed model significantly improves over the baseline on both the few-shot and fully supervised setting. The improvement is more evident when only 10% annotations are available, with a leap of 11 and 7 BLEU scores on E2E and WebNLG respectively. It also outperforms systems relying on task-dependent heuristics. In comparison, Qader et al. (2019), though with access to all text samples at all percentages, still underperforms our model with tangible margin. On the fully supervised setting, it brings little to no difference compared with the seq2seq baseline as no more extra data is incorporated in the training process. As such, we also observe that the text augmentation from finetuned GPT-2 model helps the proposed model on the few-shot setting, but its advantage also vanishes when all data annotations are available.

In Figure 4, we draw the model performance with varying number of data annotations. All models are trained from scratch with 10 different random initializations and the standard deviation of the BLEU-4 score is visualized. We can see our model (LSTM-based), though with a relatively larger standard deviation due to the uncertainty of text augmentation sampling, still consistently outperforms other baselines significantly and even surpasses the fully supervised seq2seq model with less than 10% of data annotations.

Ablation Study on Cycle Consistency In Table 2, we study how the four directions, input noise and parameter sharing affect the performance of cycle-consistency. The experiments are conducted with 10% annotations and *no further unpaired text*

---

[6] The author did not open-source their code. We reproduced their model based on our implementation. The results on 10k annotations matches their reports in the paper.

[7] https://github.com/czyssrs/Few-Shot-NLG

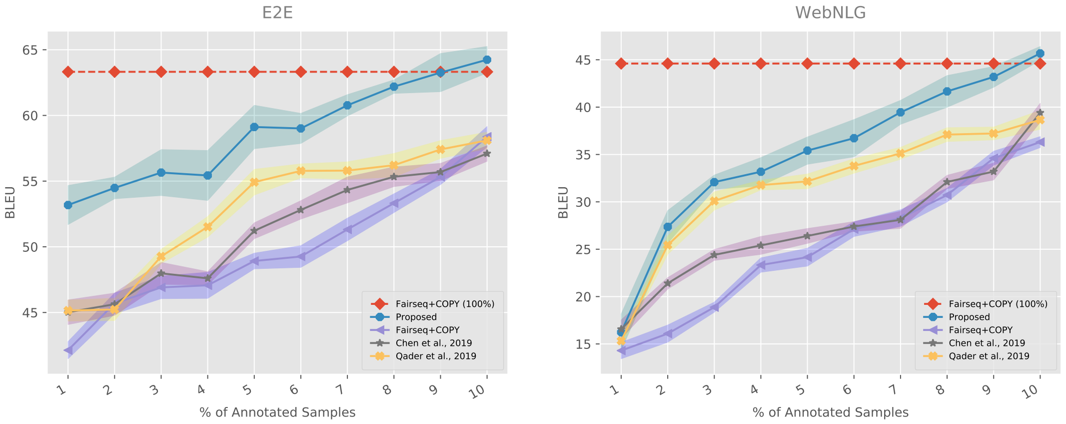

Figure 4: Model performance with varying number of data annotations. Our model with 10% annotations outperforms the seq2seq model trained on 100% pairs (dotted line) on both datasets. Shades are the sample standard deviation based on 10 runs of different model initializations.

samples are available.

As can be observed, adding the training direction $t \rightarrow d' \rightarrow t$ (i.e. back translation) has little effects on top of the supervised seq2seq baseline. This is expected since back translation is naturally designed to incorporate additional unpaired text samples. When run only on the few-shot annotations, its power is very limited. The backward direction $d \rightarrow t' \rightarrow d$ is surprisingly useful when the encoder is shared between the data and text. Though this direction will not affect the text decoder at all, the improvement suggests the model can benefit a lot by simply structuring its encoded space and mapping aligned data-text pairs to similar vector space. The autoencoding directions brings a little improvement. When combined with input noise, the performance further increases. This is similar to previous findings that denoising autoencoding is more helpful in inducing meaningful latent space (Lample et al., 2018) in comparison to simply learning to copy the original input.

The results also suggest encoder sharing is important for the cycle consistency objective to work in our few-shot setting. Decoder sharing, in contrast, makes little or even negative influence. This is kinda similar as in multilingual machine translation where sharing the decoder among languages might negatively interfere with the performance (Johnson et al., 2017).

Ablation Study on Text Augmentation On top of the four-direction cycle consistency training, we study the effects of text augmentation in Table 3. We compare our proposed info + LM augmentation with (1) random augmentation, where a random text from Wikipedia is sampled to the augmented text space, (2) unsupervised data augmentation (Xie et al., 2019) where text samples are augmented with paraphrases of current annotations and (3) ground-truth augmentation with reference obtained from the left training corpus, which can serve as an upper bound of text augmentation techniques. We test the performance with 1%, 5%, 10% and 20% annotations to see the effects with varying number of supervisions.

Text Augmentation	**1%**	**5%**	**10%**	**20%**
None	44.18	50.22	57.37	63.28
Random	41.30	49.62	57.71	62.79
UDA	44.24	50.09	57.66	61.30
Info	45.63	52.22	58.80	63.22
+ LM	48.67	53.53	59.04	**64.78**
Reference	**55.33**	**54.92**	**59.11**	64.26
Random (+RM)	42.32	50.10	58.53	63.29
UDA (+RM)	44.32	52.22	58.80	61.27
Info (+RM)	48.63	56.66	60.80	63.52
+ LM (+RM)	53.18	59.12	64.24	**65.38**
Reference (+RM)	**62.74**	**63.28**	**64.93**	65.27

Table 3: Ablation study for text augmentation with varying number of annotations. Experiments are performed on the E2E dataset. **LM** augmentation outperforms **Random** by a large margin, and even outperforming augmentation with ground-truth references on some occasions. Representation matching (**RM**) boosts the overall performance further.

Model	E2E			WebNLG		
	Fluency	Miss	Wrong	Fluency	Miss	Wrong
Seq2Seq	3.68	49	63	3.95	57	48
Cycle-only	4.08	46	66	4.23	48	44

seq2seq/info-aug: Blue Spice restaurant near Rainbow Vegetarian Café has a *5 star rating. prices start at £30.*

+LM-aug: located near Rainbow Vegetarian Café is a Chinese theme eatery and restaurant called Blue Spice. It is in the city centre area.

Figure 5: Generation examples with different text augmentation techniques. Trained on 5 data annotations (see the above toy training set). The attribute combination of input data is unseen in the 5 annotations. Hallucinated contents are *italitized*.

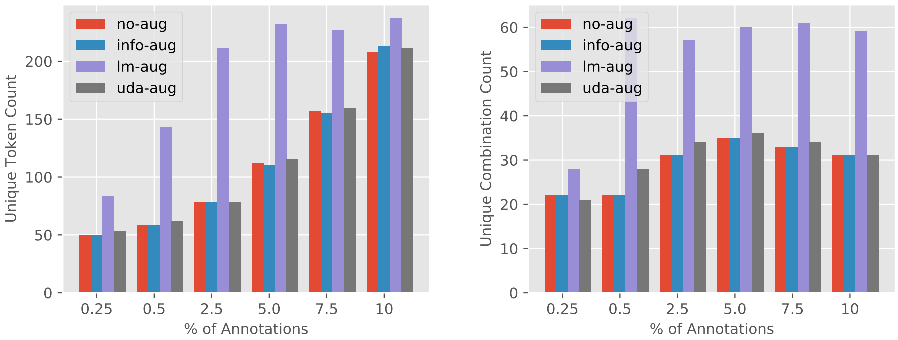

Figure 6: Additional number of decoded unique tokens (non-copied) and unique combinations of information on the testset with varying number of annotations.

harms the model performance, suggesting reasonable in-domain text augmentation are necessary for the model improvement. UDA augmentation also makes rather little difference as it simply paraphrases the current available annotations but cannot bring any new information. The information augmentation by slot-value replacement helps improve a bit. When combined with LM, the performance can be further boosted, especially for lower-resource scenarios. The representation matching always helps lift the performance, with gains of up to 10 BLEU points. As expected, the benefit from text augmentation gradually vanishes as more annotations are collected, especially for datasets with relatively simple patterns as E2E.

How text augmentation helps Intuitively the GPT-2 augmentation is expected to impose new tokens and combination patterns to the few-shot annotations. To investigate whether this is the case, for the decoded text in the test phase, we count the number of unique tokens (excluding copied data values) and unique information combination patterns (attribute combinations in E2E). The results in Fig. 6 show that LM-augmentation indeed greatly enriches the vocabulary space, even doubling the generated unique tokens in low-resource scenarios. The same happens for new combination patterns. In contrast, *info-aug* cannot insert new tokens or combinations at all since all it does is replacing data values based on the same text annotation. UDA can impose new tokens by paraphrasing the annotations, but it hardly helps the model generalize to new combinations of information. Moreover, when trained on a toy dataset, we observe from the generation outputs that Seq2seq and info-aug produce the wrong outputs and overfit to the information in the 5 training instances. With LM augmentation, it adapts to the new combination and connects information correctly. Figure 5 shows a generation example with different text augmentation techniques. We train the systems in a toy setting with only 5 data annotations (Trainset in the Appendix). We pick an input data with an unseen attribute combination to test if models can generalize correctly. Seq2seq and info-aug produce the wrong generation overfit to the information in the 5 training instances. With LM augmentation, it adapts to the new combination and connects information correctly.

Human Evaluation We further run a human evaluation on the model outputs to closely check the generation quality. We compared four types of models: the seq2seq baseline, seq2seq plus cycle-consistency as in Qader et al. (2019), finetuned GPT-2 as in Chen et al. (2020) and our proposed model. All models are LSTM-based apart from the finetuned GPT-2 one. We sample 100 data instances from the test set and apply all the models to generate corresponding text. The data and generated text are evaluated by 50 crowdworkers on Prolific[8]. For each data-text pair, the annotator is instructed to evaluate (1) if the text is fluent (score 0-5 with 5 being fully fluent), (2) if it misses information contained in the source data and (3) if it includes wrong information. The average fluency scores, count of information miss and wrong information are presented in Table 4. The scores are generally consistent with the automatic evaluation results, our proposed model outperforms other ones by a large margin, even though cycle-only can access all unpaired text and finetuned GPT-2 is significantly larger than our LSTM-based seq2seq. The generated text are more fluent, yet maintaining the information completeness and correctness to a large extent.

7 Conclusion

We study few-shot data-to-text generation with only limited annotated data. We propose text augmentation with slot-value replacement followed by GPT-2 generation. The augmented text, when combined with cycle consistency and representation matching, is shown to help the model to generalize to unseen new tokens and patterns of token combinations. With less than 10% annotations, it outperforms supervised seq2seq model trained on 100% annotations and is extensible enough to be combined with pretraining techniques.

Abstract

A sufficient amount of annotated data is usually required to fine-tune pre-trained language models for downstream tasks. Unfortunately, attaining labeled data can be costly, especially for multiple language varieties and dialects. We propose to self-train pre-trained language models in zero- and few-shot scenarios to improve performance on data-scarce varieties using only resources from data-rich ones. We demonstrate the utility of our approach in the context of Arabic sequence labeling by using a language model fine-tuned on Modern Standard Arabic (MSA) only to predict named entities (NE) and part-of-speech (POS) tags on several dialectal Arabic (DA) varieties. We show that self-training is indeed powerful, improving zero-shot MSA-to-DA transfer by as large as ~10% F_1 (NER) and 2% accuracy (POS tagging). We acquire even better performance in few-shot scenarios with limited amounts of labeled data. We conduct an ablation study and show that the performance boost observed directly results from training data augmentation possible with DA examples via self-training. This opens up opportunities for developing DA models exploiting only MSA resources. Our approach can also be extended to other languages and tasks.[1]

1 Introduction

Neural language models (Xu and Rudnicky, 2000; Bengio et al., 2003) with vectorized word representations (Mikolov et al., 2013) are currently core to a very wide variety of NLP tasks. In specific, using representations from transformer-based (Vaswani et al., 2017) language models (Devlin et al., 2018; Liu et al., 2019), pre-trained on large amounts of unlabeled data and then fine-tuned on labeled task-specific data, has become a popular approach for improving downstream task performance. This pre-training then fine-tuning scheme has been successfully applied to several tasks, including question answering (Yang et al., 2019), social meaning detection (Abdul-Mageed et al., 2020d), text classification (Liu et al., 2019), named entity recognition (NER), and part-of-speech (POS) tagging (Tsai et al., 2019; Conneau et al., 2019). The same setup also works well for cross-lingual learning (Lample and Conneau, 2019; Conneau et al., 2019).

Given that it is very expensive to glean labeled resources for all language varieties and dialects, a question arises: "How can we leverage resource-rich dialects to develop models nuanced to downstream tasks for resource-scarce ones?". In this work, we aim to answer this particular question by applying self-training to unlabeled target dialect data. We empirically show that self-training is indeed an effective strategy in *zero-shot* (where no gold dialectal data are included in training set, Section 4.2) and *few-shot* (where a given number of gold dialectal data points is included in training split, Section 4.4).

Our few-shot experiments reveal that self-training is always a useful strategy that *consistently* improves over mere fine-tuning, even when *all* dialect-specific gold data are used for fine-tuning. In order to understand why this is the case (i.e., why combining self-training with fine-tuning yields better results than mere fine-tuning), we perform an extensive error analysis based on our NER data. We discover that self-training helps the model most (% = 59.7) with improving false positives. This includes DA tokens whose MSA orthographic counterparts (Shaalan, 2014) are either named entities or trigger words that frequently co-occur with named entities in MSA. Interestingly, such out-of-MSA tokens occur in highly dialectal contexts (e.g., interjections and idiomatic expressions employed in interpersonal social media communication) or ones

where the social media context in which the language (DA) is employed affords more freedom of speech (Alshehri et al., 2020) and a platform for political satire. We present our error analysis in Section 5.

Context: Language use in social media tends to diverge from 'standard', offline norms (Danet and Herring, 2007; Herring et al., 2015). For example, users employ slang, emojis, abbreviations, letter repetitions, and other types of playful practices. This poses a challenge for processing social media data in general. However, there are other challenges specific to Arabic that motivate our work. More specifically, we choose Arabic to apply our approach since it affords a rich context of linguistic variation: In addition to the standard variety, MSA, Arabic also has several spoken dialects (Abdul-Mageed et al., 2018; Bouamor et al., 2019; Abdul-Mageed et al., 2020b,c), which differ significantly from the written MSA (Zaidan and Callison-Burch, 2014) thus offering an excellent context for studying our problem. Arabic dialects differ among themselves and from MSA at various linguistic levels: lexical, phonological, morphological, and syntactic. This makes our case much more challenging than that of standard vs. social media English, for example. For a good zero-shot performance in our case, a model is required to accommodate not only lexical distance between MSA and DA, but also differences in word formation and syntax (related to POS tags, for example) and lexical ambiguity (as the meaning of the same token can vary cross-dialectically). This makes the zero-shot setting even harder, where the performance drops 20% F1 points (See section 4.2).

From a geopolitical perspective, Arabic also has a strategic significance. This is a function of Arabic being the native tongue of 400 million speakers in 22 countries, spanning across two continents (Africa and Asia)[2]. In addition, the three dialects of our choice, namely Egyptian (EGY), Gulf (GLF), and Levantine (LEV), are popular dialects that are widely used online. This makes our resulting models highly useful in practical situations at scale. Pragmatically, ability to develop NLP systems on dialectal tasks with no-to-small labeled dialect data immediately eases a serious bottleneck. Arabic dialects differ among themselves and from MSA at all linguistic levels, posing challenges to traditional NLP approaches. We also note that our method is language-independent, and we hypothesize it can be directly applied to other varieties of Arabic or in other linguistic contexts for other languages and varieties.

Tasks: We apply our methods on two sequence labeling tasks, where we have access to both MSA and DA gold data. In particular, as mentioned above, we perform experiments on POS tagging and NER. Each of these tasks has become an integral part of various other NLP applications, including question answering, aspect-based sentiment analysis, machine translation, and summarization, and hence our developed models should have wide practical use. Again, we note that our approach itself is task-independent. The same approach can thus be applied to other tasks involving DA. We leave testing our approach on other languages, varieties, and tasks for future research.

Contributions: Our work offers the following contributions:

1. We study the problem of MSA-to-DA transfer in the context of sequence labeling and show that when training on MSA data only, a wide performance gap exists between testing on MSA and DA. That is, models fine-tuned on MSA generalize poorly to DA in zero-shot settings.
2. We propose self-training to improve zero- and few-shot MSA-to-DA transfer. Our approach requires little-to-no labeled DA data. We evaluate extensively on 3 different dialects, and show that our method indeed narrows the performance gap between MSA and DA by a margin as wide as $\sim$10% F_1 points.
3. We develop state-of-the-art models for the two sequence labeling tasks (NER and POS).

We now introduce our method.

2 Method

While the majority of labeled Arabic datasets are in MSA, most daily communication in the Arab world is carried out in DA. In this work, we show that models trained on MSA for NER and POS tagging generalize poorly to dialect inputs when used in zero-shot-settings (i.e., no dialect data used during training). Across the two tasks, we test how self-training would fare as an approach to leverage unlabeled DA data to improve performance

```

on DA. As for self-training, it involves training a model using its own predictions on a set of unlabeled data identical from its original training split. Our proposed self-training procedure is given two sets of examples: a labeled set L and an unlabeled set U. To perform zero-shot MSA-to-DA transfer, MSA examples are used as the labeled set, while unlabeled DA examples are the unlabeled set. As shown in Figure 1, each iteration of the self-training algorithm consists mainly of three steps. First, a pre-trained language model is fine-tuned on the labeled MSA examples L. Second, for every unlabeled DA example u_i, we use the model to tag each of its tokens to obtain a set of predictions and confidence scores for each token $p_{u_i} = (l_1^{(i)}, c_1^{(i)}), (l_2^{(i)}, c_2^{(i)}), ...(l_{|u_i|}^{(i)}, c_{|u_i|}^{(i)})$, where $(l_j^{(i)}, c_j^{(i)})$ are the label and confidence score (softmax probability) for the j-th token in u_i. Third, we employ a selection mechanism to identify examples from U that are going to be added to L for the next iteration.

For a selection mechanism, we experiment with both a thresholding approach and a fixed-size (Dong and de Melo, 2019) approach. In the thresholding method, a threshold τ is applied on the minimum confidence per example. That is, we only add an example u_i to L if $\min_{(l_j^{(i)}, c_j^{(i)}) \in p_{u_i}} c_j^{(i)} \geq \tau$. See Algorithm 1. The fixed-size approach involves, at each iteration, the selection of the top S examples with respect to the minimum confidence score $\min_{(l_j^{(i)}, c_j^{(i)}) \in p_{u_i}} c_j^{(i)}$, where S is a hyper-parameter. We experiment with both approaches and report results in Section 4.

For our language model, we use XLM-RoBERTa (Conneau et al., 2019), XML-R for short. XLM-R is a cross-lingual model, and we choose it since it is reported to perform better than the multilingual mBERT (Devlin et al., 2018). XLM-R also uses Common Crawl for training, which is more likely to have dialectal data than the Arabic Wikipedia (used in mBERT), making it more suited to our work. We now introduce our experiments.

3 Experiments

We begin our experiments with evaluating the standard fine-tuning performance of XLM-R models on both NER and POS tagging against strong baselines. We then use our best models from this first round to investigate the MSA-to-DA zero-shot transfer, showing a significant performance drop even when using pre-trained XLM-R. Consequently, we employ self-training for both NER and POS tagging in zero- and few-shot settings, showing substantial performance improvements in both cases. We now introduce our datasets.

3.1 Datasets

NER: For our work on NER, we use 4 datasets: ANERCorp (Benajiba et al., 2007), ~150K tokens; ACE 2003 (Mitchell et al., 2003) BNews (BN-2003), ~15K tokens; ACE 2003 Newswire (NW-2003), ~27K tokens; and Twitter (Darwish, 2013), ~81K tokens. Named entity types in all datasets are *location (LOC)*, *organization (ORG)*, and *person (PER)*.

POS Tagging: There are a number of Arabic POS tagging datasets, mostly on MSA (Maamouri et al., 2004) but also on dialects such as EGY (Maamouri et al., 2014). To show that the proposed approach is able to work across multiple dialects, we ideally needed data from more than one dialect. Hence, we use the multi-dialectal dataset from (Darwish et al., 2018), comprising 350 tweets from each of the 4 varieties MSA, EGY, GLF and LEV. This dataset has 21 POS tags, some of which are suited to social media (since it is derived from Twitter). We show the POS tag set from (Darwish et al., 2018) in Table 10 in Appendix A. We now introduce our baselines.

3.2 Baselines

For the **NER task**, we use the following baselines:

- **NERA (Abdallah et al., 2012)**: A hybrid system of rule-based features and a decision tree classifier.
- **WC-BiLSTM (Gridach, 2016)**: A character- and a word-level Bi-LSTM with a conditional random fields (CRF) layer.
- **WC-CNN (Khalifa and Shaalan, 2019)**: A character- and a word-level CNN with a CRF layer.
- **mBERT (Devlin et al., 2018)**: A fine-tuned multilingual BERT-Base-Cased (110M parameters), pre-trained with a masked language modeling objective on the Wikipedia corpus of 104 languages (including Arabic). For fine-tuning, we find that (based on experiments on our development set) a learning rate of 6×10^{-5} works best with a dropout of 0.1.

In addition, we compare to the published results in (Shaalan and Oudah, 2014), AraBERT (Antoun et al., 2020), and CAMel (Obeid et al., 2020) for the ANERCorp dataset. We also compare to the published results in (Khalifa and Shaalan, 2019) for the 4 datasets.

For the **POS tagging task**, we compare to our own implementation of WC-BiLSTM (since there is no published research that uses this method on the task, as far as we know) and run mBERT on our data. We also compare to the CRF results published by (Darwish et al., 2018). In addition, for the Gulf dialect, we compare to the BiLSTM with compositional character representation and word representations (CC2W+W) published results in (Alharbi et al., 2018).

3.3 Experimental Setup

Our main models are XLM-RoBERTa base architecture XLM-R$_\text{B}$ $(L = 12, H = 768, A = 12,$ 270M params) and XLM-RoBERTa large architecture XLM-R$_\text{L}$ $(L = 24, H = 1024, A = 16,$ 550M params), where L is number of layers, H is the hidden size, A is the number of self-attention heads. For XLM-R experiments, we use Adam optimizer with $1e^{-5}$ learning rate, batch size of 16. We typically fine-tune for 20 epochs, keeping the best model on the development set for testing. We report results on the test split for each dataset, across the two tasks. For all BiLSTM experiments, we use the same hyper-parameters as (Khalifa and Shaalan, 2019).

For the standard fine-tuning experiments, we use the same train/development/test split as in (Khalifa and Shaalan, 2019) for NER, and the same split provided by (Darwish et al., 2018) for POS tagging. For all the self-training experiments, we use the dialect subset of the Arabic online news commentary (AOC) dataset (Zaidan and Callison-Burch, 2011), comprising the EGY, GLF, and LEV varieties limiting to equal sizes of 9K examples per dialect (total =27K) [3]. We use the split from (Elaraby and Abdul-Mageed, 2018) of AOC, removing the dialect labels and just using the comments themselves for our self-training. Each iteration involved fine-tuning the model for $K = 5$ epochs. As a stopping criterion, we use early stopping with patience of 10 epochs. Other hyper-parameters are set as listed before. For selecting confident samples, we experiment with a fixed number of top samples $S = [50, 100, 200]$ and selection based on a probability threshold $\tau = [0.80, 0.90, 0.95]$ (softmax values) [4]. For all evaluations, we use the *seqeval* toolkit.[5]

4 Results

4.1 Fine-tuning XLM-R

Here, We show the resuts of standard fine-tuning of XLM-R for the two tasks in question. We start by showing the result of fine-tuning XLM-R on the **named entity task**, on each of the 4 Arabic NER (ANER) datasets listed in Section 3.1. Table 1 shows the test set macro F$_1$ score on each of the 4 ANER datasets. Clearly, the fine-tuned XLM-R models outperform other baselines on all datasets,

---

[3] We note that our approach could be scaled with an even bigger unlabeled dataset, given the performance gains we report with self-training in this work.

[4] It is worth noting that our S values are similar to those used in (Dong and de Melo, 2019). We also experimented with other values for τ and S, but found them sub-optimal and hence we report performance only for the listed values of these two hyper-parameters here.

[5] `https://github.com/chakki-works/seqeval`.

except on the NW-2003 where WC-CNN (Khalifa and Shaalan, 2019) performs slightly better than XLM-R_L.

For **POS Tagging**, Table 2 shows test set word accuracy of the XLM-R models compared to baselines. Again, XLM-R models (both base and large) outperform all other models. A question arises why XLM-R models outperform both mBERT and AraBERT. As noted before, for XLM-R vs. mBERT, XLM-R was trained on much larger data: CommonCrawl for XLM-R vs. Wikipedia for mBERT. Hence, the *larger dataset* of XLM-R is giving it an advantage over mBERT. For comparison with AraBERT, although the pre-training data for XLM-R and AraBERT may be comparable, even the smaller XLM-R model (XLM-R_B) has more than twice the number of parameters of the BERT_BASE architecture on which AraBERT and mBERT are built (270M v. 110M). Hence, XLM-R model *capacity* gives it another advantage. We now report our experiments with zero-shot transfer from MSA to DA.

4.2 MSA-DA Zero-Shot Transfer

We start by the discussion of **NER experiments**. Since there is no publicly available purely dialectal NER dataset on which we can study MSA-to-DA transfer, we needed to find DA data to evaluate on. We observed that the dataset from (Darwish, 2013) contains both MSA and DA examples (tweets). Hence, we train a binary classifier[6] to distinguish DA data from MSA. We then extract examples that are labeled with probability $p > 0.90$ as either DA or MSA. We obtain 2,027 MSA examples (*henceforth*, `Twitter-MSA`) and 1,695 DA examples (*henceforth*, `Twitter-DA`), respectively. We split these into development and test sets with 30% and 70% ratios. As **for POS Tagging**, we already have the three previously used DA datasets, namely EGY, GLF and LEV. We use those for the zero-shot setting by omitting their training sets and using only the development and test sets.

We first study how well models trained for NER and POS tagging on MSA data only will generalize to DA inputs during test time. We evaluate this zero-shot performance on both the XLM-R_B and XLM-R_L models. **For NER**, we train on ANERCorp (which is pure MSA) and evaluate on both Twitter-MSA and Twitter-DA. While for POS tagging, we train on the MSA subset (Darwish et al., 2018) and evaluate on the corresponding test set for each dialect. As shown in Table 3, for NER, a significant generalization gap of around 20 % F_1 points exists between evaluation on MSA and DA using both models. While for **POS tagging**, the gap is as large as 18.13 % accuracy for the LEV dialect with XLM-R_B. The smallest generalization gap is on the GLF variety, which is perhaps due to the high overlap between GLF and MSA (Alharbi et al., 2018). In the next section, we evaluate the ability of self-training to close this MSA-DA performance gap.

4.3 Zero-shot Self-Training

Here, **for NER**, similar to Section 4.2, we train on ANERCorp (pure MSA) and evaluate on Twitter-MSA and Twitter-DA. Table 4 shows self-training NER results employing the selection mechanisms listed in Section 2, and with different values for S and τ. The best improvement is achieved with the thresholding selection mechanism with a $\tau = 0.90$, where we have an F_1 gain of 10.03 points. More generally, self-training improves zero-shot performance in all cases albeit with different F_1 gains. It is noteworthy, however, that the much higher-capacity large model deteriorates on MSA if self-trained (dropping from 68.32% to 67.21%). This shows the ability of the large model to learn representations very specific to DA when self-trained. It is also interesting to see that the best self-trained base model achieved 50.10% F_1, outperforming the large model before the latter is self-trained (47.35% in the zero-shot setting). As such, we conclude that ***a base self-trained model, with less computational capacity, can (and in our case does) improve over a large (not-self-trained) model*** *that needs significant computation*. The fact that, when self-trained, the large model improves 15.35% points over the base model in the zero-shot setting (55.42 vs. 40.07) is remarkable.

As **for POS tagging**, we similarly observe consistent improvements in zero-shot transfer with self-training (Table 5). The best model achieves accuracy gains of 2.41% (EGY), 1.41% (GLF), and 1.74% (LEV). Again, this demonstrates the utility of self-training pre-trained language models on the POS tagging task even in absence of labeled dialectal POS data (zero-shot).

---

[6] The model we use is XLM-R_B fine-tuned on the AOC using (Elaraby and Abdul-Mageed, 2018) split. We achieve development and test accuracies of 90.3% and 89.4 %, respectively, outperforming the best results in (Elaraby and Abdul-Mageed, 2018).

Table 2: Test set accuracy for POS Tagging.

4.4 Few-Shot Self-Training

We also investigate whether self-training would be helpful in scenarios where we have access to some gold-labeled DA data (as is the case with POS tagging). Here, we evaluate the few-shot performance of self-training as increasing amounts of predicted DA data are added to the gold training set. This iteration of experiments focuses exclusively on **POS tagging**, using a fixed-size $S = 100$ of predicted cases for self-training and the XLM-R base model. Figure 2 shows how POS tagging test accuracy improves as the percentage of gold DA examples added to the MSA training data increases from 0% to 100% on the three dialects (EGY, GLF, and LEV). Comparing these results to those acquired via the standard fine-tuning settings without self-training, we find that self-training does *consistently* improve over fine-tuning. This improvement margin is largest with only 20% of the gold examples.

4.5 Ablation Study

Here, we conduct an ablation study with the NER task as our playground in order to verify our hypothesis that the performance boost primarily comes from using unlabeled DA data for self-training. By using a MSA dataset with the same size as our unlabeled DA one[7], we can compare the performance of the self-trained model in both settings: MSA and DA unlabeled data. We run 3 different self-training experiments using 3 different values for τ using each type of unlabeled data. Results are shown in table 6. While we find slight performance boost due to self-training even with MSA unlabeled data, the average F1 score with unlabeled DA is better by 2.67 points, showing that using unlabeled DA data for self-training has helped the model adapt to DA data during testing.

5 Error analysis

To understand why self-training the pre-trained language model, when combined with fine-tuning, improves over mere fine-tuning, we perform an error analysis. For the error analysis, we focus on the NER task where we observe a huge self-training gain. We use the development set of Twitter-DA (See section 4.3) for the error analysis. We compare predictions of the standard fine-tuned XLM-R_B model (FT) and the best performing self-training ($\tau = 0.9$) model (ST) on the data, and provide the confusion matrices of both models with gold labels in Table 11 (in Appendix B). The error analysis leads to an interesting discovery: The greatest benefit from the ST model comes mostly from reducing *false positives* (see Table 7). In other words, self-training helps regularize the model predictions such that tokens misclassified by the original FT model as a named entities are now correctly tagged as *unnamed entity* "O".

To understand why the ST model improves false positive rate, we manually inspect the cases it cor-

---

[7] We use a set of MSA tweets from the AOC dataset mentioned before.

Model	NER		POS			
	MSA	DA	MSA	EGY	GLF	LEV
XLM-R$_B$	60.42	40.07	96.30	78.38	83.72	78.17

Table 5: Zero-shot POS tagging transfer accuracy when training on MSA only. **ST:** self-training.

rectly identifies that were misclassified by the FT model. We show examples of these cases in Table 8. As the table shows, the ST model is able to identify dialectal tokens whose equivalent MSA forms can act as trigger words (usually followed by a PER named entity). We refer to this category as ***false trigger words***. An example is the word نبي "prophet" (row 1 in Table 8). A similar example that falls within this category is in row (2), where the model is confused by the token الى ("who" in EGY, but "to" in MSA and hence the wrong prediction as LOC). A second category of errors is caused by ***non-standard social media language***, such as use of letter repetition in interjections (e.g., in row (3) in Table 8). In these cases, the FT model also assigns the class PER, but the ST model correctly identifies the tag as "O". A third class of errors arises as a result of ***out-of-MSA*** vocabulary. For example, the words in rows (4-6) are all out-of-MSA where the FT model, not knowing these, assigns the most frequent named entity label in train (PER). A fourth category of errors occurs as a result of a token that is usually part of a named entity in MSA, that otherwise functions as part of an ***idiomatic expression*** in DA. Row (7) in Table 8 illustrates this case. Table 12 in Appendix B provides more examples.

We also investigate errors shared by both the FT and ST models (errors which the ST model also could not fix). Some of these errors result from the fact that often times both MSA and DA use the same word for both person and location names.

Setting	Unlabeled MSA	Unlabeled DA
ST, $\tau = 0.80$	43.88	44.46
ST, $\tau = 0.90$	44.69	47.83
ST, $\tau = 0.95$	43.43	46.87
Avg	43.67	**46.34**

Table 6: Ablation experiment with MSA unlabeled data for zero-shot NER. Development set macro F1 is shown when using both unlabeled MSA and DA data with the same size. Average performance with DA unlabeled data is higher showing the effect of unlabeled DA on model final performance.

Measure	FT	ST	% improvement
True Positives	155	165	6.5 %
False Positive	159	64	**59.7 %**
False Negative	162	168	-3.7 %
True Negative	5,940	6,035	1.5 %

Table 7: Comparison of error categories in percentage between the fine-tuned model (FT) and the model combining fine-tuned+self-trained (ST) model, based on the dialectal part of the dev set of the NER task.

Row (1) in Table 13 (in Appendix B) is an example where the word "Mubarak", name of the ex-Egypt President, is used as LOC. Other errors include *out-of-MSA* tokens mistaken as named entities. An example is in row (3) in Table 13, where بأمارة ,("proof" or "basis" in EGY) is confused for بإمارة ("emirate", which is a location). *False trigger words*, mentioned before, also play a role here. An example is in row (7) where يابطل is confused for PER due to the trigger word يا "Hey!" that is usually followed by a person name. ***Spelling mistakes*** cause the third source of errors, as in row (4). We also note that even with self-training, detecting ORG entities is more challenging than PER or LOC. The problem becomes harder when such organizations are not seen in training such as in rows (8) الاخوان المسلمين, (9) قناة العربية and (10) المجلس العسكري, all of which do not occur in the training set (ANERCorp).

False negatives. The "regularizing" effect caused by self-training we discussed thus far can sometimes produce *false negatives* as shown in Table 9. We see a number of named entities that were misclassified by the self-trained model as unnamed ones. As an example, we take the last name الجنزوري which was classified both correctly and incorrectly in different contexts by the self-trained model. Context of correct classification is "هاش تاج لكمال الجنزوري", while it is "ماسك على الناس كلها سي دي الا الجنزوري ماسك عليه فلوبي" for the incorrect classification. First, we note that الجنزوري is not a common name (zero occurrences in the MSA training set). Second, we observe that in the correct case, the word was preceded by the first name كمال which was correctly classified as PER, making it easier for the model to assign PER to the word afterwards as a surname.

6 Related Work

Sequence Labeling. Recent work on sequence labeling usually involves using a word- or character-level neural network with a CRF layer (Lample et al., 2016; Ma and Hovy, 2016). These architectures have also been applied to Arabic sequence tagging (Gridach, 2016; Alharbi et al., 2018; Khalifa and Shaalan, 2019; Al-Smadi et al., 2020; El Bazi and Laachfoubi, 2019), producing better or comparable results to classical rule-based approaches (Shaalan and Oudah, 2014). We refer the interested reader to (Shoufan and Alameri, 2015) and (Al-Ayyoub et al., 2018) for surveys on Arabic NLP.

Pre-trained Language Models. Language models, based on Transformers (Vaswani et al., 2017), and pre-trained with the masked language modeling (MLM) objective have seen wide use in various NLP tasks. Examples include BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), MASS (Song et al., 2019), and ELECTRA (Clark et al., 2020). While they have been applied to several tasks, including text classification, question answering, named entity recognition (Conneau et al., 2019), and POS tagging (Tsai et al., 2019), a sufficiently large amount of labeled data is required for good performance. Concurrent with our work, Abdul-Mageed et al. (2020a) released MARBERT, a language model trained on a large amount of dialectal Arabic data. However, the extent to which dialect-specific models such as MARBERT can alleviate lack of labeled data remains untested.

Cross-lingual Learning. Cross-lingual learning is of particular importance due to the scarcity of labeled resources in many of the world's languages. The goal is to leverage existing labeled resources in high-resource languages (such as English) to optimize learning for low-resource ones. In our case, we leverage MSA resources for building DA models. With proximity to our work, Kim et al. (2017) trained a POS tagger for different languages

no.	Token	Eng.	MSA	Context/Explanation	FT Pred.
(1)	نبي	we want	نريد	نبي نعرف من... (*we want to know who*)	PER
(2)	ماكانوا	wasn't	لم يكونوا	أغلب الي ماكانوا مصدقين (*most of those who wasn't believing*)	LOC

(6)	زين يسون	PER	PER	O

Table 9: **NER task.** Sample false negatives produced by self-training.

using English-resources only using two BiLSTM networks to learn common and language-specific features. Xie et al. (2018) made use of bilingual word embeddings with self-attention to learn cross-lingual NER for low-resource languages.

Multilingual extensions of LMs have emerged through joint pre-training on multiple languages. Examples include mBERT (Devlin et al., 2018), XLM (Lample and Conneau, 2019) and XLM-RoBERTa (Conneau et al., 2019). Such multilingual models have become useful for few-shot and zero-shot cross-lingual settings, where there is little or no access to labeled data in the target language. For instance Conneau et al. (2019) evaluated a cross-lingual version of RoBERTa (Liu et al., 2019), namely XLM-R, on cross-lingual learning across different tasks such as question answering, text classification, and named entity recognition.

Self-Training. Self-Training is a semi-supervised technique to improve learning using unlabeled data. Self-training has been successfully applied to NER (Kozareva et al., 2005), POS tagging (Wang et al., 2007), parsing (Sagae, 2010) and text classification (Van Asch and Daelemans, 2016). Self-training has also been applied in cross-lingual settings when gold labels are rare in the target language. Hajmohammadi et al. (2015) proposed a combination of active learning and self-training for cross-lingual sentiment classification. Pan et al. (2017) made use of self-training for named entity tagging and linking across 282 different languages. Lastly, Dong and de Melo (2019) employed self-training to improve zero-shot cross-lingual classification with mBERT (Devlin et al., 2018).

7 Conclusion

Even though pre-trained language models have improved many NLP tasks, they still need labeled data for fine-tuning. We show how self-training can boost the performance of pre-trained language models in zero- and few-shot settings on various Arabic varieties. We apply our approach to two sequence labeling tasks (NER and POS), establishing new state-of-the-art results on both. Through in-depth error analysis and an ablation study, we uncover why our models work and where they can fail. Our method is *language*- and *task-agnostic*, and we believe it can be applied to other tasks and language settings. We intend to test this claim in future research. Our research also has bearings to ongoing work on language models and self-training, and interactions between these two areas can be the basis of future work. All our models and code are publicly available.

Multiple Tasks Integration: Tagging, Syntactic and Semantic Parsing as a Single Task

Timothée Bernard[*]
LLF, Université de Paris, France
`timothee.bernard@ens-lyon.org`

Abstract

Departing from both sequential pipelines and monotask systems, we propose Multiple Tasks Integration (MTI), a multitask paradigm orthogonal to weight sharing. The essence of MTI is to process the input iteratively but concurrently at multiple levels of analysis, where each decision is based on all of the structures that are already inferred and free from usual ordering constraints. We illustrate MTI with a system that performs part-of-speech tagging, syntactic dependency parsing and semantic dependency parsing. We observe that both the use of reinforcement learning and the release from sequential constraints are beneficial to the quality of the syntactic and semantic parses. We also observe that our model adopts an easy-first strategy that consists, on average, of predicting shorter dependencies before longer ones, but that syntax is not always tackled before semantics.

1 Introduction

Historically, Natural Language Processing (NLP) systems have generally been built as sequential pipelines, where each module adds another layer of annotation, in order of (supposed) increasing complexity. Progress in neural networks has, however, led to the development of state-of-the-art systems that completely bypass intermediate levels of analysis that were previously considered essential. For example, the system of Zhou and Xu (2015) perform Semantic Role Labeling (SRL; Carreras and Màrquez, 2005) without referring to any explicit (morpho)syntactic information.

A well known problem of sequential systems is *error propagation*, which happens when an incorrect prediction at some point in the process leads to more incorrect predictions at a later stage. In traditional pipelines, one of the roots of error propagation lies in the fact that they feature a unidirectional flow of annotation between their different stages.

End-to-end systems with no intermediate level of analysis, in contrast, are protected against one form of error propagation. Since such systems are not contingent on possibly faulty levels of analysis, they are free from the interference they could cause. However, the absence of any intermediate decisions — symbolic traces of the system's computation — raises questions about generalisation ability and interpretability (Lipton, 2018). What is more, by reducing the information in the prediction and training signals at their disposal, they might not leverage the full power of the neural networks they are usually based on. Indeed, in their reintroduction of syntactic dependencies to the training process, Strubell et al. (2018) managed to develop a state-of-the-art system for SRL that at the same time computes good-quality syntactic parses.

Departing from these two kinds of architectures, we propose *Multiple Tasks Integration* (MTI). The principles of MTI are (i) to let the system take actions pertaining to different levels of analysis without constraining their order, and (ii), at any given point of the process, to feed all layers of annotation as input for the next predictions. The different tasks can therefore fully interact with each other as if they were a single task. Our main contribution lies in an illustration of these principles with a system that performs part-of-speech (POS) tagging, syntactic dependency parsing and semantic dependency parsing (SDP), on English data. We have chosen these specific tasks not only for their strong interdependence but also for their generality: many other tasks in NLP (e.g. SRL, coreference resolution, relation extraction) can be reduced to labelling or bi-lexical dependencies creation problems. We show that in this specific case, letting the system order freely its actions across all three tasks leads to better performance, and that this im-

provement concerns the syntactic layer as well as the semantic one, although to a lesser extent.

2 Related work

Fighting error propagation Lê and Fokkens (2017) identify two kinds of error propagation. First, error propagation happens when an incorrect action makes a subsequent correct action unavailable, because the two are logically inconsistent. Second, it also happens when an action leads to an unusual state (unseen during the training process), thus disrupting the system in such a way that a subsequent correct action is not taken even though both are logically compatible.

Since its apparition for speech recognition (Lowerre, 1976), *beam search* has become ubiquitous in NLP and artificial intelligence. Exploring multiple paths of actions in parallel instead of a single one mitigates the risk of error propagation of both kinds. An orthogonal approach consists in designing systems able to attain the gold annotation via multiple paths (usually involving different orderings of subsequences of actions) and training them to infer an *easy-first strategy*. Such a strategy corresponds to performing easy actions first so as to maximise the amount of reliable information available when having to tackle harder decisions. This idea has been applied to various NLP problems (Shen et al., 2007; Goldberg and Elhadad, 2010; Stoyanov and Eisner, 2012; Xie et al., 2015), but, to the extent of our knowledge, only in single-task contexts. Another promising research direction is the one of *iterative refinement*. The idea here is to use a baseline system in order to produce an initial output and to then correct it, possibly multiple times, with a refinement system that has access to both the previous output and the input of the problem. Iterative refinement techniques have been used for tasks such as machine translation (Lee et al., 2018) and SRL (Lyu et al., 2019).

Other techniques are designed to help to fight error propagation of the second kind, which focus on the training of the system to make it robust to its own mistakes. One possibility consists in training the system to predict the next best action in any state it find itself in, instead of simply staying on the (errorless) gold path. Doing so requires the possibility for a next best action to be determined, which, while trivial in some cases such as POS tagging, is not in others, in particular for structured prediction. Hence the introduction of the notion of *dynamic oracle* by Goldberg and Nivre (2012) for syntactic parsing. An alternative is *reinforcement learning* (RL; Sutton and Barto, 2018), which also trains the system from its actual trajectories, but depends instead on *rewards* defined for each action in the particular state it is taken. Note that in adequate settings, RL has been shown to lead to the emergence of easy-first strategies. This is the case in semantic parsing, as shown in the work of Kurita and Søgaard (2019), which we extend here to both POS tagging and syntactic parsing following our proposed Multiple Tasks Integration principles rather than implementing a traditional MultiTask Learning scheme.

MultiTask Learning (MTL) The main idea behind MTL is that one can often increase the performance of a given neural-based system by sharing some of its weights with other systems trained to perform other tasks (Caruana, 1997). Doing so tends to strengthen the training signal of the shared parts and to drive the model to develop richer and more relevant distributional representations. Refer to the texts of Ruder (2017) and Zhang and Yang (2018) for reviews of the wide NLP literature on the subject.

While MTL deals with tasks usually done rather independently, an alternative approach — which does not require weight sharing — is explored by Peng et al. (2018a). They work with pipelines where intermediate layers are expressed as solving a constrained maximisation problem, a setting for which they develop a technique, SPIGOT, to backpropagate gradient through argmax operations (which are discrete, hence non-differentiable). This allows for a lower module to be trained to predict structures used by a higher module so as to optimise the predictions of the latter. Note that the gain in performance obtained by introducing SPIGOT in a pipeline cannot necessarily be attributed to a reduction in error propagation: a lower module might end up generating less accurate yet more helpful predictions.

Joint syntactic-semantic parsing In 2008 and 2009, the CoNLL shared tasks were focused on the joint parsing of syntactic and SRL-based semantic dependencies (Surdeanu et al., 2008; Hajič et al., 2009). Most participants developed sequential systems that parse syntax before semantics, one notable exception being the proposal of Henderson et al. (2008), further developed by Henderson et al.

(2013) and on which the work of Swayamdipta et al. (2016) is based. These joint parsers are transition-based systems that alternate between sequences of syntactic actions and semantic ones. Both types of actions share the same symbolic structure, meaning that these systems allow for a strong interaction between syntax and semantics. While they exhibit no sequentiality globally over the two subtasks, the alternation of actions still enforces a strict ordering locally: once a new token is shifted from the input queue, it is processed syntactically before being processed semantically. This contrasts with the method adopted by Constant and Nivre (2016) for joint syntactic parsing and multiword expression detection, who compute, at each time step, a distribution of probability over actions pertaining to both tasks — as in our system. However, their linear (left-to-right) processing still imposes strong constraints on possible action orders.

More recently, Strubell et al. (2018) designed a model for SRL on the basis of the transformer architecture (Vaswani et al., 2017) in which one attention head is trained to attend to the syntactic head of the corresponding tokens. At inference time, the model is able to recover good-quality syntactic parses after (argmax) discretisation of the attention vectors. In this system and in stark contrast with our approach, the interaction between the two tasks can only take place during the single pass within the transformer network, where SRL and syntactic dependencies are only present under distributional forms (what we could call the "distributional soup of information"), before they are independently discretised into symbolic structures.

Semantic Dependency Parsing (SDP) The SDP task, introduced for the SemEval workshop (Oepen et al., 2014, 2015), represents semantic analysis as a directed acyclic graph (DAG) the nodes of which are tokens of the sentence. This means that each token may have zero or more parents. In addition, zero or more tokens in each sentence may be annotated as *top predicates*.

A wide range of techniques has been applied in the literature in order to tackle SDP. Peng et al. (2017, 2018b,a) propose graph-based constrained maximisation systems based on the AD^3 decoding algorithm (Martins et al., 2011). Dozat and Manning (2018) adapt a graph-based syntactic parser to DAG parsing while Wang et al. (2018) adapt a transition-based one. Zhang et al. (2019) present a very general sequence to graph transduction system. Wang et al. (2019) obtain excellent results by scoring not only the potential dependencies but also some of the potential pairs of dependencies. A second-order parser is thus defined, which relies on a (differentiable) mean field variational inference layer (or, alternatively, a loopy belief propagation one). The model closest to ours is the one of Kurita and Søgaard (2019), who see SDP as an iterated head-selection problem. They take inspiration from Zhang et al. (2017)'s system, which builds a syntactic tree by selecting a head for each token and correcting the corresponding dependencies with well-formedness heuristics. In this work, we see both syntactic and semantic parsing head-selection problems, that we tackle jointly with POS tagging.

3 Model

3.1 Overview

We define six types of *actions*. Relative to a token i, TAG-t corresponds to tagging i with POS tag t, SYN-j-l to creating a syntactic dependency labelled l from token j to i, ROOT to setting i as the (syntactic) root, SEM-j-l to creating a semantic dependency labelled l from token j to i, TOP_PRED to setting i as a (semantic) top predicate and, finally, HALT to doing nothing.

The inference process is summarised in Algorithm 1. At each time step s, the system first encodes the current state of the analysis into a sequence of one vector per token. These encodings contain information from the three different layers of annotation being built. Then, for each token i independently, its *policy* — a distribution of probability over all possible actions (TAG-t, SYN-j-l, etc.) —, $\pi_{i,s}$, is computed. From each policy $\pi_{i,s}$, an action $a_{i,s}$ is then selected and performed, thus enriching the annotation structure.[1] This means that, at any given step, one action per token is applied, as opposed to a single action for (typical) transition systems. At that point, either the next step starts, or, in case all tokens selected the HALT action, the analysis (or *episode*) stops.[2]

The system is designed to perform one action per token at each time step for computational reasons. Indeed, doing so allows to drastically reduce the number of steps required to analyse a sentence.

---

[1] During training, we sample from the distribution. At inference time, we take the argmax.

[2] If s reaches a limit $s_{\max}$, HALT is imposed to all tokens, leading to the end of the episode. $s_{\max}$ is set to 1.5 times the minimum number of steps required to correctly analyse any training instance (namely, 12).

Algorithm 1: Inference algorithm

