
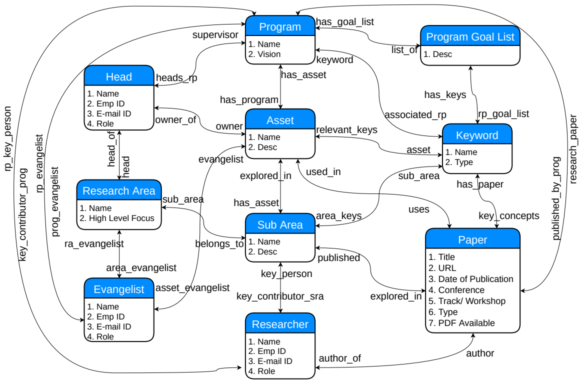

Figure 2: Schema of our propreitary KG LOCA.

in accumulation of errors Dubey et al. (2018). Further, most of the KGQA tasks are not as complex as LOCA. For example, a) All questions of SimpleQA Bordes et al. (2015) can be answered using single triple, b) NLQs for most of the datasets (e.g., SimpleQA, Meta QA) contain only one metioned entity, and c) Even if multiple relations are required for answer entity retrieval, they are organized in a sequence, i.e., chain.

Our motivating example contains specific types of questions that pose many challenges with respect to each of the aforementioned tasks. Moreover, some of the questions can only be answered via a model that attempts more than one sub-tasks together. For example, the first two questions of Figure 1 mention the same words, i.e., "deep learning" but they get associated with two different entity nodes of the KG. Additionally, the prior work could detect the set of relations when the schema sub-graph follows a specific topology, however, in our example, most of the questions follow a different topology. We demonstrate in Section 5 that most of the prior art approaches fail to solve such challenges. We provide a summary of such challenges in Section 2.

In this paper, we propose CQA-NMT, a novel transformer-based, NMT (neural machine translation) model to solve the aforementioned challenges by performing four tasks jointly using a single model, i.e., i) Detection of mentioned entities, ii) prediction of entity types of answer nodes, iii) prediction of topology and relations involved, and iv) question type classification such as 'Factoid', 'Count', etc. CQA-NMT not only performs the four sub-tasks but also helps downstream tasks of mentioned entity disambiguation and subsequent answer retrieval from the KG. The key contributions of this paper are:

(i) We propose a multi-task model that performs all tasks for parsing of natural language question together, rather than the traditional approach of performing these tasks in a sequential manner, which also involves candidate generation based on upstream task and then short-listing them to make the final prediction. We also demonstrate that using such an approach newer types of challenges of the KGQA task can be solved, which have not been attempted by prior work so far.

(ii) We propose the use of neural machine translation based approach to retrieve the variable number of relations involved in answering a complex NLQ against a KG.

(iii) We also demonstrate that every sub-task of parsing an NLQ is complementary to other tasks and helps the model in performing better towards the final goal of KGQA. In Table 3, we have demonstrated that via joint training on more than one task, the accuracy of individual tasks improves as compared to training them separately. For example, when trained separately, the best F1-score for detecting mentioned entity(s) was 83.3, and the best accuracy for the prediction of entity types of answer nodes was 75.7. When trained jointly, we get the corresponding metrics as 87.1 and 76.3. When trained jointly for all tasks, the results improve even further.

(iv) CQA-NMT predicts the relations involved in a sub-graph of KG and also helps to predict the topology of the sub-graph, resulting in compositional reasoning via a neural network on the KG. However, the prior work predicts the relations for a specific topology only[1].

(v) We also demonstrate that our approach outperforms the state-of-the-art approaches on the MetaQA dataset, and therefore we present a new baseline on this dataset. Our approach also performs better than standard approaches

---

[1] Topology is a specific arrangement of how the mentioned entities, and answer entities are connected to each other via the predicted relations. Sample topologies are given in Figure 1. Our approach can be used to answer questions of any topology, if adequate number of samples are included in the training data. The prior works have not attempted a dataset such as LOCA which contains many different topologies. To the best of our efforts we could not find another such dataset, which has led to our aforementioned belief.

as applicable to our dataset and helps us solve most of the real-world industrial challenges.

2 KGQA Problem and Challenges

For answering natural language questions (NLQ), we assume that the background knowledge is stored in a knowledge graph G, comprising of a set of nodes $V(G)$, and edges $E(G)$. Here, nodes represent entities, and edges represent the relationship between a pair of entities or connect an entity to one of its properties. An NLQ (q) is a sequence of words w_i of a natural language (e.g., English), i.e., $q = \{w_1, w_2, ..., w_N\}$. We also assume that the NLQs can mention zero, one, or more entities present in G and enquire about another entity of G, which is connected with the mentioned entity(s). We pose the KGQA problem as a supervised learning problem and next, describe the labels assumed to be available for every question in the training data and that need to be predicted for every question in the test data.

Entity Linking Annotation Some of the n-grams (η_i) in an NLQ refer to entity(s) of KG. Such n-grams have been underlined in Figure 1. The entity-id (as shown in the third column of Figure 1) of the mentioned entity is also assumed to be available as part of label annotation for every question.

Answer Entity Type Annotation (AET), τ: We assume that every NLQ has an entity type (t_i) for the answer entities. These are shown in the middle column of Figure 1. We refer τ as a set of all entity types in the knowledge graph G.

Relation Sequence and Topology Annotation **(path)** Sequence of relations connecting the linked entities to the answer entities can be considered paths $(path_i)$, each of which can contain one or more relations. These paths are connected to form a topology, as shown in Figure 1. This topology of the paths and relations are also assumed to be available for an NLQ in training data. These paths need not be the shortest paths between the linked entities and the answer entities. For example, the last three columns of Figure 1 indicate a) the set of paths separated by a semicolon (;), b) whether this is the shortest path, and c) topology of the paths connecting the linked entities to the answer entities.

Question Type Annotation (q_{type}) Some NLQs can be answered by a single triple of the knowledge graph('Simple'), while some of them require traversal along with more complex topology as indicated earlier('Factoid'), some questions require an aggregate operation such as count ('Count', see question 6, in Figure 1), and finally, some questions perform existence check ('Boolean', see question 8, in Figure 1). Such information is also assumed to be available for every NLQ in training data.

We now describe the challenges that need to be addressed while performing the KGQA task. To the best of our efforts we could not find any prior work that covers all these challenges together.

1. ***Incomplete Entity Mention***: In the NLQ users often do not mention the complete name of the intended entity Huang et al. (2019), e.g., only the first name of a person, short name of a group, etc., e.g., question 8 in Figure 1.

2. ***Co-occurrence disambiguation***: For situations when a mentioned entity should be linked to KG entity with help of another mentioned entity in the question, e.g., in question 7 of Figure 1, there can be many people who have the same first name ('Libby') but there is only one of them who works on NLP, the models needs to use this information to conclusively resolve the mentioned entities Mohammed et al. (2017).

3. ***Avoid un-intended match***: Some of the words in a sentence coincidently match with an entity name but are not an intended mention of an entity, e.g., the word 'vision' may get matched with 'Computer Vision' which is not intended in question 9 of Figure 1.

4. ***Duplicate KG Entity*** The intended entity names may be different from the words used in the NLQ, and there can be more than one entity in the KG that has the same name Shen et al. (2019), for example, "Life Sciences" is the name of a research area, as well as a keyword (see KG schema given in Figure 2). The model needs to link the entity using other words, similar to how it is shown in questions 1 and 2 of Figure 1.

5. ***Relation names mismatch***: Often the words of the KG relations and the words of the NLQ do not match, Huang et al. (2019), e.g., questions 2, 4, 6, etc. in Figure 1.

6. ***Implicit Relations Indication***: Sometimes words of the NLQ do not even make any mention of the relations involved, however, they

need to be inferred Zhang et al. (2018). For example, in question 4 of Figure 1, some of the relations are not mentioned in the question.

Problem Definition: The objective of the proposed approach is to output 1) the mentioned entity(s) (s_i) in the query, 2) the answer entity type , 3) the path or set of predicates, $P_q = \{p_q^1, p_q^2, p_q^3, ..., p_q^N\}$ where, each $p_i \in E(G)$ and, 4) the question type. The set P_q is a sequence of predicates, such that if traversed along these edges from the mentioned entity node(s), we can arrive at the answer entity(s) node(s). The final answer is then retrieved from KG and is post-processed as per the outputs of question type and the 'answer entity type' modules. We assume that we have N training samples $D_{Train} = \{(q_i, \eta_i, t_i, qt_i, path_i)\}_{i=1}^{N}$ available to us where, $q_i \in Q, s_i \subseteq V(G), t_i \in \tau, qt_i \in q_{type}$, and, $path_i \subseteq 2^{E(G)}$.

3 Related Work

In this section, we present a view of prior work, on the KGQA problem as an NLP task, and then on set of techniques used for this task.

3.1 KGQA Task

Berant et al. (2013); Berant and Liang (2014); Reddy et al. (2014); Luo et al. (2018) proposed an approach to perform KGQA by mapping a query to its logical form and then converting it to a formal query to extract answers. However, these are not joint learning tasks as proposed in our work.

Multi-Task based approaches Similar to us, many works like Lukovnikov et al. (2019); Huang et al. (2019); Shen et al. (2019) rely on the jointly learning multiple sub-tasks tasks of KGQA problem. However, all these approaches focus on single-hop relations only, and therefore we cannot take such approaches as a baseline for our model. In a more complex setting, Shen et al. (2019) proposed a joint learning task for entity linking, path prediction (chains topology only), and question type. However, their model does not predict answer entity type. We do not compare our approach with Shen et al. (2019) because they focus on the implicit mention of the entities in previous sentences of dialogue, and also because they do not attempt to predict non-chain topology or the answer entity type.

Non-Chain Multi-Hop Relations Agarwal et al. (2019) proposed an embedding based approach to predict non-chain multi-hop relation prediction (for a fixed and small set of topologies). They perform only one task of relationship prediction.

3.2 Techniques used for KGQA

Transformers and Machine Translation: Transformer Vaswani et al. (2017) has proved to be one of the most exciting approaches for NLP research. They have shown dominating results in Vaswani et al. (2017); Devlin et al. (2018), etc. The paper Lukovnikov et al. (2019) closely resembles our approach as they proposed a joint-learning based multi-task model using Transformer. However, they handle only 1-hop questions and consider relation prediction as a classification task. In its current form it cannot be used to solve the variable length path prediction form, as required in our motivating example. In an extension to the work of using logical forms for KGQA Dong and Lapata (2016) proposed the usage of attention-based seq2seq model to generate the logical form of an input utterance. However, they use an LSTM model and not Transformer.

Graph-Based Approaches GraftNet Sun et al. (2018) and PullNet Sun et al. (2019) approached the problem of KGQA using graph-based solutions. The approach extracts a subgraph related to query and then performs reasoning over it to extract the final answer(s). KV-MEM Bordes et al. (2015) proposed a memory network-based approach for a single relationship prediction.

Embedding Based Approaches Approaches for KGQA using KG embeddings (such as TransE Bordes et al. (2013) and TransR Lin et al. (2015)) were used by Huang et al. (2019) when only one relation (i.e., one RDF triple) is involved. In Bordes et al. (2013); Socher et al. (2013); Dettmers et al. (2018) also one-hop KG modeling approaches were proposed. Recently, Saxena et al. (2020) presented an approach, EmbedKGQA, for joint learning, again using KG Embeddings, in the context of multi-hop relations. However, their approach is not truly a joint model as they perform answer candidate selection via the model, i.e., they arrive at the candidates before executing the model.

Our proposed approach has outperformed PullNet and EmbedKGQA on the MetaQA dataset, as shown in Section 5.

4 Proposed Architecture

In this section, we describe our proposed joint model (CQA-NMT) which is an encoder-decoder

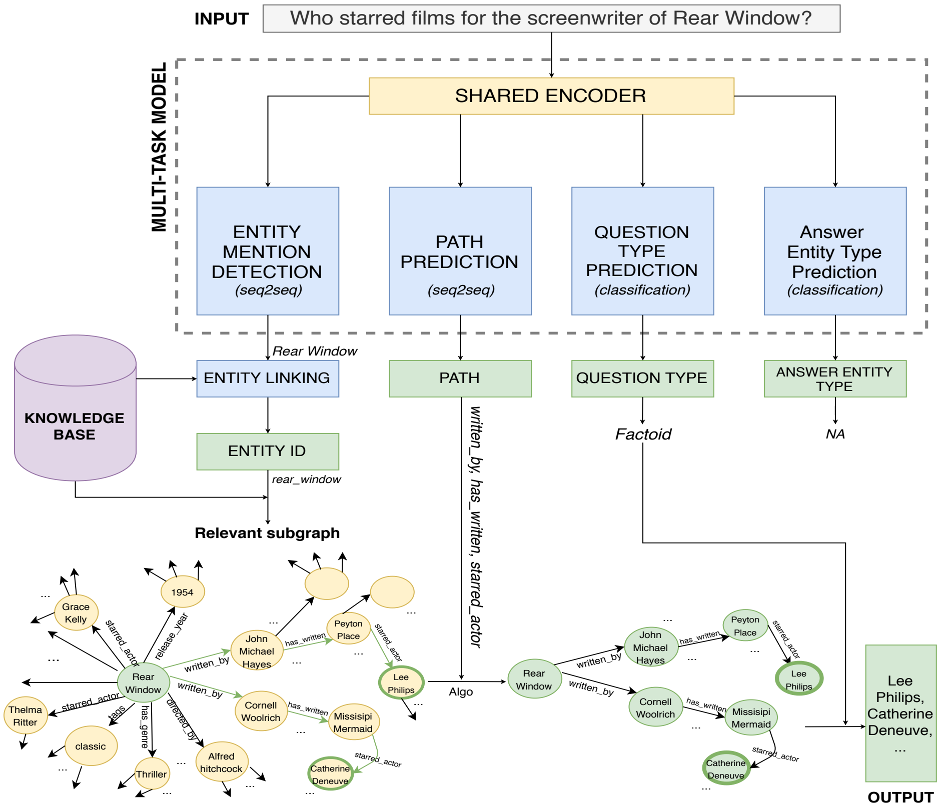

Figure 3: Proposed Multi-task model CQA-NMT. The query is passed through all the modules to (1) Extract the mentioned entity and link it to a KG node. (2) Generate the sequence of predicates required for traversal. (3) Predict the Question type and, (4) Predict AET. After extracting all the information from query, a corresponding formal query such as, SPARQL, is generated to retrieve the final answer.

based model where, BERT Devlin et al. (2018) is used as an Encoder and a Transformer Vaswani et al. (2017) as a decoder. Figure 3 illustrates a high-level view of the proposed model.

Joint Model for KGQA

In this paper, we extend BERT to generate path (or *inference chains*), perform sequence labeling and classification jointly. Details of each module are described next.

1. Entity Mention Detection Module: To extract the mentioned entity(s) from NL query, we performed a sequence labeling task using BERT's hidden states (Figure 4). Sequence labeling is a seq2seq task that tags the input word sequence $x = (w_1, w_2, ..., w_T)$ with the output label sequence $y_{seq} = (y_1, y_2, ..., y_T)$. In this paper, we augmented CQA-NMT to jointly infer the type of the mentioned entity(s) along with its(their) '*span*'. We feed the final hidden states of the tokens $h_2, h_3, ..., h_{T-1}$, into a softmax layer to generate output sequence. Also, we ignore the h_1 and h_T i.e., [CLS] and [SEP] tokens as they can never be a part of an entity(s) and are only required as a preprocessing step of BERT. Since BERT uses WordPiece tokenization, we assigned the same label to the other tokenized input corresponding to their first sub-token. For e.g., the output of BERT's Wordpiece tokenizer is 'Jim Hen ##son' for the input 'Jim Henson'. We assigned the labels for the tokenized output as 'B-Per I-Per I-per', i.e., the second sub-word '##son' was given the same label as the first sub-word 'Hen'. The output of the softmax layer is:

$$y^i_{etype} = softmax(\mathbf{W_{etype}}.h_i + b_{etype}) \quad (1)$$

where, h_i is the hidden state corresponding to the i^{th} token.

2. Entity Linking: The output of the *Entity Mention Detection Module* is a sequence of tokens along with its type (t_i) for a candidate entity. These mentioned entities still need to be linked to a KG node for traversal. In our work, we do not use any neural network for the linking process. Instead, we rely on an ensemble of string matching algorithms[2] and PageRank Page et al. (1999) to break the ties between candidate entities.

The Entity Mention Detection Module outputs as

---

[2] We used Levenshtein Distance and SequenceMatcher packages available in Python

many entities as provided in a query and their associated type (t_i). To link the mentioned entity in the NL query, we extract the candidates from V(G) of type t_i. We then apply 3 string-matching algorithms, similar to (Mohammed et al., 2017) , and take a majority voting to further break the ties. Finally, we apply the PageRank algorithm to link the mentioned entity with a KG entity. One way to understand the usability of the PageRank algorithm is to consider the notion of *popularity*. For e.g., if a user queries 'Where was Obama born?', the user here is more likely referring to the *famous Barack Obama*, compared to any other. A detailed description of the entity mention detection and the entity linking procedure is shown in Figure 4.

3. Path prediction Module: To generate the sequence of predicates for an input query, we augmented our architecture with a Transformer-based Vaswani et al. (2017) decoder which is often used in Neural Machine Translation (NMT) tasks.

We define y_{path}={$p_1, p_2, ..., p_N$} where each $p_i \in E(G)$. In our work, we do not constraint the number of predicates (multiple-hops) that are required to extract the final answer. Hence, an obvious choice was to use a decoder module which can stop generating the predicates once it has predicted the *end-of-sentence* ([EOS]) token (Figure 4).

4. Question Type and Answer Entity Type prediction module: In our work, we formulate the task of determining the question type and the AET as a classification task since we have a discrete set for both q_{type} and *Answer Entity Types*. Using the hidden states of the first special token from BERT, i.e., [CLS], we predict:

$$y_{q_{type}} = softmax(\mathbf{W}_{qt}.h_1 + b_{qt}) \qquad (2)$$

$$y_{\tau} = softmax(\mathbf{W}_{tgt}.h_1 + b_{tgt}) \qquad (3)$$

To jointly model all the task using a single architecture, we define our training objective as:

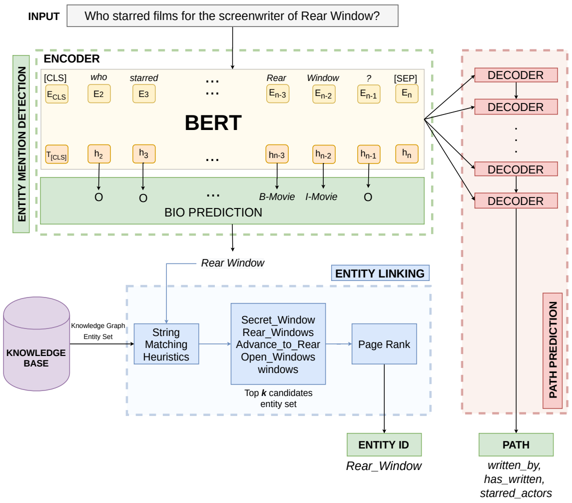
$$p(y|\mathbf{x}) = p(y_{e_{type}}, y_{path}, y_{q_{type}}, y_{\tau}|\mathbf{x}) \qquad (4)$$

$$p(y|\mathbf{x}) = p(y_{q_{type}}|\mathbf{x}).p(y_{\tau}|\mathbf{x}).p(y_{e_{type}}|\mathbf{x}).p(y_{path}|\mathbf{x}) \qquad (5)$$

The path and AET components of CQA-NMT are defined as,

$$p(y_{e_{type}}|\mathbf{x}) = \prod_{n=1}^{N} p(y^i_{e_{type}}|\mathbf{x}), \qquad (6)$$

$$p(y_{path}|\mathbf{x}) = \prod_{t=1}^{T} p(p_t|p_1, p_2, ..., p_{t-1}|\mathbf{x}). \qquad (7)$$



.

Figure 4: Entity Mention and Entity Linking Modules.

where,

$$y_{q_{type}} \in \{\text{factoid, count, boolean, simple}\} \qquad (8)$$

$$y_{\tau} \in \{\text{entity types in KG}\} \qquad (9)$$

$$y^i_{e_{type}} \in \{B, I\} \times \{\text{entity\_types}\} \cup \{O\} \qquad (10)$$

$$p_i \in E(G). \qquad (11)$$

For training we maximize the conditional probability $p(y_{e_{type}}, y_{path}, y_{q_{type}}, y_{\tau}|\mathbf{x})$. The model is fine-tuned end-to-end via minimizing the cross-entropy loss.

5 Experiments and System details

In this section, we first introduce the datasets used for our experiments. We pre-process all NLQs (of all datasets) by downcasing and tokenizing.

5.1 Datasets, Metrices, and Baselines

LOCA Dataset: We introduce a new challenging dataset *'LOCA'*, which consists of 5010 entities, 42 unique predicates, and a total of 45,869 facts. The dataset has 3,275 one or multi-hop questions that have 0, 1, or more entities mentioned in the questions. It contains multiple question types like *count, factoid, and boolean.*

For the questions with multiple entities, we used an operator ";" as a delimiter to separate paths corresponding to each entity (in Figure 1, query 5, 7, and 8). For the scope of this paper, we considered queries involving the only *intersection* which can be replaced with other operators like *union, set-difference, etc.* without loss of any generality. The operator ";" help us detect and predict the different topologies involved in an NL

	Train	Dev	Test
MetaQA 1-hop	96,106	9,992	9,947
MetaQA 2-hop	118,980	14,872	14,872
MetaQA 3-hop	114,196	14,274	14,274
LOCA 1-hop	2,000	250	250
LOCA 2-hop	400	50	50
LOCA 3[or more]-hop	220	28	28

Table 1: Statistics of MetaQA and LOCA dataset

query.

MetaQA: The dataset proposed in Zhang et al. (2018) consists of 3 different datasets namely, *Vanilla*, *NTM*, and, *Audio Data*. All the datasets contain single and multi-hop (maximum 3-hop) questions from the *movie* domain. For our experiments, we used the Vanilla and the NTM version of the datasets and the KB as provided in Zhang et al. (2018). Since, both versions of MetaQA do not consider the AET and question type, we assigned a default label to both the tasks.

Metrics: We used different metrics for different subtasks. Since a query can contain partially mentioned entities, we used F-score to evaluate mention and its type detection module. For Inference Chain (or Path prediction), question type, and, answer entity type prediction we use the accuracy measure. In Table 2, similar to prior works, we have used the Hits@1 to evaluate the query-answer accuracy.

Baselines: We have used, KV-mem Bordes et al. (2015), GraftNet Sun et al. (2018), PullNet Sun et al. (2019), VRN Zhang et al. (2018), and EmbedKGQA Saxena et al. (2020) as the baselines.

5.2 Training Details

All the baselines and the proposed approach were trained on DGX 32GB NVIDIA GPU using TensorFlow Abadi et al. (2015) and Texar Hu et al. (2018) libraries. For CQA-NMT, we used the small uncased version of pre-trained BERT Devlin et al. (2018) model. Adam Kingma and Ba (2014) optimizer was employed with a learning rate of $2e$-5 for BERT and default for others. The training objective of each model was maximized using the cross-entropy loss and the best models were selected using the validation loss. Dropout values were set to .5 and were optimized as described in Srivastava et al. (2014). For BERT we used 10% of total training data for the warmup phase of BERT Vaswani et al. (2017). Finally, for the division of dataset into train, test, and, dev, we used the same split as provided by Zhang et al. (2018) for the MetaQA dataset and a ratio of 80-10-10 for LOCA dataset.

5.3 Main Results

In this section, we report the results of the experiments on the MetaQA and the LOCA dataset. Next, we provide insights into the model outputs and results of error-analysis performed on LOCA dataset.

5.3.1 LOCA

The experimental results for LOCA dataset are shown in the last row of table 2. The results affirm that the proposed approach outperforms the baselines. We observed that the baselines' inability to handle ***Duplicate KG Entity*** (Section 2 challenge 4) limits their performance. Additionally, the ability of the NMT Bahdanau et al. (2014) model to effectively handle complex and un-known topologies helped us retrieve answers with better accuracy for variable-hop (v-hop) queries.

5.3.2 MetaQA

The experimental results for MetaQA are shown in table 2. For *Vanilla* MetaQA, we achieved better answer accuracy on 1-hop and 3-hop settings. However, in a 2-hop setting, we were able to achieve comparable results to the state-of-the-art. An increment of about 2% and 4.9% Hits@1 can be seen in the 1-hop and 3-hop settings.

To obtain the performance of each baseline on v-hop (variable-hop) dataset, we re-use the existing models for 1-hop, 2-hop, and 3-hop and assume that there is an oracle which can redirect query to the correct model. Thus estimated accuracy of various approaches is shown in the 4^{th} row of Table 2, while the actual results on v-hop dataset are shown in the 5^{th} row. It is evident that CQA-NMT outperforms all the baselines on MetaQA dataset in variable hop setting.

To gauge the effectiveness and robustness of our model, we used the same models trained on vanilla MetaQA dataset and evaluated its performance on *NTM* MetaQA, i.e., in zero-shot setting. For this, we achieved better results on 1 and 3-hop. The worse performance of CQA-NMT on MetaQA-NMT(2-hop) can be because of zero shot setting. Because, as compared to VRN, we have not trained CQA-NMT on MetaQA-NTM dataset, we trained it on MetaQA vanilla dataset only.

	KV-Mem	GraftNet	PullNet	EmbedKGQA	VRN	CQA-NMT
MetaQA(1-hop)	96.2	97.0	97.0	97.5	97.5	**99.96**
MetaQA(2-hop)	82.7	94.8	**99.9**	98.8	89.9	99.45
MetaQA(3-hop)	48.9	77.7	91.4	94.8	62.5	**99.78**
MetaQA(V-hop) Estimated	73.79	89.11	96.05	-	-	**99.69**
MetaQA(V-hop)	-	83.67*	-	-	-	**95.85**
MetaQA-NTM(1-hop)	-	-	-	-	81.3	**83.3**
MetaQA-NTM(2-hop)	-	-	-	-	**69.7**	62.1
MetaQA-NTM(3-hop)	-	-	-	-	38.0	**81.3**
LOCA	51.07	72.27	-	-	-	**78.29**

Table 2: Results of the baselines and CQA-NMT on MetaQA (vanilla and NTM) and LOCA dataset. Results for MetaQA-NTM were obtained in zero-shot setting for CQA-NMT. All other baseline results are taken from Sun et al. (2019), Zhang et al. (2018), and Saxena et al. (2020), except for * marked numbers. Note: Source code for PullNet, VRN is not available. We were not able to replicate the same results of KV-Mem.

	Mention Detection (F1-score)	AET (Accuracy)	Inference Chains (Accuracy)	Question Type (Accuracy)	Answer (Accuracy)
Unsupervised	*67.12*	*53.3*	*51.0*	-	42.9
BERT (mention only)	83.3	*53.22*	*51.9*	-	47.22

5.4 Further Results and Analysis

Advantage of Transformers: In the LSTM based implementation of mentioned entity detection, it could not detect different entity types for the same phrase "deep learning" in query 1 and 2 of Figure 1. However, in BERT-based approach it was able to. We therefore infer that such phenomenon could occur due to key features of BERT such as multi head attention, WordPiece embeddings, Positional embeddings, and/ or Segment embeddings. Moreover, in a different context, it was able to assign different types to the entities with the same mentions (Query 1 and 2 from Figure 1).

Effects of using less annotations: To study the importance of annotation in our approach, we removed several components from our proposed approach and studied the effects (Table 3). We first studied CQA-NMT after removing all the supervision and used heuristics-based-approaches for AET and Mention Detection (both the approaches were taken from Mohammed et al. (2017)). The shortest path, similar to Sun et al. (2018, 2019), between the linked KG entity and AET, was then taken to retrieve the answers. This setting (row 1) results in the worst performance. In row 2, 3, and 4 of Table 3, we kept only one component of CQA-NMT as supervised and applied heuristics for others as mentioned above. As evident from these rows, mention detection plays a crucial role in extracting the correct answer (a jump in range of 2%-5% in answer accuracy). A similar analysis can be found in Dong and Lapata (2016); Guo et al. (2018); Srivastava et al. (2020), where authors found that entity linking error is one of the major errors leading to wrong predictions in KGQA.

In summary, while testing each components of CQA-NMT, we tried supervising different components at a time and used heuristics based approaches for the remaining components. The heuristics are:

a) Shortest path algorithm, similar to Sun et al. (2018, 2019), for Path Prediction Task.

b) Candidate and Relation Pairing Score Mohammed et al. (2017) for Entity Linking.

c) LSTM based Classifier Mohammed et al. (2017) for Answer Entity Type Prediction. [however in Row 1 "Unsupervised", we identify the AET if name of the entity-type is present in the NLQ].

Benefits of joint training: From row 5-7 of Table 3, we infer that joint training not only improves the scores of individual components (in range 15%-20%) but also, the overall answer accuracy. We observed that the challenges 5 and 6 from section 2 were handled significantly better after jointly training CQA-NMT for AET and mention detection (row 5). We found that the context used by a mentioned entity for AET was different in different queries. For e.g., in queries 'Who heads Deep Learning?' and 'papers in Deep Learning', *Deep Learning*, is a *research area* with AET 'head' in the former, and in the later, is a *keyword* with AET 'paper.title'. After jointly training the mention detection model with AET or IC, a jump of ∼4% can be observed for the individual components and ∼11-20% in answer accuracy.

Errors with Joint Training: From table 3, it seems that the joint-training helps. However, we also found that the error made by a single module produces a cascading of errors. For example, if for a **single** mention span 'deep learning and ai' with the gold label as 'B-research_area I-research_area I-research_area I-research_area', the entity detection predicts 'B-research_area I-research_area O B-keyword', the path prediction module generates two different paths, one for each entity, leading to wrong answer.

Similarly, if AET prediction module makes an 'error', it gets propagated to all the other modules simultaneously. The frequency of such error, however, was considerably small and in range of 1-2% of total training or test data.

Robustness against variable hops: We combined all the 3 vanilla MetaQA datasets into a single dataset. The results on this new dataset, *MetaQA v-hop (variable-hop)* is shown in table 2. Since the other approaches in the literature did not perform such analysis, MetaQA v-hop is a new challenge that we propose.

Motivation for PageRank: When we have more than one candidate entity for a mentioned entity, we want to choose the one with higher popularity (Sec 4). One of the most well established measure of popularity of nodes in graphs is PageRank. Therefore we have used it. Further, when more than one entity are mentioned in an NLQ, there can be more than one candidate entity for each of them. The graph-based approach also helps us choose the candidates that are well connected.

We also experimented using other measures such as in-degree and out-degree of nodes. However, for LOCA dataset, we achieved an increment of 22% using PageRank on Entity Linking task, as compared to the in-degree and out-degree measures. PageRank also helped in reducing the challenges 1-2 from Sec. 2.

5.4.1 Retrieval of answer(s) from KG

The final objective of a KG-QA system is to retrieve the correct answer from KG against a query q. To this end, we use the outputs of the different components of CQA-NMT and feed them to complete the pre-written SPARQL sketchs. We defined a bunch of rules for different question-types and used a simple-mapping rules to map the queries to the sketches. For e.g., consider the query, q = "Who is working in automated regulatory compliance and has published a paper in NLP?". The output of CQA-NMT contains all the information that is required to form a structured query such as SPARQL. The outputs of CQA-NMT are:

1. Linked Entities: {e5: automated regulatory compliance (sub-area), e6: NLP (keyword)}
2. Inference Chain: key_person; has_paper, author
3. Answer Entity Type (AET): researcher.name
4. Question Type (q_{type}): Factoid

After using the q_{type} information, we fill a sketch using other outputs. The generated SPARQL query is:

SELECT DISTINCT ?uri WHERE {<e5> <key_person> <?uri> . <e6> <has_paper> <?x> . <?x> <author> <?uri>}.

Where, e5 and e6 are unique identities assigned to 'automated regulatory compliance' (of type *sub-area*) and NLP (of type *keyword*).

6 Conclusion

We presented a complex version of the KGQA problem, which involves mention of multiple entities in the question. Multiple sequence of relationships combined in complex topologies, are required to answer such questions. It is evident that such questions, while required to be answered in real world industrial setting, cannot be answered using prior approaches. We propose a novel CQA-NMT model to answer such questions and have performed a detailed comparison of our approach with prior art on MetaQA and Loca datasets. We have shown that CQA-NMT not only solves more complex task, but also performs better on MetaQA dataset as compared to baseline approaches.

Abstract

There has been recent success in pre-training on monolingual data and fine-tuning on Machine Translation (MT), but it remains unclear how to best leverage a pre-trained model for a given MT task. This paper investigates the benefits and drawbacks of freezing parameters, and adding new ones, when fine-tuning a pre-trained model on MT. We focus on 1) Fine-tuning a model trained only on English monolingual data, BART. 2) Fine-tuning a model trained on monolingual data from 25 languages, mBART. For BART we get the best performance by freezing most of the model parameters, and adding extra positional embeddings. For mBART we match or outperform the performance of naive fine-tuning for most language pairs with the encoder, and most of the decoder, frozen. The encoder-decoder attention parameters are most important to fine-tune. When constraining ourselves to an out-of-domain training set for Vietnamese to English we see the largest improvements over the fine-tuning baseline.

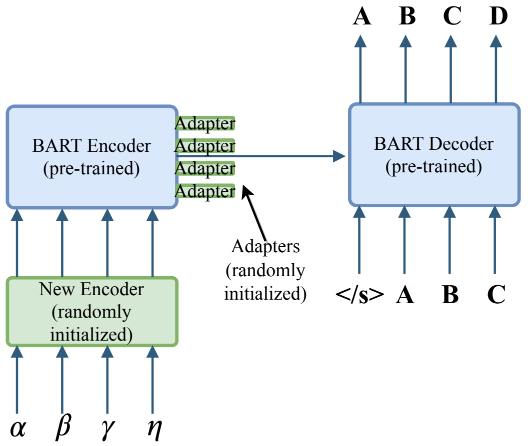

Figure 1: Schematic diagram showing the components of our system for adapting BART to MT. We learn a new encoder that takes as input the source language, with a potentially different vocabulary to the original BART system. We freeze most BART parameters (frozen model components are shown in blue).

1 Introduction

Machine Translation (MT) has recently seen significant advances, with improvements in modeling, especially since the advent of neural models (Sutskever et al., 2014; Bahdanau et al., 2015), and the availability of large parallel corpora for training such systems (Smith et al., 2013; Kocmi and Bojar, 2017; Tiedemann, 2012). However, often standard neural systems do not perform well on *low-resource* language pairs (Koehn and Knowles, 2017), especially when the language pairs are only distantly related. Since these languages are spoken by a large fraction of the world's population, reducing the gap in performance between high and low-resource MT could have a large impact.

An explosion of interest in large-scale pre-training in Natural Language Processing has led to increased performance on smaller datasets, by simple *fine-tuning* of large pre-trained models on downstream tasks. The typical approach is to train a large model on text from the web (for example English Wikipedia), with a common objective predicting masked out tokens using the unmasked context. For Natural Language Generation (for example summarization of text), performance can be improved by pre-training a sequence-to-sequence model (Song et al., 2019; Lewis et al., 2019).

However previous work has shown that on NLP tasks such as Natural Language Inference, the relative performance of fine-tuning vs. keeping the pre-trained model frozen depends on the similarity of the pre-training and downstream tasks (Peters et al., 2019). We observe empirically that simple fine-tuning of a monolingual model for MT can result in worse performance than training from scratch (e.g. Table 1). For MT the more common mono-

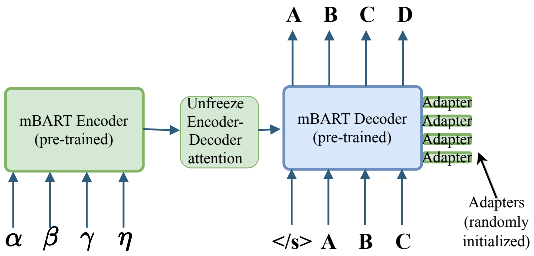

Figure 2: Schematic diagram showing one method of adapting mBART to MT, unfreezing the encoder and encoder-decoder attention, and adding adapters in the decoder. Model components colored blue are not updated during fine-tuning.

lingual (usually only English) pre-training (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019; Yang et al., 2019b; Liu et al., 2019) may be inadequate since the input or output domain for the downstream task will be a non-English language.

Multilingual pre-training offers a solution, by modifying the pre-training objective to include many languages. Using a multilingual pre-trained model for MT gives good performance, especially on lower-resource language directions (Liu et al., 2020). However it is challenging to balance the training data so that higher-resource languages do not overwhelm lower-resource ones (Arivazhagan et al., 2019; Conneau et al., 2019). For a particular language it may be hard to source monolingual data, or it may be simply not included in training.

We also consider multilingual MT (training on many language pairs and sharing all or most model parameters) as a downstream task. Sharing 'knowledge' across language directions can improve performance on low-resource language pairs by transfer from other pairs included in training. Previous work observed problems of performance degradation, often on high-resource languages, due to interference and constrained capacity (Johnson et al., 2017; Tan et al., 2019). And when initialising from a pre-trained model, we want to avoid 'catastrophic forgetting', where by fine-tuning on a particular language pair we lose the knowledge about another language pair that is stored in the model weights.

Previous work has explored how to improve on simple fine-tuning, by freezing pre-trained model parameters (Peters et al., 2019; Houlsby et al., 2019) and using lightweight 'adapter modules' (Houlsby et al., 2019; Stickland and Murray, 2019) which are inserted between the layers of the pre-trained network. We aim to explore and improve on these approaches for both bilingual and multilingual MT (in contrast to previous work largely focusing on text classification). We explore freezing different subsections of the pre-trained model.We expect freezing to be particularly useful when the parallel data is of low quality, in which case naive fine-tuning may, for example, over-specify the pre-trained model to a particular domain.

Our main contributions are:

- A novel fine-tuning approach, similiar to Lewis et al. (2019) but with adapter modules in the encoder of the pre-trained sequence-to-sequence model and combining both learnable, and fixed sinusoidal, positional embeddings in the input module (see sections 3.1 and 3.2) that feeds into the pre-trained encoder.

- Extensive experiments with fine-tuning a multilingual pre-trained model for MT, showing the benefits and drawbacks of freezing various parameters. We find we should freeze the decoder but unfreeze the encoder-decoder attention when fine-tuning on $Xx \rightarrow En$ data, and in the other direction we should freeze the encoder but unfreeze the entire decoder (section 5.3). We find monolingual models benefit more from freezing parameters than multilingual models (section 5.2).

- Results on fine-tuning a multilingual pre-trained model for multilingual MT showing that freezing parameters improves performance on some, mostly distantly related, language directions (section 5.5).

2 Background and Related Work

BART and mBART We briefly describe the pre-trained models we focus on in this work. In order to perform machine translation with the minimum of modifications to the pre-trained model, we prefer models that can perform conditional sequence generation. We concentrate on the BART (Bidirectional and Auto-Regressive Transformer) model (Lewis et al., 2019) and the multilingual BART (mBART; Liu et al., 2020) model. BART and mBART are sequence-to-sequence models with the standard transformer-based neural machine translation architecture, i.e. an encoder and autoregressive decoder. The pre-training task they are trained on is reconstructing a document from a noisy version of that document (so called 'denoising autoencoder'). Examples of noise added to the training data include randomly shuffling the order of the original sentences, randomly changing the start position of the document, and using a masking scheme where arbitrary length spans of text are replaced with a single mask token. BART and mBART are trained entirely on monolingual data from the web, with English data for BART and data from 25 different languages for mBART.

BART and mBART have almost identical architectures, with 12 encoder layers and 12 decoder layers with model dimension of 1024 and 16 attention heads. BART has a vocabulary of approximately 40k and $\sim$ 406M parameters, whereas mBART has a larger vocabulary of size 250k and $\sim$ 610M parameters.

Pre-trained Models for MT There has been much recent progress in pre-training for NLP applications (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019; Yang et al., 2019b; Liu et al., 2019), with the most relevant for our work focusing on text generation (Radford et al., 2019; Song et al., 2019; Dong et al., 2019; Raffel et al., 2019; Lewis et al., 2019) Specifically for MT, Ramachandran et al. (2017) proposed pre-training the encoder-decoder modules as two separate language models, and Yang et al. (2019a); Zhu et al. (2020) explored approaches incorporating BERT model weights into the usual seq-to-seq architecture.

Multilingual MT *Multilingual translation* (Firat et al., 2016; Viégas et al., 2016; Aharoni et al., 2019; Arivazhagan et al., 2019) aims to jointly train one translation model that translates multiple language directions, and shares representations to improve the translation performance on low-resource languages (Gu et al., 2018). Our freezing approach is similar in spirit to Sachan and Neubig (2018) who investigate which parameters are most useful to share for multilingual MT with transformer models. We start from a multilingual pre-trained model, and decide between sharing or freezing parameters.

Transfer Learning for MT *Transfer learning* hopes to leverage a related task to perform well on a target task, for example by initialising the model weights from those resulting from training on a related task. For MT various approaches have been explored, with a common method training on high-resource language(s) and fine-tuning on a low-resource language (Neubig and Hu, 2018).

Closely related to our work is that of Bapna and Firat (2019), who introduce freezing and adapters (extra parameters inserted within the transformer) for domain adaption in MT. They take an MT model trained on a large parallel corpus, and fine-tune in a different domain (e.g. legal text). We differ in that we start from a pre-trained model that has not been trained on parallel text, and study adapting it to MT. Approaches based on freezing various model components have also been proposed (Thompson et al., 2018; Zoph et al., 2016), but have focused on RNN models pre-trained with parallel data, not transformer models pre-trained on monolingual data.

3 Methods

Because BART has been trained on only English input, we need to use different techniques when fine-tuning BART and mBART for MT, with a schematic overview shown in Figure 1 and Figure 2. BART and mBART are standard sequence-to-sequence models, where an *encoder* consumes a sequence of source-side tokens, and a *decoder* acts as a conditional language model, generating target tokens given a source sequence. Intuitively, we want the encoder and decoder to be performing roughly the same tasks during fine-tuning as they were during pre-training. For BART this means the input to the encoder should be similar to (embedding vectors of) noisy English text. Therefore when training on say, Vietnamese to English, we first transform the Vietnamese source sentence into a representation useful for BART. We introduce new parameters (the 'Input Module') that consume the source sentence and produce hidden vectors we can feed into the BART encoder. We describe the Input Module architecture in section 3.1.

mBART can be fine-tuned without modification since during pre-training it saw the languages it will be fine-tuned on. To increase flexibility when freezing parts of the network, we optionally add extra parameters to both BART and mBART, described in section 3.3.

3.1 Input Module Architecture

We refer to the network that takes in the source language text and outputs hidden vectors useful for BART as an 'Input Module' or $\mathrm{IM}(\cdot)$. To improve performance on low-resource MT, we use smaller token embedding vectors on the source side of size $d_{\mathrm{s}} = 512$, whereas BART uses hidden vectors of size $d_{\text{BART}} = 1024$. The full network is as follows, with $\{\mathbf{e}_t\}_{t=0}^{l}$ token embeddings for a source sentence with l tokens,

$$\text{BART}(\text{IM}(\{\mathbf{e}_t\}_{t=0}^{l})), \tag{1}$$

where $\text{BART}(\cdot)$ is the full BART encoder-decoder model. Where we would normally input token embeddings to the BART model we use the outputs of the Input Module. The t-th element of $\text{IM}(\{\mathbf{e}_t\}_{t=0}^{l})$ as follows:

$$\alpha\text{LN}(\mathbf{W}\text{Transformer}(\{\mathbf{e}_t\}_{t=0}^{l})_t) \tag{2}$$

and where $\text{LN}(\cdot)$ is layer-norm, $\mathbf{W}$ is a matrix projecting up from d_{s} to d_{BART}, and $\text{Transformer}(\cdot)$ is the application of a series of Transformer layers. α is a scalar, in our case equal to $\sqrt{d_{\text{BART}}}$, which is required to insure the input to BART is on the same scale as the embedding vectors BART was trained on. If we remove $\text{LN}(\cdot)$, $\mathbf{W}$ and α, and set $d_{\text{s}} = d_{\text{BART}}$, we recover the method introduced by Lewis et al. (2019) for fine-tuning BART on MT.

3.2 Extra Positional Embeddings

We found empirically that the details of positional embedding vectors are important for good performance (see Table 1), perhaps because of the need for the BART model to deal with different word order to that it was trained on. Transformer models normally have either learnable positional embedding vectors, or fixed sinusoidal positional embedding (Vaswani et al., 2017) vectors $\mathbf{p}^t$, with $\mathbf{p}_i^t = \sin(t/10000^{i/(d_s/2-1)})$, if $0 \leq i < d_s/2$, and $\mathbf{p}_i^t = \cos(t/10000^{(i-(d_s/2-1))/(d_s/2-1)})$ if $d_s/2 \leq i < d_s$, where t indexes position and i indexes dimension.

Note that positional embedding are typically only added to the token embeddings. We use learnable positional embeddings at the embedding layer. But to get extra positional information, we optionally add fixed sinusoidal positional embedding to the input of each transformer layer in $\text{IM}(\cdot)$, i.e. the input to layer i, $\mathbf{h}_t^i = \mathbf{o}_t^{i-1} + \mathbf{p}^t$, with $\mathbf{o}_t^{i-1}$ the previous layer output. This means the network has access to both *learned positional embeddings* (only at the embedding layer), and *fixed sinusoidal* ones at the input to each layer.

3.3 Within-Network Adapter Architecture

When freezing parts of a pre-trained model (either BART or mBART in our case), we may want to add flexibility by modifying the pre-trained model architecture. One approach is to use 'adapters', introduced by Houlsby et al. (2019); Stickland and Murray (2019) which are newly-initialised neural network layers that can be 'slotted in' to the layers of the pre-trained model.

We only considered simple adapter architectures, essentially feed-forward networks, with one hidden layer, and a residual connection to the output. The dimension of the hidden layer can be much smaller than the model dimension to reduce computational cost and parameter count. We use one adapter per transformer layer, inserting them at the end of the layer (Stickland and Murray, 2019; Bapna and Firat, 2019). We use the following architectures, with $\mathbf{h}$ the hidden state of a particular token after the usual transformer layer, and $\mathbf{h}_{\text{out}}$ the hidden state of the token after the adapter layer:

$$\begin{aligned} \mathbf{z} &= \text{gelu}(\mathbf{W}_d\mathbf{h}) \\ \mathbf{h}_{\text{out}} &= \tanh(\mathbf{W}_u\mathbf{z}) + \mathbf{h} \end{aligned} \tag{3}$$

The $\tanh$ non-linearity helped with stability in early experiments, probably because it prevents the adapter output exploding by constraining it between -1 and 1.

We also considered a version of the adapter based on the 'gated linear unit' (GLU; Dauphin et al., 2016) architecture:

$$\begin{aligned} \mathbf{z} &= 2\sigma(\mathbf{W}_g\mathbf{h}) \odot \text{gelu}(\mathbf{W}_d\mathbf{h}) \\ \mathbf{h}_{\text{out}} &= \tanh(\mathbf{W}_u\mathbf{z}) + \mathbf{h}. \end{aligned} \tag{4}$$

We found the network was sensitive to changes in the magnitude of the hidden states the adapter produced, and therefore multiply the sigmoid gate by 2 so that it approximately leaves the magnitude of the hidden states unchanged.

3.4 Freezing Details

BART We freeze all parameters of BART except the weights and biases of the layer-norm modules (following Houlsby et al. (2019)), and additionally unfreeze the self-attention module of the first layer in the BART encoder, which is a small fraction of total BART parameters ($24 \cdot 2d_{\text{BART}}$ from layer-norm parameters and $4d_{\text{BART}}^2$ from the self-attention module). We freeze BART token embeddings (used in the softmax layer).

mBART In most of our experiments we unfreeze layer-norm parameters, positional and token embeddings, and either the entire encoder or decoder

Languages	Vi-En	Tuned Params (m)
(1): BART + InputModule (unfreeze all)	9.5	374
(2): BART (frozen) + InputModule	27.9	26

Table 1: Ablation study for various choices in the frozen BART method, with validation set BLEU score. We organise model settings by a number in brackets, (n), and define a new model configuration in bold as **(n)**:. We use '+' to indicate the addition of new model settings on top of the previous ones. Method **(2)** is similar to the method introduced by Lewis et al. (2019). '+ sinusoidal positional embeddings' refers to adding sinusoidal positional embeddings to token embeddings, while '+ extra positional embeddings' refers to adding them within each transformer layer (see section 3.2). 'Tuned Params (m)' refers to the number of tunable parameters for each method in millions. Test set results are listed in Table 3 (as 'Frozen BART').

module (or the encoder and subsections of the decoder). We unfreeze the self-attention module of the first layer in the mBART encoder and decoder.

4 Experimental Settings

We use the fairseq (Ott et al., 2019) library for all experiments. The final models are selected based on validation likelihood, except for multilingual fine-tuning where we evaluate the models after 10000 training steps. We use beam-search with beam size 5 for decoding, and evaluate all BLEU scores using SacreBLEU (Post, 2018) [1]. We use ISO 693-2 language codes in this work for convenience, and use the same parallel data as Liu et al. (2020), both listed in listed in Table 11 of the Appendix.

We fine-tune frozen BART and an Input Module on bilingual parallel text, feeding the source language into the Input Module. For mBART we feed the source language into the encoder, and use the same hyper-parameters as Liu et al. (2020). When using adapters we use 0.1 dropout in the adapter bottleneck layer (**z** in section 3.3), and a hidden dimension of either 128, or $\lfloor 2/3 \cdot 128 \rceil$ when using a gated linear unit adapter. We use the Adam (Kingma and Ba, 2015) optimizer. Hyper-parameters are listed in Appendix B, and we use the same hyper-parameter search space for frozen and non-frozen models.

4.1 Multilingual MT

We train with a very large effective batch size, training on 32 GPUs with a per-GPU batch size of 4096 tokens, meaning our total batch size is $N \cdot 32 \cdot 4096$ tokens, where N is the number of language pairs. We evaluate our model after 10000 training steps (amounting to $N \cdot 10000$ forwards-backwards passes through the model).

4.2 Vocabulary

BART uses the GPT-2 tokenizer, which uses the BPE (Sennrich et al., 2016) approach (on the level of bytes, not characters). BART could technically take any Unicode string as input, however the BPE is learned on English text. When fine-tuning BART on machine translation we therefore learn a

new subword vocabulary (using the sentencepiece (Kudo and Richardson, 2018) library) on the source data from the fine-tuning dataset, and use a smaller vocabulary size of 5000, which empirically performs better for low-resource MT (Guzmán et al., 2019; Sennrich and Zhang, 2019). We don't change the mBART tokenizer or vocabulary.

5 Results and Discussion

5.1 Frozen BART

Table 1 shows the effects of various choices we made in fine-tuning BART for MT. *Freezing* is important: we see an 18.4 BLEU point improvement from fine-tuning a frozen BART model compared to fine-tuning an unfrozen BART (both with an Input Module; see section 3.1).

Adding extra flexibility with within-network adapters helps performance, especially when added to the BART *encoder*. It is important to use *learned positional embeddings* at the embedding layer in the Input Module, with an 10.1 BLEU score drop if we use fixed positional embeddings (at the embedding layer). We see consistent gains in Table 1 and Table 2 by adding additional, fixed sinusoidal positional embeddings to the input of every transformer layer of the Input Module (see section 3.2), even when using an unfrozen BART. The BART encoder 'expects' English input, and it may be the Input Module with extra fixed embeddings can better account for the different word order in the input language. In the next section we compare to mBART and baselines.

5.2 Frozen mBART

In Table 3 and Table 5 we list results from freezing various parts of mBART. We get better performance than fine-tuning ('ft all' in Table 3) with our freeze decoder + fine-tune encoder-decoder attention method ('ft enc-attn' in Table 3) on Ne-En and Cs-En for $Xx \rightarrow En$, and mostly similar results to

the baseline otherwise.

We believe a benefit to freezing, when fine-tuning on training data from a different domain to test data, will be avoiding specialising the pre-trained model to the fine-tuning train data domain. To test this we constructed a new Vi-En parallel dataset (Vi-En† in Table 3) using the some of the same sources as the Flores (Guzmán et al., 2019) training data (the Si-En and Ne-En training sets used in this work), specifically GNOME/KDE/Ubuntu domain from the OPUS repository[2] and Bible translations from the bible-corpus[3], and use the same test and validation sets as the IWSLT15 Vi-En dataset. By constraining ourselves to this out-of-domain training set we see the largest gains out of the language pairs we considered over the fine-tuning baseline (0.9 BLEU).

We also consider the effect of the size of the fine-tuning dataset. If we constrain the training data to a random subset of 200k training examples from Ro-En (Table 6), the 'ft enc-attn' method outperforms simple fine-tuning. This effect generalises to an mBART variant that was pre-trained on only Ro and En monolingual data (using the same data as Liu et al. (2020)). Further results on Ro-En data are available in the Appendix, Table 10, and show similar trends to Table 3, with fine-tuning encoder-decoder attention the most important.

Table 3 shows the relative performance of frozen BART, frozen mBART and baselines. Fine-tuning mBART gave consistently better results than frozen BART especially for distantly related languages. For Si, Ne and My the performance of frozen BART is roughly on par with a randomly initialised model (or much worse in the case of Ne-En). The parallel data for these languages is often lower quality, and the BART system has to learn about the non-English language from noisy or out-of-domain text (e.g. text from the Ubuntu manual for the En-Ne pair). For Vi and It, we have high quality parallel data, and the frozen BART method is only approximately 1.5 BLEU points behind the best mBART results. We note mBART was trained on more English data than BART, and with different noising function hyper-parameters.

5.3 What Should be Unfrozen?

Layer-Norm We find large benefits to simply fine-tuning the weights and biases of the pre-trained layer-norm weights (recall that after normalisation, the layer-norm module multiplies each hidden dimension by a weight and adds a bias); this was observed in the setting of BERT by Houlsby et al. (2019). This gains e.g. 0.5 BLEU for frozen BART (see Table 1) and an average of 0.8 BLEU across five languages for mBART (see Table 4 compared to Table 3). Since these weights and biases are only $2d$ parameters per layer-norm, where d is the model dimension. This is parameter-efficient, with adding more parameters with 'Adapters' on top of unfrozen layer-norm providing a smaller improvement.

Encoder vs Decoder For the *Xx* → *En* direction (Table 3) we can see that freezing the decoder always performs better than freezing the encoder (except for It-En where they perform roughly the same.) For the *En* → *Xx* direction (Table 5) we see slightly weaker evidence for the opposite trend, with the decoder more useful to fine-tune; but for the high resource languages Es and Cs freezing the decoder works better. There is more English data in mBART pre-training than data in other languages, which may account for better results with a frozen encoder (when English is the source language) or decoder (when English is the target language). Adding flexibility with adapters in the frozen layers

Table 7: Test set BLEU score on many-to-one (*Xx* → *En*) multilingual MT with a simple round-robin training schedule. 'Ft enc-attn' refers to fine-tuning the encoder, and fine-tuning the encoder-decoder attention module in every decoder layer, leaving the other decoder sub-modules frozen. The 'Ft enc-attn' model setting uses adapter modules in the decoder to increase flexibility after freezing parameters. Bold indicates the best score and all scores whose difference from the best is not statistically significant (with p-value less than 0.05). For clarity we underline language pairs where the 'Ft enc-attn' method matches or outperforms naive fine-tuning.

improves performance in all languages and directions, except for Ne→En.

We explore more fine-grained unfreezing for the *Xx* → *En* direction (Table 3). We fine-tuned three equally sized subsets of the decoder: the encoder-decoder attention layers (approx. $12 \cdot 4d^2_{\text{BART}}$ parameters), the self-attention layers in the decoder (approx. $12 \cdot 4d^2_{\text{BART}}$ parameters), or the entire last three layers of the decoder (approx. $3 \cdot 16d^2_{\text{BART}}$ parameters). We observe that fine-tuning the encoder-decoder attention performed well (note the last three layers include three encoder-decoder attention layers), with fine-tuning self-attention the least useful. We hypothesize that the pre-training task of mBART (reconstructing noisy monolingual sentences) does not help with teaching the encoder-decoder attention to align source and target text of different languages.

	Tokens per GPU
Finetune all	2304
(1): Freeze decoder	4096
Freeze encoder	3584
(2): (1) + decoder adapters	4096
(2) + ft enc-attn	3328

Table 8: Maximum number of tokens that would fit on one NVIDIA Volta GPU when fine-tuning mBART on the En-Vi training set. We evaluated batch sizes in increments of 256 tokens.

5.4 Memory Cost

Freezing parameters means we no longer need to allocate memory to storing their gradients. We will obtain additional memory savings when using an optimizer that stores various other quantities (i.e. the Adam optimizer stores running averages of the first and second moments of gradients.). The memory savings allow for roughly 45-75% larger batches for the methods we consider in this work (see Table 8 for our mBART methods), but for larger pre-trained models the proportion of GPU memory freed up by freezing will increase. At inference time we no longer require gradients and we have the same memory cost.

5.5 Multilingual Fine-tuning of mBART

We explore freezing parts of the mBART model when fine-tuning on a challenging multilingual MT task. Table 7 lists results from a naive fine-tuning baseline, and results from freezing most of the decoder but unfreezing the encoder-decoder attention (when freezing we use GLU adapters in the decoder, see section 3.3). Freezing parameters hurts performance on some language pairs, and since freezing removes flexibility from the model and we have to adapt to 25 different directions this is perhaps not surprising. The language pairs where we match or improve on the baseline are Zh, Es, Fi, Ne, Ja, Vi and Kk. These are mostly (five out of seven) non-European languages, and distantly related to En. However since most of these results are not statistically significant further study is needed to verify this. Note we see a clear benefit over bilingual fine-tuning for some language pairs (e.g. compare our best Ne result from Table 3, 14.6 BLEU vs. 20.8 BLEU for multilingual fine-tuning). We leave to future work a more thorough investigation of the multilingual MT setting.

6 Conclusion

We recommend: For a language with high quality parallel data but without a pre-trained model trained on monolingual data from that language, using a frozen (English-only) BART model with additional parameters at the source side (the 'input module') improves performance over a randomly initialised baseline. For this approach it is important to freeze the pre-trained model. We also give the model both learned positional embeddings at the embedding layer, and fixed sinusoidal positional embeddings at each layer of the input module.

For a multilingual pre-trained model, we found performance improvements on some (mostly distantly related) languages for multilingual many-to-one fine-tuning. For bilingual $En \rightarrow Xx$ fine-tuning we did not see any improvement, although the performance drops are small, and by freezing parameters we need less memory at training time compared to fine-tuning. For $Xx \rightarrow En$ bilingual fine-tuning it is important to unfreeze the encoder-decoder attention, and keep the rest of the decoder frozen. This can improve on simple fine-tuning, especially for distantly-related language pairs or those with out-of-domain training data.

We recommend fine-tuning layer-norm parameters as a parameter-efficient complement to adapter layers. For our mBART experiments we found it was necessary to fine-tune the token embeddings, which correspond to a large number of parameters, and future work could remove this cost by working out a subset of the vocabulary to fine-tune, or another method.

Acknowledgments

We'd like to thank James Cross, Mike Lewis, Naman Goyal, Jiatao Gu, Iain Murray, Yuqing Tang and Luke Zettlemoyer for useful discussion. We also thank our colleagues at FAIR and FAIAR for valuable feedback.

A Additional Ablation Study

In Table 9 we reproduce Table 4 of the main paper with more context to study the effect of unfreezing layer-norm parameters when fine-tuning mBART. Across all language pairs we see improvements from fine-tuning layer norm parameters over not fine-tuning them, and additional, smaller, improvements from adding adapters, indicating both forms of adding flexibility are useful. In Table 10 we present additional results on the Ro-En pre-trained model (see section 3.2 of the main body).