```
input: A sentence $\mathbf{x}$.
Initialise empty POS tag, syntactic and
  semantic annotation structures:
  $(s_{\text{tag}}, s_{\text{syn}}, s_{\text{sem}})$;
$s \longleftarrow 0$;
$continue \longleftarrow True$;
while $continue = True$ do
    $\mathbf{l} \longleftarrow encode(\mathbf{x}, s_{\text{tag}}, s_{\text{syn}}, s_{\text{sem}})$;
    for $i \in shuffle([\![1, |\mathbf{x}|]\!])$ do
        if $s < s_{max}$ then
            $\pi_i \longleftarrow policy(l_i)$;
            $a_i \longleftarrow select(\pi_i)$;
        else
            $a_i \longleftarrow$ HALT;
        apply $a_i$ on $(s_{\text{tag}}, s_{\text{syn}}, s_{\text{sem}})$;
    if $\forall i,\ a_i =$ HALT then
        $continue \longleftarrow False$;
    $s \longleftarrow s + 1$;
return $(s_{tag}, s_{syn}, s_{sem})$
```

Note that this does not entail that analyses are three steps long, as (i) tokens can have more than a single semantic head and (ii) any token can decide to wait with a HALT action.

We do not ensure that the syntactic (resp. semantics) structure computed is a tree (resp. DAG); we leave the implementation of relevant heuristics as a subject of future work. We do impose several constraints, however: (i) a token can be annotated with only one POS tag, (ii) there can be at most one root, (iii) there can be no incoming syntactic dependency on a root, (iv) there can be at most one syntactic (resp. semantic) dependency from token j to i. Our strategy is to always perform the selected action, overwriting possible incompatible previous annotations.[3]

While POS tags, syntactic and semantic dependencies are used during training (see Section 4), only the raw tokens are required at inference time.

3.2 Training

We typically train our model with a supervised pre-training phase followed by a reinforcement learning (RL) phase. During the pre-training phase, the log-likelihood of the model on *goldish* sequences of actions is maximised: for each token of a sentence, we generate a sequence of actions of minimum length leading to the gold annotation, randomly permute it (each time with a different permutation) and pad it with HALT so as to match the length of the longest sequence (over the sentence), before a final HALT is added. For example, for a token tagged with the POS tag of id 7, syntactically dependent (label of id 12) on the token 3, and that is neither a top predicate nor semantically dependent on any token, one of the two goldish sequences is

[SYN-3-12, TAG-7, HALT, HALT, HALT]

(if all tokens in the sentence can be fully annotated with a maximum of four actions). Using such sequences intuitively teaches the system to predict all annotations as quickly as possible, with no ordering preference. When the performance of the model on the SDP task saturates (early stopping on the development set), we switch to the RL phase, during which we expect the model to infer a good strategy as to how to order the different actions.

In relation to the reinforcement process, each action $a_{i,s}$ is associated with a reward $r(a_{i,s}, i, s)$. The role of RL is to train the model to maximise the expected sum of rewards $J = \mathbb{E}(R)$, where $R = \sum_s R_s$ and $R_s = \sum_i r(a_{i,s}, i, s)$. We compute the rewards in the following way. Let #pos be the number of POS annotations (which is also the number of tokens) in the training set, while N is the number of sentences. We then define $r_{\text{pos}} = \frac{N}{\#\text{pos}}$. The creation of a correct POS annotation and the suppression of an incorrect one (which can happen by overwriting) both correspond to a reward of r_{pos}, while the creation of an incorrect POS annotation and the suppression of a correct one correspond to a reward of $-r_{\text{pos}}$. Syntactic and semantic dependencies are treated similarly, with syntactic root (resp. semantic top predicate) annotations counted as a virtual syntactic (resp. semantic) dependencies. As a consequence, the construction of the full gold structure corresponds on average to a reward of 3 per sentence, equally balanced across the three layers. The reward associated to a given action is then computed as the sum of the reward of its effects, minus a small constant negative penalty

---

[3] This is also ensured within the actions selected for the different tokens of the sentence during a given time step, which, strictly speaking, we do not perform “in parallel”, but in random order, as can be seen in Algorithm 1. As a result, if ROOT is selected for two tokens, one of them is set first as the root (deleting any incoming syntactic dependencies) — information that is immediately overwritten by setting the other one as the root.

in the case of non HALT actions (set at a tenth of the average reward per token in the training set) aimed at discouraging the model from loitering.

The RL algorithm we use to optimise our model is a modification of REINFORCE (Williams, 1992). We adapt it to take into account the fact that multiple actions (one per token) are performed at each time step. To do so, we simply distribute future rewards to each token's discounted reward equally. More formally, given the *discount factor* γ, the discounted reward for token i at time step s is defined as

$$G_{i,s} = r(a_{i,s}, i, s) + \sum_{s' \geq 1} \gamma^{s'} \frac{R_{s+s'}}{n},$$

where n is the length of the sentence.[4] The direction of the parameters update for a given episode is then the one obtained from REINFORCE summed over all tokens:

$$\nabla_\theta L_p = \sum_{s \geq 0, i} (G_{i,s} - b_{i,s}) \nabla_\theta \log \pi_{i,s}(a_{i,s})$$

where $b_{i,s}$ is the *baseline term*.[5] We use a *state value* baseline, which is trained by minimising its squared error with the observed return:

$$\nabla_\theta L_b = \sum_{s \geq 0, i} 2\,(\nabla_\theta b_{i,s} - G_{i,s}).$$

The policy and baseline parameters updates are weighted with coefficients 0.67 and 0.33 respectively. Note that we update the baseline term also during the pre-training phase, using the rewards obtained following the goldish sequences. Finally, we additionally maximise the entropy of each policy with a coefficient 0.002.

Optimisation is done using Adam (Kingma and Ba, 2015). The search for learning rates has been done manually, optimising the semantic F1 on the development set using the DM formalism.[6] We first found that a learning rate of 5.10^{-4} during pre-training gave satisfying results (the other optimiser parameters are left as set by default in TensorFlow, i.e. $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 10^{-8}$), then that using a learning rate of 5.10^{-5} during the subsequent RL phase was a reasonable choice.

3.3 Token representations

We first define a *base encoding* for each token, composed of a 100-dimensional pre-trained GloVe word embedding (Pennington et al., 2014) concatenated to a POS tag embedding[7], a sum of prefix embeddings, a sum of suffix embeddings, a few other *tagging* features and two binary features indicating whether the token is currently predicted as the root or a semantic top predicate. (More detail is given in appendix A.) These base encodings are first sent through a dense ReLU layer before serving as input to the *token representation module*, which is composed of two layers of the architecture depicted in Figure 1. These layers contain a *syntax encoder* and a *semantics encoder*, the role of which are to linearise the partial syntactic and semantic structures respectively. These graph encoders are inspired by the work of Kurita and Søgaard (2019); the main difference lies in the use here of summation instead of a more powerful but also more expensive recurrent neural network.

Given a labelled graph — defining a set of parents *parents*(i) and of children *children*(i) for each token i along with $l(j, i)$, the label of the arc from j to i when it exists — and noting u_i for the input corresponding to token i and v_l for the embedding of label l, we define the *downward encoding* of i as $w_i^d = \sum_{j \in \mathit{children}(i)} \mathit{Dense}([u_j, v_{l(i,j)}])$ (where *Dense* represents a dense ReLU layer). Similarly, the *upward encoding* of i is defined as $w_i^u = \sum_{j \in \mathit{parents}(i)} \mathit{Dense}([u_j, v_{l(j,i)}])$ (where *Dense* represents another dense ReLU layer). Finally, the *bothward encoding* of i is defined as the concatenation of the two previous vectors: $w_i = [w_i^d, w_i^u]$. For the output of the syntax encoder, we use the bothward encodings of the syntactic graph while for the output of the semantic encoder we use only the upward encodings of the semantic graph.

The output of the second layer of the token representation module is sent (i) to a multilayer perceptron (MLP) that computes the state value $b_{i,t}$ (the baseline term) and (ii) to different sub-networks that compute the logits of the actions (i.e. the values from which the probabilities are obtained by applying softmax), which are described in the next section.[8]

---

[4] Kurita and Søgaard (2019) do not discuss the definition of the discounted rewards and only use the immediate local reward (corresponding to a discounting factor $\gamma = 0$). We use here the fairly standard value $\gamma = 0.99$.

[5] The baseline term is not strictly necessary: its goal is to reduce the variance of the estimate of the gradient in order to speed the learning process (Sutton and Barto, 2018, §13).

[6] See Section 4 about the different formalisms.

[7] The corresponding vocabulary includes a "not tagged yet" embedding.

[8] All BiLSTMs that we use are actually 2-layer BiLSTMs, and all MLPs have two hidden layers.

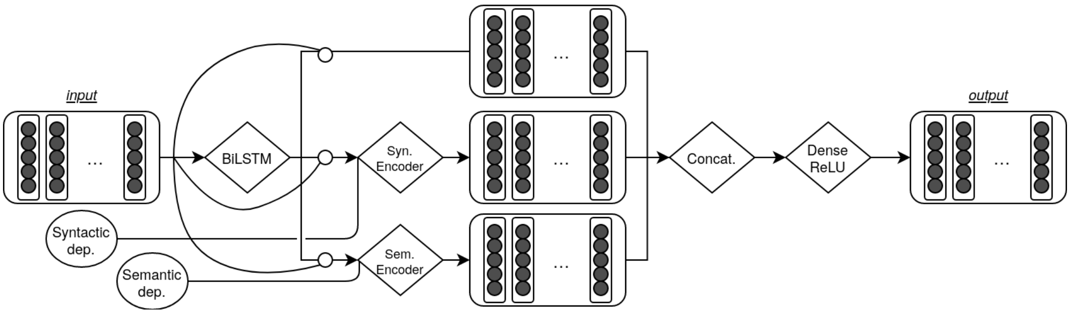

Figure 1: One layer of the token representation module. Each sequence is composed of one vector per token. Each of the circles directly linked to the output of the BiLSTM is a gate parametrised by a scalar α and represents the function $(v_1, v_2) \mapsto \sigma(\alpha)v_1 + (1 - \sigma(\alpha))v_2$. See the text for the definition of the syntax and semantics encoder.

3.4 Action logits

The logit of each action is computed by one of three sub-networks. The first one is an MLP that returns the logits for TAG-t actions, ROOT, TOP_PRED and HALT. The second returns the logits for SYN-j-l actions: the logit, for token i, to select token j as governor, for all possible dependency labels is given by MLP($[v_i, v_j, v'_{i,j}]$) $\in \mathbb{R}^{|L|}$, where $|L|$ is the number of dependency labels and $v'_{i,j} \in \mathbb{B}^{|L|+1}$ is a one-hot vector indicating whether j is currently governor of i and if so, what is the label of the corresponding dependency. The last sub-network returns the logits for SEM-j-l actions in exactly the same way. The policy is then obtained by applying the softmax function to the concatenation of the output of these different sub-networks.

4 Experiments

To test whether MTI is a viable paradigm and determine the impact of RL, in this section we test the model described above along with three variants. These four models can be seen as combinations of two binary traits. The first trait pertains to the ordering of the actions: *sequential* models simulate sequential pipelines, while for *free* models, as above, no particular constraint is imposed. A sequential model can only select TAG-t actions during the first step of an episode, only SYN-j-l and ROOT during the second and only SEM-j-l, TOP_PRED and HALT afterwards. This is ensured by using as policy for each token the vector obtained by normalising a masked version of its usual policy.[9] The second trait pertains to the learning process: *supervised* models are only trained in the pre-training phase while *RL* models, as above, are further trained using reinforcement learning.

4.1 Data

We use data from the SemEval 2015 Task 18 (Oepen et al., 2015), which provides POS tags, lemmas, syntactic parses and semantic parses for English, Chinese and Czech texts. Concerning English, the same data is annotated with three distinct formalisms: DELPH-IN MRS-Derived Bi-Lexical Dependencies (DM), Enju Predicate–Argument Structures (PAS) and Prague Semantic Dependencies (PSD). They all represent a semantic analysis as a bi-lexical dependency DAG. We use here the standard split of the English data. The train set is composed of 33,964 sentences from sections 0–19 of the WSJ corpus, the development set of 1,692 from section 20 and the (in-domain) test set of 1,410 from section 21. During training, for simplicity, we always use the gold (morpho)syntax annotation provided under the form of Stanford Basic dependencies derived from the PTB, even when working with the DM formalism (which comes with different annotations).[10]

4.2 Semantics

Table 1 shows the average F1 for labelled semantic dependencies over the three formalisms in each setting. Three randomly initialised runs are used for each formalism, with each performance computed using the script provided by the shared task. Everywhere in this text, F1 are *micro*-F1 (i.e. computed over the whole dataset instead of at the sentence level). We first observe that RL models perform better than their supervised-only counterparts, a

---

[9] The goldish sequences used during pre-training are modified accordingly. The ordering of the selection of the possibly multiple semantic parents of any given token is still random.

[10] All data and evaluation scripts can be found on the shared task's website: `http://alt.qcri.org/semeval2015/task18/`.

(sem.)	sequential	free	Δ
supervised	84.9 (86.4)	85.7 (87.2)	0.8 (0.8)
RL	86.5 (87.9)	87.3 (88.5)	0.8 (0.6)
Δ	1.6 (1.5)	1.6 (1.3)	

Table 1: Average of the F1 over the three semantic formalism on the in-domain test set. Scores on the development set are given in brackets.

result consistent with the findings of Kurita and Søgaard (2019). This indicates that RL allows the model to infer a good ordering strategy (limited to the ordering of the semantic actions in the sequential regime) and/or trains it to be more robust to its own mistakes (an effect similar to that of dynamic oracles). Second, we observe that free models perform better than their sequential counterparts. This indicates, as we had hypothesised, that a strict ordering of actions following a traditional hierarchy of levels of analysis is not optimal and that MTI is a potentially powerful form of MTL (note that the sequential models here implement a relatively traditional form of MTL). Finally, we see that these two effects are additive.

4.3 Syntax and POS tagging

Let us turn to the performance of our model on the syntactic parsing and POS tagging tasks in the four settings. Table 2 shows the F1 for labelled syntactic dependencies[11], averaged over all nine corresponding runs. Following Chen and Manning (2014)'s recommendation, punctuation is excluded from the evaluation. What we observe is that while the use of RL and (more particularly) non-sequentiality have a small impact on syntactic parsing, it is still noticeable. All scores on the test set are statistically different according to Pitman's permutation test, with a p-value under 10^{-3}.[12] The combination of RL with free-ordering appears a particularly good combination.

As shown in Table 3, the use of RL also has a statistically significant impact on POS tagging, although of very low magnitude. Free-ordering, however, has no perceptible effect (the corresponding deltas are in fact positive but strictly smaller than 0.05 and the distributions they compare are not distinguishable).

(synt.)	sequential	free	Δ
supervised	91.0 (91.1)	91.1 (91.4)	0.2 (0.3)
RL	91.8 (91.9)	92.3 (92.2)	0.5 (0.4)
Δ	0.8 (0.8)	1.2 (0.8)	

Table 2: Average syntactic F1 on the in-domain test set. Scores on the development set are given in brackets.

(tag.)	sequential	free	Δ
supervised	96.9 (97.1)	96.9 (97.1)	0.0 (0.0)
RL	97.1 (97.2)	97.2 (97.2)	0.0 (0.0)
Δ	0.2 (0.1)	0.2 (0.1)	

Table 3: Average tagging F1 on the in-domain test set. Scores on the development set are given in brackets.

Note that while we do not use the same split of the WSJ Corpus as them, a comparison with the 91.87 LAS on syntax and 96.92 accuracy on POS tagging obtained by the model of Strubell et al. (2018) — which is also trained to perform these tasks jointly with a form of semantic parsing — indicates that our free+RL model, with 92.3 F1 on syntax and 97.2 on POS tagging, performs at least reasonably well.

4.4 Inferred strategies

In order to better understand why our MTI paradigm leads to better performance not only on the syntactic task but also on the semantic one, we now perform a brief study of the ordering strategy inferred by our free+RL model. We focus here on the SYN-j-l and SEM-j-l actions and look at the average time step at which they are created as a function of their length.[13] Figure 2 shows that for the PAS formalism, on average, the system creates (i) syntactic dependencies before semantic ones and (ii) short dependencies before long ones.[14] This tends to indicate that the model follows an easy-first strategy and that, as often assumed, it is preferable

---

[11] As we do not constrain the model to produce complete syntactic trees, the natural measure here is indeed F1. In practice, however, the *parsing rate* (the ratio of tokens that either have an incoming dependency or are predicted to be the root) is always higher that 99%, meaning that recall and precision are almost equal and that F1 is very similar to a labelled attachment score (LAS). A similar remark applies to POS tagging.

[12] We use the permutation test to check whether the distributions of the scores in each setting (nine runs) are distinct from each other. See the work of Dror et al. (2018) for an NLP-oriented discussion of statistical significance.

[13] Sometimes, though rarely, does the model select the same action multiple times (for the same token) over a single episode. We filter out useless actions, that is to say, the ones that do not modify the structure when they are applied.

[14] Each figure mentioned in this paragraph corresponds to a randomly picked run. The behaviour observed is very consistent across the different runs for a given semantic formalism.

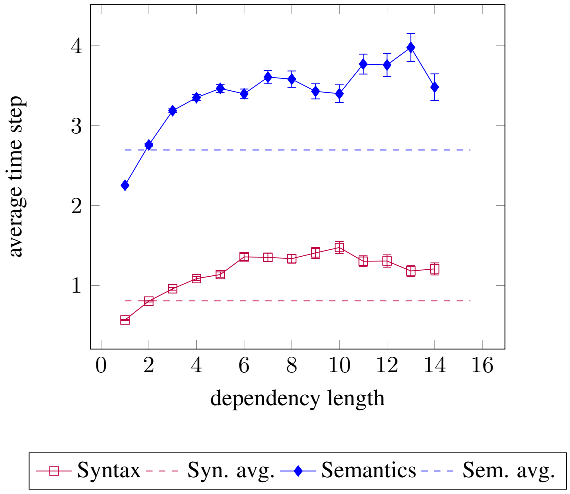

Figure 2: PAS semantic formalism: average time step (from 0) at which syntactic and semantic dependencies are created as a function of their length. Error bars indicate the standard error of the mean.

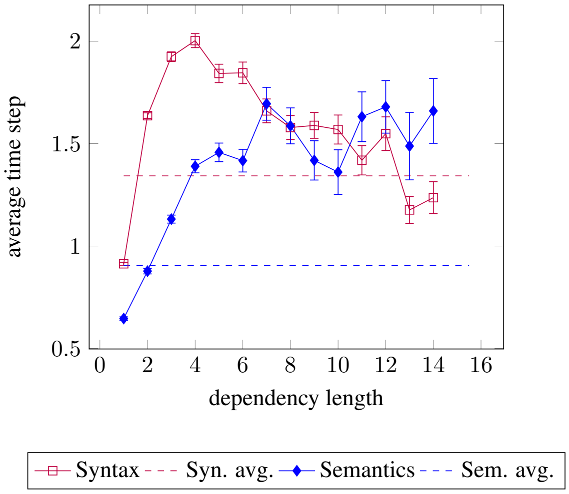

Figure 3: DM semantic formalism: average time step (from 0) at which syntactic and semantic dependencies are created as a function of their length. Error bars indicate the standard error of the mean.

Model	DM	PAS	PSD	all	avg.
FREDA3	90.4	92.7	78.5	88.0	87.2
K&S (-lem.)	91.2	92.9	78.8	88.5	87.6
SPIGOT	91.6		78.9		
MF	**93.0**	**94.3**	**80.9**		89.4
free+RL	91.1	91.7	79.0	88.1	87.3

Table 4: Semantic F1 on the in-domain test set for each of the three formalisms, along with the F1 over all formalisms (*all*) and the average of the F1 over all formalisms (*avg.*). *All* tends to be higher than *avg.* because PAS happens to be both the most simple formalism and the one introducing the highest number of dependencies, while the opposite is true of PSD.

to perform syntactic before semantic parsing[15], at least when dealing with this specific semantic formalism. Indeed, figure 3 shows that the strategy inferred when training on the DM formalism is radically different: short dependencies are still created before long ones (note that the number of dependencies decreases very rapidly with their length), but the syntactic and the semantic structures are built much more concurrently, with semantic structures being, on average, generated *before* syntactic ones of the same length. The strategy inferred for the PSD formalism, not depicted here, is qualitatively similar to the one for DM. In light of these observations, we can better understand why both tasks benefit from MTI: it is *not* true, in general, that syntactic parsing should be performed (even on average) before semantic parsing.

4.5 Comparison with other parsers

Finally, table 4 compares the performance of our free+RL model with state-of-the-art SDP parsers that, for fairer comparison, do not use ELMo or BERT embeddings, nor rely on lemma input: Peng et al. (2017)'s FREDA3, Peng et al. (2018a)'s SPIGOT, Wang et al. (2019)'s MF model and a model by Kurita and Søgaard (2019).[16] Note that our model is the only one that does *not* rely on the provided POS tags at inference time.[17]

Wang et al. (2019)'s second-order model, based on mean field variational inference, is clearly ahead in terms of performance. Among the other four, our model achieves competitive performance on the DM and PSD formalisms. It is, however, somewhat behind when it comes to the PAS formalism. Understanding why this is so is left as a subject of future research.

5 Conclusion and future work

We have defined Multiple Tasks Integration as a set of principles for joint processing, orthogonal to weight sharing. The essence of MTI is to process the input iteratively but concurrently on multiple

---

[15] On average only, as some semantic dependencies are still created before syntactic ones.

[16] Dozat and Manning (2018) report very high scores, but as indicated in the Q&A session of their ACL 2018 talk (`https://vimeo.com/285804230`) — a fact pointed out by Kurita and Søgaard (2019) —, these scores correspond to a macro-F1 instead of the micro-F1 computed by the shared task tool, thus giving more relative weight to shorter sentences.

[17] In the English data, the PAS and PSD graphs come with the tags of the PTB (Marcus et al., 1993) while the DM ones come with the tags of DeepBank (Flickinger et al., 2012).

levels of analysis, basing each decision on all of the structures already inferred and free from usual ordering constraints. This way, the different tasks can interact in the full sense of the term. To train such a system, we propose using reinforcement learning algorithms, thus allowing it to infer its own ordering strategy.

In practice, we have trained a system to perform part-of-speech tagging, syntactic dependency parsing and semantic dependency parsing. We have observed that both the use of reinforcement learning and the release from sequential constraints are beneficial, not only to the (seemingly) highest level task (i.e. semantic parsing), but also to some intermediate ones (i.e. syntactic parsing). If the inferred strategies are interpreted as being easy-first — which is supported by the fact that shorter dependencies have a strong tendency to be generated before longer ones —, then we have observed that syntactic parsing is not necessarily simpler than semantic parsing and that both benefit from being executed concurrently.

While our model is not yet as effective as today's most complex systems, it is still competitive with most of the parsers presented in the recent literature, even though it uses a poorer input signal for inference (consisting of the raw tokens only). Furthermore, several aspects of the current system are open to developments that seem likely to improve performance. For instance, we do not use here the full potential of reinforcement learning, as what we optimise (the expected sum of rewards) is not the metric we are interested in (which would be either an average of the three F1 or the semantic one). For each of the three tasks, the sum of the rewards we have defined approaches, up to a multiplicative constant, the corresponding F1 of the system when the latter approaches 100%, but a better approximation might prove more successful. In a similar vein, Kurita and Søgaard (2019), who work with a similar architecture as far as SDP is concerned, penalise HALT actions when relevant dependencies are still missing, which intuitively boosts recall. Note also that our network is still rather simple, in that it does not use any form of regularisation nor any advanced technique to handle out-of-vocabulary words.

We would also be interested in applying MTI to other tasks and in studying how well it can learn from incomplete annotations. Our architecture can be straightforwardly adapted to any labelling or graph building task, as long as all nodes are tokens of the input sentence. In contrast, work remains to be done in order to handle formalisms such as Abstract Meaning Representation (AMR, Banarescu et al., 2013) or on how to integrate a generation component with, for example, the goal of translating the sentence being analysed.

A Appendix: Base encodings

The base encoding of a given token (introduced in Section 3.3) is composed of the concatenation of four vectors and five binary values.

- The GloVe embeddings that we use are the 100-dimensional vectors of the 6B (uncased) release. We do not fine-tune them. All words present in the training set use their corresponding GloVe entry. All other words are considered unknown and are assigned the average of these embeddings.
- For POS tag embeddings, we use randomly initialised 50-dimensional vectors.
- We use a sum of prefix embeddings. We first consider all cased prefixes of length 1, 2 or 3 and then filter out all those that appear in less that a thousandth of the tokens and less that a thousandth of the word forms in the training set. The remaining prefixes are assigned a randomly initialised 32-dimensional vector. (Unknown prefixes correspond to a zero vector.)
- We use a sum of similar suffix embeddings.
- One binary value indicates whether the token starts with an upper case letter.
- One binary value indicates whether there is any upper case letter in the token.
- One binary value indicates whether the token is a number (matching the `\d+(\.\d+)?` regular expression).
- One binary value indicates whether the token is currently annotated as the (syntactic) root.
- One binary value indicates whether the token is currently annotated as a (semantic) top predicate.

In future work, we plan to substitute a more general character-level word embedding model for the tagging features (i.e., the prefix and suffix embeddings and the three first binary features).

Coordinate Constructions in English Enhanced Universal Dependencies: Analysis and Computational Modeling

Abstract

In this paper, we address the representation of coordinate constructions in Enhanced Universal Dependencies (UD), where relevant dependency links are propagated from conjunction heads to other conjuncts. English treebanks for enhanced UD have been created from gold basic dependencies using a heuristic rule-based converter, which propagates only core arguments. With the aim of determining which set of links *should* be propagated from a semantic perspective, we create a large-scale dataset of manually edited syntax graphs. We identify several systematic errors in the original data, and propose to also propagate adjuncts. We observe high inter-annotator agreement for this semantic annotation task. Using our new manually verified dataset, we perform the first principled comparison of rule-based and (partially novel) machine-learning based methods for conjunction propagation for English. We show that learning propagation rules is more effective than hand-designing heuristic rules. When using automatic parses, our neural graph-parser based edge predictor outperforms the currently predominant pipelines using a basic-layer tree parser plus converters.

1 Introduction

The Universal Dependencies (UD) formalism (de Marneffe et al., 2014) is a framework for representing syntactic dependencies between words, prioritizing links between content words. UD parses provide two levels of analysis. *Basic* dependencies form standard syntactic dependency trees in which each node has exactly one governor (black links on top in Figure 1). *Enhanced* dependencies (Schuster and Manning, 2016) are extensions of these trees including additional relations (blue links below sentence) with the aim of representing linguistic phenomena such as coordination, control, or relative clauses. They have been shown to provide valuable input for information extraction tasks (Schuster et al., 2017). One of the most frequent phenomena addressed by enhanced UD is coordination. In the English Web Treebank (EWT), more than 15% of all sentences contain conjoined verbs. Hence, a good representation of coordination clearly is crucial for downstream tasks. For example, in Figure 1, the enhanced layer explicitly captures that the arguments of the predicate "wrote" also fill the corresponding slots of "published," which is highly relevant for natural language understanding tasks.

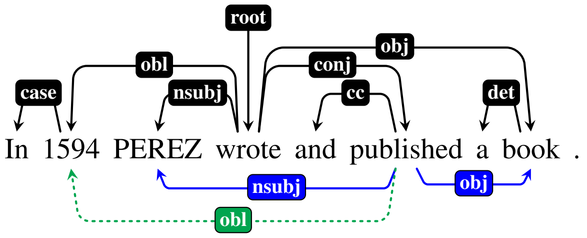

Figure 1: UD **basic** (top) and **enhanced** (bottom) dependencies. **Green dotted link:** proposed addition.

In many cases, enhanced representations can be derived from the gold basic layer in a rule-based fashion (Schuster and Manning, 2016). The currently available English enhanced UD treebanks have been created by applying such a converter. However, we are not aware of a large study regarding their correctness and completeness. Focusing on precision, the converter only propagates core arguments. In this paper, we take a complementary approach, performing a large-scale annotation study in order to determine which set of links *should* be propagated from a semantic perspective. On a new dataset of 1,417 sentences from the EWT containing conjoined verbs, we verify and if necessary modify/extend the links involved in coordinate constructions. We argue that adjuncts such as obliques should in fact be propagated at times, e.g., in Figure 1, the additional (green dotted) link that

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 795–809
April 19 - 23, 2021.

we propose to add facilitates answering questions like "When was the book published?". To the best of our knowledge, our work constitutes the first large-scale annotation effort of this kind.

On the basis of our new dataset, we make the following contributions. First, we estimate the degree of **correctness and completeness of the rule-based converter/existing treebanks**. We find that the converter usually generates correct graphs when applied on gold basic trees, with some notable exceptions involving non-parallel syntactic constructions (e.g., conjuncts having different voice or mood). In addition, the converter does not propagate links correctly in presence of multiple interacting conjunctions. Our inter-anntotator agreement study shows high overlap for propagation decisions, with F1 between pairs of annotators of about 0.9 on average and around 0.75 for obliques.

Second, we address the question of **how to create high-quality treebanks** for enhanced UD from gold basic dependencies, again focusing on coordinate constructions. Based on the findings of our corpus study, we improve the rule-based converter by Schuster and Manning (2016). We also compare machine-learning (ML) based conjunction propagation classifiers in the form of (a) SVM-based classifiers as previously used for Finnish, Swedish and Italian (Nyblom et al., 2013; Nivre et al., 2018), and (b) a novel neural approach integrating tree- and RoBERTa-based features. We find that all systems mostly rely on tree-based features, but contextual embeddings also provide useful information. Performance on propagation decisions has promising F1 around 0.9, already similar to human agreement. ML-based classifiers outperform the rule-based converters on the EWT test set.

Third, we compare methods for **extracting propagated dependencies in an automatic parsing setting.** The currently predominant approach is to run a basic-layer tree parser and then the same converter that has been used for gold standard construction. We propose to use a neural graph-parser based edge predictor with an architecture similar to Dozat and Manning (2018) instead, and show that this approach outperforms pipelines by around 9 points F1 on propagating links in conjunctions.

In sum, our contributions include: (1) a manually curated large-scale dataset of 1,417 sentences addressing semantically motivated correct and complete conjunction propagation in enhanced UD; (2) the proposal of novel neural approaches to conjunction propagation; and (3) experimental evidence that these models outperform rule- and pipeline-based approaches in both gold standard treebank enhancing and automatic parsing settings. To the best of our knowledge, our work constitutes the first principled comparison of various approaches to propagating conjunctions in enhanced UD on manually corrected gold standard data for English. Both our model implementations and the dataset are freely available.[1] We will contribute our changes to the EWT corpus to the next UD release.

2 Related Work

Coordinate Constructions in UD are represented using the *conj* relation, with the first conjunct being the head to which all dependencies of the phrase are attached (see Figure 1). In the basic layer, all governors and dependents of a conjoined phrase are attached to the first conjunct. In the enhanced layer, relations are propagated to the dependent if suggested by the semantics of the sentence.[2] Schuster and Manning (2016) present an algorithm for creating enhanced dependencies automatically based on the basic layer. While it propagates links with high precision, it propagates *only* core arguments by design (see Appendix A). In addition, it is highly reliant on correct basic dependencies (see Sec. 5).

Conjunction propagation classifiers. Nyblom et al. (2013) present an SVM-based approach for enhancing Finnish syntax trees. They observe high performance on conjunction propagation when operating on gold basic trees, but markedly worse results when using automatic parser output. Nivre et al. (2018) evaluate a similar approach for Swedish and Italian. We show that their approach also works well for English, and extend it with neural models and contextualized word embeddings. Simi and Montemagni (2018) de-lexicalize their rule-based converter developed for Italian, showing that their language-independent system also correctly produces most of the propagations for English. However, they evaluate on EWT, which is itself the result of a rule-based system. In contrast, we evaluate on manually checked gold data.

For the related task of dealing with **gapping** constructions such as "Paul likes coffee and Mary tea,"

---

[1] `https://github.com/boschresearch/coordinate_constructions_english_enhanced_ud_eacl2021`

[2] `https://universaldependencies.org/u/overview/enhanced-syntax.html`

Schuster et al. (2018) reconstruct elided predicates by first parsing into an intermediate representation and then applying either a rule-based or an ML-based algorithm to copy over lexical material. We here focus on dependency propagation and operate on gold tokens as annotated in the enhanced UD treebanks, which already include traces. Other related work exists in the area of manual and rule-based error correction on UD treebanks (Wisniewski, 2018; Alzetta et al., 2018).

There is still little published work regarding **fully automatic enhanced UD parsing**, however, the topic has recently been addressed by the IWPT 2020 Shared Task (Bouma et al., 2020). Among the top-performing systems, several approaches first parse into basic UD and then added transformation rules (e.g., Heinecke, 2020; Dehouck et al., 2020). Others directly employ graph parsing techniques (e.g., Wang et al., 2020; He and Choi, 2020; Hershcovich et al., 2020). The overall winner TurkuNLP (Kanerva et al., 2020) transforms enhanced UD into a tree format and then makes use of UDify (Kondratyuk and Straka, 2019). In addition, much work exists on **semantic dependency parsing** (SDP, Oepen et al., 2014, 2015; May and Priyadarshi, 2017). These works differ from UD-based approaches as the respective formalisms represent meaning less close to syntactic structure, thus not requiring propagation. From a modeling point of view, our work is most similar to that of Grünewald and Friedrich (2020), who also use a graph-based biaffine architecture for enhanced UD parsing, and to that of Dozat and Manning (2018), who achieve state-of-the-art results for SDP.

3 Coordinate Constructions Dataset

In this section, we describe our creation of our manually created dataset and analyse the results.

	conj. sentences	**edited**
train	1,926	999
dev	222	222
test	196	196
total	2,344	1,417

Table 1: Coordinate constructions dataset statistics. **conj. sentences**: sentences in EWT containing verb phrase conjunctions; we edited 60% of these.

3.1 Data

Our dataset consists of 1,417 sentences collected from EWT,[3] containing data from five genres of web media (weblogs, newsgroups, emails, reviews, and Yahoo! answers).[4] The basic dependencies of this UD gold standard have been derived from the original Stanford dependencies (de Marneffe et al., 2006) and were then hand-corrected. The enhanced layer has been created using the automatic converter (Schuster and Manning, 2016, see Appendix A). We retrieve all sentences containing at least one *conj* link between two verbs. More than 15% of all sentences in EWT contain conjoined verbs. Out of these sentences, we edit all sentences of the dev and test sets, and 999 sentences of the training set, amounting to more than 60% of all relevant sentences in EWT (see Table 1). The careful curation of each sentence took around 10 minutes on average, amounting to a total annotation effort of around 240 hours (total costs ca. $4,750). We exclude 18 sentences when reporting our statistics: In 12 cases, the *conj* relation is annotated wrongly in the basic layer and six sentences contain syntactically non-standard English.[5]

3.2 Annotation Methodology

The manual corrections of the treebank were performed by a French native speaker with an extensive background in linguistics. The annotation project involved regular discussions among all authors to decide on uncertain cases and to ensure consistency. Additionally, in case of doubt, an English native speaker with an extensive linguistics background was consulted. Dependencies were checked carefully sentence-wise using the ConLL-U-Editor tool (Heinecke, 2019). If necessary, the full document was consulted to make sure interpretations were correct in context.

Annotation Guidelines. We verify and modify all links involved in coordinate constructions including conjoined verbs, but also noun or adjectival phrases. First, we make sure that the automatically constructed enhanced representations adhere to the official guidelines for enhanced UD (see Sec. 2), propagating heads and dependents of conjuncts if

B	95.2	-	97.2
C	80.5	77.9	-

Table 2: Inter-annotator agreement on propagated links for 100 sentences: **precision** when treating the row annotator as gold standard (or, equivalently, **recall** when treating the column annotator as gold standard).

the interpretation of the sentence suggests additional syntactic relations between words.

As each verb may also have its own complements, this task requires a semantic interpretation leveraging context and knowledge about selectional preferences. If an ambiguity has already been resolved in the basic layer,[6] we follow this interpretation unless obviously wrong. Second, we propose to also propagate non-core dependents such as *obl*, *advcl* and *advmod* if suggested by semantics, an annotation task similar to prepositional phrase attachment resolution. We only propagate such links if the adjunct clearly modifies each conjunct (as in Figure 1). Finally, we extend the attachment of relative pronouns (*ref*) to all antecedents if involved in coordinations. We focus on propagating dependencies between content words, not propagating relations such as *aux* or *cop*, which could be handled as traces.

Inter-annotator agreement study. We sampled 100 sentences, half of them from cases where the primary annotator had judged the original version to be correct, and half of them cases that included modifications. This sample was blindly re-annotated by two secondary annotators, both German native speakers with an extensive computational linguistics background. Table 2 shows agreement in terms of precision and recall on the set of dependencies resulting from conjunction propagation, i.e., the links involved in conjunctions that are present in the enhanced layer but not in the basic layer. For a formal definition, see Appendix B. Agreement is generally high, particularly between annotators A and B. Annotator C was more conservative in propagating links, especially in generally ambiguous cases. However, the links that C propagates are also propagated by A and B. Pairwise agreement was high on *nsubj*, *obj* and *xcomp*. Modifier clauses (*acl*, *advcl*) and adverbials (*advmod*) were common sources of disagreement, indicating the more ambiguous nature of these propagations. Pairwise scores and more details can be found in Appendix B.

3.3 Analysis and Discussion

In this section, we analyse and discuss the modifications made to the original treebanks.

Quantitative Analysis of Changes. Table 3 presents the numbers of dependency relations that have been added and removed in coordinate constructions in the enhanced layer. More specifically, we consider only the set of links not present in the basic tree and count modifications regarding links starting or ending at conjuncts.[7] Counts for coarse-grained labels (e.g., *nmod*) include all subtypes (e.g., *nmod:for*) not explicitly listed in the table. During our manual correction of the treebank, around 15% of the total enhanced links involved in conjoined phrases were added and about 3% were removed. This confirms that the converter by Schuster and Manning (2016) is optimized for precision rather than recall, though our additions of course include labels that the converter does not address. Note that in these cases, removed relations in Table 3 are caused by fixes regarding attachment in the basic layer, whose errors had been propagated to the enhanced layer. In total, we fixed errors in 57 sentences in the basic layer. In 42 of these, this led to changes in the enhanced layer.

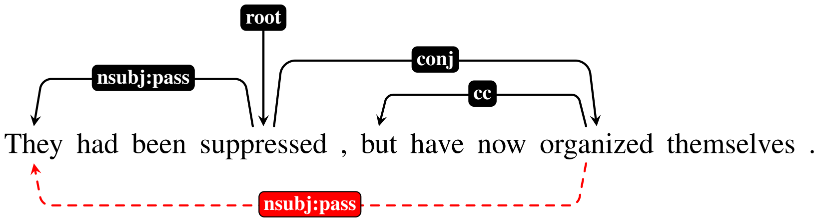
Linguistic Analysis of Changes. One systematic error involves **links to subjects in passive constructions**: 18 out of 225 *nsubj:pass* links were actually wrongly propagated. All of them have been changed to *nsubj*. The reason is that the converter automatically propagates an *nsubj:pass* link if the first conjoined verb is in the passive form, as, e.g., in “These Shiite movements had been suppressed by Saddam Hussein’s regime, but have now organized and armed themselves” (see Figure 2a). Another common error (occurring 12 times) is the propagation of the first conjoined verb’s subject to the second verb, even though the latter is in **imperative mood**, as, e.g., in “I think it was the Lincoln Square area but don’t quote me on that” (see Figure 2b).

In sentences containing **multiple coordinate constructions**, such as “Dr. Fortier and his girlfriend lashed two canoes together and paddled

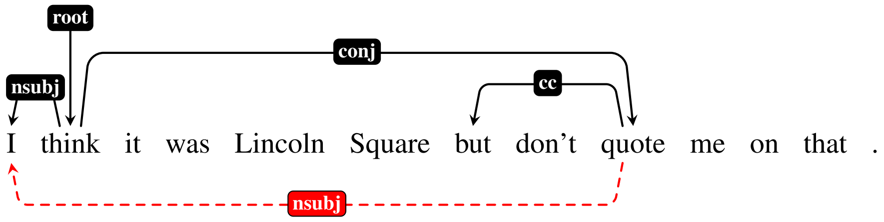
---

[6] For example, in “She was reading or watching a movie,” “movie” is attached to the second conjunct “watching” in the basic layer, hence resolving the syntactic ambiguity.

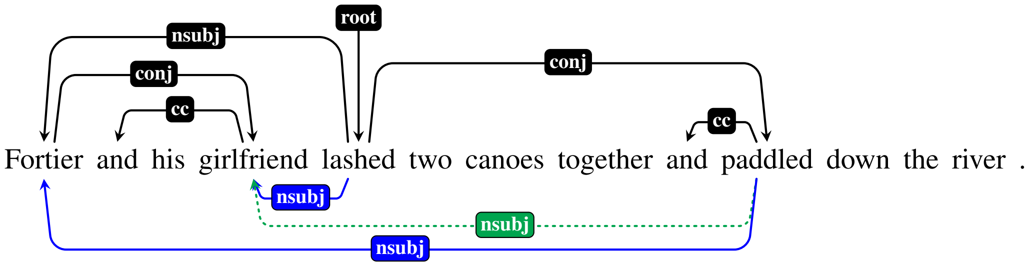
[7] We made some additional fixes (not necessarily related to coordinations) to the original treebank, see Appendix C.



(a) Passive voice: *nsubj:pass* links should not be propagated verbatim if the second conjunct is in active voice.



(b) Imperative mood: *nsubj* links should not be propagated if the second conjunct is in imperative mood.



(c) Multiple coordinate constructions: *nsubj* links should be propagated between the second conjuncts of each coordination.

Figure 2: Systematic errors found in the automatic propagation of dependencies. (Only coordination-relevant links are depicted.) **Red dashed link:** Incorrect propagation or incorrectly labeled propagation. **Green dotted link:** Missing propagation.

eight kilometres along the Soper River," *nsubj* links should be present in the enhanced layer between both conjuncts of the subject noun phrase and both verbs. However, in the original treebank, the second subject conjunct was never propagated to the second verb (see Figure 2c). Similarly, we also added many relations in cases of **nested coordinations** as in "These Shiite movements had been suppressed by Saddam Hussein's regime, but have now organized and armed themselves." The second conjunct of the conjoined verb phrase is a conjoined verb phrase itself, but the *nsubj* link to "armed" was missing. In total, 194 sentences contain several coordinations, and we modified 92 of them. This phenomenon also accounts for 45 of the added *nsubj* links.

Some originally missing propagations concern **adjectival and adverbial modifiers** (*acl, amod, advcl, advmod*), which are known to be ambiguous cases. In "Handwritten notes and files on a laptop were seized," the adjective "handwritten" clearly modifies the first conjunct "notes" only, but in "Several Indian scholars and politicians have been ready to say and endorse anything," the propagation of "several" and "Indian" was added during our modifications. These cases involve world knowledge that the converter currently does not handle.

Finally, consider the sentence "We recognize that the state may not require religious groups to officiate at, or bless, same-gender marriages." Both conjuncts take "marriages" as their argument, but as an *obl* and as an *obj* relation, respectively. The resolution of such non-parallel constructions requires detailed subcategorization information.

4 Modeling

In this section, we describe three approaches to generating links propagated due to coordination: (1) an improved version of an existing converter (Sec. 4.1); (2) ML-based propagation classification operating on basic trees (Sec. 4.2); and (3) a graph-parser based approach for directly predicting edges between tokens (Sec. 4.3). While (1) and (2) may be used to construct "silver standard" enhanced UD graphs from gold trees, (3) is applicable in the automatic parsing setting only.

4.1 Modifications to Rule-based Converter

Based on the error analysis in Sec. 3.3, we modify the rule-based converter by Schuster and Manning (2016) as follows. In order to fix errors related to subject propagation in passive and imperative constructions, we take the conjunction dependent's morphological features into account. In the gold standard, the *Voice* feature is considered to be *active* by default. Hence, if the conjunction dependent does not have a *Voice* feature or is explicitly marked as *active*, an *nsubj:pass* dependency will be propagated as *nsubj*. Similarly, if it has the feature *Mood=Imp*, an *nsubj* link will not be propagated. Our second modification propagates common adjuncts of verbs as well (*obl*, *advmod*, and *advcl*). We maintain the rule from object propagation that a dependency is only propagated if the dependent comes after the potential target in the sentence. Finally, to handle multiple and nested coordinations, we iterate the converter's conjunction propagation function until the dependency graph does not change any more. This allows dependencies that result from propagation to be propagated themselves, retrieving links that would otherwise be missed.

4.2 Conjunction Propagation Classifiers

The core idea of ML-based conjunction propagation classifiers is to take a basic-layer tree and to decide for each incoming or outgoing dependency of the head of a coordinated phrase whether to propagate this dependency to the other coordinated item(s). We refer to the coordinated nodes as **conjunction head** and **conjunction dependent** and to the candidate governor/dependent of the second conjunct as the propagation **target**. In Figure 1, these three nodes correspond to "wrote," "published" and "1954" (or "PEREZ"/"book"), respectively. The output is a binary decision whether to propagate the given dependency or not. In addition to the features described below, we always provide the candidate dependency label and direction.

SVM-based Classifier. We re-implement the method proposed by Nyblom et al. (2013) using scikit-learn's SVC with a polynomial kernel of degree 2.[8] The features comprise morphological information about the tokens for the conjunction head/dependent and the target, as well as structural tree features extracted from the basic-layer tree. For a detailed description, see Appendix D.

Neural network classifier. We pass the sentence through the transformer-based neural language model RoBERTa (Liu et al., 2019) and extract the word embeddings for the first wordpiece tokens of the conjunction head, the conjunction dependent, and the propagation target. In addition, we use equivalents of the SVM tree features using learned embeddings or one-hot encodings (see Appendix D). The inputs are concatenated and fed to a multi-layer perceptron, which then outputs the binary decision whether to propagate the dependency or not. The multi-layer perceptron consists of two linear layers with hidden sizes 1500 and 500 respectively. We implement the model using Huggingface's Transformers library (Wolf et al., 2019). RoBERTa weights are not fine-tuned.

4.3 Graph-Parser Based Edge Prediction

In addition to the above approaches, we also evaluate a graph-parser based approach that predicts dependencies between tokens directly, i.e., which does not rely on a basic-layer tree. Our unfactorized architecture is similar to that of Grünewald and Friedrich (2020), i.e., our model predicts presence of edges and the corresponding labels in a single

---

[8] `https://scikit-learn.org`

step, treating nonexistence of an edge as simply another label (∅). As we focus on the dependencies involved in conjunctions, we do not require the parser's output to constitute valid graphs.

Embeddings for input tokens are generated by feeding gold tokens to the RoBERTa tokenizer and then running the resulting word-pieces through the RoBERTa-large model. We then generate an embedding $\mathbf{r}_i$ for the token at position i by forming a weighted sum of the hidden layers' embeddings at the positions corresponding to the first word-piece token of the original token as suggested by Kondratyuk and Straka (2019). Weights for this scalar mixture of layers are learned during training. Layers are randomly dropped during training to prevent the model from focusing on only a single layer.

For each input embedding $\mathbf{r}_i$, we create a head representation h_i^{head} and a dependent representation h_i^{dep} via two feed-forward neural networks:

$$\mathbf{h}_i^{head} = \text{FNN}^{head}(\mathbf{r}_i) \tag{1}$$

$$\mathbf{h}_i^{dep} = \text{FNN}^{dep}(\mathbf{r}_i) \tag{2}$$

For each ordered pair (i, j) of tokens, we feed their respective head and dependent representations to a biaffine classifier (Dozat and Manning, 2017) predicting logits $\mathbf{s}_{i,j}$ over the possible dependency labels. We use these logits to extract the probabilities $P(y_{i,j})$ for each label:

$$\text{Biaff}(\mathbf{x}_1, \mathbf{x}_2) = \mathbf{x}_1^\top \mathbf{U} \mathbf{x}_2 + W(\mathbf{x}_1 \oplus \mathbf{x}_2) + \mathbf{b} \tag{3}$$

$$\mathbf{s}_{i,j} = \text{Biaff}\big(\mathbf{h}_i^{head}, \mathbf{h}_j^{dep}\big) \tag{4}$$

$$P(y_{i,j}) = \text{softmax}(\mathbf{s}_{i,j}) \tag{5}$$

$\mathbf{U}$, W and $\mathbf{b}$ in (3) are learned parameters; $\oplus$ denotes concatenation. The model is trained to minimize cross entropy loss w. r. t. the true dependency label between each pair of tokens. If a token is not assigned any head due to ∅ scoring highest for all other tokens, we assign the highest-scoring non-∅-relation and the corresponding head.

The model is simply trained to predict all link types in enhanced UD graphs. In the training section of the EWT corpus, we replace every sentence that contains a coordinated verb phrase with our manually corrected version of that sentence, or remove it from the corpus if it is one of the 927 conjunction sentences in the training section which we did not correct. For hyperparameter settings, see Appendix E.

5 Experiments

In this section, we describe our experiments on creating enhanced UD representations for coordinate constructions. Analogous to Nyblom et al. (2013), we measure precision, recall and F1 on enhanced links that are the result of propagation in coordinate constructions. For all experiments, we use gold sentence segmentation and tokenization, and evaluate on our manually corrected sentences from the dev and test sets of the EWT corpus.

5.1 Gold Standard Treebank Enhancing

We first address the research question of how to best generate enhanced representations for treebanks with gold standard basic annotations. We compare the following models: (1) an "Always" baseline, which simply propagates all incoming and outgoing links from the conjunction head to the conjunction dependent(s); (2) the rule-based converter by Schuster and Manning (2016) and the variations thereof we developed inspired by our corpus study; (3) our re-implementation of the SVM-based classifier by Nyblom et al. (2013); and (4) our neural-network (NN) based classifier. The latter uses AdamW (Loshchilov and Hutter, 2017) with a learning rate of 5e-5, a batch size of 1 and early stopping. Table 4 reports the results on the development and test sets of our manually verified conjunction dataset. The recall of the "Always" baseline is not at 100% because a small number of relations change their label during propagation, e.g., *nsubj→nsubj:pass*.

Rule-based conversion. We show results for successively adding components to the original converter (**RBC**). On the test set, adding propagation of non-core dependents and allowing several iterations increases recall and improves F1 by more than 2 points. On the dev set, in contrast, we do not observe these effects.[9] Adding our suggested passive/imperative fix surprisingly decreased performance. Analysis showed that the cases that our converter got wrong were caused by erroneous morphological feature annotations in the basic layer. In sum, our suggested improvements (**RBC2**) of heuristically propagating adjuncts (*obl*, *advmod*, *acl*) and allowing several resolution passes of the

---

[9] We assume that the reason is the presence of several informal-language sentences in the dev set that include multiple conjunctions (e.g., "etc. etc. etc."), whose annotation is unclear even in the basic gold standard.

converter seem to improve treebank enhancing, provided that the basic layer is correct.

ML-based conversion. Overall, the SVM and NN models show similar performance. As they perform already close to human agreement (see Table 2), further improvement may actually indicate overfitting. On the test set, the ML-based methods outperform the heuristic rule-based methods, surpassing the original converter by over 4 points F1. We conclude that learning structural rules based on actual gold standard data is more effective than hand-designing them. Differences on the dev set are less pronounced despite models being optimized on this data, again hinting to some qualitative differences between the two sets.

In order to determine which sources of information are most relevant, we perform ablation experiments for both classifiers. The features representing the candidate dependency label and the direction of the link are essential and kept in each case. Both the SVM and the NN classifiers draw most of their information from tree-based features. This effect is particularly pronounced for the SVM classifier, where performance drops by 10 to almost 20 points F1 when ommitting these features. The NN classifier's performance does not deteriorate as strongly under the same condition, indicating that some syntactic information can also be retrieved from contextualized word embeddings (see e.g., Tenney et al., 2019). Nonetheless, in most experiments, adding token features improves performance slightly, showing that they do contain important information for propagation decisions.

	Dev			**Test**		
	P	R	F	P	R	F
"Always" baseline	*23.1*	*99.6*	*37.5*	*28.0*	*99.6*	*43.7*

Table 4: **Predicting relation propagation for coordinate constructions on gold basic trees**. Precision, recall and F1 on propagated relations in the predicted vs. gold dependency graphs in our manually verified conjunction dataset. The gold dev and test sets contain 273 and 281 instances, respectively.

5.2 Propagating Conjunction Links in Automatic Parsing Setting

For the scenario of parsing from raw tokens, we compare two state-of-the-art parsers, StanfordNLP (Qi et al., 2018) and UDify (Kondratyuk and Straka, 2019), combined with the rule-based converter or ML-based conjunction propagators, and our graph-parser based edge predictor. The latter is trained on the subset of training sentences that either do not contain coordinated verb phrases or that were corrected by us. Hyperparameters and training settings are given in Appendix E.

Results for these experiments can be found in Table 5. The impact of the quality of the parsed basic dependencies is evident: Results are much better for the UDify parser (LAS F1 of 89.4 for basic dependencies on the EWT dev set) than for StanfordNLP (LAS F1 of 87.4). In the automatic setting, our heuristic extensions improve results compared to using the original converter, and there is no decrease in F1 on dev. As in the gold standard settings, ML-based extensions improve upon RBC on test, but not dev. Of the systems based on basic-layer tree parsers, RBC2 works best. However, performance of all pipeline systems show rather poor performance at or below an F1 of 70. Our graph-parser based edge predictor achieves by far the best results, outperforming all other models by a margin of over 7 points F1. This shows that in an automatic setting, most robust results are achieved by directly inducing dependency links between tokens, modeling conjunction only indirectly.

To estimate the impact of our corrections to the gold standard, we also train the graph parser on uncorrected data. The model trained on the corrected data has higher recall, but lower precision. This is expected to some extent as we introduce semantically motivated propagations of adjuncts, and we suspect that they may require a larger training set.

5.3 Discussion

The main insights comparing our experiments in the gold standard vs. the automatic parsing setting are as follows. Overall, our heuristic extensions for the rule-based converter are beneficial in both settings. In the gold setting, ML-based extensions lead to higher accuracy; when applying them on noisy parser output, they do not work well. However, using *one* end-to-end machine-learning model

	Dev			Test

Table 5: **Predicting relation propagation for coordinate constructions on parser output**. Otherwise same evaluation setup as in Table 4.

directly to generate enhanced representations for conjunctions outperforms the pipeline version. A possible reason for this might be that these models were all developed on gold data, while the graph-based parser does not rely on potentially wrong structural tree features and is also able to use internal confidence information for edges. Another advantage of the end-to-end model may stem from the fact that its training allows to leverage semantic information from training data of a larger number of dependency links, i.e., including those not occurring in coordinate constructions. This points to a promising future research direction, i.e, generating additional semi-artificial training data for conjunction propagation.

6 Conclusion and Outlook

We have presented a large-scale manually curated **dataset for conjunction propagation** in English. In contrast to previous work focusing on high-precision rule-based propagation, we propagate links in all cases that semantically suggest argument or adjunct sharing. In the gold standard treebank enhancing setting, we found **ML-based models** to outperform the de-facto standard rule-based converter by learning to exploit mostly structural features. However, one of our main insights is that neither rule-based nor ML-based classifiers work well on noisy parser output precisely because of this reliance on structural information. We propose to use a graph-parser based edge predictor instead and show that it outperforms pipeline-based models by a large margin. Our model reaches F1 scores between 0.75 and 0.78 with a precision of more than 0.82, a level of performance that may already be useful in downstream tasks.

Our models could be used for creating high-quality enhanced-level representations of conjunctions for the remaining English data, and could thus help in a UD community effort to continuously **improve the UD treebanks**. Future work also includes the study of conjunction propagation methods for **further languages**. Our in-depth study on English data provides several insights that we expect to be transferable cross-linguistically. First, conjunction propagation can to some extent be addressed using heuristic rules, but capturing the full semantic nature of the task requires manual annotation. Second, given appropriate training data, our machine-learning based approaches are also applicable to other languages.

In addition, it would be interesting to see if manually annotated data for coordinate constructions may be useful in natural language understanding tasks such as natural language inference (NLI). This is especially true for "stress test" datasets such as CONJNLI (Saha et al., 2020), which are designed to specifically test models' capabilities to process coordination.

Finally, as morphological features are generally important for this task, improving their automatic prediction (see e.g., Ramm et al., 2017; Myers and Palmer, 2019) as well as UD's gold standard seems to be a promising way to go. Our work has demonstrated the value of a linguistically motivated corpus study of a syntactic-semantic phenomenon, and shown that given manually curated data, rules for conjunction propagation can be learned effectively.

Acknowledgments

We would like to thank Sherry Tan and Johannes Hingerl for their support, as well as Jonas Kuhn, Heike Adel, Jannik Strötgen, and the anonymous reviewers for their useful comments regarding this work. In addition, we are grateful to the UD community, especially Nathan Schneider, for answering our questions.

Appendix

A Detailed converter description

In this section, we describe the algorithm implemented by the converter proposed by Schuster and Manning (2016).[10]

For each *conj* relation, the converter decides whether links ending or starting at the conjunction head (`gov`) should be propagated to the conjunction dependent (`dep`):

1. Governors of `gov` are always propagated to `dep`, unless the relation is explicitly treated as an exception (e.g., *vocative*, *discourse*, or *root*).
2. Dependents of `gov` are propagated to `dep` as follows:
    (a) If the dependent is attached via *nsubj* or *csubj*, it is only propagated if `dep` does not already have a subject. If `dep` has an *aux:pass* dependent, the relation is propagated as *nsubj:pass* / *csubj:pass*.
    (b) If the dependent is attached via a non-subject core relation (*obj*, *iobj*, *ccomp*, or *xcomp*), it is propagated if and only if it comes after `dep` in the linear order of the sentence.
    (c) Non-core dependents (such as *obl*) are never propagated.

The algorithm is able to handle many syntactically ambiguous cases, provided the underlying basic dependencies have resolved the ambiguity correctly. Consider the sentence "She was reading or watching a movie." If "movie" is correctly attached as an object of the conjunction dependent "watching," it will not be propagated to "reading" in the enhanced representation.

B Inter-annotator agreement study

Detailed comparisons between the three annotators can be found in Table 6, Table 7, and Table 8. In our study, we consider only links that are part of the enhanced layer, but not of the basic layer. For each annotator, we count for each label how often it occurs as an incoming or outgoing relation of a conjunct (columns labeled with the annotator's ID). Formally, the set E^l_A is the set of enhanced-layer edges that are (i) not present in the basic layer and (ii) involved in conjunctions as incoming or outgoing links of the conjuncts, with label l marked by annotator A. We also count the overlap of links for pairs of annotators. Using these counts, we then compute precision, recall and F1, treating one annotator as the system and one as the gold standard. For instance, when treating A as the gold standard and B as the system, this leads to:

$$Precision_{BA} = \frac{|E^l_A \cap E^l_B|}{E^l_B} \qquad (6)$$

$$Recall_{BA} = \frac{|E^l_A \cap E^l_B|}{E^l_A} \qquad (7)$$

Note that when reversing this order, P and R are simply reversed, F1 stays the same.

The following numbers compare each annotator to the original gold standard (not in tables). For modifier clauses (*acl*, *advcl*) and adverbials (*advmod*), B was the most aggressive in propagating dependencies, adding 55 links in total for these labels, while A and C only added 39 and 32 links, respectively. While all annotators propagated *obl* dependencies roughly to the same extent, agreement was high between A and B but lower (F1 64-68%) between C and the others, indicating that there are more ambiguities among these dependencies as well. Annotator C is generally more conservative in propagating dependencies. This is reflected in the relatively low recall when comparing to the other annotators, as well as the lower overall number of added links (285 as compared to 309 for A and 312 for B).

C Statistics on Treebank Modifications

As mentioned in Sec. 3.3, we made changes to the original treebank in 1,417 sentences containing coordinate verb phrases. While we focused on the dependency links starting or ending at conjuncts, we also fixed some additional errors that we spotted during this process. Table 9 gives statistics on these modifications (compare to Table 3, which includes only changes related to conjuncts).

Table 9: Statistics of modifications made to 1,417 sentences of the EWT, including both basic and enhanced layer. **#sents** reports the number of sentences in which the respective reported changes were made, **#total** reports the number of occurrences of the label in the original treebank.

D ML-based classifiers: features

Table 10 lists the features used in our SVM and NN models. Token features are extracted for conjunction head, conjunction dependent, and propagation target each. In addition to the listed features, we also experimented with including lemmas and POS tags, but did not find them to be useful in our ablation experiments.

E Graph-based edge predictor: Training Setup

Label lexicalization. At training time, we only use a limited label set of 56 labels where lexical material is replaced with placeholders, such as *obl:[case]*. At prediction time, we retrieve the missing lexical material from the dependency graph in a rule-based fashion. In the simplest case, this means simply substituting the word form of the dependent of the required type (e.g., a *case* relation). In conjunctions, the token in question may not have its own dependent of the correct type, instead "inheriting" if from its conjunction head. In that case, we retrieve the lexical material from the conjunction head's dependent.

Hyperparameters We perform only a minimal amount of hyperparameter tuning, mostly sticking with the values used by Kondratyuk and Straka (2019). One notable exception is the training regime, where we found low batch size and the AdamW optimizer to yield the best results. The full hyperparameter configuration can be found in Table 11.

RoBERTa embeddings

Ellipsis Resolution as Question Answering: An Evaluation

Rahul Aralikatte[1], **Matthew Lamm**[2], **Daniel Hardt**[3], and **Anders Søgaard**[1]

[1]University of Copenhagen, [2]Stanford University
[3]Copenhagen Business School

Abstract

Most, if not all forms of ellipsis (e.g., '*so does* Mary') are similar to reading comprehension questions ('*what does* Mary do'), in that in order to resolve them, we need to identify an appropriate text span in the preceding discourse. Following this observation, we present an alternative approach for English ellipsis resolution relying on architectures developed for question answering (QA). We present both single-task models, and joint models trained on auxiliary QA and coreference resolution datasets, clearly outperforming the current state of the art for Sluice Ellipsis (from 70.00 to 86.01 F_1) and Verb Phrase Ellipsis (from 72.89 to 78.66 F_1).

1 Introduction

Ellipsis resolution is a hard, open problem in NLP, and an important source of error in machine translation, question answering, and dialogue understanding (Vicedo and Ferrández, 2000; Dzikovska et al., 2009; Chung and Gildea, 2010; Macketanz et al., 2018; Petrn Bach Hansen and Sgaard, 2020). There are no large annotated text corpora for this phenomenon, even for English, and we only have annotations for a subset of the known ellipsis constructions. Since annotation is expensive and cumbersome, any synergies with existing NLP tasks could be useful and enable us to leverage auxiliary data when learning models for ellipsis resolution.

This paper presents a simple yet strong approach to ellipsis resolution based on a straightforward observation, depicted in Figure 1, that ellipsis resolution can be converted to a QA problem. Ellipsis and questions put in focus *referentially dependent* expressions (Carlson, 2006), or free variables (Partee, 1978), that need to be resolved in order to comprehend the discourse. For similar observations about different tasks, see McCann et al. (2018) and Gardner et al. (2019).

This straightforward observation leads us to suggest treating different forms of ellipsis resolution – and later, as an auxiliary task, coreference resolution – as a QA problem, and to apply state-of-the-art architectures for QA to ellipsis resolution tasks, as well as to experiment with using training data for QA and coreference resolution to improve our new ellipsis resolution models.

Sluice Ellipsis

Context: … But the way things are structured now you have to set aside your ego to make things happen. **The whole thing worked out**. I don't know **how**, but it did. Both sides had to work to make it happen …

Question: I don't know how, but it did.

Answer: The whole thing worked out

Verb Phrase Ellipsis

Context: … It has to be considered as an additional risk for the investor," said Gary P. Smaby of Smaby Group Inc., Minneapolis. "Cray Computer will be a concept stock," he said. "You either **believe Seymour can do it** again or you **don't** …

Question: You either believe Seymour can do it again or you don't.

Answer: believe Seymour can do it again

Figure 1: Examples of Sluice Ellipsis and Verb Phrase Ellipsis, represented as "questions" about their associated contexts. Wh-phrases and auxiliary verbs are marked in red and elided phrases are marked in blue.

Contributions We cast ellipsis as a QA problem, enabling us to induce models for it using neural architectures originally developed for QA. Applying these architectures out of the box enables us to establish strong results[1] for ellipsis resolution tasks, improving significantly over previous work. Using the same architecture for the different ellipsis resolution tasks, as well as for QA and coreference resolution, enables us to explore syn-

---

[1] Though we report state-of-the-art results for both sluice and verb phrase ellipsis, we consider these models as strong baselines for future research as they are obtained purely using existing methods.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 810–817
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

ergies between the tasks, and we show that training joint models on these tasks leads to even better performance.

2 Methodology

In this section, we briefly describe the various datasets used for training, and explain how they are converted into QA format. We then move on to the choice of model architectures and the reasoning behind their selection.

Sluice Ellipsis For training and evaluation of Sluice Ellipsis resolution models, we use the corpus introduced by Anand and McCloskey (2015), which contains 3,103 annotated examples of embedded sluices, collected from the New York Times section of the English Gigaword corpus. Since the annotators were free to paraphrase the antecedent, in some cases, a string match on the context does not return antecedent span indices. To ensure a fair comparison, we follow previous work (Rønning et al., 2018), which is also the current state-of-the-art, in ignoring these instances, and use their split for training, development and testing.

Verb Phrase Ellipsis Bos and Spenader (2011) provide Verb Phrase (VP) Ellipsis annotations for the WSJ part of the Penn Treebank. All 25 sections were annotated, and we follow them in using sections 0-19 for training, and 20-24 for testing. We further hold out sections 18-19 from the training data for development. This also enables to us compare our results directly with the current state-of-the-art for VP Ellipsis (Zhang et al., 2019).

Coreference Resolution For coreference resolution, which we use as an auxiliary task, we train and evaluate on two corpora: (i) the English portion of the OntoNotes 5.0[2] corpus with the standard data split used in the CoNLL-2012 shared task (Pradhan et al., 2012), and (ii) the WikiCoref corpus (Ghaddar and Langlais, 2016), which contains annotations of 30 documents from the English Wikipedia. From this dataset, we use 22 documents for training, 4 documents for development, and 4 for testing.

QA We also use SQuAD v1.1 (Rajpurkar et al., 2016) as an auxiliary reading comprehension dataset.

Task	Train	Dev	Test	ACL
	ELLIPSIS			
Sluice Ellipsis	1.4k	480	992	351
VP Ellipsis	264	20	78	984
	AUXILIARY			
OntoNotes	153k	18.8k	19.5k	463
WikiCoref	5.6k	630	638	2.2k
SQuAD	87.6k	10.6k	-	117

Table 1: QA pair counts and average context lengths (ACL) for different datasets, after conversion

Data Conversion For converting the various datasets into the QA format of `<context, question, answer>` triples, we perform a simple restructuring as shown in Figure 1. We consider the entire document as the context; the sentence in which the ellipsis/mention is present becomes the question, and the antecedent/entity becomes the answer. In case of coreference resolution, where a single sentence can have n mentions, we create n questions where every question is the same sentence with a different mention $i \in \{1 \ldots n\}$ marked for resolution with `<ref>` and `</ref>` tags. Table 1 shows the number of QA pairs created from each dataset and the average number of words in their contexts.

QA Architectures Generally, QA models have two main components: (i) an encoder module which learns to represent the question and its context, and (ii) a span selection module which predicts the start and end span indices of the answer if it is present in the context. In this work, we present experiments with three diverse models which take entirely different approaches to build the encoder module: (i) DrQA (Chen et al., 2017), with an LSTM encoder, (ii) QANet (Yu et al., 2018), with a CNN encoder, and (iii) BERT (Devlin et al., 2019), with a (pretrained) transformer encoder. We use the three different models to show that the between-task synergies are relatively robust across architectures; but one architecture (BERT) is clearly superior to the others and will be the standard baseline we propose for future research.[3]

---

[2] `https://catalog.ldc.upenn.edu/LDC2013T19`

[3] Note that there are many differences between these architectures; not only the encoder networks. The number of parameters differ, and BERT is pre-trained on large volumes of data. Our purpose here is not comparing strategies, but simply showing that synergies can be seen across all architectures. For more details, see Appendix B.

TASK	SOTA	SINGLE TASK			JOINT		
		DRQA	QANET	BERT	DRQA	QANET	BERT
Sluice Ellipsis	70.00 (Rønning et al., 2018)	**77.48**	**75.70**	**<u>85.10</u>**	**80.17**	**77.11**	**<u>86.01</u>**
VP Ellipsis	72.89 (Zhang et al., 2019)	62.86	1.93	**76.42**	63.54	22.49	**<u>78.66</u>**

Table 2: Ellipsis resolution scores are token-level F_1. Bold-faced results are better than the previous state-of-the-art; underlined results are the new state-of-the-art. When evaluated, our best joint architecture scores 72.31 on OntoNotes and 65.30 on WikiCoref (macro-averages of MUC, B^3, and $CEAF_{\phi_4}$ scores). See Appendix C.2 for why these numbers are not directly comparable to previously reported coreference resolution results in literature.

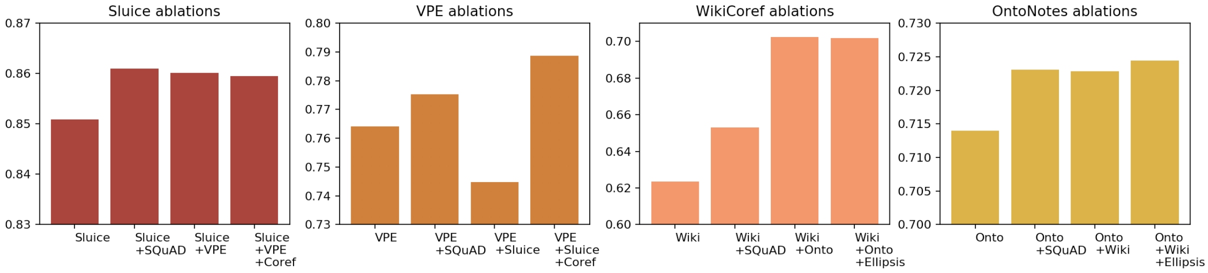

Figure 2: Dataset ablations (F_1)

3 Experiments & Results

We conduct two sets of experiments: (i) the SINGLE-TASK experiments, in which we train and evaluate separate models for the two ellipsis resolution tasks; and (ii) the JOINT modelling experiments, where we train on the best possible combination of ellipsis resolution, coreference resolution and QA data, as determined on the validation set. The results can be seen in Table 2.[4]

Single-Task Setup The SINGLE-TASK DrQA model improves the state-of-the-art on sluice ellipsis by 7.48 F_1. The SINGLE-TASK QANet model also improves the state-of-the-art on sluice ellipsis by 5.7 F_1, but fails to learn anything meaningful for VP ellipsis. We hypothesise this is due to the fact that 264 training examples are not enough to train the model's large stack of encoder blocks from scratch.

The SINGLE-TASK BERT model achieves state-of-the-art results in both the ellipsis datasets with absolute error reductions of 50.33% (Sluice Ellipsis) and 13.02% (VP Ellipsis). Interestingly, it also achieves a 17.10% error reduction over the best previously reported results on WikiCoref, but see Appendix C.2 for why such a direct comparison of numbers is not entirely fair.

Joint Setup The JOINT models always perform on-par with, or better than the SINGLE-TASK models. In this setup, the BERT models beat the previous state-of-the-art for both Sluice and VP Ellipsis with 53.37% and 21.28% absolute error reductions respectively.

4 Dataset ablations

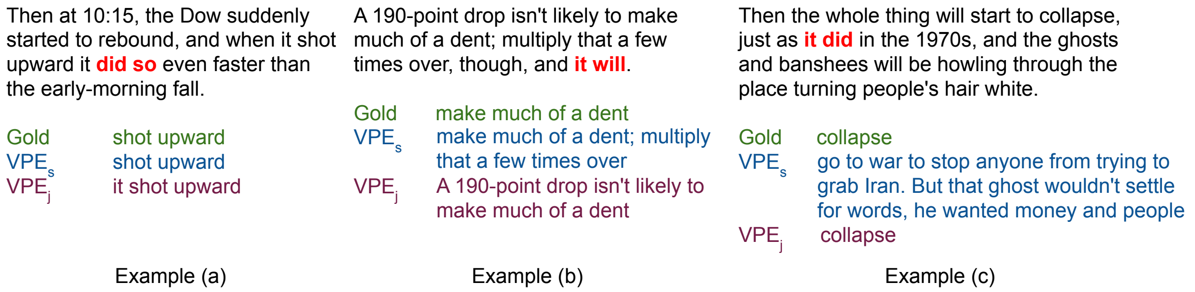
We determine the best task combinations on held-out validation data for each ellipsis resolution task.[5] For Sluice Ellipsis, the best results are obtained by training the models on a combination of Sluice and VP Ellipsis data. For VP Ellipsis, the best performance is attained when the models are trained with a combination of all datasets. When training a model for a particular task, we sample auxiliary data from other datasets to match the size of the main task's dataset. For each dataset, the variations in its F_1 scores of the best performing architecture when combined with other datasets are shown in Figure 2. The most interesting findings from these ablations are mentioned below.

When the two ellipsis datasets are combined, the overall performance of the models increase for both tasks by around 1% each. This shows that the two types of ellipsis are similar, and that when learning ellipsis resolution models, there is considerable synergy between the two resources. If we add subsampled coreference data when training these models, the Verb Phrase Ellipsis models gain up to 2.9%. One possible explanation

---

[4] The reported results are the average of three independent runs with different random seeds.

[5] These ablations are performed on the best performing (BERT) model.



Then at 10:15, the Dow suddenly started to rebound, and when it shot upward it **did so** even faster than the early-morning fall.

Gold	shot upward
VPE_s	shot upward
VPE_j	it shot upward

Example (a)

A 190-point drop isn't likely to make much of a dent; multiply that a few times over, though, and **it will**.

Gold	make much of a dent
VPE_s	make much of a dent; multiply that a few times over
VPE_j	A 190-point drop isn't likely to make much of a dent

Example (b)

Then the whole thing will start to collapse, just as **it did** in the 1970s, and the ghosts and banshees will be howling through the place turning people's hair white.

Gold	collapse
VPE_s	go to war to stop anyone from trying to grab Iran. But that ghost wouldn't settle for words, he wanted money and people
VPE_j	collapse

Example (c)

Figure 3: Selected gold and predicted antecedent spans from SINGLE-TASK Verb Phrase Ellipsis (VPE_s in figure) and JOINT Verb Phrase Ellipsis (VPE_j in figure) models.

could be more similarities between noun phrases and verb phrases, than between noun phrases and the sentences that are elided in Sluice Ellipsis resolution.

5 Error Analysis

We now look at some errors made by our best performing models. First, we compare the errors made by our SINGLE-TASK and JOINT Sluice Ellipsis resolution models before moving on to VP Ellipsis.[6]

Sluice Ellipsis The JOINT Sluice Ellipsis results improve modestly over the SINGLE-TASK Sluice Ellipsis results. This is noteworthy, since the added VP Ellipsis data is quite small compared to the size of the sluice data. These models consistently select an antecedent of the right syntactic form, which is normally a complete sentence. Many of the errors consist of empty outputs: SINGLE-TASK Sluice Ellipsis produces 58 empty outputs, while JOINT Sluice Ellipsis produces 63. Another source of error is discontiguous antecedents. It is not unusual for the gold antecedent to be a discontiguous span (Donecker, 1996), but our models are not permitted to produce such antecedents, so these cases will always be a source of error.

All the systems have problems when the antecedent follows the ellipsis, as in the following example: *I don't know why, but they seem to need a story.* We also compared the right and left periphery scores of sluices, and found better results predicting the right periphery: for SINGLE-TASK Sluice Ellipsis, there were 678 matches on the left edge, and 733 on the right edge; for JOINT Sluice Ellipsis, there were 703 left matches and 734 right matches.

Verb Phrase Ellipsis The SINGLE-TASK VP models trained with just VP Ellipsis data improves on the current state of the art, and further improvement is observed when trained on auxiliary data, especially the Sluice Ellipsis resolution dataset. While the JOINT VP Ellipsis model is generally better than the SINGLE-TASK model, joint training with Sluice Ellipsis resolution data also seems to introduce unfortunate biases. While the SINGLE-TASK model always selects antecedents of the right syntactic form, i.e., verb phrases, the JOINT model may select sentential antecedents. See examples in Figure 3.

In Example (a), the JOINT VP model incorrectly includes the subject *it*, presumably because the sluice data includes complete sentences as antecedents. Similarly in Example (b) – though the SINGLE-TASK model correctly chooses an antecedent beginning with the verb *make*, it continues with additional material that does not form a coherent antecedent. The JOINT result is also incorrect, but note that it consists of the complete sentence containing the correct VP antecedent. Example (b) presents the advantages and disadvantages of the joint ellipsis training data. While the two types of ellipsis require antecedents of different forms, they have similar requirements in terms of where in the context the antecedent is to be found. Example (c) further supports this point. Here the JOINT result is perfect, while the SINGLE-TASK result finds an antecedent that is in the wrong part of the discourse. The SINGLE-TASK model is slightly better with left periphery matches than right: we found 58 left and 55 right matches. This is reversed with the JOINT model, with 54 left and 60 right matches.

---

[6] We also briefly discuss how coreference resolution benefits from synergies with ellipsis in Appendix C.1.

6 Related Work

We are not the first to use question answering to redefine a set of tasks. Recently, He et al. (2015) showed that semantic role labeling annotations could be solicited by asking simple questions that implicitly target predicate-argument relations in a sentence. Parallel to our work, Hou (2020) cast bridging anaphora resolution as question answering based on context. Wu et al. (2020) and Li et al. (2020) also reformulate coreference resolution and named entity recognition as QA. In the realm of re-framing relation extraction as a QA problem, Levy et al. (2017) and Abdou et al. (2019) create monolingual and multilingual template based QA datasets respectively, which yield relation extraction models which were better at generalizing in the zero-shot setting. Extending this idea, McCann et al. (2018) introduced the DecaNLP challenge, which casts 10 core tasks in NLP as question-answering problems. Similar to our work, their architecture jointly learns across all of these tasks. DecaNLP includes pronoun resolution, a subset of coreference resolution, but it does so only on a small, hand-crafted dataset; it does not address ellipsis.

Limitations of our approach One limitation of our approach is that, like most previous work, we assume ellipsis and coreference resolution amount to finding antecedent spans that corefer with the target mention. This is not always the case; the elided material can: (i) have extra-linguistic antecedents, and (ii) refer to something that is contextually implied.

7 Conclusion

We present strong models for Sluice and Verb Phrase ellipsis resolution problems, by reformulating them as machine reading comprehension problems, significantly outperforming the previously best reported results. We also empirically show that training these models jointly and with auxiliary data from coreference resolution and question-answering further improves their performance. Our code is publicly available at https://github.com/rahular/ellipsis-baselines.

A Similarity between Ellipsis and Coreference Resolution

Linguists have long pointed out deep links among different forms of ellipsis, as well as between ellipsis and pronominal anaphora. For example, Merchant (2001) presents a unified account of ellipsis phenomena within a minimalist syntactic framework, and theorists such as Postal (1966) and Elbourne (2013) go so far as to argue that pronouns are also elliptical forms. The exact nature of the connections between ellipsis and anaphoric constructions remains a subject of controversy among linguists. However it is clear that there are rooted connections, and in our view these connections represent potential areas to be exploited with forms of knowledge transfer among datasets of different types.

Typically in NLP, ellipsis and coreference have been treated as distinct tasks. Possible exceptions include Lin et al. (2016), who present a rule-based, feature-rich system for handling ellipsis and coreference in Chinese medical dialogues, but the synergy between the two subsystems is limited; and Banjade et al. (2015), who reduce ellipsis and coreference to problems of alignment to an auxiliary text implicitly describing the universe of the dialogue in question.

B QA Models

We briefly describe the architectures of the QA models below. All experiments are conducted on a single 12 GB GPU. For all models, we use the hyperparameter values recommended in their respective papers.

DrQA The Document Reader component of DrQA consists of a context and a question encoder followed by two span prediction classifiers. The context encoder is a multi-layer bidirectional LSTM (Hochreiter and Schmidhuber, 1997) which takes in word embeddings (Pennington et al., 2014, GloVe), similarity based features (whether the token appears in the question in it's original, lowercase or lemma form), and other token level features (positional tags, named entities and term frequency) as input. The concatenation of each layer's hidden units is used as the context vector. The question encoder is another LSTM which takes word embeddings as input and combines the resulting hidden units using a simple attention mechanism to form the question vector. A bilinear term which captures the similarities between context and question vectors is used to combine the two vectors and the resulting vector used as input to the span prediction classifiers. The two classifiers predict the start and the end span respectively and are trained independently.

QANet In QANet, each encoder layer is a stack of depthwise separable convolutions followed by a multi-head self-attention mechanism placed inside a residual block. Initially, words in the context and question are embedded using a combination of GloVe and character embeddings. They are then contextualized individually with an encoder block. The representations are then passed through a context-query attention layer to obtain a combined representation of the context and question. This is further passed through three encoding blocks before feeding it into a classifier for predicting the answer spans.

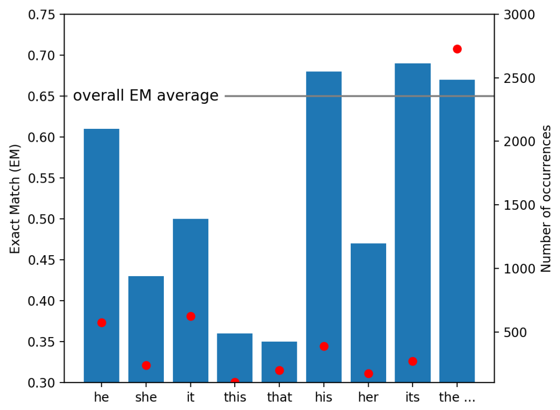

Figure 4: Exact match percentage (bars) and number of occurrences (dots) of referential forms in OntoNotes

BERT We use the pre-trained BERT$_{BASE}$ uncased model to encode questions and their contexts. It has 12 Transformer blocks, 12 self-attention heads, and a hidden size of 768. Word piece tokenization (Wu et al., 2016) is performed, both on the context paragraph and the question. The boundaries of the two sequences are marked by dummy symbols. The context and the question are joined with a $[SEP]$ token in between, and the $[CLS]$ token is prepended at the beginning to form the input. The representation of the $[CLS]$ token is fed into a single-layer MLP with 2 outputs which is used to predict the span indices.[7]

C Coreference Resolution

In this section, we analyse the best performing coreference models and discuss why they cannot be compared with other works in literature.

C.1 Error Analysis

The JOINT OntoNotes model improves a little over the SINGLE-TASK counterpart. Here we examine specific referential forms in OntoNotes (WikiCoref has similar traits), as shown in Figure 4. In general, performance is better on frequent pronouns – e.g., 'he' over 'she', 'this' and 'that'. An exception to this is that 'it' is less accurate, but more frequent than 'he'. It is notable that the possessive pronouns ('his', 'her', 'its') are all more accurate than their nominative counterparts ('he', 'she', 'it'), perhaps because they tend to have a closer connection to their antecedents. Overall, the single-word referential forms are less accurate than multiple-word forms. For example, definite descriptions (forms beginning with 'the') are more accurate than any of the single-word forms, with the exception of 'its'. We speculate that multi-word forms provide more specific information, thus limiting the set of potential antecedents. It is also interesting to break down error by the grammatical gender of the pronouns. Male pronouns generally tend to be more accurate than their female counterparts. Antecedents of 'he' and 'his' are matched 20% more frequently than for 'she' and 'her'. This is probably due to an unfortunate bias in OntoNotes, where female pronouns are 50% rarer than male pronouns.

C.2 Result Comparability

Converting coreference into QA fundamentally changes the coreference resolution problem: It, on the one hand, makes the coreference resolution problem harder, in that we require the identification of a specific antecedent span, rather than any mention in the entity chain; on the other hand, the problem becomes easier by providing the bracketing of the mention that needs to be resolved. Due to these differences, it is not possible to directly compare our results with others in literature. For analysis, to make our results more comparable with Lee et al. (2018), we provided their model with the bracketing of the mentions and considered the first mention to be the antecedent. This way we can reinterpret their clusters as question-answer pairs and do not penalize them for mention bracketing errors, only considering pairs where they correctly identify mentions. Note this gives their model an advantage over ours, as their model considers multiple sources of evidence for inferring the coreference links, and gets to pick the subset of data on which the models are compared. On OntoNotes, in this setting, and after pruning around $7,358$ mentions Lee et al. (2018) bracketed wrongly, their new average F$_1$ score is 75.9. Our performance on the same subset of the data is 72.1. Upon manual inspection, we see the model in Lee et al. (2018) has a strong bias favoring nominal antecedents, whereas our model is more likely to predict clausal antecedents. On WikiCoref, our model remains better than the previous state of the art by some margin, with an F$_1$ of 69.2 over 43.6.

---

[7] We use the implementation detailed in Wolf et al. (2020).

Jointly Improving Language Understanding and Generation with Quality-Weighted Weak Supervision of Automatic Labeling

†Ernie Chang, †Vera Demberg, *Alex Marin
†Dept. of Language Science and Technology, Saarland University
*Microsoft Corporation, Redmond, WA
cychang@coli.uni-saarland.de

Abstract

Neural natural language generation (NLG) and understanding (NLU) models are data-hungry and require massive amounts of annotated data to be competitive. Recent frameworks address this bottleneck with generative models that synthesize weak labels at scale, where a small amount of training labels are expert-curated and the rest of the data is automatically annotated. We follow that approach, by automatically constructing a large-scale *weakly-labeled data* with a fine-tuned GPT-2, and employ a semi-supervised framework to jointly train the NLG and NLU models. The proposed framework adapts the parameter updates to the models according to the estimated label-quality. On both the E2E and Weather benchmarks, we show that this weakly supervised training paradigm is an effective approach under low resource scenarios with as little as 10 data instances, and outperforming benchmark systems on both datasets when 100% of training data is used.

1 Introduction

Natural language generation (NLG) is the task that transforms meaning representations (MR) into natural language descriptions (Reiter and Dale, 2000; Barzilay and Lapata, 2005); while natural language understanding (NLU) is the opposite process where text is converted into MR (Zhang and Wang, 2016). These two processes can thus constrain each other – recent exploration of the duality of neural natural language generation (NLG) and understanding (NLU) has led to successful semi-supervised learning techniques where both labeled and unlabeled data can be used for training (Su et al., 2020; Tseng et al., 2020; Schmitt and Schütze, 2019; Qader et al., 2019; Su et al., 2020).

Standard supervised learning for NLG and NLU depends on the access to labeled training data – a major bottleneck in developing new applications.

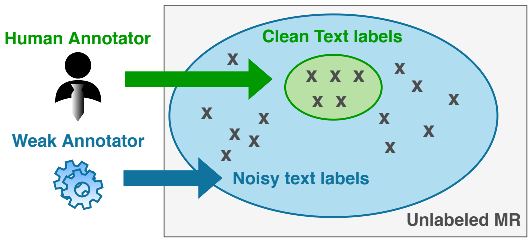

Figure 1: **Training scenario**: Each × represents a labeled data instance. The goal is to learn both from few human-labeled instances (inner) and large amounts of weakly labeled data (outer).

In particular, neural methods require a large annotated dataset for each specific task. The collection process is often prohibitively expensive, especially when specialized domain expertise is required. On the other hand, learning with weak supervision from noisy labels offers a potential solution as it automatically builds imperfect training sets from low cost labeling rules or pretrained models (Zhou, 2018; Ratner et al., 2017; Fries et al., 2020). Further, labeled data and large unlabeled data can be utilized in semi-supervised learning (Lample et al., 2017; Tseng et al., 2020), as a way to *jointly* improve both NLU and NLG models.

To this end, we target a weak supervision scenario (shown in Figure 1) consisting of small, high-quality expert-labeled data and a large set of unlabeled MR instances. We propose to expand the labeled data by automatically annotating the MR samples with noisy text labels. These noisy text labels are generated by a *weak annotator*, which is built upon recent works that directly fine-tune GPT-2 (Radford et al., 2019) on joint meaning representation (MR) and text (Mager et al., 2020; Harkous et al., 2020). Then, we jointly train the NLG and NLU models in a two-step process with semi-supervised learning objectives (Tseng et al., 2020). First, we use pretrained models to estimate quality scores for each sample. Then, we down-weight the

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 818–829
April 19 - 23, 2021.

loss updates in the back-propagation phase using the estimated quality scores. This way, the models are guided to avoid mistakes of the *weak annotator*.

On two benchmarks, E2E (Novikova et al., 2017b) and Weather (Balakrishnan et al., 2019), we utilize varying amount of labeled data and show that the framework is able to successfully learn from the synthetic data generated by *weak annotator*, thereby allowing jointly-trained NLG and NLU models to outperform other baseline systems.

This work makes the following contributions:

1. We propose an automatic method to overcome the lack of text labels by using a fine-tuned language model as a *weak annotator* to construct text labels for the vast amount of MR samples, resulting in a much larger labeled dataset.
2. We propose an effective two-step weak supervision using the dual mutual information (DMI) measure which can be used to modulate parameter updates on the weakly labeled data by providing quality estimates.
3. We show that the approach can even be used to improve upon baselines with 100% data to establish new state-of-the-art performance.

2 Related Work

Learning with Weak Supervision. Learning with weak supervision is a well-studied area that is popularized by the rise of data-driven neural approaches (Ratner et al., 2017; Safranchik et al., 2020; Bach et al., 2017; Wu et al., 2018; Dehghani et al., 2018; Jiang et al., 2018; Chang et al., 2020a; de Souza et al., 2018). Our approach incorporates similar line of work, by providing noisy labels (text) with a fine-tuned LM which incorporates prior knowledge from general-domain text and data-text pair (Budzianowski and Vulić, 2019; Chen et al., 2020; Peng et al., 2020; Mager et al., 2020; Harkous et al., 2020; Shen et al., 2020; Chang et al., 2020b, 2021b,a), and use it as the *weak annotator*, similar by functionality to that of fidelity-weighted learning (Dehghani et al., 2017), or data creation tool *Snorkel* (Ratner et al., 2017).

Learning with Semi-Supervision. Work on semi-supervised learning considers settings with some labeled data and a much larger set of unlabeled data, and then leverages both labeled the unlabeled data as in machine translation (Artetxe et al., 2017; Lample et al., 2017), data-to-text generation (Schmitt and Schütze, 2019; Qader et al., 2019) or more relevantly the joint learning framework for training NLU and NLG (Tseng et al., 2020; Su et al., 2020). Nonetheless, these approaches all assume that a *large collection of text* is available, which is an unrealistic assumption for the task due to the need for expert curation. In our work, we show that both NLU and NLG models can benefit from (1) automatically labeling MR with text, and (2) by semi-supervisedly learning from these samples while accounting for their qualities.

3 Approach

We represent the set of meaning representation (MR) as X and the text samples as Y. There are no restrictions on the format of the MR: each $x \in X$ can be a set of slot-value pairs, or can take the form of tree-structured semantic definitions as in Balakrishnan et al. (2019). Each text $y \in Y$ consists of a sequence of words.

In our setting, we have (1) k labeled pairs and (2) a large quantity of unlabeled MR set X_U where $|X_U| \gg k > 0$. (We force $k > 0$ as we believe a reasonable generation system needs at least a few demonstrations of the annotation.) This is a realistic setting for novel application domains, as unlabeled MR are usually abundant and can also be easily constructed from predefined schemata. Notably, *we assume no access to outside resources containing in-domain text*. The k annotations are all we know about in-domain text.

The core of our approach consists of first labeling MR samples with text, and then training on the expanded dataset. We start with describing the process of creating weakly labeled data (§4). Next, we delve into the semi-supervised training objectives for the NLU and NLG models, which allow the models to learn from labeled and unlabeled data (§5). Lastly, we explain the training process where NLG and NLU models are jointly optimized in two steps: In *step 1*, we pretrain the models on the weakly-labeled corpus, then *continue updating the models* on the combined data consisting of the weak and real data in *step 2*. Importantly, to account for the noise that comes with the automatic weak annotation, *step 2* trains the model with quality-weighted updates (§6). We depict this process in Figure 2.

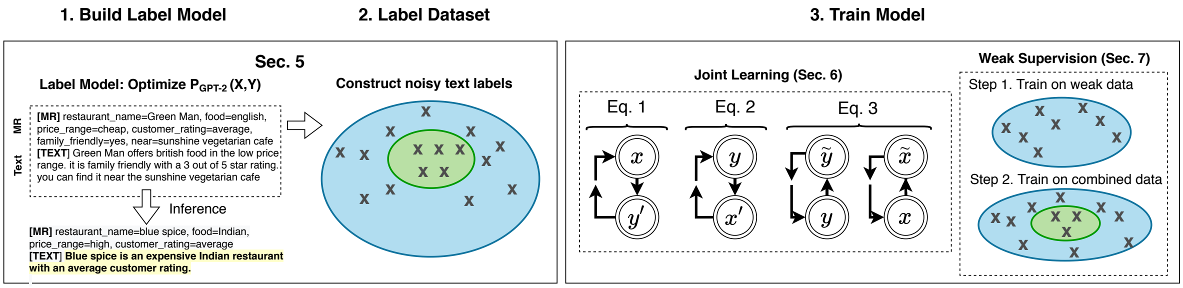

Figure 2: Depiction of the proposed framework. In *joint learning*, gradients are back-propagated through solid lines.

4 Creating Weakly Labeled Data

We construct synthetic data in two ways: (1) creating more MR samples (see §4.1), and (2) by creating a larger parallel set of MRs with texts (see §4.2).

4.1 Generating Synthetic MR Samples

We consider a simple way of MR augmentation via value swapping. This creates more unlabeled MR to be annotated by the *weak annotator* and also provide a substantial augmentation that benefits the autoencoding on MR samples (see Equation 3) by exposing it to a larger set of MR.

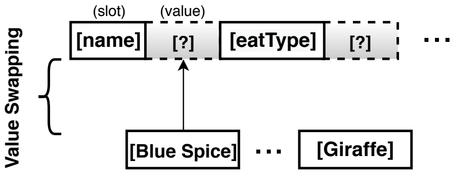

Figure 3: Depiction of MR augmentation in the E2E corpus.

Since each slot in the MR samples corresponds to multiple possible values, we pair each *slot* with a randomly sampled value collected from the set of all MR samples to obtain new combination of slot-value pairs. This way, we create a large synthetic MR set.

4.2 Creation of Parallel MR-to-Text Set

GPT-2 (Radford et al., 2019) is a powerful language model pretrained on the large WebText corpus. Recent work on conditional data-to-text generation (Harkous et al., 2020; Mager et al., 2020) demonstrated that fine-tuning GPT-2 on the joint distribution of MR and text for text-only generation yields impressive performance.

The fine-tuned model generates in-domain text by conditioning on samples from the augmented MR set (X_U). Rather than using GPT-2 outputs directly, we employ them in a process analogous to knowledge distillation (Tan et al., 2018; Tang et al., 2019; Baziotis et al., 2020) where the fine-tuned GPT-2 provides supervisory signals instead of being used directly for generation.

We now describe the process of GPT-2 fine-tuning. Given the sequential MR representation $x_1 \cdots x_M$ and a sentence $y_1 \cdots y_N$ in the labeled dataset (X_L, Y_L), we maximize the joint probability $p_{\text{GPT-2}}(X_L, Y_L)$, where each sequence is concatenated into "[MR] $x_1 \cdots x_M$ [TEXT] $y_1 \cdots y_N$". In addition, we also freeze the input embeddings when fine-tuning had positive impact on performance, following Mager et al. (2020). At test time, we provide the MR samples as context as in conventional conditional text generation:

$$\tilde{y}_j = \arg\max_{y_j}\{p_{\text{GPT-2}}(y_j \mid y_{1:j-1}, x_{1:N})\}$$

The fine-tuned LM conditions on augmented MR sample set X_U to generate the in-domain text[1], forming the weak label dataset $\mathcal{D}_W = (X_U, \tilde{Y}_L)$ with noisy labels $\tilde{y}_i \in \tilde{Y}_L$. In practice, the fine-tuned LM produces malformed, synthetic text which does not fully match with the MR it was conditioned on, as it might hallucinate additional values not consistent with its MR counterpart. Thus, it is necessary to check for factual consistency (Moryossef et al., 2019). We address this point next.

Past findings showed (e.g. (Wang, 2019)) that the removal of utterance with "hallucinated" facts (MR values) from MR leads to considerable performance gain, since inconsistent MR-Text correspondence might misguide systems to generate incorrect facts and deteriorate the NLG outputs. We filter out the synthetic, poor quality MR-text

---

[1] We adopt the Top-k random sampling with $k = 2$ to encourage diversity and reduce repetition (Radford et al., 2019)

pairs by training a separate NLU model on the original labeled data to predict MR from generated text labels. These MRs can then be checked against the paired MR in $\mathcal{D}_W$ via pattern matching as inspired by Cai and Knight (2013); Wiseman et al. (2017). Specifically, we use a measure of semantic similarity in terms of *f-score via matching of slots between the two MRs*. We keep all MR-text pairs with f-scores above 0.7, as we found empirically that this criterion retains a sufficiently large amount of high-quality data. The removed text sentences are used for unsupervised training objectives as in Eq. 1-3. Using this method, we create a collection of parallel MR-text samples (~500k) an order of magnitude larger than even the full training sets (~40k for E2E and ~25k for Weather).

5 Joint learning of NLG and NLU

For both NLU and NLG models, we adopt the same architecture as Tseng et al. (2020), which use two Bi-LSTM-based (Hochreiter and Schmidhuber, 1997) encoders for each model. The NLU decoder for slot-value structured data (e.g., E2E, Mrkšić et al., 2017) contains several 1-layer feed-forward neural classifiers for each slot; while for tree-structured meaning representation in Balakrishnan et al. (2019), the decoder is LSTM-based. In this framework, both NLU and NLG models are trained to infer the shared latent variable repeatedly – starting from either MR or text, in order to encourage semantic consistency. Each model can be improved via gradient passing between them using REINFORCE (Williams, 1992). This way, the models benefit from each other's training in a process known as the *dual learning* (Su et al., 2020), which consists of both *unsupervised* and *supervised* learning objectives. We now go into details describing them.

Unsupervised Learning. Starting from either a MR sample or a text sample, the models project the sample from one space into the other, then map it back to the original space (either MR or text sample, respectively), and compute the reconstruction loss after the two operations. This repetition will result in aligned pairs between the MR samples and corresponding text (He et al., 2016). Specifically, let $p_\theta(y|x)$ be the probability distribution to map x to its corresponding y (NLG), and $p_\phi(x|y)$ be the probability distribution to map y back to x (NLU). Starting from $x \in X$, its objective is:

$$\max_{\phi} \mathbb{E}_{x \sim p(X)} \log p_\phi(x|y');\; y' \sim p_\theta(y|x) \quad (1)$$

which ensures the semantic consistency by first performing NLG accompanied by NLU in direction $x \to y' \to x$. Note that only p_ϕ is updated in this direction and p_θ serves only as as an auxiliary function to provide pseudo samples y' from x. Similarly, starting from $y \in Y$, the objective ensures semantic consistency in the direction where the NLU step is followed by NLG: $y \to x' \to y$[2]:

$$\max_{\theta} \mathbb{E}_{y \sim p(Y)} \log p_\theta(y|x');\; x' \sim p_\phi(x|y) \quad (2)$$

We further add two autoencoding objectives on both MR and text samples:

$$\max_{\theta,\phi} \mathbb{E}_{x \sim p(X), y \sim p(Y)} \log p_\phi(x|x) p_\theta(y|y) \quad (3)$$

Thus, unlabeled text samples can be used as they are shown to benefit the text space (Y) by introducing new signals into learning directions $y \to x' \to y$ and $\tilde{y} \to y$. Thus, *we use all in-domain text data* whether they have corresponding MR or not. Note that following (Tseng et al., 2020), we also adopt the variational optimization objective upon the latent variable z which was shown to pull the inferred posteriors $q(z|x)$ and $q(z|y)$ closer to each other. In this case, the parameters of both NLG and NLU models are updated.

Supervised Learning. Apart from the above unsupervised objectives, we can impose the supervised objective on the k labeled pairs:

$$\max_{\theta,\phi} \mathbb{E}_{x,y \sim p(X_L, Y_L)} \log p_\theta(y|x) + \log p_\phi(x|y) \quad (4)$$

Each MR is flattened into a sequence and fed into the NLG encoder, giving NLG and NLU models an inductive bias to project similar MR/text into the surrounding latent space (Chisholm et al., 2017). As we observed anecdotally[3], the information flow enabled by REINFORCE allows the models to utilize unlabeled MR and text, boosting the performance in our scenarios.

---

[2] This direction is usually termed as *back translation* in MT community (Sennrich et al., 2016; Lample et al., 2018)

[3] Tseng et al. (2020) noticed similar trend in the experiments.

6 Learning with Weak Supervision

The primary challenge that arises from the synthetic data is the *noise* introduced during the generation process. Noisy and poor quality labels tend to bring little to no improvements (Elman, 1993; Frénay and Verleysen, 2013). To better train on the large and noisy corpus described in section §4 (size ~500k), we employ a two-step training process motivated by fidelity-weighted learning (Dehghani et al., 2018). The two-step process consists of (1) *pretraining* and (2) *quality-weighted fine-tuning* to account for the heterogenous data quality.

Step 1: ***Pre-train two sets of models on weak and clean data, respectively.*** We train the first set of models (*teacher*) consisting of NLU, NLG, and autoencoder (AUTO) models on the clean data. The second set of models (i.e. NLU and NLG) is the *student* that pretrains on the weak data.

Step 2: ***Fine-tune the student model parameters on the combined clean and weak datasets.*** We use each *teacher model* to determine the step size for each iteration of the stochastic gradient descent (SGD) by down-weighting the training step of the corresponding *student model* using the sample quality given by the teacher. Data points with true labels will have high quality, and thus will be given a larger step-size when updating the parameters; conversely, we down-weight the training steps of the student for data points where the teacher is not confident. For this specific fine-tuning process, we update the parameters of the student (i.e. NLG and NLU models) at time t by training with SGD, where $\mathcal{L}(\cdot)$ is the loss of predicting $\hat{y}$ for an input x_i when the label is $\tilde{y}$. The weighted step is then $c(x_i, \tilde{y}_i)\nabla\mathcal{L}(\hat{y}, \tilde{y})$, where $c(\cdot)$ is a scoring function learned by the *teacher* taking as input MR x_i and its noisy text label $\tilde{y}_i$. In essence, we control the degree of parameter updates to the *student* based on how reliable its labels are according to the *teacher*.

We denote $c(\cdot)$ as the function of the label quality based on the *dual mutual information (DMI)*, defined as the *absolute* difference between mutual information (MI)[4] in inference directions $x \rightarrow y$ and $y \rightarrow x$. Bugliarello et al. (2020) shows that $\text{MI}_{x\rightarrow y}$ correlates to the difficulty in predicting y from x, and vice versa. Thus we expect the difference between $\text{MI}_{x\rightarrow y}$ and $\text{MI}_{y\rightarrow x}$ for clean sample (x, y) to be relatively small compared to noisy samples, since the level of difficulty is largely *proportional* between NLU and NLG on the samples – difficulty in inferring x from y will result in harder prediction of y from x. Based on this intuition, the DMI score of the sample (x, y) is defined as:

$$exp\left\{\left|\underbrace{\log\frac{q_{\text{AUTO}}(y)}{q_{\text{NLG}}(y|x)}}_{\text{MI}_{x\rightarrow y}} - \underbrace{\log\frac{q_{\text{AUTO}}(x)}{q_{\text{NLU}}(x|y)}}_{\text{MI}_{y\rightarrow x}}\right|\right\}.$$

where $q(\cdot)$ are the two respective models. The DMI for a clean MR-text pair should be *relatively small*, as the two sides contain proportional semantic information[5], and so poor quality samples tend to have higher DMI scores and lower $c(\cdot)$ as they are *less semantically aligned*. Thus, $c(\cdot)$ defines the *confidence* (quality) the teacher has about the current MR-text sample. We use $c(\cdot)$ to scale η_t. Note that $\eta_t(t)$ does not necessarily depend on each data point, whereas $c(\cdot)$ does. We define $c(x_t, y_t)$ as:

$$c(x_t, y_t) = 1 - \mathcal{N}(\text{DMI}(x_t, y_t))$$

where $\mathcal{N}(\cdot)$ normalizes DMI over all samples in both clean and weak data to be in $[0, 1]$.

7 Experiment Setting

Data. We conduct experiments on the Weather (Balakrishnan et al., 2019) and E2E (Novikova et al., 2017b) datasets. Weather contains 25k instances of tree-structure annotations. E2E is a crowd-sourced dataset containing 50k instances in the restaurant domain. The inputs are dialogue acts consisting of three to eight slot-value pairs.

Configurations. Both NLU and NLG models are implemented in PyTorch (Paszke et al., 2019) with 2 Bi-LSTM layers and 200-dimensional token embeddings and Adam optimizer (Kingma and Ba, 2014) with initial learning rate at 0.0002. Batch size is kept at 28 and we employ beam search with size 3 for decoding. The score is averaged over 10 random initialization runs. In our implementation, the sequence-to-sequence models are built upon the bi-directional long short-term memory (Bi-LSTM) (Hochreiter and Schmidhuber, 1997). For LSTM cells, both the encoder and decoder have 2 layers, amounting to 18M parameters for

---

[4] Mutual information for $x \rightarrow y$ can be seen as $H(x \rightarrow y) = H_{AUTO}(y) - H_{NLG}(y|x)$ (Bugliarello et al., 2020).

[5] We found that mutual information for $x \rightarrow y$ is usually greater than that of $y \rightarrow x$ since NLG is a one-to-many and more difficult process as opposed to NLU.

the seq2seq model. All models were trained on 1 Nvidia V100 GPU (32GB and CUDA Version 10.2) for 10k steps. The average training time for seq2seq model was approximately 1 hour, and roughly 2 hours for the proposed semi-supervised training with 100% data. The total number of updates is set to 10k steps for all training and patience is set as 100 updates. At decoding time, sentences are generated using greedy decoding.

8 Results

We first compare our model with other baselines on both datasets, then perform a set of ablation studies on the E2E dataset to see the effects of each component. Finally, we analyze the strength of the *weak annotator*, and the effect of the quality-weighted weak supervision, before concluding with the analysis of dual mutual information.

In particular, we experiment with various low resource conditions of training set (10 instances, 50 instances, 1% of all data, 5% of all data). To show that our proposed approach is consistently better, we include the scenario with 0-100% of the data at 10% interval, to show that performance does not deteriorate as more training samples are added (Figure 4). Table 2 shows the summary of training data used for all models in Table 1. We compare our model with (1) a fine-tuned GPT2 model (GPT2-FT) that uses a switch mechanism to select between input and GPT2 knowledge (Chen et al., 2020)[6], (2) a fine-tuning approach to be used as the weak

annotator (WA) that predict text from MR or MR from text, depending on the input format during fine-tuning (Harkous et al., 2020)[7], and (3) the semi-supervised model [8] (JUG) from Tseng et al. (2020). Note that the specialized encoder in *GPT2-FT* cannot be easily adapted to the tree-structured input in Weather, and so we do not provide its score on the Weather dataset.

In Table 1, we show that our proposed approach (*step 1+2*) generally performs better than the baselines for both tasks (NLG and NLU) for most selected labeled data sizes. We show that even with only 10 labeled instances, our approach (*step 1+2*) is able to yield decent results compared to the baselines. The difference between models tends to be larger for settings with few training instances, and the advantage of the method diminishes *as the amount of labeled data available for* JUG *increases*, to the point where JUG is able to outperform the proposed approach. Overall, the benefit of the noisy supervisory signal from the weak data is able to boost performance, especially at lower resource conditions.

We observe that training with weakly labeled data alone (step 1) is not sufficient, and so strong data is required to provide the supervisory signals necessary (step 2). Further, the fact that *joint+aug* displays noticeable improvements over *joint* suggests that simply having augmented text helps to improve the encoded latent space as projected by both the NLU and NLG encoders. This also shows an alternative way to introduce additional in-domain information to both models, even though the NLU model does not benefit directly from additional text. Importantly, our approach shows that the *weak annotator* is able to bridge the gap as defined by the access to ground-truth text labels in JUG – outperforming it significantly at low resource conditions (10, 50, 1%, 5%) with the difference in NLG being as large as 48.7 BLEU points with 10 instances. We find that the proposed model also performs well in the high resource (100% of labeled data) condition, as shown in Table 3. Moreover, with 100% labeled data, our model is still able to produce superior performance over some of the baselines, which shows that weak annotation does capture additional useful patterns that benefit the NLG process.

9 Analysis

Error Analysis. Since word-level overlapping scores usually correlate rather poorly with human judgements on fluency and information accuracy (Reiter and Belz, 2009; Novikova et al., 2017a), we perform human evaluation on the E2E corpus on 100 sampled generation outputs. For each MR-text pair, the annotator is instructed to evaluate the *fluency* (score 1-5, with 5 being most fluent), *miss* (count of MR slots that were missed) and *wrong* (count of included slots not in MR) are presented in Table 4, where fluency scores are averaged over 50 crowdworkers. We show that with 1% data, both NLU and NLG models yield signif-

Method	NLG BLEU-4 (Accuracy (%))	NLU Accuracy (%) (F1)
w/ *DF*	0.683 (77.69)	24.71 (0.6443)
with *DF*	0.703 (79.08)	27.19 (0.6840)
with *WS*	0.733 (82.65)	30.23 (0.7028)
with *WS+CW*	**0.754 (86.44)**	**34.09 (0.7200)**

Table 5: Ablation study of weak supervision (1% E2E labeled data D_L) including data fidelity (*DF*), the proposed model (step 1+2) with weak supervision (*WS*), and *WS* with quality-weighted weak supervision (*WS+CW*).

icantly fewer errors in terms of *misses* and *wrong* facts, while having more fluent outputs. However, it generates more redundant slot-value pairs which we attribute to the noisy augmentation that "misguided" the NLU model.

How Strong is the *Weak Annotator*? To assess the strength of the weak annotator (WA) itself, we also computed its NLG scores with varying amounts of labeled data (see Table 1). We observe that the WA suffers from a performance drop in lower resource conditions (i.e. 0.195 BLEU with 10 labeled instances), when the given training samples are not sufficient for the pretrained model to converge upon a region of in-domain generation. However, it yields some quality data when conditioned on a large number of possible MR (i.e. 50% data), forming a useful in-domain text set (See Table 6).

Analysis of Weak Supervision. In Table 5, we present the results of an ablation study on weak supervision (see §6) where the effect of *data fidelity* is stronger on NLU than on NLG, which is due to the nature of the filtering process which removes faulty text labels which influences both $x \rightarrow y$ and $y \rightarrow y$ training directions. Next, though weak supervision boosted the model by giving direct supervision in training directions $x \rightarrow y$ and $y \rightarrow x$, the noisy nature of the augmentation limits its effectiveness. The model is further improved with the proposed quality-weighted update that takes into account the sample quality and alleviate the influence of poor quality samples. Refer to Table 7 for output comparison.

Analysis of the Two-Step Training Process. As inspired by Dehghani et al. (2018), we justify the two-step training process by performing two types of experiments with 5% data (see Figure 4): In the first experiment, we use all the available strong data but consider different ratios of the entire weak dataset – as used in our 2-step approach. In the second, we fix the amount of weak data and provide the model with varying amounts of strong data. The results show that the *student* models are generally better off by having the *teacher*'s supervision. Further, pretraining on weak data prior to fine-tuning on strong data appears to be the better approach and this motivates the reasoning behind our two-step approach.

Analysis of the Dual Mutual Information. Figure 5 depicts DMI with the visualization of $MI_{x \rightarrow y}$ as x-axis and $MI_{y \rightarrow x}$ as y-axis, in which 100 randomly sampled noisy and ground-truth samples are plotted for both datasets. On the plot, the diagonal reference represents the scenario in which NLG and NLU inference are equally difficult, and we see that annotated data cluster more around the diagonal reference. This means that expert-labeled samples' DMI scores tend to be smaller, where NLU and NLG inference for these samples carry similar levels of difficulty. Importantly, since DMI scores are normalized over both clean and noisy samples, *the proximity of data to the trendlines can then be used to estimate the sample quality* – clean data are closer as compared to the noisy sam-

ples. Thus clean data will have smaller normalized scores, higher $c(\cdot)$, and a larger update step. This further supports the use of the proposed sample quality-based updates on the parameters.

10 Conclusion and Future Work

In this paper, we show the efficacy of the framework where data is automatically labeled and both NLU and NLG models learn with quality-weighted weak supervision so as to account for the individual data quality. Most importantly, we show that not only is the two-step training process useful in improving the model, it yields decent quality text. This work serves as a starting point for weakly-supervised learning in natural language generation, especially for topics related to instance-based weighting approaches.

For future work, we hope to extend on the framework and propose ways with which it can be incorporated into existing text annotation systems.

Continuous Learning in Neural Machine Translation using Bilingual Dictionaries

Jan Niehues
Department of Data Science and Knowledge Engineering (DKE)
Maastricht University, Maastricht, The Netherlands
jan.niehues@maastrichtuniversity.nl

Abstract

While recent advances in deep learning led to significant improvements in machine translation, neural machine translation is often still not able to continuously adapt to the environment. For humans, as well as for machine translation, bilingual dictionaries are a promising knowledge source to continuously integrate new knowledge. However, their exploitation poses several challenges: The system needs to be able to perform one-shot learning as well as model the morphology of source and target language.

In this work, we proposed an evaluation framework to assess the ability of neural machine translation to continuously learn new phrases. We integrate one-shot learning methods for neural machine translation with different word representations and show that it is important to address both in order to successfully make use of bilingual dictionaries. By addressing both challenges we are able to improve the ability to translate new, rare words and phrases from 30% to up to 70%. The correct lemma is even generated by more than 90%.

1 Introduction

Recent advances in neural machine translation (NMT) have led to astonishing translation quality of research systems in evaluation campaigns as well as for commercial systems. These improvements even led to discussions whether automatic machine translation is already on par with human translation (Barrault et al., 2019). One challenge that has raised less attention is the ability of these systems to continuously learn over time. In contrast, humans are continuously improving their skills and adapting to an ever-changing environment.

There are several reasons why this is necessary: First, nobody is fluent in all possible domains. Even professional translators need to adapt to the specific vocabulary of different domains. Secondly, language is not static but developing over time and translators need to learn new terms, meanings and expressions.

For humans, one successful approach to adapt to the environment is the usage of a dictionary [1]. Learning translations from a dictionary has several advantages: Dictionaries contain minimal examples. We do not need to collect full sentences, but can directly learn translations from a single phrase. Furthermore, this can even be generalized to other inflected forms of the same lexem. Secondly, it enables the system to directly integrate correction. If a user sees a specific problem, the user can interact with the system by adding a specific dictionary entry. This is very important if a specific terminology should be used.

Motivated by the success for human translators, in this work we will enable NMT to also successfully integrate knowledge from bilingual dictionaries. Thereby, we will focus on learning translations that could not be learned from parallel data. This poses several interesting research challenges as shown in the example in Table 1. When training a system on the proceedings of the European Parliament, it might never have seen the word *giraffe* and needs to learn the translation from the dictionary. First of all, we have to address one-shot learning. The system needs to be able to continuously learn new dictionary entries and then should directly be able to translate all occurrences of this phrase.

Secondly, the model must be aware of the morphology of the source and target language. In a dictionary only the base form of a word is given. In the example only the lemma *giraffe* is in the dictionary, but not the plural form *giraffes*. Therefore, we must enable the system to translate different lexemes of a lemma by knowing only the translation of the base form. This involves analysing the mor-

---

[1] In this work the dictionary entries can consist of a single word or whole phrases

phological form of the source word, transferring the information about the form to the target and finally generating the correct morphological form of the target word based on the dictionary entry as well as on the morphological form of the source word. In German the plural of the dictionary entry *Giraffe* is *Giraffen*.

In order to assess the approaches on this challenging condition, it is essential to define an appropriate evaluation scheme. While the ability to continuously learn new translations is essential in many practical applications, the newly learned terminology will only occur rarely. Therefore, standard methods for evaluating machine translation are not able to measure the effect appropriately.

In order to address these challenges, we develop the following contributions:

- We developed a targeted evaluation approach for the continuous learning of new translations (Section 2)
- We showed that character-based representation is essential to inflect unknown words correctly. (Section 3)
- We show that only the combination of word representation and one-shot learning enables the successful integration of bilingual dictionaries (Section 3)

2 Evaluation scenario

The first important research question that needs to be addressed in the targeted continuous learning scenario is the evaluation approach. While the evaluation of machine translation is well-established (e.g. using BLEU (Papineni et al., 2002)), new learned words are typically rare words and therefore their influence on a BLEU score calculated on all words is very limited.

In order to have a valid evaluation approach, the evaluation should focus on phrases that cannot be learned from the parallel data. These are typically very rare phrases. Furthermore, we want to translate them in a real world situation. Therefore, the evaluation data should not be synthetic sentences. Finally, the approach should be using the standard parallel data without the need of collecting additional parallel data.

A first attempt would be to use existing test data and select sentences where dictionary entries are needed as e.g. done in (Dinu et al., 2019). However, if we limit ourselves to phrases that do not occur in the parallel data or only a few times, the number of occurring words in the test sets are too low to draw any conclusions.

Therefore, we evaluate our approach by proposing a new test-train split of existing parallel data. In a first step, we filter a large background dictionary for entries that help to translate phrases that only occur a few times in the existing parallel data. In a second step, we select some of the sentences with their matching dictionaries entries as the new test sets. An overview of the process is shown in Figure 1. Finally, we specifically evaluate the ability of the translation system to translate the dictionary entries.

In addition, it is important to ensure that the proposed methods do not have negative side effects on the overall translation quality. Therefore, we also evaluate the model using standard evaluation metrics on well-established test sets and on the proposed test set. Due to the weakness of these metrics to measure improvements in rare words, we do not expect that the proposed methods improve on these metrics, but it is important that the performance measured in these metrics does not decrease significantly.

2.1 Dictionary filtering

In a first step, we create a large background dictionary for each considered language pair by extracting a bilingual dictionary from the English Wiktionary. Therefore, we extracted the translation from a Wiktionary dump[2] using wiktextract [3].

Secondly, we match the dictionary entries to the

---

[3] https://github.com/tatuylonen/wiktextract

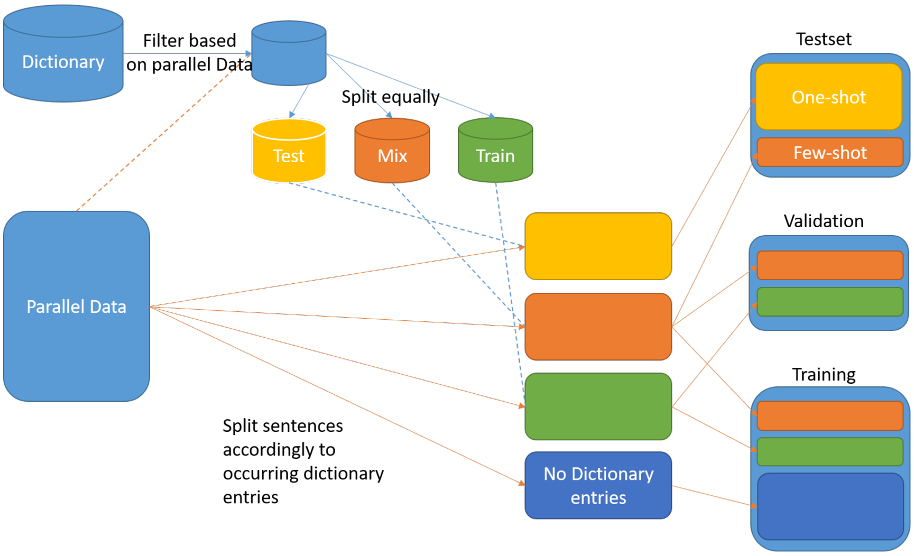

Figure 1: Overview of the evaluation approach: Based on the parallel data and dictionary, a new split of the data is generated

targeted corpus. Therefore, we lemmatize all dictionary entries as well as both sides of the parallel data. This is done to also find matches for all morphological variants of the dictionary entries. Finally, we calculate the statistics mentioned in Table 2 for each dictionary entry about its matches to the parallel data.

In a third step, we filter the dictionary based on the statistics. We only select words that are rare in the corpus. If the words are common and occur often in the training data, a dictionary entry would not be helpful. Secondly, we want to analyse the ability of the system to generate different morphological forms. Therefore, we only consider entries that occur at least with two different morphological variants on the target side. Finally, in this work we focus on words that are not ambiguous. We leave an integration of word sense disambiguation to also handle ambiguous dictionary entries for future work. Therefore, we only consider phrases, where both, the source and target phrase, occur less than 10 times with a different translation than the one given in the dictionary.

Statistic	Threshold
Occurrences	$3 \leq k \leq 80$
target inflected phrases	≥ 2
only source/target match	< 10

Table 2: Dictionary filtering

2.2 Train-Test Split

Finally we generate a split of the corpus into training, validation and test sets based on the selected dictionary entries as shown in Figure 1. The model needs to learn how to use the dictionary. Therefore, several training sentences need to be annotated with dictionary entries. Furthermore, we want to evaluate the ability of the model to translate phrases it has seen a few times in training (*Few-Shot learning*) as well as words it only has seen in the dictionary (*One-shot learning*). Therefore, we split the entries in the dictionary equally into three sets (*Test (yellow)*, *Mix (orange)* and *Train (green)*). All sentence pairs associated with entries from the *Test* set are added to the newly created test set.

In a second step, we select all the sentences from the remaining training sentences, where an entry from the *Mix* set occurs. For each entry, half the sentences are added to the test set and a quarter to the validation and training set.

Finally, all sentences with entries from *Train* are equally distributed to the training and validation set. Since we want to concentrate on modelling the morphology when using the dictionary and not the translation ambiguity for dictionary entries, we removed all sentences from the training where the source entry from the dictionary occurs, but the target sentence does not contain the target entry. Due to our selection of the dictionary, where we focus on words that have only very few different translations (less than 10 times a different one), we only removed very few sentences here. All remaining sentences with no annotations (most of the sentences) were used for training.

2.3 Evaluation

When evaluating we want to focus on the system's ability to translate the phrases from the dictionary. Therefore, we measure the accuracy of translating the dictionary entries in addition to the commonly used BLEU score. In addition to calculating the accuracy by comparing the inflected words of hypothesis and reference (*Exact match*), we calculate further statistics to analyse the approaches.

In addition, we measure the ability of the system to at least create the correct lemma by ignoring errors made due to wrong inflection of the words. Therefore, for each sentence, we compare the target lemmatized phrase of the dictionary entry with the lemmatized version of the generated translation. We will refer to this metric as *Lemma match*

Finally, we are especially interested in the ability of the model to generate the correct inflected form. For many words, this is quite straightforward since it is the same as the lemma. Therefore, we also measure the exact match on the subset of the dictionary entries, where the target side of the dictionary is different from the inflect form occurring in the reference. To generate the correct translation, in this case the model really needs to change the output. We will refer to this metric as *Morph. Adjustment*.

In addition to these three evaluation scores, we also investigate the performance on the different types of entries. We evaluate all metrics on all entries and independently on the one-shot (*OneS*) and few-shot (*FewS*) entries.

3 NMT Dictionary Integration

To successfully integrate the dictionary into the NMT system, we need to address two challenges: First, we need to enable the system to perform one-shot learning. It should be able to translate a phrase after seeing it only once in the bilingual dictionary. Furthermore, it needs to be possible to continuously add new translations. Secondly, we need to model the morphology of the dictionary entries. We need to use the dictionary for different inflected forms of the word and also generate various inflected forms of the target phrase.

3.1 One-shot learning

In order to achieve one-shot learning, we need to combine the dictionary with our neural machine translation system. The combination should ensure fast learning, so a single dictionary entry is enough to learn the translation. Furthermore, it needs to be flexible, so new dictionary entries can be continuously added to the system and it is able to perform life-long learning by using the newly added entries.

One large advantage of deep learning approaches is that they are able to easily incorporate additional information. By annotating the input with additional information, the model is able to learn automatically how to make use of this additional information. This has been successfully done, for example, for the translation of other MT systems (Niehues et al., 2016), for domain information (Kobus et al., 2017) or information about formality (Sennrich et al., 2016a).

For the integration of additional knowledge about specific phrases, we follow similar approaches presented in Pham et al. (2018) and Dinu et al. (2019). The main idea is that we annotate each source phrase, for which a dictionary translation is available with this translation. This is done by appending the translation to the source phrase within the sentence as shown in Table 1. Since this is done during training and testing, the system is able to learn to copy and modify these suggestions. No further adaptation to the architecture of the NMT system is necessary. The system will learn how to exploit these systems and can transfer this knowledge to new translations that have not been seen in training. Therefore, the translations need only to be added once to the dictionary, which enables the system to perform one-shot learning as well as to continuously learn new translation by extending the dictionary.

The main difference to previous work is that we are focusing on very rare words and morphological variants of the dictionary phrases. Therefore, we investigate the matching of the dictionary entries as well as the number of necessary entries.

In order to find the dictionary entries for a given source sentence, we first lemmatize the sentence. In a second step, we then match the dictionary to the lemmatized sentences. Finally, we map back the found entries to the original sentence.

In annotating the source sentence, we follow the related work and append the translation to the source phrase. As shown in Figure 1, we replace the source word *giraffes* by the entry *# giraffes # Giraffe #*. In contrast to the original work, we do not have the inflect target words, but only put the lemmatized target string to the sentence. For the source side, we keep the inflected form for the source sentence so the system is able to extract important morphological information from the source (e.g. grammatical number) and map it to the target. This is done for the training and test data. Then the baseline neural machine translation system is trained normally on the annotated sentences. We did not adapt the architecture since in Dinu et al. (2019) the standard transformer based system was able to learn to copy the suggested translations into the target side.

While the system should learn to also use dictionary entries it has not seen during training, the system needs enough examples in order to learn how to use dictionary entries in general. Since we are concentrating on very rare words, the number of dictionary entries in the parallel data is relatively small. For larger corpora, we therefore explore whether it is helpful to annotate additional phrases. This was done by also extracting phrases that occur more often (*add. Annot*). However, we did use the same split and also evaluated our approach only on the rare phrases.

3.2 Word representations

A second challenge when building a machine translation system for the targeted scenario is the generation of the correct inflected word form. Since we have seen the new words only in the dictionary, we will often need to generate different inflected word forms that we have neither seen in the dictionary nor in the corpus.

While there have been attempts to generate unknown inflected word forms for dictionary entries (e.g. Niehues and Waibel (2011)) prior to neural machine translation, the ability to represent parts of the words in neural machine translation offer a unique opportunity to model morphological inflection. Therefore, in this work, we concentrated on the word representation used in the NMT system. Thereby, we always use the same representation for the source and the target language. The most commonly used word representation used in state-of-the-art neural machine translation systems are byte-pair-encodings (BPE) (Sennrich et al., 2016b). A second successful approach to represent words in a neural machine translation system are character-based representations, where each word is split into its characters.

While there have been several works on comparing these two representations(e.g. Sennrich (2017), they are mostly concentrating on generating the overall best translation performance. However, in this work, we will focus on the rare words. Since only for these words we need to learn how to generate different inflected forms. For the more frequent words, this is often not that important since all word forms occur several times in the corpus.

Besides the generation of unknown inflected forms, the word representation is also important when learning to copy the annotations to the target. If we look at the example dictionary entry *concentric* → *konzentrisch*, the lemma *konzentrisch* got split into the subwords *konzent@@ ris@@ ch* while the inflect form *konzentrischer* into *kon@@ zentr@@ ischer*. In this case there is no overlap in the subwords between the lemma and the inflected form. Therefore, it is difficult for the system to learn from the suggested translation. In contrast, when looking at the character-based representation, the model can copy the lemma and only has to learn to add additional tokens at the end.

In a first step, we compared character-based and sub-word based models. Thereby, we highlight their ability to generate new inflected forms of rare words. For both we used exactly the same NMT architecture. The only difference is that the input and output length for the character-based models is significantly larger since the number of characters is higher than the number of subwords.

We will see that the character-based models are significantly better in generating the different inflected forms for rare words. However, a major challenge is the training time. Due to the significant longer sequence length, also the training and decoding time is much slower. Therefore, we also propose a combination of word-based and character-based models.

In the mixed representation, we split each word that occurs less than k times into its characters, while the other words are kept as they are. Since only frequent words are not split into characters, no further subword segmentation for these words is performed. Thereby, we can speed up the processing due to a short sequence length, but still have the ability to learn how to inflect rare words. Some dictionary entries contain phrases with many frequent words. In order to be able to better inflect these words, in a second approach we in addition split also all words within a dictionary phrase into characters. We refer to this technique as *Mix+Ann*.

4 Experiments

We evaluate the approaches on three different data sizes and on two different language pairs (English-German and English-Czech). Since we are focusing on the generation of different morphological forms, we always use the morphologically rich language as the target language.

4.1 Data

For English-to-German we created two datasets with different sizes. A first series of experiments is run on the TED (Cettolo et al., 2012) corpus. We split the corpus into training, validation and test sets as described in Section 2. In addition, we evaluate the system also on the official test sets *tst2014*, *tst2015* and *2018* and report average metrics for these test sets.

For the second system, we use the Europarl corpus (Koehn, 2005). This corpus is around 10 times bigger than the TED corpus as shown in Table 3. In addition to the target test set, we also tested the systems on the test2006 and test2007, which are the most recent official test sets from the same domain used for the WMT.

Finally, we also tested the techniques on a different language pair. For this we choose English to Czech and also use the Europarl corpus for these experiments. Since there is no official in-domain corpus available, we tested the systems also on the newstest2019 test set.

As shown in Table 3, the parameters mentioned in Section 2 lead to a reasonable test set size for all corpora. As mentioned in Section 3.1, we evaluate the system on Europarl with different amounts of training annotations. All data sets with their splits are available for further experiments [4].

	EN-DE		EN-CS
	TED	Europarl	Europarl

- add. Annot		14.5K	24.3K
Valid	1610	1196	2000
Test	3181	2140	5360

Table 3: Data size in number of sentences

4.2 System

All data was processed using the Stanza toolkit (Qi et al., 2020) for tokenization and lemmatization. The lemmatization was only used for matching the dictionary entries, the translation systems were built on the inflected words. If BPE is applied, we used a BPE size of 20K. For the mixed representation, words occurring less than $k = 50$ times were represented as individual characters.

We use the standard transformer architecture (Vaswani et al., 2017) and increase the number of layers to eight. The layer size is 512 and the inner size is 2048. Furthermore, we apply word dropout (Gal and Ghahramani, 2016) with $p = 0.1$. We use the same learning rate schedule as in the original work and the implementation presented in (Pham et al., 2019) [5]. All systems were always trained from scratch with random initialization.

4.3 TED

A first series of experiments were performed on the TED task. We evaluated the one-shot learning approach by source sentence annotation as well as the three different word representations described in Section 3.2. In a first step, we evaluated the translation performance using BLEU (mteval-v14.pl) and characTER (Wang et al., 2016) on the continuous learning test set as well as on the official test set (Table 4).

The baseline systems using no one-shot learning do not annotate the source at all and are trained on the standard parallel data. If we take a look at the official test set, we see systems using character-based representation (*Character* and *Mix*) perform slightly better than the subword-based models. This might be due to the fact that the TED training data is rather small. Secondly, the one-shot learning approach has no influence on the translation performance of this test set. This is not surprising, since only 94 phrases in the 4343 sentences of the test sets were annotated. Therefore, we also evaluated our approach on the dedicated continuous-learning test set (*CL test*), created by the new train-test split.

The improvements by character-based representation on the CL test set are even larger. This might be due to the fact that there are more rare words in these sentences and therefore the advantages of the character-based models is stronger. Secondly, in this case, the one-shot approach improvements improve the translation quality. Since the improve-

Table 5: Rare word accuracy on TED tasks

ments for the BPE-based system are only measured by characTER and not by BLEU might indicate that for this system it is more challenging to generate the correct inflected form.

To better analyse this, we also perform a detailed evaluation as described in Section 2.3 and shown in Table 5. First of all, the experiments show the difficulty of the task. The baseline system is only able to translate 34% of the phrases correctly. For the one-shot subset this even drops to 22%.

Secondly, the experiments show that the challenge can only successfully be addressed by modelling both: one-shot learning and word representation. On the last two lines using character-based word representation and one-shot learning are able to achieve high accuracy. We see an improvement by 50% percent absolutely, which is a relative improvement by more than 300%. Furthermore, for these models there is no longer a clear difference between the one-shot and few-shot examples (Comparison of Columns *OneS* and *FewS*).

By looking at them separately, we see that only using one-shot learning improves the quality slightly. However, even when ignoring the word infection, the model often is not able to produce the correct lemma. The example in Section 3.2, motivates one challenge when learning to copy with different subword segmentations. If we only use character-based representations, we see improvements, especially for phrases that do not occur in training. In this case, the model is more often able to find the correct translation based on translations of other words. However, a similar performance between the few-shot and one-shot learning is only achieved by combining both techniques.

Finally, when only looking at the words where the lemma is different from the inflected form, we still see open research challenges. While we also could improve the accuracy from around 20% or 30% to nearly 60%, it is still the most difficult case.

While there is no clear difference between the character-based model and the mixed model on the output quality, there is a clear difference in training speed. For the full training on 64 epochs, the character-based model needs 14h, while the mixed representation only needs around 4h. While this is still slower than the subword-based model (2.5h), it still allows for a fast training of the model. Therefore, we only compared the mixed and the sub-word based representation for the remaining experiments on larger corpora.

4.4 Europarl

In a second set of experiments, we evaluated the approach on the larger data set on two different language pairs. In addition to the two word representation from the last experiment (*BPE* and *Mix*), we also applied *Mix+Ann*, where we also represent

Table 6: Translation Performance on the Europarl data set

all words within dictionary entries as characters as described in Section 3.2. Furthermore, we also investigate *add. Annot*, where additional dictionary entries were used for more training examples. The results are shown in Table 6.

The overall picture for these experiments and the previous experiments is quite similar. For all three scenarios, the quality of the various systems on the official test sets is relatively similar, however the systems differ when looking especially at the accuracy of translating the dictionary entries. Only when combining one-shot learning with character-based representation, we are able to successfully translate the dictionary entries. Independent of the language pair and data size, we are able to achieve an accuracy of around 70% and an accuracy of around 90% when only looking at the lemmas only. Furthermore, the model performs as good in one-shot learning as in few-shot learning.

However, beside the evidence that the approach works on various language pairs and data sizes, the additional experiments give some more insights. First, although the data is larger, we do not see a difference between the models using additional annotation and the models using only the baseline annotation. So it seems to be sufficient to have around 1000 examples in order to learn to copy the suggestions from the source sentence.

Furthermore, although there are no longer clear improvements for character-based representation on the overall translation performance, also for this experiment with larger data size these representations are essential for the dictionary integration. This is highlighted by the improvements of using characters for all words in dictionary entries (*Mix+Ann*) instead of only for rare words (*Mix*).