B Fine-tuning Hyper-parameters

For all experiments with bilingual datasets we use a batch size of 2048×16 tokens, i.e. 2048 tokens per GPU and 16 GPUs (we investigate larger batch sizes for frozen models only to test GPU memory usage, and do not evaluate models trained with larger batch sizes). Ranking of hyper-parameters was done by validation set BLEU score.

Frozen BART We train with 0.3 dropout for the frozen BART parameters, and 0.2 dropout for the Input Module parameters, 0.1 label smoothing, 0.2 dropout for the self-attention scores in the Input Module, 5000 warm-up steps, and $7\text{e}{-4}$ maximum learning rate. We performed a grid search over learning rates in $\{7\text{e}{-4}, 5\text{e}{-4}, 3\text{e}{-4}\}$, dropout for Input Module parameters in $\{0.2, 0.1\}$, and dropout for self-attention scores in $\{0.2, 0.1\}$. We train for a maximum of 50K training updates for all low and medium resource pairs and 100K for high resource pairs (which takes roughly 8 hours and 16 hours respectively).

Frozen mBART We train with 0.3 dropout, 0.2 label smoothing, 2500 warm-up steps, and $3\text{e}{-5}$ maximum learning rate. We did not search over hyper-parameters, simply re-using those of Liu et al. (2020). Despite the adapter parameters being randomly initialised, the small learning rate did not affect performance (we performed a small sweep of larger learning rates and found only marginal gains, and so kept the same settings for simplicity). We use a maximum of 40K training updates for all low and medium resource pairs and 100K for high resource pairs (Es and Cs in our case), this takes roughly 12 hours and 30 hours respectively.

Multi-lingual MT We train with 0.3 dropout, 0.1 dropout for self-attention scores, 4000 warm-up steps, and $1\text{e}{-4}$ maximum learning rate.

Out-of-domain Vi-En Baseline To train a randomly initialised baseline for the out-of-domain Vi-En data (Vi-En† in Table 3 of the main body) we used the same model architecture and training settings as those of Guzmán et al. (2019) use for training MT systems on similar data (but with Si or Ne source language). Specifically a seq2seq transformer with 5 encoder and decoder layers, hidden dimension 512. shared embeddings between the input and softmax layers, and strong regularisation (e.g. 0.4 dropout on hidden states, 0.2 dropout on attention scores, 0.2 label smoothing). We learn a BPE vocabulary (joint across source and target data) of size 5000 on the training data. For full details of hyper-parameters we refer the reader to Guzmán et al. (2019) and the associated GitHub repository[4].

C Pre-training Languages

We reproduce in Table 11 the details from Liu et al. (2020) of the size of each pre-training language corpus for mBART.

Abstract

The distributions of orthographic word types are very different across languages due to typological characteristics, different writing traditions, and other factors. The wide range of cross-linguistic diversity is still a major challenge for NLP, and for the study of language more generally. We use BPE and information-theoretic measures to investigate if distributions become more similar under specific levels of subword tokenization. We perform a cross-linguistic comparison, following incremental BPE merges (we go from characters to words) for 47 diverse languages. We show that text entropy values (a feature of probability distributions) converge at specific subword levels: relatively few BPE merges (around 200 for our corpus) lead to the most similar distributions across languages. Additionally, we analyze the interaction between subword and word-level distributions and show that our findings can be interpreted in light of the ongoing discussion about different morphological complexity types.[1]

1 Introduction

In NLP, one of the predominant methods for obtaining subword units is Byte-Pair Encoding (BPE). These subwords have proven to be useful for improving several NLP tasks, most likely because they capture morphological patterns to some extent (and also phonological and orthographic ones).

BPE is based on a compression algorithm which finds frequently ocurring patterns in a text by means of incrementally merging adjacent symbols into longer strings (Gage, 1994; Sennrich et al., 2015). The granularity of the subword units is controlled by the number of merge operations applied to the text (few merges lead to a text tokenization closer to the character level, while more merges lead to a tokenization closer to the word level). Usually the number of BPE merges is chosen arbitrarily depending on the application.

It is rarely analyzed how the distribution of these subwords changes across different merge operations. Our goal is to investigate if languages get 'closer' in terms of their subword distributions under specific levels of tokenization. We quantify this cross-linguistic variation using information-theoretic measures.

Information theory provides a useful tool for exploring variation, and for quantifying the predictability/organization of patterns, e.g., in morphological systems (Ackerman and Malouf, 2013). We measure Shannon entropy and redundancy over varied subword tokenizatons of texts obtained with BPE. At each incremental merge, we compare the values across 47 typologically diverse languages.

Cross-linguistic corpora are widely used as a means of quantifying linguistic diversity. For instance, the range of entropy values measured over word-level types varies greatly across languages. This is a reflection of the diversity of morphological systems. However, we show that this cross-linguistic variation is not so pronounced at the subword level. Namely, a convergence of entropy values across languages is achieved at a relatively low number of merge operations. The entropy of subword distributions grows quickly before this turning point, while the growth is considerably slower after it.

Furthermore, in this turning point, the subword distributions start to correlate with the ones observed at the word-level. We interpret this change of trend in light of previous findings regarding the difference between subword and word-level complexity: a language that is complex at the word level (rich inflectional morphology), is not necessarily complex at a more atomic subword level (predictable subword patterns).

2 Background

2.1 Byte-pair Encoding (BPE)

Originally, BPE is a data compression technique based on replacing the most common pair of consecutive bytes with a new symbol (Gage, 1994). This is currently one of the predominant approaches for subword tokenization (or morphological segmentation). It is widely used to improve tasks like machine translation or language modeling (Sennrich et al., 2015; Provilkov et al., 2020). Another popular method is provided by Morfessor (Smit et al., 2014).

When BPE is applied to text, each iteration merges two adjacent symbols. The main hyperparameter of BPE is the number of merge operations applied to the data, which controls the granularity of the subword units. In NLP, this hyperparameter is usually chosen empirically, e.g., based on the dataset size or on the task, regardless of the typological features of a specific language.

2.2 Text and information theory

Bentz et al., (2016) distinguish between corpus-based and paradigm-based approaches for quantifying morphological complexity. While the former approaches measure morphological productivity directly on raw text corpora, the latter make use of higher level language descriptions, i.e., grammars, and inflectional paradigms.

In corpus-based approaches, a text is usually regarded as a sequence of symbols. Each symbol is generated with a certain probability, and hence carries a certain information content (Juola, 1998; Ehret and Szmrecsanyi, 2016a; Ehret, 2016b; Koplenig et al., 2017; Bentz et al., 2017). The higher the probability of a symbol, the lower its information content. Against this backdrop, the average information content of a text can be estimated by Shannon entropy, and approximated with type-token-ratios (TTR). For instance, if we consider orthographic words as symbols, languages with a greater diversity of word types will have higher entropy (word types are less predictable, due to, e.g., richer morphology). In fact, such corpus-based measures have been shown to be correlated also with paradigm-based approaches that quantify morphosyntactic distinctions based on grammars (Bentz et al., 2016; Kirov et al., 2017).

The complexity of the morphological system of a language is not only related to the diversity of word types that can be produced, but also to the way in which subwords are organized within them.

On the corpus-based side, there are some studies which have focused on the predictability of internal word structure. For instance, there are cross-linguistic accounts illustrating the trade-off between the size of syllables and the size of words: languages with structurally simple and short syllables need more syllables for encoding the same content (Fenk-Oczlon and Fenk, 1999; Coupé et al., 2019). Another line of research proposes to quantify the amount of word-internal information by comparing the (character level) entropy of the original text with a version where the regularities within orthographic words have been masked (Juola, 1998; Ehret and Szmrecsanyi, 2016a; Ehret, 2016b; Koplenig et al., 2017).

Most recently, morphological complexity has been approached through the lense of neural language models, and their learning of subword structure (Vania and Lopez, 2017; Mielke et al., 2019). Gutierrez-Vasques and Mijangos (2020) propose a measure reflecting the predictability of the internal structure of words. It relies on the entropy rate of a neural language model that is trained to predict sequences of character n-grams within a word. We here compare the results of this latest neural network approach with the entropy of subword units based on BPE.

3 Data and methods

Our general proposal comprises calculating several measures over varied subword tokenizatons of texts obtained with BPE. In each consecutive tokenization, we hence regard a different set of strings of characters as symbols of our "alphabet". In merge 0, a text is a sequence of single UTF-8 characters; in the last merges, a text is a sequence closer to orthographic word types (i.e. original tokenization given by white spaces and punctuation). At each incremental step, we compare the values across parallel corpora in 47 typologically diverse languages.

3.1 Parallel corpus

Using parallel corpora facilitates meaningful comparisons across languages, as seen in cross-linguistic studies on morphological typology, lexical typology, and word order typology (Cysouw and Wälchli, 2007; Wälchli and Cysouw, 2012; Östling, 2015; Kelih, 2010; Mayer et al., 2014). In fact, the idea to compare language complexity through parallel corpora can be traced back to

Greenberg (1960).

In this work, we use a publicly available parallel corpus for 47 languages that was extracted from the Parallel Bible Corpus (PBC) (Mayer and Cysouw, 2014). This specific dataset[2] contains 115 preprocessed parallel verses per language consistently coded in UTF-8. The set of 47 languages is a subset of the WALS 100-language sample, which aims to maximize both genealogical and areal diversity. See the list of languages, their ISO639-3 code and linguistic families in Appendix A.

3.2 Scripts and Writing Systems

The respective texts are written in different scripts (Arabic, Cyrillic, Devanagari, Georgian (Mkhedruli), Korean Hangul, Latin, Modern Greek, Myanmar (Burmese), Thai), and reflect different writing systems (abugida, abjad, alphabet, syllabary). Since BPE starts to operate at the level of UTF-8 characters, the ideosyncrasies of encodings are relevant for our analyses. For instance, the word *beginning* in English consists of 9 UTF-8 character tokens and 5 types ('b','e','g','i','n'), while the corresponding word written in Korean Hangul 시작 (transliterated as 'sijak') consists of two syllable blocks, namely 시 ('si') and 작 ('jak'). It is these syllable blocks – rather than individual letters of the Korean alphabet – which are represented as UTF-8 characters. Thus, while English texts typically contain 26 UTF-8 character types (bare punctuation), Korean texts might display hundreds and thousands. A similar proliferation of UTF-8 characters is found in texts written with Abugidas (e.g. Hindi, Thai, Burmese), or in latinized scripts with many special characters and diacritics (e.g. Vietnamese).

3.3 BPE merge operations

The BPE algorithm starts by splitting words into a sequence of characters. We can think of this as characters separated by white spaces. In the first operation, the algorithm merges the most frequent pair of consecutive characters within the corpus, e.g., ('e','d') $\rightarrow$ ('ed'), thus creating a new symbol that is added to the vocabulary. In each of the following operations, the algorithm calculates the co-occurrence frequency of pairs of all the current consecutive symbols and it merges again the most frequent pair.

When the algorithm merges a frequent pair of symbols, it automatically removes many of the white spaces in the text (this is one aspect of how BPE achieves text compression). As more merges are applied, longer symbols (in terms of number of characters) are obtained – we are getting closer to the word level. The algorithm stops when a pre-specified number of merge operations has been reached, or when it cannot find a pair of consecutive symbols with frequency greater than 1.

A worked out toy example can be found in Table 1. Note that symbols occurring at the end of a word are considered different from the ones that occur at any other position. The symbols that are merged in BPE are hence character sequences of variable sizes. These can be interpreted as subword units. This is why BPE is usually seen as a morphological segmentation technique in NLP.

We applied an existing BPE implementation[3] to the texts of the parallel corpus. For each language, we obtain many different segmented versions of the text depending on the number of merges applied. In specific, we go from merge 0 to merge 10K.

We traverse the range of merge operations by using different step sizes. We simply do this to ease the computational load. Moreover, the different trends that we observe are already stable by merge 350.

- Fine-grained merges:
  0 to 350 (step size: 1)
- Coarse-grained merges:
  350 to 5K merges (step size: 50)
  5k to 10K merges (step size: 1K)

3.4 Information-theoretic measures

Once the texts are segmented, we apply two different information-theoretic measures. Both take as input a text T with a vocabulary of types $V = \{t_1, t_2, ..., t_V\}$ of size $|V|$. At the word level, these types correspond to words (strings separated by spaces). Analogously, at the subword level, the types are the subword units obtained at a specific number of merge operations. We distinguish between the subword units that are at the end of a word and the rest of them, e.g. *-ed* and *-ed-* are considered different types in the vocabulary.[4]

We use **entropy** as a measure of the average information content of types in a text. We can

Table 1: Example of BPE merge operations. Original text: *God created the heaven [...] and God divided the light [...]*

calculate the entropy as follows (Shannon, 1948):

$$H(T) = -\sum_{i=1}^{V} p(t_i) \log_2 p(t_i) \tag{1}$$

Where the probability of a type $p(t)$ is estimated using the so-called maximum likelihood method (i.e. its relative frequency in the text). Higher values of entropy indicate higher complexity (less predictability). We take this as our main measure of text-based morphological complexity through merges.

We also use **redundancy,** a measure that is related to entropy. The entropy of a source of data is maximum when the symbols comprising a message can be chosen freely and they are equiprobable (maximum uncertainty). The redundancy, as defined here, quantifies how close the empirically estimated entropy $H(T)$ is to the maximum value it can take, assuming that we utilize the same alphabet (or types in our case). It can be defined as follows (Partridge, 1981; Karmeshu, 2003):

$$R(T) = 1 - \frac{H(T)}{max\{H(T)\}} = 1 - \frac{H(T)}{\log_2 |V|} \tag{2}$$

Where $H(T)$ is the entropy of a text, calculated as in (1). The maximum entropy can be calculated as $max\{H(T)\} = log_2|V|$, i.e, the entropy when the probability distribution of types is uniform $p(t_i) = \frac{1}{|V|}$. The values of R range from 0 to 1. Values closer to 1 indicate higher redundancy.

3.5 Spearman's rank correlation

We use correlations for exploring the connection between values yielded by the complexity measures described above. We rank languages according to these measures. In particular, we use Spearman's rank correlation, which tests for a correlation between the rankings of two variables (monotonic relationships, not necessarily linear).

We apply Spearman's rank correlation to the following variables:

1. Final merge (the number of merge operations needed to reach the final step of the BPE algorithm);
2. Average word length (at the word level);
3. Size of the vocabulary of characters (of the original texts);
4. Entropy and redundancy measured over the texts at different merges;
5. Two external morphological complexity measures (based on unigrams and trigrams of characters).

Since we have many variables, and hence pairwise correlations, we apply the Bonferroni correction on p-values. We select the correlations that are still significant after correcting for multiple testing, see Appendix C.

4 Results

4.1 From characters to words: the turning point

Figure 1 shows the entropy of languages at different merge operation stages: merge 0, merge 30, merge 200, and the word level. We choose these specific merges for the sake of illustration. In particular, merge 200 is representative of the turning point of several trends.

At the very first merges, texts are closer to character level tokenizations, i.e., small subword units. The initial point is merge 0 (roughly corresponding to the character level). Here, the texts' entropies range between $4.01 - 7.77$ bits. We notice that languages with a larger inventories of UTF-8 characters start with higher entropy values. For instance,

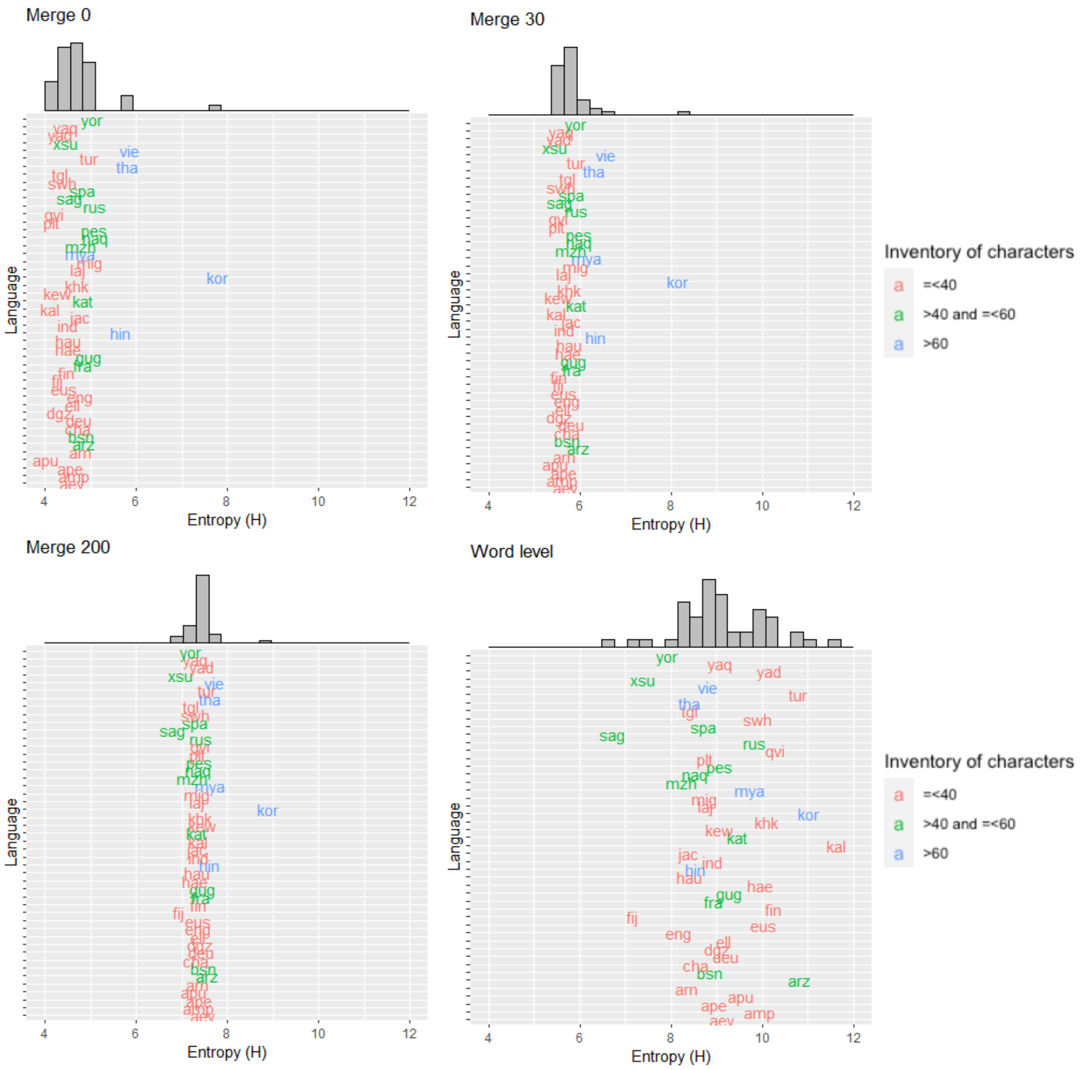

Figure 1: Entropies of languages at different merge operations. Histograms of the distributions are shown above the panels. The sizes of the original UTF-8 character sets are indicated by colors.

Korean *(kor)* is an outlier due to its alpha-syllabary writing system (Section 3.2).

In the subsequent merges, all languages start increasing their entropy. However, the values also start to become less dispersed across languages. In fact, we can see that, in merge 200, the majority of languages are centered around 7.3 bits. This means that, at this merge, the frequency distributions of subwords are similar across languages. Moreover, the size of the initial inventory of characters seems not to affect the texts' entropy at these later merges.

As BPE approaches tokenizations which are closer to orthographic words, entropy values start to disperse again. If we measure entropies over the original texts (without any subword tokenization), we can see that the cross-linguistic variation is considerably wider than the one obtained when the texts are represented by subwords (fewer merges).

This trend is also observable in Fig. 2, where the standard deviation (σ) of entropy across languages is shown as a function of the number of merges. A minimum is reached at merge 200; in fact, between merges 190-240 there is practically no variation of σ. This means that, around this number of merges, the entropies of subword distributions' across languages are closest to one another. After 240 merges, the values start to slowly disperse again and keep dispersing up to the final merges.

Moreover, if we rank languages by their entropy, the rankings obtained before merge 200 are not correlated with the ones observed in later merges (see Section 4.3). From this point onward, the rankings start to gradually correlate with the one observed at the word-level. For instance, at merge 350 (a relatively low number of merges) the vocabularies still contain many short subword units, and the variance

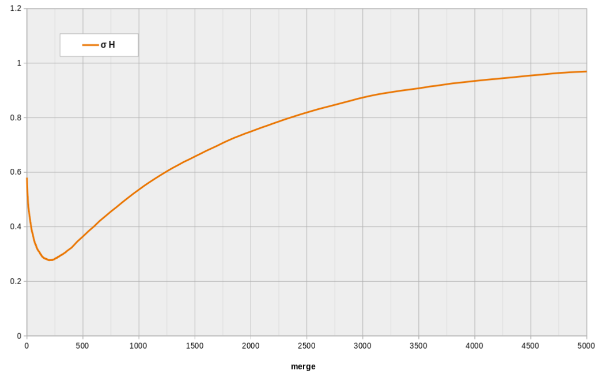

Figure 2: Standard deviations (σ) of entropies across languages per each BPE merge operation.

of entropies across languages is still close to the minimum. Despite of this, the language rankings obtained at this merge are already similar to the rankings observed at the word level.

For some languages, the entropy at the subword level (fewer merges) is systematically different from that at the word level (higher number of merges). For instance, Kalaallisut (*kal*), typically seen as polysynthetic, starts with low H in the first merges – it ranks almost last. However, at merge 200, it is rather in the middle range, and it further increases in entropy with subsequent merges, to the point where it ranks highest of all languages, namely at the word level (Fig. 1).

As we discussed earlier, the entropy (H) has its minimum at merge 0. After each merge operation, H increases. The first merges cause the most drastic changes in the entropy. After the first hundreds of merges, the entropy increases more slowly, i.e., each merge does not cause a big increment of the text entropy anymore. In contrast, redundancy starts decreasing since the first merges. R reaches a minimum after a certain number of merges for all languages (297 merges on average), and then it starts increasing again as the word level is approached. Figure 3 shows an example of the entropy (H) and redundancy (R) across merges for the French text. Appendix B contains the entropy and redundancy curves for all languages.

The first operations merge very frequently adjacent symbols, which impacts the subword distributions of the texts. This is the reason why redundancy and entropy are changing quickly for the early merges. These first merges find the most frequent and productive patterns, e.g., inflectional markers (‘-ed’ and ‘-ing’), and orthographic practices for representing sounds (e.g. ‘th’) in English. When highly recurrent patterns get merged, the redundancy of the texts is reduced. We can think of this in terms of skewed distributions. At merge 0, the vocabulary’s initial distribution of elements is skewed (few UTF-8 characters, high frequencies). When BPE starts merging the most salient patterns, the distribution of subwords gets closer to a uniform distribution (more symbols, lower frequencies), and a minimum of redundancy is reached. After this, the merge operations lead again to skewed distributions (redundancy grows again). However, these latter distributions across languages are correlated to the ones observed at the word level and not to the first merges’ skewed distributions.

Interestingly, the number of merges at which entropies start to grow slower, and redundancies reach a minimum, are in the same range of merges in which languages start to change their trends between subword and word level, ca. 200-300 merges. This is also the turning point in which the cross-linguistic standard deviation of entropies reaches a minimum.

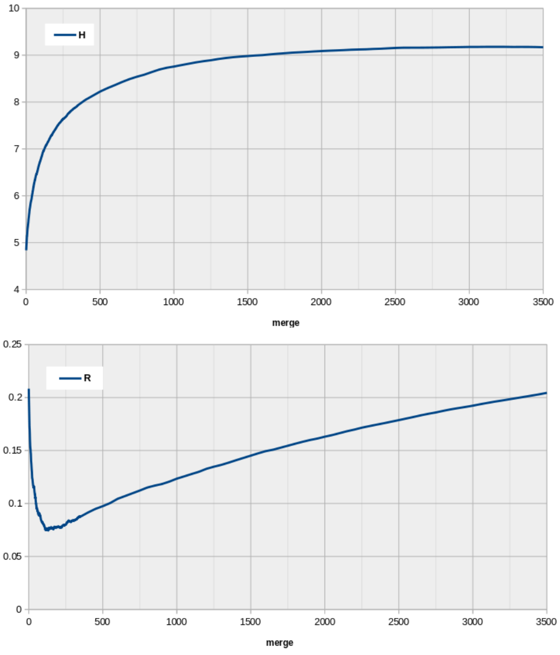

Figure 3: H and R across BPE merges for French (fra).

4.2 Max. number of merges per language

Not all languages require the same number of operations to reach the point where no pair of subwords can be merged anymore. In our corpus, languages needed between 1.1K and 7K operations for reaching this final merge (Figure 4).

We can see that languages with lower values

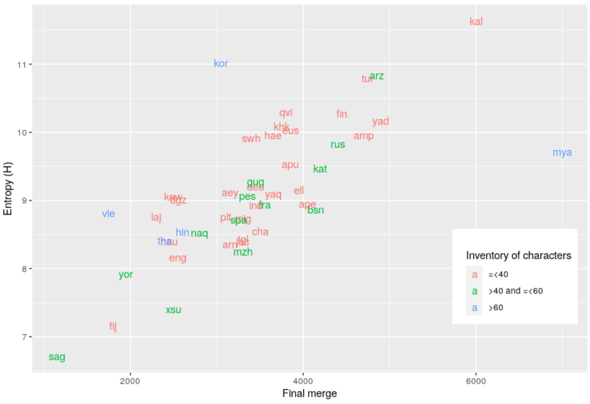

Figure 4: Maximum number of BPE merges for each language (x-axis) against word level entropy (y-axis).

of word entropy require fewer merges. This is the case for languages with isolating tendencies: Sango (*sag*), Vietnamese (*vie*), Fijian (*fij*), Yoruba (*yor*). The Indo-European language that requires the least merges is English (*eng*). These are also the languages that reach the entropy plateau faster, i.e., the first merges capture very productive recurrences, but after a relatively small number of operations, the text entropy does not change that much anymore.

On the other hand, languages with richer morphological processes (polysynthetic, agglutinative, or template morphology) require more merges to reach this final point. Namely, Kalaallisut (*kal*), Burmese (*mya*), Yagua (*yad*), Egyptian Arabic (*arz*), Turkish (*tur*), Alamblak (*amp*), Finnish (*fin*), require the most merges. Note that Burmese (*mya*) is not generally considered a morphologically complex language; it has very long orthographic words on average. This is related to the Burmese script, which uses white spaces differently from other scripts (therefore, it has very long character string sequences).

Notice that despite this outlier, the figure illustrates that characters' inventory size is not strongly influencing the final number of merge operations (Fig. 4). A language that has a small character inventory to start with can still require many merge operations to reach the final merge, as exemplified by Kalaallisut (kal), Turkish (tur), Yagua (yad), and Finnish (fin).

4.3 Correlations between measures

In order to investigate relationships between measures, a correlation matrix is shown in Figure 5 with the variables explained in Section 3.5. We only include correlations for the entropy and redundancy taken at merges 0, 30, 200, 350, and the word level in this matrix. See Appendix C for the complete correlation matrix, which includes a wider range of merges.

The final merge is strongly correlated with the entropy at the word level and the average word length of a language. This is expected since languages with higher entropy/TTR (at the word level) tend to have longer words because they encode more morphosyntactic distinctions within a word. Therefore, under this conceptualization of complexity, complex languages will require more merges during BPE encoding. We did not find any strong correlations between word length and any of the early merges' measures.

The entropy of the texts on the first operations (from merge 0 to merge 100) showed no strong correlation with the entropy at the word level, either positive or negative ($\rho < \pm 0.14$). Therefore, there is not a general trade-off between subword and word level complexities. Some languages display such a trade-off, e.g., being very complex at the word level, while having low complexity on the first merges. However, others are more stable across merges.

Interestingly, it seems that after the 'turning point', the correlation between subword tokenizations and the word level starts to be more prominent. At merge 200 the correlation is $\rho = 0.47$, this gradually increases, e.g., by merge 350, there is already a strong correlation with the word level ($\rho = 0.72$). As we saw in Section 4.1, the rankings obtained at the first merges (somewhere below 200) differ from the trend observed at the subsequent merges, .i.e., after merge 200 the complexity rankings of languages start to be more similar to the one observed at the word level.

Regarding redundancy, there is a strong trade-off between entropy and redundancy at the word level ($\rho = 0.72$). This is understandable since a language with high entropy at the word level will have a wide diversity of word forms, few repetitions, hence, less possibility of compression (low redundancy). However, entropy and redundancy are not always correlated. As shown in Fig. 3 (and Appendix B), the entropy tends to grow through merges, while redundancy first decreases and then grows again. In fact, cross-linguistically, we did not find a strong correlation between H and R during the early merges. By merge 200, H and R

already start to be negatively correlated. This trade-off is maintained in further operations and at the word level.

Even though R and H are not correlating on the first merges, they show similar behavior, i.e., both of them seem to follow a trend on the first merges, not correlated with their respective values at the word level, but then this trend changes (around the turning point).

We can also see that the size of a language's character inventory is correlated with the entropy on the first merges (around 0.6). While for redundancy, this correlation is not significant.

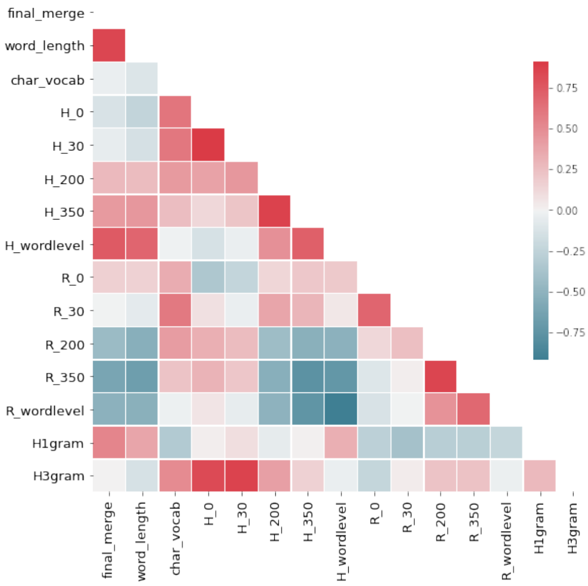

Figure 5: Spearman's rank correlation (subset of variables)

4.3.1 Predictability of sequences

Entropy is reflecting the degree of organization or predictability of subword types across several merges. This provides a glimpse of the morphological complexity of languages. However, one might argue that to really approach morphological complexity, our measures would have to consider the restrictions given by the allowed sequences of subword units within a word.

To address this concern, we compare our results with a corpus-based morphological complexity measure that aims to quantify the predictability of subword sequences within a word. This external approach uses a neural language model for estimating the predictability of sequences of n-grams within a word (Gutierrez-Vasques and Mijangos, 2020). H_{1gram} is the entropy rate obtained at the character level, H_{3gram} is the entropy rate using sequences of character trigrams.

The entropies of texts at merge 0 are already strongly correlated with H_{3gram} ($\rho = 0.81$). A higher correlation is obtained at merge 30 ($\rho = 0.86$). This means that at this point, the subword distribution is reflecting a complexity that is related to the predictability of its morphs – or at least of its character trigrams. This correlation starts to vanish in later merges, especially after the turning point (since we are probably starting to capture predictability more related to the word level).

Interestingly, H_{1gram} does not correlate with BPE entropies, not even at merge 0. This could be related to the fact that, even at merge 0, we distinguish between the characters at the end of an orthographic word versus any of the remaining positions. This already captures some degree of sequentiality that seems more related to H_{3gram}.

The measure H_{3gram} is restricted to predicting fixed-size overlapping sequences of characters within a word, while the tokenizations that we obtain with BPE contain subwords of variable lengths across merges. Despite this, it is interesting that these two measures strongly correlate at the first merge operations, suggesting that they reflect a similar phenomenon at the subword level.

5 Discussion

The "turning point" we discussed here reflects several phenomena. Firstly, languages become more similar in terms of their subword entropies around this point. Secondly, the trends of entropy and redundancy start to change (redundancy starts to grow, while entropy growth slows down). Thirdly, there is a shift in several cross-linguistic correlations around the same region of merges. It seems that two different subword distributions emerge, one before the turning point, and one afterward.

The entropy measured over word-level types reflect one dimension of diversity, i.e., some languages have rich inflectional morphology while others do not mark grammatical information word-internally. However, in another dimension, at the subword level, this variation is reduced.

If we rank languages by their entropy, the first merges' rankings are not correlated to the ones closer to the word level. In some of the languages, we see a clear trade-off across merges. For instance, some languages with high word entropy (low predictability, long words with the potential of combining many different morphological distinctions), have highly predictable subword distributions.

Languages where this trade-off is observed include: Basque (*eus*), Imbabura Highland Quichua (*qvi)*, Finnish (*fin*), Yagua (*yad*), Kalaallisut (*kal*). There are also examples of languages that start with high complexity on the first merges but they are not the most complex ones at the word level: Vietnamese (*vie*), Thai (*tha*), Hindi (*hin*), Yoruba (*yor*), Nama (*naq*). English (*eng*) is also an example of a language that has comparatively low entropy at the word level, probably due to a relative lack of productive inflections, but is not one of the least complex at the subword level (first merges).

However, this trade-off was not general, as we did not find a significant negative correlation between the entropies at first merges with the entropies at last merges.

Taking a linguistic perspective, several accounts have focused on the structure of the morphological paradigm and the predictability between the inflected forms (Blevins, 2006, 2016; Ackerman and Malouf, 2013; Cotterell et al., 2018). For instance, Ackerman and Malouf (2013) distinguish between two types of complexity: a) enumerative complexity (E-complexity), reflecting the diversity of morphological distinctions, word forms, paradigm size; and b) integrative complexity (I-complexity), related to systematic paradigmatic organization underlying the morphological surface patterns.

The entropy values of I-complexity tend to be lower and less disperse than the ones exhibited by E-complexity (Ackerman and Malouf, 2013). According to these observations, a morphological paradigm could grow (many different word forms, many morphosyntactic distinctions) as long as it maintains its predictive structure. This is argued to be the reason why languages vary more widely in the dimension of E-complexity, while being more constrained in the I-dimension. Even though our work is not based on paradigms, and it did not require the use of linguistically annotated data, our findings seem to point in a similar direction, at least in the sense that the internal predictability of words is more similar across languages than than their word-level predictability.

However, note that there is some evidence from language learning experiments – with neural networks and human participants – which suggests that both are more sensitive to E-complexity than I-complexity (Johnson et al., 2020). It is an open question how our word-internal predictability measures relate to language learning.

On a practical note, the fact that certain numbers of BPE merges lead to more similar entropies across languages could be beneficial for NLP multilingual tasks. To our knowledge, the entropy and redundancy of tokenized texts have not been used as a criterion for choosing an appropriate number of BPE merge operations. There is recent work that investigates how the number of merges can lead to more balanced distributions of subwords, improving tasks like NMT (Gowda and May, 2020).

Another important question is to what extent our findings can be generalized to other corpora. The corpus size, type of register, etc., are likely to influence the turning point. As a general trend we expect this convergence to arise in a relatively low number of BPE operations.

6 Conclusions

In this paper, we went from single characters to orthographic words through incremental merges of BPE. We observed that text entropy values across 47 typologically diverse languages are less dispersed at the subword level than at the word-level. Our findings revealed a curious turning point, around the merge 200, where the values are least dispersed. Around this point, subword token distributions gradually start to look like word-level distributions (subword- and word-level entropy rankings are correlated only after this point). Additionally, this is approximately the point where text redundancy starts to grow after an initial drop and also where entropy growth slows down considerably after initial fast growth.

At the early merges, the entropy of texts is strongly correlated with an independent measure based on modeling character trigrams sequences. This provides new evidence that contributes to the ongoing discussion regarding different types of linguistic complexity.

Finally, our analysis could provide a useful insight for NLP processing. Choosing the number of merges that result in more similar distributions across languages could lead to more suitable subword representations for multilingual settings.

A Large-scale Evaluation of Neural Machine Transliteration for Indic Languages

Anoop Kunchukuttan, Siddharth Jain, Rahul Kejriwal
Microsoft India, Hyderabad
`{ankunchu,sija,rakejriw}@microsoft.com`

Abstract

We take up the task of large-scale evaluation of neural machine transliteration between English and Indian languages, with a focus on multilingual transliteration to utilize *orthographic similarity* between Indian languages. We create a corpus of 600K word pairs mined from parallel translation corpora and monolingual corpora, which is the largest transliteration corpora for Indian languages mined from public sources. We perform a detailed analysis of multilingual transliteration and propose an improved multilingual training pipeline for Indic languages. We analyse various factors affecting transliteration quality like language family, transliteration direction and word origin.

1 Introduction

Transliteration is an essential technology for multilingual and cross-lingual capabilities in NLP applications to handle named entities, support cross-script input methods. Transliteration between English and Indic languages is important since English is widely used in the Indian subcontinent. Indic languages are written in different scripts from various writing systems. We focus on languages using scripts derived from the ancient Brahmi script. Their character sets are very different from the Latin script - making transliteration non-trivial.

These scripts are *abugida* scripts, where the basic unit is the *akshar* which consists of one or more consonants along with a vowel diacritic (Daniels and Bright, 1996). They exhibit a high degree of grapheme-to-phoneme correspondence. There is a large overlap in the logical character sets of these scripts, though the visual appearance of the characters varies. The languages utilizing these scripts are said to exhibit *orthographic similarity* on account of various shared characteristics (Kunchukuttan et al., 2018a).

We undertake a systematic, large-scale evaluation of neural machine transliteration for 10 major Indic languages from 2 major language families (Indo-Aryan and Dravidian languages) spoken by more than a billion speakers. Other than *BrahmiNet* (Kunchukuttan et al., 2015) and *Dakshina* (Roark et al., 2020), no other previous work has explored a wide range of Indic languages; Dakshina only explores transliteration into Indic languages. Our major contributions are:

- For a large-scale evaluation, we mine 600K transliteration pairs across 10 languages from publicly available parallel and monolingual sources. This is much larger than existing corpora like MSR-NEWS (Banchs et al., 2015), Brahminet (Kunchukuttan et al., 2015), Dakshina (Roark et al., 2020) and other small datasets (Banchs et al., 2015; Kunchukuttan et al., 2018b; Gupta et al., 2012; Khapra et al., 2014). The BrahmiNet and Dakshina datasets span multiple languages; BrahmiNet is small and Dakshina by design consists mostly of Indian origin words.
- From the mined corpus, we create a high-quality, manually validated testset annotated with foreign and Indian origin words.
- We propose various improvements to the multilingual transliteration system proposed by Kunchukuttan et al. (2018a) for Indian languages, and suggest a *recipe* for building multilingual transliteration systems for Indic languages.
- We present an evaluation of transliteration systems according to various factors like language family, word origin and transliteration direction.

2 Mining transliteration corpus

This section explains our transliteration mining methods (from parallel and monolingual corpora) and presents an analysis of the mined corpus. We mine transliteration corpora from English to 10 In-

dian languages from 2 major language families: (a) Indo-Aryan branch of Indo-European family (Hindi, Marathi, Gujarati, Bengali, Odia, Punjabi), (b) Dravidian family (Kannada, Telugu, Malayalam, Tamil).

2.1 Mining from Parallel Translation Corpus

While very little transliteration corpora exists, a reasonable amount of parallel translation corpora between English and Indian languages are available in the public domain.

Method. Alignments between words in parallel sentences from two languages can be discovered from parallel translation corpora. The aligned words can either be translations or transliterations. We use the unsupervised method suggested by Sajjad et al. (2012) to mine transliteration pairs from these word alignments by distinguishing translation and transliterations. For morphologically rich languages, the approach can discover partial transliterations also. For instance, the English-Marathi pair word (*station*, स्टेशनावर [sTeshanaavara]). The Marathi word includes the locative case marker. To remove such transliteration pairs, we identify morphological variants by clustering together Marathi words corresponding to the same English word in the candidate transliteration pairs. We only retain the pair with the root word.

Mining Details. We mined transliteration pairs from English to Indian language parallel translation corpora from different sources (7.4 million sentence pairs across all languages, see Appendix A for details). We use the Moses transliteration mining module (Durrani et al., 2014) implementation of Sajjad et al. (2012) to mine transliteration pairs using the default settings.

2.2 Mining from Monolingual Corpora

Monolingual text corpora often have borrowed words from other languages (particularly English). We mine such transliteration pairs using only the vocabularies in the source and target languages.

Method. We first train initial transliteration models using available data in both directions ($L_e \rightarrow L_x$,$L_x \rightarrow L_e$) and build vocabularies for both languages (L_e, L_x). Given words in L_e, we identify the most promising transliteration candidates from L_x and then re-score these candidates. The scoring is based on edit-distance between Double Metaphone[1] representations of the words, which we found works well in practice. We consider scores in L_e as well as L_x. We use ITRANS[2] conversion from Indic scripts to Latin in order to be able to compute Double Metaphone representations on the Indic language side. Note that the phonetic nature of Indic scripts enables conversion of Indic scripts to Double Metaphone that is sufficient for transliteration mining. Thus, the score for a candidates pair $s(e, x)$ is $E(e, T_{XE}(x)) + E(x, T_{EX}(e))$, where E is the edit-distance function and T_{xy} denotes transliteration from x to y. As mentioned above, the strings are converted to Double Metaphone representation prior to edit-distance computation. Finally, we prune the generated pairs based on a chosen threshold of scores.

Mining Details. We use monolingual vocabulary from the AI4Bharat IndicNLP dataset (Kunchukuttan et al., 2020) and the OSCAR corpus (Ortiz Suarez et al., 2019) for Indic languages. For English, we use the AI4Bharat IndicCorp dataset (Kakwani et al., 2020) which contains crawls from English newspapers from India - this helps mining

Indian named entities.

2.3 Characteristics of the Mined corpora

Corpora Statistics. Across 10 languages, we mined ~373k and ~339k transliteration pairs from the parallel translation and monolingual corpora respectively. The final train set of 606k word pairs was created after deduplicating and creating train, test and dev splits (See Table 1 for a summary of the mined corpus). We estimate that the training set has 55% non-Indian origin words and 45% Indian origin words.

Quality of the mined corpus. We evaluated the quality of mined transliterations via crowdsourcing. We used an internal, managed crowd-sourcing platform to validate the testsets and retained the transliteration pairs judged as correct in the final testset. The testset for every language had transliterations for 1500 English words and all their mined transliterations. This manual evaluation also gave us an estimation of the transliteration mining quality. We asked native-speaker judges for each language to report whether the pair is a transliteration or not. Our guidelines specified that pairs should be marked as valid if the pair is phonetically equivalent and are canonical spellings. In case no canonical spelling exists, the judges may mark the pairs solely on only phonetic equivalence. To control for quality, we used 3 judges per pair and used majority-voting for establishing correctness of a transliteration pairs. We added honey-pot pairs to tasks to filter out judges spamming our task.

Table 1 also shows the transliteration mining accuracies (average accuracy of 84.18%). An analysis of the errors revealed that an overwhelming majority involved wrong/missing/extra inflections (plurals and/or Indic casemarkers). These word pairs are also partial transliterations which are useful for learning transliteration models.

Test Set Creation. The test and dev sets were created by selecting 1500 English words each that are common across all language corpora along with their transliterations. We ensure that the test and dev set do not have any overlap with training set across languages. The testset were verified via crowdsourcing. The test set contains 928 foreign origin words and 572 Indian origin words.

Study of orthographic similarity. Following Kunchukuttan and Bhattacharyya (2020), we estimate the orthographic similarity between languages using the n-way parallel testset. For every language pair, it is the average Longest Common Subsequence Ratio (LCSR) (Melamed, 1995) between word pairs in the test set (See Figure 1) and follows linguistic genealogy. Tamil and Malayalam are most divergent to other languages. Punjabi is also divergent to other languages, possibly on account of: (a) some of its special characters like *tippi* and *addak*, (b) little use of conjunct consonants unlike other Indian languages.

3 Analysis: Multilingual Transliteration

We study multilingual transliteration models with the intent of identifying factors that improve multilingual models. First, we describe our baseline multilingual model and then introduce different variants to improve the baseline model.

Baseline Multilingual model (Kunchukuttan et al., 2018a). It is a character-level, attention-based, encoder-decoder model with all the model components shared amongst all the languages. We train joint EX (multi-target, English to Indian languages) and XE models (multi-source, Indian languages to English) separately. For EX models, we append a special target language token to the input sequence (Johnson et al., 2017).

Language Partitioning. To understand the role of orthographic similarity, we investigate two language groupings: (a) all the Indic languages are jointly trained, (b) Indo-Aryan and Dravidian languages are separately trained.

Vocabulary. Indic languages use a variety of scripts with a high overlap in the logical character set, but assigned unique characters in the Unicode character set. We investigate if transfer learning works better with a combined vocabulary by mapping logically equivalent characters across scripts for better transfer learning. We use the IndicNLP Library (Kunchukuttan, 2020) for mapping all Indic scripts to the Devanagari script, thus combining the vocabularies of all languages. We experiment with two configurations: (a) disjoint vocabularies (*i.e.,* different scripts), (b) combined vocabularies (*i.e.,* same script). Combining the vocabularies reduces the vocabulary significantly as the number of scripts reduces from 9 to 1.

Source language tag. In spite of the high degree of orthographic similarity between Indian languages, there are few cases of language-specific variations. For instance, the Malayalam script overloads a few characters with multiple sounds, Bengali pronunciation of the *aa* vowel differs, *etc.* To make the model sensitive to these language-

Table 2: Multilingual Transliteration results (%accuracy). The *all Indic* experiment trains with a common script.

specific variations in XE models, we add an special source language token in the input sequence.

Addressing divergence between Tamil and other Indic scripts. The Tamil script is highly under-specified and has fewer characters than sounds in the English language (unlike other Indic scripts). When training a multilingual model, there is an inconsistency in learnt mappings between Tamil and other Indic scripts. We address this issue by training a Tamil-specific multilingual model for Dravidian languages where all characters from other scripts are mapped to the closest character in the Tamil script via deterministic rules using the IndicNLP library.

3.1 Experimental Setup

We use *Marian* (Junczys-Dowmunt et al., 2018) to train our transliteration models. We use 128 LSTM units for encoder and decoder (1 layer for bilingual models and 2 layers for multilingual models). The encoder uses a bidirectional LSTM. The input embeddings are also 128 units in size. These hyperparameters were decided based on a parameter sweep on the dev set. We use a batch size of 100 sequences and early stopping with patience=100. We use beam-search for decoding (beam size=4).

3.2 Results and Discussion

Table 2 shows the top-1 accuracy of the different models. For translation into Indian languages, multiple references are available.

Bilingual models. Bilingual results show some trends about Indic transliteration. Transliteration is more difficult for non-Indian origin words than Indian origin words. EX direction accuracies are higher than XE direction. Tamil transliteration accuracy is the least in the XE direction (due to deficient orthography), while Malayalam has the least accuracy in the EX direction (possibly due to overloading of some characters).

Impact of multilingual training. In the XE direction, multilingual systems provide significant gains over bilingual systems (~20%). Most gains come from improved accuracy on non-Indian words. The multilingual system is better at generating canonical spelling in contrast to phonetically-equivalent incorrect spellings. More gains are observed for Indo-Aryan languages compared to Dravidian languages. Tamil benefits the most among Dravidian languages, but it still lags behind other languages. In the EX direction, accuracy improves by 6-7% for both Indian and non-Indian words. Both Indo-Aryan and Dravidian languages benefit from multilingual training.

Effect of language family. We do not observe any major advantage in training the two language families together. Hence, in subsequent experiments we train separate models. There are some differences in the spelling conventions between these languages. Thus, it seems a reasonable conservative choice to train separate model for the two families in the face of data not bringing any clarity.

Effect of source language tag. Adding source language tag improves XE transliteration accuracy 6-7% for some languages with divergent spelling conventions (Bengali, Malayalam and Tamil).

Effect of script conversion. It significantly reduces the vocab size (reducing number of scripts from 9 to 1), but results in just a small drop in accuracy. For the XE direction, the drop in accuracy is recovered by using the source language tag.

Mapping to Tamil Script. The table below show that this simple approach improves the Tamil transliteration accuracy by 2-5 points on non-Indian as well as Indian words in both directions.

Experiment	ta-en		en-ta	
	foreign	indic	foreign	indic
hiscript	44.04	50.6	73.5	81.72
tascript	**47.37**	**53.3**	**78.8**	**83.9**

4 Conclusion

We present a study of transliteration between English and Indic languages. We mine a 600k parallel transliteration corpus having a good coverage of Indian and non-Indian origin words as well as create a manually validated testset. We recommend the following recipe for Indic multilingual transliteration: (a) all training data in the same script, (b) separate models for IA and DR languages, (c) source language tags for XE transliteration. Multilingual training significantly improves non-Indian word transliteration. Our results validate previous results on benefits of multilingual transliteration on a wider set of languages and larger datasets. We also improve Tamil to English transliteration by representing multilingual data in Tamil script. More details about the corpus is available at `https://github.com/anoopkunchukuttan/indic_transiteration_analysis`.

Communicative-Function-Based Sentence Classification for Construction of an Academic Formulaic Expression Database

Kenichi Iwatsuki[1]

`iwatsuki@nii.ac.jp`

Akiko Aizawa[21]
[2]National Institute of Informatics
`aizawa@nii.ac.jp`

Abstract

Formulaic expressions (FEs), such as '*in this paper, we propose*' are frequently used in scientific papers. FEs convey a communicative function (CF), i.e. 'showing the aim of the paper' in the above-mentioned example. Although CF-labelled FEs are helpful in assisting academic writing, the construction of FE databases requires manual labour for assigning CF labels. In this study, we considered a fully automated construction of a CF-labelled FE database using the top–down approach, in which the CF labels are first assigned to sentences, and then the FEs are extracted. For the CF-label assignment, we created a CF-labelled sentence dataset, on which we trained a SciBERT classifier. We show that the classifier and dataset can be used to construct FE databases of disciplines that are different from the training data. The accuracy of in-disciplinary classification was more than 80%, while cross-disciplinary classification also worked well. We also propose an FE extraction method, which was applied to the CF-labelled sentences. Finally, we constructed and published a new, large CF-labelled FE database. The evaluation of the final CF-labelled FE database showed that approximately 65% of the FEs are correct and useful, which is sufficiently high considering practical use.

1 Introduction

Formulaic expressions (FEs), such as '*in this paper we propose*', are a type of multi-word expressions and are repeatedly used in scientific papers. Some FEs convey a communicative function (CF) of a sentence, which represents intentions of authors. For example, '*in this paper, we propose*' conveys the CF of 'showing the aim of the paper'.

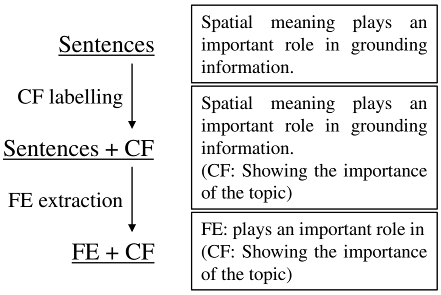

Figure 1: Process of creating FE database.

Databases comprising CF-labelled FEs are required from a pedagogical perspective (Martinez and Schmitt, 2012), and a computer-based academic writing assistance system[1] that uses such CF-labelled FEs has been proposed (Mizumoto et al., 2017). Several attempts have been made to extract FEs from scientific corpora and categorise them based on CFs (Cortes, 2013; Ädel, 2014; Mizumoto et al., 2017; Morley, n. d.; Simpson-Vlach and Ellis, 2010; Lu et al., 2018). A CF-labelled FE database can be constructed using two main approaches: top–down and bottom–up approaches (Biber et al., 2007; Durrant and Mathews-Aydınlı, 2011). By using the top–down approach, sentences are first assigned CF labels, and then FEs are extracted, while in the case of the bottom–up approach, FEs are first extracted and then assigned CF labels. To date, both the approaches have been adopted because CF assignment is performed manually (Table 1). In this paper, we propose a fully automated construction of the CF-labelled FE database, where we consider the top–down approach to be more beneficial (Figure 1). This is because the bottom–up approach requires FEs to be classified, which is difficult because a perfect FE-extraction technique is yet to be realised, and FE embeddings have not been investigated intensively. The top–down approach requires sentence classification, which has highly improved with the recent advancements on pre-trained models.

	Method for creating DB			DB statistics			
	Approach	CF	FE	Discipl.	#CFs	#Docs	#FEs
Simpson-Vlach and Ellis (2010)	bottom–up	manual	corpus	mixed	15	-	200
Morley (n. d.)	-	manual	manual	mixed	146	100	$\simeq 2,000$
Mizumoto et al. (2017)	top–down	manual	corpus	specific	52	1,000	-
Lu et al. (2018)	bottom–up	manual	corpus	mixed	12	600	454
Ours	top–down	automated	sentence	specific	32	61,728	86,931

Table 1: Properties of the existing and proposed methods for the construction of CF-labelled FE databases and the statistics of the databases. The approach of Morley (n. d.) is unknown. For the CF assignment (CF), we adopted supervised machine-learning. The FE extraction (FE) was conducted manually using a corpus- or sentence-level method. Either FEs specific to one discipline were extracted or FEs used in a corpus in which several disciplines were mixed were extracted. The number of documents used for extraction and the extracted FEs of the existing and presented database were shown. Some studies did not disclose the number of documents or FEs. Morley (n. d.) constantly revises the database, and therefore the number of FEs is not fixed.

For CF-based sentence classification, we created a dataset for supervised learning. The dataset consists of a small number of sentences that were assigned CF labels. We collected the sentences from scientific papers of multiple disciplines. By using this dataset, we fine-tuned SciBERT (Beltagy et al., 2019). Additionally, because there are preferences for CF usage depending on disciplines and as the preparation and coverage of all CFs of every discipline are difficult, sentences to which any prepared CF label should not be assigned may appear in a corpus (no-CF sentences). These no-CF sentences will have a negative effect on the classification performance. Based on the recent work on out-of-distribution detection in natural language processing (Hendrycks and Gimpel, 2017; Hendrycks et al., 2020), we used the maximum value of the softmax layer as the threshold to filter no-CF sentences in order to improve the final precision. The experimental results show that the maximum value of the softmax layer works well as the threshold to filter out undesirable sentences.

We carefully considered multidisciplinary problems in the classification. Although the development of a training dataset for every discipline in the world is obviously impossible, demonstrating a successful classification using a single disciplinary dataset is not sufficient for practical use. In this study, we determined whether a model trained on a corpus of one discipline can be applied to that of another discipline. Moreover, the effects of a pre-training dataset were examined by comparing SciBERT and BERT (Devlin et al., 2019). The experimental results show that the classifiers performed fairly well in terms of both in-discipline and cross-discipline data, and the performance was only slightly affected when scientific papers were not used as pre-training data.

For the FE-extraction process, one FE should be extracted from one sentence because CF labels are assigned to each sentence; this is termed as sentence-level approach (see Section 2.2). Therefore, we propose a sentence-level FE extraction method that is based on an existing method (Iwatsuki et al., 2020b). The method consists of three steps: named and scientific entity removal, dependency-structure-based word removal, and word-association-measure-based word removal.

Finally, we created a new, large, multidisciplinary CF-labelled FE database and evaluated it by asking human evaluators whether each instance was assigned a correct CF label and whether an FE was useful for writing a paper. The results show that approximately 65% of the collected FEs are appropriate.

The contributions of our study are as follows:

- we created and published the CF-labelled sentence dataset, which is the first dataset for training and evaluation of CF-based classification;
- we showed that a simple SciBERT-based neural classifier performed reasonably well for the CF labelling problem;
- we showed that the SciBERT classifier can be used even though the discipline of the training data is different from the inferred one;
- we proposed an FE extraction method; and

- we constructed a CF-labelled FE database with the top–down approach, which is larger than the existing databases but still maintains high quality.

2 Related Work

2.1 CFs in Scientific Papers

The CFs of scientific papers were first introduced by Swales (1990), who focused on the CFs in the introduction section. The author proposed a hierarchical structure of CFs, in which *move* was considered a larger unit of CF and *step* was a smaller unit belonging to *move*. He found that the introduction section consists of three *moves*: 'establishing a territory', 'establishing a niche', and 'occupying the niche'. Each *move* has several *steps*, such as 'claiming centrality' and 'presenting research questions or hypotheses' (Swales, 2004). Following his work, a host of studies extended the concept to all parts of a scientific paper. Most studies focused on very limited part of scientific papers; only the introduction (Ozturk, 2007), methods (Lim, 2006; Cotos et al., 2017), results (Basturkmen, 2009; Lim, 2010), discussion sections (Peacock, 2002; Basturkmen, 2012), or the abstracts (Lorés, 2004; Darabad, 2016; Rashidi and Meihami, 2018; Saboori and Hashemi, 2013).

The concept was extended to all parts of a scientific paper. For example, Kanoksilapatham (2005) proposed the CF structure of all the sections in biochemistry papers. Cotos et al. (2015) proposed a CF set for all four sections, i.e. introduction, methods, results, and discussion sections. Maswana et al. (2015) compared the usage of the CFs in five engineering fields and found that certain CFs are preferred depending on the discipline.

Argumentative Zoning is a similar concept based on the rhetorical moves (Teufel, 1999). It had seven categories, which were later extended to 15 categories by Teufel et al. (2009)

Previous studies on CF-based classification used conditional random fields (Hirohata et al., 2008), a classifier chain with sequential minimum optimisation, Rakel with the J48 algorithm (Dayrell et al., 2012), a Bayes classifier, and a decision tree (Soonklang, 2016). However, these studies only focused on abstracts of scientific papers. Therefore, existing CF-labelled FE lists were created by manually assigning CF labels (Table 1), complicating the construction of a large CF-labelled FE database. Recently, Fiacco et al. (2019) used a hierarchical Bi-LSTM+CRF to classify sentences. However, CF-labelled sentence corpora are yet to be made available to the public.

2.2 FE-Extraction Methods

Two approaches are used for extracting FEs: corpus- and sentence-level approaches. Based on the intuition that FEs appear frequently or words composing FE are strongly associated, most studies use the corpus-level approach, in which statistical metrics, such as frequency or mutual information, are applied to a whole corpus. To extract FEs, word n-grams were collected from a whole corpus by using the metrics (Biber et al., 2004; Simpson-Vlach and Ellis, 2010; Kermes, 2012; Mizumoto et al., 2017). However, this approach results in the extraction of an explosive number of overlapping n-grams, thus causing a serious problem in the CF-labelled FE database construction. For instance, suppose '*in this paper we propose*', '*this paper we propose a*', and '*in this paper we propose a new method*' are extracted, a criterion is needed to determine which of these are regarded as FEs; however, determining such a criterion is difficult.

The n-gram lattice method (Brooke et al., 2017) is one approach to address this problem; here, scores of various aspects of *formulaicity* are first calculated for all word n-grams. Next, an objective function that contains all scores of the n-grams is maximised to determine which n-grams should be disregarded and which should remain. However, this method is still not focused on FEs conveying CFs but on general phrasal expressions; thus, it is thus not suitable for our setting.

The sentence-level approach assumes that one FE occurs in one sentence. Thus, '*in this paper we propose a new method*' can be extracted, but '*this paper we propose a*' cannot be extracted from a sentence. This approach is also useful for extracting FEs with a slot (Vincent, 2013), into which some words can be inserted, such as '*however, * have not been reported*'. This setting is regarded as a sequence-labelling problem, in which each word of a sentence is labelled as either formulaic or non-formulaic. Liu et al. (2016) proposed removing topic-specific words as non-formulaic words, using latent Dirichlet allocation. They used a corpus consisting of papers from various disciplines, and tried to remove discipline-specific vocabulary. Thus, this is not suitable for extracting discipline-specific FEs. Iwatsuki et al. (2020b) proposed removing scientific and named entities in addition to dependency-based word removal.

The evaluation of the FE extraction model is another problem. Brooke et al. (2015) pointed out that the comparison of newly extracted FEs with existing reference is unreasonable because if a reference is on point, a new lexicon need not be created. Thus, Iwatsuki et al. (2020b) proposed evaluating FE extraction methods by a CF-based sentence retrieval task as an extrinsic task based on the idea that FEs convey a CF of a sentence.

2.3 CF-Labelled FE Databases

Table 1 describes the existing CF-labelled FE databases. Previous studies have shown that FEs are discipline-specific, and the resource of academic vocabulary should be presented for each discipline (Hyland and Tse, 2007; Liu, 2012). Thus, the development of CF-labelled FE databases for each discipline is important; however, many studies have focused on *general* FEs, which were extracted from a mixed corpus consisting of scientific papers on multiple disciplines. Some studies adopted the discipline-specific approach; Mizumoto et al. (2017) considered only the journals on applied linguistics, while Lu et al. (2018) used only the introductions of social-science papers. Moreover, only a small number of documents were used because the existing resources require manual labour for assigning CF labels.

Hence, we contend that the automated CF-based classification is helpful for constructing a large, comprehensive CF-labelled FE database. In this study, we developed a discipline-specific database based on large corpora of scientific papers from four disciplines.

3 Methods

3.1 Corpora and Datasets

3.1.1 Corpora of Scientific Papers

In this study, we considered the corpora which satisfy the following conditions. First, because we use full text of scientific papers and have made all the data public, papers must be open access. Second, to construct a comprehensive database, the corpora size is important. Third, for cross-discipline analyses, a discipline-specific journal is preferred to a multidisciplinary journal. We selected a corpus containing at least 10,000 papers.

Under these three conditions and based on the diversity of the disciplines, we selected four corpora: ACL Anthology Sentence Corpus[2] for computational linguistics (CL), Molecules[3] for chemistry (Chem), Oncotarget[4] for oncology (Onc), and Frontiers in Psychology[5] for psychology (Psy). Each corpus comprises more than 10,000 papers and is open access to full text (creative commons licence).

For pre-processing, we performed sentence splitting using ScispaCy (Neumann et al., 2019) and replaced citations and mathematical formulae with a special token. By using a simple rule-based method, section labels were normalised into five classes: introduction, methods, results, discussion, and other. Each sentence was assigned a section label; we did not use sentences belonging to the 'other' class. The numbers of sentences and documents are listed in Table 2.

Corpus	#Doc.	#Sent.	#Words
CL	13,921	1,612,921	32,698,072
Chem	15,949	1,703,902	39,303,460
Onc	19,541	3,029,285	68,719,634
Psy	12,317	1,948,082	49,329,526

Table 2: Number of documents (doc), sentences (sent), and words in each corpus.

3.1.2 CF Set and CoreFEs

Till date, there is no established CF set, and some CFs are not used or are frequently used in a specific discipline. Proposing a new CF set is beyond the scope of this study; however, we must select a CF set. We adopted the CF set proposed by Iwatsuki et al. (2020a), which was based on CFs used in Academic Phrasebank (Morley, n. d.). Table 3 describes the numbers of CFs in each section. (All the CFs are listed in Table 13 in the appendix.) CoreFE is an FE that is shortened so that it can be used as a query for sentence retrieval (Generally, longer phrases result in few or no results in sentence retrieval). We used CoreFEs to create the CF-labelled sentence dataset.

3.1.3 CF-Labelled Sentence Dataset

For the CF-based classification, we created a sentence dataset by using the aforementioned corpora. To effectively collect labelled sentences, we used the following procedures. First, the CoreFEs were

Methods	6
Results	6
Discussion	9

Table 3: Numbers of CFs for each section.

used as queries to retrieve sentences from the corpora. Although the CoreFEs have CF labels, the retrieved sentences may not always have the same CFs.

Next, we used Amazon Mechanical Turk (AMT) to check if each sentence was assigned correct labels; this process was three-fold. First, a *correct* set of sentences was prepared. Two experts were asked whether the sentences in the correct set were correctly labelled, and the sentences whose labels were judged incorrect by at least one expert were removed. Another set of sentences, called the *incorrect* set, was prepared, in which the same sentences were randomly assigned incorrect labels. Second, by using these sets, a pilot test was conducted on AMT. Five annotators were recruited and asked to check whether the labels were correct or not. Based on this pilot test, we determined the threshold to cut off sentences. Finally, a larger set of sentences was prepared, which was different from the set used in the pilot test. Another five annotators were asked to perform the same task on the set. The final dataset comprises the sentences satisfying the threshold.

3.2 Sentence Classification

3.2.1 Classifier

We assigned each sentence a CF label, and this task can be regarded as a CF-based sentence-classification problem. In addition, we used SciBERT (Beltagy et al., 2019) with an additional linear layer for classification. We split the CF-labelled sentence dataset into training/development and evaluation sets so that four sentences for each CF were in the evaluation set. Then, we conducted five-fold cross validation using the training/development set for parameter tuning. Subsequently, we fine-tuned the classifier and evaluated the classification accuracy.

Because CF sets in scientific papers have not been established, the CF set we used cannot satisfactorily cover all sentences written in papers. Additionally, pre-processing errors, such as sentence splitting, sometimes result in no-CF sentences. Thus, in some scenarios, no CF should be assigned to a sentence and no-CF sentences must be removed. The no-CF class is not contained in the training dataset; this problem is regarded as the out-of-distribution detection problem. Although the maximum value of the softmax layer is not a perfect metrics for out-of-distribution detection, pre-trained transformers, such as BERT and RoBERTa, with a softmax layer are good detectors of out-of-distribution data (Hendrycks and Gimpel, 2017; Hendrycks et al., 2020).

To manage the no-CF sentences, we used the maximum softmax value of the classifier, and verified its performance. The verification was performed in the same manner as the creation of the CF-labelled sentence dataset. That is, we asked five AMT annotators whether the output label was correct. The threshold was also the same: 5/5.

3.2.2 Multidisciplinary Perspectives

To create a multidisciplinary database, the classification must be applied to various disciplinary texts. As it is costly to create a training dataset manually for each discipline, we tested whether the classifier trained on a dataset of one discipline can be immediately applied to the datasets of other disciplines.

SciBERT was trained on scientific papers from Semantic Scholar[6] (Beltagy et al., 2019). The corpora used in this study are open access and were also included in Semantic Scholar. Thus, we hypothesise that the cross-disciplinary adaptation is successful because the sentences are (partly) contained in the pre-training dataset. Therefore, the method cannot be applied to disciplines that are not covered by the pre-training dataset. To verify this hypothesis, we compared SciBERT to BERT, which was pre-trained on the book corpus and Wikipedia and not on scientific papers (Devlin et al., 2019), for cross-discipline sentence classification.

3.3 FE Extraction

To extract FEs, we propose a method based on Iwatsuki et al. (2020b), which is a sentence-level method; one FE was extracted from one sentence. We applied this method, which comprises three steps, to the classified sentences.

In the first step, the named and scientific entities are removed from a sentence. The entity recognition was performed using SpERT (Eberts and

---

[6] `https://www.semanticscholar.org/`

Ulges, 2020), which sits atop the leader-board of NER tasks for scientific entities[7]. For training, we used CoNLL04 (Roth and Yih, 2004), a corpus labelled with general-purpose named entities, and SciERC (Luan et al., 2018), a corpus of scientific papers labelled with scientific entities. The CoNLL04 labels are *location*, *organisation*, *people*, and *other*; SciERC labels are *task*, *method*, *evaluation metric*, *material*, *other scientific terms*, and *generic*. By removing the named entities, a sentence was split into several spans.

In the second step, we used the dependency structure of a sentence analysed by Stanford CoreNLP (Qi et al., 2018). Words that were neither in the span containing a sentence's root nor organised by the root were then removed. The assumption here was that FEs representing CFs of sentences appeared in the structural centres in the sentence dependency structures (Iwatsuki et al., 2020b).

Steps 1 and 2 work well if several named entities are contained in a sentence; otherwise, an almost full sentence is produced, which is too long to be an FE. Thus, we propose an additional filtering step that further removes non-relevant generic terms from the candidate FE spans. This is based on the assumption that each word of an FE is strongly associated with each other. Thus, the association between fragments of an FE should be strong. For instance, '*in this paper we*' and '*propose*' are strongly associated, while '*in this paper we*' and '*talk*' are not.

On the basis of this observation, we first extracted all pairs of an n-gram and its neighbour word from each candidate span obtained after Step 2. For example, pairs such as ('*in this*', '*paper*') or ('*paper we*', '*propose*') are obtained when $n = 2$. Next, for each pair, we calculated the association measures between an n-gram and a neighbour word. We used the local mutual information (LMI), which is formalised as follows:

$$\mathrm{LMI}(a, b) = f(a, b) \cdot \log \frac{p(a, b)}{p(a)p(b)}, \qquad (1)$$

where a and b denote a word, a, b denotes the co-occurrence of the words, $p(a)$ is a probability of occurrence of a, and $f(a)$ is a frequency of a in a corpus (Evert, 2005). Finally, the pairs with the top k scores were labelled as an FE. To avoid generating FEs that are too short, this third process was applied only when the length of the resulting word sequence of Step 2 was more than k words. From our preliminary experiments, we determined to use $(n, k) = (2, 7)$.

CF: Suggestion of future work
Sentence:
In the future, we plan to explore how to combine more features such as part-of-speech tags into our model.

Figure 2: Example of the database evaluation. An FE is underlined in the sentence, which has been retrieved from Cao et al. (2014).

Because FEs are assumed to be used as they are, we did not lemmatise them. Formulaicity sometimes does not allow the replacement of a word in an FE with another word or flection. For example, tenses can be section-specific (present or past): '*in this paper we proposed*' rarely occurs in the introduction sections. Formulaicity also avoids grammatical errors such as '*little researches have been done*'. Many previous studies did not lemmatise FEs (Simpson-Vlach and Ellis, 2010; Mizumoto et al., 2017; Pan et al., 2016; Esfandiari and Barbary, 2017).

3.4 Constructing CF-Labelled FE Database

We created the CF-labelled FE database using the following steps. Step 1: CF labels were assigned to each sentence in a corpus and no-CF sentences were removed. Step 2: FEs were extracted from each sentence. Step 3: Noisy FEs were filtered out. If an FE was assigned multiple CF labels, only one CF was selected by majority voting. If none of the CFs took the majority, the FE was removed. Any CF-labelled FE occurring less than three times was also removed.

We evaluated the final database from two perspectives: whether a sentence was assigned a correct label and whether an FE was useful for writing a scientific paper.

The evaluation was conducted on the AMT. A sentence and its CF label were shown to evaluators, and an FE was highlighted in the sentence (see Figure 2). The evaluators were asked whether the sentence conveyed the CF and whether the FE was useful. Each FE was annotated by five evaluators, and if it was not evaluated by all as correct or useful, it was regarded as incorrect or useless.

Table 5: Numbers of sentences in the final dataset.

4 Results

4.1 CF-Labelled Sentence Dataset

The correct and incorrect sets consist of 55 sentences. The results of the pilot test are shown in Table 4. Accordingly, we set the threshold to 5/5 because high precision was important for creating the FE database rather than recall, and the strictest threshold did not significantly reduce the sentences. Table 5 lists the total number of sentences.

4.2 CF-Based Sentence Classification

The classification results are shown in Table 6. SciBERT worked well, which implies that this BERT-based classifier has the ability to capture CFs of sentences.

We also verified with SciBERT whether the maximum value of the softmax layer can be used as the threshold to filter out no-CF sentences. We first classified all the sentences in the corpora, and then split the classified sentences into six categories based on the maximum softmax score: [0.00, 0.60], (0.60, 0.70], (0.70, 0.80], (0.80, 0.90], (0.90, 0.99], (0.99, 1.00]. Next, we randomly sampled 100 sentences from each range, and the sentences were evaluated by five annotators on AMT. The evaluation method was the same as that used for collecting the CF-labelled sentences. The accuracy of each range is shown in Table 7. For database construction, we removed the sentences with a score of 0.80 or lower.

Discipline	I	M	R	D	Avg.

(0.60, 0.70]	0.51	2.1%
(0.00, 0.60]	0.43	3.3%

Table 7: Accuracy scores of each range of the maximum value of the softmax layer, and the proportion of sentences in the corpora.

4.3 Multidisciplinary Perspective

We tested whether SciBERT trained on one discipline can be applied to different disciplines. The results are shown in Table 8.

We also tested the effects of the pre-trained dataset by comparing the results of SciBERT and BERT. Table 9 and 10 show the BERT results; compared with the results shown in Table 6 and 8, the two models did not show a considerable difference.

4.4 Constructing CF-Labelled FE Database

The CF-labelled FE database was evaluated by sampling 200 FEs. The results are shown in Table 11.

Incorrect sentence–CF pairs were obtained because the classifier made errors and some sentences were not a complete sentence. An example of an incomplete sentence is ‘*of three independent experiments.*’; this was produced because of the error of sentence splitting. Examples of useful FEs are

	Psy	0.87	0.92	0.88	0.92

Table 10: Average accuracy scores by BERT.

'*plays a crucial role in*' (CF: Showing the importance of the topic) and '*no significant differences were detected in*' (CF: Description of the results), while '*et al demonstrated that*' (CF: Showing background provided by past work) and '*is to use a*' (CF: Showing brief introduction to the methodology) were judged useless.

The statistics of the database are shown in Table 2. To show discipline-specific FEs, we calculated odds ratio for each CF of each discipline. Table 12 illustrates the top 5 high odds ratio FEs in the 'description of the process' CF in the introduction section. These FEs are not considered rare, as some of them occur more than a thousand times in a corpus. The differences between disciplines are relative, and these results may change if another corpus of a different discipline is added; however, preference for FEs still exists across disciplines. This reinforces the previous claim that FEs are discipline-specific (Hyland and Tse, 2007; Hyland, 2008; Durrant, 2015; Jalilifar et al., 2016). All the discipline-specific FEs are listed in Table 15 in the appendix.

5 Discussion

5.1 CF-Based Sentence Classification

The classification accuracy was quite high, and thus the results can be a good baseline for a CF-based sentence classification task. We published the dataset so that other researchers can tackle the classification task.

The no-CF detection worked fairly. From Table 7 it can be said that the maximum value is often too high; 30% of the CF labels assigned scores higher than 0.99 were incorrect. However, much lower ($\leq$ 0.80) scores tended to cause lower accuracy. Thus, this approach is useful to improve overall precision, which is more important to construct a FE-CF database than recall.

5.2 Problems in Multidisciplinary Data

We raised two questions: Can the classifier trained on one discipline be applied to other disciplines? Does the pre-training data affect the classification performance?

The results of the sentence classification imply that the SciBERT classifier trained on a dataset of one discipline can be applied to datasets of other disciplines. This mitigates the labour of creating a training dataset for all other disciplines. Therefore, we argue that to create another FE-CF database of another discipline, the CF-labelled sentence dataset we created can be used as a training dataset.

The comparison of SciBERT (Table 6) and BERT (Table 9) denied our hypothesis that the cross-discipline adaptation worked as long as the discipline was included in pre-training data. Therefore, the ability of discipline adaptation does not come from the pre-training dataset, which implies that the classifier could be used irrespective of whether a discipline is covered by the pre-training dataset.

5.3 Quality of the FE-CF Database

The results of the evaluation (Table 11) imply that if five CF-labelled FEs are retrieved, approximately three (130/200) are good FEs. Considering scenarios where users search for FEs to write a scientific paper, the selection of one FE from five candidates containing two incorrect FEs can be considered realistic.

Consider another case in which users use an FE as a query to obtain some example sentences that play the role of a specific CF. In this case, the evaluation results imply that approximately 90% (130/142) of the retrieved sentences are satisfying results. In some cases, the same FEs appear in different CF categories. For example, '*play critical roles in*' is used in 'Showing the importance of the topic (introduction)' and 'Showing background provided by past work (discussion)'. Thus, compared to the mere collection of FEs, the addition of CF labels to FEs is proved to be more helpful.

6 Conclusion

In this paper, we proposed the fully-automated construction of a CF-labelled FE database, by solving the problem of CF-based sentence classification. We carefully considered a practical case of creating a FE database of other disciplines. The experimental results showed that the proposed classification method and dataset can be utilised to construct FE databases for disciplines different from those that we used. We proposed the FE extraction method that utilised the named and scientific entity removal, dependency-structure-based word removal, and word-association-measure-based word removal. Combining the proposed methods, we finally constructed the new CF-labelled FE database. The CF-labelled sentence database and the CF-labelled FE database are available on our website[8]. We expect that the proposed database could be used by pedagogical practitioners and for computer-aided academic-writing assistance such as sentence retrieval and automated proofreading.

A Dataset and Databases

On our website[9], we published the following dataset and databases:

1. The CF-labelled sentence dataset for training and evaluation,
2. The CF-labelled sentence database, which was constructed by applying SciBERT classifier to every sentence in the corpora we used, and
3. The CF-labelled FE database, which was constructed by applying the proposed FE extraction method to the CF-labelled sentence database.

These data were formatted in tab-separated text. In the CF-labelled sentence dataset, a line consists of an ID and a sentence. In the CF-labelled sentence database, a line consists of a sentence ID (from the corpora), an ID, the maximum softmax value, and a sentence. In the CF-labelled FE database, a line consists of a CF, an FE, and the number of appearance in the corpus.

B CF Set

Table 13 lists the CF we used. The ID in the table corresponds to the ID used in the sentence dataset and database.

C General and Discipline-Specific FEs

General FEs are FEs that appear commonly in multiple disciplines. We calculated the average rank of each FE and Table 14 lists the top-5 general FEs for each CF. For most of the CFs, general FEs were not found. We also calculated the odds ratio and Table 15 lists the top-5 discipline-specific FEs for each CF. Some CFs did not happen in a corpus.

Abstract

Major scandals in corporate history have urged the need for *regulatory compliance*, where organizations need to ensure that their controls (processes) comply with relevant laws, regulations, and policies. However, keeping track of the constantly changing legislation is difficult, thus organizations are increasingly adopting Regulatory Technology (RegTech) to facilitate the process. To this end, we introduce *regulatory information retrieval* (REG-IR), an application of *document-to-document information retrieval* (DOC2DOC IR), where the query is an entire document making the task more challenging than traditional IR where the queries are short. Furthermore, we compile and release two datasets based on the relationships between EU directives and UK legislation. We experiment on these datasets using a typical two-step pipeline approach comprising a pre-fetcher and a neural re-ranker. Experimenting with various pre-fetchers from BM$_{25}$ to k nearest neighbors over representations from several BERT models, we show that fine-tuning a BERT model on an in-domain classification task produces the best representations for IR. We also show that neural re-rankers underperform due to *contradicting* supervision, i.e., similar query-document pairs with opposite labels. Thus, they are biased towards the pre-fetcher's score. Interestingly, applying a date filter further improves the performance, showcasing the importance of the time dimension.

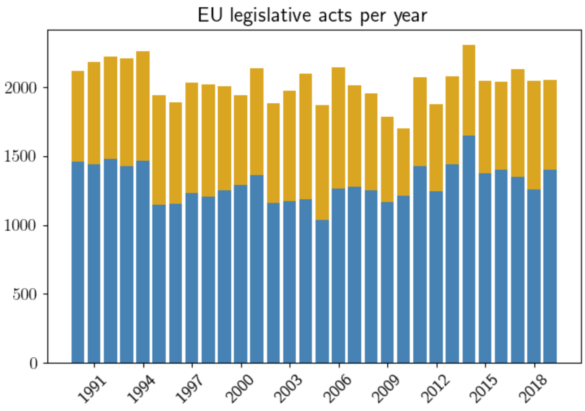

Figure 1: Number of legislative acts issued by the EU per year. The gold color of the bars indicates how many of the published acts are amendments to older ones.

1 Introduction

Major scandals in corporate history, from Enron to Tyco International, Olympus, and Tesco,[1] have led to the emergence of stricter regulatory mandates and highlighted the need for *regulatory compliance* where organizations need to ensure that they comply with relevant laws, regulations, and policies (Lin, 2016). However, keeping track of the constantly changing legislation (Figure 1) is hard, thus organizations are increasingly adopting Regulatory Technology (RegTech) to facilitate the process.

Typically, a compliance regimen includes three distinct but related types of measures, *corrective*, *detective*, and *preventive* (Sadiq and Governatori,

April 19 - 23, 2021. ©2021 Association for Computational Linguistics

2015). Corrective measures are usually undertaken when new regulations are introduced to update existing controls. Detective measures, ensure "after-the-fact" compliance, i.e., following a procedure, a manual or automated check is carried out, to ensure that every step of the procedure complied with the corresponding regulations. Finally, preventive measures ensure compliance "by design", i.e., during the creation of new controls. All types of measures include an underlying information retrieval (IR) task, where laws need to be retrieved given a control or vice versa. We identify two use cases:

1. *Given a new law retrieve all the controls of the organization affected by this law*. The organization can then apply corrective measures to ensure compliance for these controls.
2. *Given a control retrieve all relevant laws the control should comply with.* This is useful for ensuring compliance after a procedure has been carried out (detective measures) or when creating new controls (preventive measures).

Regulatory information retrieval (REG-IR), similarly to other applications of *document-to-document* (DOC2DOC) IR, is much more challenging than traditional IR where the query typically contains a few informative words and the documents are relatively small (Table 1). In DOC2DOC IR the query is a long document (e.g., a regulation) containing thousands of words, most of which are uninformative. Consequently, matching the query with other long documents where the informative words are also sparse, becomes extremely difficult.

Although legislation is available, organizations' controls are strictly private and very hard to obtain. Fortunately, the European Union (EU) has a legislation scheme analogous to regulatory compliance for organizations. According to the Treaty on the Functioning of the European Union (TFEU),[2] all published EU *directives* must take effect at the national level. Thus, all EU member states must adopt a law to transpose a newly issued directive within the period set by the directive (typically 2 years). Notably, the United Kingdom (UK) having a high compliance level with the EU (Figure 2),[3] is a good test-bed for REG-IR. Thus we compile and release two datasets for REG-IR, EU2UK and UK2EU, containing EU directives and UK regulations, which can serve both as queries and documents under the ground truth assumption that a UK law is relevant to the EU directives it transposes and vice versa.

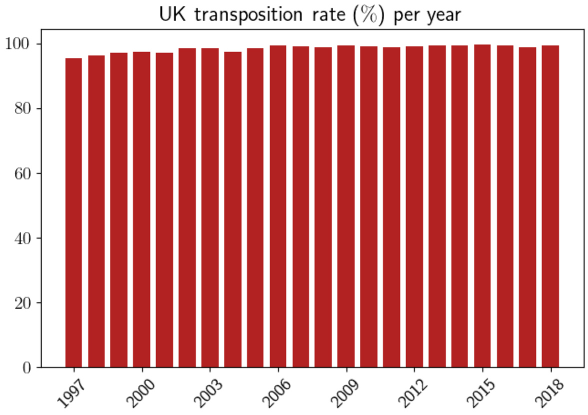

Figure 2: The percentage of EU directives transposed by UK legislation per year. Over 98% of the published EU directives have been transposed.

Table 1: Statistics for query and document length for IR datasets used in literature.

Since REG-IR is a new task, our starting point is the two-step pipeline approach followed by most modern neural information retrieval systems (Guo et al., 2016; Hui et al., 2017; McDonald et al., 2018). First, a conventional IR system (*pre-fetcher*) retrieves the k most prominent documents. Then a neural model attempts to rank relevant documents higher than irrelevant ones. In most approaches, the pre-fetcher is based on Okapi BM$_{25}$ (Robertson et al., 1995), a bag-of-words scoring function that does not consider possible synonyms or contextual information. To overcome the first limitation, we follow Brokos et al. (2016) who employed k nearest neighbors over tf-idf weighted centroids of word embeddings, without however improving the results, probably because the centroids are noisy considering many uninformative words. Furthermore, we employ BERT (Devlin et al., 2019) to extract contextualized representations for queries and documents but again the results are worse than BM$_{25}$. We also experiment with S-BERT (Reimers

Query: DIRECTIVE 2006/66/EC OF THE EUROPEAN PARLIAMENT AND OF THE COUNCIL of 6 September 2006 on batteries and accumulators and waste batteries and accumulators and repealing Directive 91/157/EEC

BM$_{25}$ rank	Relevant	Document title
1	No	The Batteries and Accumulators (Placing on the Market) (Amendment) Regulations 2012
2	No	The Batteries and Accumulators (Containing Dangerous Substances) (Amendment) Regulations 2000
3	No	The Batteries and Accumulators (Placing on the Market) (Amendment) Regulations 2015
4	No	The Batteries and Accumulators (Containing Dangerous Substances) Regulations 1994
5	No	The Waste Batteries and Accumulators (Amendment) Regulations 2015
6	Yes	The Waste Batteries and Accumulators Regulations 2009
12	Yes	The Batteries and Accumulators (Placing on the Market) Regulations 2008

Table 2: Example from the EU2UK dataset where the retrieved UK laws are ranked by BM$_{25}$. The top-5 documents seem similar to the query but are not relevant. Documents ranked 1st, 3rd, and 5th are amendments of the relevant documents, i.e., UK laws that transpose the query.

and Gurevych, 2019) and LEGAL-BERT (Chalkidis et al., 2020), a model specialized in the legal domain. Both models perform better than BERT but are still worse than or comparable to BM$_{25}$. The inability of BERT-based models motivated us to find an auxiliary task that will result in better representations for REG-IR. Following Chalkidis et al. (2019), we fine-tune BERT to predict EUROVOC concepts that describe the core subjects of each text. As expected this model (C-BERT) is the best pre-fetcher by a large margin in EU2UK, while being comparable to BM$_{25}$ in UK2EU. To summarize, our contributions are:

(a) We introduce REG-IR, an application of DOC2DOC IR, which is a new family of IR tasks, where both queries and documents are long typically containing thousands of words.

(b) We compile and release the two first publicly available datasets, EU2UK and UK2EU, suitable for REG-IR and DOC2DOC IR in general.[4]

(c) We show that fine-tuning BERT on an in-domain classification task produces the best document representations with respect to IR and improves pre-fetching results.

2 Datasets curation

2.1 Data sources

EU/UK Legislation: We have downloaded approx. 56K pieces of EU legislation (approx. 3.9K directives), from the EURLEX portal.[5] EU laws are 2,642 words long on average and are structured in three major parts: the *title* (Table 2, query), the *recitals* consisting of references in the legal background of the act, and the *main body*. We have also downloaded approx. 52K UK laws, publicly available from the official UK legislation portal.[6] UK laws are 1,849 words long on average and contain the *title* (Table 2, document title) and the *main body*.

Transpositions: We have retrieved all transposition relations (approx. 3.7K) between EU directives and UK laws from the CELLAR database. CELLAR only provides the mapping between the CELLAR ids of EU directives and the title of each UK law. Therefore we aligned the CELLAR ids with the official UK ids based on the law title.[7] One or more UK laws may transpose one or more EU directives.

2.2 Datasets compilation

Let $\mathcal{E}, \mathcal{U}$ be the sets of EU directives and UK laws, respectively. We define REG-IR as the task where the query q is a document, e.g, an EU directive, and the objective is to retrieve a set of relevant documents, $\mathcal{R}_q$, from the pool of all available documents, e.g., all UK laws. We create two datasets:

EU2UK: $q \in \mathcal{E}, \mathcal{R}_q = \{r_i \colon r_i \in \mathcal{U}, r_i \xrightarrow{\text{transposes}} q\}$.

UK2EU: $q \in \mathcal{U}, \mathcal{R}_q = \{r_i \colon r_i \in \mathcal{E}, q \xrightarrow{\text{transposes}} r_i\}$.

Table 3 shows the statistics for the two datasets, which are split in three parts, *train*, *development*, and *test*, retaining a chronological order for the queries. EU2UK has a much larger pool of available documents than UK2EU (52.5K vs. 3.9K) which may impose an extra difficulty during retrieval. More importantly, the average number of relevant documents per query is small (at most 2) for both datasets, as our ground truth assumption is strict, i.e., relevant documents are those linked to the query with a transposition relation. Also, EU legislation is frequently amended (Figure 1) which also

---

[4] The datasets are available at `https://archive.org/details/eacl2021_regir_datasets`.

[5] `eur-lex.europa.eu`

[6] `legislation.gov.uk`

[7] See Appendix A for details on the dataset curation.

Dataset	Documents in pool	Train		Development		Test	
		Queries	Avg. relevant	Queries	Avg. relevant	Queries	Avg. relevant
EU2UK	52,515	1,400	1.79	300	2.09	300	1.74
UK2EU	3,930	1,500	1.90	300	1.46	300	1.29

Table 3: Detailed statistics for EU2UK and UK2EU. Both datasets have relatively small number of relevant documents while EU2UK has also large pool which may impose extra difficulties in the retrieval.

imposes difficulty in the retrieval task. Let $d_1 \in \mathcal{E}$ be a directive transposed by $u_1 \in \mathcal{U}$ and $d_2 \in \mathcal{E}$ be a directive amending d_1. The UK must adopt a law, u_2, to transpose d_2. Both d_2 and u_2 cover similar concepts to those of d_1 (d_2 is an amendment and u_2 must comply with d_2), but, strictly speaking u_2 is relevant only to d_2. Table 2 shows an example from EU2UK, where the top-5 documents seem very similar to the query but are not considered relevant. Note that the documents ranked 1st, 3rd and 5th, are amendments of the relevant documents.

3 IR pipelines

Modern neural IR systems usually follow a two-step pipeline approach. First, a conventional IR system (*pre-fetcher*) retrieves the top-k most prominent documents aiming to maximize its recall. Then a neural model attempts to re-rank the documents by scoring relevant higher than irrelevant ones. While this configuration is widely adopted in literature, the re-ranking step could be omitted provided an effective pre-fetching mechanism, i.e., the pre-fetcher will act as an end-to-end IR system.

3.1 Document pre-fetching

Okapi BM$_{25}$ (Robertson et al., 1995) is a bag-of-words scoring function estimating the relevance of a document d to a query q, based on the query terms appearing in d, regardless their proximity within d:

$$\sum_{i=1}^{n} \mathrm{idf}(q_i) \cdot \frac{\mathrm{tf}(q_i,d)\cdot(k_1+1)}{\mathrm{tf}(q_i,d)+k_1\cdot\left(1-b+b\cdot\frac{L}{\bar{L}}\right)} \quad (1)$$

where q_i is the i-th query term, with $\mathrm{idf}(q_i)$ inverse document frequency and $\mathrm{tf}(q_i,d)$ term frequency. L is the length of d in words, $\bar{L}$ is the average length of the documents in the collection, k_1 is a parameter that favors high tf scores and b is a parameter penalizing long documents.[8]

W2V-CENT: Following Brokos et al. (2016), we represent query/document terms with pre-trained embeddings. For each query/document we calculate the tf-idf weighted centroid of its embeddings:

$$\mathrm{cent}(t) = \frac{\sum_{i=1}^{l} \boldsymbol{x}_i \cdot \mathrm{tf}(x_i,t)\cdot \mathrm{idf}(x_i)}{\sum_{i=1}^{l} \mathrm{tf}(x_i,t)\cdot \mathrm{idf}(x_i)} \quad (2)$$

where t is a text (query or document) and x_i is the i-th text term with embedding $\boldsymbol{x}_i$. The documents are ranked, with respect to the query, by a k nearest neighbours (kNN) algorithm with cosine distance:

$$\cos_{\mathrm{d}}(q,d) = 1 - \frac{\mathrm{cent}(q)\cdot\mathrm{cent}(d)}{\|\mathrm{cent}(q)\|\cdot\|\mathrm{cent}(d)\|} \quad (3)$$

BERT, similarly to W2V-CENT, relies in pre-trained representations which now are extracted from BERT, thus being context-aware. A text can be represented by its `[cls]` token or by the centroid of its token embeddings. In the latter case the embeddings can be extracted from any of the 12 layers of BERT.[9] Note that the texts in our datasets do not entirely fit in BERT. We thus split them into c chunks (2 to 3 per text) and pass each chunk through BERT to obtain a list of token embeddings per layer (i.e, the concatenation of c token embeddings lists) or c `[cls]` tokens. The final representation is either the centroid of the token embeddings or the centroid of the `[cls]` tokens.

S-BERT (Reimers and Gurevych, 2019) is a BERT model fine-tuned for NLI. According to the authors, training S-BERT for NLI results in better representations than BERT for tasks involving text comparison, like IR. We use the same setting as in BERT.

LEGAL-BERT: Our datasets come from the legal domain which has distinct characteristics compared to generic corpora, such as specialized vocabulary, particularly formal syntax, semantics based on extensive domain-specific knowledge, etc., to the extent that legal language is often classified as a 'sub-language' (Tiersma, 1999; Williams, 2007; Haigh, 2018). BERT and S-BERT were trained on generic corpora and may fail to capture the nuances of legal language. Thus we used a BERT model further pre-trained on EU legislation (Chalkidis et al., 2020), dubbed here LEGAL-BERT, in a similar fashion.

---

[8] We use *elastic*, a widely used IR engine with the BM$_{25}$ scoring function. See `www.elastic.co/`.

[9] BERT is not fine-tuned during this process.

C-BERT: EU laws are annotated with EUROVOC concepts covering the core subjects of EU legislation (e.g., environment, trade, etc.). Our intuition is that a UK law transposing an EU directive will most probably cover the same subjects. Thus we expect that a BERT model, fine-tuned to predict EUROVOC concepts, will learn rich representations describing these concepts which may be useful for pre-fetching. We fine-tune BERT following Chalkidis et al. (2019)[10] and use the resulting model to extract query and document representations similarly to the previous BERT-based methods.

ENSEMBLE is simply a combination of our best two pre-fetchers, C-BERT and BM25:

$$\text{ENS}(q,d) = \alpha \cdot \text{CB}(q,d) + (1-\alpha) \cdot \text{BM}_{25}(q,d) \quad (4)$$

where CB is the score of C-BERT and α is tuned on development data and the scores of the pre-fetchers are normalized in $[0,1]$.

3.2 Document re-ranking

Modern neural re-rankers operate on pairs of the form (q,d) to produce a relevance score, $\text{rel}(q,d)$, for a document d with respect to a query q. Note, however, that the main objective is to rank relevant documents higher than irrelevant. Thus, during training the loss is calculated as:

$$\mathcal{L} = \max(0, 1 - \text{rel}(q,d^+) + \text{rel}(q,d^-)) \quad (5)$$

where d^+ is a relevant document and d^- is an irrelevant document. We have experimented with several neural re-ranking methods each having a function that produces a relevance score s_r for each of the top-k documents returned by the best pre-fetcher. The final relevance score of a document is calculated as: $\text{rel}(q,d) = w_r \cdot s_r + w_p \cdot s_p$, where s_p is the normalized score of the pre-fetcher and w_s, w_p are learned during training.

Given the concerns on the strictness of the ground truth assumption raised in Section 2.2, we hypothesize that re-rankers will eventually over-utilize the pre-fetcher score, s_p, when calculating document relevance, $\text{rel}(q,d)$. As shown in Table 2, in many cases both relevant and irrelevant documents may have high similarity with the query. This in turn may confuse and therefore degenerate the re-ranker's term matching mechanism, i.e., MLPs or CNNs over term similarity matrices.

DRMM (Guo et al., 2016) uses pre-trained word embeddings to represent query and document terms. A histogram captures the cosine similarities of a query term, q_i, with all the terms of a particular document. Then an MLP consumes the histograms to produce a document-aware score for each q_i, which is weighted by a gating mechanism assessing the importance of q_i. The sum of the weighted scores is the relevance score of the document. A caveat of DRMM is that it completely ignores the context of the terms which could be of particular importance in our datasets where texts are long.

PACRR (Hui et al., 2017) represents query and document terms with pre-trained embeddings and calculates a matrix S containing the cosine similarities of all query-document term pairs. A row-wise k-max pooling operation on S keeps the highest similarities per query term (matrix S_k). Then, wide convolutions of different kernel (filter) sizes ($n \times n$) with multiple filters per size are applied on S. Each filter of size $n \times n$ attempts to capture n-gram similarities between queries and documents. A $\max$-pooling operation keeps the strongest signals across filters and a row-wise k-$\max$ pooling keeps the strongest signals per query n-gram, resulting in the matrix $S_{n,k}$. Subsequently, a row-wise concatenation of S_k with all $S_{n,k}$ matrices (for different values of n) is performed and a column containing the softmax-normalized idf scores of the query terms is concatenated to the resulting matrix (S_{sim}). In effect, each row of the matrix contains different n-gram based similarity views of the corresponding query term, q_i, along with an idf-based importance score. The relevance score is produced as the last hidden state of an LSTM with one hidden unit, which consumes the rows of S_{sim}. PACRR tries to take into account the context of the query and document terms using n-grams but this context sensitivity is weak and we do not expect much benefits in our datasets which contain long texts.

BERT-based re-rankers: Recent work tries to exploit BERT to improve re-ranking. Following MacAvaney et al. (2019), we use DRMM and PACRR on top of contextualized BERT embeddings derived from BERT. Based on the results of Figure 4, we use C-BERT as the most promising BERT model. We call these two models C-BERT-DRMM and C-BERT-PACRR. We also experiment with two settings depending on whether C-BERT weights are updated (*tuned*) or not (*frozen*) during training.

---

[10] We use all EU laws excluding EU directives that exist in our development and test sets.

Figure 3: Heatmaps showing R@100 for different values of k_1 and b on EU2UK (left) and UK2EU (right). The selected optimal values (green boxes) are outside the proposed ranges in the literature (blue boxes).

4 Experimental setup

4.1 Pre-trained resources

As several methods rely on word embeddings, we trained a new WORD2VEC model (Mikolov et al., 2013) in both corpora (EU and UK legislation) to better accommodate legal language. Preliminary experiments showed that domain-specific embeddings perform better than generic 200-dimensional GloVe embeddings (Pennington et al., 2014) in development data (EU2UK: 66.5 vs. 59.3 at R@100 and UK2EU: 72.6 vs. 69.8 at R@100).[11]

All BERT (pre-fetching) encoders and BERT-based re-rankers use the -BASE version, i.e., 12 layers, 768 hidden units and 12 attention heads, similar to the one of Devlin et al. (2019).[12]

4.2 Pre-processing - document denoising

One of the major challenges in DOC2DOC IR, as opposed to traditional IR, is the length of the queries and the documents which may induce noise (many uninformative words) during retrieval. Thus we applied several filters (stop-word, punctuation and digits elimination) on both queries and documents and reduced their length by approx. 55% (778 words for UK laws and 1,222 words for EU directives on average). Further on, we filtered both queries and documents by eliminating words with idf score less than the average idf score of the stopwords. Our intuition is that words (e.g., regulation, EU, law, etc.) with such a small idf score are uninformative. Still, the texts are much longer (387 words for UK laws and 631 words for EU directives on average) than the queries used in traditional IR (Table 1). As an alternative to drastically decrease the query size, we experimented with using only the title of a legislative act as a query but the results were worse, i.e., approx. 5-20% lower R@100 on average across datasets, indicating that the full-text is more informative, although the information is sparse. Hence, we only consider the full-text, including the title, for the rest of the experiments.

4.3 Evaluation measures

Pre-fetching aims to bring all the relevant documents in the top-k, thus we report R@k. We observe that for $\mathrm{k} > 100$ the best pre-fetchers have not significant gains in performance in development data, thus we select $\mathrm{k} = 100$, as a reasonable threshold.[13] For re-ranking we report R@20, nDCG@20 and R-Precision (RP) following the literature (Manning et al., 2009). We report the average and standard deviation across three runs considering the best set of hyper-parameters on development data for neural re-rankers.

4.4 Tuning BM_{25}: The case of DOC2DOC IR

The effectiveness of BM_{25} is highly dependant on properly selecting the values of k_1 and b. In traditional (ad-hoc) IR, k_1 is typically evaluated in the range$[0, 3]$ (usually $k_1 \in [0.5, 2.0]$); b needs to be in $[0, 1]$ (usually $b \in [0.3, 0.9]$) (Taylor et al., 2006; Trotman et al., 2014; Lipani et al., 2015). As a general rule of thumb BM_{25} with k_1=1.2 and b=0.75 seems to give good results in most cases (Trotman et al., 2014). We observe that in the case of DOC2DOC IR where the queries are much longer, the optimal values are outside the proposed ranges

---

[11] See also the discussion for legal language in Section 3.1.

[12] See Appendix B for more details.

[13] See Appendix A.3 for an extended ($\mathrm{k} \in [0, 2000]$) performance evaluation on pre-fetching.

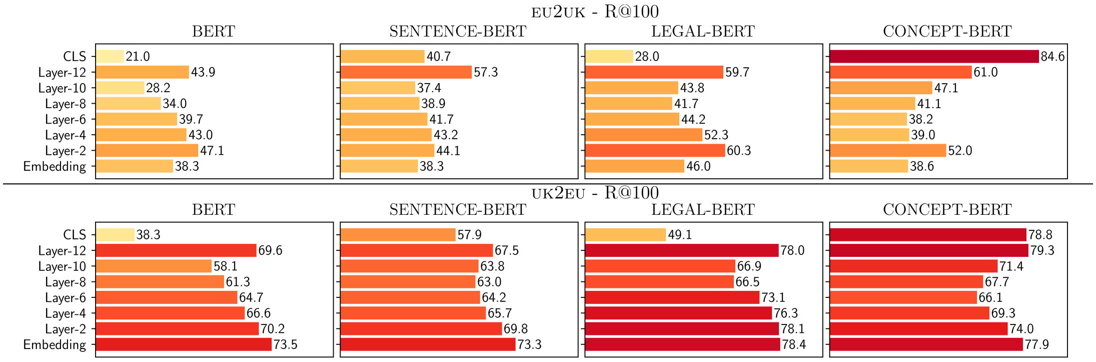

Figure 4: Heatbars showing R@100 (on development data) for text representations extracted from different layers of the various BERT-based pre-fetchers we experimented with.

(Figure 3). In both datasets the optimal values for k_1 and b are relatively high, favoring terms with high tf, while penalizing long documents. In effect BM_{25} uses k_1 and b as a denoising regularizer to over-utilize highly frequent query terms normalized by document length.

4.5 Extracting representations from BERT

Recently there has been a lot of research on understanding the effectiveness of BERT's different layers (Liu et al., 2019; Hewitt and Manning, 2019; Jawahar et al., 2019; Goldberg, 2019; Kovaleva et al., 2019; Lin et al., 2019). Figure 4 shows heatbars comparing representations extracted from different layers of the various BERT-based pre-fetchers we experimented with.[14] LEGAL-BERT and C-BERT which have been adapted in the legal domain perform much better than BERT and S-BERT which were trained on generic corpora. An interesting observation is that the `[cls]` token is a powerful representation only in C-BERT where it was trained to predict EUROVOC concepts. Also, in UK2EU the embedding layer produces the best representations in all BERT variants except C-BERT, where the embedding layer achieves comparable results to the top-2 representations (`[cls]`, Layer-12). This is an indication that the context in this dataset is not as important as in EU2UK.

4.6 Implementation details

All neural models were implemented using the Tensorflow 2 framework. Hyper-parameters were tuned on development data, using early stopping and the Adam optimizer (Kingma and Ba, 2015).

Method	EU2UK	UK2EU
	R@100	R@100
BM_{25} (Robertson et al., 1995)	57.5	93.7

C-BERT (ours)	83.8	92.9
ENSEMBLE (BM_{25} + C-BERT)	**86.5**	**95.0**

Table 4: Pre-fetching results across test datasets.

5 Experimental results

Pre-fetching: Table 4 shows R@100 on the test datasets for the various pre-fetchers considered. On EU2UK, C-BERT is the best method by a large margin, followed by S-BERT and LEGAL-BERT, verifying our assumption that the concept classification task is a good proxy for obtaining rich representations with respect to IR. Both S-BERT and LEGAL-BERT are better than BERT for different reasons. LEGAL-BERT was adapted to the legal domain and is, therefore, able to capture the nuances of the legal language. S-BERT was trained to produce representations suitable for comparing texts with cosine similarity, a task highly related to IR. Nonetheless, having been trained on generic corpora with small texts, it performs much worse than C-BERT. Interestingly, BM_{25} is comparable to both S-BERT and LEGAL-BERT despite its simplicity. As expected, combining C-BERT with BM_{25} further improves the results. In UK2EU R@100 is much higher compared to EU2UK probably because of the shortest queries. Also, as discussed in Section 4.5, the contextual information is not so critical in this dataset, thus we expect the context unaware BM_{25} and W2V-CENT to perform well. Indeed, BM_{25} achieves the best results followed closely by C-BERT and LEGAL-BERT, while W2V-

---

[14] Recall that a text can be represented by its `[cls]` token or by the centroid of its token embeddings which can be extracted from any of the 12 layers of BERT.

Table 5: Re-ranking results across test datasets. The upper zone shows the results of neural re-rankers on top of the best pre-fetchers with respect to (w_s, w_p). It also reports re-ranking results of the best pre-fetchers. The lower zone reports the re-ranking results after applying temporal filtering.

CENT outperforms S-BERT and BERT. Again the ENSEMBLE improves the results.

Re-ranking: Table 5 shows the ranking results on test data for EU2UK and UK2EU. We also report results for BM_{25}, C-BERT, ENSEMBLE and an ORACLE, which re-ranks the top-k documents returned by the pre-fetcher placing all relevant documents at the top. On EU2UK ENSEMBLE performs better than the other two pre-fetchers. Interestingly, neural re-rankers fall short on improving performance and are comparable (or even identical) with ENSEMBLE in most cases, possibly because very similar documents may be relevant or not (Section 2.2, Table 2), leading to *contradicting* supervision.[15] As we hypothesized (Section 3.2), re-rankers overutilize the pre-fetcher score when calculating document relevance, as a defense mechanism (bias) against contradicting supervision, which eventually leads to the degeneration of the re-ranker's term matching mechanism. Inspecting the corresponding weights of the models, we observe that indeed $w_p >> w_s$ across all methods. This effect seems more intense in BERT-based re-rankers (C-BERT + DRMM or PACRR), especially those that fine-tune C-BERT, possibly because these models perform term matching considering sub-word units, instead of full words. In other words, relying on the neural relevance score (s_r) is catastrophic. Similar observations can be made for UK2EU. In both datasets all methods have a large performance gap compared to the ORACLE, indicating that there is still large room for improvement, possibly utilizing information beyond text.

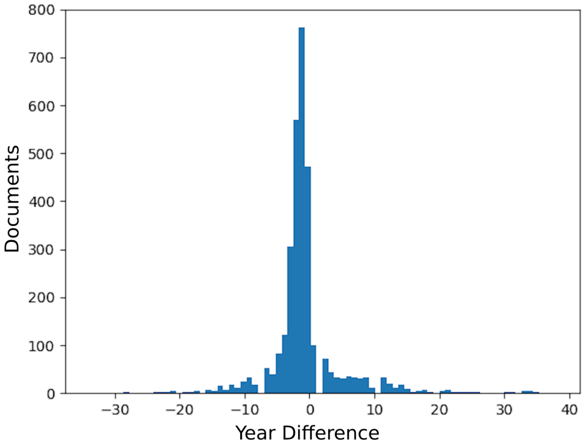

Figure 5: Relevant documents according to their chronological difference with the query on EU2UK development data.

Filtering by year: We have already highlighted the difficulties imposed to our datasets by the frequently amended EU directives (Section 2.2, Table 2). Also, recall that each EU directive defines a deadline (typically 2 years) for the transposition to take place. On the other hand, as we observe in Figure 5, EU directives may already be transposed by earlier legislative acts of member states (the member states act in a proactive manner), or they may delay the transposition for political reasons. In effect, the relevance of a document to a query depends both on the textual content and the time the laws were published. Thus, we filter out documents that are outside a predefined distance

---

[15] By *contradicting* supervision we mean similar training query-document pairs with opposite labels.

(in years) from the query in two ways, *pre-filtering* and *post-filtering*. Pre-filtering is applied to the pre-fetcher, i.e., prior to re-ranking, while post-filtering is applied after the re-ranking. Note that our main goal is to improve re-ranking. We thus apply the filtering scheme to the ENSEMBLE, DRMM and PACRR. The lower zone of Table 5 shows the results of the whole process. In EU2UK, the hardest out of the two datasets, the time filtering has a positive impact, improving the results by a large margin. On the other hand, filtering seems to have a minor effect in UK2EU.

5.1 EU2UK $\neq$ UK2EU

Across experiments, we observe that best practices vary between the EU2UK and UK2EU datasets. EU2UK benefits from C-BERT representations, while in UK2EU context-unaware and domain-agnostic BM_{25} has comparable or better performance than C-BERT. Similarly, we observe that time filtering further improves the performance in EU2UK, while we have a contradicting effect in UK2EU. Given the overall results, we conclude the two datasets have quite different characteristics. Thus, it is important to consider both EU2UK and UK2EU independently, although one may initially consider them to be symmetric.

6 Related work

IR in the legal domain is widely connected with the Competition on Legal Information Extraction/Entailment (COLIEE). From 2015 to 2017 (Kim et al., 2015, 2016; Kano et al., 2017), the task was to retrieve Japanese Civil Code articles given a question, while in COLIEE 2018 and 2019 (Kano et al., 2018; Rabelo et al., 2019), the task was to retrieve supporting cases given a short description of an unseen case. However, the texts of these competitions are small compared to our datasets. Also, most submitted systems do not consider recent advances in IR, i.e, neural ranking models (Guo et al., 2016; Hui et al., 2017; McDonald et al., 2018; MacAvaney et al., 2019), which have recently managed to improve rankings of conventional IR, or end-to-end neural models which have recently been proposed (Fan et al., 2018; Khattab and Zaharia, 2020). Again, these end-to-end methods were applied on small texts. On the other hand, there has been some work trying to cope with larger queries, i.e., *verbose* or expanded queries, (Paik and Oard, 2014; Gupta and Bendersky, 2015; Cummins, 2016). Nonetheless, the considered queries are at most 60 tokens long, contrary to our datasets where, depending on the setting, the average query length is 1.8K or 2.6K tokens (Table 1). Neural methods greatly rely on text representations, thus Reimers and Gurevych (2019) proposed S-BERT which is trained to compare texts for an NLI task and could thus be used to extract representations suitable for IR. Towards the same direction, Chang et al. (2020) experimented with several auxiliary tasks to extract better representations. However, the latter two methods have been evaluated on datasets with much smaller texts than the ones we consider.

7 Conclusions and future work

We proposed DOC2DOC IR, a new family of IR tasks, where the query is an entire document, thus being more challenging than traditional IR. This family of tasks is particularly useful in regulatory compliance, where organizations need to ensure that their controls comply with the existing legislation. In the absence of publicly available DOC2DOC datasets, we compile and release two datasets, containing EU directives and UK laws transposing these directives. Experimenting with conventional (BM_{25}) and neural pre-fetchers we showed that a BERT model fine-tuned on an in-domain classification task, i.e., predict EUROVOC concepts, is by far the best pre-fetcher in our datasets. We also showed that neural re-rankers fail to improve the performance, as their term matching mechanisms degenerates, and over-utilize the pre-fetcher score. In the future, we would like to investigate alternatives in exploiting additional information that may be critical in the newly introduced tasks (EU2UK, UK2EU). In this direction naively utilizing chronological information leads to vast performance improvement in EU2UK dataset. One possible direction is to model the cross-document relations (e.g., amendments) using Graph Convolutional Networks (Kipf and Welling, 2016), while better modeling the dimension of time (i.e., chronological difference between a query and a document) is also crucial. Further on, to better deal with long documents, we plan to investigate text summarization by employing a state-of-the-art neural summarizer, e.g., BART of Lewis et al. (2020), or sentence selection techniques, e.g., rationale extraction (Lei et al., 2016; Chang et al., 2019), to find the most important sections or sentences and create shorter and more informative versions of queries/documents.

A Dataset Compilation: Technical Details

In this section, we present the technical details associated with the compilation of both datasets described in the main paper. More specifically we present the procedure of creating both corpora as well as modelling the transposition relations between EU and UK entries.

A.1 EU corpus

The compilation of the EU corpus is more straightforward than its UK counterpart but involves some in-domain knowledge to filter unwanted legislation.

- We initially download the core metadata associated with each document in the EU corpus by utilizing the SPARQL endpoint of the EU Publications Office (`http://publications.europa.eu/webapi/rdf/sparql`) and the EURLEX platform (`https://eur-lex.europa.eu`), as a REST-ful API.
- Following the metadata collection, we proceed to filter out documents based on their type in order to retain only EU directives and regulations. This involves excluding corrigendums. Corrigendums introduce corrections to prior EU legislation. Usually these corrections are minimal and change single phrases such as ("In Regulation X, for: '… 4 July 2019 …', read: '… 4 July 2015 …'."). Thus these documents lack the context to be both classified and correlated with other documents. [16] and decisions, both of which are irrelevant to our use case. The final EU corpus contains approximately 60k entries.

A.2 UK corpus

Compiling the UK corpus is not as trivial, since the `legislation.gov.uk` API is not as evolved and we therefore have to manually crawl large parts of the database to build our corpus.

- The collected UK laws from the `legislation.gov.uk` portal form the initial corpus which includes approximately 100k documents.
- Similarly to our processing of the EU corpus, we only retain documents in specific legislation types (UK Public General Acts, UK Local Acts, UK Statutory Instruments and UK Ministerial Acts). We then eliminate laws that aim to align English legislation with the rest of the United Kingdom's, more specifically Scotland, Northern Ireland and Wales. The final UK corpus includes 52K UK entries.

A.3 EU2UK Transpositions

Transpositions are relations between entries in the EU and UK corpora which we use to define relevance for our retrieval tasks. Processing these relations is the most challenging aspect of compiling our datasets and involves several steps.

- We use the aforementioned SPARQL endpoint, to retrieve the transpositions between EU directives and the corresponding UK regulations

---

[16] See `https://eur-lex.europa.eu/legal-content/EN/TXT/?qid=1593684165879&uri=CELEX:32004L0038R(02)` as an example.

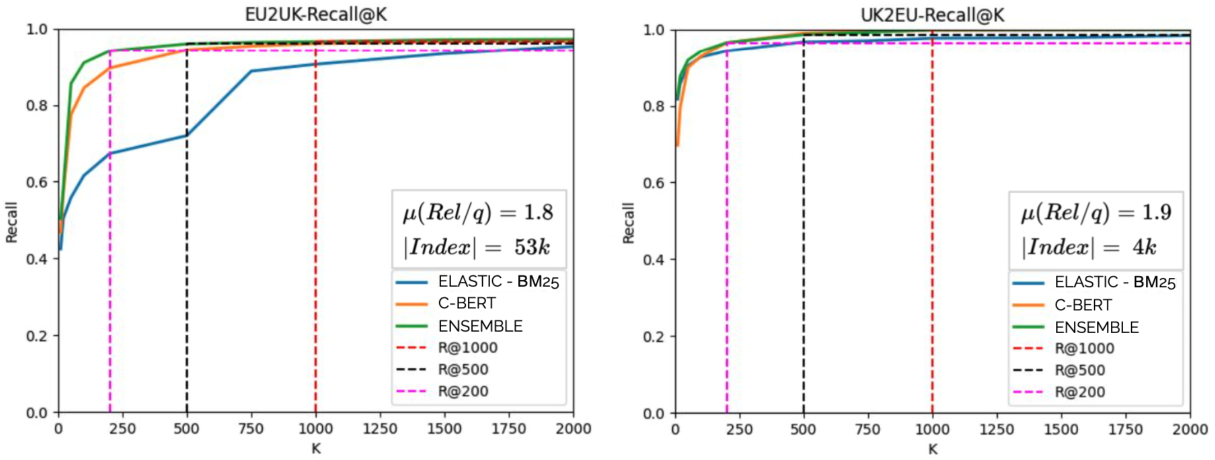

Figure 6: Recall@k, where $k \in [0, 2000]$, across the three best pre-fetchers (i.e., BM$_{25}$, C-BERT and ENSEMBLE) on the development dataset.

that implement them. We initially collect approximately 10k EU2UK pairs. In these pairs the transposed EU law is referred to by its unique portal ID but the transposing UK law is referred to by its title. This is the primary challenge in modelling the transposition relations, since mapping legislation titles to unique entries in our UK corpus is not trivial. We hypothesize that these relations are manually inserted in the database and therefore human errors make performing exact matches often impossible. Apart from the matching difficulties, some of the pairs in the pool are inserted mistakenly and hence need to be filtered.

- We first filter the noisy pairs. Pairs are considered noisy either because they are duplicates or because the do not meet some manually set criteria. In turn, duplication can occur either because identical pairs are inserted more than once or because pairs in which the UK title is mildly paraphrased are erroneously considered different. Our pool is reduced to 8k pairs after resolving the former and to 7k pairs after also resolving the latter. We further reduce the pool size by filtering pairs in which the UK title refers to non-English legislation (Scotland, Northern Ireland, Wales or Gibraltar) Non-English legislation usually has an almost identical counterpart within the pure english corpus. [17]. or in which the title does not contain certain keywords (e.g., Act, Regulation, Order, Rule). Documents that do not contain any of these keywords are not officially published in the `legislation.gov.uk` portal. Most of these are official releases from national governmental bodies, e.g. Ministries. For instance the *First Annual Report of the Inter-Departmental Ministerial Group on Human Trafficking* is not part of the UK's national legislation..
- To resolve the matching challenge, we employ a complex matching scheme where for each pair we gradually normalize the UK title until we find either a singular match or multiple ones. In the latter case, we resolve the matches with heuristics. Our normalizations include lower-casing, leading and trailing phrase removal, punctuation elimination, date removal and manually inserted substitutions.
- After reducing our pair pool and then implementing our matching scheme we can with high confidence present 4k transposition pairs which we use in our datasets.

B BERT models

All BERT variants (BERT, S-BERT, LEGAL-BERT) are publicly available from Hugging Face:

- **BERT**: The original BERT pre-trained for Masked Language Modeling (MLM) and Next Sentence Prediction (NSP) in English Wikipedia and Books corpus. Available at `https://huggingface.co/nlpaueb/bert-base-uncased-eurlex`.
- **S-BERT**: This is the original BERT fine-tuned in STS-B NLI dataset. Available at `https://`

---

[17] See `https://www.legislation.gov.uk/uksi/2017/407/contents` and `https://www.legislation.gov.uk/nisr/2017/81/contents`

`huggingface.co/deepset/sentence_bert`.

- **LEGAL-BERT (EURLEX)**: This is the original BERT further pre-trained in EU legislaiton. Available at `https://huggingface.co/nlpaueb/bert-base-uncased-eurlex`.

C Selecting k for pre-fetching

In Section 4.1, we stated that we report $\mathrm{R@k}$ with $\mathrm{k} = 100$ in order to evaluate and compare pre-fetching methods. In Figure 6, we present the performance of the best pre-fetching methods (i.e., BM25, C-BERT and ENSEMBLE) for different values of $k \in [0, 2000]$ on the development set. We observe that after $k = 100$, the ENSEMBLE pre-fetcher has not significant gains in performance, thus we select $k = 100$, as a reasonable threshold.

The Chinese Remainder Theorem for Compact, Task-Precise, Efficient and Secure Word Embeddings

`gpenn@cs.toronto.edu`

Abstract

The growing availability of powerful mobile devices and other edge devices, together with increasing regulatory and security concerns about the exchange of personal information across networks of these devices has challenged the Computational Linguistics community to develop methods that are at once fast, space-efficient, accurate and amenable to secure encoding schemes such as homomorphic encryption. Inspired by recent work that restricts floating point precision to speed up neural network training in hardware-based SIMD, we have developed a method for compressing word vector embeddings into integers using the Chinese Reminder Theorem that speeds up addition by up to 48.27% and at the same time compresses GloVe word embedding libraries by up to 25.86%. We explore the practicality of this simple approach by investigating the trade-off between precision and performance in two NLP tasks: compositional semantic relatedness and opinion target sentiment classification. We find that in both tasks, lowering floating point number precision results in negligible changes to performance.