5 Related work

In recent years, several different approaches to integrate additional data into neural machine translation have been suggested. If this is parallel data, fine-tuning on the additional, better matching data (Luong and Manning, 2015; Lavergne et al., 2011) is often successful. If the additional data is provided in other forms, different techniques have been investigated.

For human feedback, Turchi et al. (2017) suggested to use fine-tuning on the human generated post edits. Pham et al. (2018) used phrase pairs extracted by statistical machine translation to annotate translations of rare phrases. In the similar scenario Li et al. (2019) used a neural network to store the external phrase pairs.

Even more work has been done to integrate dictionaries into neural machine translation. A first work by Arthur et al. (2016) used the additional dictionary to influence the softmax probabilities of the neural machine translation. Another possibility is to include the dictionary as an additional knowledge source during training using posterior regularization (Zhang et al., 2017). A different approach is chosen by Zhang and Zong (2016) using the dictionary as additional training sentences or generating synthetic sentences. In contrast to this work, these do not allow the integration of new words after training the NMT system.

Several authors investigate the integration of the dictionary as an additional constraint during the coding process (Chatterjee et al., 2017; Hokamp and Liu, 2017; Hasler et al., 2018). This leads to a larger complexity in decoding that has been addressed by Post and Vilar (2018). However, the dictionary is typically a hard constraint which makes it difficult to learn words forms that do not occur in the dictionary.

Most similar to this work is the approach by Dinu et al. (2019), which like this work and Pham et al. (2018) annotates the source sentence with possible translations. They showed that state-of-the-art models no longer need architecture changes, but can directly learn to copy form the source sentences. In this work, we additionally focus on generating new word morphological forms not occurring in the dictionary. We investigated different word representations and analysed their influence on the ability to copy the dictionary entries.

6 Conclusion

By introducing the new continuous learning test set using a different train-test split for existing corpora we could highlight the challenges of state-of-the-art neural machine translation systems. While they achieve very good performance, they are still challenged by new emerging terms. The baseline system was only able to correctly translate 20 to 30 percent of these phrases.

Our integration of bilingual dictionaries into the systems improves the translation performance to correctly translate the words by up to 70%. In 90% of the cases at least the lemma of the word is predicted correctly. Furthermore, in this case, we see no difference in accuracy between words only seen in the dictionary and words also seen a few times in the parallel data. However this is only possible by modelling both: enabling the model to perform one-shot learning and modeling the different morphological forms of the rare phrases. The first one is addressed by annotating the source sentence with dictionary translation while the second one is addressed by using character-based models. By combining character-based and word-based representations we are able to model the different morphological variants of a word as well as enabling the system for fast training.

As mentioned before, this work concentrates on the morphological variants of the dictionary entries and ignores ambiguities due to different possible translation. In the future, we intend to address this by including word sense disambiguation into the translation process.

Adv-OLM: Generating Textual Adversaries via OLM

Abstract

Deep learning models are susceptible to adversarial examples that have imperceptible perturbations in the original input, resulting in adversarial attacks against these models. Analysis of these attacks on the state of the art transformers in NLP can help improve the robustness of these models against such adversarial inputs. In this paper, we present **Adv-OLM**, a black-box attack method that adapts the idea of **O**cclusion and **L**anguage **M**odels (OLM) to the current state of the art attack methods. OLM is used to rank words of a sentence, which are later substituted using word replacement strategies. We experimentally show that our approach outperforms other attack methods for several text classification tasks.

1 Introduction

In recent times, deep learning models have become pervasive across different domains. Many of the recent deep models have shown SOTA performance on a variety of NLP tasks (Wang et al., 2018). Consequently, deep models are being deployed in a variety of production systems for real-life applications. Hence, it becomes imperative to ensure the reliability and robustness of such models as it might pose a threat to security.

Recent studies have pointed out the vulnerability of deep models to adversarial attacks (Goodfellow et al., 2014). Adversarial attack comprises generating adversarial samples by performing small perturbations to the original input, making them imperceptible to humans while fooling the deep learning models to give incorrect predictions.

Adversarial attack on textual data is much more difficult due to the discrete nature of the text. The basic requirement of imperceptibility of perturbation by human judges is much more challenging in a language data setting. Therefore, the adversarial sample needs to be grammatically correct and semantically sound. Perturbations at word or character level that are perceptible to human judges have been explored in-depth (Ebrahimi et al., 2017; Belinkov and Bisk, 2017; Jia and Liang, 2017; Gao et al., 2018). Work on defense against misspellings based attacks (Pruthi et al., 2019) and use of optimization algorithms for attacks like genetic algorithm (Alzantot et al., 2018; Wang et al., 2019) and particle swarm optimization (Zang et al., 2020) have also been explored. With the rise of pre-trained language models, like BERT (Devlin et al., 2018) and other transformer-based models, generating human imperceptible adversarial examples has become more challenging. Wallace et al. (2019), Jin et al. (2019), and Pruthi et al. (2019) have explored these models from different perspectives.

Adversarial examples can be generated using black-box, where no knowledge about the model is accessible, and white-box, where information about the technical details of models are known. Generation of textual adversarial samples in a black-box setting consists of two steps 1) Finding words to replace in a sample (Word Ranking) 2) Replacing the chosen word (Word Replacement). Word Ranking is necessary to ensure that the word that contributes the most to the output prediction is considered as the candidate for replacement in the next step. Other constraints like generating semantically similar adversarial samples, human imperceptibility, and minimal perturbation percentage are also considered. Previous work has obtained word ranking by performing deletion of words (e.g., BAE-R (Garg and Ramakrishnan, 2020), TextFooler (Jin et al., 2019)), and replacement of words with *[UNK]* token (e.g., BERT-Attack (Li et al., 2020)) and then ranking the words based on the output logits difference.

Recently in the model explainability domain, the method of Occlusion and Language Models (OLM)

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 841–849
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

(Harbecke and Alt, 2020) has been proposed, the authors argue that the data likelihood of the samples obtained after either deleting the token or replacement with *[UNK]* token is very low, which makes these methods unsuitable for determining relevance of the word towards the output probability. The authors propose the use of language models for calculating the relevance of the words in a sentence. Taking inspiration from OLM, we propose **Adv-OLM**, a black box attack method, that adapts the idea of OLM (as the Work Ranking Strategy) to find the relevant words to replace. We empirically show that OLM provides a better set of ranked words compared to the existing word ranking strategies for the generation of adversarial examples.

We summarize our contributions as follows:

- We propose a new method Adv-OLM, to rank words for generating adversarial examples.
- We empirically show that Adv-OLM has a higher success rate and lower perturbation percentage than previous attacking methods.

The implementation for the proposed approach is made available at the GitHub repository: `https://github.com/vijit-m/Adv-OLM`.

2 Problem Formulation

We are given a corpus consisting of n input samples, $\mathbb{X} = \{x_1, \ldots, x_n\}$ with corresponding labels $\mathbb{Y} = \{y_1, \ldots, y_n\}$ and a trained classification model $f(f : \mathbb{X} \rightarrow \mathbb{Y})$ that maps an input samples to its correct label. We assume a black-box setting where the attacker can only query the classifier for output label probabilities for the given input. For an input sample $x \in \mathbb{X}$, the task is to construct an adversarial sample x' such that, $f(x) = y, \quad f(x') = y'$ with $\quad y \neq y'$, and $Similarity(x', x) \geq \epsilon$. Here, $Similarity : \mathbb{X} \times \mathbb{X} \rightarrow (0, 1)$ can be both the semantic and syntactic similarity function, and ϵ is the minimum similarity threshold. Ideally, the amount of perturbation should be minimized. The first step is to rank the words of the sample x. Based on the ranking, starting from the most important word, the word is replaced by some candidate word that keeps the perturbed sample x' semantically similar and grammatically sound but changes the output prediction.

3 Methodology

Adv-OLM uses the idea of Occlusion and Language Models to perform Word Ranking using both OLM and OLM-S methods. OLM uses a language model to sample some candidate instances for a word and then replaces the word. Let x_i be a word of the input x and $x_{\setminus i}$ be the incomplete input without this word. Then the OLM relevance score r given the prediction function f and label y is (Here f_y is the logit value corresponding to the label y.)

$$r_{f,y}(x_i) = f_y(x_i) - f_y(x_{\setminus i}) \tag{1}$$

Here, $f_y(x_{\setminus i})$ is not accurately defined and needs to be approximated since $x_{\setminus i}$ is the incomplete input. A language model p_{LM} generates input by predicting the masked word as $\hat{x}_i$ that is as natural as possible for the model and thus approximates to:

$$f_y(x_{\setminus i}) \approx \sum_{\hat{x}_i} p_{LM}(\hat{x}_i | x_{\setminus i}) f_y(x_{\setminus i} \cup \hat{x}_i) \tag{2}$$

where, $f_y(x_{\setminus i} \cup \hat{x}_i)$ is the prediction of the classification model after the language model's prediction $\hat{x}_i$ is added to the incomplete input $x_{\setminus i}$.

The other method OLM-S calculates the sensitivity of a position in the text and has nothing to do with the word present at that position in the original input. The sensitivity score of OLM-S is calculated

$$s_{f,y}(x_i) = \sqrt{\textstyle\sum_{\hat{x}_i} p_{LM}(\hat{x}_i | x_{\setminus i})(f_y(x_{\setminus i} \cup \hat{x}_i) - \mu)^2}$$

where μ is the mean value from Equation 2. The sensitivity score $s_{f,y}(x_i)$ is used for word ranking in OLM-S.

After performing the Word Ranking step using the relevance scores generated by OLM and OLM-S, the next step is to replace highly scored words with semantically similar words that form grammatically correct sentences (Word Replacement) such that the output prediction changes. Word replacement strategy is kept similar to existing methods. TextFooler uses Synonym Extraction, POS checking and semantic similarity checking whereas BAE-R uses a Language Model for word replacement. (details in Appendix C).

Dataset	Classes	Train	Test	Avg. Length
Classification				
IMDB	2	25K	500	245.12
Yelp	2	560K	500	132.33
AG's News	4	120K	500	40.41
Natural Language Inference				
MNLI	3	433K	500	29.72

Table 4: Comparison between previous methods and Adv-OLM for IMDB dataset across different models. Our method Adv-OLM has OLM (or OLM-S) as the word ranking strategy.

comparison is provided between the attacks generated through original word ranking, and OLM adapted word ranking (including comparison with PWWS attack method (Ren et al., 2019)) in table 2, table 3 and table 4. PWWS (Probability Weighted Word Saliency) method considers the word saliency along with the classification probability. The change in value of the classification probability is used to measure the attack effect of the proposed substitute word, while word saliency shows how well the original word affects the classification. We use the default language model (BERT) employed in the OLM and OLM-S, and kept the number of samples generated by the OLM language model as 30 in all the experiments.

The following evaluation metrics are used:

- **Attacked Acc.**: Accuracy of the model after attack. Lower the better.
- **Success Rate:** Ratio of number of successful attacks and the total number of attempted attacks[1]. Higher the better.
- **Perturbed Percentage:** Ratio of number of words that were modified by the attack and the total number of words in the input example. Lower the better.

We use TextAttack's (Morris et al., 2020) fine tuned models on these datasets and used it to execute the attacks, including Adv-OLM (Appendix B).

Number of queries in Adv-OLM: From equations 2 and 3, it is clear that unlike other methods of deletion and *[UNK]* token replacement, which perform only a single query, we need to perform multiple queries. We set the number of samples

---

[1] Note that total number of attempted attacks are not the same as number of input examples i.e., the samples which were originally wrongly classified by the model even before an attack are skipped

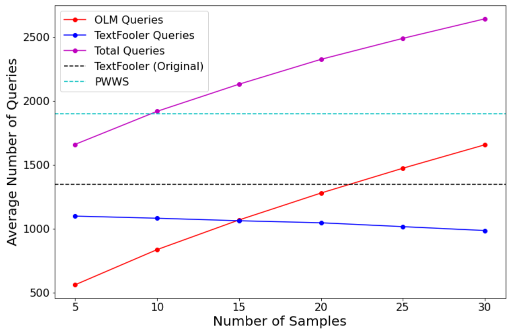

Figure 2: Average Number of Queries vs Number of samples in Adv-OLM attack on BERT on IMDB dataset.

generated by the OLM language model to 30 for our experiment. In the worst case, we would have all 30 samples of the token as unique, which will query the model 30 times. However, experimentally it was not the case. To study this, we varied the number of samples and evaluated the OLM ranking step's number of queries. In fig 2, we plotted the number of queries for OLM averaged over the input samples against the number of samples. We can see that there is not a significant difference in the total number of samples in our case (OLM + Textfooler queries) when compared with PWWS.

5 Results and Analysis

Results are shown in Tables 2, 3 and 4. Table 2 provides the results on AG News and Yelp datasets on fine-tuned BERT and ALBERT model. Our method performs better on both datasets by increasing the success rate by about 1-3% than the previous methods and also decreasing the perturbation percentage. Table 3 gives the results of attacking a fine-tuned BERT on MNLI. Although we did not perform better than original BAE-R, we were still able to outperform TextFooler. Due to the unavailability of MNLI fine-tuned ALBERT model in TextAttack, we did not perform an attack on ALBERT. It can also be seen from Table 2 that the perturbation percentage for AG's News exceed more than 20%, which seems to be a perceptible change, but since the average length of the article is only 40.41, making the space for finding relevant words less, the perturbation percentage becomes very high.

To compare attacks across different transformer-based models, we evaluate the performance of Adv-OLM on IMDB dataset. Table 4 provides the results of different attack methods on BERT, ALBERT, RoBERTa, DistilBERT and BiLSTM. Adv-OLM was able to outperform previous attack methods on BERT, ALBERT, RoBERTa by increasing the success rate up to 10% for BAE-R and up to 6% for TextFooler. Perturbation percentage was also reduced by 1-2%. On DistilBERT, Adv-OLM showed no change in the success rate, but the perturbation percentage was lowered slightly. We also performed an attack on a non-transformer based BiLSTM model which did not show any improvements in the success rate. For BAE-R, it even showed a decrease in the success rate for Adv-OLM. One possible reason for this might be that in both OLM and OLM-S word sampling is performed using a transformer-based BERT language model. We also have qualitative results on IMDB dataset (Figure 1a, 1b).

Experimentally it was observed that better words were ranked when OLM/OLM-S was used as the Word Ranking strategy (Figure 1b). When comparing with the original methods, Adv-OLM has more number of queries, which is due to the fact that for word rankings, OLM/OLM-S queries the model a number of times, thus increasing the overall queries. However, the difference in the number of Adv-OLM queries with the existing attacking methods is not very significant since the model is queried only for unique words from the samples generated from the language model.

6 Conclusion

In this work, we present **Adv-OLM**, a black box attacking method that uses OLM based word ranking strategy, improving the attack performance significantly over previous methods. We also studied how replacing a single variable in a complex system with a new existing method can improve upon the previously existing attack strategies. For future work, we would like to experiment with other language models in the OLM algorithm. We plan to study the effect of using different transformers for the language model and the target model.

Appendix

A Datasets

We evaluate our adversarial attacks on text classification and natural language inference datasets. We evaluate our method on 500 samples randomly selected from the test set of the given dataset.

Text classification We used the following text classification datasets:

- **IMDB:** Document-level large Movie Review dataset for binary sentiment classification. [2]
- **Yelp:** The Yelp reviews dataset consists of reviews from Yelp. This is a dataset for sentiment classfication. It is extracted from the Yelp Dataset Challenge 2015 data. [3]
- **AG's News:** Sentence level news-type classification dataset, containing 4 types of news: World, Sports, Business, and Science. [4]

Natural Language Inference

- **MNLI:** The corpus of sentence pairs manually labeled for classification with the labels entailment, contradiction, and neutral, supporting the task of natural language inference (NLI). Unlike SNLI, MNLI is more diverse, based on multi-genre texts, covering transcribed speech, popular fiction, and government reports. [5]

Average Length is the average number of words in the randomly chosen 500 samples taken from its test set for each dataset.

B Textattack

TextAttack is an open-source python framework for adversarial attacks, data augmentation and adversarial training in NLP.

Because of the modularity that TextAttack provides, it enables researchers to construct new attacks from a combination of novel and existing approaches or perform analysis on the already existing approaches. This helps in composing and comparing the attacks in a shared environment. TextAttack makes it easy to perform benchmark comparisons across all the previous attacks performed across models. Text Attack provides clean, readable implementations of 16 adversarial attacks from the literature. Out of which two are sequence to sequence attacks and nine are classification based attacks from the GLUE benchmark. A list of these attacks is presented in Table 5. TextAttack is directly integrated with HuggingFace's transformers and NLP libraries. This allows users to test attacks on models and datasets.

Seq2Sick (Cheng et al., 2020)	TextBugger (Li et al., 2018)
Kuleshov (Kuleshov et al., 2018)	Fast Alzantot (Jia et al., 2019)

Table 5: Adversarial attacks implemented in Textattack

TextAttack builds attacks from four components:

1. A **search method** that selects the words to be transformed.
2. A **transformation** that generates a set of possible perturbations for the given input.
3. A **set of constraints** implied on the transformation to ensure that the perturbations are valid with respect to the original input.
4. A **goal function** that determines whether an attack is successful in terms of model outputs. For classification tasks, untargeted, and targeted. For a sequence to sequence tasks, non-overlapping output, and minimum BLEU score.

For our approach, we attack TextAttack's fine-tuned models on datasets discussed in A, that are publically available on huggingface[6] Textattack is also used for the execution of all the previous attacking methods and our Adv-OLM as well.

C Word Replacement Strategies

C.1 TextFooler Word Replacement Strategy

Following workflow was proposed by the paper:

Synonym Extraction: Gather a candidate set CANDIDATES for all possible replacements of the selected word w_i and every other word in the vocabulary. To represent the words, counter fitting word embeddings were used. Using this set

[3] Yelp dataset

[4] AG's News dataset

[5] MNLI dataset

[6] TextAttack fine-tuned models on HuggingFace

of embedding vectors, top N synonyms whose cosine similarity with w is higher than some δ were chosen.

POS Checking: In the set CANDIDATES of the word w_i, only the ones with the same part-of-speech(POS) as w_i were kept. This step assures that the grammar of the text is mostly maintained.

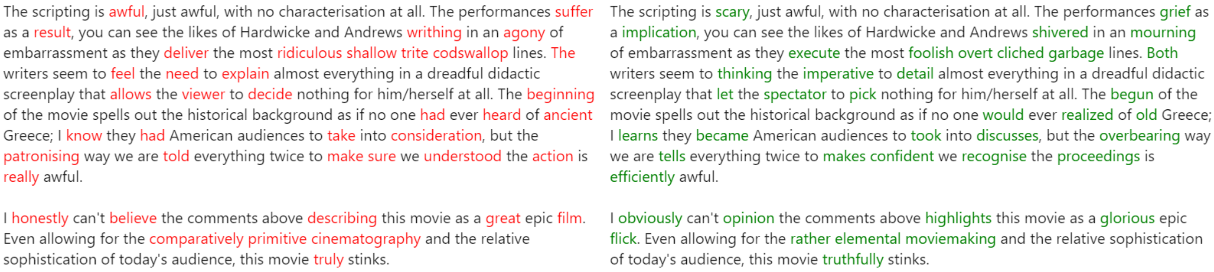
Semantic Similarity Checking: For each remaining word $c \in$ CANDIDATES, these were substituted for w_i in the sentence X, and an adversarial example X_{adv} was obtained. Universal Sentence Encoder (USE) was used to encode the two sentences into high dimensional vectors and then use their cosine similarity score to calculate the sentence similarity between X and X_{adv}. The words resulting in similarity scores above a preset threshold ϵ were placed in a final candidate pool (FINCANDIDATE).

Finally, every candidate word from the FINCANDIDATE was chosen one by one, and the one that resulted in the least confidence score of label y was considered as the best replacement for word w_i.

C.2 BAE-R Word Replacement Strategy

BAE uses a pre-trained BERT masked language model(MLM) to predict the mask tokens for replacement. Since BERT is powerful and trained on the large training corpus, the predicted mask tokens fit well grammatically in the sentence. BERT-MLM does not, however, guarantee semantic coherence to the original text. To ensure semantic similarity on introducing perturbations in the input text, a set of K masked tokens were filtered out using Universal Sentence Encoder(USE) based on sentence similarity score. An additional check for grammatical correctness of the generated adversarial example by filtering out predicted tokens that do not form the same part of speech(POS) as the original token in the sentence was performed.

D More Examples



The scripting is awful, just awful, with no characterisation at all. The performances suffer as a result, you can see the likes of Hardwicke and Andrews writhing in an agony of embarrassment as they deliver the most ridiculous shallow trite codswallop lines. The writers seem to feel the need to explain almost everything in a dreadful didactic screenplay that allows the viewer to decide nothing for him/herself at all. The beginning of the movie spells out the historical background as if no one had ever heard of ancient Greece; I know they had American audiences to take into consideration, but the patronising way we are told everything twice to make sure we understood the action is really awful.

I honestly can't believe the comments above describing this movie as a great epic film. Even allowing for the comparatively primitive cinematography and the relative sophistication of today's audience, this movie truly stinks.

The scripting is scary, just awful, with no characterisation at all. The performances grief as a implication, you can see the likes of Hardwicke and Andrews shivered in an mourning of embarrassment as they execute the most foolish overt cliched garbage lines. Both writers seem to thinking the imperative to detail almost everything in a dreadful didactic screenplay that let the spectator to pick nothing for him/herself at all. The begun of the movie spells out the historical background as if no one would ever realized of old Greece; I learns they became American audiences to took into discusses, but the overbearing way we are tells everything twice to makes confident we recognise the proceedings is efficiently awful.

I obviously can't opinion the comments above highlights this movie as a glorious epic flick. Even allowing for the rather elemental moviemaking and the relative sophistication of today's audience, this movie truthfully stinks.

Abstract

This paper addresses the task of (complex) conversational question answering over a knowledge graph. For this task, we propose LASAGNE (mu**L**ti-task sem**A**ntic par**S**ing with tr**A**nsformer and **G**raph atte**N**tion n**E**tworks). It is the first approach, which employs a transformer architecture extended with Graph Attention Networks for multi-task neural semantic parsing. LASAGNE uses a transformer model for generating the base logical forms, while the Graph Attention model is used to exploit correlations between (entity) types and predicates to produce node representations. LASAGNE also includes a novel entity recognition module which detects, links, and ranks all relevant entities in the question context. We evaluate LASAGNE on a standard dataset for complex sequential question answering, on which it outperforms existing baseline averages on all question types. Specifically, we show that LASAGNE improves the F1-score on eight out of ten question types; in some cases, the increase in F1-score is more than 20% compared to the state of the art.

1 Introduction

Since their inception in the late 2000s, publicly available Knowledge Graphs (e.g., DBpedia (Lehmann et al., 2015) and Yago (Suchanek et al., 2007)) have been widely used as a source of knowledge in several natural language processing (NLP) tasks such as entity linking, relation extraction, fact-checking, and question answering. Question answering (QA), in particular, is an essential task that maps a user natural language question to a query over a knowledge graph (KG) to retrieve the correct answer (Singh et al., 2018). With the increasing popularity of intelligent personal assistants (e.g., Alexa, Siri), the research focus has been shifted to conversational question answering that involves multi-turn dialogues, incorporating the phenomenon of anaphora and ellipses (Christmann et al., 2019; Shen et al., 2019)(c.f. Figure 1).

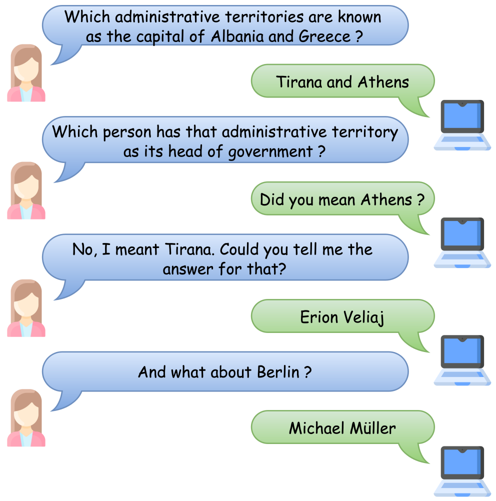

Figure 1: Conversational Question Answering task with examples similar to CSQA dataset (Saha et al., 2018).

Conversational QA is often realised by using semantic parsing approaches, mapping an utterance to a logic form for extracting answers from a KG (Guo et al., 2018; Shen et al., 2019). The state of the art for semantic parsing approaches decomposes the semantic parsing process into two stages (Shen et al., 2019). First, a logical form is generated based on low-level features and then

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 850–862
April 19 - 23, 2021.

the missing details are filled by considering both the question and the template. Other approaches (Dong and Lapata, 2016; Guo et al., 2018; Liang et al., 2017) first employ an entity linking model to identify entities in the question and subsequently use another model to map the question to a logical form. (Zhang et al., 2018; Shen et al., 2019) point out that the modular approaches suffer from the common issue of error propagation along the QA pipeline, resulting in accumulated errors. To mitigate these errors, Shen et al. (2019) proposed a multi-task framework, where a pointer-equipped semantic parsing model was designed to resolve coreference in conversations and empower joint learning with a type-aware entity detection model. Furthermore, the authors used simple classifiers to predict the required (entity) types and predicates for the generated logical forms. In this paper, we argue that Shen et al. (2019) model (the current SotA) has the following shortcomings: 1) the (entity) type and predicate classifiers share no common information, except for the supervision signal propagated to them. 2) Hence, due to missing common information, the model can produce ambiguous results, since the classifiers can predict entities and predicates that do not correlate with each other.

Approach and Contributions: We tackle the problem of conversational (complex) question answering over a large-scale knowledge graph. We propose LASAGNE (muLti-task semAntic parSing with trAnsformer and Graph atteNtion nEtworks) - a multi-task learning framework consisting of a transformer model extended with Graph Attention Networks (GATs) (Veličković et al., 2018) for multi-task neural semantic parsing. Our framework handles semantic parsing using the transformer (Vaswani et al., 2017) model similar to previous approaches. However, in LASAGNE we introduce the following two novel contributions: 1) the transformer model is supplemented with a Graph Attention Network to exploit the correlations between (entity) types and predicates due to its message-passing ability between the nodes. 2) We propose a novel entity recognition module that detects, links, filters, and permutes all relevant entities. (Shen et al., 2019) uses a pointer equipped decoder that learns and identifies the relevant entities for the logical form using only the encoder's information. In contrast, we use both sources of information, i.e., the entity detection module and the encoder, to filter and permute the relevant entities for a logical form. This avoids re-learning entity information in the current question context and relies on the entity detection module's information. Our empirical results show that the proposed novel contributions lead to substantial performance improvements.

LASAGNE achieves the state of the art results in 8 out of 10 question types on the Complex Sequential Question Answering (CSQA) (Saha et al., 2018) dataset consisting of conversations over linked QA pairs. The dataset contains 200K dialogues with 1.6M turns, and over 12.8M entities from Wikidata[1]. Our implementation, the annotated dataset with the proposed grammar, and the results are publicly available to facilitate reproducibility and reuse[2].

The structure of the paper is as follows: Section 2 summarises the related work. Section 3 presents the proposed LASANGE framework. Section 4 describes the experiments, including the experimental setup, the results, the ablation study and error analysis. We conclude in Section 5.

2 Related Work

We point to the survey by (Gao et al., 2018) that provides a holistic overview of neural approaches in conversational AI. In this paper, we stick to our closely related work, i.e., semantic parsing-based approaches in conversations. (Liang et al., 2017) introduce a neural symbolic machine (NSM) extended with a key-value memory network, where keys and values are the output of the sequence model in different encoding or decoding steps. The NSM model is trained using the REINFORCE algorithm with weak supervision and evaluated on the WebQuestionsSP dataset (Yih et al., 2016).

(Saha et al., 2018) propose a hybrid model of the HRED model (Serban et al., 2016) and the key-value memory network model (Miller et al., 2016). The model consists of three components. The first one is the Hierarchical Encoder, which computes a representation for each utterance. The next module is a higher-level encoder that computes a representation for the context. The second component is the Key-Value Memory Network. It stores each of the candidate tuples as a key-value pair where the key contains the concatenated embedding of the relation and the subject. In contrast, the value contains

Action	Description
set → find(e, p)	set of objects part of the triples with subject e and predicate p
set → find_reverse(e, p)	set of subjects part of the triples with object e and predicate p
set → filter_type(set, tp)	filter the given set of entities based on the given type
set → filter_multi_types(set_1, set_2)	filter the given set of entities based on the given set of types
dict → find_tuple_counts(p, tp_1, tp_2)	extracts a dictionary, where keys are entities of $type_1$ and values are the number of objects of $type_2$ related with p
dict → find_reverse_tuple_counts(p, tp_1, tp_2)	extracts a dictionary, where keys are entities of $type_1$ and values are the number of subjects of $type_2$ related with p
set → greater(dict, num)	set of those entities that have greater count than *num*
set → lesser(dict, num)	set of those entities that have lesser count than *num*
set → equal(dict, num)	set of those entities that have equal count with *num*
set → approx(dict, num)	set of those entities that have approximately same count with *num*
set → atmost(dict, num)	set of those entities that have at most same count with *num*
set → atleast(dict, num)	set of those entities that have at least same count with *num*
set → argmin(dict)	set of those entities that have the most count
set → argmax(dict)	set of those entities that have the least count
boolean → is_in(entity, set)	check if the entity is part of the set
number → count(set)	count the number of elements in the set
set → union(set_1, set_2)	union of set_1 and set_2
set → intersection(set_1, set_2)	intersection of set_1 and set_2
set → difference(set_1, set_2)	difference of set_1 and set_2

Table 1: Predefined grammar with respective actions to generate logical forms.

the embedding of the object. The last component is the decoder used to create an end-to-end solution and produce multiple types of answers.

(Guo et al., 2018) present a model that converts an utterance in conversation to a logical form. The model follows a flexible grammar, in which the generation of a logical form is equivalent to predicting a sequence of actions. A dialogue memory management is proposed and integrated into the model, so that historical entities, predicates, and action sub-sequences can selectively be replicated. (Shen et al., 2019) proposed the first multi-task learning framework that learns type-aware entity detection and pointer-equipped logical form generation simultaneously. The multi-task learning framework takes advantage of the supervision from the subtasks.

3 LASAGNE

In a conversation, the input data consists of utterances u and their answers a, extracted from the knowledge graph. Our framework LASAGNE employs a multi-task semantic parsing approach. In particular, it maps the utterance u to a logical form z, depending on the conversation context. Figure 2 shows the architecture of LASAGNE.

3.1 Grammar

For the semantic parsing task, we propose a grammar that can be used to capture the entire context of the input utterance with the minimum number of actions. Table 1 illustrates the complete grammar with all the defined actions. We considered the work by (Guo et al., 2018) as a starting point for generating them, however, we have updated many of the semantic actions. For instance, for a couple of actions, we also define their reverse occurrence (e.g. *find*, *find_reverse*)).

3.2 Transformer

To translate the input conversation into a sequence of actions (logical form), we utilise a transformer model (Vaswani et al., 2017). Specifically, the transformer here aims to map a question q, that is a sequence $x = \{x_1, \ldots, x_n\}$, to the answer label l, that can be also defined as a sequence $y = \{y_1, \ldots, y_m\}$, by modelling the conditional probability $p(y|x)$.

3.2.1 Input and Word Embedding

We have to incorporate the dialog history from previous interactions as an additional input to our model for handling coreference and ellipsis. To do so, we consider the following utterances for each turn: 1) the previous question, 2) the previous answer, and 3) the current question. Utterances are separated from one another by using a $[SEP]$ token. At the end of the last utterance, we append a context token $[CTX]$, which is used as the semantic representation for the entire input question. In the next step, given an utterance q containing n words $\{w_1, \ldots, w_n\}$ we first tokenise the conversation context using WordPiece tokenization (Wu et al., 2016), and after that, we use the pre-trained model GloVe (Pennington et al., 2014) to embed the words into a vector representation space of di-

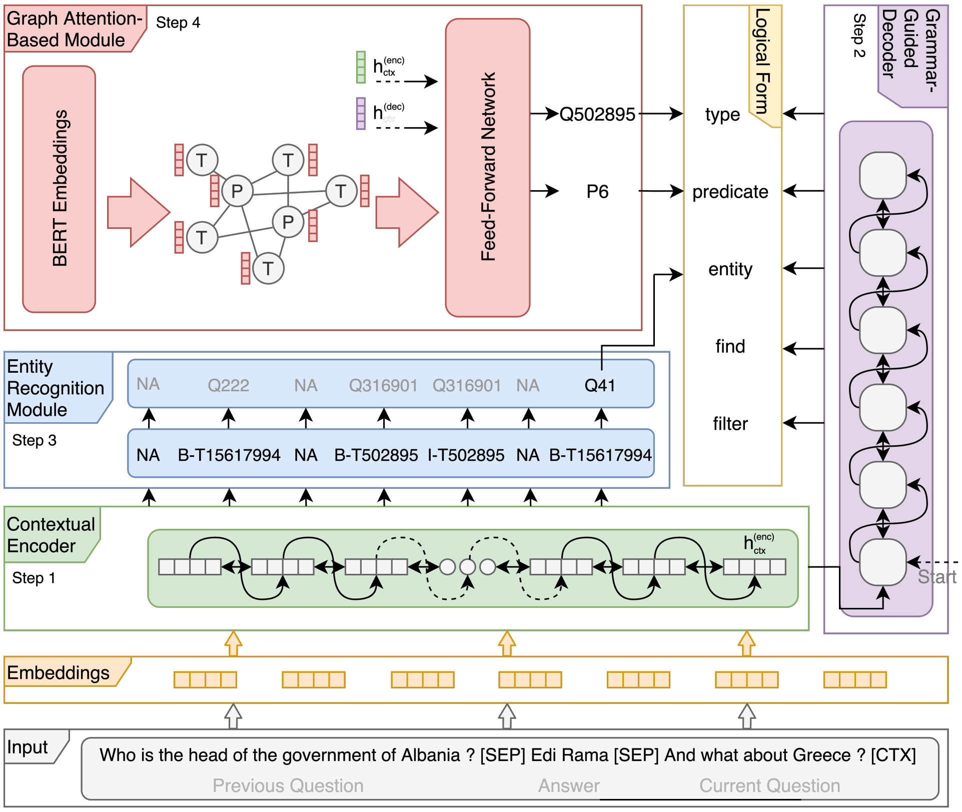

Figure 2: LASAGNE (Multi-task Semantic Parsing with Transformer and Graph Attention Networks) architecture. It consists of three modules: 1) A semantic parsing-based transformer model, containing a contextual encoder and a grammar guided decoder using the grammar defined in Table 1. 2) An entity recognition module, which identifies all the entities in the context, together with their types, linking them to the knowledge graph. It filters them based on the context and permutes them, in case of more than one required entity. Finally, 3) a graph attention-based module that uses a GAT network initialised with BERT embeddings to incorporate and exploit correlations between (entity) types and predicates. The resulting node embeddings, together with the context hidden state (h_{ctx}) and decoder hidden state (d_h), are used to score the nodes and predict the corresponding type and predicate.

mension d [3]. Our word embedding model provides us with a sequence $x = \{x_1, \ldots, x_n\}$ where x_i is given by, $x_i = GloVe(w_i)$ and $x_i \in \mathbb{R}^d$.

3.2.2 Contextual Encoder

The word embeddings x, are forwarded as input to the contextual encoder, which uses the multi-head attention mechanism described by (Vaswani et al., 2017). The encoder here outputs the contextual embeddings $h^{(enc)} = \{h_1^{(enc)}, \ldots, h_n^{(enc)}\}$, where $h_i^{(enc)} \in \mathbb{R}^d$ and it can be defined as:

$$h^{(enc)} = encoder(x; \theta^{(enc)}), \tag{1}$$

where $\theta^{(enc)}$ are the encoder's trainable parameters.

3.2.3 Grammar-Guided Decoder

We use a grammar guided decoder for generating the logical forms. The decoder also employs the multi-head attention mechanism. The decoder output is dependent on the encoder contextual embeddings h. The main task of the decoder is to generate each corresponding action, based on Table 1, alongside with the general semantic object from the knowledge graph (entity, type, predicate). In other words, the decoder will predict the main logical form without using or initialising any specific information from the knowledge graph. Here we define the decoder vocabulary as $V^{(dec)} = \{find, find\_reverse, \ldots, entity, type, predicate, value\}$, where all the actions from Table 1 are included. On top of the decoder stack, we employ a linear layer alongside a softmax to calculate each token's probability scores in the vocabulary. We define the decoder stack output as follows:

$$\begin{aligned} h^{(dec)} &= decoder(h^{(enc)}; \theta^{(dec)}), \\ p_t^{(dec)} &= softmax(\boldsymbol{W}^{(dec)} h_t^{(dec)}), \end{aligned} \tag{2}$$

---

[3] Across the model, we use the same dimension d for all the representations, unless it is explicitly noted.

where $h_t^{(dec)}$ is the hidden state in time step t, $\theta^{(dec)}$ are the decoder trainable parameters, $\boldsymbol{W}^{(dec)} \in \mathbb{R}^{|V^{(dec)}| \times d}$ are the linear layer weights, and $p_t^{(dec)} \in \mathbb{R}^{|V^{(dec)}|}$ is the probability distribution over the decoder vocabulary in time step t. The $|V^{(dec)}|$ denotes the decoder's vocabulary size.

3.3 Entity Recognition Module

The entity recognition module is composed of two sub-modules, where each module is trained using a different objective.

3.3.1 Entity Detection and Linking

Entity Detection It aims to detect and link the entities to the KG. The module is inspired by (Shen et al., 2019) and performs type-aware entity detection by using BIO sequence tagging jointly with entity type tagging. Specifically, the entity detection vocabulary is defined as $V^{(ed)} = \{O, \{B, I\} \times \{TP_i\}_{i=1}^{N^{(tp)}}\}$, where TP_i denotes the *i-th* entity type label, $N^{(tp)}$ stands for the number of the distinct entity types in the knowledge graph and $|V^{(ed)}| = 2 \times N^{(tp)} + 1$. For performing the sequence tagging task we use an LSTM (Hochreiter and Schmidhuber, 1997) and the module is defined as:

$$\begin{aligned} h^{(l)} &= LeakyReLU(LSTM(h^{(enc)}; \theta^{(l)})), \\ p_t^{(ed)} &= softmax(\boldsymbol{W}^{(l)} h_t^{(l)}), \end{aligned} \tag{3}$$

where $h^{(enc)}$ is the encoder hidden state, $\theta^{(l)}$ are the LSTM layer trainable parameters, $h_t^{(l)}$ is the LSTM hidden state for time step t, $\boldsymbol{W}^{(l)} \in \mathbb{R}^{|V^{(ed)}| \times d}$ are the linear layer weights and $p_t^{(ed)}$ are the entity detection module prediction for time step t. $|V^{(ed)}|$ denotes the entity detection vocabulary size.

Entity Linking Once the entity BIO labels and their types are recognised, the next steps for the entity linking are: 1) the BIO labels are used to locate the entity spans from the input utterances. 2) An inverted index built for the knowledge graph entities is used to retrieve candidates for each predicted entity span. Finally, 3) the candidate lists are filtered using the predicted (entity) types. From the filtered candidates, the first entity is considered as correct.

3.3.2 Filtering and Permutation

After finding all the input utterances' entities, we perform two additional tasks in order to use entities in the generated logical form. First, we filter the relevant entities, and then we need to permute the entities in the order required for the logical form. The module receives as an input the concatenation of the hidden states of the encoder $h^{(enc)}$ and the hidden states of the LSTM $h^{(l)}$ from the entity detection model. The module here learns to assign index tags to each input token. We define the module vocabulary as $V^{(ef)} = \{0, 1, \ldots, m\}$ where 0 is the index assigned to the context entities that are not considered. The remaining values are indices that permute our entities based on the logical form. Here, m is the total number of indices based on the maximum number of entities from all logical forms. Overall, our filtering and permutation module is modelled using a feed-forward network with two linear layers separated with a Leaky ReLU activation function and appended with a softmax. Formally we define the module as:

$$\begin{aligned} h^{(ef)} &= LeakyReLU(\boldsymbol{W}^{(ef_1)}[h^{(enc)}; h^{(l)}]), \\ p_t^{(ef)} &= softmax(\boldsymbol{W}^{(ef_2)} h_t^{(ef)}), \end{aligned} \tag{4}$$

where $\boldsymbol{W}^{(ef_1)} \in \mathbb{R}^{d \times 2d}$ are the weights of the first linear layer and $h_t^{(ef)}$ is the hidden state of the module in time step t. $\boldsymbol{W}^{(ef_2)} \in \mathbb{R}^{|V^{(ef)}| \times d}$ are the weights of the second linear layer, $|V^{(ef)}|$ is the size of the vocabulary and $p_t^{(ef)}$ denotes the probability distribution over the tag indices for the time step t.

3.4 Graph Attention-Based Module

A knowledge graph (KG) can be denoted as a set of triples $\mathcal{K} \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$ where $\mathcal{E}$ and $\mathcal{R}$ are the set of entities and relations respectively. To build the (local) graph, we consider the relations and the types of entities that are linked with these relations in the knowledge graph $\mathcal{K}$. We define a graph $\mathcal{G} = \{\mathcal{T} \cup \mathcal{R}, \mathcal{L}\}$ where $\mathcal{T}$ is the set of types, $\mathcal{R}$ is the set of relations and $\mathcal{L}$ is a set of links (tp_1, r) and (r, tp_2) such that $\exists(e_1, r, e_2) \in \mathcal{K}$ where e_1 is of type tp_1 and e_2 is of type tp_2.

To propagate information in the graph and to project prior KG information into the embedding space, we use the Graph Attention Networks (GATs) (Veličković et al., 2018).

We initialise each node embedding $h^{(g)} = \{h_1^{(g)}, \ldots, h_n^{(g)}\}$ using pretrained BERT embeddings, and $n = |\mathcal{T} \cup \mathcal{R}|$. A GAT layer uses a parameter weight matrix, and self-attention, to produce a transformation of input representations $\overline{h}^{(g)} = \{\overline{h}_1^{(g)}, \ldots, \overline{h}_n^{(g)}\}$, where $\overline{h}_i^{(g)} \in \mathbb{R}^d$ as shown below:

$$\overline{h}^{(g)} = g(h^{(g)}; \theta^{(g)}),^{4} \tag{5}$$

and $\theta^{(g)}$ are the trainable parameters. We model the task of predicting the correct type or predicate in the logical form as a classification task over the nodes in graph $\mathcal{G}$, given the current conversational context and decoder hidden state. For each time step t in the decoder, we calculate the probability distribution $p_t^{(g)}$ over the graph nodes as:

$$p_t^{(g)} = softmax(\overline{h}^{(g)T} h_t^{(c)}), \tag{6}$$

where $\overline{h}^{(g)} \in \mathbb{R}^{d \times n}$ and $h_t^{(c)}$ is a linear projection of the concatenation of the context representation and the decoder hidden state, given as follows,

$$h_t^{(c)} = LeakyReLU(\boldsymbol{W}^{(g)}[h_{ctx}^{(enc)}; h_t^{(dec)}]), \tag{7}$$

and $\boldsymbol{W}^{(g)} \in \mathbb{R}^{d \times 2d}$.

3.5 Learning

The framework consists of four trainable modules, grammar guided decoder, entity detection, filtering and permutation, and the GAT-based module for types and predicates. Every module consists of a loss function that contributes to the overall performance of the framework, as shown in Section 4.3. To account for multi-tasking, we perform a weighted average of all the single losses:

$$L = \lambda_1 L^{dec} + \lambda_2 L^{ed} + \lambda_3 L^{ef} + \lambda_4 L^{g}, \tag{8}$$

where $\lambda_1, \lambda_2, \lambda_3, \lambda_4$ are the relative weights, which are learned during training by taking into account the difference in magnitude between losses by incorporating the log standard deviation (Armitage et al., 2020; Cipolla et al., 2018). L^{dec}, L^{ed}, L^{ef}, and L^{g} are the respective negative log-likelihood losses of the grammar guided decoder, entity detection, filtering and permutation, and GAT-based modules. These losses are defined as follows:

$$\begin{aligned}
L^{dec} &= -\sum_{k=1}^{m} logp(y_k^{(dec)}|x), \\
L^{ed} &= -\sum_{j=1}^{n} logp(y_j^{(ed)}|x), \\
L^{ef} &= -\sum_{i=1}^{n} logp(y_i^{(ef)}|x), \\
L^{g} &= -\sum_{k=1}^{m} I_{(y_k^{(dec)} \in \{type, pred\})} logp(y_k^{(g)}|x),
\end{aligned} \tag{9}$$

where n and m are the length of the input utterance x and the gold logical form, respectively. $y_k^{(dec)} \in V^{(dec)}$ are the gold labels for the decoder, $y_j^{(ed)} \in V^{(ed)}$ are the gold labels for entity detection, $y_j^{(ef)} \in V^{(ef)}$ are the gold labels for filtering and permutation, and $y_k^{(g)} \in \{\mathcal{T} \cup \mathcal{R}\}$ are the gold labels for the GAT-based module. The model benefits from multiple supervision signals from each module, and this improves the performance in the given task.

4 Experiments

4.1 Experimental Setup

Datasets We use the Complex Sequential Question Answering (CSQA) dataset[5] (Saha et al., 2018). CSQA was built on the large-scale knowledge graph Wikidata. Wikidata consists of 21.2M triples with over 12.8M entities, 3,054 entity types, and 567 predicates. The CSQA dataset consists of around 200K dialogues where each partition – train, valid, test contains 153K, 16K, 28K dialogues, respectively. The questions involve complex reasoning to determine the correct answers.

Model Configurations We incorporate a semi-automated preprocessing step to annotate the CSQA dataset with gold logical forms. For each question type and subtype in the dataset, we create a general template with a pattern sequence that the actions should follow. Thereafter, we follow a set of rules to create the specific gold logical form that extracts the gold sequence of actions based on the type of question for each question. The actions used for this process are the ones in Table 1. For all the modules in the LASAGNE framework, we employ an embedding dimension of 300. We utilise the transformer model with six heads for the multi-head attention model with two layers. For the optimisation, we use the Noam optimiser proposed by (Vaswani et al., 2017), where authors use an Adam optimiser (Kingma and Ba, 2015) with several warmup steps for the learning rate. Please refer to the appendix submitted with the paper for more details.

Models for Comparison We compare the LASAGNE framework with the last three baselines that have been evaluated on the employed dataset. The first baseline is (Saha et al., 2018) where authors introduce the HRED+KVmem model. The second baseline is D2A (Guo et al., 2018), which

Table 2: LASAGNE's performance comparison on the CSQA dataset having 200K dialogues with 1.6M turns and over 12.8M entities. LASAGNE achieves "overall" (weighted average on all question types) new state of the art for both the F1 score and the question type results' accuracy metric.

uses a semantic parsing approach based on a seq2seq model. Finally, the current state of the art is MaSP (Shen et al., 2019), which is also a semantic parsing approach.

Evaluation Metrics We use the same metrics as employed by the authors of the CSQA dataset (Saha et al., 2018) as well as the previous baselines. The "F1-score" is used for questions that have an answer composed of a set of entities. The "Accuracy" metric is used for the question types whose answer is a number or a boolean value (YES/NO). We also provide an overall score for each evaluation metric and their corresponding question categories.

4.2 Results

Table 2 summarises the results comparing the LASAGNE framework against the previous baselines. LASAGNE outperforms the previous baselines weighted average on all question types (The row "overall" in the Table 2). Furthermore, LASAGNE is a new SotA in 8 out of 10 question types, and in some cases, the improvement is up to 31 percent.

What worked in our case? For question types that require more than two entities for reasoning, such as *Logical Reasoning (All)* and *Verification (Boolean)*, LASAGNE performs considerably better (+20.79% and +18.23% respectively). This is mainly due to the proposed entity recognition module. Furthermore, for question types that require two or more (entity) types and predicates, such as *Quantitative Reasoning (All)*, *Quantitative Reasoning (Count)* and *Comparative Reasoning (Count)* LASAGNE also outperforms MaSP (+12.92%, +11.79% and +31.08% respectively). Here, the improvement is due to the graph attention-based module, which is responsible for predicting the relevant (entity) types and predicates. Another interesting result is that LASAGNE also performs better in two out of three *Simple Question involving one entity and one predicate* categories. The performance shows the robustness of LASAGNE.

What did not work in our case? LASAGNE noticeably under-performs on the *Clarification* question type, where MaSP retains the state-of-the-art. The main reason is the spurious logical forms during the annotation process which has further impacted the Simple Questions (Ellipses) performance.

4.3 Ablation Study

Effect of GAT and Multi-task Learning Table 3 summarises the effectiveness of the GAT-based module and the multi-task learning. We can observe the advantage of using them together in LASAGNE. To show the effectiveness of GAT-based module, we replace it with two simple classifiers, one for each predicate and type categories. We can observe that the performance drops significantly for the question types that require multiple entity types and predicates (e.g. *Quantitative Reasoning (All)*, *Quantitative Reasoning (Count)* and *Comparative Reasoning (Count)*). When we exclude the multi-task learning and train all the modules independently, there is a negative impact on all question types. In LASAGNE, the filtering and

Methods	Ours	w/o GATs	w/o Multi
Question Type	F1 Score		
Clarification	66.94%	57.33%	59.43%
Comparative	69.77%	57.72%	66.41%
Logical	89.83%	78.52%	86.75%
Quantitative	86.67%	75.26%	82.18%
Simple (Coref)	79.06%	76.46%	77.23%
Simple (Direct)	87.95%	83.59%	85.39%
Simple (Ellipsis)	80.09%	77.19%	78.47%
Question Type	Accuracy		
Verification	78.86%	63.38%	75.24%
Quantitative	55.18%	40.87%	46.27%
Comparative	53.34%	41.73%	45.90%

Table 3: The effectiveness of the GAT and the multi-task learning. The first column contains the results of the LASAGNE framework, where all the modules are trained simultaneously. The second and third columns selectively remove the GAT and the multi-task learning from LASAGNE.

permutation module, along with the GAT-based module, is heavily dependent on the supervision signals received from the previous modules. Therefore it is expected that without the multi-task learning, LASAGNE will underperform on all question types, since each module has to re-learn inherited information.

4.4 Task Analysis

Tasks	Accuracy
Entity Detection	86.75%
Filtering & Permutation	97.49%
Grammar-Guided Decoder for Logical Forms	98.61%
GAT-Based Module for Type/Predicate	92.28%

Table 4: Tasks accuracy of the LASAGNE framework.

Table 4 illustrates the task accuracy of LASAGNE. The Entity Detection task has the lowest accuracy (86.75%). The main reason here is the errors in the entity type prediction. On the other hand, for all other tasks, we have accuracy above 90%.

Effect of Filtering and Permutation For justifying the effectiveness and superior performance of LASAGNE's filtering and permutation module, we compare the overall performance of the entity recognition module to the corresponding module from MaSP. Please note, entity detection modules in both frameworks adopt a similar approach as defined in section 3.3. In Table 5 we can see that the MaSP entity recognition module provides an overall accuracy of 79.8% on test data, while our module outperforms it with an accuracy of 92.1%. The main reason for the under-performance of MaSP is that it uses only token embeddings without any entity information. In contrast, our approach avoids re-learning entity information in the question context and relies on the entity detection module's information.

Model	Entity Recognition Accuracy
MaSP	79.8%
LASAGNE	92.1%

Table 5: Comparing MaSP (Shen et al., 2019) and LASAGNE for entity recognition performance.

4.5 Error Analysis

For the error analysis, we randomly sampled 100 incorrect predictions. We detail the reasons for two types of errors observed in the analysis:

Entity Ambiguity Even though our entity detection module assigns (entity) types to each predicted span, entity ambiguity remains the biggest challenge for our framework. For instance, for the question, "Who is associated with Jeff Smith ?" LASAGNE entity detection module correctly identifies "Jeff Smith" as an entity surface form and correctly assigns the (entity) type "common name". However, the Wikidata knowledge graph contains more than ten entities with exactly the same label and type. Our entity linking module has difficulties in such cases. Wikidata entity linking is a newly emerging research domain that has its specific challenges such as entities sharing the same labels, user-created non-standard entity labels and multi-word entity labels (up to 62 words) (Mulang et al., 2020b). Additional entity contexts, such as entity descriptions and other KG contexts, could help resolve the Wikidata entity ambiguity (Mulang et al., 2020a).

Spurious Logical Form For specific question categories, we could not identify gold actions for all utterances. Therefore spurious logical form is a standard error that affects LASAGNE. Specifically, we have spurious logical forms for categories such as "Comparative, Quantitative, and Clarification" but still can achieve SotA in the comparative and quantitative categories.

5 Conclusions

In this article, we focus on complex question answering over a large-scale knowledge graph containing conversational context. We provide a transformer-based framework to handle the task in a multi-task semantic parsing manner. At the same time, we propose a named entity recognition module for entity detection, filtering, and permutation. Furthermore, we also introduce a graph attention-based module, which exploits correlations between (entity) types and predicates for identifying the gold ones for each particular context. We empirically show that our model achieves the best results for numerous question types and also overall. Our ablation study demonstrates the effectiveness of the multi-task learning and of our graph-based module. We also present an error analysis on a random sample of "wrong examples" to discuss our model's weaknesses. For future work, we believe that reinforcement learning is a viable alternative to explore complex conversational question answering without gold annotations.

A Grammar

We propose a new grammar to annotate the dataset with a gold logical form to perform the semantic parsing task. We consider the work by (Guo et al., 2018) as a starting point for generating them. While we differ in many actions regarding their semantic and therefore their implementation. Our goal was to define more precise and richer actions, which gives us a more flexible grammar in terms of being used to annotate a wider range of question's complexities. For instance, for a couple of actions, we also define their reverse occurrence (e.g. *find*, *find_reverse*)). We do this in order to match the knowledge graph triple direction (*subject-predicate-object*). In some questions, we might have the subject or the object entity. Having both normal and reverse actions helps us to identify directly the correct answer based on the action the model predicted. Furthermore, we also define actions that do not exist in (Guo et al., 2018). Some of them are *find_tuple_counts*, *atmost*, *atleast*. Table 1 illustrates the complete grammar with all the defined actions. Following (Lu et al., 2008), we define each action with a function that can be executed on the knowledge graph. Finally, in order to execute a sequence of actions, we have to parse it into a tree structure. There our executor starts from the tree leaves and it recursively executes the leftmost non-terminal node until the whole tree is complete.

B Case Study

Table 9 shows examples from different question types in the CSQA dataset and the logical forms generated from our model. As we can see, our actions can cover reasoning for every question type by following certain patterns depending on them. The sequences can cover all the different complexities of the questions. For example, the logical forms pattern of *Simple Questions* to *Quantitative* or *Comparative* is slightly different due to increased complexity of the latter questions. The reasoning over *Quantitative* or *Comparative* question involves more actions in order to reach the correct answer.

For the question type *Simple Question (Direct)*, we can see the question “Which administrative territory is the birthplace of Antonio Reguero ?”. The correct logical form for this example is “filter_type(find(Antonio Reguero, place of birth), administrative territorial entity)”. Here we can distinguish two different actions; the first one is the *filter_type* and the other one is the *find* action. The *find* action receives as input an entity subject and a predicate and provides the set of object entities from the Knowledge Graph. Whereas, the *filter_type* action receives as input a set of entities along with an entity type and results to a set of entities that belong to that particular entity type.

C Hyperparamters and module configurations

Table 6 summarizes the hyperparameters used across the LASAGNE framework. For the transformer module, we use the configurations from (Vaswani et al., 2017). Our model dimension is $d_{model} = 300$, with a total number of $H = 6$ heads and $L = 2$ layers. The inner feed-forward linear layers have dimension $d_{ff} = 600$. Following the base transformer parameters, we apply residual dropout (Srivastava et al., 2014) to the summation of the embeddings and the positional encodings in both encoder and decoder stacks with a rate of 0.1. The entity detection module has a dimension of 300. Our base LSTM here is followed with a LeakyReLU, dropout, and a linear layer. The output of the linear layer is the module prediction while the LSTM hidden state is propagated to the filtering and permutation layer. The filtering and permutation module receives an input of dimension 600 where here a linear layer is responsible to reduce it to 300 which is the framework dimension. Like in the previous module, a LeakyReLU, dropout, and a linear layer are used for the final predictions. Finally, for the GAT-based module, we use pre-trained BERT embeddings for type and predicate labels. Hence the input dimension on this module is 3072. The GAT layer will produce representations with an embedding size of 300. Next, multiple linear, dropout, and LeakyReLU layers are used to produce the final predictions.

Hyperparameters	**Value**

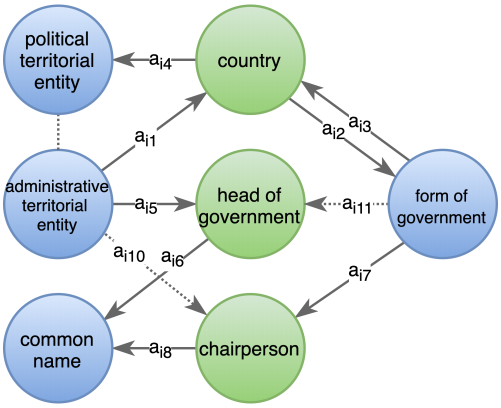

Figure 3: The aggregation process of graph attention layer between the (entity) types and predicates from Wikidata knowledge graph. The dashed lines represent an auxiliary edge, while a_{ij} represents relative attention values of the edge. We also incorporate the predicates (relations) as nodes of the graph instead of edges.

ferent level of information for a node, based on the neighborhood in the graph. We denote with $h^{(g)} = \{h_1^{(g)}, \dots, h_n^{(g)}\}$ the initial representations of the nodes, which will also be the input features for the GAT layer. To denote the influence of node j to the node i, an attention score e_{ij} is computed as $e_{ij} = a(\mathbf{W}h_i^{(g)}, \mathbf{W}h_j^{(g)})$, where $\mathbf{W}$ is a parameterized linear transformation, and a is an attention function. In our case, we follow the GAT paper, and compute e_{ij} score as follows,

$$e_{ij} = LeakyReLU(\mathbf{a}^T[\mathbf{W}h_i^{(g)} || \mathbf{W}h_j^{(g)}]), \quad (10)$$

where $\mathbf{a} \in \mathbb{R}^{2d}$ is a single-layer feedforward network, and $||$ denotes concatenation. This attention scores are normalized using a softmax function and producing the α_{ij} scores for all the edges in a neighborhood. These normalized attention scores are used to compute the output features $\overline{h}_i^{(g)}$ of a node in a graph, by applying a linear combination of all the nodes in the neighborhood as below,

$$\overline{h}_i^{(g)} = \sigma(\sum_{j \in \mathcal{N}_i} \alpha_{ij} \mathbf{W} h_j^{(g)}) \quad (11)$$

where σ is a non-linear function. Following (Veličković et al., 2018) and (Vaswani et al., 2017) we also apply a multi-head attention mechanism and compute the final output features as,

$$\overline{h}_i^{(g)} = \sigma(\frac{1}{K} \sum_{k=1}^{K} \sum_{j \in \mathcal{N}_i} \alpha_{ij}^k \mathbf{W}^k h_j^{(g)}) \quad (12)$$

where K is equal to the number of heads, and α_{ij}^k, $\mathbf{W}^k$ are the corresponding attention scores and linear transformation by the k-th attention mechanism. During our experiments, we found out the $K = 2$ was sufficient for our model.

E Experiments

Table 7 summarizes precision and recall results comparing LASAGNE framework against the previous baselines. Furthermore, a detailed task analysis for each task on each question type is illustrated on Table 8.

Tasks	Entity Detection	Filt. & Permut.	Logical Form	Type/Predicate
Question Type	Accuracy			
Clarification	92.19%	99.97%	98.36%	86.70%
Comparative Reasoning (All)	92.03%	99.88%	99.00%	97.18%

Abstract

Author stylized rewriting is the task of rewriting an input text in a particular author's style. Recent works in this area have leveraged Transformer-based language models in a denoising autoencoder setup to generate author stylized text without relying on a parallel corpus of data. However, these approaches are limited by the lack of explicit control of target attributes and being entirely data-driven. In this paper, we propose a Director-Generator framework to rewrite content in the target author's style, specifically focusing on certain target attributes. We show that our proposed framework works well even with a limited-sized target author corpus. Our experiments on corpora consisting of relatively small-sized text authored by three distinct authors show significant improvements upon existing works to rewrite input texts in target author's style. Our quantitative and qualitative analyses further show that our model has better meaning retention and results in more fluent generations.

1 Introduction

With recent advances in language modeling techniques that have resulted in powerful language models (Radford et al., 2019; Devlin et al., 2018; Brown et al., 2020) along with an increased interest in stylized text generation (Hu et al., 2017; Shen et al., 2017; Subramanian et al., 2018; Fu et al., 2018; Niu and Bansal, 2018), large language models have been successfully tuned to achieve text stylization (Lample et al., 2018; Ziegler et al., 2019; Syed et al., 2020; Singh et al., 2020). Apart from *transferring* an input text to the target style, which has received recent interest from the community, *understanding* and *measuring* style have been persistently explored over the last few decades (Kessler et al., 1997; Garera and Yarowsky, 2009; Liu, 2012; Verma and Srinivasan, 2019). Lying at the intersection of style transfer enabled by advanced language models and a deep understanding of style as a nuanced combination of several linguistic concepts, problems like *stylized generation* or *stylized rewriting* have gained further traction. A large body of work in style transfer focuses on binary aspects such as positive-negative sentiment (Li et al., 2018; Ziegler et al., 2019), formal-informal (Jain et al., 2019), and sometimes a mixture of these attributes (Subramanian et al., 2018). To fuel this interest in such binary stylization, some datasets comprising of text from the extreme ends of these spectrums have also emerged (e.g., positive-negative sentiments (Mathews et al., 2016), formal-informal (Rao and Tetreault, 2018)). As pointed by Syed et al. (2020), author stylized rewriting does not directly fit under any of these variants as the writing style of an author is an amalgamation of several such attributes and needs to be modeled in a fine-grained manner.

Apart from the distinction along style dimensions, prior works can also be categorized as supervised (using parallel corpus (Jhamtani et al., 2017)) and unsupervised (Li et al., 2018; Syed et al., 2020; Niu and Bansal, 2018). In supervised frameworks, parallel data is used to tune sequence-to-sequence models for stylized rewriting. However, annotating such parallel corpus is a tedious effort and therefore, there is an increased interest in unsupervised style transfer; i.e., when there is no direct supervision or parallel data available for training the models. In this work, we focus on such an unsupervised setting.

Existing approaches on unsupervised author stylized rewriting rely on implicitly learning the target stylistic attributes from data and do not allow finer control on generation (Syed et al., 2020). While this is a good starting point for author-stylized

April 19 - 23, 2021.

rewriting, it is desirable to further improve the rewriting model on certain aspects without compromising on other attributes that the model has already optimized. An example would be to retain the stylistic strengths while improving content retention, or vice versa. To this end, we propose **Dir**ecting **a** **G**enerator framework (DRAG). Our quantitive and qualitative experiments show the viability of the proposed approach. Experiments further indicate that the framework's setup allows it to operate efficiently in scarce data setting and improves the performance over the baseline models. Our contributions can be summarized as - **(1)** We introduce a director-generator approach to *rewrite* an input text in a target author's style. **(2)** We propose linguistic alignment scores – both at the local and global level and extend these to design *thresholds* for the generator and director. **(3)** We present experimental results on texts written by three authors from the Gutenberg corpus with very distinct writing styles, and show that our approach outperforms prior works across content retention and style alignment metrics. **(4)** We further identify and discuss shortcomings of our proposed approach, and present error analysis to aid future research in author stylized rewriting.

2 Related Work

With the rise of Transformer-based (Vaswani et al., 2017) **language models**, generative pretraining (Devlin et al., 2018; Radford et al., 2019; Brown et al., 2020) has advanced the field of NLP significantly. Fine-tuning such large language models on specific task has become very prevalent (Sun et al., 2019; Lee et al., 2020; Lample and Conneau, 2019; Raffel et al., 2019; Liu et al., 2019). Pretraining infuses the *generic* language knowledge into the language model helping it understand the specific tasks with relatively much less supervision. In fact, recent approaches (Radford et al., 2019; Brown et al., 2020) show that often, even such small supervisions are not required and a simple instruction can be used to solve specific tasks by utilizing the capabilities of such large language models trained on very large datasets.

Pretraining of such models usually involves optimizing them on **Masked Language Modelling (MLM)** (Devlin et al., 2018), **Causal Language Modelling (CLM)** (Radford et al., 2019) or other similar (Clark et al., 2020) objectives.While CLM is the task of auto-regressively predicting the next word given the previous words or context, MLM is the task of recovering masked tokens from a given input. While these approaches mostly train only an encoder or a decoder framework, Lample and Conneau (2019) explored initializing encoder-decoder frameworks using the pre-trained encoders for cross-lingual translation. Such a technique with appropriate modification has been shown to be successful in incorporating stylistic aspects of the language as well (Conneau and Lample, 2019; Syed et al., 2020). All these works utilize the task of minimizing the *denoising auto-encoder loss* for inducing style in the language models in a reconstruction framework. For our explorations, we leverage these works to initialize our DRAG framework.

There is an increased interest in **stylistic generation** or text rewriting. Most of the approaches define dimensions like formality-informality (Shen et al., 2017; Ficler and Goldberg, 2017; Jain et al., 2019; Sun et al., 2019) and achieve the alignment along these dimensions. While some of these approaches rely on parallel corpus (Ficler and Goldberg, 2017; Jhamtani et al., 2017), many of the approaches focus on unsupervised framework (Li et al., 2018; Shen et al., 2017; Jain et al., 2019), where the model *preserves* the input content in the output while *biasing* the generations towards the target style. While some approaches utilize simple *editing* to achieve the style along particular dimensions (Li et al., 2018), others focus on achieving this through discriminators (Fu et al., 2018) or scorers (Jain et al., 2019). As mentioned before, since author style is an amalgamation of several such attributes, it requires much more than a discriminator or singular dimension tuning to achieve stylization.

Due to the difficulty associated with author style understanding and fine-grained nature of that style even if understood them, the problem of **author stylized rewriting** has not been explored a lot. While Jhamtani et al. (2017) try to solve this problem for a specific author (i.e. Shakespeare), their approach is contingent on the availability of a parallel corpus. Since preparing parallel corpus is a tedious and intractable process, especially while dealing with multiple authors and multiple combinations of input and output styles, it is essential to focus on unsupervised solutions. Most recently, Syed et al. (2020) leverage the capabilities of the large language models to solve this problem in an unsupervised manner.

3 Author Style

There has been significant work on understanding binary stylization along dimensions like formal-informal, positive-negative sentiment (Rao and Tetreault, 2018; Kessler et al., 1997; Pavlick and Tetreault, 2016; Collins-Thompson and Callan, 2005; Hovy, 1990; Inkpen and Hirst, 2006; Kantrowitz, 2003), however, there is limited work on understanding an author's writing style (McCarthy et al., 2006; Forgeard, 2008; Verma and Srinivasan, 2019). While style can be a mixture of several factors including, but not limited to, lexical preferences, syntactic/sentential choices, discourse structure, narrative style, tone, we follow Syed et al. (2020) and consider an author's style at three levels:

Surface style is estimated using the frequencies of different surface elements such as the number of commas, semicolons, colons, question marks, exclamation marks, and hyphens per paragraph, from a given author's text. We, thus, quantify the surface-style elements into a 6-dimensional vector.

Lexical style of an author is reflected in the author's choice of words. To describe the same concept, different authors may use different words. For instance, Rudyard Kipling, known for his classics in children's literature, tended to use more concrete words (e.g., gongs, rockets, torch) while Abraham Lincoln, being a political writer, used more abstract words (e.g., freedom, patriotism). We enumerate lexical style categories as subjective, objective, literary, colloquial, abstract and concrete (Brooke and Hirst, 2013). We use lexicons for each of these categories (Brooke and Hirst, 2013), and define *lexical style alignment* of each word in the vocabulary to a given style category as the average and normalized point-wise mutual information (PMI) between that word and the seed words in the lexicon for that style category. The lexical style alignment for each word is thus a 6-dimensional vector. We use the EmoBank corpus (Buechel and Hahn, 2017) to compute the co-occurrence statistics for PMI computations. The inclination of a word towards a style category is positive if its normalized PMI score is positive with respect to the given category. The inclination of an author towards a style category is then estimated by the fraction of words in their text that have a positive inclination towards the category.

Syntactic style of an author is indicated by the nature of sentences used and we estimate the distribution of different types of sentences in an author's text. Sentence types may range from complex, as seen in philosophical writings, to simple, as observed in children's storybooks. We use five categories of sentence styles: (i) simple, (ii) compound, (iii) complex, (iv) complex-compound sentences, and (v) others (Feng et al., 2012; Verma and Srinivasan, 2019; Syed et al., 2020). Sentences are categorized into one of these types using the algorithm proposed by Feng et al. (2012). The resulting 5-dimensional probability distribution vector is used as the estimation of syntactic style. These vectors are estimated at corpus-level, unlike those for lexical and surface style which are computed at paragraph-level.

4 DRAG: *Di*recting *a* *G*enerator for Stylized Rewriting

Our proposed framework, DRAG, that aims to rewrite a given piece of text with a specific target author's style consists of three main stages:

(1) Pretraining a language model to infuse general linguistic knowledge into the model

(2) Adapting the pre-trained language model towards the target author's writing style by further pretraining it on text written by this author (Syed et al., 2020), and

(3) Using a director-generator framework (as discussed later) to fine-tune such *biased* language model to improve its style transfer capabilities even further while fixing content preservation issues. It is worth noting that we do not rely on the availability of parallel data for any of our experiments.

4.1 Pretraining Language Model

In order to infuse general linguistic knowledge into a language model, we leverage Tranformer-based pretrained language models (Devlin et al., 2018; Radford et al., 2019; Brown et al., 2020) due to their recent success in text processing tasks (Vaswani et al., 2017; Devlin et al., 2018; Brown et al., 2020). Similar to Conneau and Lample (2019), we first train a Transformer-based encoder on the Masked Language Modelling (MLM) task with 15% of the tokens masked (Devlin et al., 2018) on a *generic* text corpus. We initialize an encoder-decoder framework, as shown in Figure 1, with this language model.

4.2 Adapting LM for Rewriting

To adapt the pretrained LM for author stylized rewriting, Syed et al. (2020) initialize an encoder-

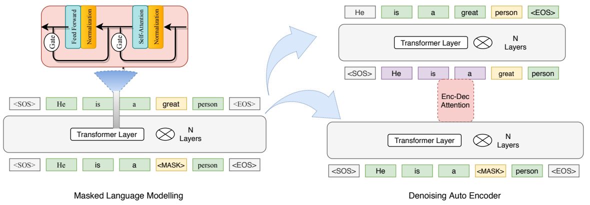

Figure 1: Language Model Pretraining using Masked Language Modelling followed by encoder-decoder initialization using pretrained models. This process still leaves the encoder-decoder attention parameters unitialized which can be initilized using the Denoising Auto Encoder training as depicted in the figure.

decoder framework with the pretrained LM, as shown in Figure 1. This is followed by optimizing it on denoising auto-encoder (DAE) loss (Lample et al., 2018; Lample and Conneau, 2019) *only* over target author's corpus. Syed et al. (2020) use the DAE loss to infuse an author's linguistic style into the reconstruction model; we refer to this framework as StyleLM. The fine-tuning using the DAE loss on a target author's corpus encourages recovering actual paragraphs from their noisy version (Lample and Conneau, 2019). For a paragraph g in corpus G and its noisy version $C(g)$ ($C(.)$ being the noise function), DAE loss is given by,

$$DAE(\theta_e, \theta_{ed}, \theta_d) = -\frac{1}{|G|} * \sum_{g \sim G} \log P(g/C(g); \theta_e, \theta_{ed}, \theta_d) \tag{1}$$

where P is the probability of reconstruction for a given encoder parameters θ_e, decoder parameters θ_d, and encoder-decoder attention parameters θ_{ed}. Please note that θ_{ed} does not refer to any additional layer but the parameters which are present in transformers and are responsible for encoder-decoder attention. In our setup, $C(.)$ function introduces two noises: (a) random dropping of words with 10% probability, and (b) word masking by replacing it with [MASK] token with 10% probability.

Given a noisy input, the encoder fills the [MASK] tokens with suitable replacements (based on the knowledge from its MLM pretraining), thus creating a pseudo *generic* input for the decoder, the target sequence for which is aligned to the target author's style. However, we identify and verify experimentally two issues with this approach:

(1) It requires a large target author corpora to achieve meaningful content preservation capability. This is evident by its very low content preservation scores (as discussed in Section 5.2) when trained on authors with relatively smaller corpora. Even with large corpora, the model still suffers from exposure bias to texts written only by the target author leading to spurious outputs for *unseen* inputs.

(2) The masking results in a significant emphasis on lexical style aspects, with a lesser focus on the surface and syntactic preferences. Since the model is completely data-driven, there is no way to explicitly add emphasis on additional style aspects.

One of the primary reasons behind (1) is the lack of explicit initialization of encoder-decoder attention parameters in StyleLM resulting in a random initialization. The model, therefore, needs a large corpus of author data to stabilize these parameters. To fix this, we propose to train the entire encoder-decoder language model using the DAE loss over the same *generic* corpus used for pre-training. The resulting model will be in the *generic* language space (English, in our case), and henceforth referred to as VanillaLM. We, further, finetune VanillaLM in the author corpus on the DAE loss to arrive at an improved version of StyleLM which we call iStyleLM. This offers better encoder-decoder attention initialization, and also removes the exposure bias of StyleLM, thus resulting in a more resilient and stable model with improved content preservation abilities (as demonstrated in Section 5.2).

However, at this point, we note that iStyleLM still fails to address (2), and its content preservation ability is also sub-optimal as the target author's style aspects which are infused at the later stage of training override some of the general linguistic knowledge. To further improve on iStyleLM, we introduce a Director-Generator component to our training framework in the next section.

4.3 Director-Generator Finetuning

For the Director-Generator finetuning, we find inspiration in the standard RL strategies (Rennie et al., 2017; Ranzato et al., 2015) where the *nearby* space is *explored* and certain actions are rewarded higher than others, consequently getting encouraged in the future. We, however, find direct rewarding unstable for our problem. Hence, we *generate* potential *directives* during exploration and *accept* or *reject* them on the basis of thresholds. A *directive*, in our context, is as an output paragraph generated from an input by a director model which is fixed and has been initialized using iStyleLM. Specifically, we create two copies of the iStyleLM as the *Director* and the *Generator*.

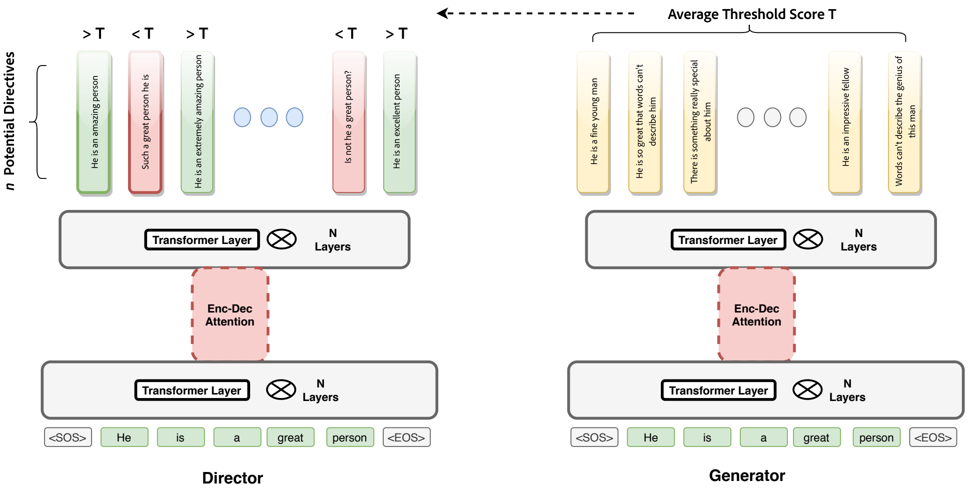

Figure 2: Both the director as well as generator, intiliazed using ISTYLELM, work together to improve the final outputs. While director remains in the space of author style generating and exploring potential directives , generator keeps changing its threshold as it gets improved on its content & style capabilities. The directives above the average threshold for same example are accepted while rest of them are rejected.

As the names indicate, for each input, the director proposes n potential directives or paragraphs, while the generator generates n *thresholding* outputs (paragraphs) as shown in Figure 2. We generate the potential directives using nucleus sampling (Holtzman et al., 2019) with a softmax temperature of 1.2, while the thresholding outputs are generated using a softmax temperature of 0.8 (the same value is used at inference time as well). We score the director and generator outputs on various content and style attributes. For content preservation, we use the BLEU score between input and output as the content score. For lexical style, the mean squared error is calculated between the 6-dimensional lexical alignment vector of the directives/generator outputs (calculated as the averaged sum of alignments of words in the proposal) and average lexical alignments of paragraphs for the target author corpus. Similarly, the mean squared error for surface style is also calculated. The scores L and S for lexical and surface styles, respectively, are then calculated as reciprocal of means squared errors (with ϵ added in the denominator to avoid zero-division). For syntactical choices, since we wish to achieve the probability distribution of different types of sentences at the corpus-level, we calculate the score for syntactic style as, $SX = \frac{sum(P_p \circ P_t)}{sum(P_p)}$ where P_p denotes the frequency distribution of different types of sentences in a directive/generator's output, P_t the probability distribution of different types of sentences in target author corpus, and $\circ$ denotes the Hadamard product. All three scores are summed to calculate the style score for the directives (and the generator outputs).

The ISTYLELM model already captures certain stylistic aspects of the target author. We want our model to leverage this understanding and improve on aspects where ISTYLELM does not perform well. To capture this, we compute the content and style scores of all the potential directives and generator outputs and retain *only* those directives which have **both** the content and style scores better than the average of the generators' outputs' scores. The *accepted* directives become *real* directives for the generator and are used to train it using the *teacher-forcing* cross-entropy loss. Note again that the director remains frozen with ISTYLELM during the entire training process. In the case of multiple potential directives being better than the generators' outputs' average, the cross-entropy loss for each directive is weighted by its marginal difference from the generator's average score on the style dimension; i.e., if the style score for a directive is D_s and average outputs' style score from the generator is G_s, its weight during the cross-entropy training is $D_s - G_s$. This objective is similar to the one used in SCST (Rennie et al., 2017) but only *accepted* directives are encouraged and nothing is explicitly discouraged.

In order to stabilize the Director-Generator fine-tuning framework, we use (a) **fixed director**, and (b) **moving generator**. Contrary to the natural expectation of exploring better directives with the training of the director, the fixed or frozen director prevents catastrophic degradation in case the training biases the model towards specific choices that further train the model. It is a known phenomenon in RL frameworks that the model quickly learns to bias towards specific choices that are more rewarding. Specifically, we observe that training the director as well leads to overfitting to the limited stylistic choices, thus resulting in the exploration of sub-optimal potential directives that seldom cross the required thresholds, especially the content preservation ones. With a moving (i.e. trained at each step) generator, its outputs scores account for the *current* state of the model against a fixed stable director, and hence only those directives get accepted which are better than the *current* capabilities (thresholds) of the generator. With a fixed generator, directives that would have been worse than *current* capabilities of the model but better than the capabilities of the fixed generator would also get accepted, thus training the model in the opposite direction. The Director-Generator finetuned iSTYLELM yields our proposed DRAG framework. At the inference time, we drop the director and use the Generator as our final rewriting model.

5 Experiments

We use a transformer encoder[1] with 512 hidden units, 16 heads, a dropout rate of 0.1, and learned positional embeddings during our MLM training. The model is trained using Adam Optimizer with a learning rate of 10^{-4}. The batch size used is 32 with a stream of 256 tokens, and the whole setup is trained until the validation performance (perplexity scores) shows no further improvement. The Transformers used in encoder-decoder setup also have the same parameters, and are initialized using the above encoder before training on further objectives. During DAE loss training, we use the same hyper-parameters used in (Conneau and Lample, 2019; Syed et al., 2020), and set p_{drop} and p_{blank} to 0.1. During director-generator training, we use n as 8 and ϵ as 0.05. The learning rate used in this case is 10^{-5}. In all the models, we use Byte Pair Encoding (Sennrich et al., 2015) with $80k$ codes learnt over the entire *generic* corpus.

5.1 Dataset

We use the 2,857 books written by 142 authors in the Gutenberg corpus (Lahiri, 2014), as used in (Syed et al., 2020), along with the Wikipedia articles, to form a corpus of about 4.6M passages. We refer to this corpus as *generic* during all our experiments, since it infuses only *generic* linguistic knowledge into the models. While MLM and VANILLALM are trained on the *generic* corpus, we select three authors with the most distinct writing styles, namely Albert Einstein, Michael Faraday, and John Stuart Mill, as measured by comparing their lexical alignments with the average lexical alignment of the Gutenberg corpus, as the target authors for author-specific style rewriting. Note that the choice of the authors is made purely on statistical basis with these three authors having maximum lexical style difference on their style vectors as described earlier when compared with the lexical style of entire *generic* corpus. For evaluation, we use the Opinosis corpus (Ganesan et al., 2010) as well as mixed author Gutenberg subset (with five passages from all the authors except the target author), which we refer to as *Generic (Test)*.

5.2 Quantitative Evaluation

Table 1 shows the results averaged over the three selected authors. The experiments are conducted on Opinosis and *Generic (Test)* datasets, using the following four models.

- **VANILLALM** is initialized using MLM-trained encoders and decoders and fine-tuned on the generic corpus using DAE loss.
- **STYLELM**, proposed by Syed et al. (2020),[2] is also initialized using MLM-trained encoders and decoders, but fine-tuned *only* on the target author corpus (instead of the generic corpus).
- **iSTYLELM**, an improved and stronger baseline compared to STYLELM, is initialized with VANILLALM and then fine-tuned on the target author corpus.
- **DRAG** is our proposed model. We use iSTYLELM to initialize both director and generator as described above, and then fine-tune them using inputs from *generic* corpus.

While the *Generic(Test)* corpus is predominantly literary due to the nature of the source, Opinosis covers everyday language. As shown in Table 1, STYLELM improves on the style alignment scores,

---

[1] As proposed by Parisotto et al. and shown in Fig. 1

[2] Note that the STYLELM code is not publicly available. Results shown in the table are using our own implementation.

Dataset	**Model**	**Content Preservation (↑)**				**Author Style (↓)**		
		ROUGE-1	**ROUGE-2**	**ROUGE-L**	**BLEU**	**Lexical(RMSE)**	**Surface(RMSE)**	**Syntactic(JSD)**
Opinosis	Vanilla LM	75.23	56.12	74.28	59.46	0.232	2.74	0.132
	StyleLM (Syed et al., 2020)	32.61	14.51	31.69	14.82	**0.174**	2.56	0.121
	iStyleLM	49.28	29.16	49.86	28.16	0.178	2.61	0.122
	DRAG	**57.23**	**36.12**	**56.98**	**37.53**	0.179	**2.48**	**0.109**
Generic	Vanilla LM	72.34	54.65	71.93	56.46	0.218	2.48	0.120
	StyleLM (Syed et al., 2020)	30.31	11.58	29.77	12.91	**0.163**	2.29	0.114
	iStyleLM	45.12	26.08	44.36	24.16	0.171	2.33	0.121
	DRAG	**52.39**	**30.66**	**51.98**	**33.28**	0.174	**2.21**	**0.097**

Table 1: ↑ indicates higher scores are better while ↓ indicates the opposite. Apart from lexical alignment where StyleLM performs marginally better, DRAG outperforms prior approaches. Vanilla LM performs best at content preservation but lacks any stylization

Table 3: Comparison between STYLELM and DRAG for Albert Einstein

but at a great cost of content preservation when the target author corpus is small. This is possibly due to the random initialization of encoder-decoder attention parameters in the DAE training over target corpus, as reflected in the superior performance of ISTYLELM. We also note that while the approach proposed in STYLELM (Syed et al., 2020) improves lexical scores significantly, it fails to bring the same level of improvement in surface and syntactic alignments, perhaps due to the due to rare chances of less frequent punctuation symbols getting masked during DAE training, even more so when the target author corpus is not large enough to cover all possible masks. Similar reasoning explains the syntactic alignment issues, The DRAG approach, however, improves on both surface and syntactic alignment along with content preservation scores even though it comes at the marginal cost of lexical alignment. Please note that the purpose of Vanilla LM is to provide an estimation of *upper limit* on the content preservation scores and is not to be treated as a baseline due to the simple objective of its task (just copying the input tokens).

5.3 Qualitative Comparisons

We also qualitatively show some comparisons for different authors and different models. In Table 2, we show the outputs of DRAG for same input and different target authors. Evidently, our model produces changes both at the lexical as well as surface levels. The word 'good' in the first input is replaced by words like 'clearly', 'wonderful', and 'pretty', depending on the author. Some words do not replace any word but still get added to change the syntactical structure of the sentences. For example, appearance of the word 'relative' starts comparison to the 'leading existence' making it a bit complex. Sometimes, surface level changes like appearance of ';' also change the complexity of sentences.

We also show the comparison between STYLELM and our proposed DRAG outputs for same inputs when the target author is Albert Einstein as shown in Table 3. Evidently, while both models try to achieve the stylistic alignment, STYLELM ends up distorting the input sentence too much resulting in poor content preservation properties. Words like 'measured', 'hypothetical', and 'physical' relative reflect the *objective* approach used in Albert Einstein's writings.

6 Discussions and Limitations

While the language generation advancements are happening at a very high pace, the notion of style and the ability of models to rewrite same content in different styles is still far from being solved. One of the most important observation as made by Lample et al. (2018) is that it is very difficult to separate content from style. In fact, previous approaches which worked on the principle of *disentangling* style from content were not found to disentangle the style so much after all (Lample et al., 2018). The notion of style is still very far from being defined and concretized. While some psycholinguistic concepts can be defined to some extent (formality, sentiment, etc.), defining it at the level of author's style is very difficult due to manifestation of style at different levels as enumerated by Verma and Srinivasan (2019). Despite, such enumeration at various levels, it is far from *exhaustive* and therefore our approach still requires more granular understanding of style to closely emulate target author's style.

Our evaluation uses automatic metrics for style due to the difficulty associated with conducting human evaluation in author attribution tasks (Syed et al., 2020). The skill needed to identify the author's style is very intense thus making the human evaluation very costly. A more granular and detailed study on understanding how humans interpret an author's style is required to design a proper feedback mechanism. This is, however, outside the scope of this work.

6.1 What Did Not Work

In this section, we discuss some of our explorations that did not work as expected to aid future research in author stylization. We experimented with various **reinforcement learning setups** as it was a more natural choice once we had scoring engines for rewards. Using the VANILLALM as a policy and we explored Self Critical Sequence Training (SCST) (Rennie et al., 2017; Ranzato et al., 2015) and Proximal Policy Optimization (Schulman et al., 2017). However, all the setups were unstable in various ways for our problem. Note that our experiments and observations here are limited to the problem of author stylized rewriting only. SCST or self-critical sequence training is aimed at bringing the advantages of reinforcement learning setups for sequence level problems. A model (or policy) generates/explores outputs (or episodes) using multinomial sampling and greedy sampling. If the greedily sampled episode reward is r_b and the non-greedily sampled episode reward is r - the whole setup is trained using REINFORCE (Sutton and Barto, 2018) with r as the actual reward and r_b as baseline reward. We found this to limit exploration considering our problem is relatively much harder than previous metrics on which SCST has been successful due to our target metric being of an exact value. It, therefore, resulted in no improvement in either style or content scores. We, therefore, shifted to its modified version to encourage exploration, where we generated multiple episodes for each input and averaged their scores to use that as baseline reward r_b and trained the setup on all generated episodes using REINFORCE (Sutton and Barto, 2018). We found this approach to be effective at style incorporation but not generalizable at all. The model learned to repeat certain patterns with poor content preservation abilities. We, tried, to balance it with occasional denoising autoencoder loss training but that only *delayed* the overfitting and not solve it. We also attempted Proximal Policy Optimization in a setup same as (Sun et al., 2019) but it resulted in even worse outputs due to the critic's failure to approximate complex value functions for our objectives.

As discussed already, we only accept those directives which have scores above the threshold. We also tried a variant of it which had even those directives which do not score above the threshold. We scored them negatively thereby resulting in a bit similar framework like SCST but within some steps, we found more negative scores than positive due to bad content preservation pushing the model away from a bad state towards some undefined state resulting in spurious and inconsistent outputs.

7 Conclusion and Future Work

In this work, we addressed the shortcomings of the prior approaches for the task of author stylized rewriting and overcame them through DRAG: a Director-Generator approach. We showed the effectiveness of our proposed approach for stylized rewriting on three different authors from the

Guteneberg Corpus. Furthermore, we discussed the limitations of our approach and some of the failure cases to aid future research. While our DRAG approach is able to stabilize the training while improving the content preservation abilities of the model, a standard reinforcement learning approach, when stabilized, has the potential to improve these scores to a much more improved level. Improved understanding of author style while keeping a human in the loop and stabilizing RL with transformers models are subjects of future research.

Leveraging Passage Retrieval with Generative Models for Open Domain Question Answering

Gautier Izacard[1,2,3] **Edouard Grave**[1]

Abstract

Generative models for open domain question answering have proven to be competitive, without resorting to external knowledge. While promising, this approach requires to use models with billions of parameters, which are expensive to train and query. In this paper, we investigate how much these models can benefit from retrieving text passages, potentially containing evidence. We obtain state-of-the-art results on the Natural Questions and TriviaQA open benchmarks. Interestingly, we observe that the performance of this method significantly improves when increasing the number of retrieved passages. This is evidence that sequence-to-sequence models offers a flexible framework to efficiently aggregate and combine evidence from multiple passages.

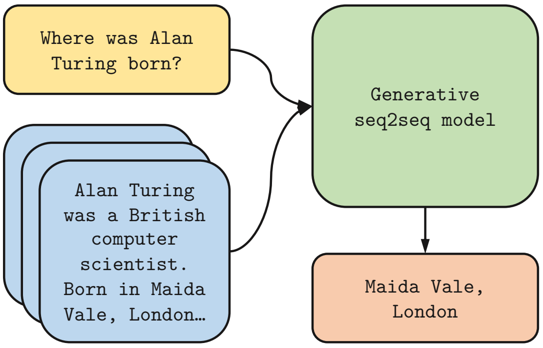

Figure 1: A simple approach to open domain question answering. First, it retrieves support text passages from an external source of knowledge such as Wikipedia. Then, a generative encoder-decoder model produces the answer, conditioned on the question and the retrieved passages. This approach scales well with the number of retrieved passages, as the performance keeps improving when retrieving up to one hundred passages.

1 Introduction

Recently, several works have shown that factual information can be extracted from large scale language models trained on vast quantities of data (Radford et al., 2019; Petroni et al., 2019; Jiang et al., 2019; Talmor et al., 2019). Building on that observation and the advances in pretraining of natural language processing models, Roberts et al. (2020) introduced a generative model for open domain question answering. Without relying on external knowledge, this method obtained competitive results on several benchmarks. However, it requires models containing billions of parameters, since all the information needs to be stored in the weights. This makes models expensive to query and train. In this paper, we investigate how much this method could benefit from having access to an external source of knowledge, such as Wikipedia.

Retrieval based approaches were previously considered in the context of open domain question answering with extractive models (Chen et al., 2017). In that case, systems start by retrieving support documents, before extracting the answer from these documents. Different retrieval techniques have been considered, either using sparse representations based on TF/IDF or using dense embeddings (Guu et al., 2020; Karpukhin et al., 2020). The models which extract the answers are often based on contextualized word representations such as ELMo or BERT (Peters et al., 2018; Devlin et al., 2019), and predict a span as answer. Aggregating and combining evidence from multiple passages is not straightforward when using extractive models, and multiple techniques have been proposed to address this limitation (Clark and Gardner, 2018; Min et al., 2019a).

In this paper, we explore a simple approach having the best of both worlds, by building on the exciting developments in generative modeling and retrieval for open domain question answering. This method proceeds in two steps, by first retrieving supporting passages using either sparse or dense

April 19 - 23, 2021.

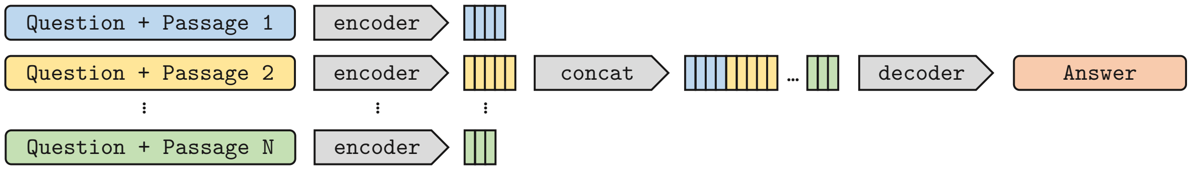

Figure 2: Architecture of the Fusion-in-Decoder method.

representations. Then, a sequence-to-sequence model generates the answer, taking as input the retrieved passages in addition to the question. While conceptually simple, this method sets new state-of-the-art results on the TriviaQA and NaturalQuestions benchmarks. In particular, we show that the performance of our method significantly improves when the number of retrieved passages increases. We believe that this is evidence that generative models are good at combining evidence from multiple passages, compared to extractive ones.

2 Related work

Open domain question answering is the task of answering general domain questions, in which the evidence is not given as input to the system. While being a longstanding problem in natural language processing (Voorhees, 1999), this task has recently regained interest following the work by Chen et al. (2017). In that version of the problem, strong supervision is available to the learning system, in the form of spans corresponding to answers. Chen et al. (2017) proposed to solve the problem by first retrieving support document from Wikipedia, before extracting the answer from the retrieved document. Different methods were proposed to tackle the setting where no gold spans are given to the system, but only the correct answer. Clark and Gardner (2018) proposed to use a global normalization over all the span corresponding to the answer, which was later applied to BERT based models (Wang et al., 2019). Min et al. (2019a) introduced a method based on hard expectation-maximization to tackle noisy supervision from this setting. Wang et al. (2018b) described a technique to aggregate answers from different paragraphs, using confidence and coverage scores.

Passage retrieval is an important step in open domain question answering, and is an active area of research to improve QA systems. Initially, sparse representations based on TF/IDF were used to retrieve support documents (Chen et al., 2017). Lee et al. (2018) introduced a supervised learning method to rerank paragraphs based on BiLSTM, while Wang et al. (2018a) trained a ranking system with reinforcement learning. A second approach to improve the retrieval step of QA systems is to used additional information such as the Wikipedia or Wikidata graphs (Min et al., 2019b; Asai et al., 2020). Recently, multiple works show that retrieval systems entirely based on dense representation and approximate nearest neighbors were competitive with traditional approaches. Such models can be trained using weak supervision in the form of question-answer pairs (Karpukhin et al., 2020), or pretrained using a cloze task and finetuned end-to-end (Guu et al., 2020; Lee et al., 2019).

Generative question answering was mostly considered in previous work for datasets requiring to generate answers, such as NarrativeQA (Kočiskỳ et al., 2018), CoQA (Reddy et al., 2019) or ELI5 (Fan et al., 2019). These datasets were generated in a way that answers do not correspond to spans in support documents, thus requiring abstractive models. Raffel et al. (2020) showed that generative models are competitive for reading comprehension tasks such as SQuAD (Rajpurkar et al., 2016), where answers are spans. Roberts et al. (2020) proposed to use large pretrained generative models, without using additional knowledge, for open domain question answering. Closest to our work, Min et al. (2020) and Lewis et al. (2020b) introduced retrieval augmented generative models for open domain question answering. Our approach differs from these works by how the generative model processes the retrieved passages. This allows to scale to large numbers of documents, and to benefit from this large amount of evidence.

3 Method

In this section, we describe our approach to open domain question answering. It proceeds in two steps, first retrieving support passages before processing them with a sequence to sequence model.

Table 1: Comparison to state-of-the-art. On TriviaQA, we report results on the open domain test set (left), and on the hidden test set (right), `competitions.codalab.org/competitions/17208#results`).

Retrieval. For the retrieval of support passages, we consider two methods: BM25 (Robertson et al., 1995) and DPR (Karpukhin et al., 2020). In BM25, passages are represented as bag of words, and the ranking function is based on term and inverse document frequencies. We use the implementation from Apache Lucene[1] with default parameters, and tokenize questions and passages with SpaCy.[2] In DPR, passages and questions are represented as dense vector representations, computed using two BERT networks. The ranking function is the dot product between the query and passage representations. Retrieval is performed using approximate nearest neighbors with the FAISS library.[3]

Reading. Our generative model for open domain QA is based on a sequence-to-sequence network, pretrained on unsupervised data, such as T5 or BART (Raffel et al., 2020; Lewis et al., 2020a). The model takes as input the question, as well as the support passages, and generates the answer. More precisely, each retrieved passage and its title are concatenated with the question, and processed independently from other passages by the encoder. We add special tokens `question:`, `title:` and `context:` before the question, title and text of each passage. Finally, the decoder performs attention over the concatenation of the resulting representations of all the retrieved passages. The model thus performs evidence fusion in the decoder only, and we refer to it as *Fusion-in-Decoder*.

By processing passages independently in the encoder, but jointly in the decoder, this method differs from Min et al. (2020) and Lewis et al. (2020b). Processing passages independently in the encoder allows to scale to large number of contexts, as it only performs self attention over one context at a time. This means that the computation time of the model grows linearly with the number of passages, instead of quadratically. On the other hand, processing passages jointly in the decoder allows to better aggregate evidence from multiple passages.

4 Experiments

In this section, we report empirical evaluations of Fusion-in-Decoder for open domain QA.

Datasets. We consider the following datasets, and use the same setting as Lee et al. (2019):

- NaturalQuestions (Kwiatkowski et al., 2019) contains questions corresponding to Google search queries. The open-domain version of this dataset is obtained by discarding answers with more than 5 tokens.

- TriviaQA (Joshi et al., 2017) contains questions gathered from trivia and quiz-league

websites. The *unfiltered* version of TriviaQA is used for open-domain question answering.

- SQuAD v1.1 (Rajpurkar et al., 2016) is a reading comprehension dataset. Given a paragraph extracted from Wikipedia, annotators were asked to write questions, for which the answer is a span from the corresponding paragraph.

Following Lee et al. (2019) we use the validation as test, and keep 10% of the training set for validation. We use the Wikipedia dumps from Dec. 20, 2018 for NQ and TriviaQA and from Dec. 21, 2016 for SQuAD. We apply the same preprocessing as Chen et al. (2017); Karpukhin et al. (2020), leading to passages of 100 words, which do not overlap.

Evaluation. Predicted answers are evaluated with the standard exact match metric (EM), as introduced by Rajpurkar et al. (2016). A generated answer is considered correct if it matches any answer of the list of acceptable answers after normalization. This normalization step consists in lowercasing and removing articles, punctuation and duplicated whitespace.

Technical details. We initialize our models with the pretrained T5 models (Raffel et al., 2020), available in the HuggingFace Transformers library.[4] We consider two model sizes, base and large, containing respectively 220M and 770M parameters. We fine-tune the models on each dataset independently, using Adam (Kingma and Ba, 2014) with a constant learning rate of 10^{-4} and a dropout rate of 10%. We train the model for 10k gradient steps, with a batch size of 64, using 64 Tesla V100 32Gb. We evaluate models every 500 steps and select the best one on the validation set based on the Exact Match score. During training on NaturalQuestions and SQuAD, we sample the target among the list of answers, while for TriviaQA, we use the unique human-generated answer. For TriviaQA, answers in uppercase are normalized by converting all letters in lowercase except the first letter of each word, using the `title` Python string method. For both training and testing, we retrieve 100 passages (unless said otherwise), and truncate them to 250 word pieces. Following the results of Karpukhin et al. (2020), passages are retrieved with DPR for NQ and TriviaQA, and with BM25 for SQuAD. We generate answers by using greedy decoding.

Comparison to state-of-the-art. In table 1, we compare the results obtained by Fusion-in-Decoder with existing approaches for open domain question answering. We observe that while conceptually simple, this method outperforms existing work on the NaturalQuestion and TriviaQA benchmarks. In particular, generative models seem to perform well when evidence from multiple passages need to be aggregated, compared to extractive approaches. Our method also performs better than other generative models, showing that scaling to large number of passages and processing them jointly leads to improvement in accuracy. Second, we observe that using additional knowledge in generative models by using retrieval lead to important performance gains. On NaturalQuestions, the *closed book* T5 model obtains 36.6% accuracy with 11B parameters, while our approach obtains 44.1% with 770M parameters plus Wikipedia with BM25 retrieval. Both methods use roughly the same amount of memory to store information, indicating that text based explicit memories are competitive for knowledge retrieval tasks.

Scaling with number of passages. In Figure 3, we report the performance with respect to the

Training Passages	NaturalQuestions w/o finetuning	NaturalQuestions w/ finetuning	TriviaQA w/o finetuning	TriviaQA w/ finetuning
5	37.8	45.0	58.1	64.2
10	42.3	45.3	61.1	63.6
25	45.3	46.0	63.2	64.2
50	45.7	46.0	64.2	64.3
100	46.5	-	64.7	-

Table 2: Performance depending on the number of passages used during training. Exact Match scores are reported on dev sets.

number of retrieved passages. In particular, we observe that increasing the number of passages from 10 to 100 leads to 6% improvement on TriviaQA and 3.5% improvement on NaturalQuestions. On the other hand, the performance of most extractive models seems to peak around 10 to 20 passages (Wang et al., 2019; Yang et al., 2019). We believe that this is evidence that sequence-to-sequence models are good at combining informations from multiple passages.

Impact of the number of training passages. In the previous section, the model was trained and evaluated with the same number of passages. To reduce the training computational budget, a simple solution consists in training the model with fewer passages. In Table 2, we report the performance obtained by training with different numbers of passages, while testing with 100 passages. We observe that reducing the number of training passages leads to a decrease of accuracy. Further, we propose to finetune the previous models using 100 passages for 1000 steps. This allows to reduce the accuracy gap, while using significantly less computational resources: we can reach 46.0 EM on NaturalQuestions, using 147 GPU hours, compared to 425 GPU hours when training on 100 passages.

5 Conclusion

In this paper, we study a simple approach to open domain question answering, which relies on retrieving support passages before processing them with a generative model. We show that while conceptually simple, this approach is competitive with existing methods, and that it scales well with the number of retrieved passages. In future work, we plan to make this model more efficient, in particular when scaling to large number of support passages. We also plan to integrate the retrieval in our model, and to learn the whole system end-to-end.

Abstract

Outcome prediction from clinical text can prevent doctors from overlooking possible risks and help hospitals to plan capacities. We simulate patients at admission time, when decision support can be especially valuable, and contribute a novel *admission to discharge* task with four common outcome prediction targets: Diagnoses at discharge, procedures performed, in-hospital mortality and length-of-stay prediction. The ideal system should infer outcomes based on symptoms, pre-conditions and risk factors of a patient. We evaluate the effectiveness of language models to handle this scenario and propose *clinical outcome pre-training* to integrate knowledge about patient outcomes from multiple public sources. We further present a simple method to incorporate ICD code hierarchy into the models. We show that our approach improves performance on the outcome tasks against several baselines. A detailed analysis reveals further strengths of the model, including transferability, but also weaknesses such as handling of vital values and inconsistencies in the underlying data.

1 Introduction

Clinical professionals make decisions about patients under strong time constraints. The patient information at hand is often unstructured, e.g. in the form of clinical notes written by other medical personnel in limited time. Clinical decision support (CDS) systems can help in these scenarios by pointing towards related cases or certain risks. Clinical outcome prediction is a fundamental task of CDS systems, in which the patient's development is predicted based on data from their Electronic Health Record (EHR). In this work we focus on textual EHR data available at admission time.

Figure 1 shows a sample admission note with highlighted parts that – according to medical doctors – must be considered when evaluating a patient.

Encoding clinical notes with pre-trained language models. Neural models need to extract relevant facts from such notes and learn complex relations between them in order to associate certain clinical outcomes. Pre-trained language models such as BERT (Devlin et al., 2019) have shown to be able to both extract information from noisy text and to capture task-specific relations in an end-to-end fashion (Tenney et al., 2019; van Aken et al., 2019). We thus base our work on these models and pose the following questions:

- Can pre-trained language models learn to predict patient outcomes from their admission information only?
- How can we integrate knowledge about outcomes that doctors gain from medical literature and previous patients?
- How well would these models work in clinical practice? Are they able to interpret common risk factors? Where are they failing?

Simulating patients at admission time. Existing work on text-based outcome prediction focuses on progress notes after a certain time of a patient's hospitalisation (Huang et al., 2019). This is mostly due to a lack of publicly available admission notes and poses some problems: 1) Doctors might miss specific outcome risks early in admission and 2) progress notes already contain information about clinical decisions made on admission time (Boag et al., 2018). We propose to simulate newly arrived patients by extracting admission notes from MIMIC III discharge summaries. We are thus able

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 881–893
April 19 - 23, 2021.

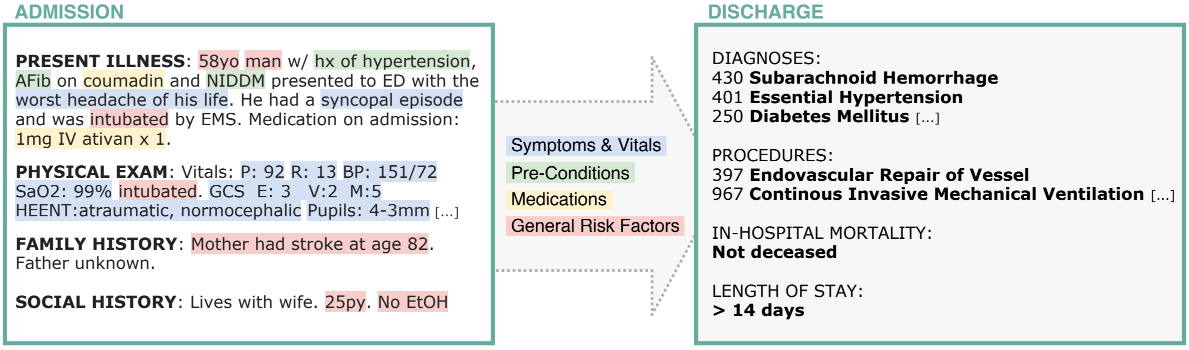

Figure 1: *Admission to discharge* sample that demonstrates the outcome prediction task. The model has to extract patient variables and learn complex relations between them in order to predict the clinical outcome.

to give doctors hints towards possible outcomes from the very beginning of an admission and can potentially prevent early mistakes. We can also help hospitals in planning resources by indicating how long a patient might stay hospitalised.

Integrating knowledge with specialised outcome pre-training. Gururangan et al. (2020) recently emphasized the importance of domain- and task-specific pre-training for deep neural models. Consequently we propose to enhance language models pre-trained on the medical domain with a task-specific *clinical outcome pre-training*. Besides processing clinical language with idiosyncratic and specialized terms, our models are thus able to learn about patient trajectories and symptom-disease associations in a self-supervised manner. We derive this knowledge from two main sources: 1) Previously admitted patients and their outcomes. This knowledge is usually stored by hospitals in unlabelled clinical notes and 2) Scientific case reports and knowledge bases that describe diseases, their presentations in patients and prognoses. We introduce a method for incorporating these sources by creating a suitable pre-training objective from publicly available data.

Contributions. We summarize the major contributions of this work as follows:
1) A novel task setup for clinical outcome prediction that simulates the patient's admission state and predicts the outcome of the current admission.
2) We introduce self-supervised *clinical outcome pre-training*, which integrates knowledge about patient outcomes into existing language models.
3) We further propose a simple method that injects hierarchical signals into ICD code prediction.
4) We compare our approaches against multiple baselines and show that they improve performance on four relevant outcome prediction tasks with up to 1,266 classes. We show that the models are transferable by applying them to a second public dataset without additional fine-tuning.
5) We present a detailed analysis of our model that includes a manual evaluation of samples conducted by medical professionals.

2 Related Work

Using clinical notes for outcome prediction. Boag et al. (2018) studied the predictive value of clinical notes with simple approaches such as bag-of-words. Recent work increasingly applies neural models to compensate for the noisy nature of the data and the complexity of patterns. Hashir and Sawhney (2020) used both convolutional and recurrent layers for outcome prediction, while Jain et al. (2019) and Qiao et al. (2019) proposed attention-based approaches. Dligach et al. (2019) explored pre-training as a strategy to mitigate data sparsity in clinical setups. Si and Roberts (2019) and Suresh et al. (2018) further showed that outcome prediction benefits from a multitask setup. In contrast to earlier work we apply neural models to admission notes in an *admission to discharge* setup.

Pre-trained language models for the clinical domain. While pre-trained language models are successful in many areas of NLP, there has been little work on applying them to the clinical domain (Qiu et al., 2020). Alsentzer et al. (2019) and Huang et al. (2019) both pre-trained BERT-based models on clinical data. They evaluated their work on readmission prediction and other NLP tasks. We are the first to evaluate pre-trained language models on multiple clinical outcome tasks with large label sets. We further propose a novel pre-training objective specifically for the clinical domain.

Prediction of diagnoses and procedures. The majority of work on diagnosis and procedure prediction covers either single diagnoses (Liu et al., 2018; Choi et al., 2018) or coarse-grained groups (Peng et al., 2020; Sushil et al., 2018). We argue that models should predict diseases and procedures in a fine-grained manner to be beneficial for doctors. Thus we use all diagnosis and procedure codes from the data for our outcome prediction tasks.

ICD coding vs. outcome prediction. There is a variety of work in the related field of automated ICD coding (Xie et al., 2018; Falis et al., 2019). Zhang et al. (2020) recently presented a model able to identify up to 2,292 ICD codes from text. However, ICD coding differs from outcome prediction in the way that diseases are directly extracted from text rather than inferred from symptom descriptions and patient history. We further discuss this distinction in Section 6.

3 Clinical *Admission to Discharge* Task

Clinical outcome prediction can be defined in different ways. We approach the task from a doctor's perspective and predict the outcome of a current admission from the time of the patient's arrival to the hospital unit. We describe our setup as follows.

3.1 Clinical Notes from MIMIC III

As our primary data source, we use the freely-available MIMIC III v1.4 database (Johnson et al., 2016). It contains de-identified EHR data including clinical notes in English from the Intensive Care Unit (ICU) of Beth Israel Deaconess Medical Center in Massachusetts between 2001 and 2012. We focus our work on discharge summaries in particular and the outcome information associated with an admission. Similar to previous work, we filter out notes about newborns and remove duplicates.

3.2 Creating Admission Notes from Discharge Summaries

The state of a patient is commonly summarized in an ongoing document, which finally concludes in a discharge summary. Since we want to support clinical decisions from the beginning of a patient's stay, we simulate the state of the patient's document at admission time. We thus filter the document by sections that are known at admission such as: *Chief complaint, (History of) Present illness, Medical history, Admission Medications, Allergies, Physical exam, Family history* and *Social history*. We further describe the filtering in Appendix B.1. Our approach results in 48,745 admission notes. As shown in Table 1 the notes contain about 400 words on average. The selection of admission sections as well as the resulting structure of the notes were verified by medical doctors.

Admission Notes Statistics			
avg (words / doc)	std (words / doc)	avg (sent / doc)	std (sent / doc)
396.3	233.3	32.5	23.1

Table 1: Numbers of words / sentences in MIMIC III admission notes. We see a high variation in length.

Multi-label tasks: ICD-9 codes per dataset split							
Diagnoses				Procedures			
Total	Train	Val	Test	**Total**	Train	Val	Test
1,266	1,201	906	1,031	**711**	672	476	563

Table 2: Distribution of ICD-9 codes per dataset split (patient-wise). Note that very rare codes do not appear in each split of the dataset.

Single-label tasks: Samples per class					
Mortality		Length of Stay (in days)			
0	1	≤ 3	> 3 & ≤ 7	> 7 & ≤ 14	> 14
43,609	5,136	5,596	16,134	13,391	8,488

Table 3: Distribution of labels for *Mortality Prediction* and *Length of Stay* task. Both tasks have unbalanced class distributions.

This newly created admission dataset enables us to make predictions on the outcome of a current admission. At inference time, doctors can then use the model's predictions on textual data from newly arrived patients.

3.3 Outcome Prediction Tasks

We select four relevant tasks for outcome prediction in consultation with medical professionals. All tasks take admission notes as input.

Diagnosis prediction. A main goal of clinical outcome prediction is to support medical professionals in the process of differential diagnosis. We thus take all diagnoses associated with an admission into account and frame the task as an extreme multi-label classification. Diagnoses are encoded as ICD-9 codes in the MIMIC III database. Following Choi et al. (2017), we group ICD-9 diagnosis codes from the database from 4- into 3-digit codes to reduce complexity while still obtaining granular suggestions. This results in a total of 1,266 diag-

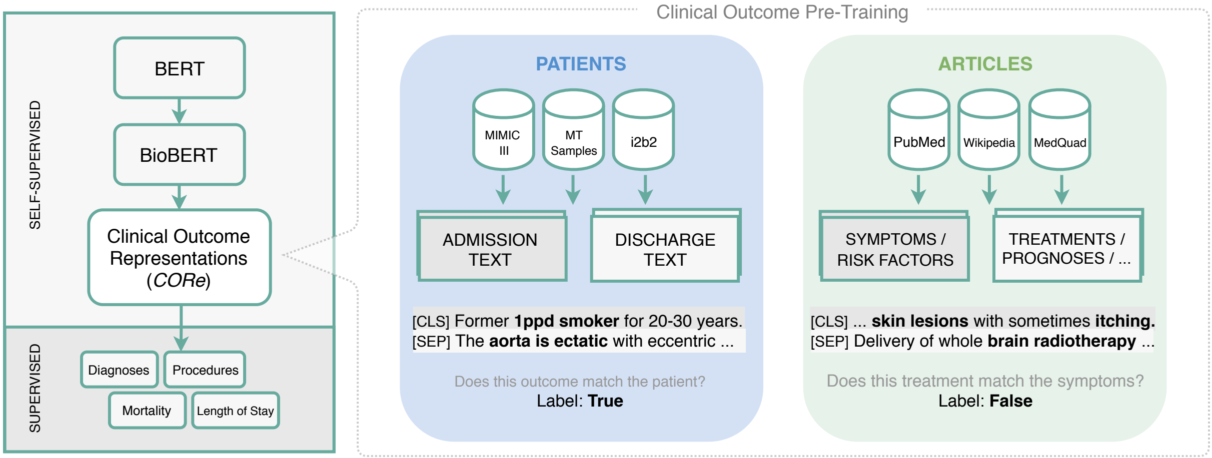

Figure 2: Schematic demonstration of *clinical outcome pre-training*. Sources of clinical knowledge are complete patient notes and medical articles. Based on that we create a self-supervised learning objective that teaches relations between symptoms, risk factors and outcomes.

nosis codes, which are distributed over our dataset splits as shown in Table 2. The labels are power-law distributed with a long tail of very rare codes.

Procedure prediction. Procedures are either diagnostics or treatments applied to a patient during a stay. Similarly to diagnosis prediction, this is an extreme multi-label task. We again group the ICD-9 codes from the MIMIC III database into 3-digit codes. In total there are 711 procedure codes labelled in the database in a power law distribution similar to the diagnosis codes.

In-hospital mortality prediction. Predicting a patient's mortality risk is a fundamental part of the triage process. In-hospital mortality in particular describes whether a patient died during the current admission and is a binary classification task. The percentage of deceased patients in the data is around 10% (see Table 3). As some notes contain direct indications of mortality such as *patient deceased* within the admission sections, we apply an additional filter for those terms.

Length-of-stay prediction. The duration of an ICU stay is an important information for hospitals in order to plan allocations of resources. We group patients into four major categories regarding their length of stay: *Under 3 days, 3 to 7 days, 1 week to 2 weeks, more than 2 weeks.* These categories were recommended by medical doctors in order to make the results as useful as possible in clinical practice. Table 3 shows the samples per class.

4 Integrating Clinical Knowledge Into Language Models

We propose *clinical outcome pre-training*, a way to integrate knowledge about clinical outcomes into pre-trained language models. We further introduce an additional step to incorporate ICD code hierarchy into our multi-label classification tasks.[1]

4.1 Clinical Outcome Pre-Training

Motivation. Language model pre-training has shown to be of use in specialised domains like the clinical (Alsentzer et al., 2019; Huang et al., 2019). However, these models lack knowledge about patient trajectories and symptom-diagnosis relations, because their training is focused on learning language characteristics.
We develop an additional pre-training step that produces *Clinical Outcome Representations (CORe)* in order to teach the model relations between symptoms, risk factors and clinical outcomes. Much of this knowledge is present and publicly available, e.g. in knowledge bases like Wikipedia or publication archives like PubMed. Another source is available to hospitals in the form of unlabelled clinical notes from previous patients. The suggested outcome pre-training is a way to use this knowledge to improve the model's capabilities in predicting clinical outcomes as described in 3.3.
Corresponding to the way doctors gain their knowledge from both experience and medical literature,

---

[1] The code to recreate the experiments and datasets described in this paper is accessible at: `https://github.com/bvanaken/clinical-outcome-prediction`

we incorporate knowledge from complete patient notes (including discharge information) and medical articles.

Training objective. Our proposed training objective (Figure 2) is strongly related to the Next Sentence Prediction (NSP) task introduced by Devlin et al. (2019). In NSP the model gets two sentences as an input and predicts whether the second follows the first sentence. This way models such as BERT learn relations between sentences. We convert this setting so that the model instead learns relations between admissions and outcomes.

From common sections in patient notes, we create two categories: Sections that are created at admission A and sections that are created after admission, e.g. at discharge time D. Given a patient note N, we split it into sections $A_N \in A$ and $D_N \in D$. We remove all other sections. We then sample token sequences from these sections to get $t_{N,1...k} \in A_N$ and $t'_{N,1...k} \in D_N$, where k is randomly set between 30 and 50 tokens. We then train the model to maximize $P(Same\_Patient|X_{N\_N})$ and $P(Other\_Patient|X_{N\_M})$ with

$$\begin{aligned} X_{N\_N} &= Enc(t_{N,1...k}, t'_{\mathbf{N},1...k}) \\ X_{N\_M} &= Enc(t_{N,1...k}, t'_{\mathbf{M},1...k}) \end{aligned} \tag{1}$$

with M being a randomly sampled document from the same batch and Enc referring to the BioBERT encoding. As in the original NSP setting, we apply negative sampling (X_{N_M}) for 50% of examples. We apply the same strategy on medical articles and case reports, so that A represents sections describing symptoms and risk factors, and D represents sections that describe outcomes of a disease or case.

Data sources. We create the pre-training dataset from multiple public sources. To integrate knowledge that doctors gain from previous patients and medical literature, we create two groups of sources:
1) *Patients*, which includes 32,721 discharge summaries from the MIMIC III training set, 5,000 publicly available medical transcriptions from the MT-Samples website [2] and 4,777 clinical notes from the i2b2 challenges 2006-2012[3] (Uzuner et al., 2007, 2008, 2010a,b, 2011, 2012; Sun et al., 2013b,a).
2) *Articles*, composed of 9,335 case reports from PubMed Central (PMC), 2,632 articles from Wikipedia describing diseases and 1,467 article sections from the MedQuAd dataset (Abacha and Demner-Fushman, 2019) extracted from NIH websites such as cancer.gov.

While *Patients* samples contain unaudited practical knowledge, *Articles* samples are built from verified general medical knowledge such as peer-reviewed studies. The sources are therefore substantially different and we evaluate their individual effect on performance in Section 5.3.

Data preparation. We create admission (A_N) and discharge parts (D_N) of the documents based on section headings. We define common sections belonging to the admission part and those belonging to the discharge part similar to the method described in Section 3.2. We ignore sections that cannot be categorized. For section heading extraction from MIMIC III discharge summaries and MTSamples transcriptions, we apply simple rule-based approaches, which is feasible because the notes are well-structured. For Wikipedia we use headings from the WikiSection dataset (Arnold et al., 2019) filtered for disease articles only. For PubMed Central we similarly use the PubMedSection dataset (Schneider et al., 2020) and filter for section headings that indicate case reports. As i2b2 notes are less well-structured in comparison to MIMIC III discharge summaries, we use a classifier as proposed by Rosenthal et al. (2019) to determine which section a sentence belongs to. The classifier is trained on an annotated set of i2b2 notes and then applied to all other notes.

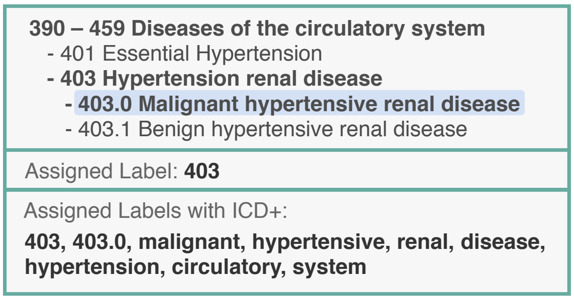
4.2 ICD+: Incorporation of ICD Hierarchy

Medical knowledge in ICD labels. Diagnosis and procedure prediction requires the model to predict ICD-9 codes in a multi-label manner. ICD-9 codes are hierarchically ordered into associated groups. Figure 3 shows the code hierarchy for *Malignant hypertensive renal disease* with the ICD-9 code *403.0*. The diagnosis has two parent groups namely *Hypertension renal disease* and *Diseases of the circulatory system*. Diagnoses or procedures in the same group often share similar medical characteristics, therefore hierarchical relations of a labelled code can be valuable information. This medical information is currently not integrated into the model. The same holds for words describing the ICD-9 codes, that often represent further important signals, such as the words *renal* or *malignant*.

---

[2] https://mtsamples.com

[3] We exclude notes from the 2014 De-identification and Heart Disease Risk Factors Challenge in order to use this set for evaluation as described in Section 5.4.



390 – 459 Diseases of the circulatory system
- 401 Essential Hypertension
- **403 Hypertension renal disease**
  - **403.0 Malignant hypertensive renal disease**
  - 403.1 Benign hypertensive renal disease

Assigned Label: **403**

Assigned Labels with ICD+:

403, 403.0, malignant, hypertensive, renal, disease, hypertension, circulatory, system

Figure 3: Example of *ICD+* labelling. *Malignant hypertensive renal disease* is assigned to nine codes (bottom row) that inform about the type and group of the disease.

Enhancing training with useful additional signals. We propose a simple method, *ICD+*, to incorporate both associated groups and words into the model weights: Instead of only classifying 3-digit codes (as mentioned in 3.3), we let the model additionally predict the 4-digit codes and the bag of associated words with a code and its parent groups. In order to create the bag of words per code, we use the descriptions of ICD-9 codes from MIMIC III and remove all stop words. As shown in Figure 3, the *ICD+* method assigns eight additional labels to the example diagnosis and therefore supplies the model with further information about the diagnosis during training.

By increasing the amount of labels per sample, we integrate relevant medical knowledge and enable the model to learn implicit relations between codes and code groups that share certain words. We evaluate the effectiveness of *ICD+* in Section 5.

5 Experimental Evaluation

5.1 Training Clinical Outcome Representations

We pre-train the *CORe* model on top of BioBERT weights[4]. We then fine-tune the model separately on the four outcome tasks. We use the same training regimen for both pre-training and fine-tuning: We tokenize the texts with WordPiece tokenization and truncate them to 512 tokens, due to the limited context length of the pre-trained models. We use early stopping and tune hyperparameters as described in Appendix C.

5.2 Baseline Models

In the following, we introduce the baseline models that we evaluate on the novel outcome prediction tasks. In order to understand the abilities of pre-trained language models we compare their performance against more traditional approaches. The first three models (*BOW, word embeddings, CNN*) are trained using the hyperparameters proposed by the authors for outcome prediction tasks. The language models are fine-tuned the same way as the *CORe* model.

Bag-of-Words. Boag et al. (2018) shows that a simple bag-of-words (BOW) approach can outperform more complex models on tasks like mortality prediction. We thus include their approach in our evaluation. We adopt their training setting except that we consider 200 instead of 20 top tf-idf words in order to make the model converge.

Pre-trained word embeddings. Boag et al. (2018) further propose the use of pre-computed word embeddings that were trained on MIMIC III data. We use the same setting as for the BOW approach and fit a support vector machine classifier on the clinical outcome tasks.

Convolutional Neural Network (CNN). Si and Roberts (2019) built a neural network for mortality prediction with two hierarchical convolutional layers at the word and sentence levels and then aggregated it to a patient level representation. We follow their approach to evaluate the model on our four *admission to discharge* tasks.

BioBERT. Following the success of BERT, Lee et al. (2020) further pre-trained the model on biomedical research articles from PubMed using abstracts and full-text articles. They reported improved performance on a range of biomedical text mining tasks.

ClinicalBERT and DischargeBERT. We further evaluate two public language models pre-trained on the clinical domain, with MIMIC III data in particular. Huang et al. (2019) pre-trained a BERT Base model on 100,000 random clinical notes (ClinicalBERT) while Alsentzer et al. (2019) further pre-trained BioBERT on all discharge summaries from MIMIC III (we refer to the model as DischargeBERT for simplicity).

---

[4] We choose BioBERT as the base for our model because it outperforms BERT on medical tasks and has not seen data from our test set during pre-training unlike DischargeBERT.

	Diagnoses (1266 classes)	Procedures (711 classes)	In-Hospital Mortality (2 classes)	Length-of-Stay (4 classes)
BOW (Boag et al., 2018)	75.87	77.47	79.15	65.83
Embeddings (Boag et al., 2018)	75.16	76.72	79.94	66.78
CNN (Si and Roberts, 2019)	61.18	73.13	75.50	64.49
BERT Base (Devlin et al., 2019)	82.08	85.84	81.13	70.40
ClinicalBERT (Huang et al., 2019)	81.99	86.15	82.20	71.14
DischargeBERT (Alsentzer et al., 2019)	*82.86*	*87.09*	***84.51***	*71.73*
BioBERT Base (Lee et al., 2020)	82.81	86.36	82.55	71.59
BioBERT ICD+	83.17	87.45	-	-
CORe Articles (w/o ICD+)	83.46 (82.89)	87.43 (86.75)	83.64	71.99
CORe Patients (w/o ICD+)	83.41 (83.40)	**88.37** (86.60)	83.60	71.96
CORe All (w/o ICD+)	**83.54** (83.39)	87.65 (87.15)	**84.04**	**72.53**

Table 4: Results on outcome prediction tasks in macro-averaged % AUROC. The *CORe* models outperform the baselines, *ICD+* adds further improvement (values in parentheses are ablation results without *ICD+*). DischargeBERT results are printed in italic because the model has seen all test data during pre-training and is therefore slightly advantaged.

5.3 Results on MIMIC III Admission Notes

Table 4 shows performances in (macro-averaged) area under the receiver operating characteristic curve (AUROC). We report scores of the *CORe* model trained only on *Articles*, *Patients* and in a combined training setting *CORe All*. We evaluate diagnosis and procedure prediction both with and without the *ICD+* method on BioBERT and the *CORe* models. In both scenarios we evaluate on 3-digit ICD codes only, in order to maintain comparability between the methods.

Pre-trained models outperform baselines. We see that the evaluated pre-trained language models clearly outperform the *BOW*, *word embeddings* and *CNN* approaches. We further observe that the *CORe* models improve scores on all tasks in comparison to the baseline models, except for DischargeBERT that reaches a higher score in mortality prediction – probably affected by its exposure to the test data. This shows that even though the language models are trained on similar data (e.g. PubMed and/or clinical notes), the specific *outcome pre-training* improves the model's ability to predict clinical outcome targets. Pre-training on *Patients* and *Articles* achieve similar improvements over the baselines, while the combined training is the most effective. An exception is the procedure prediction, where pre-training on *Patients* achieves the highest score. A probable reason is that procedures are documented in more detail in clinical notes, especially since our selection of medical articles focuses on diseases rather than procedures.

Predicting mortality risk is easier than length of stay. We see that the models reach higher scores in the binary mortality task than in length of stay prediction. Even a simple *BOW* approach can reach a relatively high score, which indicates that most of the notes contain clear hints towards an increased mortality risk. On the other hand, the length of stay task is difficult due to the many factors that can contribute to the length of a patient's stay after the admission, including nonclinical factors such as the patient's insurance situation (Khosravizadeh et al., 2016).

ICD hierarchy improves diagnosis and procedure predictions. Table 4 shows an ablation test without the *ICD+* method (in parentheses). We see that both the BioBERT model and the *CORe* models improve when incorporating code hierarchy and relations through *ICD+* into the training process. This is especially visible for ICD procedures, where the hierarchical and textual information, e.g. that a *Nephropexy* is an *operation* on the *kidney* can add important signals during training.

	i2b2 Diagnoses
BioBERT ICD+	80.43
CORe Articles	81.46
CORe Patients	**82.31**
CORe All	81.15

Table 5: Results on i2b2 diagnosis prediction task (5 classes) in % AUROC. The models reach similar results as on the MIMIC III data, indicating their transferability to other data sources without additional fine-tuning.

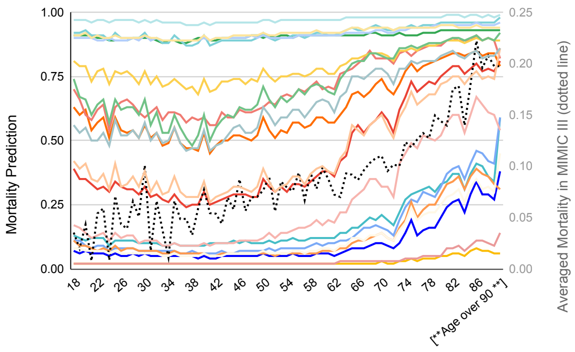


Figure 4: Impact of age on mortality prediction on 20 random samples. Mortality risk and age mostly increase proportionally as intended, with certain peaks that might indicate unintended biases in the data.

5.4 Model Transferability: Cross-Verification on i2b2 Clinical Notes

In order to verify that the fine-tuned models are transferable to ICU data from other sources, we apply it to data from the i2b2 De-identification and Heart Disease Risk Factors Challenge (Stubbs et al., 2015). We convert the clinical notes to admission notes as further described in Appendix B.2, which results in 1,118 samples labelled with up to five ICD-9 codes.

Models generalize to i2b2 data. We apply our MIMIC III-based models to predict diagnosis codes for the i2b2 notes without further fine-tuning. We then evaluate based on whether the predictions contain the five mentioned ICD-9 codes. The results in macro-averaged % AUROC are shown in Table 5. Even though the clinical notes differ from the MIMIC III notes in structure and writing style, the tested models are mostly able to identify the conditions. The scores are comparable to the MIMIC III results, which shows that the models are able to generalise on data from different sources such as other hospitals.

6 Discussion and Findings

Clinical outcome prediction is a sensitive task. We therefore conduct an extensive analysis on the *CORe All* model including a manual error analysis by medical doctors on 20 randomly chosen samples to understand how the model would perform in clinical practice.[5]

	% AUROC
All Diagnoses	83.54
Diagnoses **Mentioned** in Text	**87.10**
Diagnoses **Not Mentioned** in Text	82.35

Table 6: Analysis of the impact of directly mentioned diagnoses on the diagnosis prediction task. Mentioned diagnoses are detected more reliably. Though on unmentioned diagnoses, scores only see a small decrease compared to the overall score.

6.1 A Closer Look at the Model's Abilities

Does the model mainly extract already present diagnoses? We observe that a majority of coded diseases are already mentioned in the admission text. This is mainly due to chronic diseases (e.g. *diabetes mellitus*) or to conditions that were identified prior to the ICU admission (e.g. in the emergency ward). We want to know if our model is also able to predict diagnoses that are not mentioned in the text. We annotate the admission texts with ICD-9 diagnosis codes with the methodology described by Searle et al. (2020). We then evaluate on codes that were explicitly mentioned in the text and those that were not. Table 6 shows that the model indeed extracts many diagnoses directly from the text and thus reaches a higher score on mentioned diagnoses. On the other hand, we see that the performance on non-mentioned diagnoses does drop only slightly, indicating that the model has also learned to predict non-mentioned diagnoses.

How does age and gender impact predictions? Age and gender are common risk factors with significant impact on the potential clinical outcome of a patient. We want our models to learn that impact without overestimating it. We test the model's behaviour by switching age and gender throughout 20 random samples and analyse how the mortality prediction changes. For each sample we manually switch the age mention and iterate over it from 18 until [**Age over 90**][6]. Figure 4 shows that the analysed samples show a high variation in mortality risk and that age only impacts the prediction partially. In all cases the prediction increases with age – as expected from a medical perspective. We also observe some peaks without a medical reason that are caused by the mortality of certain age groups in the original data (black dotted line). This demonstrates how the model does not follow medical reasoning but merely statistic observations. We

---

[5] Our demo application used for this analysis is available at: `https://outcome-prediction.demo.datexis.com`

[6] De-identified age information for patients older than 89.

similarly switch the gender mention and all pronouns in the texts and observe that mortality prediction for male patients is increased by 5% on average, consistent with medical rationale.

Where is the model failing?

1. **Negation**: While our error analysis depicts that negation does not generally falsify the model's predictions, we find single samples in which especially medical-specific negations, such as *abstinent from alcohol*, are misinterpreted by the model, e.g. into *alcohol dependence syndrome*.
2. **Numerical data**: Wallace et al. (2019) show BERT's inabilities to interpret numbers. We observe this in the case that the model does not interpret life-threatening vital values (such as temperature over 105°F) as an increased mortality risk. Clinical notes contain many such relevant values, thus improving the encoding of such data is an important goal for future work.

6.2 There is no Ground Truth in Clinical Data

Incomplete and inconsistent labels. Our error analysis reveals that 60% of the analysed samples are partially under-coded. They contain indicators for a diagnosis or procedure but miss the corresponding ICD-9 code. This is consistent with results from Searle et al. (2020) showing that MIMIC III is up to 35% under-coded. Additionally we find that procedures that are almost always performed in the ICU such as *Puncture of vessel* are often coded inconsistently. While a doctor can infer these labels with medical common sense, they pose a challenge to our models. We therefore suggest a critical view towards the data and welcome additional clinical datasets to compensate for noisy labels.

Multiple possible outcomes. 85% of analysed samples contain false positive predictions that the doctors still consider medically reasonable. This demonstrates that there are many possible clinical pathways and that some might not be foreseeable at admission time. We also see many cases in which the information in the clinical note is not sufficient and therefore allows multiple interpretations. For future work, we propose including further EHR data as suggested by Khadanga et al. (2019) to extend the patient representation in these scenarios.

7 Conclusion

We reframe the task of clinical outcome prediction to consider the admission state of a patient and support doctors in their initial decision process. We show that current state-of-the-art language models outperform selected baselines on this task and present methods for further improvement: *Outcome pre-training* enables our models to learn from unlabelled sources and *ICD+* incorporates hierarchical and textual ICD representations into our models. For future work, we suggest considering pre-trained language models with larger context sizes (Beltagy et al., 2020; Zaheer et al., 2020) and languages other than English (Reys et al., 2020). We further encourage work on semantic encoding of negated terms and numerical data from clinical text.

Acknowledgments

We would like to thank Anjali Grover and Sebastian Herrmann for their support throughout the project. Our work is funded by the German Federal Ministry for Economic Affairs and Energy (BMWi) under grant agreement 01MD19003B (PLASS) and 01MK2008MD (Servicemeister).

A Distribution of Diagnosis and Procedure Labels

Figure 5 and Figure 6 show the distributions of labels in the diagnosis and procedure prediction training sets. Both distributions follow the power law with a long tail of rare codes.

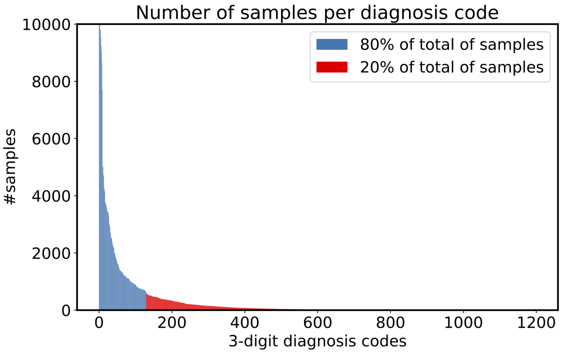

Figure 5: Distribution of ICD-9 diagnosis codes in MIMIC III training set.

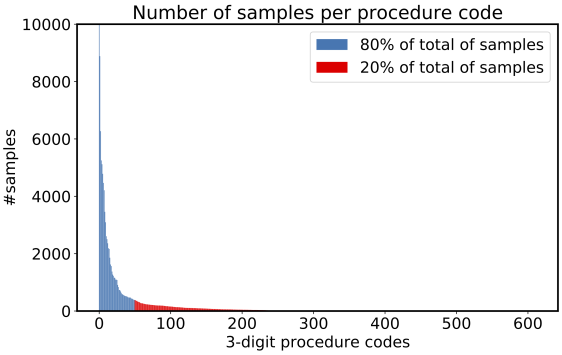

Figure 6: Distribution of ICD-9 procedure codes in MIMIC III training set.

B Pre-Processing Clinical Notes

B.1 Admission Notes From Discharge Summaries

We use MIMIC III discharge summaries that contain aggregated information about a patient such as doctor's assessments, relevant lab values, medications, and the patient's history. In order to filter the documents by admission sections, we first split all discharge summaries into sections with simple pattern matching. Together with clinical professionals, we then evaluated discharge summaries and identified sections that are known at admission time. We remove all other sections and thus hide information about the further hospital course and discharge of a patient. We exclude notes that do not contain any of the admission sections. We further apply a patient-wise split into train, validation and test set with a 70/10/20 ratio.

B.2 Converting i2b2 Data into Admission Discharge Task

The i2b2 De-identification and Heart Disease Risk Factors Challenge (Stubbs et al., 2015; Stubbs and Uzuner, 2015) introduced a dataset that contains clinical notes and discharge summaries annotated based on risk factors and disease indicators. We convert the data into an *admission to discharge* task by selecting five of the annotated conditions which correspond to ICD-9 codes as our labels, namely Hypertension (401), Hyperlipidemia (272), Coronary artery disease (414), Diabetes mellitus (250) and Obesity (278). Just like the MIMIC III diagnosis task, samples are annotated in a multi-label fashion. In order to convert the clinical notes to admission notes, we use the dataset from Rosenthal et al. (2019) that contain section labels per sentence. We then exclude sections that are not known at admission time concurrent to Section 3.2.

C Hyperparameter Setting

We use the following setting for pre-training and fine-tuning of the introduced Transformer-based models: We use early stopping and apply a random search for tuning the following hyperparameters on the validation set: learning rate [1e-4−1e-6], warmup steps [50−30k], dropout [0.1−0.3], class balancing [True/False] (fine-tuning only), gradient accumulation [1−200] with a batch size of 20.

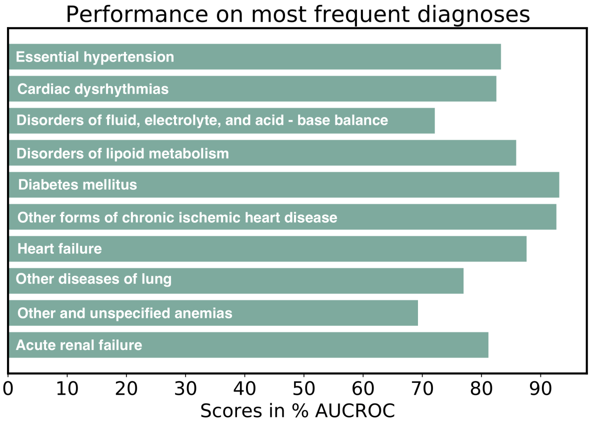

Figure 7: Top 10 diagnoses by frequency with the scores reached by the *CORe All* model.

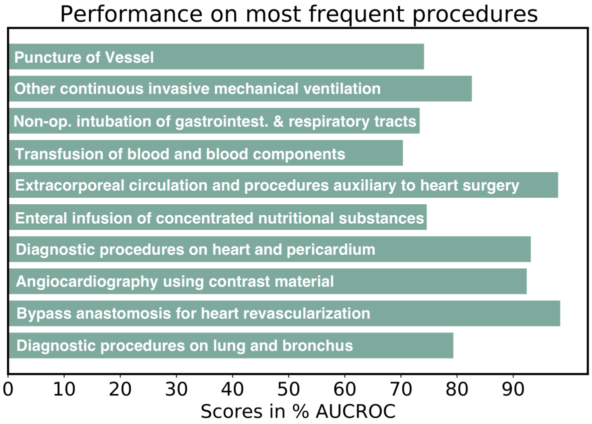

Figure 8: Top 10 procedures by frequency with the scores reached by the *CORe All* model.