1 Introduction

In recent years, NLP models, particularly language models, have come under increasing scrutiny for their potential privacy leaks (e.g., Carlini et al. (2018)). One answer has been to push NLP models onto edge devices, such as mobile phones and browsers, for on-device inference using differentially private federated learning (e.g., Yang et al. (2018)). Edge computing, in turn, requires smaller and faster models, such as DistillBERT (Sanh et al., 2019) or mobileBERT (Sun et al., 2020), which theoretically improves the viability of using BERT embeddings on these devices.

What has yet to take place, however, is careful numerical analysis of word embeddings at varying precisions for different NLP tasks. Numerical analysis can inform potential alternatives to defining the representations of word embeddings themselves. We must carefully orchestrate a balance among the size of these representations, their security, the algebra of operations that they enable, and, because many edge devices are resource-restricted relative to the GPU clusters that we do research on, the efficiency and power consumption of those operations. In particular, feature/basic phones are growing in popularity in developing nations[1][2], often with the possibility of expanding their memory to about 16GB with a MicroSD. Many privacy-enabled language models, in particular, are simply out of reach for these low-resource devices.

No work to date has proposed using the Chinese Remainder Theorem (CRT) to create software-based compressed word embeddings, adapted to Single Instruction Multiple Data (SIMD). We propose here a CRT-based method which speeds up addition by up to 48.27% and compresses GloVe (Pennington et al., 2014) word embedding libraries by up to 25.86% (up to 68.68% of the original full-precision library), depending on the precision selected. We also explore different levels of numerical precisions for a representative task, as well as more abstractly by analysing the absolute error resulting from adding and multiplying truncated and rounded values.

Related Work. A number of recent papers have explored limiting input precision in order to speed up neural network training and inference. Zhang et al. (2018) and Ling et al. (2016) specifically

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3512–3521
April 19 - 23, 2021.

looked at the effects of limiting word embedding precision. Zhang et al. (2018) evaluate embeddings of different sizes combined with hardware-implemented SIMD for an adaptation of stochastic gradient descent that achieves a memory improvement of 2X and 1.2X faster training speed. Ling et al. (2016) demonstrate that using word embeddings made up of 8-bit fixed-point values performs just as well as other embeddings on word similarity, phrase similarity, and dependency parsing tasks. Tissier et al. (2019), on the other hand, has shown how to generate binary word embeddings that fit within a CPU's cache to increase computing speed. With limited effect on task accuracy, they manage to generate 256-bit embeddings which are 37.5× smaller than traditional 300-dimensional word embeddings.

While we have demonstrated that CRT can be used to increase the efficiency of word vector addition by transforming a vector into a single large number, it is usually used for the opposite purpose: to transform larger numbers into many smaller numbers to improve multiplication efficiency. For this purpose, CRT is integrated in certain homomorphic encryption libraries.

CRT has also been proposed as a method of encrypting multiple entries in a database (e.g., a_i) as one number, each decryptable by a secret modulus (e.g., m_i) (Yan, 2002). The security of such schemes are shaky and more complexity is usually added to guarantee security (Liu et al., 2014; Lin et al., 1992).

2 Background

2.1 Single Instruction Multiple Data

Single Instruction Multiple Data is a computer architecture classification described in Flynn (1966) as a single instruction acting simultaneously on multiple operands. Flynn (1966) points out that performance increases with the number of units. Prior to Flynn (1966), SIMD was discussed in Unger (1958); Slotnick et al. (1963); Crane and Githens (1965); Hellerman (1966). More recently, the Chinese Remainder Theorem was proposed as a method for attaining SIMD in order to optimize arithmetic for homomorphically encrypted values (Gentry et al., 2012; Smart and Vercauteren, 2014). We do not know of work that takes advantage of CRT-based SIMD for NLP, despite the repetitive tasks performed within certain algorithms.

2.2 Chinese Remainder Theorem

Theorem 2.1 (The Chinese Remainder Theorem)**.** *Let $m_1, m_2, ..., m_r$ be pairwise relatively prime positive integers. Then the system of congruences*

$$X \equiv a_1 (\text{mod } m_1)$$

$$X \equiv a_2 (\text{mod } m_2)$$

$$\dots$$

$$X \equiv a_r (\text{mod } m_r)$$

has a unique solution modulo $M = m_1 m_2 ... m_3$. (Rosen, 2000)

We use $\mathbf{a}$ to denote the vector of values $a_1, a_2, ..., a_r$ and $\mathbf{m}$ to denote the vector $m_1, m_2, ..., m_r$.

The Chinese Remainder Theorem can also be used to separate very large numbers into smaller chunks on which, in certain cases, arithmetic operations can be performed more efficiently (Rosen, 2000).

3 Algorithm: Vec2int

First, we must determine a minimum floating point precision (ϕ) the values within our word embeddings must have. Since the CRT only works with positive integers (and polynomials), we will multiply each value in the word embeddings (a_i) by 10^ϕ and truncate (or round) the result, then add the lowest possible integer value that can be found within our word embeddings (s). Before running the CRT algorithm, we must pre-compute a vector $\mathbf{m}$ of moduli, each of which are coprime and strictly greater than any possible value of a_i. $\mathbf{a}$ and $\mathbf{m}$ can then be input into the CRT algorithm in order to produce an integer X. Since we know the values of $\mathbf{m}$, we can easily perform a "reverse CRT" by calculating $a_i \leftarrow X \pmod{m_i}$.

Algorithm 1 Vector To Integer

```
procedure VEC2INT($\mathbf{a}, \phi, \mathbf{m}, s$)
    for $i \leftarrow 1$ to $r$ do
        $a_i \leftarrow \text{truncate}(a_i * 10^\phi) + s$
    end for
    $X \leftarrow \text{CRT}(\mathbf{a}, \mathbf{m})$
    return $X$
end procedure
```

When two CRT-encoded vectors (say X_1 and X_2) are added together, their sum at index i can still be decoded by calculating $(X_1 + X_2)$ (mod

m_i), provided that either $X_1 + X_2 < m_i$, or $(X_1 + X_2) \pmod{2m_i}$, when $X_1 + X_2 \geq m_i$. The same property holds for multiplication; i.e., $(X_1 * X_2) \pmod{(m_i)^2}$, when $X_1 * X_2 \geq m_i$. In other words, this representation supports vector addition, multiplication and, in a more restricted range, subtraction, through executing those operations directly on integers.

Addition and multiplication are fundamental to most compositional semantics approaches, beginning with Mitchell and Lapata (2008, 2010). Addition is also central to measuring the relationship between word pairs, particularly when using the L1-norm as a metric, which is less sensitive to outliers than the L2-norm (Stratos, 2017). Word analogy is an example of such a task. Of course, the these operations can also be applied to measuring the relationship between sentence pairs and document pairs.

4 Reasoning about Precision using Numerical Analysis

One might assume that we have to perform extensive empirical analysis to determine the minimum floating point precision necessary for the inputs of a particular NLP algorithm. However, there are generalizations we can make based on concepts as simple as the absolute error and relative error of components of the operations, described in Heath (2018) as:

$$\text{Absolute error} = \text{approx. value} - \text{true value} \quad (1)$$

$$\text{Relative error} = \frac{\text{absolute error}}{\text{true value}} \quad (2)$$

For our operations, the vectors truncated or rounded at precision Φ within a dataset $|D_\Phi|$ are denoted $\mathbf{v_{\Phi i}}$, while the vectors of the original dataset are denoted $\mathbf{v_i}$. If we want to refer to index k of vector $\mathbf{v_i}$, we write it as $\mathbf{v_i}[k]$, where $|\mathbf{v_1}|$ is the size of the embeddings we are working with. The average absolute error between the vectors of the two datasets of size $|D|$ is computed as follows:

$$\frac{\sum_i \sum_k |\mathbf{v_{\Phi i}}[k] - \mathbf{v_i}[k]|}{|D| * |\mathbf{v_1}|} \quad (3)$$

We calculate the average absolute error of addition as follows:

$$\frac{\sum_i \sum_j \sum_k |(\mathbf{v_{\Phi i}}[k] + \mathbf{v_{\Phi j}}[k]) - (\mathbf{v_i}[k] + \mathbf{v_j}[k])|}{\binom{|D|}{2} * |\mathbf{v_1}|} \quad (4)$$

5 Experimentation & Analysis

5.1 Arithmetic

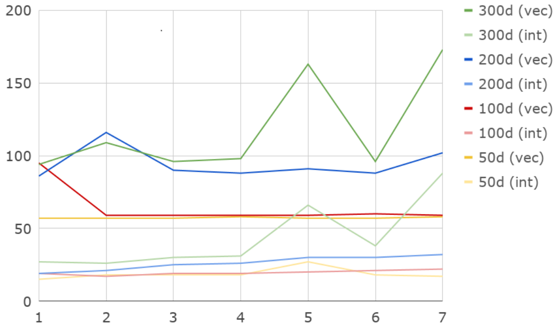

Figure 1: Milliseconds (y-axis) it takes to run 100000 element-wise additions over vectors of (*d) dimensions at ϕ precision (x-axis).

We have tested the efficiency of adding and multiplying integer representations of word embeddings compared to adding and multiplying their original vectors. On a 1.9GHz Intel i7-8650U with a 2.11 GHz burst rate, 1024MB L2 cache and 8192MB L3 cache, 100K additions (Figure 1) generally take 3x longer to perform on vectors than their integer encodings, regardless of precision and dimensionality, while the results for multiplication (Figure 2) are profound and negative at larger precisions and dimensionalities.

We may then theoretically expect the CRT-encoding of vectors as integers to result in a significant performance gain in the case of addition, but for the most part a significant performance loss in the case of multiplication. Nevertheless, in comparing the various pairs of rows in Tables 1 and 2, we notice that the computational gains made from adding CRT representations rather than word vec-

tors can considerably outweigh the losses from multiplying integer representations when the number of additions is greater or equal to the number of multiplications. In practice, as illustrated in several use cases below, the number of additions can be far greater in many important tasks. Recall also the findings of Ling et al. (2016), who did not observe a significant decrease in performance when using an 8-bit fixed-point value for word embeddings in word and phrase similarity and dependency parsing tasks. This implies that there is some room for compromise on precision practical NLP tasks as well.

5.2 Use Case 1: Compositional Semantics

A prime example of the significant performance improvements brought on by integer addition of word embeddings in the area of compositional semantics can be found in Salton and McGill (1986). It was demonstrated that vector addition is more effective than other proposed unsupervised compositional models (multiplication (Mitchell and Lapata, 2010), tensor product with convolution (Widdows and Ferraro, 2008), and dilation (Mitchell and Lapata, 2010)) for determining semantic relatedness between bigrams and other bigrams or unigrams (Asaadi et al., 2019).

Dataset and previous results. In Asaadi et al. (2019), the authors introduce BIRD, a bigram relatedness dataset created using the Best-Worst Scaling annotation method. To accomplish this task, annotators are provided with n sample, where n is often 4, and are asked which of the samples best represent the a given property and which one represents it the worst (Kiritchenko and Mohammad, 2016, 2017). Asaadi et al. (2019) compute bigram semantic relatedness using three different kinds of word embeddings; namely, pre-trained GloVe vectors[3], pre-trained fastText word embeddings[4], and word-context co-occurrence vectors extracted from a corpus of university websites (Turney et al., 2011)[5]. Specifically, the authors compute the relatedness score for the vectors representing the term pair AB-X, where AB is a bigram and X can be either a bigram or a unigram. The results of four unsupervised compositional models were compared:

- Weighted addition (Salton and McGill, 1986);
- Multiplication (Mitchell and Lapata, 2010);
- Tensor product with convolution (Widdows and Ferraro, 2008);
- Dilation (Mitchell and Lapata, 2010).

They then used Pearson correlation to compare the semantic relatedness scores, computed using these unsupervised compositional models, with the gold-standard in the BiRD. Addition turns out to be the composition method that results in the highest Pearson correlation scores.

Integrating vec2int The task introduced by Asaadi et al. (2019) is a prime candidate for using vec2int to speed up computations and reduce space: vast numbers of additions need to be performed in order to compute bigram relatedness in large datasets. These datasets often occupy a large amount of space and would also benefit from a compression method that can support addition in the compressed domain. The catch is that, in

[5] Code and data can be found at: `https://github.com/sasaadi/BiRD`

order to convert from a vector to an integer, we must limit the precision of each of the entries of the vector. Clearly, this can lead to concerns regarding the levels of accuracy that can be guaranteed by functions taking these precision-limited vectors as inputs. For our calculations, we forego any comparisons with floating point precision below 8 digits (other than the original number of digits[6]), since we want to maximize computational efficiency and minimize storage size. Recall that ϕ is the number of digits we keep after the decimal point.

Figure 3 and Figure 4 display the effects of truncating and rounding floating point numbers at various precisions then converting them to integers for determining bigram relatedness through the composition of fastText and GloVe vectors, respectively[7]. Interestingly, even sticking to a floating point precision of 1 or 2 can lead to results which are just as good as with the original precision.

Figure 5 shows the average absolute error (see Equation 3) and Figure 6, the average relative error (see Equation 4), for each possible sum of two vectors within the term context, fastText, and GloVe datasets. We can see that an increase in average absolute and relative errors lines up with the decrease in correlation score, and so we can determine at which point bigram relatedness would start to falter without computing Pearson or Spearman correlations. In fact, it appears to suffice only to calculate the average (Figure 9) and relative (Figure 10) errors of the truncated and rounded word vectors themselves (see Equations 1 and 2, respectively).

For interest, we show the average absolute error (Figure 7) and average relative error (Figure 8) for composition through multiplying fastText vectors at various precisions. fastText exhibits the most dramatic difference in performance between composition by addition and composition by multiplication at lower precisions.

5.3 Compression

We test the utility of the CRT as a method of compressing word embeddings. The results are shown in Table 3, reaching up to a 25.85% space reduction for GloVe vectors. We also calculate an upper bound of how large a dataset of word embeddings can get when compressed using CRT representations using the same relative primes $\mathbf{m}$ as the ones used to calculate the results displayed on Tables 3. Calculating the upper bound essentially comes down to associating each word in the dataset to the largest possible number N given $\mathbf{m}$:

$$N = \prod_i m_i \tag{5}$$

To demonstrate that, no matter what the vectors were the compression would work, we show the upper bounds compared to the size of the original dataset of 50-dimensional GloVe embeddings and the true CRT-compressed dataset of those embeddings on Table 4.

5.4 Use Case 2: Data Preprocessing for Private and Secure Computing

Another potential use case is if one wants to convert a text to its corresponding word embeddings directly on device, before being sent for cloud processing through homomorphic encryption or secure multiparty computation algorithms, which compute on precision-limited obfuscated data.

Arora et al. (2020) shows that pre-trained embeddings perform within 5-10% accuracy of benchmark tasks (NER, Sentiment analysis, GLUE) compared to contextual embeddings (e.g., BERT) and can even regularly match their performance when using industrial-level data.

Directly converting the words to their respective word embeddings on device is particularly useful for those algorithms, where table lookup over large amounts of data can be a fairly expensive operation. Not only can CRT representations compress the word embeddings to save valuable space on edge devices, but they can be selectively decompressed, unlike zip files, as needed. If you want to only convert the words in a user query to embeddings, there is no need to decompress the entire dataset!

We compare the results of CNN-based sentence-level sentiment analysis using GloVe vectors as input (Kim, 2014)[8] with those using

---

[6] The largest precision within the term context vector is $\phi = 20$, within fastText is $\phi = 12$, and within GloVe is $\phi = 8$.

[7] We would like to thank Shima Asaadi, Saif M. Mohammad, and Svetlana Kiritchenko for providing the code and data they used for the their Big BiRD paper. The correlation scores for term context vectors are nearly the same as those for GloVe at untruncated precision, but remain stable down to $\phi = 2$.

Table 5: Performance when varying the precision Φ of input GloVe embeddings to sentence-level sentiment analysis using a CNN.

BERT. Kim (2014) is the same work that Arora et al. (2020) used to compare with BERT over 6 different datasets. Of those datasets, we choose to analyze the variation in performance on the MR dataset (movie reviews – one sentence per review) Pang and Lee (2005) and on the opinion polarity detection subtask of the MPQA dataset (Wiebe et al., 2005).

In addition to comparing BERT-based sentiment analysis results with CNNs that take full-precision 300-dimensional GloVe vectors as inputs (which Arora et al. (2020) does), we verify the feasibility of this use case, by conducting experiments with varying precisions of 50-dimensional and 300-dimensional GloVe embeddings. Table 5 shows that sentence-based sentiment analysis with GloVe embeddings remains almost unchanged even at $\Phi = 1$ on the MR dataset, on which Arora et al. (2020) shows that BERT outperforms CNNs by 6.9. BERT therefore outperforms the CNN with 50d GloVe embeddings at precision $\phi = 1$ (which achieves a performance of 77.3) by 8.9. However, GloVe often matches BERT in this task when the BERT embeddings are trained on 16 times less data. Arora et al. (2020) also show that BERT outperforms GloVe on the MPQA dataset by a measly 0.9. We determine that BERT outperforms the CNN with 50d GloVe embeddings at precision $\phi = 1$ (which achieves a performance of 88.46) by only 1.14.

As is mentioned in Arora et al. (2020), it takes "440MB to store BERT$_{\text{BASE}}$ parameters, and on the order of 5-10 GB to store activations[, while p]retrained non-contextual embeddings (e.g., GloVe) require $O(nd)$ to store a n-by-d e-bedding matrix (e.g., 480 MB to store a 400k by 300 GloVe embedding matrix)." Our method manages to reduce this embedding matrix size by 25%. MobileBERT uncased, which is made up of 23.21% of the number of parameters of BERT$_{\text{BASE}}$, ends up with a storage size of 139 MB (compare with 421 MB for BERT$_{\text{BASE}}$ uncased). That resource-constrained model is still 2.62x larger than our 53.66MB compressed GloVe embedding matrix, and without the benefit of our significant performance gain. Indeed it is difficult to imagine how a method that manipulates 512-bit vectors could compete with adding integers. MobileBERT's performance scores are within a couple of percentage points from those of BERT$_{\text{BASE}}$.

6 Discussion and Future Work

These preliminary results suggest that the vec2int algorithm would be an efficient way of encoding word vectors for specific NLP tasks, namely those which would benefit from arithmetic-supporting vector compression (which `tar` and `zip` are not). They also suggest that analysis of average relative and absolute error can be used to tune these representations. We have yet to test the effectiveness of using integer representations of word2vec (Mikolov et al., 2013) and BERT (Devlin et al., 2018), but expect the outcomes to be similar to the results for term context vectors, fastText, and GloVe. It would also be particularly interesting to see what kind of performance improvements can be obtained by applying the CRT to sentence- as well as document-level embeddings.

Relevant to privacy concerns, some constraints on homomorphic encryption schemes include limiting the number of possible multiplications and also limiting the precision of the values being computed upon. The same sort of numerical precision analysis and computational limitations that we have done in this paper can inform how we as

---

`sentence`

NLP scientists think of how our methods are integrable into certain privacy technology. Average relative and absolute error might be useful for creating better encrypted NLP algorithms using homomorphic encryption, since many homomorphic encryption schemes tend to require integer inputs or limited-precision inputs.

Abstract

In the paraphrase generation task, source sentences often contain phrases that should not be altered. Which phrases, however, can be context dependent and can vary by application. Our solution to this challenge is to provide the user with explicit tags that can be placed around any arbitrary segment of text to mean "don't change me!" when generating a paraphrase; the model learns to explicitly copy these phrases to the output. The contribution of this work is a novel data generation technique using distant supervision that allows us to start with a pretrained sequence-to-sequence model and fine-tune a paraphrase generator that exhibits this behavior, allowing user-controllable paraphrase generation. Additionally, we modify the loss during fine-tuning to explicitly encourage diversity in model output. Our technique is language agnostic, and we report experiments in English and Chinese.

1 Introduction

Notions of semantic similarity and paraphrase are highly context dependent. Consider "I'm looking for cheap hotels in New York." vs. "What are cheap lodging options in Beijing?": from the perspective of intent classification, both express similar intents, but from the perspective of paraphrasing in a community QA application, a user looking for the answer to one question would not find the other response helpful. This is because the location "New York" anchors the information need, and any changes to it would be unacceptable to the user.

It is not always the case that named entities are "immutable" in this respect: consider a user looking for vacation destinations in the South of France. From the perspective of an advertiser, there might be good reason to tempt the user with alternative locations such as the Italian Riviera; the user may even welcome these suggestions. Also, it is not always the case that these immutable anchors are named entities: For example, some metrics assign high similarity to antonyms, and so "cheap hotels" and "expensive hotels" might be considered semantically close, but obviously not from the perspective of an end user looking for inexpensive lodging.

Although whether or not certain words can be changed without affecting the meaning of a sentence is highly dependent on context, the user of a paraphrase generation system usually would know. Consider the application of paraphrase generation in a community QA application, where a developer wishes to automatically generate question variants to increase the chances of a semantic match: A naïve system will indeed generate "What are cheap lodging options in Beijing?" as a paraphrase to "I'm looking for cheap hotels in New York."

What if we provide the user with a way to explicitly tag portions of the input so that a paraphrase generator knows what parts of the input to repeat verbatim? For example, a simple annotation scheme like "What are cheap lodging options in $\langle$tag$\rangle$ Beijing $\langle$/tag$\rangle$?", where words between $\langle$tag$\rangle$ and $\langle$/tag$\rangle$ should *not* be paraphrased. We present a paraphrase generator that implements such tags, allowing user-controllable paraphrase generation.

On a standard sequence-to-sequence model (mBART), our contribution is a novel data generation technique via distant supervision to fine-tune a paraphrase generator that supports this tagging behavior. To our knowledge, we are the first to describe such a capability—this solves a practical problem that hinders deployment of models in real-world applications.[1] Our technique is entirely language agnostic, and we report experiments in both English and Chinese. Additionally, we modify the loss during fine-tuning to explicitly encourage diversity in the paraphrase generation process.

---

[1] This is a feature requested by many of our customers.

2 Paraphrase Generator

We treat paraphrase generation as a standard supervised sequence-to-sequence task by fine-tuning mBART-large (Liu et al., 2020). Although our technique can be applied to any sequence-to-sequence framework, we selected mBART because a multilingual model is widely available. Following standard practice, custom language tags are used to denote the desired behavior of the model, but otherwise everything in our model is language agnostic.

Building on our running example, a training pair might be ("What are cheap lodging options in ⟨tag⟩ Beijing ⟨/tag⟩?", "I'm looking for cheap hotels in ⟨tag⟩ Beijing ⟨/tag⟩?"). Multiple such corpora exists (without these tags), and this is a straightforward use of mBART, but the challenge is this: Starting with an existing paraphrase dataset, how do we know where the tags should go? At inference time, the user supplies the tags, but during training, such knowledge is not available. Obviously, we could go through and manually insert tags to existing paraphrase datasets, but such large annotation efforts are impractical. Instead, we adopt a solution based on distant supervision by building three different taggers, discussed below.

2.1 Taggers

The **Oracle Tagger** represents an upper bound: tags are assigned to surround consecutive word sequences that appear in both the source and multiple references. Our intuition is that tags should go around exactly the portions of text that do not change across the paraphrases. Here, we heuristically filter out stopwords and other common n-grams. However, the Oracle Tagger won't work on datasets like QQP, where each sentence only has one reference. The two similar sentences are going to largely overlap with each other, so the Oracle Tagger will almost tag the entire sentence, which cannot be regarded as the anchors. For datasets like MSCOCO, since there are multiple references, the overlapping substrings are only a few words long therefore we can treat them as anchors.

With the **NER Tagger**, we simply tag all NERs. Since we aim to generate paraphrases in multiple languages, we use the ID-CNN language-independent named entity recognizer (Strubell et al., 2017). With the **Auto Tagger**, we use the output of the oracle tags to train a standard BERT-based (Devlin et al., 2019) token classifier.

2.2 Encouraging Diversity

During fine-tuning, our paraphrase generator learns to keep the content between ⟨tag⟩ and ⟨/tag⟩ tokens—provided by one of the three taggers above—since the content inside are not changed from a source to its reference output. We want our model to be able to keep the anchors (that are tagged) but paraphrase the other parts as much as possible.

To accomplish this, in addition to the original mBART architecture, we add another loss term to encourage diversity in generated paraphrases. During fine-tuning, we also minimize the mutual information between our paraphrase distribution and the source sentence. The mutual information term is controlled by a hyperparameter weight, indicating how "different and diverse" we want our paraphrases to be compared to the source sentence. By default, this weight is set to 0.3.

To be more specific, let $|\mathcal{D}|$ be the number of tokens in our dictionary, ϵ be the weight of label smoothing, w be the weight of the entropy term in our mutual information evaluated with source sentences. Note that a larger w means the more diversity we are encouraging our paraphrases to be. Let B be the batch size, $p(t|s_i)$ be the ground truth one-hot token probability distribution of reference sentences given a source sentence s_i where $i \in \{1, 2, ..., B\}$, and let $q_\theta(t|s_i)$ be the model predicted token probability distribution given a source sentence s_i for a fixed set of parameters θ. Our loss function can be written as:

$$\begin{aligned}\mathcal{L} =&(1-\epsilon)[-\sum_i p(\mathbf{t}|\mathbf{s_i}) \log \mathbf{q}_\theta(\mathbf{t}|\mathbf{s_i})]\\ &+\sum_i [-\frac{\epsilon}{|\mathcal{D}|} \log q_\theta(\mathbf{t}|\mathbf{s_i})]\\ &-w[-\sum_i p(\mathbf{t} == \mathbf{s_i}) \log \mathbf{q}_\theta(\mathbf{t}|\mathbf{s_i})]\end{aligned} \qquad (1)$$

where $p(\mathbf{t} == \mathbf{s_i})$ can also be viewed as a vector of results of an indicator function; the value of such a vector is one at the jth location if and only if for a source sentence s_i with length J, t_j and $s_{i,j}$ are of the same token for $j \in 1, 2, ..., J$.

3 Experimental Setup

We describe the data we used for experiments and the basic setup. At a high level, we have two types of datasets, with or without paraphrase clusters (sentences with the same meaning) to evaluate our tagging behavior and model output diversity improvement. Three English paraphrase cluster datasets were utilized, but no Chinese cluster datasets since we did not find such a dataset to be available. One English and one Chinese paraphrase pair dataset were used. Some of the datasets are widely used in paraphrase generation tasks, the others are adopted from other natural language tasks. Below we briefly describe each dataset:

MS COCO Captions 2017 (MSCOCO) (Chen et al., 2015) is an English dataset designed for automatic image caption generation. Five human-written caption descriptions were collected for each image. The total number of images is about 118k with 590k captions.

Parabank (Hu et al., 2019) is an English sentence re-writing dataset. We took its eval dataset (ParabankEval), which contains 400 semantic paraphrase with an average of 14 paraphrases in each cluster.

ComQA is an English dataset of real user questions from the WikiAnswers community QA platform. The questions are grouped into paraphrase clusters, of which 1,809 clusters have more than one question.

Quora Question Pairs (QQP) contain human-annotated duplicate English questions, with 50k training paraphrase pairs and 20k testing instances.

ATEC is a Chinese dataset that comes from Ant Technology Exploration Conference Developer competition. It contains 14,946 financial question pairs that are semantically similar.

For MSCOCO, ParabankEval, and ComQA, we randomly picked one sentence from each cluster as the paraphrase source sentence and the rest as the ground-truth references. For the other datasets, we pick one sentence as the source and the other one as the reference. We divided all datasets with 80% in the training set and 20% in the test set.

4 Results

As a preface to our results, we emphasize that, to our knowledge, user-controllable paraphrasing in the manner that we have described is a novel capability. That is, no previous work has addressed this problem—and thus, points of comparison are limited. Further note that the point of our technique is *not* to establish state-of-the-art performance on these various datasets, but rather to illustrate our tagging feature. Nevertheless, it is worth noticing that our model outperforms the previous state-of-the-art paraphrase generation model (Fu et al., 2019) on MSCOCO and QQP datasets in terms of ROUGE scores. We only present the results of ROUGE 2-gram scores for brevity, but the results of other ROUGE scores are consistent.

We choose ROUGE (Lin, 2004) instead of BLEU (Papineni et al., 2002) as our evaluation metrics for both tagger performance and diversity evaluation because of the diversity loss that we introduced. In an ideal dataset, the references of a source sentence should be able to cover all possible paraphrases. In this case, precision-based metrics like BLEU should be an even more suitable evaluation metric of generated paraphrases. However, the datasets we experimented on only contain a handful of references, far from covering all possibilities. The substituted words and diversified descriptions encouraged by our minimized mutual information will all be false negatives since they are not covered by the reference, thus leading to low precision.

4.1 Tagger Performance

Experimental results and descriptions are shown in Table 1. Compared to 118k semantic clusters in MSCOCO, ComQA and ParabankEval contain only 400 and 1809 clusters, respectively. Therefore, only MSCOCO has enough data to train a BERT-based token classifier as its Auto Tagger, while ComQA and ParabankEval's Auto Tagger results are gibberish.

How should we read the results in Table 1? We need to consider the "R" row and the "R vs. S" row together. The values in the "R" row are 2-gram ROUGE scores; the higher the score, the more similar our generated paraphrase is to the reference sentences, and therefore the "R" score means how good our paraphrases are—in other words, *quality*. The values in the "R vs. S" row are 2-gram ROUGE scores of the generated paraphrase with respect to the source; the higher the score, the more similar our generated paraphrase is to the source sentence—in other words, *diversity*. We desire both high quality and high diversity, in other words, a high "R" score and a low "R vs. S" score, but this is dataset dependent: if the references are similar to the sources (like in ParabankEval), both "R" scores and "R vs. S" scores will inevitably be high; if the references are very different from the sources (like in the MSCOCO caption dataset), both "R" scores and "R vs. S" scores will tend to be low.

Dataset	MSCOCO				ComQA			ParabankEval			QQP		ATEC	
Tagger	No Tag	Auto	NER	Oracle	No Tag	NER	Oracle	No Tag	NER	Oracle	No Tag	NER	No Tag	NER
R	20.6	30.7	28.8	22.8	38.0	42.2	47.1	30.4	77.4	79.9	35.2	38.3	35.2	36.3
R vs. S	39.5	34.6	30.5	27.9	69.5	49.4	52.4	41.5	81.5	85.8	57.5	51.3	85.4	83.3
T%		99.7	99.3	99.9		91.3	92.7		99.1	100		80.2		96.1

Table 1: Experiment results. Reading horizontally, the Tagger columns show the tagger (Auto Tagger, NER Tagger, Oracle Tagger, or no tagger) used during training for each dataset. Note that the Oracle Tagger is a realistic condition in this context because in a deployed application, the correct tags would be supplied by a human. The first row ("R") refers to the result of 2-gram ROUGE scores of the generated paraphrases against references; this measures the *quality* of the paraphrases. The second row ("R vs. S") refers to the 2-gram ROUGE scores of generated paraphrases against the source sentence; this measures the *diversity* of the paraphrases. In other words, the lower this value, the more diverse the paraphrases are. It is important to present both figures because paraphrase generation requires a balance between these two factors. The final row ("T%") shows the percentage of tagged substrings that remain unchanged during paraphrase generation; this demonstrates how well our model learns to preserve the content surrounded by tags. We can see that our tagging technique achieves the intended effect after fine-tuning.

Why don't we use BLEU (Papineni et al., 2002) score instead? Consider again generating paraphrases for our running example: "What are cheap lodging options in ⟨tag⟩ Beijing ⟨/tag⟩?" We want our generated paraphrases to retain "Beijing" and change other parts of the sentence as much as possible (but preserving the semantic meaning). Let's suppose we have ground-truth references that contain all possible paraphrases. If so, the paraphrase "I'm visiting Beijing and trying to find cheap hotels." will have a perfect "R" score and also a 0 "R vs. S" score (since it does not have any 2-gram overlaps with the source sentence); this will be the case with either ROUGE or BLEU. For paraphrases like "I'm visiting New York and trying to find cheap hotels." or "I'm visiting Beijing and trying to find the Great Wall.", the "R" score will be lower. A paraphrase like "What are cheap hotels in Beijing?" will have a higher "R vs. S" score (lower diversity). These are exactly the behaviors we desire.

More realistically, though, our references only contain a handful of paraphrases. For example, what if the term "cheap hotels" never appears in our references? Then, even though we know that "cheap hotels" is a valid paraphrase of "cheap lodging options", the related 2-grams like "cheap hotels" and "hotels in" will all be false negatives. In this case, recall-based metrics like ROUGE will be more robust than precision-based metrics like BLEU. Moreover, since we introduced the mutual information loss term to force our model to change the untagged parts of a sentence, it is likely that our model will generate correct paraphrases containing terms that are not covered by the references, and those false negatives will result in artificially (and unfair) lower BLEU scores. For this reason, we argue that ROUGE is the more appropriate metric in our study.

For three out of four English datasets, our proposed tagging approach yields not only better paraphrases (in terms of matching the reference) but more diverse paraphrases as well. ATEC also yields similar behavior with the NER tagger. However, ParabankEval seems to be an outlier here: the quality of the paraphrases increases dramatically (over double the score), although the generated output is far less diverse. This is understandable since ParabankEval only has 400 semantic clusters in total and the sentences are usually two to three times longer than MSCOCO; the paraphrase generator did not see enough examples to generate diversified long paraphrases.

4.2 Cross-Lingual Transfer

Ideally, we desire a model with strong cross-lingual capabilities—for example, along the lines of previous work in tagging tasks (Wu and Dredze, 2019) and information retrieval (Shi et al., 2020). From a practical perspective, such capabilities can reduce the need for language-specific paraphrase training data. From a scientific perspective, such explorations might help reveal language-agnostic "universals" for semantics. In this section, we present two experiments that anecdotally provide some interesting observations.

In our first experiment, we fine-tuned the model only with Chinese sentence pairs. During evaluation, we feed it English sentences and ask it to generate English paraphrases. We do not provide a formal evaluation, but it appears that our model is able to generate English paraphrases fluently, including the ability to preserve tagged substrings. For example, paraphrases of the input "How do you get deleted ⟨tag⟩ Instagram ⟨/tag⟩ chats?" include the following:

> How do I get deleted ⟨tag⟩ Instagram ⟨/tag⟩ messages?
> How do I recover deleted ⟨tag⟩ Instagram ⟨/tag⟩ messages?
> How do you get deleted ⟨tag⟩ Instagram ⟨/tag⟩ messages?
> How do I get deleted ⟨tag⟩ Instagram ⟨/tag⟩ posts?

In the second experiment, we fine-tuned our model with English sentence pairs, and then feed it Chinese sentences and ask for Chinese paraphrases. In this case, the model generates a mix of English and Chinese tokens, but, interestingly, the code switching occurs in a semantically coherent manner. For example, paraphrases of sentence "吃什么东西能⟨tag⟩补肾⟨/tag⟩呀?" (translation, "What foods can fortify the kidneys?"), where "补肾" means "fortify the kidneys"):

> What is the best food to ⟨tag⟩补肾⟨/tag⟩?
> What are some foods that ⟨tag⟩补肾⟨/tag⟩?
> Which is the best food to ⟨tag⟩补肾⟨/tag⟩?
> What is the best thing to eat to ⟨tag⟩补肾⟨/tag⟩?"

When we paraphrase sentences without any tags in our second experiment, for example, "手机如何快速散热?" (translation, "How to quickly dissipate the heat of a phone?", where "散热" means "dissipate heat" and "手机" means "phone"), the paraphrases are:

> What is the best way to散热your phone?
> What is the best way to散热your 手机?
> What is the best way to散热my phone?
> What is the quickest way to散热your phone?
> What is the quickest way to散热your 手机?

Based on the second experiment, it appears that tagged Chinese tokens are in general preserved. In the absence of tags, the model is mostly performing translation, as most of the generated tokens are in English (as well as overall word order and grammar). However, as the above examples show, some Chinese tokens are idiosyncratically preserved. Most interestingly, the code switches are semantically coherent.

Although these results are at best anecdotal, it rules out obvious and low-hanging fruit in cross-lingual transfer capabilities. We suspect these observations point to the dominance of English in the pretraining of mBART—it seems like the case that multi-lingual capabilities are pivoting through English. Even when trained on Chinese paraphrase pairs, results suggest that they are likely mapped to English latent semantic space, and that Chinese is easily "forgotten".

5 Conclusions and Future Work

This paper tackles a practical, real-world problem in paraphrase generation that to our knowledge has not been previously addressed: there are tokens that a user might wish to preserve verbatim for a variety of reasons. We further assume, that in many scenarios, the user knows exactly what those tokens are. This leads to our relatively straightforward solution—we provide the user with tags whose semantics are "don't change me".

The contribution of our work is a language-agnostic implementation of this capability using a pretrained sequence-to-sequence model (mBART), coupled with an objective that encourages diversity in the parts of the input that are not surrounded by tags. Evaluations on both English and Chinese paraphrase datasets demonstrate the empirical success of our proposed model, and additional experiments reveal interesting observations about cross-lingual transfer effects, potentially paving the way for future studies.

Abstract

Although coherence modeling has come a long way in developing novel models, their evaluation on downstream applications for which they are purportedly developed has largely been neglected. With the advancements made by neural approaches in applications such as machine translation (MT), summarization and dialog systems, the need for coherence evaluation of these tasks is now more crucial than ever. However, coherence models are typically evaluated only on synthetic tasks, which may not be representative of their performance in downstream applications. To investigate how representative the synthetic tasks are of downstream use cases, we conduct experiments on benchmarking well-known traditional and neural coherence models on synthetic sentence ordering tasks, and contrast this with their performance on three downstream applications: coherence evaluation for MT and summarization, and next utterance prediction in retrieval-based dialog. Our results demonstrate a weak correlation between the model performances in the synthetic tasks and the downstream applications, motivating alternate training and evaluation methods for coherence models.[1]

1 Introduction and Related Work

Coherence is an important aspect of discourse that distinguishes a well-written text from a poorly-written one that is difficult to comprehend (Halliday and Hasan, 1976). Computational models that can assess coherence have applications in text generation and ranking, such as summarization, machine translation, essay scoring and dialog systems.

Researchers have proposed a number of formal theories of discourse coherence, which have inspired the development of many coherence models – both traditional and neural ones. Inspired by the Centering Theory (Grosz et al., 1995), the *entity* based local models (Barzilay and Lapata, 2008; Elsner and Charniak, 2011b) formulate coherence in terms of syntactic roles (*e.g.,* subject, object) of entities in nearby sentences. Another branch of models (Pitler and Nenkova, 2008; Lin et al., 2011; Feng et al., 2014) use *coherence relations* between adjacent sentences to model local coherence, inspired by the discourse structure theories of Mann and Thompson (1988) and Webber (2004). Other traditional methods include *word co-occurrence* based local models (Soricut and Marcu, 2006), *topic* based global models (Barzilay and Lee, 2004; Elsner et al., 2007), and *syntax* based local and global models (Louis and Nenkova, 2012).

Despite continuous research efforts in developing novel coherence models, their usefulness in downstream applications has largely been ignored. They have been evaluated in mainly two ways. The most common approach has been to evaluate them on *synthetic* discrimination tasks that involve identifying the right order of the sentences at the local and global levels (Barzilay and Lapata, 2008; Elsner and Charniak, 2011b; Moon et al., 2019). The other (rather infrequent) way has been to assess the impact of coherence score as an additional feature in downstream tasks like *readability assessment* and *essay scoring* (Barzilay and Lapata, 2008; Mesgar and Strube, 2018). But since the concept of coherence goes beyond these constrained tasks and domains, so should the models.

Given the recent advances in neural NLP methods, with claims of reaching human parity in machine translation (Hassan et al., 2018), fluency in summarization (Liu et al., 2017; Celikyilmaz et al., 2018), or context-consistent response generation (Zhang et al., 2020; Hosseini-Asl et al., 2020), coherence modeling of machine-generated texts, par-

ticularly at a document-level, is now more crucial than ever (Läubli et al., 2018; Sharma et al., 2019). Traditional task-specific evaluation methods (*e.g.,* BLEU, ROUGE) may not be an accurate reflection of their real-world performance in terms of readability (Paulus et al., 2017; Reiter, 2018). However, it is unclear if existing coherence models are capable of this task, since their performance on downstream applications is rarely studied, even though that is one of the main motivations for their development.

Our main goal in this work is to assess the performance of the existing coherence models not only on standard, challenging synthetic tasks like global and local discrimination, but more importantly on real downstream text generation problems. Specifically, we investigate the performance of coherence models in three different settings:

- Traditional synthetic tasks involving discrimination of real documents from their permutations.
- Coherence evaluation for machine translations and system-generated extractive and abstractive summaries, which are more representative of real-world use cases for coherence models.
- Next utterance ranking for dialogs, which is a downstream application similar to the synthetic task of insertion, but uses conversational data from DSTC 8 (Kim et al., 2019).

We show through experiments that there is only a slight correlation between model performances on synthetic tasks and the real-world use cases. Although models perform strongly in the synthetic tasks, they show poor performance and low correlations with human judgments on distinguishing coherent machine translations and system-generated summaries from incoherent ones. They also fail to perform well on the next utterance ranking task, which is similar to the synthetic task of insertion (Elsner and Charniak, 2011b), even if re-trained with task-specific data.

However, we show that re-training the coherence models with task-specific data for machine translation evaluation leads to improved results and agreements with human judgments. This leads us to conclude that there is a possible mismatch in the task setting that is used to train coherence models. Models trained on traditional synthetic tasks do not seem to be learning features that are useful for downstream applications. We hope that our results will motivate the broadening of the standard of coherence model evaluations to include more downstream tasks, and also motivate the redesigning of the training paradigm for coherence models.

2 Coherence Models

Advancements in deep learning have inspired researchers to neuralize many of the traditional models. Li and Hovy (2014) model syntax and inter-sentence relations using a recurrent sentence encoder followed by a fully-connected layer. In a follow-up work, Li and Jurafsky (2017) use generative models to incorporate global topic information with an encoder-decoder architecture. Mohiuddin et al. (2018) propose a neural entity grid model using convolutions over distributed representations of entity transitions. Mesgar and Strube (2018) model change patterns of salient semantic information between sentences. Xu et al. (2019) propose a local discriminative model that retains the advantages of generative models and uses a smaller negative sampling space that can learn against incorrect orderings. Moon et al. (2019) propose a unified model that incorporates sentence syntax, inter-sentence coherence relations, and global topic structures in a single Siamese framework.

We benchmark the performance of five representative coherence models on the tasks discussed above. Our selected models comprise of both traditional and neural models. Moreover, two models are currently the state-of-the-art at the time of submission (Transferable and Unified Neural Model).

Entity Grid (EGRID). Barzilay and Lapata (2005, 2008) introduced the popular entity-based model for representing and assessing text coherence motivated by the Centering Theory (Grosz et al., 1995). This model represents a text with a two-dimensional array called an *entity grid*, that captures transitions of discourse entities across sentences. These local entity transitions are used as deciding patterns for text coherence; a local entity transition of length k is a sequence of $\{S,O,X,–\}^k$ representing grammatical roles (*Subject*, *Object*, *Other*, and *Absent*, respectively) played by an entity in k consecutive sentences. The *salience* of the entities, quantified by the occurrence frequency, is also incorporated to identify transitions of important entities. Elsner and Charniak (2011b) improve the basic entity grid by including non-head nouns as entities (with the grammatical role X). Instead of using a coreference resolver, they match the nouns to detect coreferent entities. In our work, we consider this version of the entity grid model.

Neural Entity Grid (NEURALEGRID). A neural version of the entity grid model was proposed by Nguyen and Joty (2017). The grammatical roles in the grid are converted into their distributed representations, and the entity transitions are modeled in the distributed space by performing convolutions over it. The final coherence scores are computed from convolved features that have gone through a spatial max-pooling operation. A global, document-level pairwise loss is used to train the model.

Lexicalized Neural Entity Grid. Mohiuddin et al. (2018) propose an improvement of the neural entity grid (LEXNEUEGRID) by *lexicalizing* the entity transitions using off-the-shelf word embeddings to achieve better generalization.

Transferable Neural Model (TRANSMODEL). In order to generalize the coherence model across domains, Xu et al. (2019) propose a transferable neural model that considers coherence at a local level, taking only adjoining sentences as input. Coupled with pre-training of the sentence encoders in a generative fashion, their model demonstrates significant improvements in performance, despite being a local coherence model.

Unified Neural Model (UNIFIEDMODEL). Moon et al. (2019) propose a unified model that captures syntax (as a proxy of intention), discourse relations, entity attention and global topic structures. The syntax is captured by incorporating an explicit language model loss. A bi-linear layer is used to capture the inter-sentential discourse relations, while light-weight convolution is used to capture the attention and topic structures.

3 Evaluation Tasks and Experiments

In this section, we present the performance of the coherence models on standard synthetic tasks (*i.e.,* Global/Local Discrimination), followed by the experiments where we apply the coherence models trained on the global discrimination task to three downstream tasks (*i.e.,*, abstractive summarization, extractive summarization, and machine translation). We then present the results of the coherence models re-trained on the next utterance ranking task.

For each of the coherence models, we conducted experiments with publicly available codes from the respective authors. The three recent methods use word embeddings: LEXNEUEGRID, TRANSMODEL and UNIFIEDMODEL use Word2vec (Mikolov et al., 2013), average GloVe (Pennington et al., 2014), and ELMo (Peters et al., 2018) embeddings respectively. We use the default settings and hyperparameters suggested by the authors.

Table 1: Statistics of the WSJ news dataset used for the **Global discrimination** task.

3.1 Synthetic Tasks

Traditionally coherence models have been evaluated mostly on synthetic tasks. For comparison with previous work, we use two representative synthetic tasks to compare the coherence models.

3.1.1 Global Discrimination.

Introduced by Barzilay and Lapata (2008), in this task coherence models are asked to distinguish an original (coherent) document from its incoherent renderings generated by random permutations of its sentences. We follow the same experimental setting of the Wall Street Journal (WSJ) news dataset as used in previous studies (Elsner and Charniak, 2011b; Moon et al., 2019; Xu et al., 2019). Similar to them, we use 20 random permutations of each document for both training and testing. Additionally, we evaluate on *inverse discrimination* (Mohiuddin et al., 2018), where the sentence order is reversed to create the incoherent version.

Setup. We follow the same experimental settings of the WSJ news dataset as used in previous works (Xu et al., 2019; Mohiuddin et al., 2018; Elsner and Charniak, 2011b; Feng et al., 2014). We use 20 random permutations of each document for both training and testing, excluding the permutations that match the original one. Table 1 summarizes the data sets used in the global discrimination task. We randomly select 10% of the training set for development purposes.

Results. Table 2 presents the results in terms of accuracy on the two *global discrimination* tasks – the *standard* and the *inverse* order discrimination. We see that UNIFIEDMODEL achieves the highest accuracy on the standard order discrimination task and TRANSMODEL performs the best on the Inverse order discrimination task. The other three

Model	Emb.	Standard	Inverse

Table 4: Results: Accuracies of the models in the **Local Discrimination task**.

models use entity grids, hence they may lose the sentence-level syntactic and semantic information.

3.1.2 Local Discrimination.

Local discrimination was proposed by Moon et al. (2019). In this task, two documents differ only in a local context (windows of 3 sentences). In this case, the models need to be sensitive to local changes. We use the same WSJ dataset as used by Moon et al. (2019).

Setup. We use the same WSJ articles used in the global discrimination task (Table 1) to create our local discrimination datasets. We use the code released by Moon et al. (2019) to generate these datasets.[2] Sentences within a local **window of size 3** are re-ordered to form a locally incoherent text. Only articles with **more than 10 sentences** are included in the dataset. Table 3 summarizes the datasets. We randomly select 10% of the training set for development purposes.

Following Moon et al. (2019), we create four datasets for our local discrimination task: $\mathcal{D}_{w=1}$, $\mathcal{D}_{w=2}$, $\mathcal{D}_{w=3}$ and $\mathcal{D}_{w=1,2,3}$. $\mathcal{D}_{w=1}$ contains the documents where only one randomly selected window is permuted, $\mathcal{D}_{w=2}$ contains the documents where two randomly selected windows are permuted; $\mathcal{D}_{w=3}$ is similarly created for 3 windows. $\mathcal{D}_{w=1,2,3}$ denotes the concatenated datasets.

Results. From Table 4, we see that the UnifiedModel achieves the highest accuracy on all four datasets. A possible reason could be the loss function it uses to train the model. Unlike other models, UnifiedModel uses an adaptive pairwise ranking loss which does not penalize the locally coherent sentences. In the local discrimination task, the difference between positive and negative examples is small; they differ only in 1-3 windows, while the other parts are locally coherent. UnifiedModel's loss function can model this better.

3.2 Coherence Evaluation Tasks

We evaluate the coherence models trained on the global discrimination task on two downstream tasks: machine translation (MT) and summarization coherence evaluation. Note that both the MT and summarization data are from the same domain (news) as the original WSJ training data.

3.2.1 Machine Translation Evaluation

The outputs of neural machine translation (NMT) systems have been shown to be more fluent than their phrase-based predecessors (Castilho et al., 2017). However, recent studies have shown that there is a statistically strong preference for human translations in terms of both adequacy and fluency at a document level (Läubli et al., 2018; Popel et al., 2020).

Smith et al. (2016) evaluated traditional (non-neural) coherence models to see if they can distinguish a reference from a system translated document, and reported very low accuracy. However, the situation has changed with the advancements of neural models; today's coherence models are claimed to be much more accurate.

Our goal therefore is to evaluate the coherence models on how well they can judge the coherence of MT outputs at the document level. To do this, we use the system translations released by the annual Workshop (now Conference) on Machine Translation (WMT) through the years 2017 and 2018. At a document level, reference (human) translations have been shown to be more coherent than MT outputs (Smith et al., 2015, 2016; Läubli et al., 2018). Therefore, we evaluate the performance of the coherence models based on their accuracy of scoring

the reference (document) higher than the system translation (document).

We also obtain rankings given by humans in a user study. Fig. 1 shows the layout of the study, where participants were shown four sentences from three candidate translations of the same source text and asked to rank them against each other. One of the given translations is the reference, used as a control, and to validate our assumption that the reference is more coherent than the system translations. 3 participants annotated 100 such samples.

Participants chose the reference as more coherent with an agreement of **0.84**, confirming our assumption.[3] We evaluate the system translations by producing a ranking between the different translations of the same source text. To do this, we first obtain scores from the coherence models for the reference and each of the corresponding system translations. Then, we *normalize* the scores of the system translations by subtracting them from score of the reference. These normalized coherence scores are used to rank the system translations, which are then used to calculate agreements.

Setup. We use the reference and the system translations provided by WMT2017-2018 as our test data, under the assumption that the reference translations are more coherent than the system translations. This results in a testset of 20,680 reference-system translation document-pairs.

Results. We report the accuracy of the coherence models trained on the global discrimination task in distinguishing the more coherent reference text from the less coherent system translations in Table 5. We can see that most models perform worse than a random baseline of 50%, showing that their training on the global discrimination task is not helpful in detecting coherence quality in MT text. The difference in performance is particularly glaring for the TransModel and the UnifiedModel, both of which have over 90% accuracy on the global discrimination tasks, but only manage 48.67% and 43.36% on this task respectively.

We also report the agreement with human rankings on the study data in Table 5. Overall, only EGrid has good agreement with human rankings, with all other models doing similarly poorly.[4]

3.2.2 Abstractive Summarization

Generating coherent summaries has always been a goal in summarization (Nenkova and McKeown, 2011). The widely used automatic evaluation metric ROUGE (Lin, 2004) measures the n-gram overlap between the generated summaries and the reference summaries at a sentence level, and thus is not sufficient for measuring coherence. Kryściński et al. (2019) also recently found almost negligible correlation between ROUGE scores and human judgments on summary coherence, especially for abstractive summaries generated by recent neural summarization models. We therefore propose to evaluate the coherence of summaries using different coherence models and measure their effectiveness on this task.

For abstractive summarization, we use summaries from popular neural abstractive summarization systems for CNN/DM dataset (Hermann et al., 2015; Nallapati et al., 2016). Since abstractive systems vary in their architectures and loss functions, they may produce very different summaries. We run a human study to validate the rankings given by the coherence models.

---

[3] Traditional correlation measures such as Cohen's Kappa are not robust to skewed distributions of annotations, which was an issue here since the annotators were always more likely to choose the reference as better. Thus, we report the more appropriate Gwet's AC1/gamma coefficient (Gwet, 2008), which controls for this.

[4] Note that the study data is different from the test data, so the accuracies and agreements may not correlate.

Models	Abs. Agr.	Ext. Agr.
EGRID	**0.71**	0.52
NEURALEGRID	0.68	**0.70**
LEXNEUEGRID	**0.71**	0.57
TRANSMODEL	0.55	0.38
UNIFIEDMODEL	0.68	0.35

Table 6: **Abs**tractive **Agr**eement and **Ext**ractive **Agr**eement shows the AC1 agreements for the pairwise ranking of the generated abstractive summaries and extractive summaries between two annotators and the models, respectively.

Setup. We use the CNN/DM (Hermann et al., 2015; Nallapati et al., 2016) for this task. We collect the reference summaries from the CNN/DM testset as well as the summaries generated by the following four representative abstractive summarization systems: (*a*) Pointer-Generator (PG) (See et al., 2017), (*b*) BERTSUMEXTABS (BSEA) (Liu and Lapata, 2019), (*c*) UniLM (Dong et al., 2019), and (*d*) SENECA (Sharma et al., 2019).

As discussed, we directly use the coherence models trained on the WSJ dataset for the global discrimination task. The coherence models predict the scores for each system-generated summary in the testset. The scores produced by the models are then used to rank the system-generated summaries of the same original article.

We conducted a user study to validate the effectiveness of the rankings produced by the coherence models. We randomly sampled 10 sets of summaries from the dataset with each set containing four generated summaries of the same article, thus resulting in $\binom{4}{2} \times 10 = 60$ pairs of system summaries. Two annotators were asked to rank each pair of the summaries in terms of coherence; see Appendix for the human study interface.

Results. For the user study, the agreement between the two annotators was **0.78**, which indicates fairly reliable data. After we obtain the rankings based on the coherence scores produced by the models, we compute the agreements between the systems and the two annotators. From the results in Table 6, we see that EGRID and LEXNEUEGRID show the highest agreement with human judgements. However, despite strong performance in synthetic tasks, models like UNIFIEDMODEL and TRANSMODEL are unable to convert the high accuracy into high human agreement, which demonstrates the inefficiency of current synthetic tasks.

3.2.3 Extractive Summarization

For evaluating the coherence of extractive summaries, we use the dataset prepared by Barzilay and Lapata (2008) for their coherence model evaluation. The dataset comes with human ratings of the summaries from the Document Understanding Conference (DUC), 2003.

Setup. The dataset from Barzilay and Lapata (2008) provides 16 sets of summaries where each set corresponds to a multi-document cluster and contains summaries generated by 5 systems and 1 human. The human ratings for these summaries based on coherence are also available.[5]

We follow the same experimental setup as in abstractive summarization. We use the coherence models trained on the WSJ dataset to produce scores that can be used to obtain the pairwise ranking of generated summaries. Based on the ratings provided by Barzilay and Lapata (2008), we can generate the human pairwise rankings.

Results. We present the agreements between the generated human ranking and the systems in Table 6. We observe the same problem as in abstractive summarization that high accuracy in synthetic tasks does not lead to high human agreement in evaluating downstream summarization systems.

3.3 Task-specific Training for Dialog

The global and local discrimination tasks are synthetic, while the MT and summarization coherence evaluation performance may be affected by the difference between the testing and training setup. To control for this, we re-train and test the coherence models on a task-specific setup for next utterance ranking. This task has the advantage of being non-synthetic while providing task specific training data, but also being similar to the synthetic task of insertion, helping us evaluate the generalizability of the coherence model performance.

3.3.1 Next Utterance Ranking

The quality of a dialog depends on various conversational aspects such as engagement, coherence, coverage, conversational depth, and topical diversity (See et al., 2019). Liu et al. (2016) show that commonly used metrics such as BLEU and ROUGE show very weak or no correlation with human judgements. They also suggest using metrics

Table 7: Statistics of the refined Advising and Ubuntu datasets for the **utterance ranking** task.

that take dialog context into account. This is particularly important as Sankar et al. (2019) empirically show that current neural dialog systems rarely use conversational history. We therefore propose to evaluate the usefulness of coherence models in dialog systems.

We evaluate the models on the Noetic End-to-End Response Selection Challenge II (NOESIS II), a track in the Dialog System Technology Challenges 8 (DSTC 8) (Kim et al., 2019). In this problem, each example consists of a conversational context $U = (u_1, \ldots, u_{|U|})$ and a set of potential utterances (candidates) $C = \{c_1, \ldots, c_{|C|}\}$ that may occur next in the dialog; the task is to select the correct next-utterance $r \in C$.

This task is a nice fit for evaluating coherence models, as a good model should rank a coherent dialog higher than an incoherent one. The correct utterance along with the conversational context forms the coherent example $P = (u_1, \ldots, u_{|U|}, r)$, while other candidate utterances $c_j \in C$ with the conversational context form the incoherent examples $N = (u_1, \ldots, u_{|U|}, c_j)$. This is a considerably harder task as the difference between coherent and incoherent dialog is only the last utterance. We train the coherence models with these coherent (P) and incoherent (N) examples. The trained models give a score for each example based on its coherence. We then use our aforementioned assumption (coherence models should score P higher than N) for the evaluation. This task resembles the (synthetic) *insertion* task (Elsner and Charniak, 2011b) in that the goal here is to find the next correct utterance for the last position.

Setup. We evaluated the coherence models on both datasets of the DSTC8 response selection track, *i.e.,* the Advising and Ubuntu datasets.[6] The former contains two-party dialogs that simulate a discussion between a student and an academic advisor, while the latter consists of multi-party conversations extracted from the Ubuntu IRC channel (Kummerfeld et al., 2019).

Table 8: **Utterance ranking** results for different coherence models on Advising and Ubuntu datasets. **R@k** indicates Recall@k, X indicates result not shared.

For a given conversational context, the goal is to select the next utterance from a candidate pool of 100 utterances, which may or may not contain the correct next utterance. We filter the datasets to suit the settings for coherence models. In our refined datasets, we exclude the conversations that have less than 7 or more than 50 utterances in the context. To ensure that we have pairwise coherent and incoherent examples, we only include the conversations that contain the correct next utterance in the candidate pool. Table 7 shows the statistics of our refined datasets for the utterance ranking task.

Results. Table 8 summarizes the results on the refined datasets for the utterance ranking task. In the last column, we report the accuracy for the number of samples in which the coherence models score the positive sample higher than the negative one. All model performances are better than a random baseline, with UnifiedModel reaching 74.49% on the Ubuntu dataset. Note, however, that because there are 100 negative samples for every positive sample, the accuracies are skewed and not representative of actual task difficulty.

---

[6] https://github.com/dstc8-track2/NOESIS-II/

The DSTC8 challenge ranking considers the average of Recall@1, Recall@5, Recall@10 and Mean Reciprocal Rank (MRR). We report both the official evaluation results and the coherence models' performance even though the latter is tested on the refined datasets. From the results, we see that the overall performance of all the coherence models is quite poor. Despite being re-trained on task specific data, we find that coherence model performance in this task is sub-par.

4 Task-specific Training for MT

As a special use case, we report the results of re-training the coherence models using machine translation data for coherence evaluation. The aim is to investigate whether changing the usual training setup, that uses negative documents which are only small variations of the positive documents, might help coherence models learn more useful task-specific features.

Setup. Under the assumption that the reference translations are more coherent at the document level than the system translations, we train the coherence models with the reference text as the positive and the system translation as the negative document, forming a positive-negative document pair. We use the data from WMT-2011 to WMT-2015 for training (28,985 document-pairs), WMT-2016 for development (7,647 document-pairs) and the same test data (WMT-2017 to WMT-2018; 20,680 document-pairs) and study data as used for the previous experiment (§3.2.1).

Results. Table 9 reports the accuracy of the re-trained models and the results of the model ranking comparison against human rankings. Many of the models show improved performance, with the agreements increasing correspondingly. The UNIFIEDMODEL has the highest accuracy improvement by far of 34%, improving from 43.36% to 77.35%. It also has the highest agreement with human rankings at 0.82. We surmise that the model's adaptive pairwise ranking loss along with its additional language model loss boosts its performance on in-domain test data.