D Results on Top 10 Diagnoses and Procedures

Figures 7 and 8 show the % AUROC scores of our *CORe All* model on the most frequent labels within the diagnosis and procedure prediction tasks. Figure 7 show that many chronic diseases such as *Essential Hypertension* or *Chronic ischemic heart disease* are among the most common within the MIMIC III dataset and present with relatively high AUROC values. We also observe that very specific codes such as *Diabetes mellitus* and *Bypass Anastomosis* are predicted more easily compared to more general codes such as *Other and unspecified anemias*.

Figure 8 further shows the negative influence of inconsistent labeling on standard procedures such as *Puncture of Vessel*.

Combining Deep Generative Models and Multi-lingual Pretraining for Semi-supervised Document Classification

Abstract

Semi-supervised learning through deep generative models and multi-lingual pretraining techniques have orchestrated tremendous success across different areas of NLP. Nonetheless, their development has happened in isolation, while the combination of both could potentially be effective for tackling task-specific labelled data shortage. To bridge this gap, we combine semi-supervised deep generative models and multi-lingual pretraining to form a pipeline for document classification task. Compared to strong supervised learning baselines, our semi-supervised classification framework is highly competitive and outperforms the state-of-the-art counterparts in low-resource settings across several languages. [1]

1 Introduction

Multi-lingual pretraining has been shown to effectively use unlabelled data through learning shared representations across languages that can be transferred to downstream tasks (Artetxe and Schwenk, 2019; Devlin et al., 2019; Wu and Dredze, 2019; Conneau and Lample, 2019). Nonetheless, the lack of labelled data still leads to inferior performance of the same model compared to those trained in languages with more labelled data such as English (Zeman et al., 2018; Zhu et al., 2019).

Semi-supervised learning is another appealing paradigm that supplements the labelled data with unlabelled data which is easy to acquire (Blum and Mitchell, 1998; Zhou and Li, 2005; McClosky et al., 2006, *inter alia*). In particular, deep generative models (DGMs) such as variational autoencoder (VAE; Kingma and Welling (2014)) are capable of capturing complex data distributions at scale with rich latent representations, and they have been used for semi-supervised learning in various tasks in NLP (Xu et al., 2017; Yin et al., 2018; Choi et al., 2019; Xie and Ma, 2019), as well as inducing cross-lingual word embeddings (Wei and Deng, 2017), and representation learning in combination with Transformers via pretraining (Li et al., 2020).

To leverage the benefits of both worlds, we propose a pipeline method by combining semi-supervised DGMs (SDGMs) based on M1+M2 model (Kingma et al., 2014) with multi-lingual pretraining. The pretrained model serves as multi-lingual encoder, and SDGMs can operate on top of it independently of encoding architecture. To highlight such independence, we experiment with two pretraining settings: (1) our LSTM-based cross-lingual VAE, and (2) the current stat-of-the-art (SOTA) multi-lingual BERT (Devlin et al., 2019).

Our experiments on document classification in several languages show promising results via the SDGM framework with different encoders, outperforming the SOTA supervised counterparts. We also illustrate that the end-to-end training of M1+M2 that was previously considered too unstable to train (Maaløe et al., 2016) is possible with a reformulation of the objective function.

2 Semi-supervised Learning with DGMs

Variational Autoencoder. VAE consists of a stochastic neural encoder $q_\phi(\mathbf{z}|\mathbf{x})$ that maps an input $\mathbf{x}$ to a latent representation $\mathbf{z}$, and a neural decoder $p_\theta(\mathbf{x}|\mathbf{z})$ that reconstructs $\mathbf{x}$, jointly trained by maximising the evidence lower bound (ELBO) of the marginal likelihood of the data:

$$\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}\big[\log p_\theta(\mathbf{x}|\mathbf{z})\big] - \mathrm{KL}\big(q_\phi(\mathbf{z}|\mathbf{x})\|p(\mathbf{z})\big) \qquad (1)$$

where the first term (reconstruction) maximises the expectation of data likelihood under the posterior distribution of $\mathbf{z}$, and the Kullback-Leibler (KL) divergence regulates the distance between the learned posterior and prior of $\mathbf{z}$.

$$\mathcal{L}(\mathbf{x},y) = \underbrace{\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z}_1)]}_{\text{Reconstruction}} - \underbrace{\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(\mathbf{z}_2|\mathbf{z}_1,y)}[\log \frac{q_\phi(\mathbf{z}_2|\mathbf{z}_1,y)}{p(\mathbf{z}_2)} + \log \frac{q_\phi(\mathbf{z}_1|\mathbf{x})}{p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)}]}_{\text{KL}} + \underbrace{\log p(y)}_{\text{Constant}}$$

$$\mathcal{U}(\mathbf{x}) = \underbrace{\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z}_1)]}_{\text{Reconstruction}} - \underbrace{\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(y|\mathbf{z}_1)q_\phi(\mathbf{z}_2|\mathbf{z}_1,y)}[\log \frac{q_\phi(\mathbf{z}_2|\mathbf{z}_1,y)}{p(\mathbf{z}_2)} + \log \frac{q_\phi(\mathbf{z}_1|\mathbf{x})}{p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)} + \log \frac{q_\phi(y|\mathbf{z}_1)}{p(y)}]}_{\text{KL}}$$

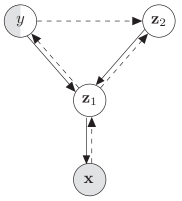

Table 1: Labelled and unlabelled objectives for M1+M2 model (left), and its corresponding graphical model (right).

Semi-supervised Learning with VAEs. The SDGM we use for semi-supervised learning is M1+M2 (Kingma et al., 2014), a graphical model (Table 1 (right)), with two layers of stochastic variables $\mathbf{z}_1$ and $\mathbf{z}_2$, with each being an isotropic Gaussian distribution. The first layer encodes the input sequence $\mathbf{x}$ into a deterministic hidden representation $\mathbf{h}$, and outputs the posterior distribution of $\mathbf{z}_1$:

$$q_\phi(\mathbf{z}_1|\mathbf{x}) = \mathcal{N}\Big(\boldsymbol{\mu}_\phi(\mathbf{h}), \mathrm{diag}\big(\boldsymbol{\sigma}^2_\phi(\mathbf{h})\big)\Big) \tag{2}$$

As our SDGM is independent of the encoding architecture, we use different pretrained multi-lingual models to obtain $\mathbf{h}$, $\boldsymbol{\mu}_\phi(\mathbf{h})$, and $\boldsymbol{\sigma}^2_\phi(\mathbf{h})$, described in §3. The second layer computes the posterior distribution of $\mathbf{z}_2$, conditioned on sampled $\mathbf{z}_1$ from $q_\phi(\mathbf{z}_1|\mathbf{x})$ and a class variable y.

When we use labelled data, i.e. y is observed, $q_\phi(\mathbf{z}_2|\mathbf{z}_1, y)$ can be directly obtained. With unlabelled data, we calculate the posterior $q_\phi(\mathbf{z}_2, y|\mathbf{z}_1) = q_\phi(y|\mathbf{z}_1)q_\phi(\mathbf{z}_2|\mathbf{z}_1, y)$ by inferring y with the classifier $q_\phi(y|\mathbf{z}_1)$, and integrate over all possible values of y. Therefore, the ELBO for the labelled data $\mathcal{S}_l = \{\mathbf{x}, y\}$ is $\mathcal{L}(\mathbf{x}, y)$:

$$\mathbb{E}_{q_\phi(\mathbf{z}_1,\mathbf{z}_2|\mathbf{x},y)}\left[\log \frac{p_\theta(\mathbf{x}, y, \mathbf{z}_1, \mathbf{z}_2)}{q_\phi(\mathbf{z}_1, \mathbf{z}_2|\mathbf{x}, y)}\right] \leq \log p(\mathbf{x}, y)$$

and for the unlabelled data $\mathcal{S}_u = \{\mathbf{x}\}$ is $\mathcal{U}(\mathbf{x})$:

$$\mathbb{E}_{q_\phi(\mathbf{z}_1,\mathbf{z}_2,y|\mathbf{x})}\left[\log \frac{p_\theta(\mathbf{x}, y, \mathbf{z}_1, \mathbf{z}_2)}{q_\phi(\mathbf{z}_1, \mathbf{z}_2, y|\mathbf{x})}\right] \leq \log p(\mathbf{x})$$

where the generation part is $p_\theta(\mathbf{x}, y, \mathbf{z}_1, \mathbf{z}_2) = p(y)p(\mathbf{z}_2)p_\theta(\mathbf{z}_1|\mathbf{z}_2, y)p_\theta(\mathbf{x}|\mathbf{z}_1)$, $p(y)$ is uniform distribution as the prior of y, $p(\mathbf{z}_2)$ is standard Gaussian distribution as the prior of $\mathbf{z}_2$, and $p_\theta(\mathbf{x}|\mathbf{z}_1)$ is the decoder, which can have different architectures depending on the encoder (§4).

The objective function maximises both the labelled and unlabelled ELBOs while training directly the classifier with the labelled data as well:

$$\mathcal{J} = \sum_{(\mathbf{x},y)\in\mathcal{S}_l} \big(\mathcal{L}(\mathbf{x}, y) + \alpha\mathcal{J}_{cls}(\mathbf{x}, y)\big) + \sum_{\mathbf{x}\in\mathcal{S}_u} \mathcal{U}(\mathbf{x})$$

where $\mathcal{J}_{cls}(\mathbf{x}, y) = \mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})}[q_\phi(y|\mathbf{z}_1)]$, and α is a hyperparameter to tune. Considering the factorisation of the model according to the graphical model, we can rewrite the $\mathcal{L}(\mathbf{x}, y)$ and $\mathcal{U}(\mathbf{x})$ as shown in Table 1(left). The reconstruction term is the expected log likelihood of the input sequence $\mathbf{x}$, same for both ELBOs. The KL term regularises the posterior distributions of $\mathbf{z}_1$ and $\mathbf{z}_2$ according to their priors. Additionally for $\mathcal{U}(\mathbf{x})$, as mentioned before, we first infer y and treat it as if it were observed, so we need to compute the expected KL term over $q_\phi(y|\mathbf{z}_1)$ regularised by $\mathrm{KL}(q_\phi(y|\mathbf{z}_1)\|p(y))$.

Due to its training difficulty, M1+M2 is trained layer-wise in Kingma et al. (2014), where the first layer is trained according to Eq. 1 and fixed, before the second layer is trained on top. However, in our experiments (§4.1) we found that M1+M2 is easier to train end-to-end. We attribute this to our mathematical reformulation of the objective functions, giving rise to a more stable optimisation schedule.

3 SDGMs with Multi-lingual Pretraining

LSTM-based Encoder with VAE Pretraining. Our pretraining is based on the framework of Wei and Deng (2017), in which they pretrain a cross-lingual VAE with parallel corpus as input. However, the parallel corpus is expensive to obtain, and only the resulting cross-lingual embeddings rather than the whole encoder could be used due to the parallel input limitation of the model. To address these shortcomings, we propose non-parallel cross-lingual VAE (NXVAE), which has the same graphical model as the vanilla VAE. Each language i is associated with its own word embedding matrix, and its input sequence $\mathbf{x}_i$ is processed via a two layer BiLSTM (Hochreiter and Schmidhuber, 1997) shared across languages. We use the concatenation of the BiLSTM last hidden states as $\mathbf{h}$, and compute $q_\phi(\mathbf{z}|\mathbf{x}_i)$ with Eq. 2, so that $\mathbf{z}$ becomes the joint cross-lingual semantic space. A language specific bag-of-word decoder (BOW; Miao et al. (2016)) is then used to reconstruct the input sequence. Additionally, we optimise a language discriminator as an adversary (Lample et al., 2018a) to encourage the mixing of different language representations and keep the shared encoder language-agnostic. After pretraining NXVAE, we transfer the whole encoder, including $\boldsymbol{\mu}_\phi(\mathbf{h})$ and

$\boldsymbol{\sigma}^2_\phi(\mathbf{h})$, directly into our SDGM framework and treat it as $q_\phi(\mathbf{z}_1|\mathbf{x})$ component of the model (§4.1).

Multi-lingual BERT Encoder. To show that our SDGM is effective with other encoding architectures, we use the pretrained multi-lingual BERT (mBERT; Devlin et al. (2019))[2] as our encoder. Given an input sequence, the pooled `[CLS]` representation is used as $\mathbf{h}$ to compute $q_\phi(\mathbf{z}_1|\mathbf{x})$ (Eq. 2). Different from NXVAE, we initialise the parameters of $\boldsymbol{\mu}_\phi(\mathbf{h})$ and $\boldsymbol{\sigma}^2_\phi(\mathbf{h})$ randomly.

4 Experiments

We perform document classification on the class balanced multilingual document classification corpus (MLDoc; Schwenk and Li (2018)). Each document is assigned to one of the four news topic classes: *corporate/industrial* (C), *economics* (E), *government/social* (G), and *markets* (M). We experiment with five representative languages: EN, DE, FR, RU, ZH, and use 1k instance training set along with the standard development and test set. For experiments with varying labelled data size, the rest training data from 1k corpus is used as unlabelled data. The full statistics are shown in Table 2. Three languages (EN, DE, FR) are tested for LSTM encoder with VAE pretraining (§4.1) and all five languages for mBERT encoder (§4.2). All documents are lowercased. We report *accuracy* for evaluation following Schwenk and Li (2018).

For all experiments, We use Adam (Kingma and Ba, 2015) as optimiser, but with different learning rates for both settings and pretraining. We implemented the model with Pytorch[3] 1.10 (Paszke et al., 2019), and use GeForce GTX 1080Ti GPUs. See the Appendix for details about model configurations and training.

4.1 LSTM Encoder with VAE Pretraining

Experimental Setup. For pretraining NXVAE, we use three language pairs: EN-DE, EN-FR and DE-FR constructed from Europarl v7 parallel corpus (Koehn, 2005),[4] where only two language pairs are available: EN-DE and EN-FR, which consist of four datasets in total: (EN, DE)$_{\text{EN-DE}}$, and (EN, FR)$_{\text{EN-FR}}$. For DE-FR, we pair DE$_{\text{EN-DE}}$ and FR$_{\text{EN-FR}}$ directly as pseudo parallel data. We trim all datasets into exactly the same sentence size, and preprocess them with: tokenization, lowercasing, substituting digits with 0, and removing all punctuations, redundant spaces and empty lines. We randomly sample a small part of parallel sentences to build a development set. For models which do not require parallel input, e.g. NXVAE, we mix the two datasets of a language pair together. To avoid KL-collapse during pretraining, a weight α on the KL term in Eq. 1 is tuned and fixed to 0.1 (Higgins et al., 2017; Alemi et al., 2018). We only run one trial with fixed random seed for both pretraining and document classification. Training details can be found in the Appendix.

Table 2: Statistics of MLDoc in five languages. Instance numbers for each class along with the total numbers are shown. For each language, three rows are training, development and test set instance numbers.

As our supervised baselines we compare with the following two groups: (I) NXVAE-based supervised models which are pretrained NXVAE encoder with a multi-layer perceptron classifier on top (denoted by NXVAE-z_1 ($q_\phi(y|\mathbf{z}_1)$) or NXVAE-h ($q_\phi(y|\mathbf{h})$) depending on the representation fed into the classifier; or NXVAE-z_1 models initialised with different pretrained embeddings: random initialisation (RAND), mono-lingual fastText (FT; Bojanowski et al. (2017)), unsupervised cross-lingual MUSE (Lample et al., 2018b), pretrained embeddings from Wei and Deng (2017) (PEMB), and our resulting embeddings from pretrained NXVAE (NXEMB).[5] (II) We also pretrain a word-based BERT (BERTW) with parameter size akin to NXVAE on the same data, and fine-tune it directly.[6]

For our semi-supervised experiments, we test

Table 4: MLDoc test accuracy for EN-DE, EN-FR and DE-FR pairs. The best results for supervised and semi-supervised models are in bold.

two types of decoders with different model capacities: BOW and GRU (Cho et al., 2014). We use M1+M2+BOW (GRU) to denote the model with joint training using a specific decoder, and M1+M2 to denote the original model in Kingma et al. (2014) with layer-wise training.[7] We also add a semi-supervised self-training method (McClosky et al., 2006) for BERTW to leverage the unlabelled data (BERTW+ST), where we iteratively add predicted unlabelled data when the model achieves a better dev. accuracy until convergence.

Qualitative Results. Table 3 illustrates the quality of the learned alignments in the cross-lingual space of NXVAE for EN-DE word pairs.

Classification Results. Table 4 (**EN-DE**) shows that within supervised models the NXVAE-z_1 substantially outperforms other supervised baselines with the exception of BERTW. The fact that NXVAE-z_1 is significantly better than NXVAE-h, suggests that pretraining has enabled $\mathbf{z}_1$ to learn more general knowledge transferable to this task. Combining with SDGMs, our best pipeline outperforms all baselines across data sizes and languages, including BERTW+ST with bigger gaps in fewer labelled data scenario. We observe the same trend of performance in both supervised and semi-supervised DGM settings on **EN-FR** and **DE-FR**.

For decoder, BOW outperforms the GRU, a finding in line with the results of Artetxe et al. (2019) which suggests a few keywords seem to suffice for this task. The poor performance of the original M1+M2, implies the domain discrepancy between pretraining and task data, and highlights the impact of fine-tuning. In addition, our NXEMB, as a byproduct of NXVAE, performs comparably well with MUSE, and better than all other embedding models including its parallel counterpart PEMB.

4.2 Multi-lingual BERT Encoder

Experimental Setup. We use the cased mBERT, a 12 layer Transformer (Vaswani et al., 2017) trained on Wikipedia of 104 languages with 100k shared WordPiece vocabulary. The training corpus is larger than Europarl by orders of magnitude, and high-resource languages account for most of the corpus. We use the best SDGM setup (M1+M2+BOW §4.1), on top of mBERT encoder against the mBERT supervised model with a linear layer as classifier (SUP-h) in 5 representative languages (EN, DE, FR, RU, ZH). We report the results over 5 runs due to the training instability of BERT (Dodge et al., 2020; Mosbach et al., 2020).

Classification Results. Figure 1 demonstrates that M1+M2+BOW outperforms the SOTA supervised mBERT (SUP-h) on average across all languages. This corroborates the effectiveness of our

---

[7] We also compared this against a more complex Skip Deep Generative Model (Maaløe et al., 2016), but found that end-to-end M1+M2 performs better. Details in the Appendix.

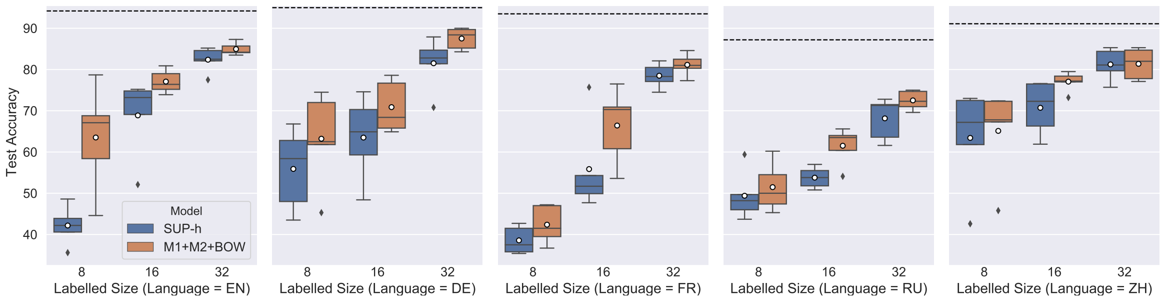

Figure 1: Boxplot of test accuracy scores for SUP-h and M1+M2+BOW over 5 runs. The mean is shown as white dot. The dashed line is the test mean accuracy of SUP-h trained on 1k labelled data of the corresponding language.

SDGM in leveraging unlabelled data within smaller labelled data regime, as well as its independence from encoding architecture.[8] As expected, the gap is generally larger with 8 and 16 labelled data, but reduces as the data size grows to 32. The variance shows similar pattern, but with relatively large values because of the instability of mBERT. Interestingly, the performance difference seems to be more notable in high-resource languages with more pretrained data, whereas in languages with fewer pretrained texts or vocabulary overlaps such as RU and ZH, the two models achieve closer results.

5 Conclusion

We bridged between multi-lingual pretraining and deep generative models to form a semi-supervised learning framework for document classification. While outperforming SOTA supervised models in several settings, we showed that the benefits of SDGMs are orthogonal to the encoding architecture or pretraining procedure. It opens up a new avenue for SDGMs in low-resource NLP by incorporating unlabelled data potentially from different domains and languages. Our preliminary results in cross-lingual zero-shot setting with SDGMs+NXVAE are promising, and we will continue the exploration in this direction as future work.

Acknowledgments

This work is supported by the ERC Consolidator Grant LEXICAL: Lexical Acquisition Across Languages (648909). The first author would like to thank Victor Prokhorov and Xiaoyu Shen for their comments on this work. The authors would like to thank the three anonymous reviewers for their helpful suggestions.

---

[8] Compared to smaller pretraining corpus (§4.1), we found that the representations pretrained on large corpus are less prune to overfit to the training instances of the task. We observe that training without the KL regularisation yields better performance for SDMGs+mBERT.

A Derivations of semi-supervised ELBOs

We derive the full ELBOs of both labelled and unlabelled data for M1+M2 and Auxiliary Skip Deep Generative Model (AUX; Maaløe et al. (2016)).[9] We first use $(\cdot)$ to represent different conditional variables for the two models so that the derivations can be unified, then we will realise it with the model-specific conditions in the end.

As written in the paper, the labelled ELBO for both models is:

$$\begin{aligned}&\mathbb{E}_{q_\phi(\mathbf{z}_1,\mathbf{z}_2|\mathbf{x},y)}\left[\log \frac{p_\theta(\mathbf{x},y,\mathbf{z}_1,\mathbf{z}_2)}{q_\phi(\mathbf{z}_1,\mathbf{z}_2|\mathbf{x},y)}\right]\\&=\mathcal{L}(\mathbf{x},y)\leq \log p(\mathbf{x},y)\end{aligned}$$

Expanding the ELBO, we will have:

$$\begin{aligned}&\mathbb{E}_{q_\phi(\mathbf{z}_1,\mathbf{z}_2|\mathbf{x},y)}[\log \frac{p_\theta(\mathbf{x},y,\mathbf{z}_1,\mathbf{z}_2)}{q_\phi(\mathbf{z}_1,\mathbf{z}_2|\mathbf{x},y)}]\\
=&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(\mathbf{z}_2|\cdot)}[\\
&\log p(\mathbf{z}_2)+\log p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)+\log p_\theta(\mathbf{x}|\cdot)+\log p(y)-\\
&\log q_\phi(\mathbf{z}_2|\cdot)-\log q_\phi(\mathbf{z}_1|\mathbf{x})]\\
=&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(\mathbf{z}_2|\cdot)}[\log p_\theta(\mathbf{x}|\cdot)]-\\
&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(\mathbf{z}_2|\cdot)}[\\
&\log q_\phi(\mathbf{z}_2|\cdot)+\log q_\phi(\mathbf{z}_1|\mathbf{x})-\\
&\log p(\mathbf{z}_2)-\log p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)-\log p(y)]\\
=&\mathbb{E}_{q_\phi(\mathbf{z1}|\mathbf{x})q_\phi(\mathbf{z}_2|\cdot)}[\log p_\theta(\mathbf{x}|\cdot)]-\\
&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(\mathbf{z}_2|\cdot)}[\\
&\log \frac{q_\phi(\mathbf{z}_2|\cdot)}{p(\mathbf{z}_2)}+\log \frac{q_\phi(\mathbf{z}_1|\mathbf{x})}{p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)}-\log p(y)]\end{aligned}$$

After realising $(\cdot)$, we can then obtain the labelled ELBO for M1+M2 and AUX in the original paper:

$$\begin{aligned}&\mathcal{L}_{\text{M1+M2}}(\mathbf{x},y)\\
=&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z}_1)]-\\
&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(\mathbf{z}_2|\mathbf{z}_1,y)}[\\
&\log \frac{q_\phi(\mathbf{z}_2|\mathbf{z}_1,y)}{p(\mathbf{z}_2)}+\log \frac{q_\phi(\mathbf{z}_1|\mathbf{x})}{p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)}-\log p(y)]\end{aligned}$$

$$\begin{aligned}&\mathcal{L}_{\text{AUX}}(\mathbf{x},y)\\
=&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(\mathbf{z}_2|\mathbf{z}_1,\mathbf{x},y)}[\log p_\theta(\mathbf{x}|\mathbf{z}_1,\mathbf{z}_2,y)]-\\
&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(\mathbf{z}_2|\mathbf{z}_1,\mathbf{x},y)}[\\
&\log \frac{q_\phi(\mathbf{z}_2|\mathbf{z}_1,\mathbf{x},y)}{p(\mathbf{z}_2)}+\log \frac{q_\phi(\mathbf{z}_1|\mathbf{x})}{p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)}-\log p(y)]\end{aligned}$$

---

[9] As mentioned in the footnote of original paper, we compare M1+M2 with AUX in LSTM encoder with VAE pretraining, but found that the simpler M1+M2 performs better. Results on AUX can be found in §D.

For the unlabelled ELBO, y is unobservable:

$$\begin{aligned}&\mathbb{E}_{q_\phi(\mathbf{z}_1,\mathbf{z}_2,y|\mathbf{x})}\left[\log\frac{p_\theta(\mathbf{x},y,\mathbf{z}_1,\mathbf{z}_2)}{q_\phi(\mathbf{z}_1,\mathbf{z}_2,y|\mathbf{x})}\right]\\&=\mathcal{U}(\mathbf{x})\leq\log p(\mathbf{x})\end{aligned}$$

After expansion:

$$\begin{aligned}
&\mathbb{E}_{q_\phi(\mathbf{z}_1,\mathbf{z}_2,y|\mathbf{x})}[\log\frac{p_\theta(\mathbf{x},y,\mathbf{z}_1,\mathbf{z}_2)}{q_\phi(\mathbf{z}_1,\mathbf{z}_2,y|\mathbf{x})}]\\
=&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(y|\cdot)q_\phi(\mathbf{z}_2|\cdot)}[\\
&\log p(\mathbf{z}_2)+\log p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)+\log p_\theta(\mathbf{x}|\cdot)+\log p(y)-\\
&\log q_\phi(\mathbf{z}_2|\cdot)-\log q_\phi(\mathbf{z}_1|\mathbf{x})-\log q_\phi(y|\cdot)]\\
=&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(y|\cdot)q_\phi(\mathbf{z}_2|\cdot)}[\log p_\theta(\mathbf{x}|\cdot)]-\\
&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(y|\cdot)q_\phi(\mathbf{z}_2|\cdot)}[\\
&\log q_\phi(\mathbf{z}_2|\cdot)+\log q_\phi(\mathbf{z}_1|\mathbf{x})+\log q_\phi(y|\cdot)-\\
&\log p(\mathbf{z}_2)-\log p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)-\log p(y)]\\
=&\mathbb{E}_{q_\phi(\mathbf{z1}|\mathbf{x})q_\phi(y|\cdot)q_\phi(\mathbf{z}_2|\cdot)}[\log p_\theta(\mathbf{x}|\cdot)]-\\
&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(y|\cdot)q_\phi(\mathbf{z}_2|\cdot)}[\\
&\log\frac{q_\phi(\mathbf{z}_2|\cdot)}{p(\mathbf{z}_2)}+\log\frac{q_\phi(\mathbf{z}_1|\mathbf{x})}{p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)}+\log\frac{q_\phi(y|\cdot)}{p(y)}]
\end{aligned}$$

Similarly, we will get unlabeled ELBO of M1+M2 and AUX:

$$\begin{aligned}
&\mathcal{U}_{\text{M1+M2}}(\mathbf{x})\\
=&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z}_1)]-\\
&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(y|\mathbf{z}_1)q_\phi(\mathbf{z}_2|\mathbf{z}_1,y)}[\\
&\log\frac{q_\phi(\mathbf{z}_2|\mathbf{z}_1,y)}{p(\mathbf{z}_2)}+\log\frac{q_\phi(\mathbf{z}_1|\mathbf{x})}{p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)}+\log\frac{q_\phi(y|\mathbf{z}_1)}{p(y)}]
\end{aligned}$$

$$\begin{aligned}
&\mathcal{U}_{\text{AUX}}(\mathbf{x})\\
=&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(y|\mathbf{z}_1,\mathbf{x})q_\phi(\mathbf{z}_2|\mathbf{z}_1,\mathbf{x},y)}[\log p_\theta(\mathbf{x}|\mathbf{z}_1,\mathbf{z}_2,y)]-\\
&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(y|\mathbf{z}_1,\mathbf{x})q_\phi(\mathbf{z}_2|\mathbf{z}_1,\mathbf{x},y)}[\\
&\log\frac{q_\phi(\mathbf{z}_2|\mathbf{z}_1,\mathbf{x},y)}{p(\mathbf{z}_2)}+\log\frac{q_\phi(\mathbf{z}_1|\mathbf{x})}{p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)}+\log\frac{q_\phi(y|\mathbf{z}_1,\mathbf{x})}{p(y)}]
\end{aligned}$$

In our experiments, we sample $\mathbf{z}_1$ and $\mathbf{z}_2$ once during inference, so both labeled and unlabeled ELBOs can be approximated by:

$$\begin{aligned}
&\mathcal{L}(\mathbf{x},y)\\
=&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(\mathbf{z}_2|\cdot)}[\log p_\theta(\mathbf{x}|\cdot)]-\\
&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(\mathbf{z}_2|\cdot)}[\\
&\log\frac{q_\phi(\mathbf{z}_2|\cdot)}{p(\mathbf{z}_2)}+\log\frac{q_\phi(\mathbf{z}_1|\mathbf{x})}{p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)}-\log p(y)]\\
\approx&\log p_\theta(\mathbf{x}|\cdot)+\log p(y)-\\
&\text{KL}(q_\phi(\mathbf{z}_2|\cdot)\|p(\mathbf{z}_2))-\text{KL}(q_\phi(\mathbf{z}_1|\mathbf{x})\|p_\theta(\mathbf{z}_1|\mathbf{z}_2,y))
\end{aligned}$$

$$\begin{aligned}
&\mathcal{U}(\mathbf{x})\\
=&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(y|\cdot)q_\phi(\mathbf{z}_2|\cdot)}[\log p_\theta(\mathbf{x}|\cdot)]-\\
&\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(y|\cdot)q_\phi(\mathbf{z}_2|\cdot)}[\\
&\log\frac{q_\phi(\mathbf{z}_2|\cdot)}{p(\mathbf{z}_2)}+\log\frac{q_\phi(\mathbf{z}_1|\mathbf{x})}{p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)}+\log\frac{q_\phi(y|\cdot)}{p(y)}]\\
\approx&\log p_\theta(\mathbf{x}|\cdot)-\text{KL}(q_\phi(y|\cdot)\|p(y))-\\
&\mathbb{E}_{q_\phi(y|\cdot)}[\text{KL}(q_\phi(\mathbf{z}_2|\cdot)\|p(\mathbf{z}_2))]-\\
&\mathbb{E}_{q_\phi(y|\cdot)}[\text{KL}(q_\phi(\mathbf{z}_1|\mathbf{x})\|p_\theta(\mathbf{z}_1|\mathbf{z}_2,y))]
\end{aligned}$$

B Factorisation of M1+M2 and AUX

The two models have different factorisations, with M1+M2 being written as:

$$\begin{aligned}
q_\phi(\mathbf{z}_1,\mathbf{z}_2|\mathbf{x},y)&=q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(\mathbf{z}_2|\mathbf{z}_1,y)\\
q_\phi(\mathbf{z}_1,\mathbf{z}_2,y|\mathbf{x})&=q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(y|\mathbf{z}_1)q_\phi(\mathbf{z}_2|\mathbf{z}_1,y)\\
p_\theta(\mathbf{x},y,\mathbf{z}_1,\mathbf{z}_2)&=p(y)p(\mathbf{z}_2)p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)p_\theta(\mathbf{x}|\mathbf{z}_1)\\
\mathcal{J}_{cls}(\mathbf{x},y)&=\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})}[q_\phi(y|\mathbf{z}_1)]
\end{aligned}$$

and AUX is factorised as follows:

$$\begin{aligned}
q_\phi(\mathbf{z}_1,\mathbf{z}_2|\mathbf{x},y)&=q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(\mathbf{z}_2|\mathbf{z}_1,\mathbf{x},y)\\
q_\phi(\mathbf{z}_1,\mathbf{z}_2,y|\mathbf{x})&=q_\phi(\mathbf{z}_1|\mathbf{x})q_\phi(y|\mathbf{z}_1,\mathbf{x})q_\phi(\mathbf{z}_2|\mathbf{z}_1,\mathbf{x},y)\\
p_\theta(\mathbf{x},y,\mathbf{z}_1,\mathbf{z}_2)&=p(y)p(\mathbf{z}_2)p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)p_\theta(\mathbf{x}|\mathbf{z}_1,\mathbf{z}_2,y)\\
\mathcal{J}_{cls}(\mathbf{x},y)&=\mathbb{E}_{q_\phi(\mathbf{z}_1|\mathbf{x})}[q_\phi(y|\mathbf{z}_1,\mathbf{x})]
\end{aligned}$$

where $q_\phi(\mathbf{z}_1|\mathbf{x})$, $q_\phi(\mathbf{z}_2|\cdot)$, and $p_\theta(\mathbf{z}_1|\mathbf{z}_2,y)$ are parameterised as diagonal Gaussians, and other distributions are defined as:

$$\begin{aligned}
q_\phi(y|\cdot)&=\text{Cat}(y|\pi_\phi(\cdot)) & p(y)&=\text{Cat}(y|\pi)\\
p(\mathbf{z}_2)&=\mathcal{N}(\mathbf{z}_2|\mathbf{0},\mathbf{I}) & p_\theta(\mathbf{x}|\cdot)&=f(\mathbf{x},\cdot;\theta)
\end{aligned}$$

where $\text{Cat}(\cdot)$ is a multinomial distribution and y is treated as latent variables if it is unobserved in unlabelled case. $f(\mathbf{x},\cdot;\theta)$ serves as the decoder and calculates the likelihood of the input sequence $\mathbf{x}$.

C Details on LSTM Encoder with VAE Pretraining

C.1 Data preprocessing and statistics

We use two pairs of data from Europarl v7 (Koehn, 2005):[10] EN-DE and EN-FR, which consist of four datasets in total: $\text{EN}_{\text{EN-DE}}$, $\text{DE}_{\text{EN-DE}}$, $\text{EN}_{\text{EN-FR}}$, and $\text{FR}_{\text{EN-FR}}$. Regarding DE-FR data, we take the datasets of $\text{DE}_{\text{EN-DE}}$ and $\text{FR}_{\text{EN-FR}}$.

For each language pair, the sentences in the same line of both datasets are a pair of parallel sentences. We do the following preprocessing to each dataset: tokenization; lower case; substitute digits with 0; remove all punctuations; remove redundant spaces and empty lines. Then we trim all four datasets into exactly the same sentence size. We randomly split a small part of parallel sentences to build a dev. set, which leads to 189m lines of training set and 13995 lines of dev. set for each language. Then we shuffle each dataset so that each language pair is not parallel anymore (for both train and dev. sets).

Our goal is to merge the two datasets of each pair and scramble them to form a single dataset. In practice, we keep each dataset separate, and sample

---

[10] `https://www.statmt.org/europarl/`.

a batch randomly from one language alternatively during pretraining, so that the data from both languages are mixed.

C.2 Model and training details

Instead of optimising the standard VAE, we optimise the following objective for NXVAE (Higgins et al., 2017; Alemi et al., 2018):

$$\mathcal{J}(\mathbf{x}) = \mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z})] - \alpha \mathrm{KL}(q_\phi(\mathbf{z}|\mathbf{x}) \| p(\mathbf{z})) \quad (3)$$

where we manually tune the fixed hyperparameter α on EN-DE data to reach a good balance between the reconstruction and the KL empirically. We select $\alpha = 0.1$ and apply it for the pretraining of other language pairs as well. The model and training details of XNVAE are shown in Table 5 (left).

C.3 Pretraining other models

For MLDoc supervised document classification, we also pretrain other baseline models to compare with ONLY for **EN-DE** pair:

Cross-lingual VAE with parallel input (PEMB; Wei and Deng (2017)): For the model of Wei and Deng (2017), we run the original code directly on the same EN-DE Europarl data without changing any of the model architecture. Since the model requires parallel input, we take the preprocessed and split EN-DE data. However, we do not shuffle each dataset, but rather feed them as parallel input to the model, so that the model and our corresponding NXVAE use the same amount and content of the data.

Subword-based non-parallel cross-lingual VAE SNXVAE: Instead of having separate vocabulary and decoders for each language, we use a single vocabulary and decoder for SNXVAE. We build the vocabulary with SentencePiece[11] of size 1e4. All other settings are the same as NXVAE. Its model and training details can be found in Table 5 (right).

Word and subword-based BERT model BERTW/BERTSW : For BERTW, we change the vocabulary and model size to be comparable with NXVAE. Note that the vocabulary size of BERTW is the same as the intersected vocabulary size of the two languages in NXVAE. We only use the masked language model objective during pretraining, and discard the objective of next sentence prediction.[12] For BERTSW, we use the same vocabulary as SNXVAE and set the model to similar parameter size as SNXVAE. The model and training details of BERTW and BERTSW are shown in Table 6.

D More Results on Document Classification

D.1 LSTM Encoder with VAE Pretraining

Supervised Learning. Our base model is NXVAE-z_1, which adds an MLP classifier $q_\phi(y|\mathbf{z}_1)$ on top of the encoder with the same architecture of the NXVAE. The similar applies to the subword-based models SNXVAE-z_1. NXVAE-h takes the deterministic $\mathbf{h}$ as the input to $q_\phi(y|\mathbf{x})$. All our baseline models with pretrained embeddings use the architecture of NXVAE-z_1. For fastText (FT), we train the embeddings of both languages with the same data of $\mathrm{EN}_{\mathrm{EN\text{-}DE}}$ and $\mathrm{DE}_{\mathrm{EN\text{-}DE}}$. For MUSE, we align on the pretrained FT embeddings. For BERTW and BERTSW, we use the library Transformers[13] for classification, and initialise the models with the corresponding pretrained parameters. All model and training details can be found in Table 7. The comparison results of word-based and subword-based models are shown in Table 8.

Semi-supervised learning with SDGMs. The main model (NXVAE) and training details are the same as in supervised learning. Besides M1+M2, we also compare with AUX (Maaløe et al., 2016) with the two decoder types. The training details are shown in Table 9. Regarding the decoding of GRU, all conditional latent variables of $p_\theta(\mathbf{x}|\cdot)$ are fed as extra input at each decoding step (Xu et al., 2017).

We tune all semi-supervised models on $\mathrm{EN}_{\mathrm{EN\text{-}DE}}$ with 32 labels in semi-supervised settings, and then apply it to all other languages and data sizes. We tune only one hyperparameter: the scaling factor β in the weight for the classification loss α in the original SDGM paper (Maaløe et al., 2016):

$$\alpha = \beta \frac{N_l + N_u}{N_l}$$

where N_l and N_u are labelled and unlabelled data point numbers. We tune β from $\{0.1, 0.2, 0.5, 1.0, 2.0, 5.0, 10.0, 20.0\}$. We pick the β with the best dev. performance for each

---

[12] Both word and subword-based models are trained with: `https://github.com/google-research/bert`.

[13] `https://github.com/huggingface/transformers`.

model, and randomly select one when there is a tie. Then we use such fixed β for all other experiments across different training data sizes and languages.

The results of AUX can be seen in Table 10 along with M1+M2 results from the original paper. The parameter size of each model is shown in Table 11.

D.2 mBERT Encoder

The supervised model (SUP-h) adds a single linear transformation layer on the pooled `[CLS]` representation of mBERT, and M1+M2+BOW adds the corresponding SDGM framework on the same mBERT output. Like BERT, as mBERT uses a shared WordPiece vocabulary across languages, the parameter size of the same model will be the same for each language. All model and training details along with parameter size can be found in Table 12.

For tuning the hyperparameter of M1+M2+BOW, different from LSTM encoder with VAE pretraining, we set α fixed to $\alpha = \beta$. We tune β on EN with 8 labels in semi-supervised settings with 5 trials from $\{0.1, 0.2, 0.5, 1.0, 2.0, 5.0, 10.0, 20.0, 50.0\}$, pick the β with the best **average** dev. performance, and then apply it to all other languages and data sizes. We report the mean and variance over 5 trials, and the full results for both models can be seen in Table 13.

E Conditional document generation

Semi-supervised deep generative models can not only explore the complex data distributions, but are also equipped with the ability to generate documents conditioned on latent codes, which is another advantage over other semi-supervised models. We follow Kingma et al. (2014) by varying latent variable y for generation, and fixing $\mathbf{z}_2$ either sampled from the prior (Table 14) or obtained from the input through the inference model (Table 15), and generate sequence samples from the trained semi-supervised models M1+M2+BOW and M1+M2+GRU.[14]

Overall, all models generate words or utterances directly related to the class, with the class labels among top nouns generated by BOW models, and subjects/objects in sentences from GRU are also pertaining to corresponding classes. However, we also observe that the utterances in GRU are not fluent with many repetitions. We argue that it is caused by the high proportion of UNK in the training corpus that makes the sequence generation harder, supported by the fact that the most probable word in all BOW decoders is always UNK.

Multi-facet Universal Schema

Rohan Paul[*] **Haw-Shiuan Chang**[*] **Andrew McCallum**

`{rohpaul,hschang,mccallum}@cs.umass.edu`

Abstract

Universal schema (USchema) assumes that two sentence patterns that share the same entity pairs are similar to each other. This assumption is widely adopted for solving various types of relation extraction (RE) tasks. Nevertheless, each sentence pattern could contain multiple facets, and not every facet is similar to all the facets of another sentence pattern co-occurring with the same entity pair. To address the violation of the USchema assumption, we propose multi-facet universal schema that uses a neural model to represent each sentence pattern as multiple facet embeddings and encourage one of these facet embeddings to be close to that of another sentence pattern if they co-occur with the same entity pair. In our experiments, we demonstrate that multi-facet embeddings significantly outperform their single-facet embedding counterpart, compositional universal schema (CUSchema) (Verga et al., 2016), in distantly supervised relation extraction tasks. Moreover, we can also use multiple embeddings to detect the entailment relation between two sentence patterns when no manual label is available.

1 Introduction

Relation extraction (RE) is a crucial step in automatic knowledge base construction (AKBC). A major challenge of RE is that the frequency of relations in the real world is a long-tail distribution but collecting sufficient human annotations for every relation is infeasible (Han et al., 2020).

Distant supervision is proposed to alleviate the issue (Mintz et al., 2009). Distant supervision assumes that a sentence pattern expresses a relation if the sentence pattern co-occurs with an entity pair and the entity pair has the relation. For example, we assume the sentence pattern *"$ARG1, the partner of fellow $ARG2"* is likely to express the spouse relation if we observe a text clip *"... Angelina Jolie, the partner of fellow Brad Pitt ..."* in our training corpus and a knowledge base tells us that *Angelina Jolie* and *Brad Pitt* has the spouse relation. Accordingly, we can infer that another entity pair is likely to have the spouse relation if we observe the text *", the partner of fellow"* between them in a new corpus.

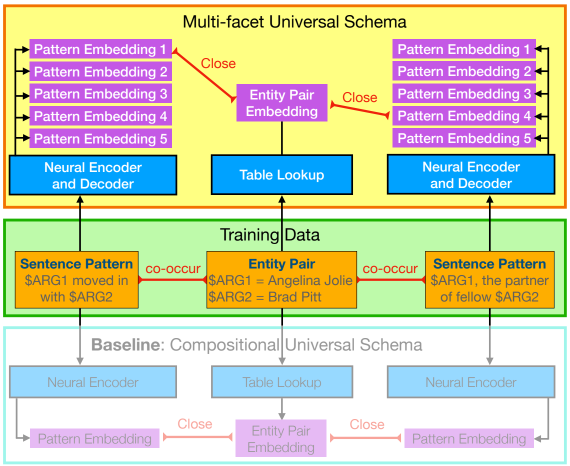

Figure 1: Comparison between the multi-facet and compositional universal schema. In our training loss, we encourage one of the facet embeddings from a sentence pattern to be similar to its co-occurred entity pair.

Universal schema (Riedel et al., 2013) extends this assumption by treating every sentence pattern as a relation, which means we assume that sentence patterns or relations in a knowledge base are similar if they co-occur with the same entity pair. For example, we assume *"$ARG1, the partner of fellow $ARG2"* and *"$ARG1, the wife of fellow $ARG2"* are similar if they both co-occur with *(Kristen Bell, Dax Shepard)*. Consequently, we can infer that *"$ARG1, the wife of fellow $ARG2"* also implies spouse relation as *"$ARG1, the partner of fellow $ARG2"* even if the knowledge base does not record the spouse relation between *Kristen*

April 19 - 23, 2021.

Bell and *Dax Shepard*.

Compositional universal schema (Verga et al., 2016) realizes the idea by using a LSTM (Hochreiter and Schmidhuber, 1997) to encode each sentence pattern into an embedding and encouraging the embedding to be similar to the embedding of the co-occurred entity pair. As in the lower part of Figure 1, the model makes the embeddings of two sentence patterns similar if they co-occur with the same entity pair. Baldini Soares et al. (2019) rely on a similar assumption and achieve state-of-the-art results on supervised RE tasks by replacing the LSTM with a large pre-trained language model.

The variants of universal schema have many different applications, including multilingual RE (Verga et al., 2016), knowledge base construction (Toutanova et al., 2015; Verga et al., 2017), question answering (Das et al., 2017), document-level RE (Verga et al., 2018), N-ary RE (Akimoto et al., 2019), open information extraction (Zhang et al., 2019), and unsupervised relation discovery (Percha and Altman, 2018).

Nevertheless, one sentence pattern could contain multiple facets, and each facet could imply a different relation. In Figure 1, *"\$ARG1, the partner of fellow \$ARG2"* could imply the entity pair has the spouse relation, the co-worker relation, or both. *"\$ARG1 moved in with \$ARG2"* could imply the spouse relation, the parent relation, ..., etc. If we squeeze the facets of a sentence pattern into a single embedding, the embedding is more likely to be affected by the irrelevant facets from other patterns co-occurred with the same entity pair (e.g., *"\$ARG1 moved in with \$ARG2"* might incorrectly imply the co-worker relation).

Another limitation is that single embedding representation can only provide symmetric similarity measurement between two sentence patterns. Thus, an open research challenge is to predict the entailment direction of two sentence patterns only based on their co-occurring entity pair information.

To overcome the challenges, we propose multi-facet universal schema, where we assume that two sentence patterns share a similar facet if they co-occur with the same entity pair. As in Figure 1, we use a neural encoder and decoder to predict multiple facet embeddings of each sentence pattern and encourage one of the facet embeddings to be similar to the entity pair embedding. As a result, the facets that are irrelevant to the relation between the entity pairs are less likely to affect the embeddings of entity pairs and other related sentence patterns. For example, the parent facet of *"\$ARG1 moved in with \$ARG2"* could be excluded when updating the embeddings of *(Angelina Jolie, Brad Pitt)*.

In our experiments, we first compare the multi-facet embeddings with the single-facet embedding in distantly supervised RE tasks. The results demonstrate that multiple facet embeddings significantly improve the similarity measurement between the sentence patterns and knowledge base relations. Besides RE, we also apply multi-facet embeddings to unsupervised entailment detection tasks. In a newly collected dataset, we show that multi-facet universal schema significantly outperforms the other unsupervised baselines.

2 Methods

Our method is illustrated in Figure 2. In Section 2.1, we first provide our problem setup: We are given a knowledge base (KB) and a text corpus during training. Our goal is to extract relations by measuring the similarity between KB relations and an (unseen) sentence pattern or to detect entailment between two sentence patterns. In Section 2.2, we introduce our neural model, which predicts multi-facet embeddings of each sentence pattern. Next, in Section 2.3, we describe our objective function, which encourages the embeddings of co-occurred entity pairs to be close to the embeddings of their closest pattern facets. Finally, in Section 2.4, we explain that multi-facet embeddings could be viewed as the cluster centers of possibly co-occurred entity pairs, and in Section 2.5, we provide our scoring functions for distantly supervised RE and unsupervised entailment tasks.

2.1 Background and Problem Setup

Our RE problem setup is the same as compositional universal schema (Verga et al., 2016). First, we run named entity recognition (NER) and entity linking on a raw corpus. After identifying the entity pairs in each sentence, we prepare a co-occurrence matrix as in Figure 2. Similarly, we represent the KB relations between entity pairs as a co-occurrence matrix and merge the matrices from the KB and the training corpus. The merged matrix has $y_{i,j} = 1$ if the ith sentence pair or KB relation co-occurs with the jth entity pair and $y_{i,j} = 0$ otherwise.

During testing, we use NER to extract an entity pair and the sentence pattern, which might not have been seen in the training corpus. Next, we extract

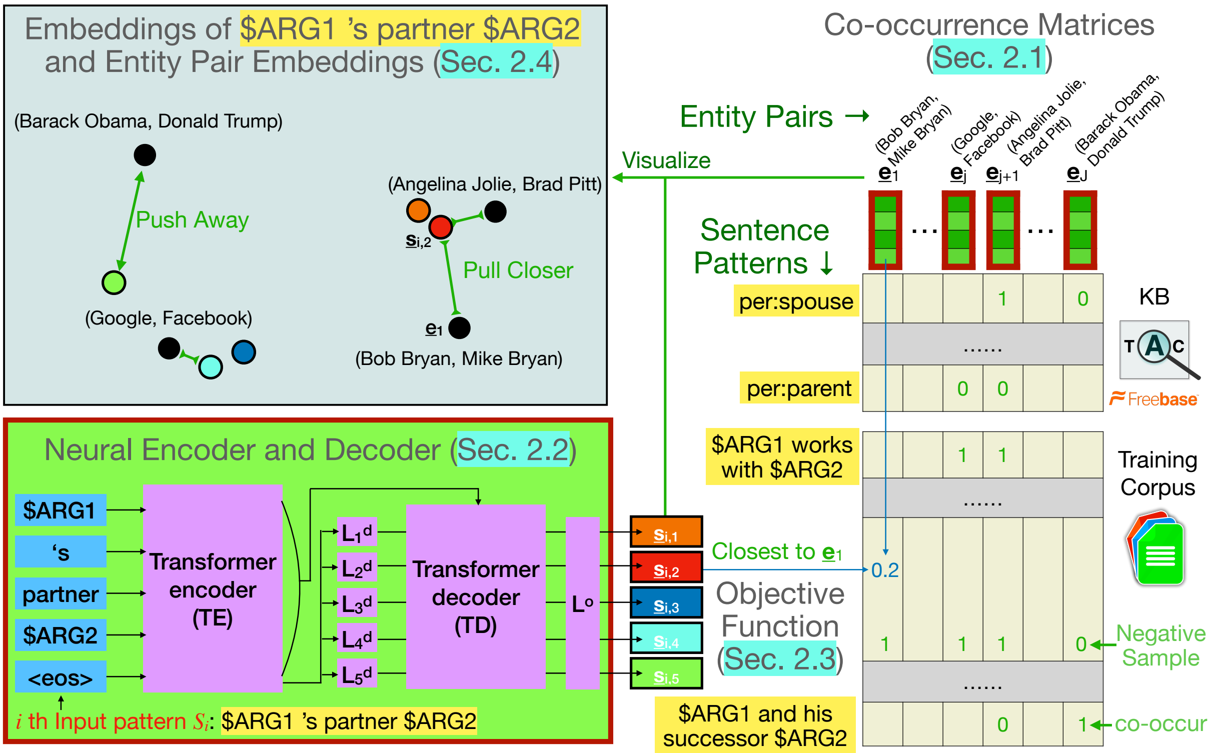

Figure 2: An illustration of the proposed method. The training signal comes from the co-occurrence matrices of the KB and training text corpus on the right. On the lower left, we visualize our neural encoder, which captures the compositional meaning of tokens in the sentence pattern, and our neural decoder, which models the dependency among multiple facet embeddings. When a sentence pattern co-occurs with an entity pair, the training loss minimizes the distance between the entity pair embedding and the closest facet embedding of the sentence pattern (e.g., 0.2 between $s_{i,2}$ and e_1). Trainable parameters in our model are highlighted using red borders. On the upper left, we visualize the embedding space to establish the connection between our method and clustering.

relations by computing the similarity between the sentence pattern embeddings and the embeddings of the applicable KB relations. Besides RE, we also detect the entailment between two sentence patterns by comparing their embeddings.

2.2 Neural Encoder and Decoder

We use a neural model to predict K facet embeddings of each sentence pattern. The goal is similar to Chang et al. (2021), which predict a fixed number of embeddings of a sentence, so we adopt their neural model as shown in Figure 2.

For the ith sentence pattern S_i, we append an <eos> to its end and use a 3-layer Transformer (Vaswani et al., 2017) encoder TE to model the compositional meaning of the input word sequence: $\underline{\boldsymbol{u}}_{i,1}...\underline{\boldsymbol{u}}_{i,|S_i|}\underline{\boldsymbol{u}}_{i,<\text{eos}>} = TE(S_i\text{<eos>})$, where $\underline{\boldsymbol{u}}_{i,l}$ is an embedding contextualized by the encoder. In the experiment, we also replace the Transformer with a bidirectional LSTM (bi-LSTM) to show that the improvement of multi-facet embeddings is independent of the encoder choice.

The embedding $\underline{\boldsymbol{u}}_{i,<\text{eos}>}$ represents the whole sentence pattern; we use K different linear layers L^d_k to transform the embedding into the inputs of our decoder: $\underline{\boldsymbol{b}}_{i,k} = L^d_k(\underline{\boldsymbol{u}}_{i,<\text{eos}>})$.

The facets in a sentence pattern often have some dependency. For example, the patterns that express the partnership between two people might also express the collaboration relation between two companies. To leverage the dependency, we use another 3-layer Transformer as our decoder TD. Besides the self-attention, we allow the hidden states in the decoder to query the contextualized word embeddings $\underline{\boldsymbol{u}}_{i,l}$ from the encoder (Vaswani et al., 2017) and output the embeddings corresponding to the different facets $\underline{\boldsymbol{d}}_{i,k}$: $\underline{\boldsymbol{d}}_{i,1}...\underline{\boldsymbol{d}}_{i,K} = TD(\underline{\boldsymbol{b}}_{i,1}...,\underline{\boldsymbol{b}}_{i,K},\underline{\boldsymbol{u}}_{i,1}...\underline{\boldsymbol{u}}_{i,<\text{eos}>})$. Notice that we do not use autoregressive decoding as in Vaswani et al. (2017), so our decoder could also be viewed as another encoder with attention to the output of the encoder TE. Finally, to convert the hidden state size to the entity embedding size, we let the outputs of decoder go through another linear layer

L^o to get the facet embedding (i.e., sentence pattern embedding): $\underline{\boldsymbol{s}}_{i,k} = L^o(\underline{\boldsymbol{d}}_{i,k})$.

2.3 Objective Function

When measuring the distance between the jth entity pair and the ith sentence pattern, we compute the Euclidean distance between the entity pair embedding $\underline{\tilde{\boldsymbol{e}}}_j$ and its closest facet embedding of the ith sentence pattern. The distance is defined as

$$D(\{\underline{\boldsymbol{s}}_{i,k}\}_{k=1}^{K}, \underline{\tilde{\boldsymbol{e}}}_j) = \min_{k=1}^{K} \min_{0 \leq \eta_k \leq 1} ||\underline{\tilde{\boldsymbol{e}}}_j - \eta_k \underline{\boldsymbol{s}}_{i,k}||^2, \quad (1)$$

where the entity pair embedding is normalized (i.e., $||\underline{\tilde{\boldsymbol{e}}}_j|| = 1$). During testing, we ignore the magnitude of facet embeddings, so we use η_k to eliminate the magnitude of facet embeddings $\underline{\boldsymbol{s}}_{i,k}$ during training. We do not allow negative η_k to prevent the gradient flow from pushing $\underline{\boldsymbol{s}}_{i,k}$ toward the inverse direction of $\underline{\tilde{\boldsymbol{e}}}_j$ and we ensure $\eta_k \leq 1$ to avoid the neural model from outputting $\underline{\boldsymbol{s}}_{i,k}$ with a very small magnitude.

As in Figure 2, we minimize the distance $D(\{\underline{\boldsymbol{s}}_{i,k}\}_{k=1}^{K}, \underline{\tilde{\boldsymbol{e}}}_j)$ in our loss function when the ith sentence pair co-occurs with the jth entity pair (i.e., $y_{i,j} = 1$). For negative samples (i.e., $y_{i,j} = 0$), we maximize the distance instead. That is, the major term of our loss function is defined as

$$\sum_{(i,j) \in R} (2 \cdot y_{i,j} - 1) r_{i,j} D(\{\underline{\boldsymbol{s}}_{i,k}\}_{k=1}^{K}, \underline{\tilde{\boldsymbol{e}}}_j), \quad (2)$$

and the other regularization term Ω in the loss function will be described in the appendix. R is a set that includes all positive and negative samples. Positive samples are (i, j) such that $y_{i,j} = 1$ and the negative samples are constructed by pairing a randomly selected sentence pattern with the jth entity pair. To balance the influence of popular entity pairs (i.e., entity pairs that co-occur with many sentence patterns) and rare entity pairs on our model, we set the weight of each pair, $r_{i,j} \propto \frac{1}{\sum_i y_{i,j}}$ and $\frac{\sum_{(i,j) \in R} r_{i,j}}{|R|} = 1$.

We generate the embeddings for KB relations in a similar way. We use a single token to represent the relation and append an <eos> (e.g., *per:spouse* <eos>) to form the input of our neural model. The KB relations usually co-occur with more entity pairs, so we set the number of facet embeddings for KB relations K_{rel} to be larger than the number of facet embeddings for sentence patterns K.

2.4 Connection to Clustering

If a sentence pattern contains multiple facets that describe different relations between the entity pairs, the pattern often co-occurs with different kinds of entity pairs. For example, *"$ARG1 's partner $ARG2"* in Figure 2 could express the collaboration relationship between two companies or the partnership between two people, so the sentence patterns could co-occur with two companies such as *(Google, Facebook)* and two people such as *(Bob Bryan, Mike Bryan)*.

Different kinds of entity pairs often have very different embeddings, so we could discover the facets of sentence patterns by clustering the embeddings of entity pairs. Here, a facet refers to a mode of the embedding distribution of the entity pairs that could possibly co-occur with the sentence pattern. A facet could be represented by multiple facet embeddings and each facet embedding corresponds to a cluster center of the entity pair embeddings. Hence, although the number of facet embeddings K is fixed for all the sentence patterns, our model can capture the facets of the sentence patterns well when the number of facets is less than K.

In equation 1, we choose the closest facet embedding of the sentence pattern for each co-occurring entity pair embedding and minimize their distance. For example, $\underline{\boldsymbol{s}}_{i,2}$ and the embedding of *(Bob Bryan, Mike Bryan)* are pulled closer in Figure 2. Minimizing equation 1 by passing the gradient through the scaled facet embedding $\eta_k \underline{\boldsymbol{s}}_{i,k}$ is the same as minimizing a Kmeans loss, so the loss term induced by positive sample pairs encourage each $\underline{\boldsymbol{s}}_{i,k}$ to become the cluster center of its nearby co-occurring entity pair embeddings. The details of our training algorithm could be found in the appendix.

The co-occurrence matrices in RE tasks are usually extremely sparse, and most of the sentence patterns only co-occur with a few entity pairs, which makes it difficult to derive multiple high-quality embeddings by clustering the co-occurring entity pair embeddings as in multi-sense word embedding methods such as Neelakantan et al. (2014). The proposed method solves this sparsity challenge by predicting the cluster centers using a neural model. For instance, even if *"$ARG1 's partner $ARG2"* does not co-occur with many entity pairs, its embeddings are encouraged to be close to the embeddings of entity pairs that co-occur with other similar patterns (e.g., *"$ARG1 and her partner $ARG2"*).

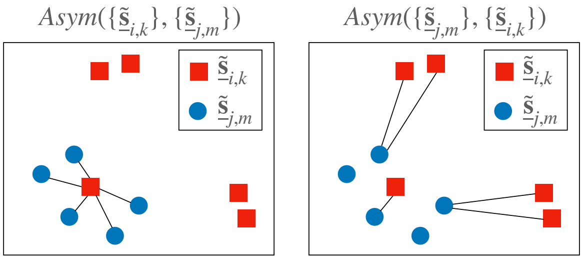

Figure 3: Comparison of the asymmetric similarities. $Asym(\{\underline{\tilde{\mathbf{s}}}_{i,k}\}, \{\underline{\tilde{\mathbf{s}}}_{j,m}\}) > Asym(\{\underline{\tilde{\mathbf{s}}}_{j,m}\}, \{\underline{\tilde{\mathbf{s}}}_{i,k}\})$ because the average cosine distance on the left is smaller than that on the right.

2.5 Scoring Functions

In compositional universal schema, the similarity between the ith and jth sentence patterns are measured by the symmetric cosine similarity $\underline{\tilde{\mathbf{s}}}_{i,1}^{T}\underline{\tilde{\mathbf{s}}}_{j,1}$, where $\underline{\tilde{\mathbf{s}}}_{i,1} = \frac{\underline{\mathbf{s}}_{i,1}}{||\underline{\mathbf{s}}_{i,1}||}$. When using multiple embeddings to represent a sentence pattern, we can compute the asymmetric similarity as

$$Asym(\{\underline{\tilde{\mathbf{s}}}_{i,k}\}, \{\underline{\tilde{\mathbf{s}}}_{j,m}\}) = \frac{\sum_{m=1}^{K} \max_{k=1}^{K}(\underline{\tilde{\mathbf{s}}}_{i,k}^{T}\underline{\tilde{\mathbf{s}}}_{j,m})}{K}. \quad (3)$$

In an example of Figure 3, a red square $\underline{\tilde{\mathbf{s}}}_{i,k}$ is close to all the blue points, which leads to a high $Asym(\{\underline{\tilde{\mathbf{s}}}_{i,k}\}, \{\underline{\tilde{\mathbf{s}}}_{j,m}\})$.

Between two sentence patterns with entailment relation, we empirically find that the embeddings of a premise (the more specific pattern) often have some facet embeddings that are far away from all the embeddings of its hypothesis (the more general pattern). Relying on the tendency, we could detect the direction of the entailment relation. For example, the ith sentence pattern (red squares) in Figure 3 is more likely to be premise if the ith and jth (blue circles) sentence patterns have an entailment relation.

We suspect the reason is that more specific patterns could contain more words that are similar to the words of other patterns expressing different relations. For example, *"$ARG1 , the wife of fellow $ARG2"* have a facet embedding for spouse relation and another facet embedding for the co-worker relation because the pattern has high word overlapping with *"$ARG1 , the wife of $ARG2"* and *"$ARG1 and her fellow $ARG2"*. Another possible reason is that the articles in our corpus tend to use more specific patterns to express the relation between a pair of entities (Shwartz et al., 2017).

When performing RE, we compute the symmetric similarity between ith sentence pattern and jth KB relation $Sim(\{\underline{\tilde{\mathbf{s}}}_{i,k}\}, \{\underline{\tilde{\mathbf{s}}}_{j,m}\})$ by

$$\frac{Asym(\{\underline{\tilde{\mathbf{s}}}_{i,k}\}, \{\underline{\tilde{\mathbf{s}}}_{j,m}\}) + Asym(\{\underline{\tilde{\mathbf{s}}}_{j,m}\}, \{\underline{\tilde{\mathbf{s}}}_{i,k}\})}{2}. \quad (4)$$

3 Experiments

We primarily compare our method with compositional universal schema (CUSchema) (Verga et al., 2016) because CUSchema is one of the state-of-the-art RE methods in the small model regime (without using large pre-trained language models) (Chang et al., 2016; Chaganty et al., 2017).[1]

In Section 3.1, we visualize and analyze the facet embeddings. Next, we use distant-supervised RE tasks to evaluate our symmetric similarity measurement in Section 3.2, and detect entailment between sentence patterns to evaluate our asymmetric similarity measurement in Section 3.3.

3.1 Embedding Visualization

We visualize the embeddings of sentence patterns and a KB relation from the single embedding model and multi-facet embedding model that perform the best in the RE tasks (i.e., **Ours (Single-Trans)** and **Ours (Trans)** in Table 1). We project the facet embeddings to a 2-dimensional space using multidimensional scaling (MDS) (Borg and Groenen, 2005) and visualize the embeddings of one KB relation and three related sentence patterns in Figure 4. The three sentence patterns are selected from our validation set, so the model is not aware of the entity pairs that actually co-occur with the patterns during training. For each facet embedding, we show two among five of its closest entity pairs to visualize the meaning of the embedding space.[2]

---

[1] We have not yet applied the multi-facet embeddings approach to the models that rely on a large pretrained language model (LM) (Baldini Soares et al., 2019) due to computational and evaluation considerations. Computationally speaking, training state-of-the-art models requires intensive GPU resources. Besides, a smaller model size might be desired when we need to construct a knowledge base from a large corpus in real time. Moreover, there is no existing pretrained LM in some domains (Zhang et al., 2019), and training the LM in a new domain from scratch requires even more GPU resources.

In terms of the evaluation consideration, our method is an improvement over CUSchema, so we want to compare it with CUSchema fairly. Furthermore, evaluating entailment between two full sentences is more difficult than between the sentence patterns, and we are not aware of a LM-based model that only considers the text between the entity pairs.

[2] Notice that our training signal is sparse and noisy and the projection does not necessarily preserve the original distances, so the entity pairs with similar relations might be relatively far away from each other.

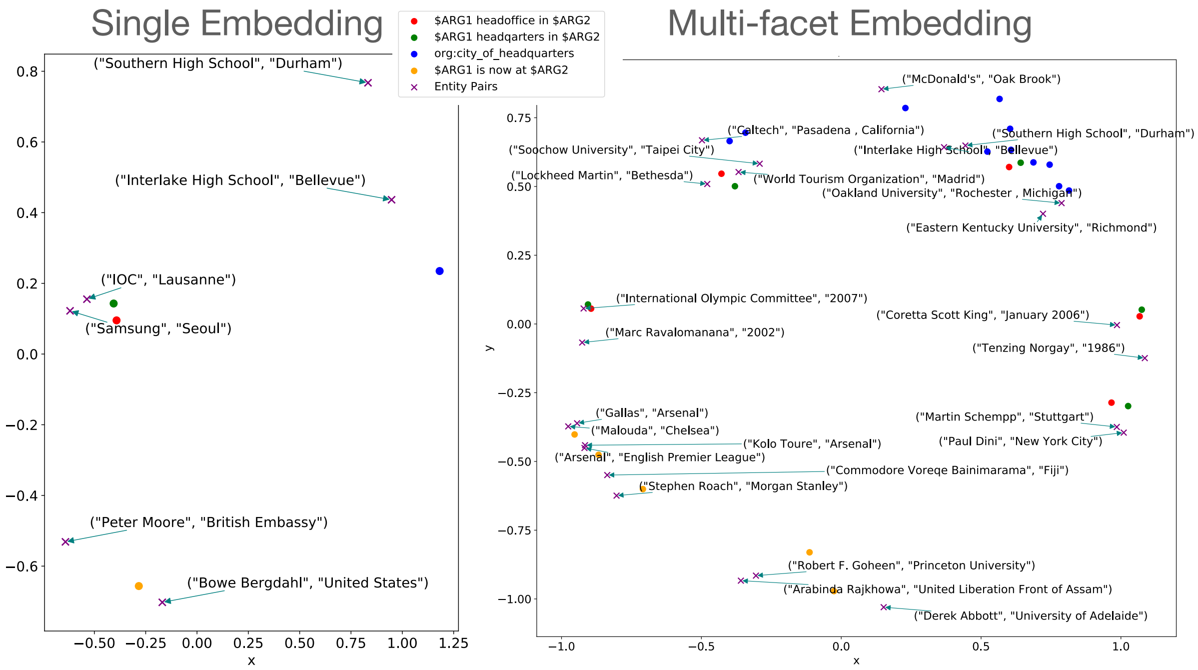

Figure 4: Facet embedding visualization of **Ours (Single-Trans)** on the left and **Ours (Trans)** on the right. Dots are the facet embeddings outputted by our models and crosses are their nearby entity pair embeddings

In the single embedding model, the embedding of *org:city_of_headquarter* is close to the embedding of *(school, location)* while *"$ARG1 headoffice in $ARG2"* is close to *(company, location)* and *"$ARG1 headquarter in $ARG2"*.

In the multi-facet embedding model, some embeddings of *org:city_of_headquarter* are closer to *(school, location)* and others are closer to *(company, location)*. In addition to these entity pairs, *"$ARG1 headoffice in $ARG2"* and *"$ARG1 headquarter in $ARG2"* also co-occur with *(people, location)* and *(people/organization, year)*. Using the visualization of multi-facet embedding, we can understand which facets of *org:city_of_headquarter* are similar or dissimilar to *"$ARG1 headoffice in $ARG2"*, which cannot be done if all facets are averaged into a single embedding as in the traditional models.

The facet embeddings of *"$ARG1 is now at $ARG2"* are close to *(people, organization)* where the organization could be school, sports team, and company. Using multiple embeddings could avoid enforcing the closeness of these entity pairs with different relations. The results also indicate that our model can output reasonable cluster centers despite learning from the sparse and noisy training data. Finally, we can see that if a sentence pattern has fewer facets than K, our model learns to output some very similar facet embeddings, which makes the performance less sensitive to the setting of K.

3.2 Relation Extraction

We follow the same training data and testing protocol in compositional universal schema (CUSchema) (Verga et al., 2016)[3] to highlight the benefit of predicting multiple facet embeddings, and the relation extraction step in TAC KBP slot-filling tasks is used to compare the different models.

Setup: The training data for our RE models are prepared by distant supervision without requiring any manually labeled data. The relations in Freebase (Bollacker et al., 2008) are mapped to TAC relations (e.g., *org:city_of_headquarter*) and the NER tagger and entity linker are run in a raw text corpus. Then, the training data is cleaned using the methods in Roth et al. (2013).

During testing, we are given a query containing the head entity and a query TAC relation in the slot-filling tasks, and the goal is to extract the tail entity from the candidate sentences. The NER tagger and query expansion are used to gather the candidate sentence patterns, and we compute the similarity scores from different models between the candidate sentence patterns and query relation. Finally, we compare the extracted second entity with the ground truth using exact string matching and report the precision, recall, and F1 scores.

Following Verga et al. (2016), we use TAC 2012

Table 1: Distantly supervised relation extraction using different versions of the universal schema. All numbers are %. CUSchema refers to compositional universal schema. Trans is an abbreviation of Transformer. The best scores of the single models and ensemble models are highlighted. *The performance of TAC 2013 and 2014 are copied from Verga et al. (2016).

as our validation set to determine the threshold score for each TAC relation. Each model's hyperparameters are tuned separately using the validation set (TAC 2012) to ensure a fair comparison.

We compare the following methods:

Ours (Trans): Our method that measures the similarity between the sentence pattern $\{\underline{\tilde{s}}_{i,k}\}$ and TAC relation $\{\underline{\tilde{s}}_{j,m}\}$ using $Sim(\{\underline{\tilde{s}}_{i,k}\}, \{\underline{\tilde{s}}_{j,m}\})$ in equation 4. Trans is an abbreviation of the Transformer encoder. We set $K = 5$ and $K_{rel} = 11$ based on the validation set.

Ours (LSTM): The same as Ours (Trans) except that we use bi-LSTM as our encoder instead.

Ours (Single-*): Our methods that use single facet embedding to represent each sentence pattern or KB relation. When setting $K = K_{rel} = 1$, our decoder becomes the interleaving feedforward layers and cross-attention layers attending to the output embeddings of the encoder.

CUSchema (LSTM): Compositional universal schema (Verga et al., 2016). The method is similar to Ours (Single-LSTM) but uses a different loss function, neural architecture (no decoder), and hyperparameter search procedure.

USchema: Universal schema (Riedel et al., 2013) estimates every sentence pattern embedding by factorizing the co-occurrence matrices (i.e., replacing the bi-LSTM in CUSchema with a look-up table).

USchema + *: Verga et al. (2016) show that taking the maximal similarity between USchema and CUSchema model improves the F1. We also apply the same merging procedure to our model.

Results: In Table 1, the proposed method **Ours (Trans)** significantly outperform **CUSchema (LSTM)** before and after combining with universal schema. As far as we know, our proposed multi-facet embedding is the first method that outperforms compositional universal schema using the same training signal in the distant-supervised RE benchmark they proposed.

Although the recall of **USchema** is low because it does not exploit the similarity between the patterns (e.g., *"$ARG1 happily married $ARG2"* is similar to *"$ARG1 married $ARG2"*), **USchema** has a high precision because it also won't be misled by the similarity (e.g., *"$ARG1, and his wife $ARG2"* expresses the *spouse* relation but *"$ARG1, his wife, and $ARG2"* does not) (Verga et al., 2016). Thus, combining **USchema** and **Ours (Trans)** leads to the best performance.

Ours (Trans) and **Ours (LSTM)** perform similarly. Furthermore, **Ours (LSTM)** performs much better than **Ours (Single-LSTM)**, which demonstrates the effectiveness of using multiple embeddings. Notice that multiple facet embeddings could improve the performance even after the training data have been cleaned. This indicates that our method is complementary to the noise removal methods in Roth et al. (2013).

3.3 Entailment Detection

Entailment is a common and fundamental relation between two sentence patterns. Some examples could be seen in Table 2. Unsupervised hypernym detection (i.e., entailment at the word level) is extensively studied (Shwartz et al., 2017), but we are not aware of any previous work on unsupervised entailment detection at the sentence level, nor any existing entailment dataset between sentence patterns. Thus, we create one.

Dataset Creation: We use WordNet (Miller, 1998) to discover the entailment candidates of sen-

Premise (Specific Pattern)	Hypothesis (General Pattern)	Label	Ours	CUSchema	Ours Diff	Freq Diff
$ARG1 , the president of the $ARG2	$ARG1 , the leader of the $ARG2	Entailment	0.98	0.94	+	+
$ARG1 's chairman , $ARG2	$ARG1 's leader , $ARG2	Entailment	0.95	0.87	+	-
$ARG1 's father , $ARG2	$ARG1 's leader , $ARG2	Other	0.08	0.52	NA	NA
$ARG1 worked with $ARG2	$ARG1 deal with $ARG2	Entailment	0.92	0.83	+	-
$ARG1 had with $ARG2	$ARG1 deal with $ARG2	Other	0.96	0.88	NA	NA
$ARG1 said the $ARG2	$ARG1 say the $ARG2	Paraphrase	0.93	0.92	NA	NA

Table 2: Example of sentence pattern pairs, its label, and our predictions in our entailment experiment. **Ours** and **Ours Diff** are the predictions from **Ours (Trans)**. **Freq Diff** is the frequency difference baseline.

Method	Classification	Direction Detection	
	AP@all	Micro Acc	Macro Acc
Random	21.9	50.0	50.0
Freq Diff	21.4	54.5	47.3
CUSchema	31.2	50.0	50.0
Ours (Single)	23.6	50.0	50.0
Ours	**37.8**	**63.1**	**55.4**

Table 3: Comparison of entailment detection methods. AP and Acc are average precision and accuracy, respectively. All numbers are %. Our methods use a Transformer as their encoder.

tence pattern pairs and manually label the candidates. For each sentence pattern in the training data of Verga et al. (2016), we replace one word at a time with its hypernym based on the WordNet hierarchy. The two sentence patterns before and after replacement form an entailment candidate.

We label 1,500 pairs of the most popular sentence pattern, which co-occurs with the highest number of unique entity pairs. Each candidate could be labeled as entailment, paraphrase, or other. Finally, around 20% of the candidates are randomly chosen to form the validation set, and the rest are in the test set. More details of the dataset creation process could be seen in the appendix

In this dataset, only 22% and 10% of candidates are labeled as entailment and paraphrase, respectively. This suggests that entailment relation between two sentence patterns is hard to be inferred by only the hypernym relation (i.e., entailment relation at the word level) in WordNet.

Setup: We evaluate entailment detection using the typical setup and metrics in hypernym detection (Shwartz et al., 2017). Negative examples include the candidates labeled as paraphrases and others. We compare the average precision of different methods (i.e., AUC in the precision-recall curve) (Hastie et al., 2009). In addition, we predict the direction of entailment relation in each pair (i.e., which pattern is the premise) and report the accuracy. Many hypotheses have the same hypernyms such as the *leader* in Table 2, so we also report the macro accuracy of direction detection averaged across every hypernym in the hypotheses.

The task is challenging because all the candidates have a word-level entailment relation if their compositional meaning is ignored. Furthermore, we cannot infer the entailment direction based on the tendency that longer sentence patterns tend to be more specific because most of the candidate pairs in this dataset have the same length.

As described in Section 2.5, our models detect the direction by computing **Ours Diff** as $Asym(\{\underline{\tilde{\mathbf{s}}}_{i,k}\}, \{\underline{\tilde{\mathbf{s}}}_{j,m}\}) - Asym(\{\underline{\tilde{\mathbf{s}}}_{j,m}\}, \{\underline{\tilde{\mathbf{s}}}_{i,k}\})$ and predict the ith sentence pattern to be premise if **Ours Diff** > 0. When performing entailment classification, we use as the asymmetric similarity scores $Asym(\{\underline{\tilde{\mathbf{s}}}_{i,k}\}, \{\underline{\tilde{\mathbf{s}}}_{j,m}\})$. We report the performance of **Ours (Trans)**, which is the same best model in the RE experiment.

In entailment classification, we compare the results with cosine similarity from **Ours (Single-Trans)** and **CUschema**. We also test the frequency difference, which is a strong baseline in hypernym direction detection (Chang et al., 2018). **Freq Diff** = Freq(S_j) - Freq(S_i) where Freq(S_i) is the number of unique entity pairs co-occurred with the ith sentence pattern. The baseline predicts S_i to be premise if **Freq Diff** > 0 because more general sentence patterns should co-occur with more entity pairs. As a reference, we also report the performance of random scores.

Results: The quantitative and qualitative comparison are presented in Table 3 and Table 2, respectively. Our model that uses multi-facet embeddings significantly outperforms the other baselines. We hypothesize that a major reason is that the sentence patterns with an entailment relation are often similar in some but not all of the facets, and our asymmetric similarity measurement is better at capturing the facet overlapping.

4 Related Work

Relation extraction (RE) is widely studied. Han et al. (2020) summarize the trend of recent studies and point out one of the major challenges is the cost of collecting the labels. Distant supervision (Mintz et al., 2009) and its follow-up work enable us to collect a large amount of training data at a low cost, but the violation of its assumptions often introduces substantial noise into the supervision signal. Our goal is to alleviate the noise issue by representing every sentence pattern using multiple embeddings.

Other noise reduction methods have also been proposed (Roth et al., 2013). For instance, we can adopt multi-instance learning techniques (Yao et al., 2010; Surdeanu et al., 2012; Amin et al., 2020), global topic model (Alfonseca et al., 2012), or both (Roth and Klakow, 2013). We can also reduce the noise by counting the number of shared entity pairs between a sentence pattern and a KB relation (Takamatsu et al., 2012; Su et al., 2018). Nevertheless, the studies focus on mitigating the noise caused by assuming similarity between the sentence patterns and KB relations that co-occur with the same entity pairs, while our method can also reduce the noise from two sentence patterns sharing the same entity pair. Besides, our method is complementary to popular noise reduction methods because our improvement is shown in the training data that have been cleaned (Verga et al., 2016).

Our method is conceptually related to some studies for lexical semantics. For example, word sense induction or unsupervised hypernymy detection can be addressed by clustering the co-occurring words (Neelakantan et al., 2014; Athiwaratkun and Wilson, 2017; Chang et al., 2018). However, the clustering-based methods do not apply to RE because the co-occurring matrix for RE is much sparser (see Section 2.4 for more details).

Finally, our work is inspired by Chang et al. (2021), but they focus on improving the sentence representation rather than RE. We encourage the facet embeddings to become the centers in Kmeans clustering instead of NNSC (non-negative sparse coding) clustering used in Chang et al. (2021), due to its simplicity, efficiency, and better RE performance. Moreover, we discover that an additional regularization described in the appendixis crucial to overcome the sparsity challenge in RE.

5 Conclusion

In this work, we address the limitation of representing each sentence pattern using only a single embedding, and our approach improves the distantly-supervised RE performances of compositional universal schema.

Relying on only a very sparse co-occurrence matrix between the sentence patterns and entity pairs, we show that it is possible to predict reasonable cluster centers of entity pair embeddings and to predict the entailment relation between two sentence patterns without any labels.

Exploring Transitivity in Neural NLI Models through Veridicality

Abstract

Despite the recent success of deep neural networks in natural language processing, the extent to which they can demonstrate human-like generalization capacities for natural language understanding remains unclear. We explore this issue in the domain of natural language inference (NLI), focusing on the *transitivity* of inference relations, a fundamental property for systematically drawing inferences. A model capturing transitivity can compose basic inference patterns and draw new inferences. We introduce an analysis method using synthetic and naturalistic NLI datasets involving clause-embedding verbs to evaluate whether models can perform transitivity inferences composed of veridical inferences and arbitrary inference types. We find that current NLI models do not perform consistently well on transitivity inference tasks, suggesting that they lack the generalization capacity for drawing composite inferences from provided training examples. The data and code for our analysis are publicly available at `https://github.com/verypluming/transitivity`.

1 Introduction

Deep neural networks (DNNs) have shown impressive performance in many natural language processing tasks. In particular, DNN models pretrained with large-scale data such as BERT (Devlin et al., 2019) have achieved high accuracy in various benchmark tasks (Wang et al., 2019a,b), which suggests that they might possess some generalization capacities that are a hallmark of human cognition. However, recent analyses (Talmor and Berant, 2019; Liu et al., 2019; McCoy et al., 2019) have shown that high accuracy on a test set drawn from the same distribution as the training set does not always indicate that the model has obtained the intended ability, so it remains unclear to what extent DNN models can learn the systematic generalization in natural language from training instances.

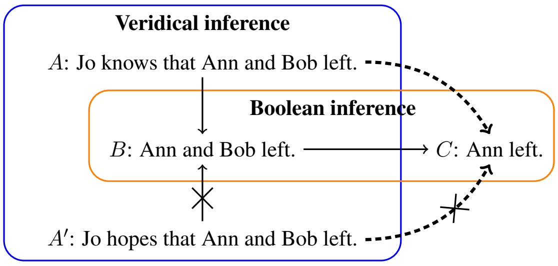

Figure 1: Illustration of transitivity inferences (indicated by ⇢) composed of two basic inferences, veridical and Boolean. Arrows indicate *entailment* and arrows with a cross (×) indicate *non-entailment*.