Model	**Acc. (%)**	**AC1 Agr.**

5 Discussion

Compared to the downstream tasks of coherence evaluation in MT and extractive and abstractive summarization, the traditional global discrimination task can be considered to be a simpler task (Elsner and Charniak, 2011b), since the difference between the positive and the negative document is a permutation/re-ordering of the sentences. This may be rendering the models unable to learn features that are useful for downstream applications, which are likely to have other, different kinds of errors.

On the next utterance ranking task, the models fail to generalize and perform quite poorly despite task-specific re-training. The best model performance for the synthetic task of insertion, which is similar, also barely reaches 26% (Elsner and Charniak, 2011b; Nguyen and Joty, 2017). This indicates that the training procedures may not be providing the right setting to learn features that are generic enough to apply to tasks in a harder setup.

In the synthetic tasks, the models' self-supervision comes from distinguishing an original coherent document from its incoherent renderings generated by random permutations of its sentences. This permutation-based self-supervision tries to capture document-level language properties. However, it is quite likely that this is simply a poor approximation of real-world coherence problems. Consider for example that MT systems mostly translate at the sentence-level. Consecutive sentences may lack coherence, but if two system translations of a text are compared, the translations themselves will be in the same order for both. The coherence models are not trained for such (real-world) settings.

Another possibility is that outputs from downstream tasks have different error distributions that are captured to varying degrees by different models, since they are originally designed based on synthetic tasks. That is, models that perform very well on the permutation task might be overfitting on this task, and therefore failing to find coherence issues that are more subtle than shuffled text. Thus, we conclude that the current self-supervision for coherence modeling is not suitable for downstream coherence problems.

When re-trained on machine translation data, most of the model performances improve, implying that a different training setting may be required to make the models applicable to actual downstream tasks. This is not apparent from the evaluation results that are usually reported, which show performances crossing the 90% mark.

Elsner and Charniak (2011a) show a similar lack of generalizability and applicability of coherence models to the downstream task of chat disentanglement. Our results suggest that despite nearly a decade of research since, the standard training and testing paradigm for coherence modeling continues to be inadequate in its capability to generalize to real-world use-cases and even to similar task settings, and also fails in being indicative of real-world task performance.

6 Conclusions

We benchmark the performance of representative traditional and neural coherence models on standard synthetic discrimination tasks, and contrast this with their performance on various downstream application tasks in NLP. We show that higher accuracies on synthetic tasks do not translate into better performance on downstream tasks. We demonstrate this for real-world tasks like MT and summarization coherence evaluation, and next utterance ranking. Our results signal a need for change in the way coherence models are typically trained and evaluated.

Other downstream applications like coherence evaluation of language model generated text and tasks such as chat disentanglement are also good candidates for testing coherence models. It would be worthwhile to build a coherence testset that is independent of the training tasks and similar to downstream applications, which could be used by the community to test the generalization ability of their models. In future work, we also hope to investigate the possible training scenarios that will result in more generalizable coherence models which can be used for evaluating downstream tasks.

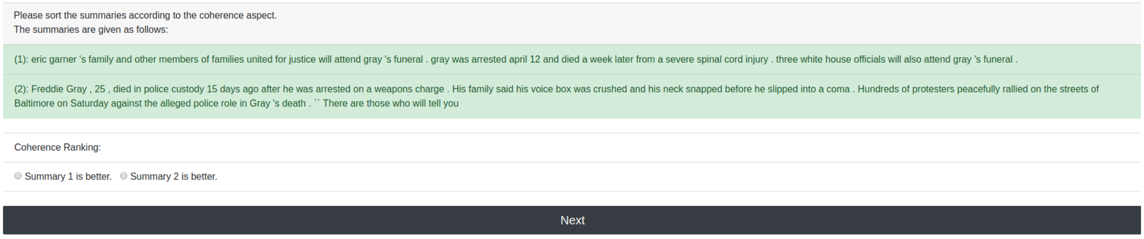
A Appendix

A.1 Human Study Interface for Abstractive Summarization

We show the interface of human study for abstractive summarization in Figure 2.

A.2 Human Study for Extractive Summarization

We briefly describe the human study for extractive summarization. The human study was conducted by Barzilay and Lapata (2008). Coherence ratings for summaries were collected during an elicitation study by 177 unpaid native speakers of English. The annotators were asked to use a seven point-scale to rate each summary based on how coherent the summaries were without having seen the source texts. The ratings (approximately 23 per summary) given by the subjects were averaged to provide a final rating score between 1 and 7 for each summary.



Please sort the summaries according to the coherence aspect.
The summaries are given as follows:

(1): eric garner 's family and other members of families united for justice will attend gray 's funeral . gray was arrested april 12 and died a week later from a severe spinal cord injury . three white house officials will also attend gray 's funeral .

(2): Freddie Gray , 25 , died in police custody 15 days ago after he was arrested on a weapons charge . His family said his voice box was crushed and his neck snapped before he slipped into a coma . Hundreds of protesters peacefully rallied on the streets of Baltimore on Saturday against the alleged police role in Gray 's death . `` There are those who will tell you

Coherence Ranking:

○ Summary 1 is better. ○ Summary 2 is better.

Abstract

Political discussions revolve around ideological conflicts that often split the audience into two opposing parties. Both parties try to win the argument by bringing forward information. However, often this information is misleading, and its dissemination employs propaganda techniques. In this work, we analyze the impact of propaganda on six major political forums on Reddit that target a diverse audience in two countries, the US and the UK. We focus on three research questions: *i*) who is posting propaganda? *ii*) how does propaganda differ across the political spectrum? and *iii*) how is propaganda received on political forums?

1 Introduction

Propaganda, translated from Latin as "things that must be disseminated", represents information intended to persuade an audience to accept a particular idea or cause by using specific strategies or stirring up emotions. Our work is the first study that leverages a high quality annotated dataset of propaganda techniques (Da San Martino et al., 2019) to understand the impact of propaganda on online conversations.

In this paper, we perform an in-depth and long-term analysis of propaganda on online forums. We focus on six subreddits from two English speaking countries, the US and the UK, for one year. We select a popular subreddit for political news with no party affiliation and two subreddits dedicated to each country's dominant parties. In the US, the two main parties are the Democrat and the Republican party. The Democrat party is center-left; however, it contains several factions with ideologies varying from the center to the left. The Republican Party is a center-right party and has shifted in recent years towards national conservatism. In the UK, the most popular parties are the Labour Party and the Conservative Party. Similarly to the US, these parties represent the center-left and the center-right. The Labour Party has social democratic and socialist factions, while the Conservative Party has many factions, such as one-nation conservatism, liberal conservatism, or social conservatism. In recent years, both countries passed through significant political turmoil, such as Donald Trump's election in the US and the referendum on leaving the EU in the UK. However, a recent opinion piece in the Washington Post highlights an essential difference between the political discourse in the two countries. The journalist believes that the division between the left and the right in America is driven by the different interpretations the two parties give to the words "rights", "liberty" or "freedom", which have a strong moral imperative. This difference is not present in the UK, hence political parties there might find it easier to reach common grounds.

Our contribution to the study of propaganda in online discussions is in investigating the following research questions: *i*) Who is posting propaganda? *ii*) How does propaganda differ across the political spectrum or different countries? and *iii*) How is propaganda received on political forums? We believe we are the first to investigate these important questions in forums with different political leaning. For the first question, we find that media sources' political bias is a strong indicator of the tendency of using propaganda and that a smaller community of users is disproportionately spreading propagandistic articles. Regarding the second question, we find that forums dedicated to less popular parties in a country are more likely to post biased news and that cultural differences might dictate which propaganda techniques are employed. Finally, we find that if a submission or comment has more propaganda content, it might receive more user engagement, measured either as the number of comments or as upvotes and downvotes.

2 Related Work

Analysis of political discussions. (Roozenbeek and Salvador Palau, 2017) explore the role of online communities in elections and how different types of new events impact their dynamics. In (Soliman et al., 2019), the authors analyze political communities (subreddits on Reddit), comparing them to the content posted, their relationships to other subreddits, and the distribution of attention received in these subcommunities. They compare left-leaning with right-leaning communities, with significant differences emerging, such as higher use of derogatory language in the right-leaning communities, stronger connectivity between the US and the European right-leaning communities, and more substantial focus on media sources reflecting their political leaning in the left-leaning subreddits. In (Guimaraes et al., 2019), the authors identify different conversation patterns that refine the notion of controversy into disputes, disruptions, and discrepancies and perform a systematic analysis of discussion threads based on essential facets of a conversation like users, sentiments, and topics. (An et al., 2019) proposes an analytical template to explore the nature of political discussions by studying the interaction and linguistic patterns within and between politically homogeneous and heterogeneous communication spaces on Reddit. (Carman et al., 2018) analyzes the effects of vote manipulation on article visibility and user engagement by comparing political threads on Reddit whose visibility is artificially increased.

Propaganda detection. Previous works on propaganda have focused on proposing datasets to foster further research, including document-level annotations (Rashkin et al., 2017; Barrón-Cedeño et al., 2019) and fragment level annotations (Da San Martino et al., 2019). Efforts for constructing annotated datasets have also been made in other European languages different from English (Kmetty et al., 2020; Baisa et al., 2019). Automatic propaganda detection approaches are almost always proposed alongside new corpora. (Rashkin et al., 2017) defines a four-class text classification task that detects propaganda, satire, hoaxes, and real news, while (Barrón-Cedeño et al., 2019) uses a binary classification to detect propaganda and non-propaganda articles. (Da San Martino et al., 2019, 2020) perform fine-grained analysis of texts by detecting all fragments that contain propaganda techniques, as well as their type. In (Kellner et al., 2020), the authors quantify the influence of trolls on Twitter that contribute to the propaganda spread during political elections in online communities. Studies on the use of propaganda have also helped understand how terrorist organizations share their ideology and attract new members (Al-Rawi and Groshek, 2020; Bisgin et al., 2019). (Martino et al., 2020) reviews the state of the art of computational propaganda detection from both an NLP and a network analysis perspective, arguing on the need to combine these communities' efforts.

Bot detection in political discussions. Research on political discussions has mostly focused on specialized topics such as adversarial debates between two parties, like election campaigns and referendums. (Rizoiu et al., 2018; Davis et al., 2016) use machine learning approaches to study social bots' influence in the diffusion of tweets containing partisan hashtags surrounding a political debate. (Hurtado et al., 2019) studies political discussions on Reddit and uses graph-based methods to reveal a fully connected community of users who exhibit a bot-like behavior. (Costa et al., 2015) introduces a generative model based on users' temporal activity patterns to study abnormal posting behavior both on Twitter and Reddit data.

Journalistic efforts in studying online content. There have been some relevant initiatives by communities of expert journalists or volunteers to raise awareness of different online news issues by evaluating the content published by news outlets and social media. For instance, Media Bias/Fact Check (MBFC) is an independent organization that analyzes media in terms of their factual reporting, bias, and propagandist content, among other aspects. Full Fact, an independent fact-checking organization in the UK, provides free tools, information, and advice for checking claims by politicians and the media. Similar initiatives have been taken by US News and World Report and the European Union.

3 Propaganda Techniques

Propaganda is a communication technique primarily used to influence public opinion towards an a-priory established agenda.

According to the Institute for Propaganda Analysis, propaganda had its definition pinned in 1938 as being "the expression of an opinion or an action by individuals or groups deliberately designed to influence the opinions or the actions of other individuals or groups with reference to predetermined ends" (for Propaganda Analysis, 1938).

In the past century, spreading propaganda required controlling traditional journalism media, such as newsprint, TV, and radio stations. It represented a form of communication that only large institutions and governments could afford. With the recent rise of the Internet and its use as online mass media, "computational propaganda" appeared (Bolsover and Howard, 2017) as a social and technical phenomenon that made propaganda campaigns easily accessible to a wide variety of small organizations and individuals that targeted audiences of unprecedented size. Recent striking examples include the propaganda allegedly set to influence the 2016 US presidential elections (Mueller, 2018) and the 2016 Brexit referendum (Howard and Kollanyi, 2016).

While the definition of propaganda has reached consensus in the literature, the complete list of techniques considered propagandist are still under discussion, Wikipedia[1] mentioning 68 of them. We adhere to the hypothesis previously made by (Barrón-Cedeño et al., 2019; Da San Martino et al., 2019) that argues that *propaganda is a communication technique that does not depend on the document topic and its topic-specific vocabulary and for which representations based on writing style, readability, and stylistic features generalize better than word-level based representations.* (Da San Martino et al., 2019) chooses to investigate a curated list of eighteen propaganda techniques found in journalistic articles that can be judged intrinsically, without the need to retrieve supporting information from external resources. Many of these techniques are also fallacies since propagandists use arguments that are sometimes convincing and not necessarily valid. A fallacy is an argument where the evidence does not support the claim that is put forward. The other techniques employ emotional language or use rhetorical, psychological, and disinformation strategies to present an idea.

We leverage the list of eighteen propaganda techniques proposed by (Da San Martino et al., 2019).

- *Appeal to authority (fallacy)* cites an expert's opinion to support an argument, without any other supporting evidence.
- *Appeal to fear or prejudice (fallacy)* supports a claim by increasing fear towards an alternative, possibly based on preconceived judgments.
- *Bandwagon (argumentum ad populum fallacy)* persuades the audience that a claim is true because many people believe so.
- *Black and white fallacy* presents only two choices out of many available, with the choice on the agenda as being the better one.
- *Causal oversimplification (fallacy of the single cause)* assumes only one cause for a complex issue out of many possible ones.
- *Flag waving (fallacy)* exploits strong patriotic feelings for a group or idea to justify an action or a claim.
- *Name calling or labeling* uses names, labels, or euphemisms to construct a good/bad image of a group or idea that is to be supported/denounced.
- *Red herring (fallacy)* presents an irrelevant, although possible convincing argument to divert the attention from the matter at hand.
- *Reductio ad Hitlerum (fallacy)* persuades the target audience to disapprove of a claim by associating it with a group widely held in contempt.
- *Straw man (fallacy)* addresses and refutes a superficially similar claim instead of the real one.
- *Whataboutism (fallacy)* discredits the opponent's claim by accusing them of hypocrisy without directly addressing the original argument.
- *Doubt* questions the credibility of an idea by disseminating negative information about it.
- *Exaggeration or minimization* makes the reality look more meaningful or more insignificant than it is.
- *Loaded language* uses words and phrases with substantial emotional implications.
- *Obfuscation, intentional vagueness, confusion (ambiguity fallacy)* deliberately employs

---

[1] https://en.wikipedia.org/wiki/Propaganda_techniques, visited October 2020

vague generalities leaving the audience to draw its interpretations.

- *Repetition* repeatedly uses the same symbol or idea to make it unforgettable.
- *Slogans* make use of brief and striking phrases to deliver the intended message.
- *Thought terminating cliches* take advantage of short, generic phrases that divert the attention or seem to offer simple answers to complex problems to stop an argument from proceeding further.

4 Reddit Dataset

We select six subreddits: Politics, Democrats, Republican, UKPolitics, LabourUK, and Tories. Politics is a subreddit for "current and explicitly political U.S. news.". The subreddit does not claim any political affiliation. The Democrats subreddit description contains "We are here to get Democrats elected up and down the ballot.", and it is a partisan subreddit. Republican is "a partisan subreddit" and the place where "Republicans discuss issues with other Republicans", hence it is a subreddit for people supporting the US Republican party. UKPolitics is a forum for "political news and debate concerning the United Kingdom" and does not claim any political affiliation. LabourUK is a subreddit that discusses breaking news concerning the British Labour Party. Finally, Tories is a subreddit for news concerning the Conservative Party in the UK, also known as the Tories. When there are several subreddits on the same topic (for example, BritishPolitics is also a subreddit for politics in the United Kingdom), we select the subreddit with the largest number of members. We note that Reddit does not ask for or encourages users to share personal data, such as their locations. Statistics on Reddit users are available only through data gathered from independent polls and surveys. For example, we know that the US and UK are the best-represented countries among the Reddit users. In the light of the surveys, we hypothesize that there are many users from the US and UK that engage in political subreddits.

We take all content posted for a period of one year, January 2019 to December 2019, from the PushShift dataset (Baumgartner et al., 2020). On Reddit, a discussion is started by a **submission**, e.g. a news article or a piece of text, and users will engage by writing **comments**. A comment is described by *author*, *body* (the content of the comment), and *score* (computed as upvotes minus downvotes) among others. We remove comments tagged as "[deleted]" or "[removed]", which are comments removed by the moderators or the users themselves. A submission has several properties, including *content* (often linked via a URL), *number of comments*, *score* (upvotes minus downvotes), and *author*. For simplicity, we refer to the submission and the article linked in the submission using the term *submission*. We retrieve the external articles by following the link in the submission. We filter out the submissions whose corresponding articles were not found by the crawler, either because cookie permissions cannot be given automatically or because the link is no longer valid. We also filter out the submissions linking to articles with less than 200 words. We want to focus on journalistic like content, a piece of text large enough to develop well an idea. Overall, we keep around $43-71\%$ of the original submissions, depending on the subreddit.

Subreddit	Submissions	Comments
Politics	317K	20M
Democrats	9.8K	54K
Republican	8.2K	41K
UKPolitics	42K	1.8M
LabourUK	7K	58K
Tories	1.1K	12K

Table 1: Reddit dataset

An overview of our dataset is given in Table 1.

To further understand the subreddits' dynamics, we report the overlap between the users commenting or posting a submission in the forums over the period we study. In the US related forums, there are $736K$ unique users, out of which $730K$ unique users in Politics, $8.5K$ in Democrats, and $7.7K$ in Republican. We have that 75% of users in Democrats and 57% of users in Republican also post in Politics, while only 5% of users posting in Republican also post in Democrats. In the UK forums, we have $46K$ unique users, out of which $44K$ post in UKPolitics, $3.3K$ in LabourUK, and $1K$ in Tories. The overlap between the forums shows a more balanced dynamics, with 61% of the LabourUK users and 63% of the Tories users also posting in UKPolitics, and 23% of the Tories users posting in LabourUK.

5 Methodology

The dataset introduced in (Da San Martino et al., 2019) consists of news articles manually annotated with propaganda techniques. The propaganda techniques are in order of frequence of instances: loaded language (2547), name-calling (1294), repetition (767), exaggeration or minimization (571), doubt (562), appeal to fear and prejudice (367), flag-waving (330), causal oversimplification (233), slogans (172), appeal to authority (169), black and white fallacy (134), thought-terminating cliches (95), whataboutism (76), reductio ad hitlerum (66), red herring (48), bandwagon (17), labeling, obfuscation or intentional vagueness (17), straw men (15). The annotations are fined-grained, with each propaganda instance being labeled at the token level. One technique might span more than one sentence.

We define two classification tasks based on the propaganda dataset described in Section 4: *i*) **propaganda identification**, which predicts if a sentence contains any propaganda techniques and *ii*) **propaganda technique identification**, which given a sentence containing propaganda, predicts the type of technique.

For each task, we test the following classifiers: a random classifier which predicts a class uniformly at random, a suite of transformer classifier BERT (Devlin et al., 2019), ROBERTA (Liu et al., 2019) and XLNet (Yang et al., 2019), and an ensemble classifier that makes a prediction based on the most confident label given by one of the three classifiers (BERT, ROBERTA or XLNet). Finally, we add the multi granularity model proposed in (Da San Martino et al., 2019), MGN ReLU. To fine-tune the transformer models, we add a final linear layer. We use a sequence length of 210, a learning rate of 0.01, a mini-batch of size 16, anneal factor of 0.5, patience of 2, and the maximum number of epochs to 20. To deal with dataset imbalance in both tasks, we weight the loss function samples according to the class weight.

The first task, propaganda identification, is a binary classification task, with classes propaganda and nonpropaganda. We present the results in Table 2. We note that propaganda identification is a difficult task, and all the classifiers obtain moderately good results, however much better than random selection.

Classifier	Precision	Recall	F1
Random	24.14	25.65	28.87
BERT	58.52	52.02	55.08
ROBERTA	**63.96**	41.41	50.28
XLNet	53.27	59.29	56.12
Ensemble	62.72	48.57	54.74
MGN ReLU	60.41	**61.58**	**60.98**

Table 2: Precision, recall and $F1$ score for propaganda identification.

The second task allowed us to understand if we have enough instances of each propaganda technique to classify them. We ran an experimental study, and we observed that bandwagon, obfuscation, red herring, straw men, and thought-terminating cliches were never recognized in the test set by our classifiers. Given this, we removed them from the annotations, and we kept the remaining techniques for the first and second tasks. We present the results in Table 3.

Classifier	F1-micro	F-macro
Random	17.07	15.76
BERT	29.75	22.17
ROBERTA	**26.96**	22.00
XLNet	29.07	**23.95**
Ensemble	28.17	22.71

Table 3: $F1$ score for technique identification.

Topical confounds. Finally, we study the effect of topical confounds in propaganda and technique classification. This analysis aims to understand if there are topical biases in the annotated dataset, which might bias our analysis. For example, if the data contains many articles on Trump, we might tend to label as propaganda any article referring to him. To identify topical biases, we use the approach presented in (Kumar et al., 2019). We first identify statistically overrepresented words in each propaganda technique in the training set and then replace them with a special token in the test set. The overrepresented words are computed using log-odds ratio with Dirichlet prior (Monroe et al., 2008), and we present the results in Table 4. We recall that we removed the techniques bandwagon, obfuscation, red herring, straw men, and thought-terminating cliches from our labeled dataset. As we can observe, for certain categories, the words are very intuitive. For example in reductio ad hitlerum we have many words related to totalitarian regimes, or in flag-waving we have many words around the notion of country. However, for most techniques, the words do not form cohesive topics, which is

Appeal to authority	thousands, regard, voter, altering, bea, notes, schema, muhammad, homosexual, viganò
Appeal to fear or prejudice	student, eucharist, jewish, easiest, bds, cliff, lew, eucharistic, campus, mcgill
Black-and-White Fallacy	easiest, uk, die, focus, burn, throw, dear, blessing, bless, chop
Causal oversimplification	anderson, backlash, cia, hillary, continued, god, alleging, knows, ruined, shahada
Doubt	guardian, story, wills, harding, assange, fake, claims, luke, failed, evidence
Exaggeration,Minimization	absolutely, history, worse, impossible, biggest, world, extraordinary, greatest, ukrainians, ingenious
Flag-Waving	american, america, europe, country, people, hungary, orban, nation, americans, citizen
Loaded Language	advantage, neo, devastating, democrats, shocking, lies, church, voice, grave, jews
Name calling, labeling	partisan, bergoglio, witch, hunt, dems, spy, assange, google, guardian, righteous
Reductio ad hitlerum	hitler, german, nazis, vichy, labour, communists, farrakhan, nazi, soviet, occupation

Slogans	hat, character, jimenez, duke, school, america, sadikov, whataburger, foot, home
Whataboutism	admitting, guys, prosecute, focus, jihad, interpreted, ship, prosecuting, west, happened

Table 4: Top 10 words statistically overrepresented in each propaganda technique in the training set.

expected as propaganda represents a communication technique, and it is not restricted to a topic. To further verify that our classifiers learn style and not the topic, in the test set, we replace with a special token the top k words strongly associated with each technique, computed from the training set. For both $k = 10$ and $k = 20$ we report a very small decrease in $F1$ score for the BERT classifier in the propaganda classification task, from 55.08 to 52.47 and from 55.08 to 53.08. For the technique classification task, for $k = 10$ we do not observe a drop in performance, while for $k = 20$ we pass from 29.75 $F1$-micro score to 27.26, and from 22.17 $F1$-macro to 19.85. Besides, we note that the decrease in performance for this task is distributed among techniques. For flag waving and reductio ad hitlerum, for which certain words were important with respect to their definition, we do not observe a large decrease in $F1$ score. For example, the F1 scores for flag waving for $k = 10$ and $k = 20$ decrease from 43.98 to 39.57 and to 39.36, respectively. Given the small decrease in performance, we can conclude that our classifier does not learn topical confounds but the language patterns of propaganda techniques.

We leverage the propaganda identification classifier to define a **propaganda score**. The propaganda score of a document is the percentage of sentences that were labelled as containing propaganda. We compute the propaganda score of each submission, and based on the distribution of the score values in a subreddit, we define two groups: the **least propaganda**, which represents the 25% submissions with the lowest propaganda score, and the **most propaganda**, which represents the 25% submissions with the highest propaganda score. Our aim in defining the two groups is to mitigate part of the classifier's imprecision and make our analysis more robust.

6 Propaganda on Reddit

In this section, we focus on several research questions around propaganda on online forums.

RQ1. Who is posting propaganda? In the context of political forum discussions, this question targets two different groups: *media outlets and social media users*. The initial publishers are the media outlets, but users handpick what news to share on political forums. To study what media outlets are present and in which measure they are responsible for the propaganda content, we look at the groups defined in Section 5, least propaganda submissions, and most propaganda submissions. We compute the top-level domain for each submission in the two groups, which corresponds to the media outlet. We give each media outlet a label measuring its political leaning, according to MediaBiasFactCheck: center, left-center, right-center, left, right, questionable, and others. The center label is interpreted as having no or little political bias, left-center and right-center have a slight bias, left and right have a moderate bias, while the questionable label has a strong bias. The others label is given to sites that are not found in our dataset. MediaBiasFactCheck computes a media source's political bias taking into account bias by story selection, bias by omission, or bias by labeling, among others. In Table 5, we observe a strong relationship between the political bias of the media sources and the groups we computed using our propaganda score. Hence, we can infer that political bias often translates into the use of propaganda techniques.

Concerning users posting propaganda content on Reddit, we cannot link them to real entities; however, we can observe them as a community. We find

	Politics
Least Propaganda	(LeftCenter, 34.49%), (Center, 24.81%), (Left, 22.4%), (RightCenter, 3.08%), (Right, 2.91%), (Questionable, 1.44%), (Others, 10.88%)
Most Propaganda	(Left, 39.1%), (LeftCenter, 25.41%), (Center, 17.09%), (Right, 6.92%), (RightCenter, 3.3%), (Questionable, 3.07%), (Others, 5.11%)
	Democrats
Least Propaganda	(LeftCenter, 33.82%), (Left, 27.98%), (Center, 21.74%), (RightCenter, 2.76%), (Right, 0.53%), (Questionable, 0.41%), (Others, 12.78%)
Most Propaganda	(Left, 41.74%), (LeftCenter, 24.44%), (Center, 15.72%), (Right, 1.13%), (RightCenter, 1.05%), (Questionable, 0.4%), (Others, 15.51%)
	Republican
Least Propaganda	(Right, 35.94%), (Questionable, 23.69%), (LeftCenter, 7.67%), (RightCenter, 7.28%), (Center, 6.27%), (Left, 1.98%), (Others, 17.14%)
Most Propaganda	(Right, 41.58%), (Questionable, 29.28%), (RightCenter, 6.58%), (Left, 2.81%), (LeftCenter, 2.58%), (Center, 2.24%), (Others, 14.93%)
	UKPolitics
Least Propaganda	(LeftCenter, 47.66%), (Center, 10.42%), (Right, 3.84%), (Questionable, 2.22%), (RightCenter, 2.18%), (Left, 1.04%), (Others, 32.64%)
Most Propaganda	(LeftCenter, 40.65%), (Right, 11.31%), (Questionable, 6.11%), (Left, 5.33%), (RightCenter, 4.48%), (Center, 3.76%), (Others, 28.37%)
	LabourUK
Least Propaganda	(LeftCenter, 48.87%), (Left, 3.94%), (Center, 3.1%), (RightCenter, 1.69%), (Right, 0.96%), (Questionable, 0.45%), (Others, 40.99%)
Most Propaganda	(LeftCenter, 49.63%), (Left, 10.46%), (RightCenter, 2.7%), (Right, 1.74%), (Center, 1.24%), (Questionable, 0.73%), (Others, 33.5%)
	Tories
Least Propaganda	(LeftCenter, 47.18%), (Right, 9.86%), (Center, 4.93%), (Questionable, 2.11%), (RightCenter, 1.76%), (Left, 1.06%), (Others, 33.1%)
Most Propaganda	(LeftCenter, 28.87%), (Right, 27.11%), (Questionable, 5.63%), (RightCenter, 3.87%), (Center, 2.82%), (Left, 1.06%), (Others, 30.63%)

Table 5: There is a strong relation between the political bias of the media sources and the groups we computed using our propaganda score. For example, on Politics, the majority of media sources are *left center* in the least propaganda group, while the majority of sources are *left* in the most propaganda group.

that the most propaganda group's submissions are created by a smaller number of unique users than the submissions in the least propaganda group, on all subreddits except LabourUK, where we observe the opposite trend. On Politics, the least propaganda group has 9% more unique submitters, on Democrats 5%, on Republican 32%, on UKPolitics 9%, on Tories 10% while on LabourUK the most propaganda group has 28% more unique users that created a submission. This trend might indicate that certain users are more active in publishing propaganda content.

One follow-up question that we ask is how many of these users are bots. The presence of bots could explain why in one group there are fewer users posting articles. While there are several lists of Reddit bots, none of them is complete. Given this, we employ Rest-Sleep-and-Comment (RSC) (Ferraz Costa et al., 2015), a generative method that can distinguish human from bot posting activity. The method receives in input the intervals between two consecutive posts of a user, and these intervals are then compared with the aggregated distributions of intervals of all the users. The authors provide an initial training set of normal users and bots consisting of 37 bots and 999 users, to which we add 94 extra bots to make the model more robust. RSC has an average $F1$-score of 77.3 in cross-validation. The model requires at least 800 consecutive timestamps at which a user has written a comment. We retrieve from our subreddits all the users that posted a submission, and we keep the users for which we could retrieve the required number of timestamps. We note that the timestamps for a user are retrieved such that they represent consecutive chronological posts. Hence we do not restrict the subreddits in which the user might have posted. We find 748 possible bots on Politics, 91 on Democrats, 21 on Republican, 135 on UKPolitics, 23 on LabourUK and 9 on Tories. We investigate if these suspicious users posted a larger percentage of most propaganda articles in comparison with least propaganda articles. We find that this is the case on all subreddits, except Republican. However, the results are not statistically significant $(p > 0.05)$ and the differences are close, as seen in Table 6. Hence, we can conclude that the bots' automatic activity in our dataset is not necessarily linked to posting propaganda content. Also, the small percentage of content in most propaganda group published by the bots shows that the majority of the propaganda content is published by real users.

Subreddit	% articles in LP	% articles in MP
Politics	2.86	3.17
Democrats	7.70	9.13
Republican	2.36	1.95
UKPolitics	3.46	4.19
LabourUK	0.78	1.23
Tories	2.81	3.16

Table 6: The percentage of submissions posted by suspicious users in the least propaganda group (LP) and the most propaganda group (MP)

RQ2. Does propaganda differ across the political spectrum? For this analysis, we will distinguish between US-based subreddits and UK subreddits. We compare these subreddits using our propaganda score. We find that there is a statistically significant difference between the median propaganda score of articles on all subreddits in US ($p < 0.001$), with the most propagandistic content being shared on the subreddit Republican ($median = 0.307$), followed by Democrats ($median = 0.250$), and finally Politics ($median = 0.222$). In the UK subreddits, UKPolitics ($median = 0.214$) and Tories ($median = 0.217$) contains less propaganda than LabourUK ($median = 0.257$). There is no statistical difference between UKPolitics and Tories, tested using Kruskal–Wallis one-way analysis of variance, followed by Conover posthoc tests. These results indicate that *right leaning forums are not more likely to post propaganda than left leaning*. However, the tendance of using propaganda could result from the popularity of the respective party in the country. The Conservative Party in the UK has been in government since 2010, and a 2019 survey showed the party 15 points ahead of the Labour party. Even if the Republican party in the US won the White House in 2016, it didn't win the popular vote, and according to surveys more Americans identify as democrats. We also note that the subreddits that don't claim any political affiliation, Politics and UKPolitics, have less propagandistic content, which is consistent with the results in Table 5.

A second question is if the propaganda techniques employed differ according to the subreddits' political leaning or according to the country. We annotate using our propaganda technique identification classifier the sentences we previously labeled as propaganda to test this. We restrict ourselves to articles in the group most propaganda, using the intuition that if many sentences in the same article raise flags in the classifier, it is more likely that the article contains propaganda. For each subreddit, we rank the propaganda techniques by their frequency. We find that the relative ranking of techniques does not differ much between subreddits from the same country. The top 5 most frequent techniques are in the US *loaded language, name-calling, exaggeration or minimization, flag waving, doubt*, while in the UK based subreddits we have *loaded language, name calling, doubt, appeal to fear or prejudice, exaggeration or minimization*. Given the low accuracy of our technique classifier, we cannot make any definitive claims. However, such differences between the subreddits discussing politics in the two countries are plausible when considering the cultural differences. For example, Americans might be more susceptible to flag-waving, the technique of using patriotic feelings to justify an action. In 2017, 67% of Americans believed that the US is the leader of the free world according to a survey by the Public Broadcasting Service.

RQ3. How is propaganda received on political forums? To answer this last question, we aim to understand if more propaganda content will create more engagement. On Reddit, engagement is measured in the number of comments or the number of votes.

Firstly, we investigate if users comment more on submissions with higher propaganda score. We compare the median number of comments between the least propaganda group and the most propaganda group for each subreddit using the one sided Mann–Whitney U test. We find that on Politics, Democrats, Republican, UKPolitics and LabourUK, submissions in the most propaganda group receive more comments, while on Tories we observe the opposite effect.

We usually associate propaganda with media outlets. However, people can employ the same techniques to persuade the audience. We investigate how comments with propagandistic undertones are received on Reddit. For this we look at the comment's score, which is the difference between the upvotes and downvotes that a comment received. We construct two groups of comments: *positively received* comments that have the $score \geq t_{pos} \geq 10$, and *negatively received* comments with the score $score \leq t_{neg} \leq -5$. We compute the average propaganda score in the positively and negatively received groups while increasing the absolute value of the thresholds (t_{pos} from 10 to 50 and t_{neg} from -5 to -50), as shown in Figure 1. We observe that the average propaganda score of a comment increases with the engagement it generates, measured as the number of upvotes or downvotes it received. However, the trend is not observed on Republican and on Tories, one of the smaller subreddits for which we have very few data points in the plot.

7 Conclusion

In this work, we perform an extensive analysis of propaganda on online forums. We study for one year six subreddits from two English-speaking

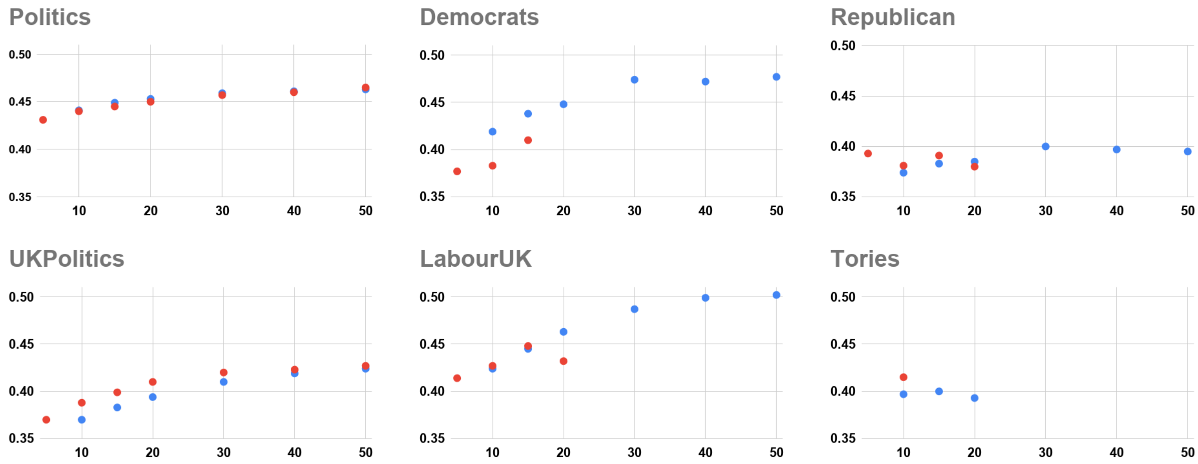

Figure 1: The average propaganda score in the positively received (blue) and negatively received (red) groups, while increasing the absolute value of the threshold. A data point represents a group with more than 100 comments.

countries, the US and the UK. We find several interesting patterns that can be leveraged by Reddit users and moderators to create better online discussions. We have found trends that we believe were not observed before in the literature. For example: *i*) the parties which represent a minority in a country might tend to use more propaganda; *ii*) political bias (either towards the right or the left) might be an indication of propaganda; *iii*) users that post more biased content form smaller communities; *iv*) differences in the use of propaganda techniques across countries might be rooted in cultural differences; *v*) submissions and comments having more propaganda content tend to receive more engagement in the form of number of comments, upvotes or downvotes. We note that while we have thoroughly tested all our hypotheses, our work is based on the automatic labelling of submissions and comments, with all the imprecision of such a method. We believe that understanding how propaganda affects us is of utmost importance for ensuring we live in democratic societies.

Abstract

Contextualised word representation models have been successfully used for capturing different word usages, and they may be an attractive alternative for representing idiomaticity in language. In this paper, we propose probing measures to assess if some of the expected linguistic properties of noun compounds, especially those related to idiomatic meanings, and their dependence on context and sensitivity to lexical choice, are readily available in some standard and widely used representations. For that, we constructed the Noun Compound Senses Dataset, which contains noun compounds and their paraphrases, in context neutral and context informative naturalistic sentences, in two languages: English and Portuguese. Results obtained using four types of probing measures with models like ELMo, BERT and some of its variants, indicate that idiomaticity is not yet accurately represented by contextualised models.

1 Introduction

Contextualised word representation models, like BERT (Devlin et al., 2019) and ELMo (Peters et al., 2018), seem to represent words more accurately than static word embeddings like GloVe (Pennington et al., 2014), as they can encode different usages of a word. In fact, representations of a word in several contexts can be grouped in different clusters, which seem to be related to the various senses of the word (Schuster et al., 2019), and they can be used to match polysemous words in context to specific sense definitions (Chang and Chen, 2019). However, multiword expressions (MWEs) fall into a continuum of idiomaticity[1] (Sag et al., 2002; Fazly et al., 2009; King and Cook, 2017) and their meanings may not be directly related to the meanings of their individual words (e.g., *graduate student* vs. *eager beaver* as a hardworking person). Therefore, one question is whether and to what extent idiomaticity in MWEs is accurately incorporated by word representation models.

In this paper, we propose a set of probing measures to examine how accurately idiomaticity in MWEs, particularly in noun compounds (NCs), is captured in vector space models, focusing on some widely used representations. Inspired by the semantic priming paradigm (Neely et al., 1989), we have designed four probing tasks to analyse how these models deal with some of the properties of NCs, including non-compositionality (*big fish* as an important person), non-substitutability (*panda car* vs. *bear automobile*), or ambiguity (*bad apple* as either a rotten fruit or a troublemaker), as well as the influence of context in their representation. To do so, we have created the new Noun Compound Senses (NCS) dataset, containing a total of 9,220 sentences in English and Portuguese. This dataset includes sentence variants with (i) synonyms of the original NCs; (ii) artificial NCs built with synonyms of each component; or (iii) either the head or the modifier of the NC. Moreover, it is composed of naturalistic and controlled sense-neutral sentences, to minimise the possible effect of context words.

We compare five models (one static, GloVe, and four contextualised, ELMo and three BERT-based models) in English and Portuguese. The probing measures suggest that the standard and widely adopted composition operations display a limited ability to capture NC idiomaticity.

Our main contributions are: (i) the design of novel probes to assess the representation of id-

---

[1] We understand idiomaticity as *semantic opacity* and its continuum as different *degrees of opacity* (Cruse, 1986).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3551–3564
April 19 - 23, 2021.

iomaticity in vector models, (ii) a new dataset of NCs in two languages, and (iii) their application in a systematic evaluation of vector space models examining their ability to display behaviors linked to idiomaticity.

The remainder of this paper is organized as follows: First, Section 2 presents related work. Then, we describe the data and present the probing measures in Section 3. In Section 4, we discuss the results of our experiments. Finally, the conclusions of our study are drawn in Section 5.

2 Related Work

Priming paradigms have been traditionally used in psycholinguistics to examine how humans process language. For compounds, some findings suggest that idiomatic expressions are processed more slowly than semantically transparent ones, as processing the former may involve a conflict between the non-compositional and the compositional meanings (Gagné and Spalding, 2009; Ji et al., 2011). However, studies using event-related potential (ERP) data showed that idiomatic expressions, especially those with a salient meaning (Giora, 1999), have processing advantages (Laurent et al., 2006; Rommers et al., 2013). In NLP, probing tasks have been useful in revealing to what extent contextualised models are capable of learning different linguistic properties (Conneau et al., 2018). They allow for more controlled settings, removing obvious biases and potentially confounding factors from evaluations, and allowing both the use of artificially constructed but controlled sentences and naturally occurring sentences (Linzen et al., 2016; Gulordava et al., 2018). In priming tasks, related stimuli are easier to process than unrelated ones. One assumption is that, for models, related stimuli would achieve greater similarity than unrelated stimuli. These tasks have been used, for instance, to evaluate how neural language models represent syntax (van Schijndel and Linzen, 2018; Prasad et al., 2019), and the preferences that they may display, such as the use of mainly lexical information in a lexical substitution task even if contextual information is available (Aina et al., 2019).

Concerning pre-trained neural language models, which produce contextualised word representations, analyses about their abilities have shown, for instance, that they can encode syntactic information (Liu et al., 2019) including long-distance subject–verb agreement (Goldberg, 2019). Regarding semantic knowledge, the results of various experiments suggest that BERT can somewhat represent semantic roles (Ettinger, 2020). However, its improvements appear mainly in core roles that may be predicted from syntactic representations (Tenney et al., 2019). Moreover, from the representations generated by BERT, ELMo and Flair (Akbik et al., 2018) for word sense disambiguation, only the clusters of BERT vectors seem to be related to word senses (Wiedemann et al., 2019), although in cross-lingual alignment of ELMo embeddings, clusters of polysemous words related to different senses have also been observed (Schuster et al., 2019).

The use of contextualised models for representing MWEs has been reported with mixed results. Shwartz and Dagan (2019) evaluated different classifiers initialised with contextualised and non-contextualised embeddings in five tasks related to lexical composition (including the literality of NCs) and found that contextualised models, especially BERT, obtained better performance across all tasks. However, for capturing idiomaticity in MWEs, static models like *word2vec* (Mikolov et al., 2013) seem to have better performance than contextualised models (Nandakumar et al., 2019; King and Cook, 2018). These mixed results suggest that a controlled evaluation setup is needed to obtain comparable results across models and languages.

Therefore, we have carefully designed probing tasks to assess the representation of NCs in vector space models. As the same word can have different representations even in related paraphrased contexts (Shi et al., 2019), we adopt paraphrases with minimal modifications to compare the idiomatic and literal representations of a given NC.

3 Materials and Methods

3.1 Noun Compound Senses Dataset

The Noun Compound Senses (NCS) dataset is based on the NC Compositionality dataset, which contains NCs in English (Reddy et al., 2011), Portuguese and French (Cordeiro et al., 2019). Using the protocol by Reddy et al. (2011), human judgments were collected about the interpretation of each NC in 3 naturalistic corpus sentences. The task was to judge, for each NC, how literal the contributions of its component were for its meaning (e.g., "Is *climate change* truly/literally a *change* in *climate*?"). Each NC got a score, which was the average of the human judgments with a *Likert* scale from 0 (non-literal/idiomatic) to 5 (literal/compositional).[2]

For the NCS dataset, a set of probing sentences for the 280 NCs in English and the 180 NCs in Portuguese was added. For each NC, the sentences exemplify two conditions: (i) the naturalistic context provided by the original sentences (NAT), and (ii) a neutral context where the NCs appear in uninformative sentences (NEU). For the latter we use the pattern *This is a/an <NC>* (e.g., *This is an eager beaver*) and its Portuguese equivalent *Este/a é um(a) <NC>*. As some NCs may have both compositional and idiomatic meanings (e.g., *fish story* as either *an aquatic tale* or *a big lie*), these neutral contexts will be used to examine the representations that are generated for the NCs (and the sentences) in the absence of any contextual clues about the meaning of the NC. Moreover, they enable examining possible biases in the NC representation especially when compared to the representation generated for the NAT condition.

For each NC and condition, we created new sentence variants with lexical replacements, using synonyms of the NC as a whole or of each of its components. The synonyms of the NCs are the most frequent synonyms provided by the annotators of the original NC Compositionality dataset (e.g., *brain* for *grey matter*). The synonyms of each component were extracted from WordNet (Miller, 1995, for English) and from English and Portuguese dictionaries of synonyms (e.g., *alligator* for *crocodile* and *sobs* for *tears*). In cases of ambiguity (due to polysemy or homonymy), the most common meaning of each component was used. Experts (native or near-native speakers with linguistics background) reviewed these new utterances, keeping them as faithful as possible to the original ones, but with small modifications for preserving grammaticality after the substitution (e.g., modifications in determiners and adjectives related to gender, number and definiteness agreement).

NCS contains a total of 5,620 test items for English and 3,600 for Portuguese among neutral and naturalistic sentences, and it is freely available.[3]

3.2 Probing Measures

This section presents the probing measures defined to assess how accurately idiomaticity is captured in vector space models. For these measures we consider comparisons between three types of embeddings: (i) the embedding for an NC out of context (i.e. the embedding calculated from the NC words alone), represented by ϵ_{NC}; (ii) the embedding for an NC in the context of a sentence S, represented by $\epsilon_{\text{NC} \subset \text{S}}$[4] (iii) finally, the sentence embedding that contains an NC, which is represented by $\epsilon_{\text{S} \supset \text{NC}}$. Here we use the standard output of some widely used models with no fine-tuning to avoid possible interference. However, in principle, these measures could apply to any embedding even after fine-tuning.

The similarities between embeddings are calculated in terms of cosine similarity: $\cos(\epsilon, \epsilon')$ where ϵ and ϵ' are embeddings from the same model with the same number of dimensions. In NAT cases, the similarity scores for each of the three available sentences for a given NC are averaged to generate a single score. We use Spearman ρ correlation between similarities and the NC idiomaticity scores (280 for English and 180 for Portuguese) to check for any effects of idiomaticity in the probing measures. We also calculate Spearman ρ correlation between different embedding models to determine how much the models agree, and between the NAT and NEU conditions to see how much the context affects the distribution of similarities. We also analyse the distribution of cosine similarities produced by different models for each of the probing measures. All probing measures are calculated for both NAT and NEU conditions.

P1: Probing the similarity between an NC and its synonym. If a contextualised model captures idiomaticity accurately, the embedding for a sentence containing an NC should be similar to the embedding for the same sentence containing a synonym of the NC (NC_{syn}, e.g., for *grey matter*, NC_{syn} = *brain*). Thus, $\text{sim}^{(\text{P1})}_{\text{Sent}} \simeq 1$, where $\text{sim}^{(\text{P1})}_{\text{Sent}} = \cos(\epsilon_{\text{S} \supset \text{NC}}, \epsilon_{\text{S} \supset \text{NC}_{syn}})$. This should occur regardless of how idiomatic the NC is, that is, similarity scores are not expected to correlate with NC idiomaticity scores ($\rho^{(\text{P1})}_{\text{Sent}} \simeq 0$). Moreover, this should also hold for the NC and NC_{syn} embeddings generated in the context of this sentence, which means that $\rho^{(\text{P1})}_{\text{NC}} \simeq 0$ and $\text{sim}^{(\text{P1})}_{\text{NC}} \simeq 1$

---

[2] We averaged the Likert judgments for comparability with previous work, even though the median may reflect better the cases where there is more disagreement among the annotators. However, both mean and median are strongly correlated in our data: $\rho = 0.98$ (English) and $\rho = 0.96$ (Portuguese), $p < 0.001$.

[4] For non-contextualised embeddings $\epsilon_{\text{NC} \subset \text{S}} = \epsilon_{\text{NC}}$.

Naturalistic sentence	NC	NC$_{syn}$	NC$_{synW}$
***Field work** and practical archaeology are a particular focus.*	field work	research	area activity
*The town centre is now deserted - it's almost like a **ghost town**!*	ghost town	abandoned town	spectre city
*How does it feel to experience a **close call** only to come out alive and kicking?*	close call	scary situation	near claim
*Eric was being an **eager beaver** and left work late.*	eager beaver	hard worker	restless rodent
*No wonder Tom couldn't work with him; he is a **wet blanket**.*	wet blanket	loser	damp cloak

Table 1: Naturalistic examples with their NC$_{syn}$ and NC$_{synW}$ counterparts.

where $\text{sim}^{(\text{P1})}_{\text{NC}} = \cos(\epsilon_{\text{NC} \subset \text{S}}, \epsilon_{\text{NC}_{syn} \subset \text{S}})$. The baseline similarity scores can be approximated using the out-of-context embeddings for NC and NC$_{syn}$.

P2: Probing single component meaning preservation. As the meaning of a more compositional compound can be inferred from the meanings of its individual components, we evaluate to what extent an NC can be replaced by one of its component words and still be considered as representing a similar usage in a sentence. We measure $\text{sim}^{(\text{P2})}_{\text{Sent}} = \cos(\epsilon_{\text{S} \supset \text{NC}}, \epsilon_{\text{S} \supset \text{w}_i})$ and $\text{sim}^{(\text{P2})}_{\text{NC}} = \cos(\epsilon_{\text{NC} \subset \text{S}}, \epsilon_{\text{w}_i \subset \text{S}})$, where w_i is the component word (head or modifier) with the highest similarity, as for some NCs the main meaning may be represented by either its head or modifier. Similarity scores for idiomatic NCs should be low as they usually cannot be replaced by any of its components. In contrast, for more compositional NCs, the similarity is expected to be higher. For example, while for a more compositional NC like *white wine*, the head *wine* would provide a reasonable approximation as w_i, the same would not be the case for *grey matter*, a more idiomatic NC. Therefore, we expect significant correlations between the similarity values and the NC idiomaticity scores, that is $\rho^{(\text{P2})}_{\text{Sent}} > 0$ and $\rho^{(\text{P2})}_{\text{NC}} > 0$.

P3: Probing model sensitivity to disturbances caused by replacing individual component words by their synonyms. We examine whether vector representations are sensitive to the lack of individual substitutability of the component words displayed by idiomatic NCs (Farahmand and Henderson, 2016). To compare an NC with an expression made from synonyms of its component words (NC$_{synW}$, e.g., for *grey matter*, NC$_{synW}$ = *silvery material*), we measure $\text{sim}^{(\text{P3})}_{\text{Sent}} = \cos(\epsilon_{\text{S} \supset \text{NC}}, \epsilon_{\text{S} \supset \text{NC}_{synW}})$ and $\text{sim}^{(\text{P3})}_{\text{NC}} = \cos(\epsilon_{\text{NC} \subset \text{S}}, \epsilon_{\text{NC}_{synW} \subset \text{S}})$. These substitutions should provide more similar variants for compositional than for idiomatic cases, and the similarity scores should correlate to the NC idiomaticity scores, that is $\rho^{(\text{P3})}_{\text{Sent}} > 0$ and $\rho^{(\text{P3})}_{\text{NC}} > 0$.

P4: Probing the similarity between the NC in the context of a sentence and out of context. To determine how much for a given model an NC in context differs from the same NC out of context we measure $\text{sim}^{(\text{P4})}_{\text{in-out}} = \cos(\epsilon_{\text{NC} \subset \text{S}}, \epsilon_{\text{NC}})$. We expect similarity scores to be higher in the NEU condition, given their semantically vague context, than for the NAT condition.

3.3 Calculating Embeddings

We use as a baseline the static non-contextualised GloVe model (Pennington et al., 2014) and, for contextualised embeddings, four widely adopted models: ELMo (Peters et al., 2018), BERT (Devlin et al., 2019), and two BERT variants, DistilBERT (DistilB) (Sanh et al., 2019) and Sentence-BERT (SBERT) (Reimers and Gurevych, 2019b). For all the contextualised models, we use their pre-trained weights publicly available through the Flair implementation[5]. For GloVe, the English and Portuguese models described in Pennington et al. (2014) and Hartmann et al. (2017). For ELMo, we use the small model provided by Peters et al. (2018), and for Portuguese we adopt the weights provided by Quinta de Castro et al. (2018). For all BERT-based models, we used the multilingual models for both English and Portuguese.[6]

To have a single embedding for the whole sentence or its parts, e.g., the NC representation, we use the standard procedure of averaging the vectors of the involved tokens.[7] In GloVe and ELMo, we average the output embeddings of each word, while in BERT-based models we obtain the final vector by averaging those of the sub-tokens (e.g., 'wet', 'blank' and '##et' for *wet blanket*).

Different combinations of the last five layers were probed in BERT-based models. However, they led to qualitatively similar results, and for reasons of presentation clarity, have been omitted

---

[5] `https://github.com/flairNLP/flair`

[6] We also investigated dedicated models for English, however, for allowing a more direct comparison between the languages, we report results only for the multilingual models.

[7] We discuss other operations in section 4.6.

from the discussion. We focus on embeddings calculated from a combination of the last four layers as they have been found to be representative of the other combinations. For ELMo, as it is intended to serve as a contextualised baseline, we represent the word embeddings using the concatenation of its three layers, albeit it is known that separate layers and weighting schemes generate better results in downstream tasks (Reimers and Gurevych, 2019a).

4 Results

This section discusses our results for each probing measure, using cosine similarities and Spearman ρ correlations. A qualitative analyses is also presented where we compare BERT and GloVe results of the five NCs in Table 1 (which shows the naturalistic sentences for each NC, together with their respective NC_{syn} and NC_{synW})[8]. We also discuss the average results of other NCs in both conditions and these results and other examples can be found in the Appendix.

4.1 Can contextualised models capture the similarity between an NC and its synonym?

If a contextualised model successfully captures idiomaticity, we would expect (i) high cosine similarity between a sentence containing an NC and its variant using a synonym of the NC (P1), and (ii) little or no correlation with the NC idiomaticity score. The results confirm high similarity values for all models, as shown in Figure 1a. However, this is not the case if we consider only the embeddings in context for NC and NC_{syn}, which display a larger spread of similarity values (see Figure 1b). Moreover, contrary to what was expected, a moderate correlation was found between most models and the idiomaticity scores (P1 in Table 2), indicating lower similarity scores for idiomatic than for compositional cases, for both NAT and NEU conditions.

Even though the high $\text{sim}^{(\text{P1})}_{\text{Sent}}$ values seem to suggest idiomaticity is captured, lower $\text{sim}^{(\text{P1})}_{\text{NC}}$ and moderate correlations with idiomaticity scores contradict it. Therefore a possible explanation for high similarities for Sent may be the effect of the overlap in words between a sentence and its variant (i.e., the context in Sent). This is also compatible with the larger similarities observed for NAT than for NEU condition since the average sentence length for the naturalistic sentences is 23.39 for English and 13.03 for Portuguese, while for the neutral it is five words for both languages. Moreover, a similar performance was also obtained with GloVe.[9] It is also worth noting that, in contrast to static embeddings, contextualised word representations are anisotropic, occupying a narrow cone in the vector space and therefore tending to produce higher cosine similarities (Ethayarajh, 2019).

The results with the first probing measure show that even though the similarities can be relatively high, they are consistently lower for idiomatic than for compositional cases, suggesting that idiomaticity may not be fully incorporated in the models.

Qualitative analysis: In Table 3, in P1, the similarity scores between NC in Table 1 and their respective NC_{syn} for BERT and GloVe models are shown. As expected, BERT shows higher scores than GloVe for all cases, and even if the values for P1 differ, both models follow the same tendency. There is a larger spread for GloVe (e.g., $\text{sim}^{(\text{P1})}_{\text{wet blanket}} = 0.21$ vs. $\text{sim}^{(\text{P1})}_{\text{ghost town}} = 0.80$) which could be explained by the choices of NC_{syn}. For *wet blanket* NC_{syn} = *loser*, which has probably a very dissimilar representation from both *wet* and *blanket*. On the other hand, *ghost town* with NC_{syn} = *abandoned town* not only shares a word with the original NC, but we can also argue that *ghost* and *abandoned* are likely to have similar embeddings. Finally, the average results of P1 show that BERT-based models tend to intensify lexical overlap, resulting in high cosine similarities when both the NC and NC_{syn} share (sub-)words. For instance, 47 (in English) and 49 (in Portuguese) out of the 50 compounds with highest $\text{sim}^{(\text{P1})}_{\text{NC-NAT}}$ share surface tokens, whether the NCs are more compositional (e.g., *music journalist* vs. *music reporter*) or more idiomatic (e.g., *ghost town* vs. *abandoned town*).

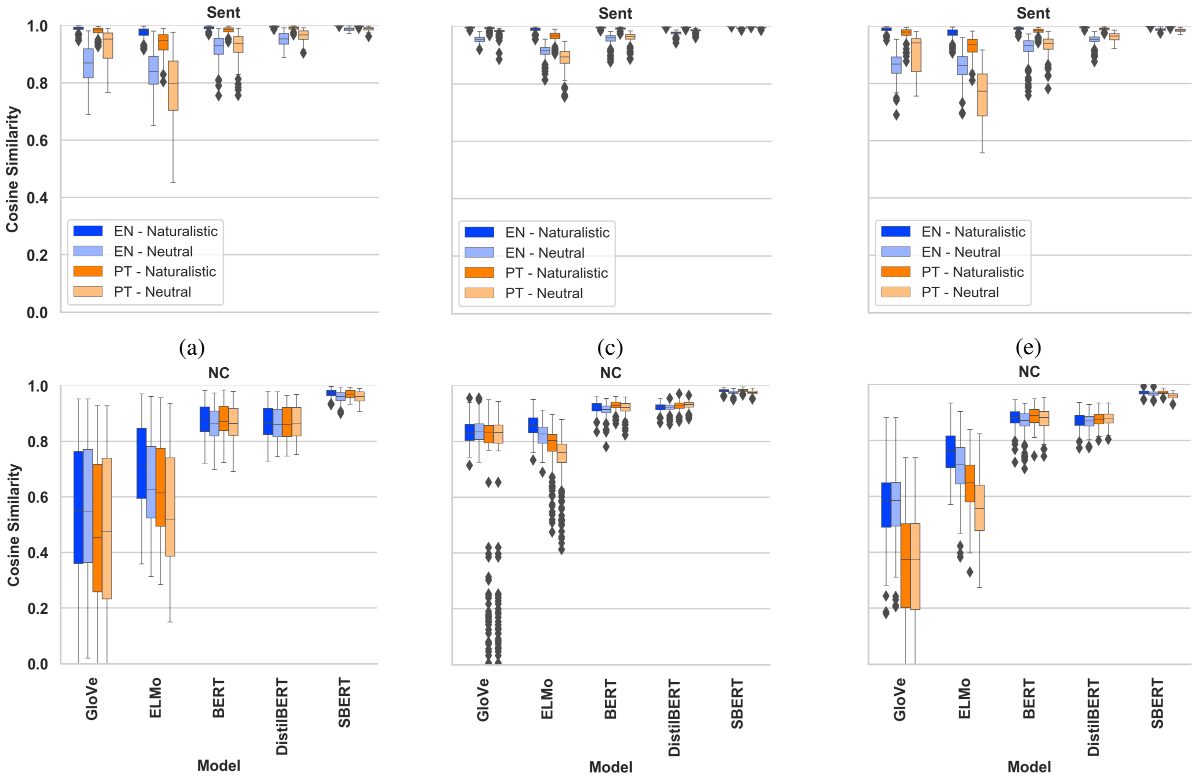
4.2 Can the lower semantic overlap between idiomatic NCs and their individual components be captured?

We would expect idiomatic NCs not to be similar to either of their individual components, which would be reflected by a larger spread of cosine similarity values for P2 than for P1. However, all models produced high similarities across the idiomaticity spectrum, see Figures 1c for Sent and 1d for NC.