Central to human-like generalization capacities is the fact that ability to understand a given sentence is related to ability to understand other sentences, called *systematicity* of human cognition in Fodor and Pylyshyn (1988). Thus, if speakers understand the meaning of the sentence *Ann loves Bob*, they must also understand the meaning of structurally related sentences such as *Bob loves Ann*. We explore whether DNN models possess this type of generalization capacity in the domain of natural language inference (NLI), which is the task to judge whether a premise entails a hypothesis (Dagan et al., 2013; Bowman et al., 2015a).

A key property underlying systematicity of drawing inferences is the *transitivity* of inference relations, illustrated in Figure 1. Schematically, if a model learns a basic inference pattern from A to B and one from B to C, it should be able to compose the two patterns to draw a new inference from A to C. If a model lacks this generalization capacity, it must memorize an exponential number of inference combinations independently of basic patterns.

Among the various inference patterns, we focus on transitivity inferences that combine *veridical* in-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 920–934
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

ferences with other types. In veridical inferences, one must distinguish two entailment types. For example, the verb *know* is called **veridical** in that "x *knows that* P" entails that P is true, while the verb *hope* is called **non-veridical** since "x *hopes that* P" does not entail that P is true. Veridical inferences can relatively easily compose transitivity inferences at scale by embedding various inference types into clause-embedding verbs. For instance, as Figure 1 shows, if a model has the ability to perform both Boolean inference and veridical inference, it is desirable to have the ability to combine both types to make a chained inference.

Such transitivity inferences are by no means trivial. For instance, if the premise is changed to *Jo knows that Ann* ***or*** *Bob left*, it does not follow that *Bob left*, even though the veridical verb *know* appears. Models relying on shallow heuristics such as lexical overlap can wrongly predict *entailment* in this case. To correctly handle such composite inferences, models must capture structural relations between veridical inferences and various kinds of embedded inference.

Previous studies on the generalization capacities of NLI models have addressed how models could learn inferences with various challenging linguistic phenomena (Bowman et al., 2015b; Dasgupta et al., 2018; Geiger et al., 2019, 2020; Yanaka et al., 2019a,b; Richardson et al., 2020). However, these studies have focused on the linguistic phenomena in isolation, and thus do not address how a model could learn the *interactions* between them. Our aim is to fill this gap by presenting a method for probing generalization capacity of DNN models performing transitivity inferences.

This study provides three main contributions. First, we create and publicly release two types of NLI datasets for testing model ability to perform transitivity inferences: a fully synthetic dataset that combines veridical inferences and Boolean inferences, and a naturalistic dataset that combines veridical inferences with lexical and structural inferences. Second, we use these datasets to systematically expose models to basic inference patterns and test them on a variety of combinations. This will demonstrate that the models lack the ability to capture transitivity of inference. Third, we investigate whether data augmentation with new combination patterns helps models to learn transitivity. Experiments show that the data augmentation improves model performance on similar combinations, regardless of the existence of basic inference patterns in the training set. These results suggest there is much room for improving the generalization capacities of DNN models for combining basic inferential abilities.

2 Related Work

Transitivity The transitivity of entailment relations, which derives $A \rightarrow C$ from $A \rightarrow B$ and $B \rightarrow C$, is incorporated into logic-based NLI systems using automated theorem proving (Abzianidze, 2015; Mineshima et al., 2015). This is a basic property of formal logic, also known as *syllogism* in traditional logic or the *cut rule* in proof theory (Troelstra and Schwichtenberg, 2000; van Dalen, 2013). Transitivity inference in its various forms has also been widely studied as a fundamental property of human reasoning in cognitive psychology (Johnson-Laird and Byrne, 1991; Khemlani and Johnson-Laird, 2012). In the context of NLP, previous works have proposed a method for training models with transitivity constraints in multi-hop reasoning tasks (Asai and Hajishirzi, 2020) and temporal relation extraction tasks (Ning et al., 2017). Clark et al. (2020) investigated a transformer's ability to perform a chain of reasoning where reasoning rules are explicitly given. In this work, we study model ability to learn transitivity of entailment relations from training examples, rather than explicitly providing rules.

Systematicity There has been extensive discussion of whether neural networks (aka Connectionist models) can exhibit systematicity of cognitive capacities (Fodor and Pylyshyn, 1988; Marcus, 2003). Recent works have explored whether modern neural networks can learn systematicity in semantic parsing tasks (Lake and Baroni, 2017; Baroni, 2020; Kim and Linzen, 2020) and question answering tasks (Sinha et al., 2019), whereas our focus is the systematicity in NLI.

In works related to the systematicity in NLI, Goodwin et al. (2020), Yanaka et al. (2020), and Geiger et al. (2020) used a manually constructed NLI dataset of monotonicity inferences with and without negation (e.g., *The child is not holding plants* $\rightarrow$ *The child is not holding flowers*) to examine DNN models' generalization capacities. While these approaches concentrate on monotonicity inferences involving quantifiers and negative expressions, our method using veridical inference is general in that it can be applied to any entailment relation that combines basic inference patterns; we generate composite inferences by embedding various types of sentences into clause-embedding verbs.

Fodor and Pylyshyn (1988) distinguished systematicity (roughly, the ability to understand sentences that are structurally related to each other) from productivity (the ability to understand an infinite set of sentences), claiming that systematicity poses a serious challenge to neural network models. Yanaka et al. (2020) tested both systematicity and productivity of DNN models with a synthetic dataset of monotonicity inferences for upward (e.g., *some, at least three*) and downward (e.g., *few, at most three*) quantifiers, where handling productivity (recursion) makes sentences more involved (e.g., iterated relative clauses and negation). Focusing on systematicity rather than productivity allows testing models with more natural and less complicated data, as compared to sentences appearing in monotonicity inferences.

Veridicality Veridical inferences, including those licensed by factive and implicative verbs, have been intensively studied in the literature of semantics and pragmatics (Karttunen and Peters, 1979; Beaver, 2001). Recent work has revealed graded and context-sensitive aspects of veridicality inferences, creating veridicality judgement datasets (de Marneffe et al., 2012; White and Rawlins, 2018; White et al., 2018). While we use only a subset of veridical predicates discussed in the literature, our method can be extended to more complex inferences, such as factive presupposition.

Ross and Pavlick (2019) presented a naturalistic veridicality dataset and compared the predictions of a BERT-based NLI model and human judgements. These previous studies on veridicality inferences have tended to focus on relations between whole sentences (e.g., *Jo remembered that there was a wild deer jumping a fence*) and its embedded material (e.g., *There was a wild deer jumping a fence*). By contrast, we consider the interactions of veridicality inferences and other inference types (see Section 3.2), including cases where the embedded material is further paraphrased via linguistic phenomena (e.g., *Jo remembered that there was a wild deer jumping a fence* ⇒ *An animal was jumping*). We also collect human judgements on our dataset and compare them with model predictions (see Section 4.4).

Probing NLI models Many studies of probing NLI models have found that current models often fail on linguistically challenging (adversarial) inferences (Rozen et al., 2019; Nie et al., 2019; Yanaka et al., 2019a; Richardson et al., 2020), learning undesired biases (Glockner et al., 2018; Poliak et al., 2018; Tsuchiya, 2018; Liu et al., 2019), and heuristics (McCoy et al., 2019). Our approach also provides adversarial test sets against such heuristics by considering combinations of veridical inferences and diverse (lexical, structural, and logical) types of inferences.

One way to learn challenging inferences is data augmentation, and prior studies (Yanaka et al., 2019b; Richardson et al., 2020; Min et al., 2020) have shown that data augmentation with synthesized datasets improves performance with challenging linguistic phenomena. However, it remains unclear whether data augmentation can help models learn *composite* inferences mixing several inference types from training instances. We address this question in Section 4.3.

3 Dataset

3.1 Overview

To investigate whether models can capture transitivity, we consider two basic inference patterns and their combinations. The first basic pattern, $\mathcal{I}_1$, is veridical inference. We write $f(s_1) \rightarrow s_1$ to denote a schematic veridical inference, where f is a clause-embedding verb and s_1 is the embedded clause. For instance, in the case of the inference pattern $A \rightarrow B$ in Figure 1, "*Jo knows that x*" corresponds to $f(x)$ and "*Ann and Bob left*" to s_1.

The second basic pattern, $\mathcal{I}_2$, provides an inference from the embedded material. We denote a premise-hypothesis pair of this second inference by $s_1 \rightarrow s_2$. Given two inferences $f(s_1) \rightarrow s_1$ in $\mathcal{I}_1$ and $s_1 \rightarrow s_2$ in $\mathcal{I}_2$, we consider a new inference $f(s_1) \rightarrow s_2$, where premise $f(s_1)$ is the same as that of $\mathcal{I}_1$ and hypothesis s_2 is the same as that of $\mathcal{I}_2$. See Table 1 and Table 2 for some examples of inferences $f(s_1) \rightarrow s_1$, $s_1 \rightarrow s_2$, and $f(s_1) \rightarrow s_2$. In this work, we consider binary labels, *entailment* and *non-entailment*, denoted by *yes* and *unk*, respectively. As Table 3 shows, the gold label on the $f(s_1) \rightarrow s_2$ pattern can be determined from those of the basic patterns $f(s_1) \rightarrow s_1$ and $s_1 \rightarrow s_2$, following the transitivity of entailment relations.

We train models with the first and second patterns, $f(s_1) \rightarrow s_1$ and $s_1 \rightarrow s_2$, and then test them

f	$f(s_1)\rightarrow s_1$	$s_1\rightarrow s_2$	$f(s_1)\rightarrow s_2$	**Example**
V	*yes*	*yes*	*yes*	$f(s_1)$: Someone **noticed** that [Henry and Daniel found Elliot, John and Fred]. s_1: Henry and Daniel found Elliot, John and Fred. s_2: Henry found John.
NV	*unk*	*yes*	*unk*	$f(s_1)$: Someone **expects** that [Tom and Ann admire Greg and Fred]. s_1: Tom and Ann admire Greg and Fred. s_2: Tom admires Greg.
NV	*unk*	*unk*	*unk*	$f(s_1)$: Someone **argued** that [it was not the case that Greg hated John or Elliot]. s_1: It was not the case that Greg hated John or Elliot. s_2: Greg hated John.

Table 1: Examples from our fully synthetic transitivity inference datasets. `V` and `NV` indicate types of clause-embedding verbs (veridical/non-veridical); *yes* means *entailment* and *unk* means *non-entailment*.

ID	f	$f(s_1)\rightarrow s_1$	$s_1\rightarrow s_2$	$f(s_1)\rightarrow s_2$	**Example**
2299	V	*yes*	*yes*	*yes*	$f(s_1)$: Someone **realized** that [a boy was playing a guitar]. s_1: A boy was playing a guitar. s_2: A kid was playing a guitar.
2049	V	*yes*	*unk*	*unk*	$f(s_1)$: Someone **remembered** that [a cat was playing with a device]. s_1: A cat was playing with a device. s_2: The boy was enthusiastically playing in the mud.
5024	NV	*unk*	*yes*	*unk*	$f(s_1)$: Someone **doubts** that [the woman is putting makeup on the man]. s_1: The woman is putting makeup on the man. s_2: A man's face is being painted by a woman.

Table 2: Examples from our naturalistic transitivity inference datasets. `V` and `NV` indicate types of clause-embedding verbs (veridical/non-veridical); *yes* means *entailment* and *unk* means *non-entailment*. **ID** indicates the original ID of $s_1\rightarrow s_2$ in the SICK dataset.

$f(s_1)\rightarrow s_1$	$s_1\rightarrow s_2$	$f(s_1)\rightarrow s_2$
yes	*yes*	***yes***
yes	*unk*	***unk***
unk	*yes*	***unk***
unk	*unk*	***unk***

Table 3: Rule for determining the $f(s_1)\rightarrow s_2$ label from the basic patterns $f(s_1)\rightarrow s_1$ and $s_1\rightarrow s_2$.

Type of f	**Verbs**
Veridical	realize, acknowledge, remember, note, find, notice, learn, see, reveal, discover, understand, know, admit, recognize, observe
Non-veridical	feel, claim, doubt, hope, predict, imply, suspect, wish, think, believe, hear, expect, estimate, assume, argue

Table 4: Clause-embedding verbs used for our dataset.

on a set of the composite inferences $f(s_1)\rightarrow s_2$ that combines them. Note that due to how they are constructed, the training and test sets do not overlap. Model capable of applying the transitivity inference from $f(s_1)\rightarrow s_1$ and $s_1\rightarrow s_2$ to $f(s_1)\rightarrow s_2$ should consistently predict the correct label of $f(s_1)\rightarrow s_2$ for any combination of $f(s_1)\rightarrow s_1$ and $s_1\rightarrow s_2$.

3.2 Data creation

We generate basic inferences $f(s_1)\rightarrow s_1$ and $s_1\rightarrow s_2$ and combine them to produce transitivity inferences $f(s_1)\rightarrow s_2$. To test diverse inference patterns, we consider two types of the second basic inference $s_1\rightarrow s_2$: synthesized Boolean inferences and naturalistic inferences using an existing NLI dataset, SICK (Marelli et al., 2014), which contains lexical inferences (e.g., *boy* → *kid* in ID 2299 in Table 2) and structural inferences (e.g., active-passive alternation in ID 5024 in Table 2). Since the ratio of the gold labels (*yes* and *unk*) is set to $1:1$ in both basic inference sets, the ratio of the gold labels for the transitivity test set is $1:3$ by the rule in Table 3. We reserve 10% of the basic inference set for the validation set.

Clause-embedding verbs We focus on clause-embedding verbs that take tensed subordinate clauses. Specifically, we collect 67 verbs appearing in both MegaVeridicality2 (White et al., 2018) and the verb veridicality dataset (Ross and Pavlick, 2019). As Table 4 shows, we select a final set of 30 clause-embedding verbs.

Following a previous study (White et al., 2018), we slot a clause-embedding verb f into a template with the form "Someone f that s_1" and generate premise $f(s_1)$ of veridical inference to avoid confounds introduced by world knowledge and pragmatic inference in the main clause. The clause-embedding verb f is in past or present tense, and we inflect the verb in the complement s_1 to match the tense of f.

When measuring the extent to which models can learn transitivity of entailment relations from training instances, it is desirable to determine the gold labels of composite inferences from those of basic inferences. Thus, we take the labels of veridical inference datasets predicted by the veridical and non-veridical distinction in lexical semantics as the gold standard. In addition, veridical inferences are sensitive to context, influenced by world knowledge and pragmatic factors (de Marneffe et al., 2012). Accordingly, we also present additional experiments to take into account such complexity of veridical inferences in Section 4.2.

Boolean inference To provide a fully synthetic transitivity inference dataset, we generate Boolean inferences with conjunction, disjunction, and negation. The data generation process is similar to the one in Yanaka et al. (2020): sentences are generated using a context-free grammar (CFG) associated with semantic composition rules in lambda-calculus. We first generate a set of premise sentences by the CFG rules and translate each sentence s_1 into a first-order-logic (FOL) formula F_1 in accordance with semantic composition rules specified in the CFG rules. Appendix A provides a set of CFG rules and semantic composition rules. We randomly select one of the atomic subformulas appearing in F_1 and take its positive or negative form, which we denote by F_2. Then we convert F_2 to a sentence s_2 using the same grammar. We set s_2 as a hypothesis.

The gold label for inference pair $s_1 \rightarrow s_2$ is determined by checking whether formula F_1 entails formula F_2 using an FOL theorem prover. The gold labels for $f(s_1) \rightarrow s_1$ and $f(s_1) \rightarrow s_2$ pairs are automatically determined according to the veridicality of a clause-embedding verb and the rule in Table 3, respectively. To restrict the complexity of generated sentences, we set the maximum number of logical connectives appearing in formula F_1 to 6.

Table 1 illustrates examples of fully synthetic transitivity inference datasets. We generate 3,000 Boolean inference examples $s_1 \rightarrow s_2$, 6,000 veridical inference examples $f(s_1) \rightarrow s_1$, and 6,000 composite inference examples $f(s_1) \rightarrow s_2$.

Naturalistic inference To generate a naturalistic transitivity inference dataset, we collect an example $s_1 \rightarrow s_2$ of naturalistic inference from the SICK dataset, which is constructed from existing sentences (image descriptions given by different people) and covers various lexical and structural phenomena. (1) is an example of lexical inference (*brush* → *comb*) in SICK, whose label is *yes*.

(1) s_1: A person is brushing a cat.
s_2: A person is combing the fur of a cat.

By selecting a clause-embedding verb f and an embedded sentence s_1, we generate a new sentence $f(s_1)$. As shown in (2), we construct a veridical inference example $f(s_1) \rightarrow s_1$ by setting $f(s_1)$ as a premise and s_1 as a hypothesis.

(2) $f(s_1)$: Someone **sees** that a person is brushing a cat.
s_1: A person is brushing a cat. (*yes*)

Likewise, as in (3), we can obtain a composite inference example $f(s_1) \rightarrow s_2$ whose label is *yes*:

(3) $f(s_1)$: Someone **sees** that a person is brushing a cat.
s_2: A person is combing the fur of a cat.

Table 2 illustrates examples of naturalistic transitivity inference datasets. We sample 1,000 naturalistic inference examples $s_1 \rightarrow s_2$ from the SICK training set and obtain 30,000 veridical inference examples $f(s_1) \rightarrow s_1$ and 30,000 composite inference examples $f(s_1) \rightarrow s_2$.

4 Experiments and Analysis

We analyze whether models trained with the basic inference set can consistently perform composite inferences on the test set. We use two DNN models, BERT and LSTM, which are known to perform well with linguistic phenomena such as subject-verb agreement and hierarchical and structural probing tasks (Linzen et al., 2016; Weiss et al., 2018; Kuncoro et al., 2018).

4.1 Experimental setup

In all experiments, we train each model for 25 epochs or until convergence and select the best-performing model based on its accuracy on the validation set. We perform five runs and report the average and standard deviation of their accuracies.

Table 6: Accuracies for the naturalistic transitivity test set and the validation set.

LSTM We use an LSTM (Hochreiter and Schmidhuber, 1997) model, where each premise and hypothesis is processed as a sequence of words using RNN with LSTM cells, and the final hidden state of each serves as its representation. The model concatenates the premise and hypothesis representations and passes the result to three hidden layers followed by a two-way softmax classifier. The model is initialized with 300-dimensional GloVe vectors (Pennington et al., 2014) and optimized using Adam (Kingma and Ba, 2015). We search dropout probabilities of $[0, 0.1, 0.2]$ on the output.

BERT We use the base-uncased pretrained BERT (Devlin et al., 2019) model[1], fine-tuned for the NLI classification task on training data in the standard way. When fine-tuning BERT, we search dropout probabilities of $[0, 0.1, 0.2]$ on the output, and hyperparameters are the same as those commonly used for MultiNLI.

4.2 Testing transitivity

We first evaluate whether the models trained with basic inferences $f(s_1) \rightarrow s_1$ and $s_1 \rightarrow s_2$ can consistently make judgements on the composite inferences $f(s_1) \rightarrow s_2$. As a previous work (Ross and Pavlick, 2019) reported that a BERT model trained with the benchmark NLI dataset MultiNLI (MNLI; Williams et al., 2018) is sensitive to verb veridicality, we regard the accuracy of models trained with MNLI as a baseline. We also analyze models trained with MNLI mixed with the basic inference set.

Table 5 shows accuracies for the fully synthetic transitivity test set that combines veridical and Boolean inferences. Models trained with the basic inference set achieved over 80% accuracy on the test cases, except for cases where $f(s_1) \rightarrow s_1$ is *yes* and $s_1 \rightarrow s_2$ is *unk*. Table 6 shows accuracies for the naturalistic transitivity test set. Again, models trained with the basic inference set performed substantially below chance for the cases $f(s_1) \rightarrow s_2$, where $f(s_1) \rightarrow s_1$ is *yes* and $s_1 \rightarrow s_2$ is *unk*. This suggests that while the models achieve over 80% accuracy on both $f(s_1) \rightarrow s_1$ and $s_1 \rightarrow s_2$ validation sets, they do not apply transitivity inference from the inferences $f(s_1) \rightarrow s_1$ and $s_1 \rightarrow s_2$, but rather predict the label for the composite inference $f(s_1) \rightarrow s_2$ by judging whether it is similar to the veridical inference $f(s_1) \rightarrow s_1$ in the training set.

Accuracy of models trained with MNLI was low because they predicted *yes* for many examples where correct labels were *unk*, as in (4).

(4) $f(s_1)$: Someone wished that **John saw Tom** or Greg.
s_2: John saw Tom. (*unk*)

---

[1] We use the Pytorch implementation of BERT released at https://github.com/huggingface/transformers.

Type	Templates
Pronoun	At that moment, we f that s
Pronoun	Then he f that s
Specific group	The customers f that s
Specific group	Some economists f that s
Proper noun	Hanson f that s

Table 7: Examples of additional templates used for generating veridical inference datasets. Here f is a place for a veridical verb and s for an embedded sentence.

The models predicted *yes* for over 80% of the fully synthetic transitivity test set and more than 60% of the naturalistic transitivity test set. These results are consistent with the findings in McCoy et al. (2019), namely, that models trained with MNLI tend to predict entailment relations when the hypothesis is a subsequence of the premise, as in (4).

When models are trained with MNLI mixed with the basic inference set, they seem to improve performance on the fully synthetic transitivity test set. One reason for this result is that the models might use heuristics to make predictions for some *unk* examples in the fully synthetic inference set. Error analysis shows that the models tend to predict *unk* when either a premise or a hypothesis contains a negation like (5).

(5) $f(s_1)$: Someone knew that Fred praised Henry or Ann.
s_2: Fred did **not** praise Ann. (*unk*)

These heuristics might be related to the annotation artifact (Gururangan et al., 2018) in MNLI, because an inference example involving negation words tends to be a *contradiction*[2]. Moreover, models can memorize the basic inference set regardless of the existence of MNLI in the training set, so performance seems to be better.

Note that models trained with MNLI mixed with the basic inference set still failed on the naturalistic transitivity inference $f(s_1) \rightarrow s_2$ where $f(s_1) \rightarrow s_1$ is *yes* and $s_1 \rightarrow s_2$ is *unk*. Since the naturalistic basic inference examples $s_1 \rightarrow s_2$ contain various linguistic phenomena, models cannot rely on the heuristics for such examples.

Is poor performance of transitivity inference due to overfitting on verbs? To determine whether models do not overfit on clause-embedding verbs, we analyze the models under two additional settings using naturalistic transitivity datasets: (I) we use various templates other than "Someone f that s_1" to generate the main clause in $f(s_1)$, and (II) we flip the gold labels of 10% veridical inference $f(s_1) \rightarrow s_1$ instances, randomly sampled, instead of using gold labels uniquely fixed from verb types. These two complex settings expose models to more natural evaluation settings that consider the context-sensitive property of veridicality.

Data			**Model**	
$f(s_1) \rightarrow s_1$	$s_1 \rightarrow s_2$	$f(s_1) \rightarrow s_2$	**LSTM-B** (△)	**BERT-B** (△)
yes	*yes*	***yes***	97.9 (+0.8)	100.0 (0.0)
yes	*unk*	***unk***	0.0 (0.0)	2.3 (−6.6)
unk	*yes*	***unk***	99.0 (+1.9)	100.0 (0.0)
unk	*unk*	***unk***	99.2 (+1.9)	100.0 (0.0)

Table 8: Accuracies of models in the setting (I). (△) is the difference from the accuracy in Table 6.

Data			**Model**	
$f(s_1) \rightarrow s_1$	$s_1 \rightarrow s_2$	$f(s_1) \rightarrow s_2$	**LSTM-B** (△)	**BERT-B** (△)
yes	*yes*	***yes***	90.0 (−7.1)	93.6 (−6.4)
yes	*unk*	***unk***	2.2 (+2.2)	17.9 (+9.0)
unk	*yes*	***unk***	89.9 (−7.2)	94.0 (−6.0)
unk	*unk*	***unk***	98.3 (+1.0)	95.6 (+1.8)

Table 9: Accuracies of models in the setting (II). (△) is the difference from the accuracy in Table 6.

For evaluation setting (I) using various templates involving clause-embedding verbs, we manually select forty main clauses of the verb veridicality dataset (Ross and Pavlick, 2019) and provide additional templates. Table 7 shows examples of additional templates involving clause-embedding verbs used for generating veridical inference datasets.

Table 8 and Table 9 show the results for (I) and (II), respectively. These results show the same trends as those in Table 6, indicating that even when we consider the complexity of veridical inference in our analysis, the models fail to consistently perform composite inferences.

4.3 Analysis with data augmentation

We further hypothesize that even if the current models fail to consistently perform composite inferences, data augmentation with a small number of composite inference examples might allow models to learn transitivity inference. Thus, we evaluate models trained with basic inferences $f(s_1) \rightarrow s_1$ and $s_1 \rightarrow s_2$ and with a subset of the composite inferences $f(s_1) \rightarrow s_2$ on a naturalistic inference test set. Considering that models fail on composite inference $f(s_1) \rightarrow s_2$ where f

yes	*yes*	***yes***	100.0 ± 2.7	100.0 ± 0.0	98.8
yes	*unk*	***unk***	0.0 ± 0.0	8.9 ± 7.8	98.8
unk	*yes*	***unk***	97.1 ± 2.7	100.0 ± 0.0	44.9
unk	*unk*	***unk***	97.3 ± 2.6	100.0 ± 0.0	99.6
Test Overall			72.9 ± 2.0	77.2 ± 2.0	85.5

Table 10: Comparison between accuracies of humans and the models trained with the basic inference set.

is veridical and $s_1 \rightarrow s_2$ is *unk*, we gradually add veridical verbs (e.g., *know*) one-by-one to generate an additional training set of composite inference $f(s_1) \rightarrow s_2$ and analyze performance on a test set. Figure 2(a) shows that this data augmentation improved performance on test examples $f(s_1) \rightarrow s_2$ where f is veridical and $s_1 \rightarrow s_2$ is *unk*, while maintaining accuracy on the remaining examples in the test set. BERT achieved 100% accuracy over the entire test set by adding composite inferences generated from four veridical verbs, whereas in the case of LSTM twelve veridical verbs were needed to achieve the same accuracy.

To determine whether models augmented with composite inference examples learn the ability to combine basic inferences to perform transitivity inference, we analyze the performance of models where basic inference examples are not included in the training set. Figure 2(b) shows that models trained with only the basic inference set $f(s_1) \rightarrow s_1$ and a subset of the composite inference set $f(s_1) \rightarrow s_2$ also had improved accuracy. This result supports findings that models do not combine the basic inference $f(s_1) \rightarrow s_1$ and $s_1 \rightarrow s_2$, but rather predict the label for a composite inference $f(s_1) \rightarrow s_2$ by judging whether it is similar to inference patterns found in the training set.

4.4 Comparison with humans

To investigate how humans perform on transitivity inference tasks, we collect human judgements for a subset of our naturalistic inference dataset. We asked crowdsourced workers to label 960 transitivity inference examples involving all the clause-embedding verbs in Table 4. Following prior works involving crowdsourced NLI datasets (Zhang et al., 2017; Ross and Pavlick, 2019), we instructed raters to label each premise-hypothesis pair with the degree of entailment on a 5-point Likert scale, with 1 meaning a hypothesis is definitely not true given the premise, and 5 meaning a hypothesis is definitely true. We collected three annotations per pair on Amazon Mechanical Turk (see Appendix D for details), and the inter-rater agreement (the Pearson correlation among raters, averaged across both examples and raters) was 0.76. As model predictions are discrete (*yes* or *unk*), we discretized human scores into evenly sized bins, setting *yes* if the score was 4 or higher and set *unk* if the score was 3 or lower. We assumed the majority of three discretized labels as the final human judgement.

Table 10 shows that humans generally follow the distinction between veridical and non-veridical verbs traditionally assumed in the lexical semantics, as well as the transitivity of entailment relation. In particular, while as we saw in Section 4.2 the DNN models performed substantially below chance for transitivity inferences where $f(s_1) \rightarrow s_1$ is *yes* and $s_1 \rightarrow s_2$ is *unk*, human performance is near perfect for such inferences.

Interestingly, however, humans tend to predict incorrect labels for transitivity inferences where the verb f is non-veridical (so $f(s_1) \rightarrow s_1$ is *unk*) and the embedded inference $s_1 \rightarrow s_2$ is *yes*. This might be because a natural complement as in (6) induces veridicality bias (Ross and Pavlick, 2019), that is, no matter whether a complement verb f is veridical or non-veridical, humans tend to decide the truth value of $f(s_1)$ by judging whether its complement s_1 is true. Thus, judgement for $f(s_1) \rightarrow s_2$ coincides with that of $s_1 \rightarrow s_2$ in this case.

(6) $f(s_1)$: Someone **believed** that a man is jumping off a low wall.
s_1: A man is jumping off a low wall.
s_2: A man is jumping a wall.

5 Conclusion

We introduced an analysis method using transitivity inferences for evaluating systematic generalization capacities of NLI models. We found that current NLI models do not perform consistently well on transitivity inference tasks. Furthermore, data augmentation analysis suggested that models can memorize composite inference examples, but do not perform the intended transitivity inferences combining basic inference examples.

Overall, our results indicated that despite the impressive performance of DNN models on standard NLI datasets, there remains much room for improving their systematic generalization capacities with respect to combining basic inferential abilities on various linguistic phenomena. Regarding what is necessary for improving the systematic generalization capacity, one interesting possibility is explicitly feeding some form of logic-guided transitivity rules to models, which is left for future work. Our analysis method using transitivity can be an effective tool for further progress in the study of compositional NLI.

A Details about the Boolean logic fragment

Table 11 shows the context-free grammar used to generate sentences for Boolean logic reasoning with conjunction, disjunction, and negation. Each rewriting rule is paired with the corresponding semantic composition rule in standard Montagovian semantics to generate the logical form of a sentence (Montague, 1973; Heim and Kratzer, 1998). We use ten items each for proper names (PN), intransitive verbs (IV), and transitive verbs (TV). Each sentence is generated with a verb in the past tense.

For sentences with multiple NPs, we assume the surface-scope reading where the subject NP takes scope over the object NP. For instance, the sentence *Ann and Bob saw Chris or Daniel*, where the subject NP is conjunctive and the object NP is disjunctive, has the logical form $(\mathbf{see}(\mathbf{ann}, \mathbf{chris}) \vee \mathbf{see}(\mathbf{ann}, \mathbf{daniel})) \wedge (\mathbf{see}(\mathbf{bob}, \mathbf{chris}) \vee \mathbf{see}(\mathbf{bob}, \mathbf{daniel}))$.

There are two types of negation, sentential negation (SNEG) and verbal negation (VNEG), which are distinguished with respect to their scope interpretation. Thus, the sentence *Ann and Bob did not swim* has the logical form $\neg\mathbf{swim}(\mathbf{ann}) \wedge \neg\mathbf{swim}(\mathbf{bob})$, while the sentence *It is not the case that Ann and Bob did not swim* has the logical form $\neg(\mathbf{swim}(\mathbf{ann}) \wedge \mathbf{swim}(\mathbf{bob}))$.

To generate a premise-hypothesis pair (s_1, s_2) using this Boolean logic fragment, we first generate a sentence s_1 and derive its logical form F_1 using the grammar in Table 11. We then randomly select one of the atomic formulas appearing in F_1, say A, and takes its positive (A) or negative ($\neg A$) form, which is in turn converted to the hypothesis sentence s_2 using the same grammar. The gold label (*entailment* or *non-entailment*) for the pair (s_1, s_2) is determined by checking whether F_1 logically entails A or $\neg A$ using a first-order-logic theorem prover[3].

B Training details

In all experiments, we trained models on eight NVIDIA DGX-1 Tesla V100 GPUs. The runtime for training each model was about 1-8 hours, depending on the size of the training set. The order of training instances was shuffled for each model.

C Supplementary results on the random train-test split

To confirm that our transitivity inference dataset is not excessively difficult, we conducted additional experiments using the random $9:1$ train:test split of transitivity inference ($f(s_1) \rightarrow s_2$) datasets. We evaluate models under two settings: (i) models trained with the train split of transitivity inference datasets and (ii) models trained with the train split mixed with MNLI. Table 12 shows the results on the random train-test split of our full-synthetic transitivity dataset, and Table 13 shows the results on the random train-test split of our naturalistic transitivity dataset. These results showed that regardless of the existence of MNLI in the training set, models achieved perfect performance on our transitivity inference test set with the standard random train-test split setting.

D Human judgement details

Using Amazon Mechanical Turk, we collected human judgements for 960 naturalistic veridical inference examples and 960 naturalistic transitivity inference examples. We required raters to have completed at least 5,000 approved tasks to maintain a 99% approval rating. Raters could indicate by a checkbox that one or both sentences did not make sense, but no rater clicked the checkbox. We collected three annotations per pair and paid $0.06 per labeled pair.

Since humans predict incorrect labels for some composite inference examples $f(s_1) \rightarrow s_2$ where the verb f is non-veridical, we checked the accuracy of human judgement on a set of premise-hypothesis pairs $f(s_1) \rightarrow s_1$ and $f(s_1) \rightarrow s_2$ involving each non-veridical verb, as shown in Table 14. Annotators tended to incorrectly make judgements for both $f(s_1) \rightarrow s_1$ and $f(s_1) \rightarrow s_2$. Regarding accuracy for each non-veridical verb, annotators correctly drew inferences containing *wish* and *hope*, while they tended to draw inferences containing *claim* and *hear* incorrectly.

In comparison with the previous veridicality dataset MegaVeridicality2 (White et al., 2018), the accuracy tended to be lower than that in MegaVeridicality2[4]. As (7) shows, while a simple complement is used for MegaVeridicality2, a natural complement like (8) might induce veridicality

---

E Supplementary results with data augmentation

In Section 4.3, we gradually added a subset of the composite inferences $f(s_1) \rightarrow s_2$ involving a veridical verb (e.g., *know*) to the training set and evaluated the performance of models on a naturalistic inference test set. We also evaluated the performance of models under two conditions: (a) models trained with the basic inference set $s_1 \rightarrow s_2$ and a subset of the composite inference set $f(s_1) \rightarrow s_2$ and (b) models trained with a subset of the composite inference set $f(s_1) \rightarrow s_2$. Figure 3(a) shows that the models significantly improved accuracy on composite inferences except for the test example $f(s_1) \rightarrow s_2$, whose label dif-

Table 14: Accuracy (%) of human judgements for each non-veridical verb. MegaV2 indicates the percentage of those annotators who judge each verb to be non-veridical in MegaVeridicality2 (White et al., 2018). A number in parentheses is a difference from the accuracy in MegaVeridicality2.

fered from that of $s_1 \rightarrow s_2$. Moreover, their performance was maintained even without composite inference examples in the training set. This indicates that models predict labels for the composite inference example only by judging whether it is similar to the basic inference example in the training set.

Figure 3(b) shows the result when models are trained only with a subset of the composite inference set $f(s_1) \rightarrow s_2$. As non-veridical verbs are not included in the training set in this setting, the models predict labels for composite inferences involving non-veridical verbs by judging whether they are similar to composite inferences involving veridical verbs in the training set. The models thus fail on composite inference examples $f(s_1) \rightarrow s_2$ where f is non-veridical and $s_1 \rightarrow s_2$ is *yes*. The labels of such non-veridical inference examples are opposite to those of veridical inference examples in the training set.

A Neural Few-Shot Text Classification Reality Check

Abstract

Modern classification models tend to struggle when the amount of annotated data is scarce. To overcome this issue, several neural few-shot classification models have emerged, yielding significant progress over time, both in Computer Vision and Natural Language Processing. In the latter, such models used to rely on fixed word embeddings before the advent of transformers. Additionally, some models used in Computer Vision are yet to be tested in NLP applications. In this paper, we compare all these models, first adapting those made in the field of image processing to NLP, and second providing them access to transformers. We then test these models equipped with the same transformer-based encoder on the intent detection task, known for having a large number of classes. Our results reveal that while methods perform almost equally on the ARSC dataset, this is not the case for the Intent Detection task, where the most recent and supposedly best competitors perform worse than older and simpler ones (while all are given access to transformers). We also show that a simple baseline is surprisingly strong. All the new developed models, as well as the evaluation framework, are made publicly available[1].

1 Introduction

Text classification often requires a large number of mappings between texts and target classes, so that it is challenging to build few-shot text classification models (Geng et al., 2019). With the recent advances of transformer-based models (Devlin et al., 2018; Wolf et al., 2019) along with their fine-tuning techniques (Sun et al., 2019), text classification has significantly improved. In few-shot settings, methods based on these extracted text representations have been historically made of semi-supervision, especially thanks to pseudo-labeling (Blum and Mitchell, 1998; Mihalcea, 2004; Zhi-Hua Zhou and Ming Li, 2005), which aims at propagating known labels to unlabeled data points in the representational space. Such methods depend on the number of collected unlabeled data, which can also be costly to obtain (Charoenphakdee et al., 2019), and also suffer from the infamous pipeline effect in NLP (Tenney et al., 2019), as cascade processing tends to make errors accumulate. In order to address the hindrance of collecting unlabeled data, modern approaches include unsupervised data augmentation techniques (Xie et al., 2019). It consists of generating samples through well-established text augmentation techniques in Neural Machine Translation, such as backtranslation (Sennrich et al., 2015; Edunov et al., 2018), and then use a consistency loss, training the classifier to assign the same prediction to all variations of the same sample text. While collecting new pseudo-labels can therefore be overcome by manipulating the dataset (especially using data augmentation techniques), the pipelining error accumulation effect instead calls for new neural architectures supporting scarcity of labeled data in an end-to-end fashion. Such end-to-end few-shot neural architectures for few-shot classification were discovered in image processing – it includes Matching Networks (Vinyals et al., 2016), Prototypical Networks (Snell et al., 2017) plus a follow-up known as Prototypical Networks++ (Ren et al., 2018), and Relation Networks (Sung et al., 2018). Ultimately Induction Networks (Geng et al., 2019) is a meta-learning based method dedicated to few-shot text classification, supposedly the state-of-the-art. Since our contribution considers this family of models, we will further detail them in Section 2. Nonetheless, it is important to stress that most of these neural architectures were originally devised to integrate image feature extractors. Despite both text and image relying on features extractors, a paragraph or sentence of few words hardly convey

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 935–943
April 19 - 23, 2021.

as much information as a full-fledged three-canals 600×400 image ($720,000$ numerical values intrinsically). It is therefore of the utmost practical interest to validate and compare if what works best for end-to-end few-shot *image* classification is the same for end-to-end few-shot *text* classification. Moreover, when applying these end-to-end few-shot models to text, two main system components are into action: the text feature extractor itself and the downstream part of the neural network that provides a learning strategy over few shots. If we want to compare these systems, we need to plug the same feature extractor (hopefully the best one, that is transformer-based currently) into each end-to-end model. For the time being, the literature on end-to-end few-shot text classification compare aforementioned techniques using a different text extractor for each system, which is the one available when the technique was discovered – these text encoding varying greatly (Section 3.3). From that point-of-view, it is hardly possible to conclude if the improvement over time in few-shot text classification is due to new few-shot learning techniques or plainly to the significant advances made by text feature extractors. The same applies to vectors metrics: one method can use the cosine and another the euclidean distance, and that choice alone can impact conclusions made on the method being the state-of-the-art, although it could well rely only on the metric at work. Ultimately, experimental setups are usually restricted to one dataset, and evaluation schemes are heterogeneous among papers (Yu et al., 2018a),

- We revise different end-to-end neural architectures for few-shot text classification using the *same* transformer-based feature extractor,
- We investigate how these re-implemented state-of-the-art solutions compete with very simple baselines found to be yet very competitive for few-shot classification in the field of image-processing,
- We introduce an evaluation framework based on a number of intent detection datasets which is significantly bigger than what is usually used as evaluation in seminal papers transposing each of these architectures from image to text classification,
- The entire framework used in this paper, including all the re-implemented methods plugged with up-to-date transformers, is provided as an open-source repository for further research.

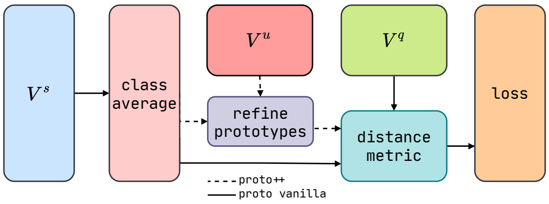
In a nutshell, we will demonstrate that providing a transformer-based encoder to a previously obsolete few-shot technique makes it the state-of-the-art again, that standard baselines are surprisingly strong, and that Induction Networks, while performing well for binary sentiment classification, struggles to perform correctly in the most common setups of few-shot text classification.

2 Few-Shot Classification Methods

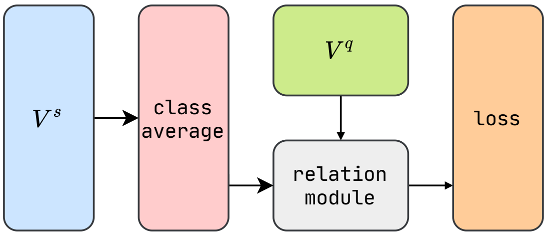
In this section, we will describe the few-shot learning methods. In the following section, sentence vectors derived from the sentence encoder are denoted v. V^s, V^q, and V^u represent vectors for support, query, and unlabeled points, respectively. The number of shots is denoted K, and the number of classes per episode is denoted C. The kth support vector of class c is denoted $v^s_{c,k}$. In the equations, $s^q_{i,j}$ (resp. $s^q_{i,c}$) will denote the similarity between the ith query vector and the jth support vector (resp. the cth class). Similarly, $s^u_{i,j}$ represents the similarity between the ith unlabeled sample and the jth support vector. When needed, the number of unlabeled data is denoted U. For each method relying on a given similarity or distance metric, we devise two experiments, using either the cosine similarity or the euclidean distance. Those additional experiments are crucial, as they allow us to compare methods directly, without introducing a metric choice bias. Architectures of the different few-shot approaches are illustrated in Figure 1. They are each detailed in Section 2.2 and onwards, yet we first introduce the common building blocks among all methods in what follows.

2.1 Common building blocks

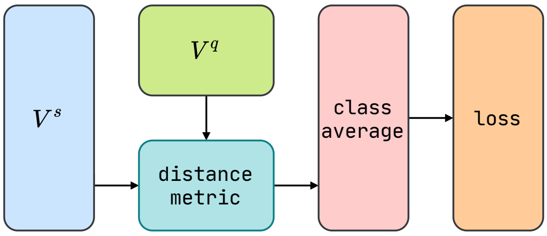
Class average All Matching, Prototypical, and Relation Networks contain a *class average* block. This step is used to directly compare a query point to a given class in order to make a prediction for this query point. In both Matching and Prototypical Networks, this step averages embeddings of support points for each class (they are class `prototypes`), which are then compared to query points to output class probabilities. In Matching Networks, this block averages similarity scores class-wise. On the contrary, in Induction Networks,



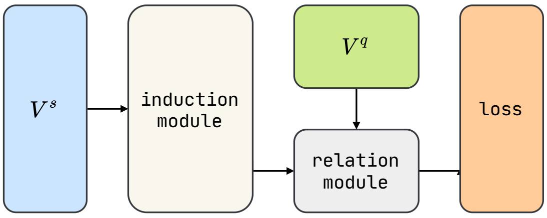
(a) Prototypical Network, with the optional proto++ step. In the original Prototypical Networks, the euclidean distance is used as distance metric.



(b) Relation Network



(c) Matching Network. In the original Matching Networks, the cosine similarity is used as a distance metric.



(d) Induction Network

Figure 1: Few-Shot classification methods and variants used in our experiments.

this step is lacking as support points are converted into prototypes using an Induction Layer, which aims at finding a better way to aggregate such knowledge than using the average (Section 2.5).

Loss Matching and Induction Networks both use the mean squared error (MSE) loss. Other methods use cross-entropy (CE). We implemented both losses on Matching and Induction networks, and it leads to very similar results – and sometimes, slightly better using CE. We therefore report results for all models using CE due to space limitations. Note that both losses are available in the publicly available source code. The cosine similarity being bounded, it would not make sense to directly apply such a loss on cosine similarities. To overcome this issue, we multiply the cosine similarities by a constant factor of 5, allowing them to reach more extreme values, hence ensuring that probabilities obtained by softmax are sparse enough.

2.2 Matching Networks

Introduced by Vinyals et al. (2016), Matching Networks (Figure 1c) rely on the comparison between query and support vectors using the cosine similarity in the seminal paper. After similarities between a query point and all support points are computed, they are averaged for each class. The predicted label for a given query point is the one with the highest average cosine similarity. In our notation framework, this process is summed up in Equation 1.

$$s_{i,c}^{q,\text{matching}} = K^{-1}\sum_{k=1}^{K}\frac{\left(v_i^q\right)^T v_{c,k}^s}{\|v_i^q\|_2\|v_{c,k}^s\|_2} \qquad (1)$$

2.3 Prototypical Networks

Prototypical Networks (Figure 1a) were introduced by Snell et al. (2017) as an extension of Matching Networks. After obtaining support vectors from the encoder, a class-wise average operation is done, as in Equation 2. This results in C prototypes denoted $\{p_c, c \in [\![1, C]\!]\}$, each one being the representative of a class. Then, a distance metric compares all query points to all prototypes. For each query point, the predicted class is the one for which this distance is the smallest. In the original Prototypical Networks, the euclidean distance was used, as in Equation 3. We also add the cosine similarity-based distance in our experiments in order to measure the impact of selecting another distance metric.

$$p_c = K^{-1}\sum_{k=1}^{K} v_{c,k}^s \qquad (2)$$

$$s_{i,c}^{q,\text{proto}} = \frac{\exp\left(-\|v_i^q - p_c\|_2^2\right)}{\sum_{c'=1}^{C}\exp\left(-\|v_i^q - p_{c'}\|_2^2\right)} \qquad (3)$$

An extension to Prototypical Networks was proposed by Ren et al. (2018), where unlabeled data points are used along with support and query points. After computing each class's prototype, a soft k-means technique is applied to further refine those prototypes using unlabeled data points. The refined prototypes, denoted $\tilde{p}_c$, are derived using Equation 4. This additional step aims at correcting the support points selection bias and making the method more robust.

$$\tilde{p}_c = \frac{\sum_{k=1}^{K} v_{c,k}^{s} + \sum_{i=1}^{U} v_i^u s_{i,c}^{u,\text{proto}}}{K + \sum_i s_{i,c}^{u,\text{proto}}} \quad (4)$$

2.4 Relation Networks

Relation Networks (Sung et al., 2018) challenge the idea of using a pre-defined metric. The Relation Module takes as an input a query vector $v_i^q \in \mathbb{R}^d$, and the prototype of a class $p_c \in \mathbb{R}^d$, the latter being obtained the same way as in Prototypical Networks (Equation 2). The idea is to use a relation module, modeling the relationship between those two vectors, yielding a similarity score $s_{i,c} \in (0,1)$. Instead of using a pre-defined distance metric like the euclidean or the cosine one, this approach allows such networks to learn this metric by themselves. Two different relation module architectures exist.

base The `base` relation module concatenates both v_i^q and p_c, and applies a small feed-forward neural network composed of two linear layers, with a ReLU activation function in between. The formula for this given relation module is described in Equation 5, where $C(\cdot,\cdot)$ denotes the concatenation operator, $f(\cdot)$ denotes the ReLU activation function, and w, M_1, M_2 are learnable parameters.

$$s_{i,c}^{q,\text{rel-base}} = \langle w, M_2 (f (M_1 (C (v_i^q, p_c))))\rangle \quad (5)$$

NTL Introduced by Socher et al. (2013), the **N**eural **T**ensor **L**ayer relation module uses intermediate learnable matrices $M_k \in \mathbb{R}^{d,d}$ to model the relation between support vectors and prototypes. The similarity score for this relation module is obtained using Equation 6, where w is a learnable parameter. Following the work done by Geng et al. (2019), we fix the number h of intermediate matrices to 100 in all our experiments.

$$s_{i,c}^{q,\text{rel-ntl}} = \left\langle w, z_{i,c}^{\text{rel-ntl}} \right\rangle \quad , \quad w \in \mathbb{R}^h \quad (6)$$

$$z_{i,c,t}^{q,\text{rel-ntl}} = f\left((v_i^q)^T M_t p_c \right) \quad , \quad t \in [\![1, h]\!] \quad (7)$$

2.5 Induction Networks

Induction Networks (Geng et al., 2019) aims at finding a general representation of each class in the support set to compare to new queries. They are composed of both an induction module and a relation module. The main motivation for such networks is that representing the class by the average vector of its data points – what is done in Prototypical and Relation networks – is too restrictive. The first part, the induction module, leverages a dynamic routing (Sabour et al., 2017) algorithm. In their contribution, Geng et al. (2019) show that their method can better *induce* (hence their name) and generalize class-wise representations. For the second part, an NTL Relation Module is used: this is the same as the one introduced earlier (Section 2.4). Such networks are illustrated in Figure 1d.

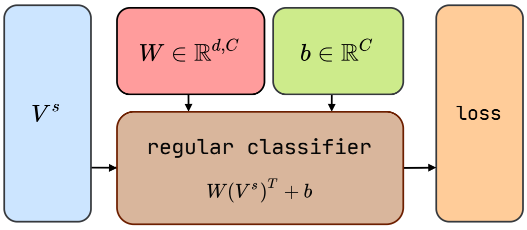
As in (Geng et al., 2019), we fix the number of routing iterations to 3, and the number of matrices in the NTL to 100.

2.6 Classifier Baselines

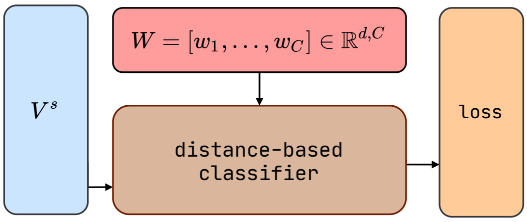
Few-shot learning algorithms are designed to overcome the data scarcity problem. With the tremendous shift in the architecture of sentence encoders using transformers, control baselines are needed to validate their ability to learn from few samples. For this reason, we include as a first `Baseline` model a traditional classifier, as described by Equation 8, added on top of BERT. Both W and b are learnable parameters, fine-tuned on the support vectors V^s. In our experiments, this method will henceforth be referred to as `Baseline`.

$$s_{i,j}^{q,\text{baseline}} = (W v_i^q + b)_j \quad ; \quad W \in \mathbb{R}^{C,d} \quad (8)$$

In addition to this `Baseline` model, we also implement a variant of it, which will henceforth be referred to as `Baseline++`. In that second baseline, the classifier design differs as follows: it measures similarities to a learnable vector instead of transforming vectors into logits using a linear layer. The matrix W used in the `Baseline` model can be writen as $[w_1, \ldots, w_C]$ where each $w_k \in \mathbb{R}^d$ is a weight vector corresponding to the k^{th} class. To measure the similarity between class j and a query vector v_i^q, we compute the similarity scores in Equation 9. After all scores $s_{\cdot,\cdot}$ are computed, we then obtain a probability vector through



(a) Baseline Network.



(b) Baseline++ Network. The distance-base classifier can either use cosine or euclidean distance

Figure 2: Few-Shot classification baselines used in our experiments.

normalization using the softmax function).

$$s_{i,j}^{q,\text{baseline++}} = \frac{w_j^T v_i^q}{\|w_j\|_2 \|v_i^q\|_2} \tag{9}$$

As in Prototypical Networks, the derived vectors $[w_1, \ldots, w_C]$ can be interpreted as class prototypes. For both baselines, at each training episode, the weights W and b are initialized, and the whole model is fine-tuned for a few iterations using support samples. This is important in practice, as it teaches the sentence encoder – a transformer, see Section 3.3 – how to produce good enough embeddings for the downstream classifier to learn efficiently. At test time, the same process is used – using test labels –, except that we freeze the encoder's weights and only fine-tune the classifier part. The baselines architectures are represented in Figure 2.

3 Experimental Setup

3.1 Few-Shot Evaluation Setup

Introduced by Vinyals et al. (2016), few-shot classification corresponds to the case when a classifier must adapt to new classes, denoted here as $\mathcal{C}_{test}$, unseen during training, and only given a few labeled examples of these new classes. To this end, the approaches assume that during training, a task-significant set of classes noted $\mathcal{C}_{train}$ is available, along with an accordingly task-significant number of labeled data for each class $c_{train_i} \in \mathcal{C}_{train}$. For each training episode, C classes are sampled from $\mathcal{C}_{train}, C \ll |\mathcal{C}_{train}|$. Then, K support examples and Q query examples are randomly drawn for each of these classes. The model is then iteratively trained using both query and support points.

At testing time, the same sampling strategy is made, this time drawing classes among $\mathcal{C}_{test}$, with $\mathcal{C}_{test} \cap \mathcal{C}_{train} = \emptyset$. The model is then evaluated on its ability to predict labels for the Q query samples, using the K support samples (unless otherwise stated, C, Q, and K values are the same at both testing and training time).

This training procedure is called C-way K-shot classification. In all our experiments, we used $K = Q = 5$. Concerning the value of C, it is fixed to 2 for ARSC, as this dataset is already composed of binary classification tasks. Regarding the intent detection datasets we introduce later (Section 3.2), in order to see the shift between ARSC binary tasks and the more common 5-way evaluation (Geng et al., 2019; Ren et al., 2018), we measured performances of the different models with C ranging from 2 to 5.

3.2 Datasets

In this section, we describe the datasets used in our evaluation framework. The first one is a popular sentiment classification dataset, while the others are intent detection datasets. All datasets are public and in English.

ARSC The **A**mazon **R**eview **S**entiment **C**lassification dataset (Blitzer et al., 2007) is composed of product reviews from 27 product categories. Each review belongs to one of the 27 domains, and contains a grade ranging from 1 to 5 stars. The usual setup (Yu et al., 2018b; Geng et al., 2019) to evaluate few-shot classification with this dataset is as follows: for each of $p \leq 27$ product category and $2 \leq t \leq 5$ score thresholds, $\mathcal{E}_{ARSC} = p \times t$ binary classification evaluation tasks are created. In each of these $p \times 4$ tasks, a competitor model must learn to classify negative ($< t$) and positive ($\geq t$) reviews. To build our test tasks, we consider the same product categories as previous works (Yu et al., 2018b; Geng et al., 2019), which are *Books*, *DVD*, *Electronics*, *Kitchen*, and $t = 3$ (thresholds are picked in the $\{2, 4, 5\}$ set) – hence 12 binary classification test tasks in our benchmark for this dataset.

Each of these twelve evaluation tasks comes with a number of support test samples ($K = Q = 5$ as stated previously). Nonetheless, in (Yu et al., 2018b) the same 5 samples per testing class are fixed for all experiments[2], which leads to a significant selection bias towards these 5 randomly selected samples used throughout the evaluation. In order to get more consistent results, we ran additional experimental runs, each of them selecting randomly new support samples. In the ARSC result table (table 1), this corresponds to the last column (`BERT + Sample shots`).

OOS The **O**ut **O**f **S**cope dataset[3] (Larson et al., 2019) is an intent detection dataset containing 150 equally-distributed classes. While initially used for out-of-scope prediction, it was also motivated by a high number of classes, a low number of examples per class (150), and its chatbot life-like style. In our experiments, we discard the out-of-scope class, keeping the remaining 150 classes to work with.

Liu Introduced by Liu et al. (2019), this intent detection dataset consists in 54 classes. This dataset was collected on the Amazon Mechanical Turk platform, where workers were given an intent and had to formulate queries for this intent with their own words. It is highly imbalanced: the most common class (`query`) holds 5, 920 samples while the least common one (`volume_other`) 24 samples.

TREC28 TREC[4] is an open-domain fact-based dataset for question classification. We use the 50 labels version of the dataset but remove the labels which have less than 40 samples. This filtering process yields a dataset with 28 classes, ranging from 40 to 962 samples per class.

3.3 Sentence Encoder

In previous works comparing few-shot text classification methods, sentence encoders were not always the same. For example, Yu et al. (2018b) use a CNN on top of word embeddings, while Geng et al. (2019) use a Bi-LSTM. Those differences make the results hard to compare since they do not use the same method to convert sentences into vectors. In our experiments, in order to reduce this selection bias, and since it is now the state-of-the-art in many applications, we use a BERT (Devlin et al., 2018) encoder, using models from the Hugging Face (Wolf et al., 2019) team.

For each dataset, instead of using an off-the-shelf pre-trained model, we fine-tune it on the masked language modeling task, as it greatly improves the quality of embeddings (Sun et al., 2019; Xie et al., 2019). This fine-tuned transformer is then used as input for all few-shot models.

4 Observations

We report results for the ARSC dataset in Table 1, and results for the Intent Detection tasks in Table 3.

4.1 Baselines are surprisingly strong

Few-shot learning methods were originally used to overcome data scarcity. In those situations, training a classifier on top of a small dataset – in our case, 5 samples per class – can be hard. However, our experiments on ARSC show that the `Baseline` and `Baseline++`, plain and simple classifiers, get surprisingly close to state-of-the-art results. Table 2 provides four correct and four incorrect classification examples for the `Baseline` model.

While it fails to predict the correct text label for some shots, it is also able to correctly classify sentences such as *What do I take home ?* among the 50 test classes of the OOS dataset. On the ARSC dataset, it is also important to note that the `Baseline++` model is significantly better than the `Baseline`, and is even on par with all other architectures, except `Prototypical Networks`.

4.2 Sample selection bias

The mean accuracy difference between the last and the second columns of Table 1 accounts for the difference of randomly selecting new support samples at each iteration (last column) as opposed to picking the same fixed pool of support samples as done previously (second to last column). We can see that this difference alone is in the range of the increments brought by each model over time (baselines aside, bringing from 1 point up to 2.6 points for Prototypical Networks). This huge gap shows the importance of using evaluation tricks like cross-validation, instead of evaluating only for one run over a fixed set of shots.

4.3 Impact of switching to transformers

One of the main contributions of our paper is to compare few-shot learning methods with the lowest bias possible (see Section 3.3). On the ARSC dataset, using transformers drastically changes the

performances of all methods. When feeding the same transformer-based encoder to all few-shot methods, Prototypical Networks are now on top, whereas metric learning approaches (Induction & Relation Networks) tend to struggle, almost reaching the same performances as Matching Networks. Such metric learning approaches rely on various weight matrices and parameters, while more traditional approaches (`Matching`, `Proto`) do not use any parameter apart from the encoding step. This hints that the upstream transformer does most of the learning and is able to model the embedding space well enough such that no more additional metric learning is needed. The massive increase in embedding quality brought by the BERT encoder makes Prototypical Network approaches reclaim the state-of-the-art position.

4.4 The curious case of induction networks

When Geng et al. (2019) introduced Induction Networks, both the ARSC dataset and a private intent detection dataset were used for evaluation (publicly unavailable). Our experiments of this method on the ARSC dataset confirm those results in an acceptable range, even when trying to get more consistent results using multiple random seeds. Nonetheless, the performances of this method are underwhelming on all three intent detection datasets, even when matching the binary classification scenario using $C = 2$. Those poor performances were observed both on the test set

as well as the train set, discarding the over-fitting argument. Such a big performance gap between sentiment and intent classification tasks show that Induction Networks, while suited for the former, are not directly applicable to any type of task.

4.5 On metric choice

Prototypical Networks were originally designed to do better than Matching Networks. The two differences between them are the placement of the `class average` step, and the choice of the metric (cosine for Matching, euclidean for Prototypical). Our results show that metric choice yields a big gap in performances for both methods, this gap being larger than the gap caused by the model design. This hints that when using a pre-defined metric – excluding the case of metric learning –, choosing the right metric is of paramount importance. Moreover, while `Matching Networks` were designed to use the cosine distance, we found here that they perform significantly better when equipped with the Euclidean distance (on all datasets for all number of given test classes).

4.6 On architectural choices

Overall, Prototypical Networks come on top of every intent detection dataset. More importantly, their gap between other competing approaches is wider as the number of classes increases. This result is important, as in practice, the number of classes is likely to be higher than what is used in the literature. The extended variant, proto++, obtains mixed results. While this shows that using unlabeled data can have some benefits, we also observe that the proto++ way of integrating this external knowledge is perfectible. Ultimately, note that our results do not mirror Computer Vision results. Since few-shot learning methods are used on top of embeddings, we could emit the hypothesis that they can be applied to any embeddings, regardless of the field. However, while Relation Networks, for example, were performing well in Computer Vision classification tasks – the tasks which they were originally designed for – as well as text classification – back in the days when transformers did not exist –, this is not the case anymore. The drawback is that all methods are very sensitive to the feature extractor used in prior steps.

5 Conclusion

We provided a fair comparison for end-to-end neural few-shot text classification methods discovered over the last few years. When they are all equipped with a transformer-based text encoder, we show that Prototypical Networks become the state-of-the-art again. We also found that a traditional classifier trained on few shots yields very competitive results, especially when given shots are re-sampled at each iteration. Ultimately, we also demonstrated the significant impact of the vector metric, illustrated by Matching Networks strongly improving by only replacing the cosine by the euclidean distance. The complete source code with the re-implementation of all the tested methods and evaluation framework used in this study is publicly available[5] – we hope that it will help the community build upon consistent comparative experiments.

Abstract

State-of-the-art multilingual machine translation relies on a universal encoder-decoder, which requires retraining the entire system to add new languages. In this paper, we propose an alternative approach that is based on language-specific encoder-decoders, and can thus be more easily extended to new languages by learning their corresponding modules. So as to encourage a common interlingua representation, we simultaneously train the N initial languages. Our experiments show that the proposed approach outperforms the universal encoder-decoder by 3.28 BLEU points on average, while allowing to add new languages without the need to retrain the rest of the modules. All in all, our work closes the gap between shared and language-specific encoder-decoders, advancing toward modular multilingual machine translation systems that can be flexibly extended in lifelong learning settings.

1 Introduction

Multilingual machine translation is the ability to generate translations automatically across a (large) number of languages. Research in this area has attracted a lot of attention in recent times both from the scientific and industrial community. Under the neural machine translation paradigm (Bahdanau et al., 2015), the opportunities for improving this area have dramatically expanded. Thanks to the encoder-decoder architecture, there are viable alternatives to expensive pairwise translation based on classic paradigms[1].

The main proposal in this direction is the universal encoder-decoder (joh, 2017) with massive multilingual enhancements (Arivazhagan et al., 2019). While this approach enables zero-shot translation and is beneficial for low-resource languages, it has multiple drawbacks: (i) the entire system has to be retrained when adding new languages or data; (ii) the quality of translation drops when adding too many languages or for those with the most resources (Arivazhagan et al., 2019); and (iii) the shared vocabulary grows dramatically when adding a large number of languages (especially when they do not share alphabets). Other limitations include the incompatibility of adding multiple modalities such as image or speech.

In this paper, we propose a new framework that can be incrementally extended to new languages without the aforementioned limitations (§3). Our proposal is based on language-specific encoders and decoders that rely on a common intermediate representation space. For that purpose, we simultaneously train the initial N languages in all translation directions. New languages are naturally added to the system by training a new module coupled with any of the existing ones, while new data can be easily added by retraining only the module for the corresponding language.

We evaluate our proposal on three experimental configurations: translation for the initial languages, translation when adding a new language, and zero-shot translation (§4). Our results show that the proposed method is better in the first configurations by improving the universal system: by 0.40 BLEU points on average in the initial training and by 3.28 BLEU points on average when adding new languages. However, our proposed system is still lagging behind universal encoder-decoder in zero-shot translation.

2 Related Work

Multilingual neural machine translation can refer to translating from one-to-many languages (Dong et al., 2015), from many-to-one (Zoph and Knight, 2016) and many-to-many (joh, 2017). Within the many-to-many paradigm, existing approaches can

---

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 944–948
April 19 - 23, 2021.

be further divided into shared or language-specific encoder-decoders.

Shared Encoder-Decoder. joh (2017) feed a single encoder and decoder with multiple input and output languages. Given a set of languages, a shared architecture has a universal encoder and a universal decoder that are trained on all initial language pairs at once. The model shares parameters, vocabulary and tokenization among languages to ensure that no additional ambiguity is introduced in the representation. This architecture provides a simple framework to develop multilingual systems because it does not require modifications of a standard neural machine translation model, and information is easily shared among the different languages through common parameters. Despite the model's advantages in transfer learning, the use of a shared vocabulary and embedding representation forces the model to employ a vocabulary that includes tokens from all the alphabets used. Additionally, recent work (Arivazhagan et al., 2019), that imposes representational invariance across language, shows increasing the number of languages varies the quality of the languages already in the system (generally enhancing low-resource pairs but being detrimental for high-resource pairs).

Language-specific Encoder-Decoders which may or may not share parameters at some point.

Sharing parameters. Firat et al. (2016b) proposed extending the bilingual recurrent neural machine translation architecture (Bahdanau et al., 2015) to the multilingual case (Vázquez et al., 2019; Lu et al., 2018) by designing a shared attention-based mechanism between the language-specific encoders and decoders to create a language independent representation. As the language specific components rely on the shared modules, modifying those components to add a new language or add further data to the system would require retraining the whole system (similarly to the previous shared approach). (Lakew et al., 2018) proposes a model based on the addition of new languages to an already trained system by vocabulary adaptation and transfer learning. While limited, it requires some retraining to adapt the model to the new task.

No sharing. The system proposed by Escolano et al. (2019) is trained on language-specific encoders and decoders based on joint training without parameter or vocabulary-sharing and on enforcing a compatible representation between the jointly trained languages. The advantage of the approach is that it does not require retraining to add new languages and increasing the number of languages does not vary the quality of the languages already in the system. However, the system has to be trained on a multi-parallel corpus and it does not scale well when there is a large number of languages in the initial system, since all encoders and decoders have to be trained simultaneously.

3 Proposed Method

Our proposed approach trains a separate encoder and decoder for each of the N languages available without requiring multi-parallel corpus. We do not share any parameter across these modules, which allows to add new languages incrementally without retraining the entire system.

3.1 Definitions

We next define the notation that we will be using when describing our approach. We denote the encoder and the decoder for the ith language in the system as e_i and d_i, respectively. For language-specific scenarios, both the encoder and decoder are considered independent modules that can be freely interchanged to work in all translation directions.

3.2 Language-Specific Proposed Procedure

In what follows, we describe the proposed training procedure in two steps: joint training and adding new languages.

Joint Training The straightforward approach is to train independent encoders and decoders for each language. The main difference from standard pairwise training is that, in this case, there is only one encoder and one decoder for each language, which will be used for all translation directions involving that language. The training algorithm for this language-specific procedure is described in Algorithm 1.

For each translation direction $s_{i,j}$ in the training schedule S with language i as source and language j as target, the system is trained using the language-specific encoder e_i and decoder d_j.

Adding New Languages Since parameters are not shared between the independent encoders and decoders, the joint training enables the addition of

Algorithm 1 Multilingual training step

```
procedure MULTILINGUALTRAININGSTEP
    $N \leftarrow$ Number of languages in the system
    $S = \{s_{0,0}, ..., s_{N,N}\} \leftarrow \{(e_i, d_j)\}$
    $E = \{e_0, ..., e_N\} \leftarrow$ Language-specific encs.
    $D = \{d_0, ..., d_N\} \leftarrow$ Language-specific decs.
    for $i \leftarrow 0$ to $N$ do
        for $j \leftarrow 0$ to $N$ do
            if $s_{i,j} \in S$ then
                $l_i, l_j = get\_parallel\_batch(i, j)$
                $train(s_{i,j}(e_i, d_j), l_i, l_j)$
```

new languages without the need to retrain the existing modules. Let us say we want to add language $N + 1$. To do so, we must have parallel data between $N + 1$ and any language in the system. For illustration, let us assume that we have $L_{N+1} - L_i$ parallel data. Then, we can set up a new bilingual system with language L_{N+1} as source and language L_i as target. To ensure that the representation produced by this new pair is compatible with the previously jointly trained system, we use the previous L_i decoder (d_{li}) as the decoder of the new L_{N+1}-L_i system and we freeze it. During training, we optimize the cross-entropy between the generated tokens and L_i reference data but update only the parameters of to the L_{N+1} encoder ($e_{l_{N+1}}$). By doing so, we train $e_{l_{N+1}}$ not only to produce good quality translations but also to produce similar representations to the already trained languages. Following the same principles, the L_{N+1} decoder can also be trained as a bilingual system by freezing the L_i encoder and training the decoder of the $L_i - L_{N+1}$ system by optimizing the cross-entropy with the L_{N+1} reference data.

4 Experiments in Multilingual Machine Translation

In this section we report machine translation experiments in different settings. Since the main difference between the shared and the language-specific encoders-decoders lies in whether they retrain the entire system when adding new languages, we accordingly design our experiments to compare the systems under this condition.

4.1 Data and Implementation

We used 2 million sentences from the *EuroParl* corpus (Koehn, 2005) in German, French, Spanish and English as training data, with parallel sentences among all combinations of these four languages (without being multi-parallel). For Russian-English, we used 1 million training sentences from the *Yandex* corpus[2]. As validation and test set, we used *newstest2012* and *newstest2013* from WMT[3], which is multi-parallel across all the above languages. All data were preprocessed using standard Moses scripts (Koehn et al., 2007)

We evaluate our approach in 3 different settings: (i) the *initial* training, covering all combinations of German, French, Spanish and English; (ii) *adding* new languages, tested with Russian-English in both directions; and (iii) *zero-shot* translation, covering all combinations between Russian and the rest of the languages. Additionally we compare two configurations which consists in using non-tied or tied embeddings. In the language-specific approach tied embeddings consists in using language-wise word embeddings: for one language, we use the same word embeddings. Whereas, in the case of non-tied, the encoder and the decoder of each language have different word embeddings. Tied embeddings in the shared system means that both encoder and decoder share the same word embeddings.

All experiments were done using the Transformer provided by Fairseq(Ott et al., 2019) [4]. We used 6 layers, each with 8 attention heads, an embedding size of 512 dimensions, and a vocabulary size of 32k subword tokens with Byte Pair Encoding (Sennrich et al., 2016) (in total for the shared encoders/decoders and per pair for language-specific encoder-decoders). Dropout was 0.1 for the shared approach and 0.3 for language-specific encoders/decoders. Both approaches were trained with an effective batch size of 32k tokens for approximately 200k updates, using the validation loss for early stopping. We used Adam (Kingma and Ba, 2015) as the optimizer, with learning rate of 0.001 and 4000 warmup steps.

4.2 Shared vs Language-specific

Table 1 and 2 show comparisons between the shared and language-specific encoders-decoders.

In contrast with our proposed approach, the shared system requires retraining from scratch to

Table 2: Adding a new language translation and Zero-shot.

add a new language. For that reason, we experiment with two variants of this system: one trained without Russian-English (*Shared*) and another one including this pair (*Shared*^{RU}). Note that, to make experiments comparable, we use the *Shared* version when comparing to our *initial* system in Table 1, and the *Shared*^{RU} version when *adding* new languages and performing *zero-shot* translation.

Initial Training Table 1 shows that the language-specific encoder-decoders outperforms the shared approach in all cases. On average, our proposed approach is better than the shared approach with a difference of 0.40 BLEU points.

Adding New Languages Table 2 shows that, when adding a new language into the system, the language-specific encoder-decoders outperform the shared architecture by 2.92 BLEU points for Russian-to-English and by 3.64 BLEU in the opposite direction. It is also worth mentioning that the Russian data is from a different domain than the frozen English modules used for training (*Yandex* corpus and *EuroParl*, respectively). As such, the language specific encoder-decoders are able to outperform the shared architecture when adding a new language and a new domain by learning from the previous information in the frozen modules. Note that additionally, retraining the shared encoder-decoder to add a new language took an entire week, whereas the incremental training with the language-specific encoder-decoders was performed in only one day.

Zero-shot The shared encoder-decoder clearly outperforms the language-specific encoder-decoders by 1.39 BLEU points on average. This difference in performance suggests that, while limiting the amount of shared information during training can improve our model performance, it may also harm zero-shot translation.

Note that employing tied embeddings has a larger impact in the language-specific architecture than in the shared one. In fact, it has been key for closing the performance gap between language-specific and shared architectures.

Previous works, e.g. (Firat et al., 2016a; Lu et al., 2018), suffered from attention mismatch which was solved by sharing intermediate layers. In our case, we believe that we do not suffer from this problem because, within an initial set of N languages, we train $N*N-1$ systems using pair-wise corpus (without requiring multi-parallel corpus as previous works (Escolano et al., 2019)). Due to our proposed joint training, once we have trained our initial system, we end up with only N encoders and N decoders ($2*N$).

5 Conclusions

In this paper, we present a novel method to train language-specific encoders-decoders without sharing any parameters at all. More relevantly, our system allows to incrementally add new languages into the system without having to retrain it and without varying the translation quality of initial languages in the system. When adding a new language, the language-specific encoder-decoders outperform the shared ones by 3.28 BLEU on average and, most importantly, the training of this new language was done in only one day, as opposed to the week taken by the shared system.

Abstract

Romanian is one of the understudied languages in computational linguistics, with few resources available for the development of natural language processing tools. In this paper, we introduce LaRoSeDa, a **La**rge **Ro**manian **Se**ntiment **Da**ta Set[1], which is composed of 15,000 positive and negative reviews collected from one of the largest Romanian e-commerce platforms. We employ two sentiment classification methods as baselines for our new data set, one based on low-level features (character n-grams) and one based on high-level features (bag-of-word-embeddings generated by clustering word embeddings with k-means). As an additional contribution, we replace the k-means clustering algorithm with self-organizing maps (SOMs), obtaining better results because the generated clusters of word embeddings are closer to the Zipf's law distribution, which is known to govern natural language. We also demonstrate the generalization capacity of using SOMs for the clustering of word embeddings on another recently-introduced Romanian data set, for text categorization by topic.

1 Introduction

Perhaps one of the most studied tasks in computational linguistics is sentiment classification, a.k.a. opinion mining or polarity classification. The task has been studied across several languages, the most popular being English (Blitzer et al., 2007; Dos Santos and Gatti, 2014; Fu et al., 2018; Giménez-Pérez et al., 2017; Huang et al., 2017; Ionescu and Butnaru, 2019; Kim, 2014; Maas et al., 2011; Pang and Lee, 2005; Shen et al., 2018; Socher et al., 2013), Chinese (Peng et al., 2017; Wan, 2008; Zagibalov and Carroll, 2008; Zhai et al., 2011; Zhang and He, 2013; Zhang et al., 2008), Arabic (Al-Ayyoub et al., 2018; Elsahar and El-Beltagy, 2015; Dahou et al., 2016; Nabil et al., 2013, 2015) or Spanish (Brooke et al., 2009; Molina-González et al., 2015; Navas-Loro and Rodríguez-Doncel, 2019; Vilares et al., 2015; Zafra et al., 2017). However, studying this task for under-studied languages, e.g. Romanian, is difficult without access to large data sets. We hereby introduce LaRoSeDa, a **La**rge **Ro**manian **Se**ntiment **Da**ta Set, which is freely available for download at https://github.com/ancatache/LaRoSeDa for non-commercial use. With a total of 15,000 positive and negative reviews collected from one of the most popular Romanian e-commerce websites, to our knowledge, LaRoSeDa is the largest data set for Romanian polarity classification.

We experiment with two baseline methods on our novel data set. The first baseline employs string kernels, an approach based on low-level features (character n-grams), that was found to work well for sentiment analysis across multiple languages, e.g. English (Giménez-Pérez et al., 2017; Ionescu and Butnaru, 2018), Chinese (Zhang et al., 2008) and Arabic (Popescu et al., 2017), requiring no linguistic resources besides a labeled training set of samples. The second baseline employs bag-of-word-embeddings (Ionescu and Butnaru, 2019; Fu et al., 2018), an approach based on high-level features (clusters of word embeddings generated by k-means), that attains good results in various text classification tasks (Butnaru and Ionescu, 2017; Cozma et al., 2018; Fu et al., 2018; Ionescu and Butnaru, 2019), including sentiment analysis. As an additional contribution, we replace the k-means clustering algorithm in the second baseline method with self-organizing maps (SOMs) (Kohonen, 2001), obtaining better results because the generated clusters of word embeddings are closer to the Zipf's law distribution (see Figure 2), which is known to govern natural language (Powers, 1998). To our knowl-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 949–956
April 19 - 23, 2021.

edge, we are the first to apply SOMs to cluster word embeddings, showing performance gains for both word2vec (Mikolov et al., 2013) and Romanian BERT (Dumitrescu et al., 2020) embeddings. We also demonstrate the generalization capacity of using SOMs in the bag-of-word-embeddings on another recently-introduced Romanian data set (Butnaru and Ionescu, 2019), for the task of text categorization by topic.

In summary, our contribution is twofold:

- We introduce LaRoSeDa, one of the largest corpora for Romanian sentiment analysis, along with a set of strong baselines to be used as reference in future research.
- To our knowledge, we are the first to employ SOMs as a technique to cluster word embeddings. We provide empirical evidence showing that SOMs produce better results than the popular k-means.

2 Related Work

To date, a small number of works targeting sentiment classification in the Romanian language have been published. Preceding the sentiment analysis efforts on Romanian texts, there are a few studies on subjectivity, that have introduced two corpora built through cross-lingual projections from English to Romanian (Mihalcea et al., 2007) or through machine translation (Banea et al., 2008). An extensive study conducted by Banea et al. (2011) looks at sentiment and subjectivity from a computational linguistics perspective, in a multilingual setup in which Romanian is also included. However, in these initial works, Romanian is studied only from a subjectivity perspective, which does not go down to the level of polarity.

On our topic (i.e. sentiment analysis in Romanian), the first study that we have found describes two word sets tagged with polarity for Romanian and Russian (Sokolova and Bobicev, 2009). Gînscă et al. (2011) introduced a sentiment analysis service intended for multiple languages, that also supports Romanian. They perform sentiment identification using a list of manually-built triggers which, to our knowledge, is not publicly available. Another effort (Colhon et al., 2016) in creating an opinion lexicon with polarity annotations introduced a collection of 2,521 Romanian tourist reviews and an extensive linguistic analysis of the corpus. The data set is not released for public use. Similarly, we did not find any public link to RoEmoLex, a lexicon with approximately 11,000 Romanian words tagged for emotion and sentiment (Briciu and Lupea, 2017; Lupea and Briciu, 2017). The only Romanian data set annotated for sentiment that we have found freely available is rather small, with 1,000 movie reviews manually extracted from several blogs and sites (Russu et al., 2014). With 15,000 reviews, our corpus is much larger.

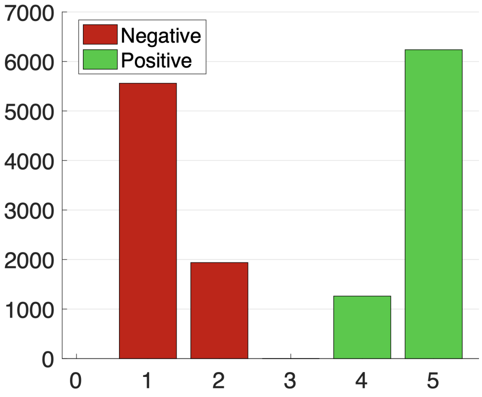

Figure 1: The rating distribution of Romanian product reviews. Negative reviews are those rated with one or two stars, while positive reviews are those rated with four or five stars. Neutral reviews are not included in our data set. Best viewed in color.

3 Data Set

In order to build LaRoSeDa, we collected product reviews from one of the largest e-commerce websites in Romania. Along with the textual content of each review, we collected the associated star ratings in order to automatically assign labels to the collected text samples. Following the same approach used for data sets containing English reviews (Blitzer et al., 2007; Maas et al., 2011; Pang and Lee, 2005), we assigned positive labels to the reviews rated with four or five stars and negative labels to the reviews rated with one or two stars. However, the star rating might not always reflect the polarity of the text. We thus acknowledge that the automatic labeling process is not optimal, i.e. some labels might be noisy. Since automatic labeling based on star ratings is a commonly accepted practice for opinion mining data sets of product reviews, we leave the analysis of noisy labels and manual labeling for future work.

We also imitate the data collection approach used for English review data sets (Blitzer et al., 2007; Maas et al., 2011; Pang and Lee, 2005), selecting a balanced set of Romanian reviews. More precisely, LaRoSeDa is formed of a total of 15,000 reviews that are perfectly balanced, i.e. half of them (7,500)

Set	Positive		Negative	
	#samples	#words	#samples	#words
Training	6,000	187,813	6,000	244,499
Test	1,500	47,661	1,500	60,314
Total	7,500	235,474	7,500	304,813

Table 1: The number of positive and negative samples (#samples) and the corresponding number of words (#words) contained in the training set and the test set of LaRoSeDa.

are positive reviews and the other half (7,500) are negative reviews. In Figure 1, we show the distribution of reviews with respect to the star ratings. We note that most of the negative reviews (5,561) are rated with one star. Similarly, most of the positive reviews (6,238) are rated with five stars. Hence, the corpus is highly polarized. We divide LaRoSeDa into a training set containing 80% of the data samples and a test set containing the remaining 20%. In Table 1, we present the number of positive and negative reviews inside each subset, along with the number of words. Our data set contains a total of 540,287 words, with an average of 36 words per review. We observe that positive reviews contain 235,474 words (44.6%) and negative reviews contain 304,813 words (56.4%). We note that, in negative reviews, people are likely to complain about several points or to explain what is wrong with the reviewed products. This could provide a natural explanation for the fact that the negative reviews contain more words than the positive reviews.

4 Methods

String kernels. A simple language-independent and linguistic-theory-neutral approach is to interpret text samples as sequences of characters (strings) and to use character n-grams as features. The number of character n-grams is usually much higher than the number of samples, so representing the text samples as feature vectors may require a lot of space. String kernels provide an efficient way to avoid storing and using the feature vectors (primal form), by representing the data though a kernel matrix (dual form). Each component K_{ij} in a kernel matrix represents the similarity between data samples x_i and x_j. In our experiments, we use the histogram intersection string kernel (HISK) (Ionescu et al., 2014, 2016) as the similarity function. For two strings x_i and x_j over a set of characters S, HISK is defined as follows:

$$k^{\cap}(x_i, x_j) = \sum_{g \in S^n} \min\{\#(x_i, g), \#(x_j, g)\}, \quad (1)$$

where $\#(x, g)$ is a function that returns the number of occurrences of n-gram g in x, and n is the length of n-grams. While being a rather shallow approach, string kernels attained strong results in some specific tasks. For instance, string kernels ranked first in the Arabic Dialect Identification tasks of VarDial 2017 (Ionescu and Butnaru, 2017) and VarDial 2018 (Butnaru and Ionescu, 2018).

Bag-of-word-embeddings. Following the seminal paper of Mikolov et al. (2013) introducing *word2vec*, word embeddings became one of the mainstream approaches in various computational linguistics tasks (Cheng et al., 2018; Conneau et al., 2017; Cozma et al., 2018; Fu et al., 2018; Kim, 2014; Kiros et al., 2015; Shen et al., 2018; Torki, 2018; Zhou et al., 2018). In order to build the bag-of-word-embeddings (BOWE), we first trained *word2vec* on the collected Romanian reviews using the continuous bag-of-words (CBOW) model. Before training, we transformed all letters to lowercase and removed punctuation. In addition to word2vec, we consider a recently introduced Romanian BERT model (Dumitrescu et al., 2020) as an alternative way to produce word embeddings, which is likely to produce much better results, considering the success of BERT (Devlin et al., 2019) in English NLP tasks. Instead of averaging the word embeddings to obtain document-level representations (Shen et al., 2018), we follow a different and more effective path suggested by some recent works (Butnaru and Ionescu, 2017; Cozma et al., 2018; Fu et al., 2018; Ionescu and Butnaru, 2019). More specifically, we cluster the word embeddings collected from the entire training set using k-means. For a document D of n words, $D = (w_1, w_2, ..., w_n)$, a word embedding model, be it word2vec or BERT, outputs a matrix of $n \times m$ components (or a set of n m-dimensional vectors), the m-dimensional vector at index i corresponding to word w_i. We apply clustering on the word vectors extracted from all training documents, thus obtaining a set of k clusters. A document D is then represented as a bag-of-word-embeddings (histogram) $H = (h_1, h_2, ..., h_k)$ in which each component h_i retains the number of word embeddings from the document D that fall in cluster i, where $i \in \{1, 2, ..., k\}$. We note that the size of the bag-of-word-embeddings is equal to the number of clusters k. In the case of BERT, we emphasize that, although the embedding vector of a word depends on the context, it is likely that the embedding vectors corresponding to a specific word will fall in the same cluster. Hence, BOWE is able to cope well with this situation.

Replacing k-means with SOMs. Quantitative linguistics studies (Powers, 1998) have pointed out that, given a corpus of text documents, the frequency of any word is inversely proportional to its rank in the frequency table, giving rise to a Zipf's law distribution of words in natural language. However, the k-means algorithm tends to ignore the data density, producing equally-sized clusters. We therefore propose to replace the k-means algorithm with an approach that takes into account the density in the word embedding space, producing a set of clusters that follow the Zipf's law. We propose to perform clustering using self-organizing maps (SOMs) (Kohonen, 2001), since these models are known to preserve the topological properties of the input space. Indeed, Figure 2 shows that SOMs produce clusters of Romanian word embeddings closer to the Zipf's law distribution than k-means.

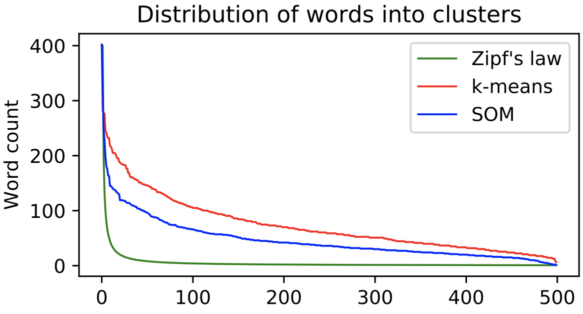

Figure 2: The distribution of words into clusters generated by k-means (in red) or by SOMs (in blue), for LaRoSeDa. The Zipf's law distribution (in green) is included for reference. Best viewed in color.

It is important to emphasize that k-means can produce clusters of different size, as shown in Figure 2. Our observation refers only to the fact that the data density is not particularly modeled by the k-means optimization process, while SOMs are optimized by shifting the neural units following the density of the data (units tend to migrate where the space is more dense). Our observation with respect to k-means is also confirmed by other studies. For example, Raykov et al. (2016) note that: *"even when all other implicit geometric assumptions of k-means are satisfied, it will fail to learn a correct, or even meaningful, clustering when there are significant differences in cluster density"*. Since natural language involves such significant differences (due to the presence of the Zipf's law), we believe that k-means is a sub-optimal choice.

5 Experiments

Corpora. First and foremost, we perform experiments on LaRoSeDa with the goal of introducing some benchmark results on our new data set. We also perform experiments on MOROCO (Butnaru and Ionescu, 2019), a data set with Moldavian and Romanian news articles, with the goal of showing the generalization capacity of using SOMs instead ok k-means.

Experimental setup. On LaRoSeDa, we present two sets of results, one based on the established train-test split and one based on 10-fold cross-validation. On MOROCO, we choose to present 10-fold cross-validation results for the intra-dialect multi-class categorization by topic task, on the 18,161 samples written in the Romanian dialect.

Parameter and model choices. For HISK, we combined character 3-grams, 4-grams and 5-grams. For BOWE-word2vec and BOWE-BERT, we set the number of clusters to $k = 500$, just as Cozma et al. (2018). We trained *word2vec* to produce 300-dimensional Romanian word embeddings, while the Romanian BERT outputs 768-dimensional embeddings. In the learning stage, we employed the linear Support Vector Machines (SVM) implementation from Scikit-learn (Pedregosa et al., 2011), providing as input pre-computed kernels. For BOWE-word2vec and BOWE-BERT, we opt for the PQ kernel, based on the findings of Butnaru and Ionescu (2017). We set the regularization parameter of SVM to $C = 10^3$ in all the experiments. We also fuse HISK with BOWE-word2vec or BOWE-BERT in the dual form by summing up the corresponding kernel matrices. We employed an open source implementation of SOMs[2]. We used the default choices for most hyperparameters, the modifications being detailed next. We set the learning rate to 0.25 and the number of epochs to 200. Before starting the training, the SOM is configured to randomly choose a number of training samples equal to number of expected outputs. We

Method	10-fold CV	Test
HISK	84.38%	84.73%
BOWE-word2vec with k-means	72.24%	70.73%
BOWE-word2vec with SOMs	75.99%	75.57%
BOWE-BERT with k-means	78.63%	77.36%
BOWE-BERT with SOMs	79.75%	80.73%
HISK+BOWE-word2vec with k-means	85.08%	83.57%
HISK+BOWE-word2vec with SOMs	87.17%	88.93%
HISK+BOWE-BERT with k-means	88.81%	89.42%
HISK+BOWE-BERT with SOMs	89.54%	90.90%

Table 2: Accuracy rates of HISK, BOWE-word2vec and BOWE-BERT with clustering based on k-means or SOMs, as well as ensemble models on LaRoSeDa. Results are reported in two cases: using a 10-fold cross-validation procedure and using the train-test split.

Method	10-fold CV
HISK (Butnaru and Ionescu, 2019)	71.27%
BOWE-BERT with k-means	63.42%
BOWE-BERT with SOMs	68.50%
HISK+BOWE-BERT with k-means	72.21%
HISK+BOWE-BERT with SOMs	73.35%

Table 3: Accuracy rates of HISK, BOWE-BERT with k-means, BOWE-BERT with SOMs and their combinations on MOROCO, for the Romanian intra-dialect multi-class categorization by topic task. Results are reported using a 10-fold cross-validation procedure.

opted for the cosine distance between data samples and SOM's weights.

Results on LaRoSeDa. In Table 2, we present the results on LaRoSeDa. Among the individual baselines, we observe that HISK attains the best accuracy rates, surpassing all BOWE configurations. We also note that by replacing k-means with SOMs, the accuracy rate of BOWE-word2vec grows by 4 or 5%. The improvements brought by SOMs can be explained by the fact that, unlike k-means, SOMs produce clusters that are closer to the Zipf's law distribution. This is proven by the word embedding counts per cluster illustrated in Figure 2. When we combine HISK with BOWE-BERT, we notice significant performance gains.

Results on MOROCO. In Table 3, we present the results on MOROCO, for the Romanian intra-dialect multi-class categorization by topic task. We notice that HISK attains better results than BOWE-BERT with k-means and BOWE-BERT with SOMs, although the differences in terms of accuracy seem to be smaller. As for LaRoSeDa, we observe a significant improvement (higher than 5%) when k-means is replaced by SOMs. There is an observable improvement over the plain HISK, when HISK is combined with BOWE-BERT based on k-means. Nonetheless, we notice a larger improvement when we combine HISK and BOWE-BERT based on SOMs.

6 Conclusion

In this paper, (i) we introduced LaRoSeDa, a large data set for polarity classification of Romanian reviews, and (ii) we employed self-organizing maps, a clustering approach that preserves the density of words in the embedding space, resulting in a more effective bag-of-word-embeddings representation. Our top accuracy rates on LaRoSeDa are 89.54% for the cross-validation procedure and 90.90% on the test set. We note that SOMs had a significant contribution in attaining these high accuracy rates. We conclude that the combination of HISK and BOWE-BERT with SOMs is a strong baseline which should encourage future research in proposing non-trivial models for Romanian polarity classification. Furthermore, the results obtained on MOROCO confirm that SOMs provide better accuracy rates than k-means when it comes to building document-level representations based on clustering word embeddings.

Elastic weight consolidation for better bias inoculation

Abstract

The biases present in training datasets have been shown to affect models for sentence pair classification tasks such as natural language inference (NLI) and fact verification. While fine-tuning models on additional data has been used to mitigate them, a common issue is that of catastrophic forgetting of the original training dataset. In this paper, we show that elastic weight consolidation (EWC) allows fine-tuning of models to mitigate biases while being less susceptible to catastrophic forgetting. In our evaluation on fact verification and NLI stress tests, we show that fine-tuning with EWC dominates standard fine-tuning, yielding models with lower levels of forgetting on the original (biased) dataset for equivalent gains in accuracy on the fine-tuning (unbiased) dataset.

1 Introduction

A number of recent works have illustrated shortcomings in sentence-pair classification models that are used for Natural Language Inference (NLI). These arise from limited or biased training data and the lack of suitable inductive bias in models. Naik et al. (2018) demonstrated that phenomena such as the presence of negation or a high degree of lexical overlap induce misclassifications on models trained on the MultiNLI dataset (Williams et al., 2018). Poliak et al. (2018) and Gururangan et al. (2018) identified biases introduced during dataset construction that were exploited by models to learn associations between the label and only one of the two input sentences without considering the other – known as *hypothesis-only* bias.

Such biases also affect fact verification (Schuster et al., 2019), typically modeled as a text-pair classification between a claim and evidence retrieved from a trusted source (Pomerleau and Rao, 2017; Thorne et al., 2018).

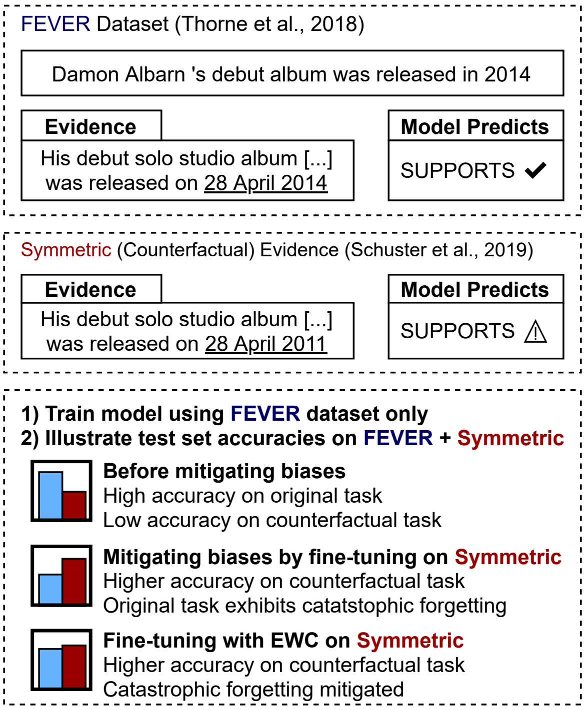

Figure 1: Hypothesis only bias in FEVER contributes to low accuracy when testing against counterfactual evidence. This is mitigated by fine-tuning on counterfactual evidence. Catastrophic forgetting from fine-tuning is reduced when using elastic weight consolidation (EWC), preserving the original task accuracy.

To mitigate these undesirable behaviors Liu et al. (2019a) fine-tune models with a small targeted number of labeled instances to “inoculate” the models. This can be contrasted to methods such as Debiased Focal Loss (DFL) and Product of Experts (POE) (Mahabadi et al., 2020) which require architectural changes to separately encode and penalize biases. In related work, Suntwal et al. (2019) delexicalize instances – replacing tokens with placeholders, preventing classifiers from exploiting mutual information between domain-specific noun-phrases and class labels. Finally, Schuster et al. (2019) re-weight the loss of in-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 957–964
April 19 - 23, 2021.

stances during training guided by the mutual information between tokens and the instance labels. Each of these methods corresponds to a multi-objective optimization problem where the original dataset accuracy is often sacrificed in favor of accuracy on a different evaluation set.

For fine-tuning specifically, the reduction in accuracy on the original task called catastrophic forgetting (French, 1999) as parameters for the original task are overridden during fine-tuning. In this paper, we show that regularizing fine-tuning with Elastic Weight Consolidation (Kirkpatrick et al., 2017, EWC) minimizes catastrophic forgetting by penalizing weight updates to parameters crucial to modeling the original dataset. EWC has previously been applied to machine translation, where Thompson et al. (2019) and Saunders et al. (2019) minimized catastrophic forgetting for models undergoing domain adaption. Extending this line of research further, we demonstrate that EWC can be used to mitigate biases present in two sentence-pair classification tasks without architectural changes to the models. We evaluate a number of popular model architectures, trained on MultiNLI and FEVER, and demonstrate that fine-tuning with EWC mitigates model bias while yielding lower reductions in accuracy on the original dataset compared to standard fine-tuning.

On all experiments on the FEVER dataset, fine-tuning with symmetric counterfactual data (Schuster et al., 2019) mitigated hypothesis-only bias, increasing the absolute accuracy of a BERT model by approximately 10%. Without EWC, accuracy on the original dataset was reduced from 87% to 79%, whereas with EWC catastrophic forgetting was mitigated and accuracy was 82%. In all experiments with EWC, the original task accuracy was significantly higher than fine-tuning without regularization and fine-tuning with L2 regularization. These gains were attained while maintaining similar performance on the fine-tuning data. Plotting the Pareto frontier, we show that equivalent gains in accuracy can be made with less forgetting of the original dataset. Furthermore, we demonstrate that fine-tuning methods can be combined with POE and DFL, yielding improvements on both the original task as well as fine-tuning data used for debiasing. Similar patterns were observed when fine-tuning MultiNLI models with lexical bias evaluation datasets (Naik et al., 2018).

2 Mitigating biases with fine-tuning

Fine-tuning broadly refers to approaches where a model is initially trained on one dataset and then further improved by training on another. We refer to these datasets as fine-tuning training and test data as *FT-train* and *FT-test* respectively. This technique is commonly used to mitigate model biases (Liu et al., 2019a), where the original data, while useful in model training, often contain biases, which are addressed by further training the model on a small set of instances targeting these biases. Fine-tuning to mitigate bias, however, can result in model parameters over-adjusting to the instances targeting it, reducing the accuracy on the original task, referred to as catastrophic forgetting (French, 1999). To ameliorate this issue, one can regularize the parameter updates so that they do not deviate too much from the original training, similar to the intuition behind multi-task training approaches (Ruder, 2017).

Elastic Weight Consolidation (Kirkpatrick et al., 2017, EWC) penalizes parameter updates according to the model's sensitivity to changes in these parameters. The model sensitivity is estimated by the Fisher information matrix, which describes the model's expected sensitivity to a change in parameters, and near the (local) minimum of the loss function used for training is equivalent to the second-order derivative $F = \mathbb{E}_{(x,y)\sim\mathcal{D}_{original}}[\nabla^2 \log p(y|x;\theta)]$. When fine-tuning with EWC (which we refer to as FT+EWC), the Fisher information is used to elastically scale the cost of updating parameters θ_i from the original value θ_i^*, controlled by the λ hyper-parameter, as follows:

$$\mathcal{L}(\theta) = \mathcal{L}_{FT}(\theta) + \sum_i \frac{\lambda}{2} F_{i,i}(\theta_i - \theta_i^*)^2 \tag{1}$$

For efficiency, we use the *empirical Fisher* (Martens, 2014): diagonal elements are approximated through squaring first-order gradients from a sample of instances, recomputed before each epoch. If the Fisher information is not used (i.e. $F_{i,i} = 1$), Eq. 1 is equivalent to L2 regularization (which we refer to as FT+L2).

3 Experimental setup

We assess the application of EWC to minimize catastrophic forgetting when mitigating model biases in the context of two sentence-pair classification tasks: fact verification and natural language inference. We compare the untreated model (original), fine-tuning (FT), FT+EWC, FT+L2, and merging instances from the FT-train dataset when training (Merged). Each model is first trained using the original dataset and splits from the respective task, using the AllenNLP implementations (Gardner et al., 2017) with default hyper-parameters and tokenize with SpaCy or pre-trained transformer tokenizers. We train five random initializations of each model, reporting the mean accuracy, standard deviation, and p-value with an unpaired t-test. For fine-tuning, the learning rate, regularization strength λ, and number of epochs are selected through 5-fold cross-validation on the FT-train data, selecting the model with the highest FT-train accuracy. 30 hyper parameter choices were evaluated with grid search over 10 choices for regularization strength between 10^6 and 10^8 and 3 choices of learning rates in $\{2 \cdot 10^{-6}, 4 \cdot 10^{-6}, 6 \cdot 10^{-6}\}$ for transformer models and $\{2 \cdot 10^{-4}, 4 \cdot 10^{-4}, 6 \cdot 10^{-4}\}$ for ESIM models. We trained the models for a max of 8 epochs. For the transformer-based models, the highest cross validation accuracy on the FT-train dataset was achieved with $LR = 4 \cdot 10^{-6}$, $\lambda = 10^7$ and 6 epochs. For the ESIM-based models, the highest FT-train accuracy was achieved with $LR = 2 \cdot 10^{-4}$, $\lambda = 10^7$ and 5 epochs. Full hyper-parameter choices are in Appendix D.

Mitigating hypothesis only bias in fact verification: The FEVER[1] task (Thorne et al., 2018) is to predict whether short factoid sentences called claims are Supported or Refuted against evidence (in the form of sentences from Wikipedia) or whether there is not enough info (NEI). When training the models, the NEI instances by definition don't have evidence: we sample negative instances for these with random sentences from the Wikipedia page closest to the claim using TF·IDF. This preprocessing is the same as Thorne et al. (2018). Schuster et al. (2019) identified a bias where the label for some claims can be predicted without the need for evidence. To evaluate this bias, they released[2] a set of 1420 symmetric counterfactual instances where each claim is supported by one Wikipedia passage and refuted by another (approximately 1% of the FEVER dataset). This is mitigating the claim-only bias by reducing the mutual information between claims and labels. The availability of counterfactual data meant that it is possible to experiment with fine-tuning as a mitigation strategy, using the published dev and test data as FT-train and FT-test respectively. Following Schuster et al. (2019)'s evaluation, we train two ESIM (Enhanced LSTM) variants (Chen et al., 2016), and a BERT (Devlin et al., 2019) transformer. We also evaluate RoBERTa (Liu et al., 2019b), as it has been shown to be more robust to adversarial testing (Bartolo et al., 2020).

Mitigating model limitations in NLI stress tests: The MultiNLI[3] task (Williams et al., 2018) requires systems to predict whether a hypothesis is entailed by a premise. Naik et al. (2018) identify limitations of models trained on this dataset where 6 phenomena such as *lexical overlap*, *numerical reasoning* and presence of *antonyms* were evaluated with 'stress-tests'. In this paper, we report on *antonyms* and *numerical reasoning* as these stress-tests exhibited catastrophic forgetting when used to fine-tune models (Liu et al., 2019a). To this end, we do not evaluate on HANS (McCoy et al., 2020), as high accuracies can be attained without forgetting.

Like Liu et al. (2019a), we mitigate these biases through fine-tuning both an ESIM (Chen et al., 2016) model on stress-test data[4]. Each contains a small number of procedurally generated instances (between 1500-9800) that specifically target one of these phenomena. We evaluate FT and FT+EWC using the same methodology, controlling the number of instances, sampled at random, in FT-train and report the change in accuracy on the FT-test and original test sets.

4 Results

4.1 Fact verification

Fine-tuning the models, rather than merging datasets, yielded the greatest improvements in accuracy on FT-test. All improvements from the untreated model were significant ($p < 0.05$, denoted #). Without L2 or EWC, catastrophic forgetting occurs due to the shift in label distribution between the FEVER and FT-train dataset, which only contains 2 of the original 3 label classes.

Table 1: Bias mitigation for FEVER classifiers comparing no treatment (original), against merging from instances from the FT-train with the original task training dataset (Merged) and FineTuning (with EWC and L2). Improvements $p < 0.05$ are marked with the following symbols: $*$ against FT, $\dagger$ against FT+L2, $\#$ against original. Deteriorations $p > 0.05$ on the symmetric dataset are marked with $\diamondsuit$ against FT and $\heartsuit$ against FT+L2

Both L2 and EWC reduced catastrophic forgetting. Improvements on the original task are significant (denoted $*$) compared to FT. However, EWC regularization retained more of the original task accuracy than L2 for all models; this was also significant (denoted $\dagger$). In all cases, there is a trade-off between original and fine-tuning task accuracies. With regularization, the FT accuracy was higher than FT+L2 and FT+EWC (with the exception of ESIM+ELMo). However, the deterioration from FT when regularizing was not significant ($p > 0.05$, denoted $\diamondsuit$). Furthermore, for the highest performing model (RoBERTa base), the deterioration of using FT+EWC against FT+L2 was also not significant (denoted $\heartsuit$).

Training a model where the FEVER training and FT-train were merged yielded modest improvements on the FT-test without harming the original FEVER task accuracy. We attribute this to the impact of these 700 instances being diluted by the large number of training instances in FEVER (FT-train is <1% the size of FEVER).

4.2 Combining FT and bias modeling

Fine-tuning can be applied to any task using a small amount of bias-mitigating labeled data, whereas explicit modeling of hypothesis-only biases (Mahabadi et al., 2020) requires architectural changes that are specific to the task and model. We consider two techniques from Mahabadi et al. (2020): Product of Experts (PoE), which multiplies the sentence-pair label probabilities with hypothesis-only label probabilities, and Debiased Focal Loss (DFL) which explicitly modulates the loss of instances according to the accuracy of a hypothesis-only classifier. For both ESIM and BERT, accuracy, when trained with PoE, was stable across different choices of hyper-parameters, whereas some hyper-parameter choices for DFL resulted in lower accuracy on both tasks. We report results for BERT+PoE and ESIM+DFL as these were best.

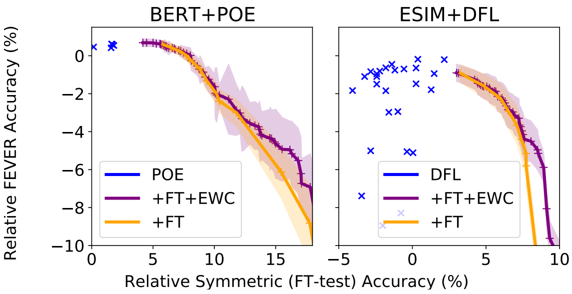

Figure 2: Pareto frontiers of fine-tuning BERT and ESIM models showing FT+EWC dominates FT.

The trade-off between accuracy on the original and FT-test datasets is visualized in Figure 2 indicating the change in accuracy for both bias modeling techniques in isolation, as well as in combination with fine-tuning.[5] This further shows that FT+EWC Pareto dominates FT for both the ESIM and BERT model. With EWC, equivalent gains on the symmetric FT-test can be attained with a lower

---

[5] All Pareto frontier lines are the result of sweeping the following: for POE, β; for DFL, β and γ; for FT, learning rate; and for FT+EWC, learning rate + EWC strength (λ in Equation 1) in Appendix D.8.

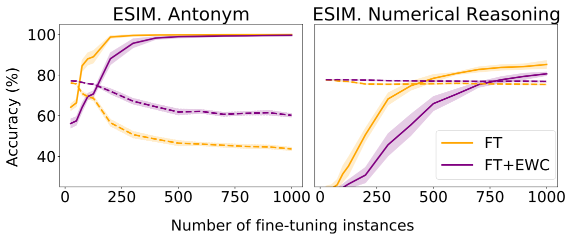

Figure 3: Training curves fine tuning MultiNLI with stress-test data. Solid lines indicate challenge dataset accuracy. Dashed lines indicate MultiNLI accuracy.

reduction in accuracy on the original FEVER task.

4.3 Natural Language Inference (NLI)

In a separate experiment, we apply EWC to a different domain. We inoculate biases on the ESIM model for natural language inference reported in Liu et al. (2019a). For both *Antonym* and *Numerical Reasoning* challenges, MultiNLI accuracy was higher with FT+EWC compared to FT (dashed lines in Figure 3).

Antonym challenge: The ESIM model was sensitive to fine-tuning, attaining near perfect accuracy (top row of Figure 3) on the FT-test data. The antonym stress-test only contains instances labeled *contradiction*: a change in label distribution that causes catastrophic forgetting. Without EWC, accuracy on MultiNLI fell to just above chance levels as the model learned only to predict contradiction (yellow dashed line). However, using an appropriate EWC penalty attained near-perfect accuracy with a smaller reduction in MultiNLI accuracy (purple dashed line).

Numerical reasoning challenge: The ESIM model was sensitive to fine-tuning to introduce numerical reasoning behaviours to the model. As the difference in label distribution in the inoculation dataset was less severe than the Antonym dataset, the catastrophic forgetting was less severe. Nevertheless, FT+EWC minimized catastrophic forgetting at the expense of reducing sample efficiency: accuracy on MultiNLI fell from 77.9% to 75.4% without EWC and 76.8% with EWC.

5 Conclusions

Fine-tuning can be used to mitigate model bias but has the risk that the model catastrophically forgets the data it was originally trained on. Incorporating elastic weight consolidation (EWC) when fine-tuning minimizes catastrophic forgetting, yielding higher accuracy on the original task. We show this holds for both the NLI stress-tests, as well debiasing fact-verification systems (Schuster et al., 2019) through fine-tuning.

A Hypothesis-only bias in other fact-verification datasets

We use the FEVER dataset in this paper due to the availability of the symmetric counterfactual data released by Schuster et al. (2019). Other datasets for fake news detection and fact verification also have the same task signature (sentence-pair classification with a claim and another sentence), but second sentence is not evidential. All tasks exhibit a hypothesis-only bias where information from the claim can be used to predict the label without considering the second sentence in the sentence-pair. If there was no mutual information between claims (without evidence) and labels, this should be 33%.

For FEVER, this bias is introduced through synthetic generation of the claims and is more problematic than the biases that occur in the datasets consisting of naturally occurring claims. In Liar and MultiFC, the claims arise from real-world events and the biases in the data reflect political viewpoints, rather than cognitive shortcuts taken by the FEVER annotators.

The RoBERTa model, trained on only the claims outperforms the sentence-pair setup for both the MultiFC (Augenstein et al., 2019) and Liar-Plus tasks (Alhindi et al., 2018) whereas for the the FEVER data the sentence-pair accuracy is higher. As FEVER is the only task that requires the use of evidence for classification, this is expected.

Dataset	Accuracy (%)	
	Claim Only	Sentence Pair
Liar-Plus	28.74	20.48
Liar-Plus (binary)	72.59	70.48
MultiFC	46.02	44.83
FEVER	61.50	88.93
FEVER (2-way)	79.09	92.24

Table 2: Validation accuracy for claim-only vs sentence pair classification for fact verification datasets trained on RoBERTa. For 2-way fever we discard instances labelled NOTENOUGHINFO. For binary Liar-Plus, we map all positive labels to true and all negative labels to false and discard neutral instances.

B Compute infrastructure

All experiments were performed on a single workstation with a single Xeon E5-2630 CPU, 64GB RAM and an Nvidia 1080Ti GPU.

C Average run-time for fine-tuning

Estimating the Fisher matrix diagonal takes approximately 2 seconds for the ESIM model using 2000 instances sampled from the original dataset. Average training duration (excluding estimating Fisher information) was 11 seconds in total with 700 instances.

Estimating the Fisher matrix diagonal takes approximately 25 seconds for the BERT and RoBERTa models using 2000 instances sampled from the original dataset. Average training duration (excluding estimating Fisher information) was 2 minutes 20 seconds in total with 700 instances.

D Hyper-parameter configurations

D.1 Base models

For the base-models, the default hyperparemters in AllenNLP are used for the ESIM, BERT and RoBERTa models.

ESIM

- Embedding dimension: 300, bidirectional
- Dropout: 0.5
- Optimizer: Adam
- Gradient Norm: 10.0
- Batch Size: 64
- Learning Rate: 0.0004
- Learning Rate Schedule: reduce on plateau, patience 0, factor 0.5
- Number of Epochs: 75
- Early Stopping: Patience 10

BERT+RoBERTa

- Embedding dimension: 768
- Optimizer: AdamW
- Gradient Norm: 10.0
- Batch Size: 8
- Learning Rate: 0.0004
- Learning Rate Schedule: slanted triangular, cut frac 0.06
- Number of Epochs: 5
- Early Stopping: Patience 0

D.2 Fine-tuning without EWC

ESIM

- FT Learning Rate: 0.0002
- FT Epochs: 8

BERT

- FT Learning Rate: 0.000004
- FT Epochs: 6

RoBERTa

- FT Learning Rate: 0.000004
- FT Epochs: 7

D.3 Fine-tuning using EWC

ESIM

- FT Learning Rate: 0.0002
- FT Epochs: 5
- EWC: 10000000

BERT+RoBERTa

- FT Learning Rate: 0.000004
- FT Epochs: 6
- EWC: 10000000

D.4 Unsupervised bias mitigation

Hyperparameters: β controls the weight update for the hypothesis-only model and γ controls the modulation of hypothesis-only model in the loss function.

- POE (BERT) $\beta = 0.4$
- POE (ESIM) $\beta = 0.05$
- DFL (BERT) $\beta = 0.4, \gamma = 0.6$
- DFL (ESIM) $\beta = 0.05, \gamma = 2.0$

D.5 Search bounds for fine-tuning

Approximately 30 configurations were considered (Cartesian product of LR+EWC). The best performing system was selected through max accuracy on the FT cross validation dataset through 5 fold cross validation.

- EWC $\{10^6, 2\cdot 10^6, 4\cdot 10^6, 8\cdot 10^6, 10^7, 2\cdot 10^7, 4\cdot 10^7, 6\cdot 10^7, 8\cdot 10^7, 10^8\}$
- Fine-tuning learning rate (ESIMs): $\{0.0002, 0.0004, 0.0006\}$
- Fine-tuning learning rate (Transformer): $\{0.000002, 0.000004, 0.000006\}$
- Epochs: Up to 10 epochs cross valudating on the FT-training dataset

D.6 Search bounds for end2end bias mitigation

We used the same range of values published by Mahabadi et al. (2020). For DFL, we performed a grid search of every value totalling 30 trials.
$\gamma \in \{0.02, 0.05, 0.1, 0.6, 2.0, 4.0, 5.0\}$
$\beta \in \{0.05, 0.2, 0.4, 0.8, 1.0\}$

D.7 Stress test sizes

Following the evaluation of (Liu et al., 2019a) we vary the number of instances from the stress test (between 1500-9800) instances. To plot Figure 3, we use 25, 50, 75, 100, 250, 400, 500, 600, 700, 800, 900, 1000 instances in our evaluation.

D.8 Pareto frontier sweeps

The Pareto frontier sweeps in Figure 2 were generated by plotting all hyperparameters from Appendix D.5. The end2end (blue) crosses are plotted by plotting the choices from Appendix D.6 in combination with the best FT model.

Hierarchical Multi-head Attentive Network for Evidence-aware Fake News Detection

Abstract

The widespread of fake news and misinformation in various domains ranging from politics, economics to public health has posed an urgent need to automatically fact-check information. A recent trend in fake news detection is to utilize evidence from external sources. However, existing evidence-aware fake news detection methods focused on either only word-level attention or evidence-level attention, which may result in suboptimal performance. In this paper, we propose a Hierarchical Multi-head Attentive Network to fact-check textual claims. Our model jointly combines multi-head word-level attention and multi-head document-level attention, which aid explanation in both word-level and evidence-level. Experiments on two real-word datasets show that our model outperforms seven state-of-the-art baselines. Improvements over baselines are from 6% to 18%. Our source code and datasets are released at `https://github.com/nguyenvo09/EACL2021`.

1 Introduction

The proliferation of biased news, misleading claims, disinformation and fake news has caused heightened negative effects on modern society in various domains ranging from politics, economics to public health. A recent study showed that maliciously fabricated and partisan stories possibly caused citizens' misperception about political candidates (Allcott and Gentzkow, 2017) during the 2016 U.S. presidential elections. In economics, the spread of fake news has manipulated stock price (Kogan et al., 2019). For example, $139 billion was wiped out when the Associated Press (AP)'s hacked Twitter account posted rumor about White House explosion with Barack Obama's injury. Recently, misinformation has caused infodemics in public health (Ashoka, 2020) and even led to people's fatalities in the physical world (Alluri, 2019).

To reduce the spread of misinformation and its detrimental influences, many fact-checking systems have been developed to fact-check textual claims. It is estimated that the number of fact-checking outlets has increased 400% in 60 countries since 2014 (Stencel, 2019). Several fact-checking systems such as *snopes.com* and *politifact.com* are widely used by both online users and major corporations. Facebook (CNN, 2020) recently incorporated third-party fact-checking sites to social media posts and Google integrated fact-checking articles to their search engine (Wang et al., 2018). These fact-checking systems debunk claims by manually assess their credibility based on collected webpages used as evidence. However, this manual process is laborious and unscalable to handle the large volume of produced false claims on communication platforms. Therefore, in this paper, our goal is to build an automatic fake news detection system to fact-check textual claims based on collected evidence to speed up fact-checking process of the above fact-checking sites.

To detect fake news, researchers proposed to use linguistics and textual content (Castillo et al., 2011; Zhao et al., 2015; Liu et al., 2015). Since textual claims are usually deliberately written to deceive readers, it is hard to detect fake news by solely relying on the content claims. Therefore, multiple works utilized other signals such as temporal spreading patterns (Liu and Wu, 2018), network structures (Wu and Liu, 2018; Vo and Lee, 2018; Shu et al., 2020) and users' feedbacks (Vo and Lee, 2019; Shu et al., 2019; Vo and Lee, 2020a). However, limited work used external webpages as documents which could provide interpretive explanation to users. Several recent work (Popat et al., 2018; Ma et al., 2019; Vo and Lee, 2020b) started to utilize documents to fact-check textual claims. Popat et al. (2018) used word-level attention in documents but treated all documents with equal im-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 965–975
April 19 - 23, 2021.

portance whereas Ma et al. (2019) only focused on which documents are more crucial without considering what words help explain credibility of textual claims.

Observing drawbacks of the existing work, we propose Hierarchical Multi-head Attentive Network which jointly utilizes word attention and evidence attention. Overall semantics of a document may be generated by multiple parts of the document. Therefore, we propose a multi-head word attention mechanism to capture different semantic contributions of words to the meaning of the documents. Since a document may have different semantic aspects corresponding to various information related to credibility of a claim, we propose a multi-head document-level attention mechanism to capture contributions of the different semantic aspects of the documents. In our attention mechanism, we also use speakers and publishers information to further improve effectiveness of our model. To our knowledge, our work is the first applying multi-head attention mechanism for both words and documents in evidence-aware fake news detection. Our work makes the following contributions:

- We propose a novel hierarchical multi-head attention network which jointly combines word attention and evidence attention for evidence-aware fake news detection.
- We propose a novel multi-head attention mechanism to capture important words and evidence.
- Experiments on two public datasets demonstrate the effectiveness and generality of our model over state-of-the-art fake news detection techniques.

2 Related Work

Many methods have been proposed to detect fake news in recent years. These methods can be placed into three groups: (1) human-based fact-checking sites (e.g. Snopes.com, Politifact.com), (2) machine learning based methods and (3) hybrid systems (e.g. content moderation on social media sites). In machine-learning-based methods, researchers mainly used linguistics and textual content (Zellers et al., 2019; Zhao et al., 2015; Wang, 2017; Shu et al., 2019), temporal spreading patterns (Liu and Wu, 2018), network structures (Wu and Liu, 2018; Vo and Lee, 2018; You et al., 2019), users' feedbacks (Vo and Lee, 2019; Shu et al., 2019) and multimodal signals (Gupta et al., 2013; Vo and Lee, 2020b). Recently, researchers focus on fact-checking claims based on evidence from different sources. Thorne and Vlachos (2017) and Vlachos and Riedel (2015) fact-check claims using subject-predicate-object triplets extracted from knowledge graph as evidence. Chen et al. (2020) assess claims' credibility using tabular data. Our work is closely related to fact verification task (Thorne et al., 2018; Nie et al., 2019; Soleimani et al., 2020) which aims to classify a pair of a claim and an evidence extracted from Wikipedia into three classes: *supported*, *refuted*, or *not enough info*. For fact verification task, Nie et al. (2019) used ELMo (Peters et al., 2018) to extract contextual embeddings of words and used a modified ESIM model (Chen et al., 2017). Soleimani et al. (2020) used BERT model (Devlin et al., 2018) to retrieve and verify claims. Zhou et al. (2019) used graph based models for semantic reasoning. Our work is different from these work since our goal is to classify a pair of a claim and a list of relevant evidence into *true* or *false*.

Our work is close to existing work about evidence-aware fake news detection (Popat et al., 2018; Ma et al., 2019; Wu et al., 2020; Mishra and Setty, 2019). Popat et al. (2018) used an average pooling layer to derive claims' representation to attend to words in evidence, Mishra and Setty (2019) focused on words and sentences in each evidence, and Ma et al. (2019) proposed a semantic entailment model to attend to important evidence. However, to the best of our knowledge, our work is the first jointly using multi-head attention mechanisms to focus on important words in each evidence and important evidence from a set of relevant articles. Our attention mechanism is different from these work since we use multiple attention heads to capture different semantic contributions of words and evidence.

3 Problem Statement

We denote an evidence-based fact-checking dataset $\mathcal{C}$ as a collection of tuples $(c, s, \mathcal{D}, \mathcal{P})$ where c is a textual claim originated from a speaker s, $\mathcal{D} = \{d_i\}_{i=1}^{k}$ is a collection of k documents[1] relevant to the claim c and $\mathcal{P} = \{p_i\}_{i=1}^{k}$ is the corresponding publishers of documents in $\mathcal{D}$. Note, $|\mathcal{D}| = |\mathcal{P}|$. Our goal is to classify each tuple $(c, s, \mathcal{D}, \mathcal{P})$ into a pre-defined class (i.e. true news/fake news).

---

[1] We use the term "documents", "articles", and "evidence" interchangeably.

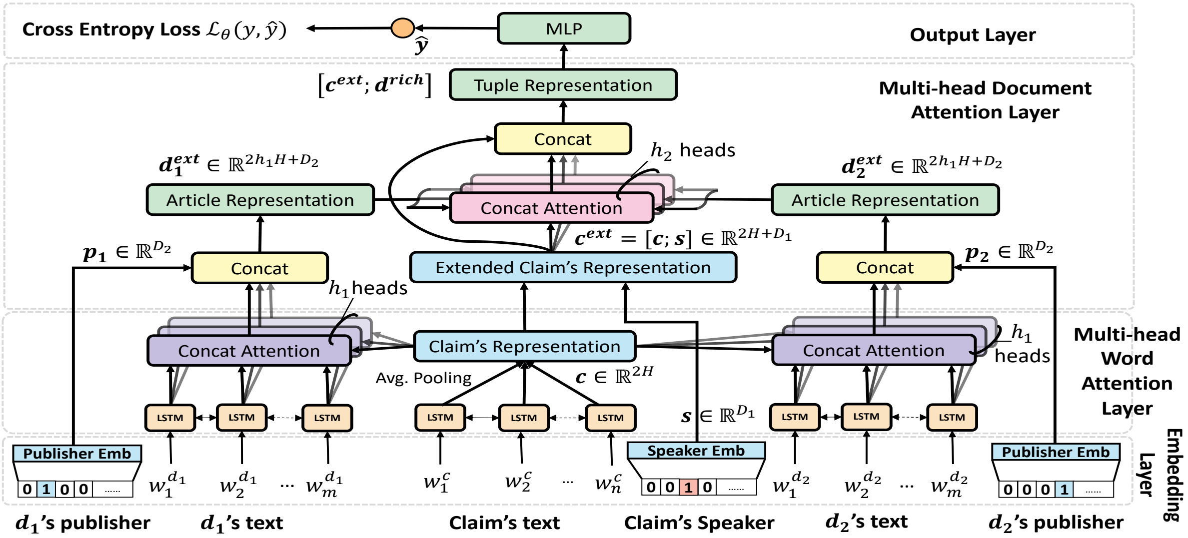

Figure 1: The architecture of our proposed model **MAC** in which we show a claim c, two associated relevant articles d_1 and d_2 and sources of the claim and the two documents. h_1 and h_2 are the number of heads of word-level attention and document-level attention respectively.

4 Framework

In this section, we describe our Hierarchical **M**ulti-head **A**ttentive Network for Fact-**C**hecking (**MAC**) which jointly considers word-level attention and document-level attention. Our framework consists of four main components: (1) embedding layer, (2) multi-head word attention layer, (3) multi-head document attention layer and (4) output layer. These components are illustrated in Fig. 1 where we show a claim and two documents as an example.

4.1 Embedding Layer

Each claim c is modeled as a sequence of n words $[w_1^c, w_2^c, ..., w_n^c]$ and d_i is viewed as another sequence of m words $[w_1^d, w_2^d, ..., w_m^d]$. Each word w_i^c and w_j^d will be projected into D-dimensional vectors $\mathbf{e}_i^c$ and $\mathbf{e}_j^d$ respectively by an embedding matrix $\mathbf{W}_e \in \mathbb{R}^{V \times D}$ where V is the vocabulary size. Each speaker s and publisher p_i modeled as one-hot vectors are transformed into dense vectors $\mathbf{s} \in \mathbb{R}^{D_1}$ and $\mathbf{p}_i \in \mathbb{R}^{D_2}$ respectively by using two matrices $\mathbf{W}_s \in \mathbb{R}^{S \times D_1}$ and $\mathbf{W}_p \in \mathbb{R}^{P \times D_2}$, where S and P are the number of speakers and publishers in a training set respectively. Both $\mathbf{W}_s$ and $\mathbf{W}_p$ are uniformly initialized in $[-0.2, 0.2]$. Note that, both matrices $\mathbf{W}_s$ and $\mathbf{W}_p$ are jointly learned with other parameters of our MAC.

4.2 Multi-head Word Attention Layer

We input word embeddings $\mathbf{e}_i^c$ of the claim c into a bidirectional LSTM (Graves et al., 2005) which helps generate contextual representation $\mathbf{h}_i$ of each token as follows: $\mathbf{h}_i^c = [\overleftarrow{\mathbf{h}_i}; \overrightarrow{\mathbf{h}_i}] \in \mathbb{R}^{2H}$, where $\overleftarrow{\mathbf{h}}_i$ and $\overrightarrow{\mathbf{h}}_i$ are hidden states in forward and backward pass of the BiLSTM, symbol ; means concatenation and H is hidden size. We derive claim's representation in $\mathbb{R}^{2H}$ by an average pooling layer as follows:

$$\mathbf{c} = \frac{1}{n} \sum_{i=1}^{n} \mathbf{h}_i^c \tag{1}$$

Applying a similar process on the top of each document d_i with a different BiLSTM, we have contextual representation $\mathbf{h}_j^d \in \mathbb{R}^{2H}$ for each word in d_i. After going through BiLSTM, d_i is modeled as matrix $\mathbf{H} = [\mathbf{h}_1^d \oplus \mathbf{h}_2^d \oplus ... \oplus \mathbf{h}_m^d] \in \mathbb{R}^{m \times 2H}$ where $\oplus$ denotes stacking.

To understand what information in a document helps us fact-check a claim, we need to guide our model to focus on crucial keywords or phrases of the document. Drawing inspiration from (Luong et al., 2015), we firstly replicate vector $\mathbf{c}$ (Eq.1) m times to create matrix $\mathbf{C}_1 \in \mathbb{R}^{m \times 2H}$ and propose an attention mechanism to attend to important words in the document d_i as follows:

$$\mathbf{a}_1 = softmax\big(\tanh\big([\mathbf{H}; \mathbf{C}_1] \cdot \mathbf{W}_1\big) \cdot \mathbf{w}_2\big) \tag{2}$$

where $\mathbf{w}_2 \in \mathbb{R}^{a_1}$, $\mathbf{W}_1 \in \mathbb{R}^{4H \times a_1}$, $[\mathbf{H}; \mathbf{C}_1]$ is concatenation of two matrices on the last dimension and $\mathbf{a}_1 \in \mathbb{R}^m$ is attention distribution on m words. However, the overall semantics of the document might be generated by multiple parts of the document (Lin et al., 2017). Therefore, we propose a multi-head word attention mechanism to capture different semantic contributions of words by extending vector $\mathbf{w}_2$ into a matrix $\mathbf{W}_2 \in \mathbb{R}^{a_1 \times h_1}$ where h_1 is the number of attention heads shown in Fig. 1. We modify Eq. 2 as follows:

$$\mathbf{A}_1 = softmax_{col}\big(\tanh([\mathbf{H}; \mathbf{C}_1] \cdot \mathbf{W}_1) \cdot \mathbf{W}_2\big) \quad (3)$$

where $\mathbf{A}_1 \in \mathbb{R}^{m \times h_1}$ and each column of $\mathbf{A}_1$ has been normalized by the softmax operation. Intuitively, $\mathbf{A}_1$ stands for h_1 different attention distributions on top of m words of the document d_i, helping us capture different aspects of the document. After computing $\mathbf{A}_1$, we derive representation of document d_i as follows:

$$\mathbf{d}_i = flatten(\mathbf{A}_1^T \cdot \mathbf{H}) \quad (4)$$

where $\mathbf{d}_i \in \mathbb{R}^{h_1 2H}$ and function *flatten(.)* flattens $\mathbf{A}_1^T \cdot \mathbf{H}$ into a vector. We also implemented a more sophisticated multi-head attention in (Vaswani et al., 2017) but did not achieve good results.

4.3 Multi-head Document Attention Layer

This layer consists of three components as follows: (1) extending representations of claims, (2) extending representations of evidence and (3) multi-head document attention mechanism.

Extending representations of claims. So far the representation of the claim $\mathbf{c}$ (Eq. 1) is only from textual content. In reality, a speaker who made a claim may impact credibility of the claim. For example, claims from some politicians are controversial and inaccurate (Allcott and Gentzkow, 2017). Therefore, we enrich vector $\mathbf{c}$ by concatenating it with speaker's embedding $\mathbf{s}$ to generate $\mathbf{c}^{ext} \in \mathbb{R}^x$, where $x = 2H + D_1$ as shown in Eq. 5.

$$\mathbf{c}^{ext} = [\mathbf{c}; \mathbf{s}] \in \mathbb{R}^x \quad (5)$$

Extending representations of evidence. Intuitively, an article published by *nytimes.com* might be more reliable than a piece of news published by *breitbart.com* which is known to be a less credible site. Therefore, to capture more information, we further enrich representations of evidence with publishers' information by concatenating $\mathbf{d}_i$ (Eq. 4) with its publisher's embedding $\mathbf{p}_i$ as follows:

$$\mathbf{d}_i^{ext} = [\mathbf{d}_i; \mathbf{p}_i] \in \mathbb{R}^y \quad (6)$$

where $y = 2h_1H + D_2$. From Eq. 6, we can generate representations of k relevant articles and stack them as shown in Eq. 7.

$$\mathbf{D} = [\mathbf{d}_1^{ext} \oplus ... \oplus \mathbf{d}_k^{ext}] \in \mathbb{R}^{k \times y} \quad (7)$$

Multi-head Document Attention Mechanism. In real life, a journalist from *snopes.com* and *politifact.com* may use all k articles relevant to the claim c to fact-check it but she may focus on some key articles to determine the verdict of the claim c while other articles may have negligible information. To capture such intuition, we need to downgrade uninformative documents and concentrate on more meaningful articles. Similar to Section 4.2, we use multi-head attention mechanism which produces different attention distributions representing diverse contributions of articles toward determining veracity of the claim c.

We firstly create matrix $\mathbf{C}_2 \in \mathbb{R}^{k \times x}$ by replicating vector $\mathbf{c}^{ext}$ (Eq. 5) k times. Secondly, the matrix $\mathbf{C}_2$ is concatenated with matrix $\mathbf{D}$ (Eq. 7) on the last dimension of the two matrices denoted as $[\mathbf{D}; \mathbf{C}_2] \in \mathbb{R}^{k \times (x+y)}$.

Our proposed multi-head document-level attention mechanism applies h_2 different attention heads as shown in Eq. 8.

$$\mathbf{A}_2 = softmax_{col}(\tanh([\mathbf{D}; \mathbf{C}_2] \cdot \mathbf{W}_3) \cdot \mathbf{W}_4) \quad (8)$$

where $\mathbf{W}_3 \in \mathbb{R}^{(x+y) \times a_2}$, $\mathbf{W}_4 \in \mathbb{R}^{a_2 \times h_2}$. The matrix $\mathbf{A}_2 \in \mathbb{R}^{k \times h_2}$, where each of its column is normalized by the softmax operator, is a collection of h_2 different attention distributions on k documents. Using attention weights, we can generate attended representation of k evidence denoted as $\mathbf{d}^{rich} \in \mathbb{R}^{h_2 y}$ as shown in Eq. 9.

$$\mathbf{d}^{rich} = flatten(\mathbf{A}_2^T \cdot \mathbf{D}) \quad (9)$$

where *flatten(.)* function flattens $\mathbf{A}_2^T \cdot \mathbf{D}$ into a vector. We finally generate representation of a tuple $(c, s, \mathcal{D}, \mathcal{P})$ by concatenating vector $\mathbf{c}^{ext}$ (Eq. 5) and vector $\mathbf{d}^{rich}$ (Eq. 9), denoted as $[\mathbf{c}^{ext}; \mathbf{d}^{rich}]$.

To the best of our knowledge, our work is the first work utilizing multi-head attention mechanism integrated with speakers and publishers information to capture various semantic contributions of evidence toward fact-checking process.

4.4 Output Layer

In this layer, we input tuple representation $[\mathbf{c}^{ext}; \mathbf{d}^{rich}]$ into a multilayer perceptron (MLP) to compute probability $\hat{y}$ that the claim c is a true news as follows:

$$\hat{y} = \sigma\big(\mathbf{W}_6 \cdot \big(\mathbf{W}_5 \cdot [\mathbf{c}^{ext}; \mathbf{d}^{rich}] + \mathbf{b}_5\big) + \mathbf{b}_6\big) \quad (10)$$

where $\mathbf{W}_5, \mathbf{W}_6, \mathbf{b}_5, \mathbf{b}_6$ are weights and biases of the MLP, and $\sigma(.)$ is the sigmoid function. We optimize our model by minimizing the standard

Table 1: Statistics of our experimental datasets

	Snopes	PolitiFact
True claims	1,164	1,867
False claims	3,177	1,701
|Speakers|	N/A	664
|Documents|	29,242	29,556
|Publishers|	12,236	4,542

cross-entropy as shown on the top of Fig. 1.

$$\mathcal{L}_\theta(y, \hat{y}) = -\big(y \log \hat{y} + (1-y)\log(1-\hat{y})\big) \quad (11)$$

where $y \in \{0, 1\}$ is the ground truth label of a tuple $(c, s, \mathcal{D}, \mathcal{P})$. During training, we sample a mini batch of 32 tuples and compute average loss from the tuples.

5 Experiments

5.1 Datasets

We employed two public datasets released by (Popat et al., 2018). Each of these datasets is a collections of tuples $(c, s, \mathcal{D}, \mathcal{P}, y)$ where each textual claim c and its credible label y are collected from two major fact-checking websites `snopes.com` and `politifact.com`. The articles pertinent to the claim c are retrieved by using search engines. Each Snopes claim was labeled as *true* or *false* while in Politifact, there were originally six labels: *true*, *mostly true*, *half true*, *false*, *mostly false*, *pants on fire*. Following (Popat et al., 2018), we merge *true*, *mostly true* and *half true* into *true claims* and the rest are into *false claims*. Details of our datasets are presented in Table 1. Note that Snopes does not have speakers' information.

5.2 Baselines

We compare our MAC model with seven state-of-the-art baselines divided into two groups. The first group of the baselines only used textual content of claims, and the second group of the baselines utilized relevant articles to fact-check textual claims. A related method (Mishra and Setty, 2019) used subject information of articles (e.g. politics, entertainment), which was not available in our datasets. We tried to compare with it but achieved poor results perhaps due to missing information. Therefore, we do not report its result in this paper. Details of the baselines are shown as follows:

Using only claims' text:

- **BERT** (Devlin et al., 2018) is a pre-trained language model achieving state-of-the-art results on many NLP tasks. The representation of [CLS] token is inputted to a trainable linear layer to classify claims.
- **LSTM-Last** is a model proposed in (Rashkin et al., 2017). **LSTM-Last** takes the last hidden state of the LSTM as representations of claims. These representations will be inputted to a linear layer for classification.
- **LSTM-Avg** is another model proposed in (Rashkin et al., 2017) which used an average pooling layer on top of hidden states to derive representations of claims.
- **CNN** (Wang, 2017) is a state-of-the-art model which applied 1D-convolutional neural network on word vectors of claims.

Using both claims' text and articles' text:

- **DeClare** (Popat et al., 2018) computes credibility score of each pair of a claim c and a document d_i. The overall credible rating is averaged from all k relevant articles.
- **HAN** (Ma et al., 2019) is a hierarchical attention network based on representations of relevant documents. It uses attention mechanisms to determine which document is more important without considering which word in a document should be focused on.
- **NSMN** (Nie et al., 2019) is a state-of-the-art model designed to determine stance of a document d_i with respect to claim c. We apply NSMN on our dataset by predicting score of each pair (c, d_i) and computing average score based on documents in $\mathcal{D}$ same as DeClare.

Note that, we also applied BERT, LSTM-Last, LSTM-Avg and CNN by using both claims' text and articles' text. For each of these baselines, we concatenated a claim's text and a document's text, and input the concatenated content into the baseline to compute likelihood that the claim is fake news. We computed average probability based on all documents of the claim and used it as final prediction. However, we did not observe considerable improvements of these baselines. In addition to deep-learning-based baselines, we compared our MAC with other feature-based techniques (e.g. SVM). As expected, these traditional techniques had inferior performance compared with neural models. Therefore, we only report the seven baselines' performance.

Table 2: Performance of MAC and baselines on Snopes dataset. MAC outperforms baselines significantly with p-value<0.05 by one-sided paired Wilcoxon test.

Method Types	Methods				True News as Positive			Fake News as Positive		
		AUC	F1 Macro	F1 Micro	F1	Precision	Recall	F1	Precision	Recall
Using only claims' text	BERT	0.60852	0.56096	0.69806	0.31574	0.40318	0.26050	0.80618	0.76011	0.85839

Imprv. over the best baseline		9.47%	8.58%	5.71%	16.01%	14.27%	18.08%	3.43%	4.23%	2.67%

5.3 Experimental Settings

For each dataset, we randomly select 10% number of claims from each class to form a validation set, which is used for tuning hyper-parameters. We report 5-fold stratified cross validation results on the remaining 90% of the data. We train our model and baselines on 4-folds and test them on the remaining fold. We use AUC, macro/micro F1, class-specific F1, Precision and Recall as evaluation metrics. To mitigate overfitting and reduce training time, we early stop training process on the validation set when F1 macro on the validation data continuously decreases in 10 epochs. When we get the same F1 macro between consecutive epochs, we rely on AUC for early stopping.