---

[8] Neutral sentences are omitted since they all follow the same pattern *This is a/an* <NC>.

[9] GloVe-NC can be viewed as the baseline for the lack of contextual information.



(a) (c) (e)

(b) (d) (f)

Figure 1: Cosine similarities in English (blue) and Portuguese (orange). First column for PI (a and b), second for P2 (c and d) and third for P3 (e and f). Sentence condition at the top and NC at the bottom.

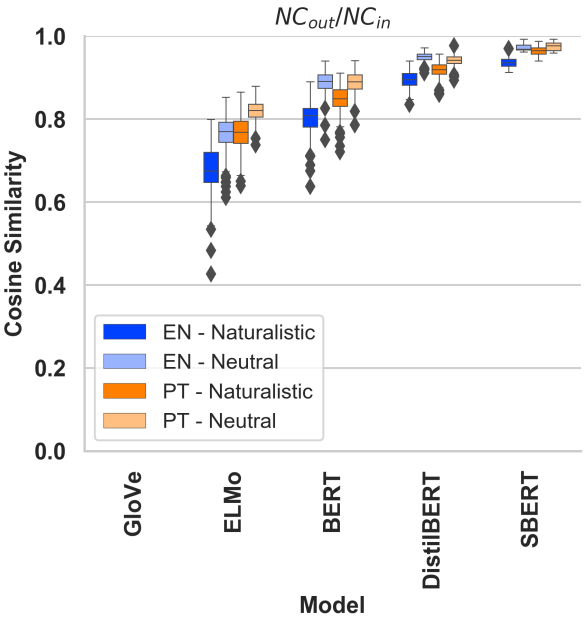


Figure 2: P4 ($\cos(\epsilon_{\text{NC} \subset \text{S}}, \epsilon_{\text{NC}})$).

The higher average similarities for P2 than for P1, compare Figures 1a and 1b with Figures 1c and 1d, reinforces the hypothesis that the models prioritise lexical overlap with one of the NC components rather than semantic overlap with a true NC synonym, even for idiomatic cases. Although there is some correlation with idiomaticity when it exists, it is lower than for P1, contrary to what would be expected (see P1 and P2 in Table 2). All of these indicate that these models cannot distinguish the partial semantic overlap between more compositional NCs and their components and the absence of overlap for idiomatic NCs.

Qualitative analysis: The P2 results in Table 3 show the highest similarity scores between each example in Table 1 and one of its components. These high similarity scores highlight the prioritisation of lexical over semantic overlap mentioned above. Furthermore, some idiomatic NCs also show strong similarities with their components, suggesting that the idiomatic meaning is not correctly represented. For instance, *poison pill* (meaning an emergency exit) has an average similarity of $\text{sim}^{(P2)}_{\text{poison pill-NAT}} = 0.94$ with its head (*pill*).

4.3 Can they capture the lack of substitutability of individual components for idiomatic NCs?

We do not expect an idiomatic NC to keep the idiomatic meaning when each of its components is

Table 3: Similarities results from P1 to P3 at NC level of the examples in Table 1. In P2, number in parenthesis corresponds to the position of the w_i with highest similarity score in the NC.

individually replaced by synonyms, and this would be reflected in lower similarity values for P3 than for P1. However, high similarity values are found across the idiomaticity spectrum, and for all models and all conditions the average similarities are higher than those for P1 (see Figures 1e and 1f). Contrary to what would be expected, the correlations with idiomaticity scores are mostly nonexistent, and when they do exist they are much lower than for P1, (see P1 and P3 in Table 2).

The overall picture painted by P3 points towards contextualised models not being able to detect when a change in meaning takes place by the substitution of individual components by their synonyms.

Qualitative analysis: For P3, Table 3 shows the similarities scores at NC level between each NC and their NC_{synW} counterpart. Again, similarity scores for GloVe are considerably lower than for BERT. As expected for GloVe, $\text{sim}^{(\text{P3})}_{\text{wet blanket}} = 0.69$ is noticeably higher than $\text{sim}^{(\text{P1})}_{\text{wet blanket}} = 0.21$, since individually the words *damp* and *cloak* are closer in meaning to *wet* and *blanket*, respectively, than *loser* is. Another evidence that contextualised models are not modelling idiomaticity well is, for NAT cases, the considerably higher $\text{sim}^{(\text{P3})}_{\text{wet blanket}} = 0.91$ in comparison to $\text{sim}^{(\text{P1})}_{\text{wet blanket}} = 0.77$, for BERT. Although for the other NCs, $\text{sim}^{(\text{P3})}_{\text{NC}}$ and $\text{sim}^{(\text{P1})}_{\text{NC}}$ are comparable, the special case of the more idiomatic *wet blanket* highlights the issues of idiomaticity representation.

4.4 Is there a difference between an NC in and out of context?

For contextualised models, the greater the influence of the context, the lower we would expect the similarity to be between an NC in and out of context. However, especially for BERT models the results (Figure 2) show a high similarity between the NC in and out of context ($\text{sim}^{(\text{P4})}_{\text{in-out}} > 0.8$). Moreover, a comparison with the similarities for the synonyms in P1 resulted in $\text{sim}^{(\text{P4})}_{\text{in-out-NEU}} > \text{sim}^{(\text{P1})}_{\text{NC-NEU}}$ and $\text{sim}^{(\text{P4})}_{\text{in-out-NAT}} \simeq \text{sim}^{(\text{P1})}_{\text{NC-NAT}}$, which indicates that these models consider the NC out of context to be a better approximation for the NC in context than its synonym. In addition, for BERT models $\text{sim}^{(\text{P4})}_{\text{in-out}}$ is only weakly correlated with the idiomaticity score (Table 4), which suggests that the context may not play a bigger role for idiomatic than it does for more compositional NCs.

Qualitative analysis: The $\text{sim}^{(\text{P4})}_{\text{in-out}}$ of the examples in Table 1 ranged from 0.78 (for *ghost town*) to 0.87 (*field work*) in the NAT condition, and from 0.84

	ELMo	BERT	DistilB	SBERT	BTRAM

EN_{NEU}	-	-	0.24	-0.24	-0.14
PT_{NAT}	0.25	0.17	0.18	-	0.21
PT_{NEU}	-	-	0.15	-	-

Table 4: Spearman ρ correlation with human judgments for P4, $p \leq 0.05$. Non-significant results are omitted.

(also for *ghost town*) to 0.90 (*eager beaver* and *wet blanket*) in the neutral sentences for BERT.[10] Together with these examples, the general results of P4 show large differences not explained by the semantic compositionality of the NCs, as suggested by the weak correlation with the idiomaticity scores. In this respect, both the largest and smallest differences between $\text{sim}^{(P4)}_{\text{in-out}}$ in NAT and NEU conditions appear in compositional NCs (*engine room* with $\text{sim}^{(P4)}_{\text{in-out-NAT}} = 0.68$, $\text{sim}^{(P4)}_{\text{in-out-NEU}} = 0.89$, and *rice paper* with $\text{sim}^{(P4)}_{\text{in-out-NAT}} = 0.84$, $\text{sim}^{(P4)}_{\text{in-out-NEU}} = 0.86$).

Besides, we expected ambiguous compounds such as *bad apple* or *bad hat* to have large $\text{sim}^{(P4)}_{\text{in-out}}$ differences between both conditions, as they occur with an idiomatic meaning in the NAT sentences. However, the differences were of just 0.06 in both cases, while other less ambiguous idiomatic NCs showed higher variations (e.g., *melting pot*, with 0.16). In sum, the results of P4 suggest that contextualised models do not properly represent some NCs.

4.5 But how informative are the contexts?

As the neutral sentences do not provide informative contextual clues, if the NCs in NAT and NEU conditions are similar, this would provide an additional indication that for these models contexts are not playing an important role in distinguishing usages (in this case between a neutral and uninformative usage and a naturalistic one). Indeed, the two conditions follow the same trends in the two languages, see Figure 1. Furthermore, there are significant correlations between NAT and NEU conditions, and some are very strong correlations. For example, for SBERT the correlations between the NC in context in naturalistic and neutral conditions are $\rho^{(P1,P2,P3)}_{\text{NC(Nat/Neu)}} > 0.85$ for English and > 0.76 for Portuguese, for probes P1, P2 and P3. This indicates that to evaluate the effect of the variants in each of these probes, a neutral sentence is as good as a naturalistic one. This reinforces the possibility that these models do not adequately incorporate the context in a way that captures idiomaticity.

In terms of the similarity between a sentence and its variants, as we assumed that the representation of a sentence corresponds to the average of the individual components, sentence length may have a strong impact on cosine similarity. This would explain the high values obtained for sentence similarities throughout the probes, as they could be more the effect of the number of words in a sentence than of their semantic similarity. Indeed, the correlation between naturalistic sentence length and the cosine similarities for the first three probes is moderate to strong for all models (Table 5), and higher for some of the contextualised models than for the baseline (e.g., DistilB in English and P2).

4.6 Other Operations

As referred in section 3.3 we have used vector averaging to obtain the NC embedding, as it is the standard procedure to represent not only MWEs but also out-of-vocabulary words, which are split into sub-tokens in contextualised models (Nandakumar et al., 2019; Wiedemann et al., 2019). However, we have also explored other methods to represent NCs in a single vector.

First, we have incorporated type-level vectors of the NCs into a BERT model, inspired by compositionality prediction methods (Baldwin et al., 2003; Cordeiro et al., 2019). To do so, we annotated the target NCs in large English and Portuguese corpora (Baroni et al., 2009; Wagner Filho et al., 2018) and used attentive mimicking with one-token-approximation (Schick and Schütze, 2019, 2020b) to learn up to 500 contexts for each NC. These new vectors encode each NC in a single representation, therefore avoiding possible biases produced by the compositional operations. Then, we used BERTRAM (Schick and Schütze, 2020a) to inject these type-level vectors in the BERT multilingual model. As expected, learning the vectors

---

[10] For Glove, $\text{sim}^{(P4)}_{\text{in-out}} = 1$.

of the NCs as single tokens improved the representation of idiomatic expressions (see BERTRAM in Tables 2 and 4), decreasing the correlation with idiomaticity in P1 (e.g., $\rho^{(P1)}_{\text{NC-NAT}} = 0.30$ in English), and increasing it in P2 ($\rho^{(P2)}_{\text{NC-NAT}} = 0.45$) and P3 ($\rho^{(P3)}_{\text{NC-NAT}} = 0.39 > \rho^{(P1)}_{\text{NC-NAT}}$). For P4, the correlation also increased in NAT contexts. In sum, these results were in general better and more statistically significant (at the expense of re-training a model).

Second, we compared the performance of averaging vs. concatenating the vectors of the NC subwords. In this case, we selected those utterances in English including NCs with the same number of sub-words of their synonyms (273 sentences), thus allowing for vector concatenation. Using this operation instead of average slightly improved the results of the BERT-based models (e.g., ≈0.06 higher correlations on average for P3 NAT) and obtained more significant values.

As the latter approach does not involve retraining a model, in further work we plan to probe other concatenation and pooling methods able to compare MWEs with different number of input vectors (e.g., *grey matter* vs. *brain*) which have achieved good results in sentence embeddings (Rücklé et al., 2018).

5 Conclusions

This paper presented probing tasks for assessing the ability of vector space models to retain the idiomatic meaning of NCs in the presence of lexical substitutions and different contexts. For these evaluations, we constructed the NCS dataset, with a total of 9,220 sentences in English and Portuguese, including variants with synonyms of the NC and of each of its components, in neutral and naturalistic sentences. The probing tasks revealed that contextualised models may not detect that idiomatic NCs have a lower degree of substitutability of the individual components when compared to more compositional NCs. This behaviour is similar in the controlled neutral and naturalistic conditions both in English and Portuguese.

The next steps are to extend the probing strategy with additional measures that go beyond similarities and correlations. Moreover, for ambiguous NCs, we intend to add probes for the different senses. Finally, we also plan to apply them to more languages, examining how multilingual information can be used to refine the representation of noun compounds and other MWEs.

Is the Understanding of Explicit Discourse Relations Required in Machine Reading Comprehension?

Abstract

An in-depth analysis of the level of language understanding required by existing Machine Reading Comprehension (MRC) benchmarks can provide insight into the reading capabilities of machines. In this paper, we propose an ablation-based methodology to assess the extent to which MRC datasets evaluate the understanding of explicit discourse relations. We define seven MRC skills which require the understanding of different discourse relations. We then introduce ablation methods that verify whether these skills are required to succeed on a dataset. By observing the drop in performance of neural MRC models evaluated on the original and the modified dataset, we can measure to what degree the dataset requires these skills, in order to be understood correctly. Experiments on three large-scale datasets with the BERT-base and ALBERT-xxlarge model show that the relative changes for all skills are small (less than 6%). These results imply that most of the answered questions in the examined datasets do not require understanding the discourse structure of the text. To specifically probe for natural language understanding, there is a need to design more challenging benchmarks that can correctly evaluate the intended skills[1].

1 Introduction

Machine Reading Comprehension (MRC) is concerned with the automatic extraction and generation of answers over unstructured textual data. Due to its complexity, the task is seen as suitable for evaluating Natural Language Understanding (NLU) (Chen, 2018). While neural MRC systems achieve impressive performance (Devlin et al., 2019; Lan et al., 2020), it has been revealed by some research efforts that existing MRC benchmarks might be insufficient to establish model performance, i.e., that the models are not being assessed for their capabilities to read and comprehend (Jia and Liang, 2017; Mudrakarta et al., 2018; Min et al., 2018; Sugawara et al., 2018; Feng et al., 2018; Jiang and Bansal, 2019; Min et al., 2019; Chen and Durrett, 2019; Schlegel et al., 2020; Sugawara et al., 2020). These analyses provide insights into the weaknesses of modern MRC gold standards. Nonetheless, to stimulate the development of robust MRC systems with generalisable NLU capabilities, it is necessary to investigate the strengths and weaknesses of MRC datasets on a deeper level.

In the task of MRC, it is assumed that questions test a cognitive process which involves various skills, such as retrieving stored information and performing inferences (Sutcliffe et al., 2013). Therefore, considering metrics that reflect skills required to answer questions is useful for analysing the capabilities of MRC datasets to benchmark NLU (Sugawara et al., 2020). This leads to the following intuition: if a question is solvable even after removing features (e.g., specific words) associated with an MRC skill, the question does not require the skill. Sugawara et al. (2020) examined 10 datasets with regard to multiple requisite skills for answering questions. One of the identified 12 skills is the *understanding of adjacent discourse relations*, which relies on information given by the sentence order in a passage. By randomly shuffling the order of the sentences in the context and comparing model performance on the original and the modified dataset, they concluded that most existing MRC datasets might be inadequate for benchmarking adjacent discourse relations understanding.

Discourse relations describe how two segments of discourse are logically connected to one another. Understanding them is key to answering reading comprehension questions correctly. Though the findings in Sugawara et al. (2020) are useful to understand MRC datasets with respect to discourse

April 19 - 23, 2021.

relations understanding, we argue that it is not enough to only consider inter-sentential relations as discourse relations also widely exist within sentences[2]. Furthermore, there also exist various types of relations and senses. Hence, to comprehensively assess the capacity of MRC datasets to benchmark discourse relations understanding, we assert that further research is needed.

In this paper, our aim is to provide a fine-grained analysis of the level of discourse relations understanding that is needed to answer questions in existing MRC datasets. Specifically, we focus on explicit discourse relations, which are expressed using explicit connectives. This allows us to perform analysis that goes beyond shuffling sentence order. In our work, we identify seven MRC skills that represent different aspects of understanding explicit discourse relations. With these, we examine three datasets using two strong MRC models. Our results show that these datasets might be insufficient for evaluating the understanding of explicit discourse relations. This work can potentially encourage the development of more challenging benchmarks that evaluate MRC models with respect to NLU capabilities that require discourse relations understanding.

2 Requisite Skills

As mentioned above, we identified a set of seven reasoning-related skills that require the understanding of explicit discourse relations, as shown in Table 1.

Skill s_1 is inspired by Sugawara et al. (2020), which aims to evaluate whether the understanding of adjacent explicit discourse relations is required in answering questions. Different from their proposed method (i.e., randomly shuffling the order of the sentences in a passage), we only shuffle those containing explicit connectives.

The selection of skills s_2 to s_7 is informed by the annotation scheme of the PDTB 3.0 corpus, which is annotated with information on discourse relations (Webber et al., 2019). The scheme defines 36 different senses of discourse relations. In the corpus, more than 24, 000 explicit connectives were annotated and categorised according to these senses. Based on this, we obtained a distribution of explicit connectives over the 36 senses (see Appendix A). Afterwards, we selected a subset of them (6 senses) based on the number of unique explicit connectives, total number of explicit connectives for which each sense was recorded, and the exclusiveness of these explicit connectives. The identification process is detailed in Appendix B. In the following, we provide an overview of skills s_2 to s_7.

Skills s_2 and s_3 are for the understanding of asynchronous temporal relations. Specifically, s_2 focuses on precedence while s_3 tests succession. Skill s_4 evaluates the understanding of causal relations, which are explicitly marked in the passage by connectives such as *because* and *due to*. Meanwhile, our motivation for selecting skill s_5 is to reveal whether explicit conditional reasoning is required to answer questions. Different from s_4, s_6 is for the understanding of negative causality, in which a causal relation expected on the basis of the first argument is negated by the situation described in the other. Finally, s_7 assesses expansions which provide further detail to an argument.

3 Methodology

For each of the seven identified skills, we defined an ablation method, as shown in Table 1. The

Skill	**NLU Tested**	**Ablation Method**
	shuffling method	
s_1	Explicit discourse relations between adjacent sentences	Shuffle the order of the sentences that contain explicit connectives in the context
	masking methods (Drop all occurrences of corresponding explicit connectives)	
s_2	Temporal reasoning (precedence)	Drop e.g. *afterward, later, …*
s_3	Temporal reasoning (succession)	Drop e.g. *earlier, since before, …*
s_4	Explicit causality reasoning	Drop e.g. *because of, due to …*
s_5	Explicit conditional reasoning	Drop e.g. *only if, depending on, …*
s_6	Negative causality reasoning	Drop e.g. *albeit, but then again, …*
s_7	Expansion of explicit discourse relations	Drop e.g. *additionally, moreover, …*

Table 1: Requisite skills and ablation methods.

---

[2] In the Penn Discourse Treebank (PDTB) 3.0 corpus (Webber et al., 2019), 24,369 and 29,818 tokens were annotated as connectives for intra-sentential and inter-sentential discourse relations, respectively.

design of these methods is based on the fact that explicit discourse relations are expressed using explicit discourse connectives (Webber et al., 2019). The scope of the proposed methodology hence captures only relations represented by explicit connectives, rather than all discourse relations-related features of the datasets. We assume that through shuffling the order of the sentences with connectives in the context, as well as through dropping these connectives, the corresponding relations will be broken. After applying the ablation method on the development set of an MRC dataset, if the performance of the model did not change significantly, we can say that most of the questions in the dataset are solvable even without the given skill; hence, the dataset does not sufficiently evaluate models with respect to the said skill. On the contrary, if the performance gap between the original and the modified dataset is large, we might infer that a substantial proportion of the questions require that skill. Nonetheless, should the model perform badly on the ablated dataset, we cannot take this as evidence that the model in fact acquired the investigated reasoning capabilities as the bad performance can stem from many different factors (e.g., distribution shift induced by dropping numerous words).

4 Experiments

In this section, we describe our experimental settings, present the results of our experiments and provide insights drawn from experimentation under an extreme setting whereby all explicit connectives were dropped.

4.1 Experimental Settings

Datasets. We examined three datasets with two answering styles. For span prediction datasets in which the goal is to identify a span in the passage as the answer, we used SQuAD 1.1 (Rajpurkar et al., 2016) and SQuAD 2.0 (Rajpurkar et al., 2018). For multiple choice datasets in which the correct answer is chosen from a candidate set of answers, we used SWAG (Zellers et al., 2018). We applied the ablation methods on the development set of each dataset. Sentence segmentation and tokenisation are performed as part of the pre-processing step.

Models. In the main experiment, we used the BERT-base (uncased) model (Devlin et al., 2019). Our goal is to analyse whether there exists at least one model architecture that can solve the MRC task without the understanding of explicit discourse relations; hence, it is enough to use a single model (Sugawara et al., 2020). Then, from the perspective of testing the effectiveness of the proposed MRC skills, we employed a stronger model, ALBERT-xxlarge (Lan et al., 2020). We fine-tuned the pre-trained BERT-base (uncased) and ALBERT-xxlarge model on the training set of each dataset and evaluated them on the original and the modified development sets by making use of the HuggingFace's *Transformers* library (Wolf et al., 2020). The hyperparameters of the models are reported in Appendix C.

Ablation methods. Method m_1: For the choice of explicit connectives, we used the 173 explicit connectives from the PDTB 3.0 corpus (Webber et al., 2019) (see Appendix D). We averaged the scores over five runs and report the mean and variance values in Appendix E. Methods m_2 to m_7: we list explicit connectives dropped for each sense in Appendix F. When a token is dropped, it is replaced with an [UNK] token to preserve the correct answer span. More in-depth results are reported in Appendix G.

4.2 Results and Discussion

In this section, we report the results for the skills in Table 2. In this table, for each of the ablation method used for skills s_2 to s_7, there are two versions of experimental results, shown in the white and shaded areas, respectively. Results written in the white areas were obtained by applying the ablation methods detailed in Section 4.1, i.e., by masking explicit connectives selected using the threshold-based method (see Appendix B) for which each sense was annotated. However, it can be seen in the table that except for s_7, the relative differences for s_2 to s_6 were extremely small (less than 1%) across all datasets. To further investigate whether these skills are truly not required to answer questions in the three datasets, we performed additional experiments as follows.

For the senses that represent a skill under evaluation, we dropped every explicit connective associated with those senses according to the PTDB 3.0 annotations (Webber et al., 2019). By applying these modified ablation methods, we obtained additional experimental results, shown in the shaded areas of Table 2. In the following, we discuss the observations for all the defined skills.

s_1: adjacent explicit discourse relations understanding. On all datasets, the relative changes

Skill	**SQuAD 1.1** *(F1)*	**SQuAD 2.0** *(F1)*	**SWAG** *(Acc.)*
Orig.	88.6	76.1	79.0
s_1	$86.2_{-2.7}$	$74.8_{-1.7}$	-
s_2	$88.3_{-0.3}$	$76.0_{-0.1}$	$79.0_{-0.0}$
	$88.0_{-0.7}$	$75.8_{-0.4}$	$79.0_{-0.0}$
s_3	$88.5_{-0.1}$	$76.1_{-0.0}$	$79.0_{-0.0}$
	$87.4_{-1.4}$	$75.4_{-0.9}$	$79.0_{-0.0}$
s_4	$87.9_{-0.8}$	$75.6_{-0.7}$	$79.0_{-0.0}$
	$78.6_{-11.3}$	$71.0_{-6.7}$	$78.6_{-0.5}$
s_5	$88.4_{-0.2}$	$76.1_{-0.0}$	$79.0_{-0.0}$
	$83.4_{-5.9}$	$73.8_{-3.0}$	$78.6_{-0.5}$
s_6	$88.4_{-0.2}$	$76.1_{-0.0}$	$79.0_{-0.0}$
	$87.5_{-1.2}$	$75.6_{-0.7}$	$78.6_{-0.5}$
s_7	$84.9_{-4.2}$	$74.1_{-2.6}$	$79.1_{+0.1}$
	$83.7_{-5.5}$	$73.7_{-3.2}$	$78.6_{-0.5}$

Table 2: The performance (%) of the BERT-base model with the ablation tests on the development set. Values in smaller font are changes (%) relative to the original performance of the model. For mask-related methods (m_2 to m_7), the results shown in the white areas are obtained from the initial test while the results shown in the shaded areas represent the further test, i.e., dropping all explicit connectives for which each identified sense was annotated. Acc.: accuracy as a percentage.

for s_1 were small. We do not apply m_1 to SWAG because its contexts are only one sentence long. On SQuAD 1.1 and SQuAD 2.0, the difference was hardly noticeable (less than 3% and 2%, respectively). These results indicate that most of the questions already solved in these datasets do not necessarily require the understanding of adjacent explicit discourse relations and are solvable even if the sentences appear unnaturally. This confirms the findings of Min et al. (2018), which reported that 92% of questions in SQuAD 1.1 are solvable by only looking at the sentence containing the answer.

s_2 and s_3: performing asynchronous temporal reasoning. We found that for the three examined datasets, the relative changes for s_2 and s_3 were extremely small (the biggest drop was even less than 1.5%), regardless of whether only a part or all associated explicit connectives were dropped. This indicates that these datasets might not adequately benchmark the understanding of asynchronous temporal relations.

s_4: explicit causality reasoning. In the initial experiment, the relative changes for s_4 on the three datasets were extremely small (less than 1%). However, surprisingly, after masking all explicit connectives cueing causality, except for SWAG which still featured a low drop (0.5%), the relative drops on SQuAD 1.1 and SQuAD 2.0 increased noticeably (from less than 1% to 11.3% and 6.6%, respectively). Particularly, for SQuAD 1.1, the decrease was the largest in all our experiments. Nevertheless, we cannot simply conclude that s_4 is needed to answer questions in the two datasets as the additionally dropped explicit connectives were also recorded as many other senses in the PDTB 3.0 corpus and not associated with this sense for the majority of occurrences. As we do not know exactly whether the decrease in model performance is due to this sense or any other senses, further analyses are necessary. Based on the PDTB 3.0 Annotation Manual (Webber et al., 2019), we calculated the percentage of each additionally dropped connective for this sense among the multiple senses for which it was annotated, and removed those which are rarely used for this sense from the candidate set of the dropped explicit connectives. The experiments demonstrated that the model achieved 85.1 and 74.3 (4.0% and 2.3% relative drop) F1 score on SQuAD 1.1 and SQuAD 2.0, respectively. This implies that the examined datasets might not correctly benchmark the understanding of causal relations and the reason why the relative drops were large after dropping all explicit connectives is that the other senses might be important.

s_5: explicit conditional reasoning. In the initial test, on all datasets, the relative changes were extremely small (less than 0.3%). Nonetheless, after dropping all explicit connectives describing conditional relations, except for SWAG which still showed a low drop (0.5%), the performance on SQuAD 1.1 and SQuAD 2.0 decreased by more than 3%. However, similarly to s_4, we cannot conclude whether such a decrease is due to sense representing s_5 or other senses that the explicit connectives are also associated with. As a result, we removed explicit connectives which are rarely used for this sense from the candidate set of explicit connectives and conducted further analyses. The experiments demonstrated that the model achieved 88.4 and 76.1 F1 on SQuAD 1.1 and SQuAD 2.0, respectively, both less than 0.5% relative difference. This indicates that s_5 might not necessarily

Dataset	**SQuAD 1.1** *(F1)*	**SQuAD 2.0** *(F1)*	**SWAG** *(Acc.)*
Original	94.4	87.6	89.0
Ablated	$92.4_{-2.1}$	$84.8_{-3.2}$	$86.3_{-3.0}$

Table 3: Performance of ALBERT-xxlarge on the original development set and on a version with all explicit connectives dropped. Acc.: accuracy as a percentage.

be required to answer questions in these datasets either.

s_6**: reasoning about negative causality.** On all datasets, the relative drops for s_6 were extremely small (less than 1.3%), whether with part of or all explicit connectives dropped. This demonstrates that most of the solved questions in the three MRC datasets do not necessarily require negative causal reasoning.

s_7**: recognising the expansion of explicit discourse relations.** In the initial experiment, the relative changes for s_7 on SWAG and SQuAD 2.0 were small, while that on SQuAD 1.1 was slightly larger (more than 4%). After dropping all explicit connectives for which sense *Expansion.Conjunction* was annotated, the performance of the model further decreased moderately – up to 5.5% for SQuAD 1.1, implying that compared to the other two datasets, SQuAD 1.1 might have more potential for benchmarking the understanding of the expansion of explicit discourse relations.

4.3 Further Analyses

Surprised by the moderate performance changes, we investigated the extent to which understanding of any explicit discourse relations is required by the datasets. Therefore, we dropped all explicit connectives and employed a stronger model, ALBERT-xxlarge (Lan et al., 2020) to generalise our assumption from the six specific senses to all senses. To mitigate the effect of distribution shift between training and evaluation data introduced by removing large parts of the context, we applied the ablation methods on the training set as well. The results are shown in Table 3. The performance drops no more than 3.2% for all three datasets, contributing further evidence towards the hypothesis that understanding the discourse structure of the text is hardly required to perform well on the investigated benchmarks.

5 Conclusion

In this paper, we proposed a methodology to assess the capabilities of MRC datasets to benchmark the understanding of explicit discourse relations. With seven fine-grained skills and corresponding ablation methods, we examined three large-scale datasets. The experimental results demonstrated that explicit discourse relations are not sufficiently evaluated by them, and thus there is a need to develop more challenging datasets so that their questions can correctly benchmark our defined skills. As for future work, we will develop a machine learning-based system that can recognise various senses of implicit discourse relations in the passage and further reveal whether the awareness of implicit discourse relations is required to do well on contemporary MRC benchmarks.

A Senses and Their Associated Explicit Connectives

This Appendix provides a distribution of the 36 distinct senses annotated for explicit connectives (Table 4), which are calculated by referring to Appendix A of the PDTB 3.0 annotation scheme (Webber et al., 2019). For each sense, the second column lists the explicit connectives for which the sense was annotated, with counts given for each connective (in parentheses). The third column lists the total number of explicit connectives for which each sense was annotated. Discontinuous connectives are indicated with a "+" symbol between their parts.

Sense	Explicit Connectives	Total
Temporal.Synchronous	as (383), as long as (4), as soon as (9), at the same time (65), by (1), in (18), in the meantime (11), in the meanwhile (1), meantime (2), meanwhile (120), now that (2), simultaneously (6), still (1), then (4), upon (2), when (509), while (163), with (5)	1306

Table 4: Senses and their associated explicit connectives annotated in the PDTB 3.0 corpus (Webber et al., 2019).

B Identification of the Senses of Explicit Discourse Relations

Table 4 provides the distribution of the 36 senses and their associated explicit connectives. To determine which kind of senses to focus on, we first defined two metrics: *"uniqueness"* and *"instances"* to measure the 36 senses. The first metric "uniqueness" measures the number of unique explicit connectives in each sense. For instance, as can be seen from Table 4, the sense "Contingency.Condition.Arg1-as-cond" was annotated for two unique explicit connectives: "and (22), then (1)". Therefore, its uniqueness is equal to 2. The second metric "instances" measures the total number of connectives for which each sense was annotated. Take the same example, we can see that the connective "and" was annotated 22 times as the sense "Contingency.Condition.Arg1-as-cond" and the connective "then" was annotated once as the same sense. Under this circumstance, there is a total of 23 (22+1) explicit connectives for which the sense "Contingency.Condition.Arg1-as-cond" was annotated, and thus its instances is equal to 23.

We propose that the two metrics can reflect the breadth and importance of these senses in a passage of text as Table 4 was developed from the large-scale PDTB 3.0 corpus (Webber et al., 2019), which provides a certain degree of representation. In this context, the higher "uniqueness" and "instances" a sense features, the more widely it might spreads in the context. Consequently, choosing such a sense to focus on is more likely to reveal whether the existing MRC benchmarks test the model's understanding of it.

Besides the two defined metrics, we also noticed that in the PDTB 3.0 corpus (Webber et al., 2019), many different senses were recorded for the same connective. For example, the connective "in the end" was annotated as seven types of senses. In this case, we cannot exactly examine which kind of senses the MRC datasets assessed by dropping their associated non-exclusive explicit connectives. This indicates that there is a need to consider the issue of managing explicit connectives for which multiple senses were annotated. To this end, we introduced the third metric: *"exclusiveness"*, which measures the degree of semantic overlap of explicit connectives in each sense. Ideally, to ensure that there are no overlapping explicit connectives among these senses, we can just remove all of the explicit connectives for which multiple senses were annotated and keep those that represent only one type of sense. However, after doing this, the "uniqueness" and "instances" of most senses are greatly decreased (see Figure 1a and Figure 1b). Based on this, we posit that the cost, i.e., most senses losing a considerable number of explicit connectives, is too high when attempting to retain their exclusiveness. Though the senses with only exclusive explicit connectives could meet the three metrics, they might not be enough for our data ablation purposes, as most of the explicit connectives were eliminated. Considering this, we need to find a balance between preserving the number and types of explicit connectives in each sense and maintaining its exclusiveness.

To minimise the loss in terms of "uniqueness" and "instances" of each sense while preserving "exclusiveness", we propose that if a connective C was annotated with multiple senses and it is used for sense X majority of the time, then we could include it in sense X. To identify the exact value of the "majority", we calculated the percentage of the distinct senses annotated for each non-exclusive connective and selected the sense with the highest percentage. Subsequently, we averaged these highest values and obtained the threshold, which is about 69%. Finally, we chose explicit connectives where the highest proportion of the sense for which they were annotated exceeds 69% and eliminated those below the threshold. From Figure 2a and Figure 2b, one can see that both the "uniqueness" and "instances" of the most senses with some retained non-exclusive explicit connectives increased, compared with those that only contain the exclusive connectives. This demonstrates that our method has effectively increased the number and types of explicit connectives in the most senses while maintaining their exclusiveness.

Finally, to select the candidate senses from the 36 senses, we visualised them in terms of their "uniqueness" and "instances", as shown in Figure 3a and Figure 3b, respectively. As can be seen in Figure 3a, there are a total of 12 senses with the number of unique explicit connectives above the mean value (sense 24, 2, 20, 12, 19, 5, 22, 3, 4, 1, 25, 36). Furthermore, it can be seen from Figure 3b that there are a total of 6 senses with the total number of explicit connectives larger than the average (sense 24, 20, 12, 2, 4, 3). Then, we took the intersection of these two sets of senses and obtained a sense set whereby "uniqueness" and "instances" of each sense is above the mean, and its

C Hyperparameters of the BERT-base and ALBERT-xxlarge Model

Hyperparameters used in the BERT-base and ALBERT-xxlarge model are shown in Table 5.

Dataset	d	b	lr	ep
BERT-base				
SQuAD 1.1	384	12	3e-5	2.0
SQuAD 2.0	384	12	3e-5	2.0
SWAG	80	8	5e-5	3.0
ALBERT-xxlarge				
SQuAD 1.1	384	12	3e-5	2.0
SQuAD 2.0	384	12	3e-5	4.0
SWAG	80	128	5e-5	3.0

Table 5: The hyperparameters used to fine-tune the BERT-base and ALBERT-xxlarge model on each dataset. *d* is the size of the token sequence fed into the model, *b* is the training batch size, *lr* is the learning rate, and *ep* is the number of training epochs. We used stride = 128 for documents longer than *d* tokens.

D A Set of Explicit Connectives

We list the set of explicit connectives used in this work in Figure 4.

E Performance Means and Variances in Shuffle-Based Method

We report the means and variances for the shuffling ablation method for skill s_1 in Table 6.

F The Six Identified Senses and Their Associated Explicit Connectives

Table 7 shows the six identified senses and their associated explicit connectives. For each sense, the associated explicit connectives were selected using the threshold-based method detailed in Appendix B.

G Detailed Results of SQuAD 2.0

We report the ablation results for has-answer and no-answer questions in SQuAD 2.0 in Table 8.

---

[3] A detailed introduction of these senses is available at https://catalog.ldc.upenn.edu/docs/LDC2019T05/PDTB3-Annotation-Manual.pdf.

Continuous explicit connectives (One token):
about, accordingly, additionally, after, afterward, afterwards, albeit, also, alternatively, although, and, and/or, as, because, before, besides, beyond, but, by, consequently, conversely, despite, earlier, else, except, finally, for, from, further, furthermore, given, hence, however, if, in, indeed, instead, later, lest, like, likewise, meantime, meanwhile, moreover, nevertheless, next, nonetheless, nor, on, once, only, or, otherwise, plus, previously, rather, regardless, separately, similarly, simultaneously, since, so, specifically, still, subsequently, then, thereafter, thereby, therefore, though, thus, till, ultimately, unless, until, upon, whatever, when, whenever, where, whereas, whether, while, with, without, yet

Continuous explicit connectives (Two tokens):
along with, and then, as if, as though, as well, because of, but also, but then, by comparison, by contrast, by then, depending on, depending upon, due to, even after, even as, even before, even if, even so, even then, even though, even when, even while, even with, for example, for instance, if only, in addition, in case, in contrast, in fact, in order, in particular, in short, in sum, in that, insofar as, instead of, later on, more accurately, much less, no matter, not only, now that, only if, or otherwise, rather than, regardless of, since before, so as, so that, such as, that is

Continuous explicit connectives (Three tokens):
as a result, as an alternative, as long as, as much as, as soon as, as well as, before and after, but then again, even before then, if and when, in any case, in other words, in the end, in the meantime, in the meanwhile, on the contrary, so long as, so much as, when and if

Continuous explicit connectives (Four tokens):
at the same time, not only because of, not so much as, on the other hand

Discontinuous explicit connectives:
both+and, either+or, if+then, neither+nor, not just+but, not just+but+also, not only+also, not only+but, not only+but also, on the one hand+on the other, on the one hand+on the other hand

	$64.7_{-17.5}$	$77.4_{+4.7}$	$71.0_{-6.7}$
5. Drop explicit connectives associated with conditional reasoning	$78.1_{-0.4}$	$74.0_{+0.1}$	$76.1_{-0.0}$
	$71.3_{-9.1}$	$76.4_{+3.4}$	$73.8_{-3.0}$
6. Drop explicit connectives associated with negative causality reasoning	$78.1_{-0.4}$	$74.0_{+0.1}$	$76.1_{-0.0}$
	$77.0_{-1.8}$	$74.2_{+0.4}$	$75.6_{-0.7}$
7. Drop explicit connectives associated with the expansion of explicit discourse relations	$73.6_{-6.1}$	$74.5_{+0.8}$	$74.1_{-2.6}$
	$72.2_{-7.9}$	$75.1_{+1.6}$	$73.7_{-3.2}$

Table 8: Results (%) on the development set of SQuAD 2.0 for subsets with normal (Has-Ans) and no-answer (No-Ans) questions. Values in smaller font are changes (%) relative to the original performance of the model. For mask-related methods (m_2 to m_7), the results shown in the white areas are obtained from the initial test while the results shown in the shaded areas represent the further test, i.e., dropping all explicit connectives for which each identified sense was annotated.

Why Is MBTI Personality Detection from Texts a Difficult Task?

Sanja Štajner, Seren Yenikent

Abstract

Automatic detection of the four MBTI personality dimensions from texts has recently attracted noticeable attention from the natural language processing and computational linguistic communities. Despite the large collections of Twitter data for training, the best systems rarely even outperform the majority-class baseline. In this paper, we discuss the theoretical reasons for such low results and present the insights from an annotation study that further shed the light on this issue.

1 Introduction

Apart from being long and requiring to be administrated by a skilled human assessor in artificial circumstances (laboratory conditions), the traditional questionnaire-based personality tests often introduce *social desirability bias* (Krumpal, 2011) and *the reference-group effect* (Heine et al., 2002), which can be introduced either from the subject's or assessor's side. To avoid those biases, it was suggested that analysing person's writing provides more objective assessment of one's personality than the traditional questionnaires (Stachl et al., 2019).

1.1 The MBTI

The original MBTI model was based on the comprehensive theoretical work of Carl Jung (1921), and was further developed by Myers and Briggs by adding the fourth dimension (judgment/perception) and several decades of extensive practical use within the industrial and educational settings (Briggs-Myers and Myers, 1995). Today, the MBTI is one of the most widely used non-clinical psychometric assessments, regularly used in understanding team building processes in work environments (Kuipers et al., 2009), for career suggestions (Garden, 1997), and in marketing and consumer behavior (Gountas and Gountas, 2001).

The MBTI lays out a binary classification based on four distinct functions, and draws the typology of the person according to the combination of those four values (e.g. INFP, ESTJ):

- **E**xtraversion/**I**ntroversion (EI) - preference for how people direct and receive their energy, based on the outer or inner world
- **S**ensing/**IN**tuition (SN) - preference for how people take information in, by five senses or by interpretation and meanings
- **T**hinking/**F**eeling (TF) - preference for how people make decisions, by relying on logic or emotions towards people and special circumstances
- **J**udgment /**P**erception (JP) - how people deal with the world, by organizing it or staying open for new information

While many studies investigated linguistic characteristics of the Big 5 personality traits (Mairesse et al., 2007; Furnham, 1990; Pennebaker and King, 1999; Gill and Oberlander, 2002; Scherer, 2003; Pennebaker and King, 1999; Gill and Oberlander, 2003), to the best of our knowledge, there have been no studies reporting on linguistic characteristics of different MBTI types. The most probable reason for this is a different nature of the MBTI framework. Unlike the Big 5 model that originated from lexical analyses (Cattell, 1946; Tupes and Christal, 1961; Goldberg, 1982; Costa and McCrae, 1992), the MBTI fundamentally makes use of the behavioral implications in theoretical and professional contexts. Hence, the available data rarely refers to any linguistic contexts, but more to practical results of the questionnaires. However, as linguistic data has been shown as one of the best indicators of personality-related characteristics such as behaviors and motivations (Pennebaker

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3580–3589
April 19 - 23, 2021.

and King, 1999; Tausczik and Pennebaker, 2010) and given that the MBTI makes use of behavioral implications to study personality, there is a room for linguistic representation of the concept with proper datasets and methods.

1.2 Automatic Detection of MBTI from Texts

Unlike automatic detection of the Big 5 personality traits that in the last 15 years has been attempted at from various types of texts, e.g. essays (Argamon et al., 2005), personal weblogs (Oberlander and Nowson, 2006), and Facebook posts (Kosinski et al., 2013), the automatic detection of MBTI gained popularity only recently and exclusively using Twitter data. Attempts were made for various languages: English (Plank and Hovy, 2015), six Western European languages (Verhoeven et al., 2016), and Japanese (Yamada et al., 2019). All those studies, despite using large training datasets (over 1M instances) and various features (word and character n-grams, or count-based meta-features such as number of followers, favourites, etc.), barely managed to outperform the majority-class baseline, and even that only in some of the four MBTI dimensions. The best English models were trained on over 1M Twitter instances using logistic regression classifier and combining linguistic and count-based meta-features. Nevertheless, they outperformed the majority-class baseline only on the IE and TF dimensions, achieving the accuracy of 72.5% and 61.5% on those binary tasks (Plank and Hovy, 2015).

Comparison of performances of the Big 5 and MBTI computational models trained on Twitter data showed that type of architecture and settings practically have no influence on the MBTI detection from such data (Celli and Lepri, 2018) indicating thus that Twitter data might not contain sufficient amounts of lexical signals.

1.3 Goals and Contributions

The main goal of our study is to investigate why the automatic detection of MBTI personality traits from texts does not outperform even the simple majority-class baseline and why its performance on Twitter data is not influenced by the architecture type and settings. Furthermore, we shed some light on the natural complexity of the task and discuss the theoretical constraints of the task. We pose two hypotheses:

- H1: *Twitter data does not contain enough signals for MBTI personality detection.*
- H2: *Textual data does not resonate well with MBTI personality scores from questionnaires.*

To test those hypotheses, we collect a new dataset, write the guidelines for human annotation, conduct an extensive human annotation task, and provide both a quantitative and qualitative analysis of the results.

The main contributions of our study are the following:

1. Proposing the guidelines that translate behavioural characteristics of the MBTI dimensions into linguistic cues in texts;
2. Releasing a new dataset for MBTI analysis from textual data;
3. Testing the two above-mentioned hypotheses (H1 and H2);
4. Revealing the specificities of the MBTI constructs that make them difficult for automatic detection from texts.

2 Datasets

To test our hypotheses, we used two datasets, a subset of the MBTI-Twitter dataset (Plank and Hovy, 2015), and a dataset that we collected especially for this purpose, the MBTI-MTurk dataset.[1]

2.1 MBTI-Twitter Dataset Selection

To test our first hypothesis (H1), we randomly selected 96 user data from the MBTI-Twitter dataset (Plank and Hovy, 2015), six for each of the 16 MBTI types, using the version with 50 concatenated tweets for each user/instance. Out of those 50 concatenated tweets, we only retained the first 10 tweets for two reasons: (1) to maintain the task managable for human annotation; and (2) to have the length of posts from each user roughly comparable to those we collected (MBTI-MTurk).

2.2 MBTI-MTurk Dataset Compilation

Our goal was to compile an 'ideal' dataset of short text snippets that would maximize the potential of finding linguistic signals of the four MBTI personality dimensions.

---

[1] Available upon request for research purposes.

We posted a human intelligence task (HIT) using the Amazon Mechanical Turk (MTurk) crowdsourcing platform. The task consisted of three open-ended questions:

1. You might have done an MBTI personality test in the past. If you did, and you know the MBTI personality type you obtained, please write it here:
2. What is your favourite type of vacation and why?
3. Which are your favourite hobbies and why?

The first question was optional, while the other two questions were required for completing the task and getting monetary compensation. For the last two questions, we enforced the answers to be at least 300 characters long, to allow for a sufficient length to capture some linguistic signals. The last two questions were selected following the assumption that how people spends their free time would be the most natural version of their personality. Research suggests that activities engaged during leisure time are the outcomes of what the person wants to be doing by choice with high levels of intrinsic motivation (Kuykendall et al., 2015). Therefore, we considered that the types of vacation and hobbies are representative realms of the participants' true personalities.

Data Collection. We posted our HIT in 20 batches spanning a two-months period. From all collected data, we first filtered out those that did not contain the answer to the MBTI personality type question.[2]

Quality Control. All collected answers were manually checked to filter out those answers that were copied from the internet (about one third of all participants tried to trick the system by copying texts from internet about favourite types of vacations and hobbies).

Consistency Check. Out of all HITs that contained the answer to the MBTI question, we only retained those for which we had two HITs from the same user completed with at least one month in between and where the asnwer to the MBTI question contained the same personality type both times. The assumption was that if a user provided two different MBTI results in those two instances it was for one of the following reasons: (1) the user gives random MBTI types to intentionally harm the study (Ipeirotis et al., 2010), or (2) in at least one of the MBTI dimensions, the user is somewhere in the middle range, and might have genuinely obtained two different scores on an MBTI questionnaire.

Final Dataset. The final dataset for this study consisted of 96 HITs, all completed by different users (MTurk IDs)[3]. Similar as in the case of the MBTI-Twitter dataset, the selected dataset comprises of equal number of HITs (six) per each of the 16 MBTI personality types. For the two pilot rounds, the additional 30 HITs were used, ensuring that each of the eight polarities (extravert, introvert, sensing, intuitive, etc.) is present at least twice.

3 Annotation

As there are no studies laying out linguistic characteristics of the MBTI model, we created the annotation guidelines starting from the behavioral characteristics. The MBTI's theoretical and practical framework provides detailed profiles for each type ranging from general and typical characteristics to real-time depictions of those characteristics, in the contexts of relationships, marriage, work, and learning settings (Briggs-Myers and Myers, 1995). We translated this behavioral information into linguistic and textual signals in general, as well as some specific signals relevant for the contexts we asked the participants to write about.

To define the characteristics that would linguistically distinguish the two polarities of the EI dimension, we focused on the processes of socialization depicted in the text. As the dimension of JP is mainly related to organizational preferences, we chose the linguistic signals referring to arrangement of schedules and plans. The fact that people high on J tend to be more exact and pay more attention to details, whereas people high on P show more flexible and accidental characteristics (Briggs-Myers and Myers, 1995) we translate into guidelines considering sentence structures and grammar. The SN dimension identifies preferences for the characteristics of tasks and information people would like to process, either using facts and five senses (S), or using imagination and abstraction

---

[2] We opted for making the MBTI personality type question optional to avoid people writing random MBTI types, as those are widely known and popular on the internet. By paying equally those who provided the answer to the MBTI question and those who did not, we tried to ensure that provided MBTI types are not just randomly chosen but rather represent the real results of the user's MBTI testing.

[3] From each user ID, that passed all above-mentioned checks, we randomly chose one answer about the hobbies and one answer about the vacations.

Extravert	Introvert
Mention of new people (e.g. *crowd*, *strangers*)	Mention of closer people rather than any group of people (e.g. *husband*, *family*)
Mention of social activities and events that contain interaction with other groups of people (e.g. *party*, *dancing*, *couchsurfing*)	Mention of individual activities or activities that can be done without interaction with other people (e.g. *by myself*, *spending time at home*)
Mention of outside world and vibrant places (e.g. *bars*, *restaurants*)	Mention of inner world, and calm and quiet places (e.g. *home*, *museum*)
We references	*I* references
Use of intensifiers and exclamation marks	Hedging
More assertive, positive, enthusiastic arguments	Less assertive arguments

Table 1: Linguistic signals of extraversion and introversion.

Sensing	Intuitive
Technical, object-based and hands-on hobbies	Inspirational and imaginative hobbies (e.g. *creating*, *exploring*)
Facts and real cases (e.g. *documentary*, *diary*)	Abstraction rather than facts (e.g. *sci-fi*, *cartoons*)
Details and examples (more adjectives and adverbs to provide details, use of the words *example*, *for instance*)	Main ideas rather than details
Needs to use the 5 senses	Needs to focus on the bigger picture
Puzzles, model planes, crafts, carving, rowing, sailing, diving, rock climbing, etc.	Painting, music, dancing, poetry, chess, literature, arts, martial arts, yoga, meditation, etc.
Simplified and straightforward writing style (short sentences)	Complex writing style (long sentences)
Clear and concise writing style	Artistic, longer, more words

Table 2: Linguistic signals of sensing and intuition.

Thinking	Feeling
Logical reasoning for their actions and choices (e.g. *reading books for learning*)	Emotional reasoning for their actions and choices (e.g. *reading books for gateway feeling*)
Mention of opinions, ideas, comparisons	Mention of people, values, feelings
Direct (e.g. *reading is nice*)	Tactful, indirect (e.g. *reading feels nice*)

Table 3: Linguistic signals of thinking and feeling.

Judging	Perceiving
Holidays that include planning such as ski holidays, city tours etc. (e.g. *tour*, *pass*, *ticket*, *reservation*)	Spontaneous holidays such as going to the beach, a new city etc. (e.g. *flexible*, *spontaneous*)
Decisive, planful, organized (e.g. *plan*, *schedule*, *followed by*)	Curiosity, anticipation of change, and spontaneity
Organizers of the plans (e.g. *invite*, *organize*)	Followers of the plans (e.g. *join*, *tag along*)
Warranty (e.g. *insurance*, *make sure*)	Autonomy and impulsiveness (e.g. *suddenly*, *out of the blue*, *last minute*)
Past tense or present perfect tense	Present simple tense
Formal and structured writing style with grammatical rules followed as much as possible (e.g. *I like ski holidays and sometimes prefer city tours.*)	Informal writing style with grammar mistakes (e.g. *I like going to the beach. Also, do art sometimes.*)

Table 4: Linguistic signals of judging and perceiving.

(N). The TF dimension is related to preferences for decision-making processes. Hence, we focus on the reasoning aspect of the linguistic characteristics, whether it is logical or emotional.

Tables 1– 4 provide linguistic signals for each label. They were provided to the hired annotators as the main annotation guidelines.

3.1 Annotators

Two annotators, one with a PhD degree in psychology and the other in computational linguistics, were hired to annotate all instances in both datasets. Both annotators underwent a six-months (paid) training which covered reading the extensive literature on personality assessment (e.g. traditional questionnaire approaches and dictionary-based methods), the MBTI framework and its use cases.

3.2 Annotation Procedure

We asked the annotators to assign to each instance (either coming from the MBTI-Twitter dataset or from Hobbies and Vacation questions in the MBTI-MTurk dataset)[4], for each of the MBTI dimensions separately, one of the following four labels: either of the two polarities (e.g. E or I for the EI dimension) etc.), *unsure* (in cases where they saw signals from both polarities and are not confident to make a binary decision), or *not enough signal* (in cases where they did not find any signals for any of the two polarities).

Both annotators were first asked to complete two pilot rounds of annotation so that they can be fully familiarised with the annotation guidelines and the procedure. In each pilot round, the dataset they were ask to annotate consisted of 15 MBTI-Twitter and 15 MBTI-MTurk user-instances which were not used for the final round. After each pilot round, a question and answering session was organized to address all potential issues with the guidelines or the procedure. Furthermore, after each pilot round, the annotators showed their annotations and commented their decisions to the other annotator to calibrate their annotations. During the pilot rounds, the annotators were asked to mark the parts of the instances which guided their decisions for assigning certain polarity.

The annotations and text mark-ups obtained during the pilot rounds are used in Section 4 to show how the proposed guidelines were used in practice, as well as to point out the most challenging aspects of the annotation process.

After finishing both pilot rounds, the annotators were given the final dataset which consisted of 96 user-instances from the MBTI-Twitter dataset and 96 user-instances from the MBTI-MTurk dataset. In total, each annotator annotated 192 user-instances for each of the four MBTI personality dimensions. The annotators were instructed to have enough breaks to avoid the fatigue effect.

4 Findings from the Pilot Rounds

The annotation and mark-up obtained during the pilot rounds revealed several important characteristics of the task.

4.1 Middle Cases

One of the recurring issues found during the pilot rounds was the case of people whose answers truly belong to the middle of the spectrum, as in the following case (the signals for introversion are shown in italics, those for extraversion are shown in bold, and those for the JP dimension are shown underlined):

(1) “I like travelling to some new places. *Mostly* I like travelling to a city I have never been before, but from time to time I *can* also enjoy just going to a nice seaside place and relax for a week without any fixed plans and sightseeing schedules. The only type of holidays **I really don’t like** is **just staying at home**. I find that OK if just for a day or two maximum, but longer than that **I get bored**.”

The words *mostly* and *can* represent hedging and are thus signals for introversion (Table 1), whereas the word *really* is an intensifier and thus a signal for extraversion (Table 1). The negation of the fixed plans and schedules signalizes a truly mid-range personality along the JP dimension, as it shows that the person does not like fixed plans and schedules, but is still aware of their existence and thus mentions them.

The ‘middle cases’ were frequent also for the other two dimensions. The following example was annotated as *unsure* for the SN dimension by both annotators (the signals for sensing are shown in bold, and the signals for intuition are shown in italics):

---

[4] The answers to the Hobbies question were used for annotating only SN and TF dimensions, and the answers to the Vacations question were used for annotating only EI and JP dimensions.

(2) “I enjoy doing sports, although its been a while since I have been active. Such like **volleyball**, **gym fitness**, and I am trying to get into *yoga*. On the complete opposite side, I also really love *baking and exploring new recipes to cook*. In my spare time I am trying to learn to appreciate being outdoors more, as I usually spend too much time binging netflix.”

The noticeable amount of such ‘middle cases’ is, however, not caused by the flaw of the guidelines, but rather reflects the drawbacks of the binary nature of the MBTI framework. Those people who have characteristics of both polarities, which is a common case (Pittenger, 1993), are by the traditional questionnaire-based assessment placed in one of the two groups (e.g. extravert or introvert). Analysis of the short posts can reveal the presence of signals for both polarities but their ratio in the short posts might be different from that obtained by the questionnaire-based assessment.

4.2 Content vs. Style

As can be seen in Tables 1– 4, the annotation guidelines contain pointers regarding both content (i.e. lexical choices and argumentation) and style (i.e. grammatical and stylistic preferences). The pilot phases discovered that in approximately 10% of the cases, a given instance shows the content-based signals of one polarity and the stylistic-based signals of the opposite polarity. One such example is the following, where the content cues are clearly of the judging polarity (shown in italics), while the stylistic cues (sentence structure, grammatical errors, and typos) are of the perceiving polarity (shown in bold):

(3) “I *would like my vacation to be well organised* so **i wont** have to deal with **anything just** enjoy the flow. I like visiting new places, that is **me** perfect vacation. **Its** not interesting for me going several times in one place just because **its quite**. **Don’t** like big buildings, crowded places and cemented environments**, i** like nature and historical places”

In all such cases, the polarity that was signalized by the stylistic preferences was in line with the reported official MBTI label. It is known that people can consciously change the content of their answers, but not the style (Chung and Pennebaker, 2007). Therefore, the content of the answers to the open-end questions can also suffer from social desirability bias, similar as the answers to the questionnaires.

4.3 Writing Style in Twitter

Another issue that was revealed during the pilot rounds was that twitter posts, by their nature, often have incorrect grammar, punctuation, and ill-formed sentences. That makes it difficult for the annotators to assign J or P labels unless there are lexical cues (which are extremely rare in Twitter), because otherwise, focusing on writing style (Table 4) the great majority of posts would be annotated as P. Similarly, the nature of the Twitter posts to overuse intensifiers and exclamation marks makes many posts stylistically extraverted, and thus, the last two points in the annotation guidelines (Table 1) may lead to false (extravert) positives.

Two examples of instances from the MBTI-Twitter dataset are given later, in Table 6.

5 Final Annotation Results

The annotation of the final dataset that consists of 96 instances from the MBTI-Twitter dataset and 96 instances from the MBTI-MTurk dataset revealed further particularities of each dataset, and shed some light on how feasible the task is, even for trained human annotators.

5.1 The Presence of the MBTI Signals

As expected, in the final datasets, the instances from the MBTI-MTurk dataset were reported to have enough signals across all four MBTI dimensions, as opposed to the instances in the MBTI-Twitter dataset (Table 5). In the MBTI-Twitter dataset, many instances were reported to have insufficient signals across the JP and SN dimensions.

These results support our first hypothesis (H1) that Twitter posts (even when grouped per user) do not always contain linguistic signals to allow for personality detection, even for the trained human annotators. Furthermore, these results give a potential explanation to the question why previously proposed binary classification models for the JP and SN dimensions did not manage to outperform even the majority-class baselines.

In Table 6, we present examples of two Twitter users, one for whom both annotators reported insufficient signals for the JP and SN dimensions, and another one whose personality was correctly annotated across all four dimensions by both annotators.

Annotator	Statistic	MBTI-Twitter				MBTI-MTurk			
		EI	SN	TF	JP	EI	SN	TF	JP
A (CL)	Not enough signal	2	31	8	59	0	0	0	0
	Unsure	14	14	22	7	31	23	38	33
	Confident (class assigned)	84	55	71	33	69	77	62	67
B (Psychologist)	Not enough signal	10	17	10	33	0	0	0	0
	Unsure	29	17	19	25	23	39	54	7
	Confident (class assigned)	61	67	71	42	77	61	46	93

Table 5: Human annotation statistics (in percentage of cases, out of the total number of 96 instances) on the MBTI-MTurk dataset (Holidays and Hobbies) and the subset of the MBTI-Twitter dataset.

Insufficient signals for any dimension	Correctly annotated (ESFP) by both annotators
“what happened in the fandom why are the makorra shippers so angry ? @URL / 5mfxado0lp photoset : calmorrison : aer-dna : sweetlikepoison 528 : aer-dna : ” just the four of us . ” remember when team ... @URL / hdcrf 7ljsc omg remind me to not go into the tags i just saw a post that essentially said makorra was baited like how ... @URL / jxdtfcmlld dylanftsw : shut the fuck up about “ shitty writing ” or the end of the show not making sense or being rushed .... @URL / r62qnjt7di photo : hellkatespangled : sleepy girlfriends and lazy art @URL / 5oq9n8P2Kd wall-maria-around-ba-sing-se : so i saw this gif : and all i could think was how it made her look like an ... @URL / gom 5newfum photo : insomniadiesdown : some kuvira sketches @URL / ahrgfwwqsb photo : joeldosreisviegas : dariucdraws :...”	“omg i just met doug adams from season 12 of top chef , here in portland , the dude was super mellow and friendly ! :D @USER craaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaling in my skiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiiii-iiiiiiiiiiiiiiiiiiiiii @USER he was super chill . i shook his hand and told him i loved his attitude and was rooting for him , and he was just like , ” cool ! ” @USER hey cat , you guys get home okay ? @USER i sure hope so ! i’ve loved doug since the beginning of this season his attitude is great , he’s talented , he never whines @USER conversion ” therapy ” is indeed the greatest sham it’d be an amazing step to see it banned , and lgbt’s treated normally @USER it’s essentially the last bastion of clinical homophobia the day it dies is the day attitudes towards us improve drunk tonight and just can’t get over how awesome bjork is <3 ...”

Table 6: An MBTI-Twitter instance which did not contain sufficient signals and could not be annotated (left) as opposed to another MBTI-Twitter instance which was correctly annotated by both annotators across all four dimensions (right). In both cases, we do not present the full instance for the space constraints.

5.2 Assigned Classes

We found that in the MBTI-MTurk dataset, a relatively high number of instances (ranging between 7% and 54% depending on the dimension and annotator, with most of them being in the range between 23% and 39%) was reported to have mixed signals (labelled as *unsure*).

As expected, the number of instances for which the annotators felt confident enough to assign one of the polarities was higher in the MBTI-MTurk than in the MBTI-Twitter dataset, in most of the cases. The difference was most noticeable in the JP dimension, where the number of instances with an assigned polarity doubled.

A closer look at the instances for which both annotators were confident enough to assign either of the polarities revealed even more prominent differences between the two datasets (Table 7). In the MBTI-Twitter dataset, only in 46% of the instances the annotators agreed on the EI dimension, and only in 50% cases they agreed on the JP dimension. In the MBTI-MTurk dataset, in contrast, the annotators agreed across those two dimensions (EI and JP) in 100% and 78% of the cases, respec-

Statistic	MBTI-Twitter				MBTI-MTurk			
	EI	SN	TF	JP	EI	SN	TF	JP
Both annotators confident	53	**30**	43	**15**	62	**54**	38	**69**
Annotators agree	**46**	*81*	61	**50**	**100**	*69*	62	**78**
Annotator A agrees with the gold label	77	64	64	53	78	54	77	44
Annotator B agrees with the gold label	47	44	54	47	60	54	85	42
Both annotators agree with the gold label	77	54	57	50	75	62	54	43

Table 7: Inter-annotator agreement statistics on the MBTI-MTurk dataset (Holidays and Hobbies) and the subset of the MBTI-Twitter dataset. The percentage of instances, out of those for which both annotators were confident to assign a polarity, for which both annotators assigned the same polarity is presented in the row "Annotators agree". Similarly, the next two rows present the percentage of cases in which each annotators label was equal to the gold label (the provided MBTI label) out of all cases for which the annotator was confident to assign a polarity (as opposed to the other two labels: 'unsure' and 'not enough signal'). The percentage of cases in which both annotators agree with the gold label is calculated taking into account only those instances on which both annotators agreed.

tively. Nevertheless, if we calculate the percentage of cases in which the 'gold' label was the same as the shared label of the two annotators (the row 'both annotators agree with the gold label' in Table 7), we find that, surprisingly, it only happens in up to 50% of the cases for the JP dimension. This indicates that the linguistic signals for the JP dimension captured from text, even with high confidences of the annotators and their inter-annotator agreement, are not correctly associated with the results of the traditional questionnaire-based MBTI personality assessment. The only MBTI dimension for which the percentage of cases in which both annotators agreed with the gold label is noticeably above the majority-class baseline (50%) in both datasets is the EI dimension. These results indicate that the EI dimension is the only dimension for which a noticeable association between the results of the traditional questionnaire-based MBTI personality assessment and the textual-analysis-based MBTI personality assessment was found. This evidence supports our second hypothesis (H2) for three out of four MBTI dimensions.

6 Discussion and Conclusions

The results of presented analyses shed some light on possible causes of the poor performances of the automatic MBTI personality detection systems proposed so far. Furthermore, they indicate that the linguistic cues found in short texts do not seem to directly correspond to the results of the questionnaire-based results, which are commonly used as the 'gold labels' in classification experiments. This is in line with academic studies that showed the psychometric inadequacy of the questionnaire (Pittenger, 1993; Boyle, 1995).[5]

The high number of instances without enough signal and with mixed signals in the MBTI-Twitter dataset across all MBTI dimensions, and especially the JP dimension, leads to high amounts of noise in the training datasets. Therefore, it is not a surprise that the best systems trained on those datasets rarely outperform even the majority-class baseline.

Even in the cases where user-instances contain sufficient signals and the agreement between the human annotators is high, the agreement between the annotators and the gold label is still very low for three out of four dimensions (Table 7). These results indicate that the constructs set up by the traditional questionnaire-based personality assessment might not have the exact equivalent translation into the linguistic cues. The only exception for this is the EI dimension where the agreement between the annotators and the gold label reaches 75%-77%. This is somewhat expected as the EI is the highest correlated dimension between the MBTI and Big 5 models amongst all dimensions (Furnham, 1996), and in the Big 5 model, the EI has a good linguistic correspondence.

Finally, the results of the in-depth analyses performed during the two pilot rounds (Section 4) revealed three phenomena that need to be taken into

---

[5] Due to the methodology followed to develop and improve the questionnaire (i.e. qualitative methods such as observations and introspection), the MBTI has received considerable criticism for not relying on a scientifically proven background (i.e. data-driven approaches).

account when using the linguistically-based MBTI personality analysis from texts:

(1) The content and the style of the text sometimes exhibit signals of the opposite polarities;

(2) Many people naturally express signals of the opposite polarities, as they probably belong to the middle ranges of those personality dimensions;

(3) The language used in Twitter shows specific stylistic characteristics in terms of tonality, use of exclamation marks, sentence structure and grammar, thus making everyone seem more extraverted than they are.

ENCONTER: Entity Constrained Progressive Sequence Generation via Insertion-based Transformer

Abstract

Pretrained using large amount of data, autoregressive language models are able to generate high quality sequences. However, these models do not perform well under hard lexical constraints as they lack fine control of content generation process. Progressive insertion-based transformers can overcome the above limitation and efficiently generate a sequence in parallel given some input tokens as constraint. These transformers however may fail to support hard lexical constraints as their generation process is more likely to terminate prematurely. The paper analyses such early termination problems and proposes the ENtity-CONstrained insertion TransformER (ENCONTER), a new insertion transformer that addresses the above pitfall without compromising much generation efficiency. We introduce a new training strategy that considers predefined hard lexical constraints (e.g., entities to be included in the generated sequence). Our experiments show that ENCONTER outperforms other baseline models in several performance metrics rendering it more suitable in practical applications. [1]

1 Introduction

The field of Natural Language Generation (NLG) (Gatt and Krahmer, 2018) has seen significant improvements in recent years across many applications such as neural machine translation (Bahdanau et al., 2015), text summarization (Chopra et al., 2016), poem generation (Zugarini et al., 2019) and recipe generation (H. Lee et al., 2020). Constrained text generation (CTG) is one of the challenging problems in NLG that is important to many real world applications but has not been well addressed. CTG imposes input constraints which may be in the form of objects expected to exist in the generated text or rules over objects in the generated text (Hokamp and Liu, 2017). The objects here can be entities, phrases, predefined nouns, verbs, or sentence fragments. The constraints can be categorized into two types: (1) *Hard-constraints* which require mandatory inclusion of certain objects and complete compliance of given rules (Post and Vilar, 2018; Hu et al., 2019; Miao et al., 2019; Welleck et al., 2019; Zhang et al., 2020); and (2) *Soft-constraints* which allow the some constraint objects or rules to be not strictly enforced in the generated text (Qin et al., 2019; Tang et al., 2019). As autoregressive models generate tokens from left to right, they cannot easily support constraints involving multiple input objects, hard-constrained text generation therefore often requires non-autoregressive models.

Recently, Zhang et al. (2020) proposed a non-autoregressive hard-constrained text generation model (POINTER) that generates a text sequence in a progressive manner using an insertion-transformer (Stern et al., 2019). To train an insertion transformer to generate a missing token between every two tokens in an input sequence, the training data is prepared by masking "less important" tokens in the original text sequence in an alternating manner. The process is then repeated using the masked input sequence as the new original sequence, and further masking alternate tokens in it. The process ends when the masked sequence meets some length criteria.

While POINTER shows promising results, it does not consider hard constraints which involve entities that must be included in the generated sequence. Such entity constraint requirements are unfortunately prevalent in many applications. For example, we may want to generate a job description with some given skills, or a food recipe with some given ingredients.

A naive approach to the problem is to apply con-

[1] Our code is available at `https://github.com/LARC-CMU-SMU/Enconter`

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3590–3599
April 19 - 23, 2021.

straints on the POINTER's masking strategy forcing it to keep entity tokens. We call this modified model POINTER-E. Although this allow entity information entering POINTER-E, another problem rises. POINTER-E suffers from *cold start problem* which refers to the inability to generate meaningful tokens at the early stages of inference forcing the generation to end prematurely. This issue can be attributed to the POINTER-E's top-down masking strategy for training the insertion transformer and the tokens of input entities not evenly spread out across the sequence.

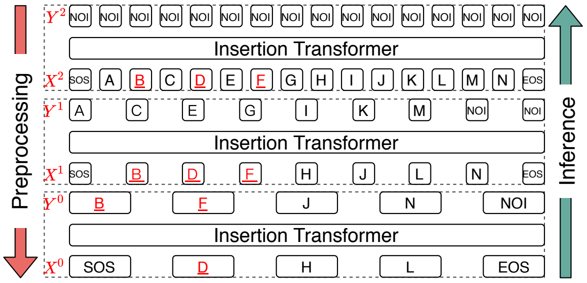
To solve the cold start generation problem, we propose ENCONTER that incorporates bottom-up masking strategy. ENCONTER supports hard entity constraints, and encourages more meaningful tokens to be generated in the early stages of generation thus reducing cold start. On top of that, we further introduce the balanced binary tree scheme (Stern et al., 2019) to reduce the number of stages in generation and to improve the efficiency of generation.

2 Entity Constrained Sequence Generation

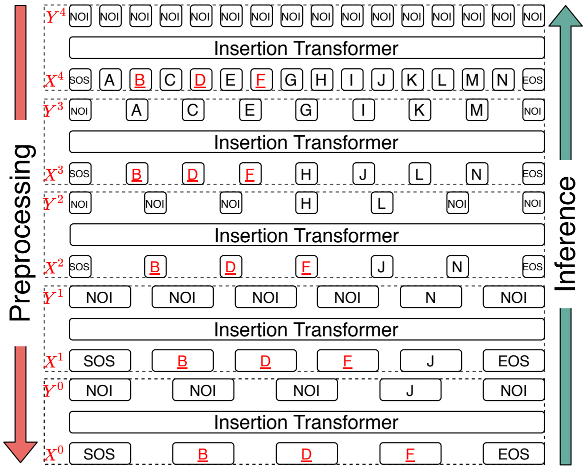
In this section, we first describe the state-of-the-art POINTER model, its preprocessing of training data and inference process. We highlight the pitfalls of the entity constrained variant of POINTER, POINTER-E. We then present our proposed entity constrained insertion transformer called ENCONTER.

2.1 POINTER

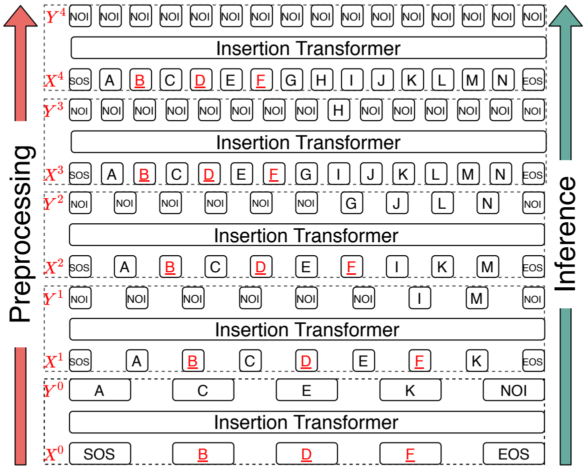
POINTER adopts a progressive masking approach to train an insertion transformer. Let $X = \{x_1, x_2, \ldots, x_T\}$ denote a sequence where $x_t \in V$, where T is the sequence length and V is a finite vocabulary set. Suppose X is a training sequence, POINTER preprocesses it to obtain the training pairs $S = \{(X^k, Y^k) | k \in \{K, \ldots, 0\}\}$ using a progressive masking strategy. As shown in Figure 1a, in each stage X^k represents the input sequence for stage k, and Y^k represents the sequence of masked tokens to be inferred. X^K is identical to the final training sequence $X^K = X$, and there should not be any additional tokens to infer. X^0 on the other hand represents the initial lexical constraints. In stage k, Y^k are the tokens to be predicted between adjacent tokens of X^k. A special no-insertion token $[NOI]$ is added to the vocabulary V and used in Y^k to indicate that no token is to be generated between adjacent tokens. Y^K is thus a sequence of all $[NOI]$'s indicating the end of generation. WordPiece (Wu et al., 2016) tokenization is applied in POINTER, and tokens split from the same word share the same score.



(a) POINTER masking.



(b) POINTER-E masking.



(c) ENCONTER insertion.

Figure 1: POINTER, POINTER-E, and ENCONTER with original sequence $X = \{A, B, C, D, E, F, G, H, I, J, K, L, M, N\}$ where B,D, and F are the tokens forming the entity constraints. The stopping criteria for POINTER is set to $n = 3$.

Token importance scoring POINTER assigns each token $x_t \in X$ an importance score α_t:

$$\alpha_t = \alpha_t^{TF-IDF} + \alpha_t^{POS} + \alpha_t^{YAKE}, \tag{1}$$

where α_t^{TF-IDF}, α_t^{POS}, and α_t^{YAKE} denote term frequency-inverse document frequency (TF-IDF), POS tag scores and YAKE (Campos et al., 2020) keyword scores, respectively. These scores are normalized to [0,1]. α_t^{POS} is defined such that the scores of nouns and verbs are higher than those of other POS tags. The token importance scores are used to derive the masking pattern Y^{k-1} of stage $k-1$ from X^k.

POINTER adopts four criteria to derive Y^{k-1} from X^k: (1) Y^{k-1} can only include non-adjacent tokens in X^k; (2) the number of tokens to be masked are maximized in each stage to make the model more efficient; (3) less important tokens are masked before more important ones and (4) A stopping criteria n is defined. The algorithm stops when $|X^k| = n$. Kadane's algorithm (Gries, 1982) has been use in POINTER to fulfill the criteria. Specifically, the algorithm selects as many unimportant tokens as possible to be masked while not masking two adjacent tokens. X^0 is automatically determined when $|X^k| = n$, it does not necessarily match the way the initial input sequence is provided by real world applications or users, including the entity constraints.

Inference Given X^0 as input sequence, POINTER starts to infer $\hat{Y}^0$ and combines the two sequences to get $\hat{X}^1 = \left\{\hat{x}_1^0, \hat{y}_1^0, \hat{x}_2^0, \hat{y}_2^0, \ldots, \hat{x}_{|\hat{X}^0|}^0, \hat{y}_{|\hat{X}^0|}^0\right\}$. If $\hat{y}_t^0$ happens to be $[NOI]$, it will be deleted and leaving only non-$[NOI]$ tokens in $\hat{X}^1$. The process repeats until all the generated tokens in $\hat{Y}^k$ are $[NOI]$s.

As shown in Figure 1a, entities may not be preserved during the preprocessing steps and the lexical constraint X^0 is not guaranteed to cover entity constraint X^e even entity tokens are assigned high importance scores. The trained POINTER therefore may not be able generate a sequence successfully when given entity constraints during the inference. We therefore propose some changes to POINTER to make it entity-aware.

2.2 Entity Aware POINTER (POINTER-E)

The entity-aware POINTER model, POINTER-E, adopts a different preprocessing approach. Let $X^e \subset X$ be an ordered sequence of entity tokens (e.g., the person names in a news document). As X^e is likely to be used as the initial generation input (i.e., $X^0 = X^e$), POINTER-E's preprocessing does not mask these entity tokens over the different preprocessing stages. This way, the model is trained to focus on generating tokens around the entities. Such tokens form the context around the entities and context relating one entity to others. We achieve such goal by ignoring the importance scores applied on entity tokens. That is, we only compute α_t for $x_t \notin X^e$.

We then apply the POINTER's masking strategy on the sub-sequence between every two entity tokens in X. Suppose $(x_i, x_j) \subset X$ is a subsequence spanned by two entity tokens $\{x_l^e = x_i, x_{l+1}^e = x_j\} \in X^e$ where $l \in \{0, \ldots, |X^e| - 1\}$. Masking is applied on this subsequence iteratively until only $\{x_l^e, x_{l+1}^e\}$ are left:

$$\begin{aligned} S = &\{(X^K = X, Y^K), \ldots, \\ &(X^0 = X^e, Y^0)\}. \end{aligned} \tag{2}$$

As shown in Figure 1b, POINTER-E always picks the optimal masking patterns while preserving the entities.

Cold Start Problem While POINTER-E is aware of entities, entities in X^e may appear very close or very far from one another in the full sequence X, i.e., the gap between entities in the sequence X can vary a lot. Consider two sub-sequences $(x_i = x_l^e, x_j = x_{l+1}^e), (x_u = x_w^e, x_v = x_{w+1}^e) \subset X$ where $w, l \in (0, T_e - 1)$ and $w \neq l$. Suppose $j - i \gg v - u$. The tokens between (x_u, x_v) will then be masked out long before tokens in (x_i, x_j) during preprocessing and training. This results in POINTER-E trained to generate a lot of $[NOI]$s in Y^k for small k's. Figure 1b depicts this cold start problem as entity tokens B, D and E are near one another in X. As tokens between them are masked in early stages, the masked sequences in stages 0 and 1, Y^0 and Y^1, contain many $[NOI]$ tokens. POINTER-E trained with such data will therefore lack the ability to generate meaningful tokens in-between these entity tokens. In the worst case, POINTER-E simply generates all $[NOI]$ tokens and ends the generation prematurely which is known as the *cold start problem.*

To better show the problem, we define:

$$NOI\ ratio = \frac{\#[NOI] \text{ in } Y^k}{\#tokens \text{ in } Y^k}. \tag{3}$$

A clear problem of high $NOI\ ratio$ is that Y^k is very similar to Y^{k+1}. When $NOI\ ratio = 1$, the generation will end, In cases where $NOI\ ratio$ is very high for masked sequences in early stages, say Y^0, the trained POINTER-E will more likely infer from X^0 all $[NOI]$'s for $\hat{Y}^0$ and end the generation process. To address this, we need to re-examine the top-down masking stratey used in POINTER and POINTER-E.

2.3 ENCONTER

In this section, we propose ENCONTER which adopts a bottom-up masking strategy to overcome the cold start problem. There are two variants: GREEDY ENCONTER and BBT-ENCONTER.

GREEDY ENCONTER Different from POINTER-E, we now construct training pairs S from X by setting X^0 to be X^e:

$$\begin{aligned} S =\{&(X^0 = X^e, Y^0), (X^1, Y^1), \ldots, \\ &(X^K = X, Y^K)\}, \end{aligned} \tag{4}$$

where Y^k represents the sequence of masked tokens to be inserted into X^k to form X^{k+1}. Similar to POINTER, Y^K contains $[NOI]$'s only. For every two adjacent tokens $\{x_t^k, x_{t+1}^k\} \in X^k$ where $t \in \{0, \ldots, |X^k| - 1\}$, we insert a mask token. Let $\{x_t^k = x_i, x_{t+1}^k = x_j\}$ and (x_i, x_j) be the span of (x_i, x_j) in X. If $i + 1 = j$, the mask token is $[NOI]$. Otherwise, we select a token $x_{t'}$ from (x_i, x_j) with maximum importance score $\alpha_{t'}$ within (x_i, x_j) as the mask token. The sequence Y^k is formed after we go through all the t's. By inserting Y^k into X^k, we obtain the next sequence X^{k+1}. The iterative process stops when all the tokens to be inserted are $[NOI]$s. This method GREEDY ENCONTER greedily selects the token with maximum importance score in the span to be generated in a bottom up insertion (or unmasking) process. By forcing more non-$[NOI]$ tokens to be included in Y^0 and Y^k of small k's, *Greedy Enconter* achieves lower $NOI\ ratio$ in the early stages of inference. Experimentally, we find that the cold start problem is eliminated.

Balanced binary tree ENCONTER (BBT-ENCONTER) To further improve the efficiency of GREEDY ENCONTER, we incorporate balanced binary tree (Stern et al., 2019) into ENCONTER to bias the masking of tokens to be those near the center of the unobserved subsequence of tokens. BBT reward is added to the importance score function as follows. Suppose x_i and x_j are two adjacent tokens in X^k, and (x_i, x_j) represents the corresponding subsequence in X. We define the distance d_p for token $x_p \in (x_i, x_j)$ as:

$$d_p = min(p - i, j - p). \tag{5}$$

We use a softmax function to compute the reward for weighted score based on d_p:

$$w_p = \frac{exp(d_p/\tau)}{\sum_{k=i}^{j} exp(d_k/\tau)}. \tag{6}$$

The weights in the span are then normalized to $[0, 1]$. Then the importance score is defined as:

$$\alpha_p = w_p \cdot (\alpha_p^{TF-IDF} + \alpha_p^{POS} + \alpha_p^{YAKE}). \tag{7}$$

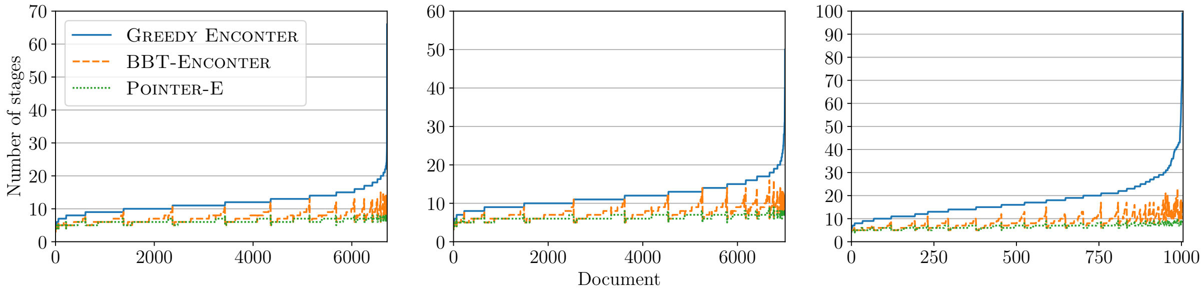
The construction of S is almost the same as GREEDY ENCONTER. The only difference is the new importance score function defined by Eq. 7. This proposed model, known as BBT-ENCONTER, will predict the center and semantically important token in X between two adjacent tokens of X^k.

2.4 Models with Entity Span Aware Inference Option (ESAI)

So far, all above-mentioned models assume that each entity consists of one single token. In real world use cases, an entity may contain more than one token. Without any control during the inference process, it is possible for other tokens to be generated in-between tokens of the same entity. For example in Table 5, "Group Consolidation" may be split into "handling Group s project / Consolidation". To avoid inserting any tokens in between any multi-token entity, we introduce the *entity span aware inference* option to the inference process of POINTER-E and ENCONTER to force the inference of $\hat{Y}^k$ to always generate $[NOI]$ in between the tokens of the multi-token entities. After applying ESAI, the multi-token entities will remain unbroken duing the generation process.

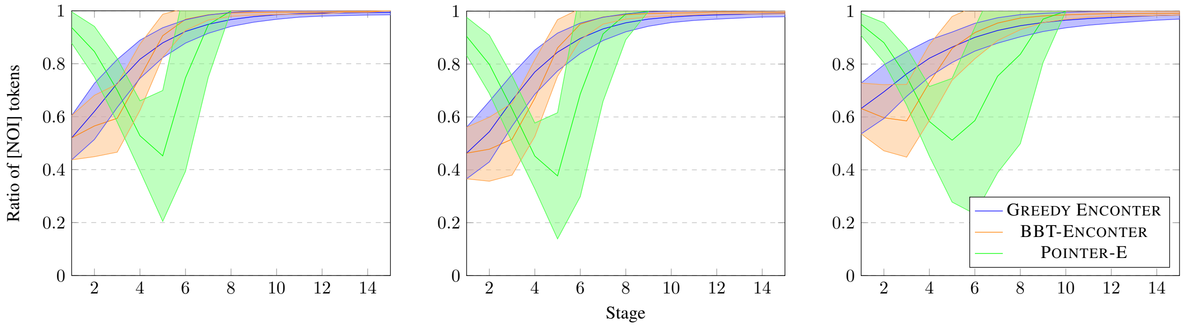
3 Empirical Analysis of POINTER-E and ENCONTER

In this section, we conduct an analysis of the data preprocessing step in POINTER-E, GREEDY ENCONTER and BBT-ENCONTER. Our objective is to empirically evaluate the characteristics of training data generated for the two models. We have left out POINTER as it is inherently not entity-aware and POINTER-E is its entity-aware variant. We first present the two datasets used in this study.



(a) SD (b) SM (c) CoNLL-2003

Figure 2: Number of stages of each document in SD, SM, and CoNLL-2003 (sorted).



(a) SD (b) SM (c) CoNLL-2003

Figure 3: Mean and standard deviation of the ratio of inserted/masked [NOI] tokens in each stage. All x axis are capped to 15 stages. The original maximum number of stages of (a), (b), and (c) are 67, 51, and 100, respectively.

3.1 Datasets

CoNLL-2003 (Tjong Kim Sang and De Meulder, 2003): We select the English version which contains 1,393 news articles labeled with four named entity types: persons, locations, organizations and names of miscellaneous. Training and development sets are used to train the model. Documents having more than 512 tokens by wordpiece tokenizer used in BERT (Devlin et al., 2019) are discarded to ensure that the whole document can fit into the models.

Jobs: This is a job post dataset collected from Singapore's Jobsbank [2]. The dataset consists of 7,474 job posts under the software developer occupation (SD) and 7,768 job posts under the sales and marketing manager occupation (SM). We extract the requirement section of these job posts as the text sequences to be generated. For each requirement text sequence (or document), we use a dictionary of skills to annotate the skill and job related entities in the sequence.

The detailed information of the datasets can be found in Table 1. Table 1 reveals that Pointer-E has much higher $NOI\ ratio$ than Enconter in all the datasets.

	CoNLL	**SM**	**SD**
#training docs	1,004	6,715	7,006
#testing docs	231	754	761
Avg length	220.7	99.4	121.1
Avg entities	24.6	24.4	27.7
#training pairs			
Pointer-E	6,557	43,913	41,343
Greedy Enconter	17,694	83,587	79,467
BBT-Enconter	8,492	52,609	48,625
$NOI\ ratio$ of Y^0			
Pointer-E	0.820	0.904	0.936
Greedy Enconter	0.546	0.463	0.519
BBT-Enconter	0.546	0.463	0.519

Table 1: Summary of the datasets. #training pairs refers to the total number of training pairs derive from each dataset

3.2 Analysis of NOI ratio and Stage Counts

We first analyse the ratio of $[NOI]$ tokens inserted or masked in every stage of the *training data*. Figure 3 shows the mean together with one standard deviation of the Pointer-E, Greedy Enconter and BBT-Enconter for each dataset. X-axis is in log scale. Note we add 1 to the stage number for showing log scale (e.g., the 10^0 in the figure indicates the ratio of $[NOI]$ tokens in Y^0). From Figure 3, we find all datasets share a few similar characteristics, namely: (1) for Pointer-E, the $[NOI]$ ratio is quite high in the first few stages, and drops when the stage is higher. A sudden increase of the ratio to 1 is due to the ending sequence consists all $[NOI]$'s; (2) for Enconter the $[NOI]$

---

[2] https://www.mycareersfuture.sg/

ratio is low in the first few stages, and slowly increase to 1. The result shows ENCONTER can learn to generate balance proportion of $[NOI]$ and non-$[NOI]$ tokens in the first few stages, and also learn not to generate to many non-$[NOI]$ tokens when approaching the end of the generation process.

Figure 2 shows the number of stages each training document requires under different models. The numbers are sorted according to the following priority: GREEDY ENCONTER, POINTER-E, then BBT-ENCONTER. Since BBT-ENCONTER incorporates the binary tree reward scheme, it is able to perform insertion in the middle stages more efficiently compare to GREEDY ENCONTER. This helps to lower the total number of stages required to derive training pairs.

4 Experiment

4.1 Models for Comparison

GPT-2 (Radford et al., 2019) GPT-2 can be used to conduct conditional generation as well (soft-constraints). For a training sequence X together with its entities X^e, we concatenate X^e with X to form a training sequence $\{X^e, X\}$. X^e is then served as a control code sequence to guide GPT-2 in the generation of X. We fine-tune the *GPT-2 small* pretrained by huggingface [3] with 10^{-5} learning rate. Warmup and weight decay are applied. 10 epochs are used for fine-tuning.

POINTER-E, GREEDY ENCONTER, and BBT-ENCONTER: We use BERT (Devlin et al., 2019) as the underlying insertion transformer for all these models similar to that of POINTER. Specifically, we use the *bert-based-cased* pretrained by huggingface. BERT with language model head is fine-tuned on all the training pairs to obtain the models. Learning rate is set to 10^{-5} with warmup and weight decay. 10 epochs are used for fine-tuning.

For POINTER-E, GREEDY ENCONTER, and BBT-ENCONTER, top-k (top-20) sampling method is used to derive $\hat{Y}^k$. For GPT-2, we feed in the $\hat{X}^e$ and let GPT-2 generate the following tokens until reaching the end-of-generation token.

4.2 Evaluation Metrics

We evaluate the models using a few criteria, namely: recall of entities, quality with respect to human crafted text, diversity, fluency, cold start, and generation efficiency. We measure recall of entity constraints by the proportion of entity tokens found in the generated text. Even without ESAI, the recall metric will allow to compare the recall ability of models. Besides recall, we also consider BLEU (Papineni et al., 2002), METEOR (MTR) (Lavie and Agarwal, 2007) and NIST (Doddington, 2002), which are common metrics for evaluating the quality of generated text against human craft text. We compute the BLEU-2 (B-2) and BLEU-4 (B-4) which are n-gram precision-based metrics. For the BLUE based evaluation metric NIST, we compute the NIST-2 (N-2) and NIST-4 (N-4). To measure the diversity of generation, Entropy (Zhang et al., 2018) and Distinction (Li et al., 2016) are used. Entropy-4 (E-4) is defined as the frequency distribution of unique 4-gram terms. Dist-1 (D-1) and Dist-2 (D-2) are used to derive distinct n-grams in the generated text. We also utilize pretrained language model to measure fluency. Perplexity (PPL) is calculated using pretrained GPT-2 (Radford et al., 2019) without fine-tuning. The lower the perplexity is, the more fluent the generation is (based on GPT-2). “AvgLen” is the averaged word counts of the generated sequence. “failure” indicates the proportion of test sequences that fail to be generated at the first step (i.e., $\hat{Y}^0$ are all $[NOI]$’s). Finally, “AvgSteps” shows the average number of steps for the model to complete the generation. Note for GPT-2, the AvgSteps is based on tokens, while the AvgLen is based on words.

4.3 Experiment Results

Tables 2, 3, and 4 show the results of different models on the different datasets. On recall, GPT-2, due to its inability to enforce hard lexical constraints, yields the worst recall. For non-autoregressive models without ESAI, they still achieve high recall. Nevertheless, the high recall of POINTER-E is “contributed by” relatively high failure ratio ("failure") as recall is 1 even when the model fails to generate anything in the first stage. In other words, POINTER-E suffers from cold start problem. GREEDY ENCONTER and BBT-ENCONTER, in contrast, enjoy both good recall and zero failure ratio. With ESAI option, all non-autoregressive models can achieve perfect recall without much additional generation steps. However, this option does not reduce the high failure ratio of POINTER-E. On generation quality compared with human crafted text, GREEDY ENCONTER and BBT-ENCONTER outperform all other models by NIST, BLEU, and

Table 4: SM result

MTR. This suggests that ENCONTER models learn the context of entities better compared to other models. On generation diversity, POINTER-E again has the highest diversity largely due to its high failure ratio. Finally, we discuss the efficiency of models measured by AvgSteps. The autoregressive nature of GPT-2 makes it the least efficient model among all. POINTER-E's ability to optimize masking patterns makes it the most efficient model. With balance binary tree reward, BBT-ENCONTER is able to finish its generation in fewer iterations than GREEDY ENCONTER.

Case example Table 5 shows a case example from Jobs SM dataset. The entities of the given constraint are underlined. Invalid entities generated are colored in red, while the remaining ones are colored in blue. There are three types of invalid cases. First, the case of entity is not the same as specified. Second, the entity is not recalled in the generation. Third, the entity has its tokens separated by some other token(s). In this example, POINTER-E and POINTER-E ESAI terminate their generations prematurely. They fail to perform generation at the very first stage.

5 Related Work

Recent years have witnessed significant success using autoregressive (Dai and Le, 2015; Peters et al., 2018; Radford, 2018) generative models to conduct conditional generation on various tasks. CTRL (Keskar et al., 2019) uses control codes trained together with large amount of data to control the content to be generated. RecipeGPT (H. Lee et al., 2020) takes ingredients as a series of control and trains the generation of recipe text. PPLM (Dathathri et al., 2020)

Greedy Enconter:
Degree / ACCA / CIMA / CA / CFA / F & B / Group Consolidation experience
Degree in General Accounting
Good track record in IFRSRSM, Fixed Assets, IFRS

Greedy Enconter ESAI:
* * Degree / ACCA / CIMA / CA / CFA / CA / CAPA / Singapore Group Consolidation / Management / General Accounting experience
* Experience in IFRS or preferred
* Experience in Fixed Assets Management
* Extensive experience in IFRS

BBT-Enconter:
Degree or ACCA / CIMA or CFA qualifications
YEARSPAN'experience in handling Group s project / Consolidation / Good Inteconor / General Accounting
Knowledge of IFRSPAN, Fixed Assets (IFRS, etc)

BBT-Enconter ESAI:
Minimum Degree / ACCA / CIMA, CFA or equivalent
Minimum of YEARSPAN of experience in Marketing and Group Consolidation and General Accounting
Knowledge of IFRS) and Fixed Assets (IFRS)

GPT-2: (missing: IFRS, CFA, Group Consolidation, Fixed Assets)
Job Requirements :
- Degree in General Accounting / ACCA Qualification
- At least YEARSPAN of applicable working experience in similar capacity
- Must be able to multi-task and handle different priorities simultaneously
- General accounting knowledge will be advantageous

directly steers the pretrained language by a bag-of-words model or simple linear discriminator. The above models in their own ways gain certain level of control over the content generation process. However, they do not provide a mechanism to directly enforce some lexical constraints in the final generation. Non-monotonic sequence generation (Welleck et al., 2019) is designed to perform hard lexical constrains generation based on binary tree structure. By leveraging level-order and in-order traversal of binary tree, the model allows text to be generated non-monotonically. Although the results from non-monotonic generation models seem promising, they do not perform token generation in parallel and the tree structure governing the generation process may produce many unused tokens during the generation.

The emergence of non-autoregressive language model provides another approach to support hard lexical constraints. Insertion transformer (Stern et al., 2019) uses transformer architecture with balanced binary tree loss to perform insertion-based generation. KERMIT (Chan et al., 2019) is proposed as a structure to unify insertion transformers. Levenshtein transformer (Gu et al., 2019) further introduces deletion as an action to take during generation. Our Enconter models differ from these previous models as they are not designed to support any lexical constraints, including entity constrains.

6 Conclusions

Constrained text generation is an important task for many real world applications. In this paper, we focus on hard entity constraints and the challenges associated with enforcing them in text generation. Our analysis of the state-of-the-art insertion transformers reveals issues, namely, cold start problems and inefficient generation. We therefore propose two insertion transformer models, Greedy Enconter and BBT Enconter, that use a bottom-up preprocessing strategy to prepare training data so as to eliminate the cold start problem caused by top-down preprocessing strategy. BBT Enconter further incorporates a balanced tree reward scheme to make the generation process more efficient. Through experiments on real world datasets, we show that the two models outperform the strong baselines, Pointer-E and GPT2, in recall, quality and failure rate while not compromising much generation efficiency. For future research, it will be interesting to consider more diverse constraints (e.g., soft constraint, rules, etc.) and user interaction in the generation process to expand the scope of applications that can benefit from this research.

Abstract

Natural language processing (NLP) tasks (e.g. question-answering in English) benefit from knowledge of other tasks (*e.g.*, named entity recognition in English) and knowledge of other languages (*e.g.*, question-answering in Spanish). Such shared representations are typically learned in isolation, either across tasks or across languages. In this work, we propose a meta-learning approach to learn the interactions between both tasks and languages. We also investigate the role of different sampling strategies used during meta-learning. We present experiments on five different tasks and six different languages from the XTREME multilingual benchmark dataset (Hu et al., 2020). Our meta-learned model clearly improves in performance compared to competitive baseline models that also include multi-task baselines. We also present zero-shot evaluations on unseen target languages to demonstrate the utility of our proposed model.

1 Introduction

Multi-task and multilingual learning are both problems of long standing interest in natural language processing. Leveraging data from multiple tasks and/or additional languages to benefit a target task is of great appeal, especially when the target task has limited resources. When it comes to multiple tasks, it is well-known from prior work on multi-task learning (Liu et al., 2019b; Kendall et al., 2018; Liu et al., 2019a; Yang and Hospedales, 2017) that jointly learning a model across tasks can benefit the tasks mutually. For multiple languages, the ability of deep learning models to learn effective embeddings has led to their use for joint learning of models across languages (Conneau et al., 2020; Conneau and Lample, 2019; Artetxe and Schwenk, 2019); learning cross-lingual embeddings to aid languages in limited resource settings is of growing interest (Kumar et al., 2019; Wang et al., 2017; Adams et al., 2017). Let us say we had access to M tasks across N different languages - *c.f.* Table 1 that outlines such a matrix of tasks and languages from the XTREME benchmark (Hu et al., 2020). How do we perform effective joint learning across tasks and languages? Are there specific tasks or languages that need to be sampled more frequently for effective joint training? Can such sampling strategies be learned from the data?

In this work, we adopt a meta-learning approach for efficiently learning parameters in a shared parameter space across multiple tasks and multiple languages. Our chosen tasks are question answering (QA), natural language inference (NLI), paraphrase identification (PA), part-of-speech tagging (POS) and named entity recognition (NER). The tasks were chosen to enable us to employ a gamut of different types of language representations needed to tackle problems in NLP. In Figure 1, we illustrate the different types of representations by drawing inspiration from the Vauquois Triangle (Vauquois, 1968), well-known for machine translation, and situating our chosen tasks within such a triangle. Here we see that POS and NER are relatively 'shallower' analysis tasks that are token-centric, while QA, NLI and PA are 'deeper' analysis tasks that would require deeper semantic representations. This representation suggests a strategy for effective parameter sharing. For the deeper tasks, the same task in different languages could have representations that are closer and hence benefit each other, while for the shallower tasks, keeping the language unchanged and exploring different tasks might be more beneficial. Interestingly, this is exactly what we find with our meta-learned model and is borne out in our experimental results. We also find that as the model progressively learns, the meta-learning based models for the tasks requiring deeper semantic analysis benefit more from joint learning compared to the shallower tasks.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3600–3612
April 19 - 23, 2021.

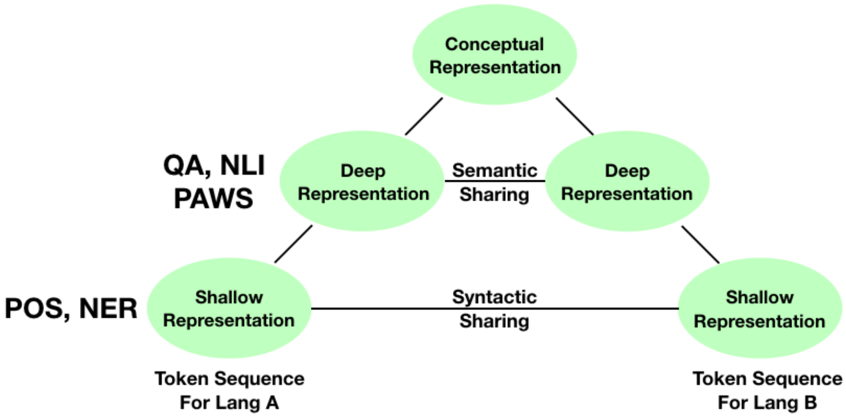

Figure 1: Illustration derived from Vauquois Triangle to linguistically motivate our setting. POS and NER being lower down in the representations (and are thus 'shallower') are further away from the same task in another language. QA, XNLI and PAWS being higher up in the representations (and are thus 'deeper') are closer to the same task in another language.

With access to multiple tasks and languages during training, the question of how to sample effectively from different tasks and languages also becomes important to consider. We investigate different sampling strategies, including a parameterized sampling strategy, to assess the influence of sampling across tasks and languages on our meta-learned model.

Our main contributions in this work are threefold:

- We present a meta-learning approach that enables effective sharing of parameters across multiple tasks and multiple languages. This is the first work, to our knowledge, to explore the interplay between multiple tasks at different levels of abstraction and multiple languages using meta-learning. We show results on the recently-released XTREME benchmark and observe consistent improvements across different tasks and languages using our model. We also offer rules of thumb for effective meta-learning that could hold in larger settings involving additional tasks and languages.

- We investigate different sampling strategies that can be incorporated within our meta-learning approach and examine their benefits.

- We evaluate our meta-learned model in zero-shot settings for every task on target languages that never appear during training and show its superiority compared to competitive zero-shot baselines.

2 Related Work

We summarize three threads of related research that look at the transferability in models across different tasks and different languages: multi-task learning, meta-learning and data sampling strategies for both multi-task learning and meta-learning. Multi-task learning (Caruana, 1993) has proven to be highly effective for transfer learning in a variety of NLP applications such as question answering, neural machine translation, *etc.* (McCann et al., 2018; Hashimoto et al., 2017; Chen et al., 2018; Kiperwasser and Ballesteros, 2018). Some multi-task learning approaches (Jawanpuria et al., 2015) have attempted to identify clusters (or groups) of related tasks based on end-to-end convex optimization formulations. Meta-learning algorithms (Nichol et al., 2018) are highly effective for fast adaptation and have recently been shown to be beneficial for several machine learning tasks (Santoro et al., 2016; Finn et al., 2017). Gu et al. (2018) use a meta-learning algorithm for machine translation to leverage information from high-resource languages. Dou et al. (2019) investigate multiple model agnostic meta-learning algorithms for low-resource natural language understanding on the GLUE (Wang et al., 2018) benchmark.

Data sampling strategies for multi-task learning and meta-learning form the third thread of related work. A good sampling strategy has to account for the imbalance in dataset sizes across tasks/languages and the similarity between tasks/languages. A simple heuristic-based solution to address the issue of data imbalance is to assign more weight to low-resource tasks or languages (Aharoni et al., 2019). Arivazhagan et al. (2019) define a temperature parameter which controls how often one samples from low-resource tasks/languages. The MultiDDS algorithm, proposed by Wang et al. (2020b), actively learns a different set of parameters for sampling batches given a set of tasks such that the performance on a held-out set is maximized. We use a variant of MultiDDS as a sampling strategy in our meta-learned model. Nooralahzadeh et al. (2020) is most similar in spirit to our work in that they study a cross-lingual and cross-task meta-learning architecture but only focus on zero-shot and few-shot transfer for two natural language understanding tasks, NLI and QA. In contrast, we study many tasks in many languages, in conjunction with sampling strategies, and offer concrete insights on how best to guide the meta-learning process when multiple tasks are in the picture.

3 Methodology

Our setting is pivoted on a **grid** of tasks and languages (with some missing entries as shown in Table 1). Each row of the grid corresponds to a single **task**. A cell of the grid corresponds to a Task-Language pair which we refer to as a TL pair (**TLP**). We denote by $q_i = |\mathcal{D}^i_{train}| / \left(\sum_{k=1}^{n} |\mathcal{D}^k_{train}|\right)$, the fraction of the dataset size for the i^{th} TLP and by $P_{\mathcal{D}}(i)$, the probability of sampling a batch from the i^{th} TLP during meta training. The distribution over all TLPs, *viz.*, is a Multinomial (say $\mathcal{M}$) over $P_{\mathcal{D}}(i)$s.

3.1 Our Meta-learning Approach

The goal in the standard meta learning setting is to obtain a model that generalizes well to new test/target tasks given some distribution over training tasks. This can be achieved using optimization-based meta-learning algorithms that modify the learning procedure in order to learn a good initialization of the parameters. This can serve as a useful starting point that can be further fine-tuned on various tasks. Finn et al. (2017) proposed a general optimization algorithm called Model Agnostic Meta Learning (MAML) that can be trained using gradient descent. MAML aims to minimize the following objective

$$\min_{\theta} \sum_{T_i \sim \mathcal{M}} \mathcal{L}_i \left(U_i^k(\theta) \right) \tag{1}$$

where $\mathcal{M}$ is the Multinomial distribution over TLPs, $\mathcal{L}_i$ is the loss and U_i^k a function that returns θ after k gradient updates both calculated on batches sampled from T_i. Minimizing this objective using first order methods involves computing gradients of the form $\frac{\partial}{\partial\theta} U_i^k(\theta)$, leading to the expensive computation of second order derivatives. Nichol et al. (2018) proposed an alternative first-order meta-learning algorithm named "Reptile" with simple update rule:

$$\theta \leftarrow \theta + \beta \frac{1}{|\{T_i\}|} \sum_{T_i \sim \mathcal{M}} (\theta_i^{(k)} - \theta) \tag{2}$$

where $\theta_i^{(k)}$ is $U_i^k(\theta)$. Despite its simplicity, a recent study by Dou et al. (2019) showed that Reptile is atleast as effective as MAML in terms of performance. We therefore employed Reptile for meta learning in all our experiments.

Algorithm 1 Our Meta-learning Approach

```
Input: $\mathcal{D}_{train}$ set of TLPs for meta training
(Also $\mathcal{D}_{dev}$ for parametrised sampling)
        Sampling Strategy (Temperature / MultiDDS)
Output: The converged multi-task multilingual model parameters $\theta^*$
Initialize $P_D(i)$ depending on the sampling strategy
while not converged do
    ▷ Perform Reptile Updates
    Sample $m$ TLPs $T_1, T_2, \ldots, T_m$ from $\mathcal{M}$
    for i = 1,2,...,m do
        $\theta_i^{(k)} \leftarrow U_i^k(\theta)$, denoting $k$ gradient updates from $\theta$ on batches of TLP $T_i$
    end for
    $\theta \leftarrow \theta + \frac{\beta}{m} \sum_{i=1}^{m} (\theta_i^{(k)} - \theta)$
    if Sampling Strategy ← MultiDDS then
        for $\mathcal{D}^i_{train} \in \mathcal{D}_{train}$ do
            $R(i;\theta) \leftarrow cos(g_{dev}, g_{train})$, $g_{dev}$ is gradient on $\{\mathcal{D}_{dev}\}$ and $g_{train}$ is gradient on $\mathcal{D}^i_{train}$
        end for
        ▷ Update Sampling Probabilities
        $d_\psi \leftarrow \sum_{i=1}^{n} R(i;\theta) \cdot \nabla_\psi log(P_{\mathcal{D}}(i;\psi))$
        $\psi \leftarrow$ GradientUpdate$(\psi, d_\psi)$
    end if
end while
```

3.2 Selection and Sampling Strategies

3.2.1 Selection

The choice of TLPs in meta-learning plays a vital role in influencing the model performance, as we will see in more detail in Section 5. Apart from the use of all TLPs across both tasks and languages during training, selecting all languages for a given task (Gu et al., 2018) and selecting all tasks for a given language (Dou et al., 2019) are two other logical choices. We refer to the last two settings as being `Task-Limited` and `Lang-Limited`, respectively.

3.2.2 Heuristic Sampling

Once the TLPs for meta training (denoted by $\mathcal{D}$) have been selected, we need to sample TLPs from $\mathcal{M}$. We investigate temperature-based heuristic sampling (Arivazhagan et al., 2019) which defines the probability of any dataset as a function of its size. $P_{\mathcal{D}}(i) = q_i^{1/\tau} / \left(\sum_{k=1}^{n} q_k^{1/\tau} \right)$ where $P_{\mathcal{D}}(i)$ is the probability of the i^{th} TLP to be sampled and τ is the temperature parameter. $\tau = 1$ reduces to sampling TLPs proportional to their dataset sizes and $\tau \rightarrow \infty$ reduces to sampling TLPs uniformly.

3.2.3 Parameterized Sampling

The sampling strategy defined in Section 3.2.2 remains constant throughout meta training and only depends on dataset sizes. Wang et al. (2020b) proposed a parameterized sampling technique called MultiDDS that builds on Differential Data Selection (DDS) (Wang et al., 2020a) for weighing multiple datasets. The $P_{\mathcal{D}}(i)$ are parameterized using ψ_i as $P_{\mathcal{D}}(i) = e^{\psi_i} / \sum_j e^{\psi_j}$ with the initial value of ψ satisfying $P_{\mathcal{D}}(i) = q_i$. The optimization for ψ and θ is performed in an alternating manner (Colson et al., 2007)

$$\psi^* = \underset{\psi}{\text{argmin}} \; J(\theta^*(\psi), \mathcal{D}_{dev}) \tag{3}$$

$$\theta^*(\psi) = \underset{\theta}{\text{argmin}} \; E_{x,y \sim P(T;\psi)}[l(x,y;\theta)] \tag{4}$$

$J(\theta, \mathcal{D}_{dev})$ is the objective function which we want to minimize over development set(s). The reward function, $R(x,y;\theta_t)$, is defined as:

$$R(x,y;\theta_t) \approx \underbrace{\nabla J(\theta_t,\mathcal{D}_{dev})^T}_{g_{dev}} \cdot \underbrace{\nabla_\theta l(x,y;\theta_{t-1})}_{g_{train}} \tag{5}$$

$$\approx cos(g_{dev}, g_{train}) \tag{6}$$

ψ's are updated using the REINFORCE (Williams, 1992) algorithm.

$$\psi_{t+1} \leftarrow \psi_t + R(x,y;\theta_t) \cdot \nabla_\psi log(P(x,y;\psi)) \tag{7}$$

The Reptile meta-learning algorithm (along with details of the parameterized sampling strategy) is outlined in Algorithm 1.

4 Experimental Setup

4.1 Evaluation Benchmark

The recently released XTREME dataset (Hu et al., 2020) is a multilingual multi-task benchmark consisting of classification, structured prediction, QA and retrieval tasks. Each constituent task has associated datasets in multiple languages. The sources of POS and NER datasets are Universal Dependency v2.5 treebank (Nivre et al., 2020) and WikiAnn (Pan et al., 2017) respectively, with ground-truth labels available for each language. Large-scale datasets for QA, NLI and PA were originally available only for English. The PAWS-X (Yang et al., 2019) dataset contains machine-translated training pairs and human-translated evaluation pairs for PA. The authors of XTREME train a custom-built translation system to obtain translated datasets for QA and NLI. For the NLI task, we train using MultiNLI (Williams et al., 2018) and evaluate on XNLI (Conneau et al., 2018). For the QA task, SQuAD 1.1 (Rajpurkar et al., 2016) was used for training and MLQA (Lewis et al., 2019) for evaluation.

Regarding evaluation metrics, for QA we report F1 scores and for the other four tasks (PA, NLI, POS, NER) we report accuracy scores.

4.2 Implementation Details

BERT (Devlin et al., 2019) models yield state-of-the-art performance for many NLP tasks. Since we are dealing with datasets in multiple languages, we build our meta learning models on mBERT (Pires et al., 2019; Wu and Dredze, 2019) base architecture, implemented by Wolf et al. (2020), with output layers specific to each task. In our experiments, we use the AdamW (Loshchilov and Hutter, 2017) optimizer to make gradient-based updates to the model's parameters using batches from a particular TLP (Alg. 1, Line 6). This optimizer is shared across all the TLPs. When performing the meta-step (Alg. 1, Line 8), we use vanilla stochastic gradient descent (SGD) (Robbins and Monro, 1951) updates. Similarly, in the case of parameterized sampling the weights are updated (Alg. 1, Line 15) using vanilla SGD.

Meta training involves sampling a set of m tasks, taking k gradient update steps from the initial parameter to arrive at $\theta_i^{(k)}$ for task T_i and finally updating θ using the Reptile update rule. For meta-

models we fix learning rate = 3e-5 and dropout probability = 0.1 (provided by XTREME for reproduction of baselines). Grid search was performed on $m \in \{4, 8, 16\}$, $k \in \{2, 3, 4, 5\}$ and $\beta \in \{0.1, 0.5, 1.0\}$ for `All TLPs` model ($\tau = 1$). The best setting ($m = 8$, $k = 3$, $\beta = 1.0$) was selected based on validation score (accuracy or F1) averaged over all TLPs. These hyperparameters were kept constant for all further experiments. Each meta-learning model is trained for 5 epochs. We then finetune the meta model individually on each TLP and evaluate the results. Finetuning parameters vary for different task and are mentioned in Appendix B.

4.3 Data Selection and Sampling Strategies

We experiment with three different configurations for the set of TLPs to be considered during meta-learning: (a) using all tasks for a given language (`Lang-Limited`) (b) using all languages for a given task (`Task-Limited`) and (c) using all tasks and all languages (`All TLPs`). Since the dataset size varies across tasks (as also across languages), we use temperature sampling within each setting for $\tau = 1, 2, 5$ and ∞. (In Table 4 of the Appendix C in the supplementary material, we report results for different choices of TLP selection and different values of the temperature.)

With respect to the **Input** in Algorithm 1, there are two sets of TLPs that need to be selected for parameterized sampling: $\mathcal{D}_{train}$ and $\mathcal{D}_{dev}$. In order to analyse the effect of the choice of task and language, we experiment with the following 4 settings -

(a) $\mathcal{D}_{train}$ = `Lang-Limited`, $\mathcal{D}_{dev}$ = `Target TLP`

(b) $\mathcal{D}_{train}$ = `Task-Limited`, $\mathcal{D}_{dev}$ = `Target TLP`

(c) $\mathcal{D}_{train}$ = `All TLPs`, $\mathcal{D}_{dev}$ = `Lang-Limited`

(d) $\mathcal{D}_{train}$ = `All TLPs`, $\mathcal{D}_{dev}$ = `Task-Limited`.

The models (a), (b) are referred to as `mDDS` and (c), (d) are called `mDDS-Lang` and `mDDS-Task` respectively. Results for these 4 models are reported in Table 2 alongside temperature sampling for comparison.

4.4 Baselines

Our first baseline system for each TLP uses mBERT-based models trained on data specific to each TLP, which is either available as ground-truth or in a translated form. We follow the same hyperparameter settings as reported in XTREME. We also present three multi-task learning (MTL) baseline systems: task limited (`Task-Limited`), language limited (`Lang-Limited`), and the use of all TLPs during training (`All TLPs MTL`). During MTL training, we concatenate and shuffle the selected datasets. The model is trained for 5 epochs with a learning rate of 5e-5. We refer the reader to Appendix A for more training details.

5 Results and Analysis

Table 2 presents all our main results comparing different data selection and sampling strategies used for meta-learning. Each column corresponds to a target TLP; the best-performing meta-learned models for each target TLP within each data selection setting have been highlighted in colour. (Light-to-dark gradation reflects improvements in performance.) From Table 2, we see that our meta-learned models outperform the baseline systems across all the TLPs corresponding to QA, NLI and PA. (POS and NER also mostly benefit from meta-learning, but the margins of improvement are much smaller compared to the other tasks given the already high baseline scores).

`Task-Limited` vs `Lang-Limited` models. For QA and NLI, we observe that the `Task-Limited` models are *always better* than

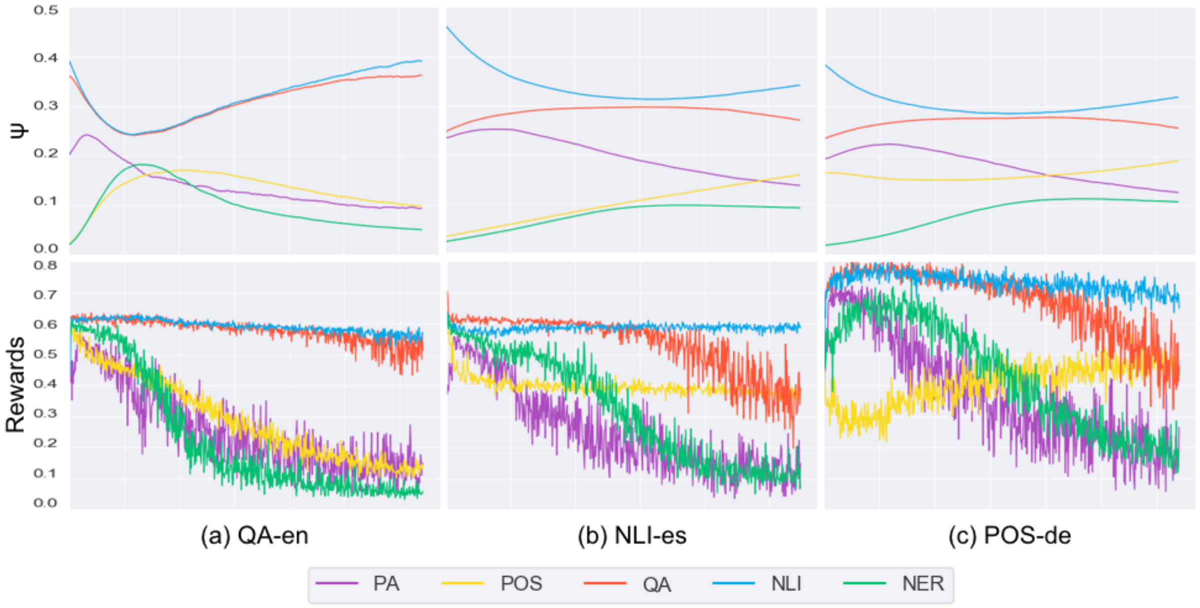
Table 2: Main results comparing different data selection and sampling strategies. Sampling strategy, SS=`Temp` refers to the temperature-based sampling strategy and SS=`mDDS` refers to the multiDDS-based sampling strategy. `mDDS-Task` and `mDDS-Lang` refer to the use of a development set for multiDDS that contains all languages for a task and all tasks for a language, respectively. The best result among Baseline and three MTL models is highlighted using orange. For each column we present the difference (positive or negative) of the meta models from the best baseline (highlighted in orange) of that column

the `Lang-Limited` models. This is in line with our intuition that tasks like QA and NLI (which require deeper semantic representations) will benefit more by using data from different languages for the same task. We see the opposite seems to hold for POS and NER where the `Lang-Limited` models are *almost always better* than the `Task-Limited` models. With POS and NER being relatively shallower tasks, it makes sense that they benefit more from language-specific training that relies on token embeddings shared across tasks.

Investigating Sampling Strategies. In Table 2, all the scores shown for the `Temp` sampling strategy are the best scores across four different values of T, $T = 1, 2, 5, \infty$. (The complete table is available in Appendix C in the supplementary material.) We also present comparisons with the



(a) QA-en (b) NLI-es (c) POS-de

Figure 3: Evolution of ψs and rewards as a function of training time for three `Lang-Limited` tasks evaluated on (a) QA-en (b) NLI-es and (c) POS-de.

`mDDS`, `mDDS-Lang` and `mDDS-Task` sampling strategies enforced within the `Lang-Limited`, `Task-Limited` and `All TLPs` models, respectively. For POS and NER, our best meta-learned models are mostly `Lang-Limited` with `Temp` sampling. It is intuitive that for these shallower tasks, `mDDS` does not offer any benefits from allowing to sample instances from other tasks.

To better understand the effects of `mDDS` sampling, Figure 3 shows plots of the rewards and sampling probabilities ψ's computed as a function of training time for two deeper tasks - QA-en and NLI-es along with a shallower task - POS-de. We note that initially all the TLPs in any `mDDS` setting would start with similar rewards, thus lending ψ's to converge towards the $T = \infty$ state. We highlight the following three observations:

- We find that the `mDDS` strategy does not help NLI at all. This is because the NLI task occupies the largest proportion across tasks at the start, as shown in Figure 2, and the proportion of NLI decreases substantially over time (since all tasks start with similar rewards at the beginning of meta training). Thus, for tasks that are over-represented in the meta-learning phase, temperature-based sampling is likely to be sufficient.

- We observe that the rewards for both QA and NLI are consistently high, irrespective of the target TLP. This suggests that both QA and NLI are information-rich tasks and could benefit other tasks in meta-learning. This is also apparent from the accuracies for PA in Table 2, where all the best meta-learned models employ `mDDS` sampling.

- From the sampling probabilities for QA-en, we see that both QA and NLI are given almost equal weightage. However, from the F1 scores in Table 2, the best numbers for QA are in the `Task-Limited` setting which suggests that QA does not benefit from any other task. One explanation for this could be that the sequence length of inputs for NLI is 128 while the inputs for QA are of length 384, thus allowing lesser room for QA to be benefited by NLI.

Zero-shot Evaluations. Zero-shot evaluation is performed on languages that were not part of the training (henceforth, we refer to them as external languages). In the case of QA, NLI and PA we select all external language for which datasets were available in XTREME. For NER and POS, the number of external languages is close to 35 so we choose a subset of these to report the results. For evaluation, we compare models that are agnostic to the target language during meta training (`Task-Limited`, `All TLPs` and `All TLPs mDDS-Task`). Since `Lang-Limited MTL` is language specific and does not offer a competitive

Table 3: Results comparing Zero-shot evaluations for several external languages with competitive MTL baselines. The best MTL model is highlighted using orange. Rows for meta models show the difference (positive or negative) of the meta model result from the best MTL setting (orange) for that column

baseline when applied to an external language, we compare against `Task-Limited MTL` and `All TLPs MTL` that are more competitive.

An interesting observation from the zero shot results in Table 3 is that for every external language, on the 'shallower' NER and POS tasks, the `Task-Limited` variant of meta-learning performs better than both the variants of MTL, *viz.*, `Task-Limited MTL` and `All TLPs MTL`. In contrast, the 'deeper' tasks, *viz.*, QA, NLI and PA benefit more from the use of meta-learning using `All TLPs` setting, presumably because, as argued earlier, the deeper tasks tend to help each other more.

6 Conclusion

We present effective use of meta-learning for capturing task and language interactions in multi-task, multi-lingual settings. The effective use involves appropriate strategies for sampling tasks and languages as well as rough knowledge of the level of abstraction (deep vs. shallow representation) of that task. We present experiments on the XTREME multilingual benchmark dataset using five tasks and six languages. Our meta-learned model shows clear performance improvements over competitive baseline models. We observe that deeper tasks consistently benefit from meta-learning. Furthermore, shallower tasks benefit from deeper tasks when meta-learning is restricted to a single language. Finally, zero-shot evaluations for several external languages demonstrate the benefit of using meta-learning over two multi-task baselines while also reinforcing the linguistic insight that tasks requiring deeper representations tend to collaborate better.

Appendices

Appendix A: Baseline Training Details

For QA learning rate is 3e-5 and sequence length is 384 and the model is trained for 2 epochs. For PA, NLI, POS and NER the learning rate is 2e-5 and sequence length is 128. NLI and PA models are trained for 5 epochs while POS and NER models are trained for 10 epochs. The choice of hyperparameters was kept constant across different languages for the same task.

Appendix B: Finetuning Details

For finetuning we kept the same number of epochs as the baseline of that task i.e 2 epochs for QA, 10 epochs for POS and NER, 5 epochs for NLI and PA. For QA we finetune with learning rate 3e-5 and 3e-6 and POS/NER we finetune with learning rate 2e-5 and 2e-6 and select the better of the two model. For PA and NLI the results for learning rate 2e-5 were consistently worse compared to 2e-6 so we just use lr = 2e-6 for PA and NLI.

Abstract

Several machine learning-based spoiler detection models have been proposed recently to protect users from spoilers on review websites. Although dependency relations between context words are important for detecting spoilers, current attention-based spoiler detection models are insufficient for utilizing dependency relations. To address this problem, we propose a new spoiler detection model called SDGNN that is based on syntax-aware graph neural networks. In the experiments on two real-world benchmark datasets, we show that our SDGNN outperforms the existing spoiler detection models.

1 Introduction

Spoilers on review websites, which reveal critical details of the original works, can ruin an appreciation for the works. Review websites, such as Rotten Tomato, IMDb, and Metacritic, provide self-reporting systems that tag spoiler information to warn users of spoilers. However, since self-reporting systems depend solely on the active participation of users, they cannot handle the fast-growing volume of newly generated reviews. During the past decade, several machine learning-based spoiler detection (SD) models have been proposed to solve the inefficiency of self-reporting systems. Guo and Ramakrishnan (2010) proposed an automatic SD model that measures the similarity between reviews and synopses of movies. Support vector machine (SVM)-based SD models using handcrafted features have been proposed (Boyd-Graber et al., 2013; Jeon et al., 2016). Recently, attention-based SD models that utilize metadata of review documents achieve state-of-the-art performance on the SD task (Chang et al., 2018; Wan et al., 2019).

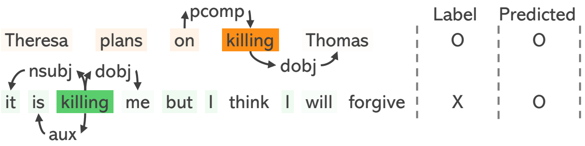

Figure 1: Attention-based models focused on the word “killing” because the word is frequently used in spoiler sentences, which results in incorrect predictions.

However, the attention-based SD models have a lack of using dependency relations between context words. Dependency relations are useful for capturing the semantics of given sentences and detecting spoilers. As shown in Figure 1, although the phrase “killing me” is not a spoiler because the phrase is a metaphor, the attention-based SD models often focus on the word “killing” and classify sentences that contain the phrase “killing me” as spoilers. By providing the information that the word “me” is used as the direct object of the verb “killing,” SD models can understand that the phrase is a metaphor.

In this paper, we propose SDGNN, which is a new **S**poiler **D**etection model based on syntax-aware **G**raph **N**eural **N**etworks (GNNs) (Marcheggiani and Titov, 2017) for leveraging dependency relations between context words in sentences to fully capture the semantics. With the success of GNNs We also propose a dependency relation-aware attention mechanism, which is a modification of the gating mechanism used by syntax-aware GNNs, to be suitable for the spoiler detection task. In SD, considering the relative importance of dependency relations. However, existing syntax-aware GNN-based models compute the importance of each dependency relation individually in sentences without considering the context of the given

sentence. Our proposed dependency relation-aware attention mechanism considers the relative importance of dependency relations. Also, we adopt a previously proposed genre-aware pooling method (Chang et al., 2018) to utilize the genre of works efficiently. In the experiments, we demonstrate the effectiveness of SDGNN on two real-world benchmark datasets in both quantitative and qualitative ways.

2 Our Approach

SDGNN classifies whether a given sentence $x = (w_1, w_2, \cdots, w_n)$ is a spoiler sentence. SDGNN consists of three stages: contextualized word representation, dependency relation-aware attention mechanism, and genre-aware pooling.

Contextualized Word Representation Each word w in the given sentence x is represented with the pretrained word embedding vector (Pennington et al., 2014). We then utilize bi-directional LSTMs (Hochreiter and Schmidhuber, 1997) to encode contextualized word representations $\mathbf{h}^{(0)} \in \mathbb{R}^d$.

Dependency Relation-Aware Attention Mechanism While the gating mechanism in syntax-aware GNNs (Marcheggiani and Titov, 2017; Nguyen and Grishman, 2018) computes the scalar weight of each dependency relation, it does not consider the relative importance of dependency relations, which varies depending on the context of the given sentence. We present a dependency relation-aware attention mechanism that considers the relative importance of dependency relations in the given sentence. The relation-aware attention weights are computed as follows:

$$a^{(k)}_{L(u,v)} = g\left(\mathbf{h}^{(k)}_u \overline{\mathbf{W}}^{(k)} \mathbf{e}^{(k)}_{L(u,v)} + \bar{b}^{(k)}_{L(u,v)}\right), \quad (1)$$

$$\hat{a}^{(k)}_{L(u,v)} = \frac{\exp\left(a^{(k)}_{L(u,v)}\right)}{\sum_{v' \in \mathcal{N}(u)} \exp\left(a^{(k)}_{L(u,v')}\right)}, \quad (2)$$

where $\hat{a}^{k}_{L(u,v)}$ is a scalar attention weight of the dependency relation label $L(u, v)$ of the edge between word nodes u, v. g is the non-linear function and $\exp(\cdot)$ is an exponential function. $\overline{\mathbf{W}}^{(k)} \in \mathbb{R}^{d \times d}$ is the attention weight matrix for the k-th layer. $\mathbf{e}^{(k)}_{L(u,v)} \in \mathbb{R}^d$ and $\bar{b}^{k}_{L(u,v)} \in \mathbb{R}$ are latent features of the dependency relation $L(u, v)$.

Finally, we aggregate the latent feature for each node u as follows:

$$\mathbf{h}^{(k)}_u = f\left(\sum_{v \in \mathcal{N}(u)} \hat{a}^{(k)}_{L(u,v)} \mathbf{W}^{(k)} \mathbf{h}^{(k-1)}_v + \mathbf{b}^{(k)}\right), \quad (3)$$

where $\mathbf{W}^{(k)} \in \mathbb{R}^{d \times d}$ and $b^{(k)} \in \mathbb{R}^d$ are the weight matrix and bias term, respectively, for the k-th layer. f is a non-linear function. $\mathbf{h}^{(0)}$ is the outputs of the bi-directional LSTMs in the previous stage.

There are two main differences between our proposed dependency-aware attention mechanism and the gating mechanism used by syntax-aware GNNS. First, the dependency-aware attention mechanism employs the softmax function to capture the relative importance of dependency relations, while the gating mechanism computes the scalar weights by the inner-product of latent features of words and dependency relations. Second, the gating mechanism utilizes only three dependency relations (*forward*, *backward*, and *self*) because of the over-parameterization issue. On the other hand, our proposed dependency relation-aware attention mechanism utilizes all the 82 types of dependency relations without suffering from the over-parameterization issue since the weight matrix in Equation 3 does not depend on the number of relations. The number of trainable parameters of SDGNN is proportionate to d^2 while that of syntax-aware GNNs is proportionate to $|L| \cdot d^2$, where $|L|$ is the number of relations.

Genre-Aware Pooling Genre information is useful for detecting spoilers. To leverage genre information, we employ a genre-aware pooling method following Chang et al. (2018). The genre-aware pooling computes the attention weights between the latent features of words and a genre feature captured from genre information of works. We then obtain a latent feature vector $\mathbf{x}$ for the given sentence x.

Optimization We compute the spoiler probability $\hat{y}$ of the given sentence x with the following the linear transformation:

$$\hat{y} = \sigma(\mathbf{w}\mathbf{x} + b), \quad (4)$$

where $\mathbf{w}$ and b are trainable parameters, and σ is a sigmoid function. We use the weighted binary cross entropy (Wan et al., 2019) as the loss function.

$$\mathcal{L} = -\frac{1}{|\mathcal{D}|} \sum_{x_i \in \mathcal{D}} (y_i \texttt{log}(\hat{y}_i) + \eta \cdot (1 - y_i) \texttt{log}(1 - \hat{y}_i)), \quad (5)$$

where y id the ground truth of spoiler information and $\mathcal{D}$ indicates the dataset. η is a hyperpameter used to balance the number of spoiler and non-spoiler labels in the training data. All the trainable parameters of SDGNN are updated by minimizing the loss function with gradient descent.

3 Experiments

3.1 Experimental Setup

Datasets We evaluated our proposed model on the two public spoiler datasets: **Goodreads** (Wan et al., 2019) and **TVTropes** (Boyd-Graber et al., 2013) [1]. The Goodreads dataset consists of spoiler sentences on book reviews, and only 3.22% of entire sentences are labeled as spoiler sentences. The TVTropes dataset consists of descriptions of 884 TV programs from the TVTropes site, and 52.7% of the descriptions are labeled as spoilers. The statistics of the datasets are summarized in Table 1.

Baseline Models We compared our proposed model with the following state-of-the-art SD models: **SVM** (Boyd-Graber et al., 2013; Jeon et al., 2016), **CNN** (Kim, 2014), **HAN** (Yang et al., 2016), **SpoilerNet** (Wan et al., 2019) and **DNSD** (Chang et al., 2018). Note that the implementation details about our experiments are described in the Appendix due to space limitations.

Metrics We use Area Under the Receiver Operating Characteristics curve (**AUROC**) used in Wan et al. (2019) as an evaluation metric. We also use an **F1** score following Chang et al. (2018).

Implemention Details We trained and evaluated the models on two TITAN X (Pascal) GPUs. We implemented SDGNN using PyTorch v1.1. We used Stanford CoreNLP (Manning et al., 2014) to generate dependency parse trees. We employed GloVe (Pennington et al., 2014) to represent word vectors in neural network-based models including SDGNN. Using the validation set and grid search, we searched optimal hyper-parameters for each SD model. All the neural network-based models were trained with the learning rate of 0.001 and the Adam optimizer (Kingma and Ba, 2014). A batch size of 1024 was used for training TextCNN, HAN, and DNSD, and a batch size of 512 was used for training SpoilerNet and SDGNN. To prevent overfitting, we applied L2-normalization with λ = 1e-5 and a dropout rate of 0.5. For TextCNN, we used 50 filters with kernel sizes of 3, 4, and 5. For efficient training on deep learning libraries, SDGNN set the maximum number of words to 50. For SDGNN, we used Leaky ReLU for the non-linear function g, and ReLU for f. We set $k = 2$ for SyntacticGCN, C-GCN, and SDGNN. We use $\eta = 0.05$ for the Goodreads dataset, which is unbalanced.

Models	Goodreads AUROC	Goodreads F1	TVTropes AUROC	TVTropes F1
SVM	0.880	0.162	0.735	0.698
TextCNN	0.904	0.188	0.779	0.738
HAN	0.915	0.190	0.785	0.750
SpoilerNet	0.924	0.194	0.808	0.768
DNSD	0.928	0.199	0.818	0.788
SDGNN	**0.938**	**0.210**	**0.828**	**0.801**

Table 2: Evaluation results on two benchmark datasets. The best results are highlighted in bold.

3.2 Results

The experimental results are summarized in Table 2. Evaluation results show that our proposed SDGNN outperforms all the baseline models including attention-based models. This result demonstrates that our proposed dependency relation-aware attention mechanism contributes to improving SD performance.

4 Analysis and Discussion

4.1 Analysis of Relative Importance

To further demonstrate the usefulness of the relative importance of dependency relations, we conducted quantitative and qualitative analysis.

Quantitative We compared SDGNN with the more syntax-aware GNN-based models, SyntacticGCN (Marcheggiani and Titov, 2017) and C-GCN (Zhang et al., 2018). We trained and evaluated the models on the Goodreads dataset. We

---

[1] We obtained the datasets from Wan et al. (2019) and Boyd-Graber et al. (2013), respectively.

Models	Genres	Sentences	Prediction	Label
DNSD	Romance	it 's killing me but i think i 'll forgive him no matter what he did or did n't do .	Positive	Negative
	Fantasy	the villains are decidedly vicious and in some cases insane .	Positive	Negative
SDGNN	Romance	it 's killing me but i think i 'll forgive him no matter what he did or did n't do .	Negative	Negative
	Fantasy	the villains are decidedly vicious and in some cases insane .	Negative	Negative

Table 4: Visualization of attention scores from DNSD, SpoilerNet, and SDGNN on test data.

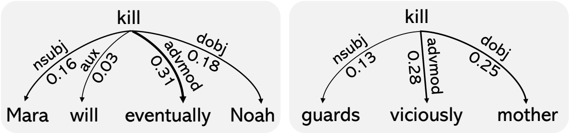

Figure 2: Partial graphs of dependency parse trees with dependency relation-aware attention weights.

utilize contextualized word representations and the genre-aware pooling method to SyntacticGCN and C-GCN. The evaluation results are summarized in Table 3. Our proposed SDGNN outperformed SyntacticGCN and C-GCN. This result demonstrates that our proposed attention mechanism is effective by considering the relative importance of dependency relations. Although SDGNN significantly reduced the number of parameters, SDGNN achieved better results compared to SyntacticGCN and C-GCN.

Qualitative In Figure 2, the attention weights of the adverbial modifier (advmod) linked to the words "eventually" and "viciously" are high, which indicates that adverbial modifiers frequently can be important hints for detecting spoilers. In the right partial graph, the attention weight of the (dobj) is relatively higher than that in the left partial graph. Since the word "mother" is not typically used as the object of the word "kill" in the original works, the phrase "kill mother" is a critical hint in detecting spoilers, and SDGNN effectively captures the phrase.

4.2 Case Study

We sample several sentences from the test set of the Goodreads dataset to explore how the models detect spoilers. Table 4 shows the visualization of attention scores in the pooling layer obtained by DNSD and SDGNN, respectively. The first sentence contains the verb "killing," but it is not a spoiler sentence because the phrase "killing me" is a metaphor. In this case, DNSD failed to correctly classify the sentence since DNSD cannot fully capture the semantics of the sentence. On the other hand, SDGNN focused on not only the word "killing" but also on the word "me" and classified the sentence correctly since SDGNN employs the dependency relation (dobj) between the word "me" and the word "killing".

The second sentence is a non-spoiler because it is obvious that villains are vicious in most original works. DNSD classified the sentence as a spoiler because the model solely focused on individual words such as "villains", "vicious", and "insane", rather than the understanding of the overall semantics of the sentence. On the other hand, SDGNN classified the sentence correctly as the word "are" is used to describe characters in many cases, and SDGNN understands the semantics of the sentence.

4.3 Discussion

Dependency Parsing on User-Generated Texts The spoiler datasets are user-generated texts, which are intrinsically noisy. To examine the influence of noises on dependency parsing results and the performance of SDGNN, we sampled 100 sentences from Goodreads. We manually classified whether the sentences are noise or not, and 28 of 100 sentences were classified as noisy sentences. Dependency parsing results on well-structured sentences seem good, but dependency parsing results on noisy sentences are poor. However, there is no significant gap in performance. SDGNN achieved 85.7% accuracy on noisy sentences and 87.5% accuracy on well-structured sentences. Since our proposed dependency relation-aware attention mechanism of SDGNN filters noisy information, SDGNN could detect spoilers even on noisy sentences.

Subjectivity in Judging Spoilers Since judging a sentence as a spoiler is a subjective task, label inconsistency occurs in spoiler datasets crawled from self-reporting systems. Guo and Ramakrishnan (2010) found that 23% of the labels of their manually labeled data is different from the original labels of IMDb reviews. One of the ways to mitigate label inconsistency is to solidify the definition of a spoiler. Although the TV Tropes site defines spoilers, efforts should be made for a more rigorous and linguistic definition in future studies. Another possible way is to employ reviewers' information in detecting spoilers. *Reviewer biases* of SpoilerNet can alleviate label inconsistency between users.

5 Conclusion

In this paper, we proposed a novel spoiler detection model called SDGNN which is based on syntax-aware GNNs that utilize dependency relations between context words. We also proposed a dependency relation-aware attention mechanism for considering the relative importance of dependency relations. In the experiments, our proposed SDGNN model achieved the state-of-the-art performance on two spoiler datasets. Our experimental results demonstrate the effectiveness of dependency relations in the spoiler detection task and our dependency relation-aware attention mechanism.

Abstract

Large pre-trained language models have been shown to encode large amounts of world and commonsense knowledge in their parameters, leading to substantial interest in methods for extracting that knowledge. In past work, knowledge was extracted by taking manually-authored queries and gathering paraphrases for them using a separate pipeline. In this work, we propose a method for automatically rewriting queries into "BERTese", a paraphrase query that is directly optimized towards better knowledge extraction. To encourage meaningful rewrites, we add auxiliary loss functions that encourage the query to correspond to actual language tokens. We empirically show our approach outperforms competing baselines, obviating the need for complex pipelines. Moreover, BERTese provides some insight into the type of language that helps language models perform knowledge extraction.

1 Introduction

Recent work has shown that large pre-trained language models (LM), trained with a masked language modeling (MLM) objective (Devlin et al., 2019; Liu et al., 2019; Lan et al., 2019; Sanh et al., 2019; Conneau et al., 2020), encode substantial amounts of world knowledge in their parameters. This has led to ample research on developing methods for extracting that knowledge (Petroni et al., 2019, 2020; Jiang et al., 2020; Bouraoui et al., 2020). The most straightforward approach is to present the model with a manually-crafted query such as *"Dante was born in [MASK]"* and check if the model predicts *"Florence"* in the *[MASK]* position. However, when this fails, it is difficult to determine if the knowledge is absent from the LM or if the model failed to understand the query itself. For example, the model might return the correct answer if the query is *"Dante was born in the city of [MASK]"*.

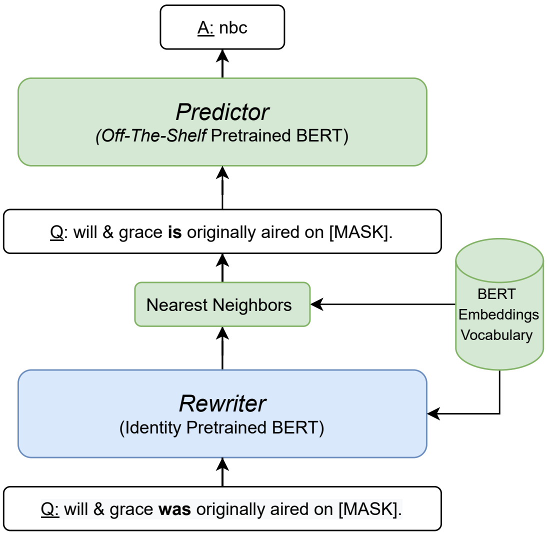

Figure 1: The BERTese Model. The model takes an input query, rewrites it, and feeds the output to a pre-trained BERT model. The untrained components are marked in green, and the blue component is trained.

Motivated by the above observation, we ask: can we automatically find the best way to "ask" an LM about its knowledge? We refer to this challenge as speaking "BERTese". In particular, we ask how to rewrite a knowledge-seeking query into one that MLMs understand better, where understanding is manifested by providing a correct answer to the query.

Prior work (Jiang et al., 2020) tackled this problem using a 2-step pipeline, where first a small list of paraphrase templates is collected using external resources, and then a model learns to extract knowledge by aggregating information from paraphrases of the input query. In this work, we propose a more general approach, where the model learns to rewrite queries, directly driven by the objective of knowledge-extraction.

Figure 1 provides an overview of our approach. Our model contains a BERT-based *rewriter*, which

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3618–3623
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

takes a query as input, and outputs for each input position a new token, which is its rewrite. This new query is fed into a different BERT *predictor* from which the answer is extracted. Importantly, the downstream predictor BERT is a fixed pre-trained model, and thus the goal is to train the rewriter to produce queries for which the predictor outputs the correct answer.

A technical challenge is that outputting discrete tokens leads to a non-differentiable model, which we tackle by adding a loss term that encourages the rewriter's output to be similar to BERT token embeddings. Moreover, we must guarantee that the BERTese query contains the *[MASK]* token from which the answer will be read. To achieve this, we first add an auxiliary loss term that encourages the model to output precisely one masked token in the query rewrite. We then add a layer that finds the token index that most closely resembles *[MASK]*, and this is where we expect the correct answer to be completed. Training of this selection process is done using the straight-through estimator (Hinton, 2012; Bengio et al., 2013).

We evaluate our approach on the LAMA dataset (Petroni et al., 2019), and show that our model significantly improves the accuracy of knowledge extraction. Furthermore, many of the rewrites correspond to consistent changes in query wording (e.g., changing tense), and thus provide information on the types of changes that are useful for extracting knowledge from BERT. While we experiment on BERT, our method is generic and can be applied to any MLM.

Taken together, our results demonstrate the potential of rewriting inputs to language models for both obtaining better predictions, and for potentially gaining insights into how knowledge is represented in these models. Our code can be downloaded from `https://github.com/adihaviv/bertese`.

2 Related Work

Choosing the right language for extracting world knowledge from LMs has attracted much interest recently. First, Petroni et al. (2019) observed that MLMs can complete simple queries with correct factual information. Jiang et al. (2020) and Heinzerling and Inui (2020) then showed that in the zero-shot setting, small variations to such queries can lead to a drop in fact recall. Orthogonally, another line of research focused on query reformulation for standard Question Answering (QA) tasks. Gan and Ng (2019) demonstrated that even minor query modifications can lead to a significant decrease in performance for multiple QA models and tasks. Buck et al. (2017) showed that it is possible to train a neural network to reformulate a question using Reinforcement Learning (RL), optimizing the accuracy of a black-box QA system. Similarly, Nogueira and Cho (2017) used RL to create a query reformulation system that maximizes the recall of a black-box information retrieval engine.

Jiang et al. (2020) proposed an ensemble method for query reformulation from LMs, that includes: (1) mining new queries, (2) using an off-the-shelf pre-trained translation model to collect additional paraphrased queries with back-translation, and (3) using a re-ranker to select one or more of the new queries. They then feed those queries to BERT to get the masked token prediction.

In this work, we take the idea of Jiang et al. (2020) a step forward and train a model in an end-to-end fashion to generate rephrased queries which are optimized to maximize knowledge extraction from the MLM.[1]

3 The BERTese Model

Recall that our goal is to build a model that takes as input a query in natural language, and re-writes it into a query that will be fed as input to an existing BERT model.

We refer to the above re-writing model as the *rewriter* and the existing BERT model as the *predictor*. We note that both input and output queries should include the token [MASK]. For example the input could be *"Obama was born in [MASK]"* and the output *"Obama was born in the state of [MASK]"*.

We first describe the behaviour of our model at inference time (see Figure 1). Given a query, which is a sequence of tokens, $S = (s_1, \ldots, s_n)$, we map S into a sequence of vectors $Q(S) \in \mathbb{R}^{d \times n}$ using BERT's embeddings of dimensionality d. This input is fed into a (BERT-based) stack of transformer layers that outputs a new sequence of vectors $\hat{Q}(S) \in \mathbb{R}^{d \times n}$.

To obtain vectors that can be used as input to the predictor, we need to map the vectors in each position to their nearest neighbor in the set of BERT

---

[1] Although knowledge retrieval has been investigated in autoregressive models as well, similar to Jiang et al. (2020), in this work we focus on MLMs only, as AR-LM only predict an answer if the masked token is at the end of the query.

embeddings. Specifically, let B_V be the set of BERT embeddings, and let $\hat{Q}_i \in \mathbb{R}^d$ be the re-written vector in position i. We map $\hat{Q}_i \in \mathbb{R}^d$ to $\arg\min_{\mathbf{v} \in B_V} \left(\left\| v - \hat{Q}_i \right\|_2^2 \right)$. We next pass the re-written query into the pre-trained predictor BERT model, and obtain an answer from the most probable token in the masked position.

Training this model involves two technical challenges. First, the nearest-neighbor operation is non-differentiable. Second, to obtain the prediction of the `[MASK]` token, we need to guarantee that the rewriter generates a `[MASK]` token, and know its position (because this is where the ground-truth answer should be predicted). We overcome these by adding two auxiliary loss functions. The first encourages the model to output vectors that are similar to BERT embeddings (thus reducing the loss in the nearest neighbor operation), and the second encourages the model to output one masked token.

Finally, we apply the straight-through estimator, which allows us to feed discrete word representations into the predictor and backpropagate the signal back to the rewriter. We next provide more details on the terms in our loss function used to train the rewriter.

Valid Token Loss: At training time we do not apply the non-differentiable nearest-neighbor operation. Thus, we would like the vectors $\hat{Q}(S)$ output by the rewriter to be as close as possible to valid BERT embeddings. This loss is the average over tokens of the distance between a re-written query token and its nearest neighbor:

$$f_1(S) = \frac{1}{|\hat{Q}(S)|} \sum_{\mathbf{q} \in \hat{Q}(S)} \min_{\mathbf{v} \in B_V} \left(\|\mathbf{v} - \mathbf{q}\|_2^2 \right). \quad (1)$$

Single [MASK] Loss: The output of the rewriter must contain the *[MASK]* token, so that the predictor can extract an answer from this token. To encourage the rewriter to output a [MASK] we add a loss as follows. We define the following "softmin" distribution over $i \in \{1, \ldots, |\hat{Q}(S)|\}$:

$$m_i(S) = \frac{e^{-\beta \left\| B_{[MASK]} - \hat{Q}_i(S) \right\|_2^2}}{\sum_j e^{-\beta \left\| B_{[MASK]} - \hat{Q}_j(S) \right\|_2^2}}, \quad (2)$$

where β is a trained parameter. The maximum value of this distribution will be highest when there is a single index i that is closest to the embedding of [MASK] (if there are two maxima, they will both have equal values). Thus the loss we consider is:

$$f_2(S) = -\max_i m_i(S). \quad (3)$$

Prediction Loss: The predictor should return the gold answer y when given $\hat{Q}$ as input. Without non-differentiability, we could find the index of the [MASK] token in $\hat{Q}$, and use cross-entropy loss between the output distribution of the predictor in that index and the gold answer y. To remedy this, we use a differentiable formulation, combined with the straight-through estimator (STE) (Bengio et al., 2013): Let $\mathbf{o}_i$ be the output distribution at the i^{th} position of the predictor, and let $\ell(y, \mathbf{p})$ be the cross-entropy between the one-hot distribution corresponding to y and a distribution $\mathbf{p}$. Then, we use the loss:

$$f_{CE}(S, y) = \sum_i m_i(S) \ell(y, \mathbf{o}_i). \quad (4)$$

Thus, if m is a one-hot on the index corresponding to [MASK], the loss will be the desired cross-entropy between the gold answer and the predicted distribution. We optimize this objective using the STE. Namely, in the forward pass, we convert m to a one-hot vector.

Our final training loss is the sum of the above three loss terms:

$$L(S, y) = f_{CE}(S, y) + \lambda_1 \cdot f_1(S) + \lambda_2 \cdot f_2(S). \quad (5)$$

The weights λ_1, λ_2 are tuned using cross-validation.

To summarize, the main challenge is that the rewriter output needs to be optimized to predict the correct label for the [MASK] token (Eq. 4). However, the [MASK] token needs to appear once in the rewriter output. In order to enforce the above, the "Single [MASK] Loss" (Eq. 3) is used. In addition, in order for the rewriter output to be a valid sentence, the "Valid Token Loss" (Eq. 1) is added. This encourages the model to output tokens that are close to BERT input embeddings. This is done by minimizing the distance between each rewriter vector to some vector in the BERT input embedding dictionary.

Rewriter pre-training We initialize the rewriter with a BERT-based model, additionally fine-tuned to output the exact word embeddings it received as input (i.e., fine-tuned to the identity mapping). Thus, when training for knowledge extraction, the rewriter is initialized to output exactly the query it received as input.

4 Experiments

Experimental setup We conduct our experiments on the LAMA dataset (Petroni et al., 2019; Jiang et al., 2020), a recently introduced unsupervised knowledge-extraction benchmark for pretrained LMs. LAMA is composed of a collection of cloze-style queries about relational facts with a single token answer. As in Jiang et al. (2020), we limit our main experiment to the T-REx (Elsahar et al., 2018) subset. The T-REx dataset is constructed out of 41 relations, each associated with at most 1000 queries, all extracted from Wikidata.

For training our model, we use a separate training set, created by Jiang et al. (2020), called T-REx-train. This dataset is constructed from Wikidata and has no overlap with the original T-REx dataset. We evaluate our model on the complete T-REx dataset.

Implementation Details Both the rewriter and the predictor are based on $\text{BERT}_{\text{base}}$ with the default settings from the Huggingface (Wolf et al., 2020) platform. We optimize BERTese using AdamW with an initial learning rate of 1e-5. We train the model on a single 32GB NVIDIA V100 for 5 epochs with a batch size of 64. For the loss coefficients (see Eq. (5)) we set $\lambda_1 = 0.3$ and $\lambda_2 = 0.5$.

Baselines We compare our method to three baselines: (a) BERT - A $\text{BERT}_{\text{base}}$ model without any fine-tuning, as evaluated in Petroni et al. (2019). (b) LPAQA - The model proposed by Jiang et al. (2020), based on mining additional paraphrase queries. We report results on a single paraphrase.[2] (c) FT-BERT: An end-to-end differentiable $\text{BERT}_{\text{base}}$ model, explicitly fine-tuned on T-REx-train to output the correct answer. This model, like ours, is trained for knowledge extraction, but does this internally, without exposing an interpretable intermediate textual rewrite.

Results We use the same evaluation metrics as Petroni et al. (2019) and report precision at one (P@1) macro-averaged over relations (we first average within relations and then across relations). As shown in Table 1, BERTese outperforms all three baselines. Compared to the zero-shot setting, where BERT is untrained on any additional data, we improve performance from $31.1 \rightarrow 38.3$. Our model also outperforms a BERT model fine-tuned for knowledge extraction on the same data as our model ($36 \rightarrow 38.3$). Last, we outperform the $\text{BERT}_{\text{base}}$ version of LPAQA by more than 4 points.

Table 2 presents example rewrites that are output by our model. It can be seen that rewrites are usually semantically plausible, and make small changes that are not meaningful to humans, but seem to help extract information from BERT, such as *was* → *is* and *a* → *the*. In some cases, rewrites can be interpreted, for example, replacing the word *airfield* with the more frequent word *airport*.

Ablation Study In Table 3 we present P@1 results on the T-REx test set after ablating different parts of the loss function. We keep the same label loss, same rewriter pretraining scheme, hyperparameters, and inference process. We show that removing all auxiliary losses hurts performance significantly on the T-REx dataset. Next, we evaluate the impact of removing the “Single [MASK] Loss”, and report a drop from 38.3 to 37.3. In addition, when further observing the rewrites the model produces, we find that those will have in some cases more than one [MASK] token. Overall, the results show that having just one of the loss terms substantially improves the performance (either “Valid Token Loss” or “Single [MASK] Loss”), but using both losses further improves accuracy.

Ablation	**P@1**
No auxilary losses	25.3
SML	36.6
VTL	37.5
SML + VTL (BERTese)	38.3

Table 3: Ablation experiments on T-REx. We abbreviate the ”Single [MASK] token” as SML and the ”Valid Token Loss” as VTL.

Part Of Speech Analysis To better understand what types of changes our rewriter performs, Table 4 shows the distribution over part-of-speech-tags replaced by the rewriter. We show all part-of-speech tags for which the frequency is higher than 1%. More than 70% of the replacements are nouns and verbs, which carry substantial semantic content. Interestingly, 15% of the replacements are determiners, which bear little semantic content.

---

[2] It is possible to improve results by aggregating over multiple rewrites, but our focus is on a single rewrite.

Corpus	**BERT**	**FT-BERT**	**LPAQA**	**BERTese**
T-REx	31.1	36	34.1	**38.3**

Table 1: Mean precision at one (P@1) for three baselines and our BERTese model on the T-REx dataset.

Modification	**Original Masked Query**	**Bertese Masked Query**

JJ	4.4%
CD	3%
NNP	1.7%
NNS	1.3%

Table 4: Part-of-speech analysis of rewrites from the T-REx test-set.

5 Conclusion

We presented an approach for modifying the input to a BERT model, such that factual information can be more accurately extracted. Our approach uses a trained rewrite model that is optimized to maximize the accuracy of its rewrites, when used as input to BERT. Our rewriting scheme indeed turns out to produce more accurate results than baselines. Interestingly, our rewrites are fairly small modifications, highlighting the fact that BERT models are not invariant to these edits.

Our approach is not limited to knowledge extraction. It can, in principle, be applied to BERT in general question answering datasets and even language modeling. In the former, we can change the predictor to a multiple-choice QA pretrained BERT and exclude the single [MASK] token loss. In the latter, we can for example envision a case where rewriting a sentence can make it easier to complete a masked word.

Our empirical setting focuses on the LAMA dataset, where a single mask token prediction is required. There are several possible extensions to multiple masks, and we leave these for future work. Finally, it will be interesting to test the approach on other masked language models such as RoBERTa (Liu et al., 2019) and ERNIE (Zhang et al., 2019), a MLM that is enhanced with external entity representations.

6 Acknowledgments

We thank Yuval Kirstain for his contribution in both the Rewriter Pretraining and overall valuable comments, and Edo Cohen-Karlik for his insightful suggestions. This project received funding from the European Research Council (ERC) under the European Union Horizon 2020 research and innovation programme (grant ERC HOLI 819080).

Abstract

The ability of humans to symbolically represent social events and situations is crucial for various interactions in everyday life. Several studies in cognitive psychology have established the role of mental state attributions in effectively representing variable aspects of these social events. In the past, NLP research on learning event representations often focuses on construing syntactic and semantic information from language. However, they fail to consider the importance of pragmatic aspects and the need to consistently update new social situational information without forgetting the accumulated experiences. In this work, we propose a representation learning framework to directly address these shortcomings by integrating social commonsense knowledge with recent advancements in the space of lifelong language learning. First, we investigate methods to incorporate pragmatic aspects into our social event embeddings by leveraging social commonsense knowledge. Next, we introduce continual learning strategies that allow for incremental consolidation of new knowledge while retaining and promoting efficient usage of prior knowledge. Experimental results on event similarity, reasoning, and paraphrase detection tasks prove the efficacy of our social event embeddings.

1 Introduction

Everyday life comprises the ways in which people typically act, think, and feel on a daily basis. Our life experiences unfold naturally into temporally extended daily events. The event descriptions can be packaged in various ways depending on several factors like speaker's perspective or the related domain. Interpretation of event descriptions will be incomplete without understanding multiple entities involved in the events and even more so when the focus is primarily on "social events", i.e., events explaining social situations and interactions. Therefore, a social event representation model must capture the semantic properties from the event text description and embed salient knowledge that encompasses the implicit pragmatic abilities. Early definitions of pragmatic aspects refer to the use of language in context; comprising the verbal, paralinguistic, and non-verbal elements of language (Adams et al., 2005). Contemporary definitions have expanded beyond just communicative functions to include behavior that includes social, emotional, and communicative aspects of language (Adams et al., 2005; Parsons et al., 2017).

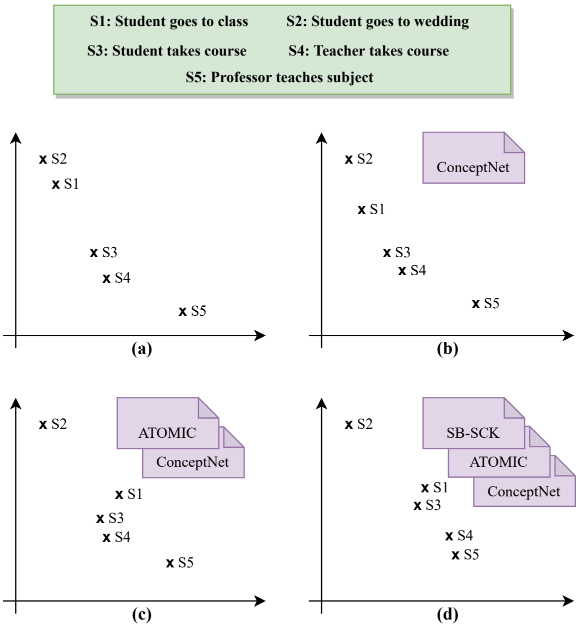

Figure 1: Illustration of functioning of our lifelong representation learning approach that produces incrementally richer social event representations. Event texts are given in the top green box. With more knowledge, social event embeddings move beyond high lexical overlap [shown in (a)] and learn to integrate semantic and pragmatic properties [shown in (b), (c)] of event texts along with social role information [shown in (d)].

Moving away from the extensively studied

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3624–3635
April 19 - 23, 2021.

speech acts, we analyze characteristics that reflect how a person behaves in social situations and how social contextual aspects influence linguistic meaning. In the context of event representations, the pragmatic properties can specifically refer to the human's inferred implicit understanding of event actors' intents, beliefs, and feelings or reactions (Wood, 1976; Hopper and Naremore, 1978).

Understanding the pragmatic implications of social events is non-trivial for machines as they are not explicitly found in the event texts. Prior studies (Ding et al., 2014, 2015; Granroth-Wilding and Clark, 2016; Weber et al., 2018) often extract the syntactic and semantic information from the event descriptions but ignore the pragmatic aspects of language. In this work, we address this shortcoming, and aim to (a) disentangle semantic and pragmatic attributes from social event descriptions and (b) encapsulate these attributes into an embedding that can move beyond simple linguistic structures and dispel apparent ambiguities in the real sense of their context and meaning.

Towards this goal, we propose to train our models with social commonsense knowledge about events focusing specifically on intents and emotional reactions of people. Such commonsense understanding can be obtained from existing knowledge bases like ConceptNet (Speer et al., 2017), Event2Mind/ATOMIC (Sap et al., 2019a; Rashkin et al., 2018) or by collecting more noisy commonsense knowledge using data mining techniques. As new domain sources emerge, each containing different knowledge assertions, it is essential that the representation models for social events keep evolving with this growing knowledge. Since it is generally infeasible to retrain models from scratch for every new knowledge source, we consider the need to employ prominent continual learning practices (Kirkpatrick et al., 2017; Lopez-Paz and Ranzato, 2017; Asghar et al., 2018; d'Autume et al., 2019) and enable semantic and pragmatic enrichment of social event representations. This problem can be addressed from the perspective of incremental domain adaptation (Asghar et al., 2018; Wulfmeier et al., 2018), which quickly adapts to new domain knowledge without interfering with existing ones. Figure 1 presents a sample functioning scenario producing incrementally richer social event embeddings. As the model gains more knowledge from different sources, it learns to discern events based on semantic and pragmatic properties, including social roles. For example, "Student takes course", and "Teacher takes course" has significant lexical and semantic relatedness. However, the social role information changes the meaning as depicted in Figure 1(d) with the introduction of our in-house dataset (SB-SCK).

In this paper, we develop a lifelong representation learning approach for embedding social events from their free-form textual descriptions. Our model augments a growing set of knowledge obtained from various domain sources to allow for positive knowledge transfer across these domains. Our contributions are as follows:

- We propose a continual representation learning approach-that integrates both text encoding and lifelong learning techniques to aid better representation of social events.

- We adopt a domain-representative episodic memory replay strategy with text encoding techniques to effectively consolidate the expanding knowledge from several domain sources and generate a semantically & pragmatically enriched social event embedding.

- We evaluate our models primarily on four different tasks: (a) intent-emotion prediction for event texts based on an in-house *Lifelong EventRep Corpus*, (b) event similarity task using hard similarity dataset (Ding et al., 2019; Weber et al., 2018), (c) paraphrase detection using Twitter URL corpus (Lan et al., 2017), and (d) social commonsense reasoning task using SocialIQA (Sap et al., 2019b) dataset.

2 Related Work

2.1 Social Events Representation Learning

Early work in the domain of events can be traced back to modeling narrative chains. Chambers and Jurafsky (Chambers and Jurafsky, 2008, 2009) introduced models for event sequences involving coreference resolution and inferring event schemas. Similar efforts (Balasubramanian et al., 2013; Cheung et al., 2013; Jans et al., 2012) have explored the use of open-domain relations to extract event schemas but suffer from reduced predictive capabilities and increased sparsity. Recent advancements, aimed at addressing the limitations of prior works, compute distributed embeddings of events involving word embeddings, recurrent sequence models, and tensor-based composition models (Modi and

Titov, 2013; Granroth-Wilding and Clark, 2016; Pichotta and Mooney, 2016; Hu et al., 2017). Specifically, tensor-based methods have demonstrated improved performance by representing events that predict implicit arguments with event knowledge (Cheng and Erk, 2018), combine (subject, predicate, object) triples information (Weber et al., 2018) and reflect thematic fit (Tilk et al., 2016).

2.2 Lifelong Learning

Lifelong learning or continual learning approaches can be grouped into regularization-based, data-based, and model-based approaches. Regularization based approaches (Kirkpatrick et al., 2017; Schwarz et al., 2018; Zenke et al., 2017) minimize significant changes to the previously learned representations as we update parameters for the current task. This is usually implemented as an additional constraint to the objective function based on the sensitivity of parameters. Recent studies (Kemker and Kanan, 2017; d'Autume et al., 2019; Lopez-Paz and Ranzato, 2017; Chaudhry et al., 2019) under data-based approaches store previous task data either using a replay memory buffer or a generative model. In NLP domain, lifelong language learning approaches have investigated the use of memory replay and local adaptation techniques (d'Autume et al., 2019).

Finally, model-based approaches allow models to allocate or grow capacity (layers or features) necessary for the tasks (Rusu et al., 2016; Lee et al., 2016). More recently, (Asghar et al., 2018) augmented RNNs with a progressive memory bank leading to increased model capacity. However, the challenges related to increased architectural complexity are tackled by hybrid models as in (Sodhani et al., 2020). In this paper, we build on ideas from the hybrid models and apply them for our learning task. While previous studies (Ding et al., 2019) have attempted to incorporate commonsense knowledge, this work is one of the first efforts to integrate multi-source knowledge and address it through the lens of incremental domain adaptation.

3 Problem Formalization

Formally, we assume that our learning framework has access to streams of social commonsense knowledge data obtained from n different domains, denoted by $\mathcal{D} = \{\mathcal{D}_1, \mathcal{D}_2, ..., \mathcal{D}_n\}$. At a particular point in time, we extract knowledge from the current domain $\mathcal{D}_i$. We produce an embedding of social events by consolidating the accumulated knowledge across the modeled domains $\mathcal{D}_{\leq i}$. Data from each domain source contains source-specific textual descriptions of social situations and their intuitive commonsense information such as intents and emotions. Training samples, drawn from a domain dataset $\mathcal{D}_i$, could contain either a significant overlap or an entirely new set of knowledge when compared with the previously processed domains $\mathcal{D}_{1:i}$. Given such a setup, we aim to generate incrementally richer social event representations using our continual learning framework.

4 Datasets

For our representation learning task, we aggregate social commonsense knowledge data from various domain sources. This knowledge contains details about pragmatic aspects like intents and emotional reactions. We create a continual learning benchmark based on these commonsense data sources[1].

4.1 Lifelong Social Events Dataset

Different domain sources of social commonsense knowledge used for training our social event representation model are explained as follows.

ATOMIC dataset consists of inferential knowledge based on 24k short events covering a diverse range of everyday events and motivations. Though each event contains nine dimensions per event, the scope of this work will be limited to intent and emotions as our inferential pragmatic dimensions.

CONCEPTNET knowledge base contains several commonsense assertions. For our purpose, we choose ConceptNet's relevant relations: /r/MotivatedByGoal, /r/CausesDesire, /r/Entails, /r/Causes, /r/HasSubevent. We convert triples in the dataset into template form.

SB-SCK Since social roles (e.g., student, mother, teacher, worker, etc.) provide additional information about the motives and emotions behind actions specified in the events (as shown in Figure 1, 2, we adopt web-based knowledge mining techniques for capturing this aspect. This dataset was collected as a part of our recent work (Vijayaraghavan and Roy, 2021) using the following steps: (a) process texts from Reddit posts containing personal narratives as in (Vijayaraghavan and

#unique social roles	586

Figure 2: **Left**: Samples from Search-based Social Commonsense Knowledge (SB-SCK) dataset with highlighted motivations for social roles, **Right**: Statistics of SB-SCK dataset.

Roy, 2021), (b) extract propositions from text using OpenIE tools, (c) perform a web search for plausible intents and emotions by attaching purpose clauses (Palmer et al., 2005) and feelings lexical units from Framenet (Baker et al., 1998) and (d) finally, remove the poorly extracted facts using a simple classifier trained on some seed commonsense knowledge. Figure 2(Left) shows samples from this dataset indicating how the same action could have different social role related motivations. We refer to this as Search-based Social Commonsense Knowledge (SB-SCK) data. Figure 2(Right) presents the data statistics.

For data from each of the above domain sources, we sample free-form event text, its paraphrase, intent, emotional reactions, and negative samples of paraphrases, intents, and emotional reactions. Based on the annotated labels for motivation (Maslow's) and emotional reactions (Plutchik) in STORYCOMMONSENSE data, we run a simple K-Means clustering on the open text intent data. We identify five disjoint clusters on each of the three domains and map them to those categories. For the purpose of our lifelong learning problem, we divide each domain data into two sets (3 clusters and 2 clusters) and consider them as different sub-domains. Therefore, this results in 6 tasks in our continual learning setup. We refer to this dataset as *Lifelong EventRep Corpus*.

4.2 Paraphrase Datasets

We use random samples of parallel texts from paraphrase datasets like PARANMT-50M corpus(Wieting and Gimpel, 2017) and Quora Question Pair dataset [2]. These paraphrase datasets are primarily used for pretraining our model. We also produce paraphrases of free-form event texts in our dataset using a back-translation approach (Iyyer et al., 2018). We used pretrained English↔German translation models for this purpose.

5 Framework

Our goal is to learn distributed representations of social events by incorporating pragmatic aspects of the language beyond shallow event semantics. Moving away from conventional supervised multi-task classification based lifelong learning approaches, we focus on a lifelong representation learning approach that enables us to adapt and sequentially learn a social event embedding model. The motivation for a lifelong learning framework is that the growing knowledge obtained from various domain sources can effectively guide the modeling of complex social events. This involves systematically updating the model by consolidating this expanding knowledge to produce richer embeddings without forgetting previously accumulated knowledge. In this section, we will explain various components of our modeling framework.

5.1 Social Event Representation

Given an input event text description, the core idea is to first encode the free-form event text and decompose the ensuing representation into pragmatic (implied emotions and intents) and non-pragmatic (syntactic and semantic information) components. Eventually, we combine these decomposed representations to obtain an overall event representation and apply it in different downstream tasks.

5.1.1 Encoder

The input to our model is a free-form event text description from i^{th} domain, $x_j^{(i)} \in \mathcal{D}_i$. This free-form event text contains a sequence of tokens, $x_j^{(i)} = [w_1, w_2, ..., w_L]$, where each token $w_{(\cdot)}$ is obtained from an input vocabulary $\mathcal{V}$. The model encodes the input event text $x_j^{(i)} \in \mathcal{R}^{L \times d_X}$ in multiple steps. First, we construct a context-dependent token embedding using a context embedding function $\mathcal{G} : \mathcal{R}^{L \times d_X} \mapsto \mathcal{R}^{L \times d_H}$, where d_X and d_H refer to the embedding and hidden layer dimensions respectively. Following this encoding step, we incorporate pooling or projection function, $\mathcal{G}_{p\bar{p}}$: $\mathcal{R}^{L \times d_H} \mapsto \mathcal{R}^{3 \times d_H}$, that transform event text from context-dependent embedding space into pragmatic and semantic space. More specifically, we produce latent vectors for intents (h_I), reactions (h_R) and non-pragmatic (h_N) information. Finally, we com-

---

[2] https://www.kaggle.com/c/quora-question-pairs/data

bine the latent vectors h_N, h_I, h_R using a simple feed-forward layer, $\mathcal{G}_{\mathcal{C}}$: $\mathcal{R}^{3 \times d_H} \mapsto \mathcal{R}^{d_H}$, to produce a powerful social event representation, h_C, capable of dispelling apparent ambiguities in the true sense of their meaning. Given positive and negative examples of intents, emotional reactions and paraphrases associated with the input event text, we learn to effectively sharpen each of these embeddings h_I, h_R and using metric learning methods.

For the sake of brevity, we drop the domain index i and the sample index j in this section. These encoding steps are summarized as:

$$H_e = [h_1, h_2, ..., h_L] = \mathcal{G}([w_1, w_2, ..., w_L]) \quad (1)$$

$$h_I, h_R, h_N = \mathcal{G}_{p\bar{p}}(H_e) \quad (2)$$

$$h_C = \mathcal{G}_C(h_I, h_R, h_N) \quad (3)$$

We denote this multi-step encoding process resulting in h_I, h_R, h_C as a function $\mathcal{G}_{event}$. Now, we experiment with the following text embedding techniques as our context embedding function ($\mathcal{G}$):

BiGRU Using bidirectional GRUs (Chung et al., 2014), we compute the context embedding of the input event text by concatenating the forward ($\overrightarrow{h_t}$) and backward hidden states ($\overleftarrow{h_t}$), $\overleftrightarrow{h_t} = [\overrightarrow{h_t}; \overleftarrow{h_t}]$.

BERT We employ BERT (Devlin et al., 2018), a multi-layer bidirectional Transformer-based encoder, as our context embedding method $\mathcal{G}$. We fine-tune a BERT model that takes attribute-augmented event text $x = [CLS]\ m\ [SEP]\ w_1, ..., w_L\ [SEP]$ as input and outputs a powerful context-dependent event representation H_e. The attribute $m \in \{xIntent, xReact, xNprag\}$ refers to special tokens for intents, reactions and non-pragmatic aspects.

In our default case, our $\mathcal{G}_{p\bar{p}}$ function is the output embedding of $[CLS]$ token associated with their respective attribute-augmented input. In cases where input event text is not augmented with attribute special tokens, we apply pooling strategies such as attentive pooling (AP) and mean (MEAN) of all context vectors obtained from the previous encoding step $\mathcal{G}$. We obtain h_I, h_R, h_N based on these techniques. Depending on the type of context embedding function, we refer our multi-step event text encoder, $\mathcal{G}_{event}$, as EVENTGRU or EVENTBERT.

5.1.2 Objective Loss

Using positive $\{u_I^p, u_R^p, u_C^p\}$ and $N-1$ negative $\{u_I^n, u_R^n, u_C^n\}$ examples of intents, emotions and paraphrases associated with the event texts, we calculate N-pair loss, $\mathcal{L}_v(h, z^p, \{z_k^n\}_{k=1}^{N-1})$, to maximize the similarity between the representation of positive examples (z_v^p) and the computed embeddings (h_v). Here, z_v^e is computed using a transformation function f_v as: $z_v^e = f_v(u_v^e)$, where $v \in \{I, R, C\}$ and $e \in \{p, n\}$. Thus, our loss function is devised as:

$$\mathcal{L}_{\mathcal{T}} = \beta_D \cdot (\mathcal{L}_I + \mathcal{L}_R) + \beta_E \cdot \mathcal{L}_C \quad (4)$$

where $\mathcal{L}_I, \mathcal{L}_R$ are used to learn disentangled pragmatic embeddings (intent and emotion), $\mathcal{L}_C$ is intended to jointly embed semantic and pragmatic aspects to produce an overall social event representation. β_D, β_E are loss coefficients that weigh the importance of disentanglement loss and an overall joint embedding loss. These coefficients are non-negative and they sum to 1.

5.2 Continual Learning

Given a never-ending list of social events, once-and-for-all training on a fixed dataset limits the utility of such models in real-world applications. Therefore, we draw ideas from lifelong learning literature to adapt our models to new data yet retaining prior knowledge. First, we implement a data-based approach, which is a variant of episodic memory replay (EMR) (Lopez-Paz and Ranzato, 2017; Chaudhry et al., 2019; d'Autume et al., 2019) for mitigating catastrophic forgetting while allowing for beneficial backward knowledge transfer. Next, we combine it with simple vocabulary expansion for incremental domain adaptation.

5.2.1 Domain-Representative Episodic Memory Replay (DR-EMR)

We augment our model explained in Section 5.1 with an episodic memory module to perform sparse experience replay. As we train our lifelong representation learning model, we create mixed training mini-batches ($\mathcal{B}_{dom}, \mathcal{B}_{rep}$) by drawing samples from: (a) new domain dataset, $\mathcal{B}_{dom} \subset \mathcal{D}_i$ and (b) episodic memory containing old domain samples, $\mathcal{B}_{rep} \subset \mathcal{M}$. Training our model using mixed mini-batches introduces parameter changes that alter past event data embeddings, including those stored in our episodic memory, $\mathcal{M}$. The episodic memory module is implemented as a "Read-Write" memory store containing selective event samples from the original domain dataset and their respective embeddings. The key memory operations are stated as follows:

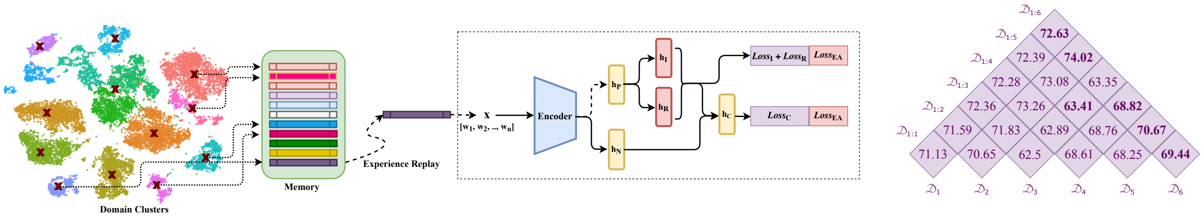

Figure 3: **Left:** Illustration of our Lifelong Social Event Representation Model, **Right:** Average accuracy score (%) of one specific permuted run across 6 domains. Table shows the dynamics of our continual learning model allowing positive backward transfer, i.e., performance increases in previous domains gradually with new knowledge.

Read Operation The read operation retrieves domain-specific random samples from our episodic memory for experience replay. These samples contain the original event training data and their representations. We choose samples from a previously trained domain at every read step assuming an overall uniform distribution over domains.

Write Operation In this work, we incorporate the following desirable characteristics of an episodic memory module: (a) $\mathcal{M}$ stores domain-representative samples that best approximate the domain's data distribution and (b) $\mathcal{M}$'s capacity is bounded or at most expands sub-linearly. To achieve this, we adopt the following strategies:

Domain-Representative Sample Selection: Past studies have explored using random writing strategy (d'Autume et al., 2019) and distribution approximation or K-Means to cluster the samples (Rebuffi et al., 2017). In our work, we perform sample selection using a CURE (Clustering Using REpresentatives) algorithm (Guha et al., 2001) to find C representative points. CURE employs hierarchical clustering that is computationally feasible by adopting random sampling and two-pass clustering. Using event representations obtained after embedding alignment transformation, we identify the domain-representative samples by computing euclidean metric-based nearest neighbors to the C representative points. We set the value of C based on the memory budget. These domain-representative samples are stored in our episodic memory with their corresponding representations.

Replacement Policy: When the memory becomes full, we follow a simple memory replacement policy that selects an existing memory entry to delete. Specifically, we replace the q^{th} memory entry which is determined by: $q = argmax_q(softmax(\phi(x_j^{(t)}) \cdot \mathcal{M}_q)$ similar to idea proposed in (Gulcehre et al., 2018).

Inspired by Wang et al. (Wang et al., 2019), we propose a variant of the alignment model that helps overcome catastrophic forgetting by ensuring minimal distortion to previously computed representational spaces. To accomplish this, we define simple linear transformations: $\mathcal{G}_{IA}, \mathcal{G}_{RA}, \mathcal{G}_{CA}$ on the top of the multi-step encoder function $\mathcal{G}_{event}$ outputs. For simplicity, we drop the subscripts (I, R, C) and denote these transformation functions as $\mathcal{G}_A$. Given a new domain i, we initialize our multi-step event encoder $\mathcal{G}_{event}^i$ and alignment function $\mathcal{G}_A^i$ with the last trained parameters as in $\mathcal{G}_{event}^{i-1}$ and $\mathcal{G}_A^{i-1}$ respectively. The optimization is implemented in the following two steps: (a) For samples from $(\mathcal{B}_{dom}, \mathcal{B}_{rep})$, we optimize the encoder output representations to be closer to their respective ground-truth examples in this linearly transformed space. Therefore, we modify the N-pair loss function to accommodate the alignment function as: $\mathcal{L}(\mathcal{G}_A^i(\mathcal{G}_{event}^i(x)),\ \mathcal{G}_A^i(z^p),\ \{\mathcal{G}_A^i(z^n)\}_{k=1}^{N-1})$;
(b) For samples from $\mathcal{B}_{rep}$, we add an extra constraint $(\mathcal{L} + \mathcal{L}_{EA})$ for each embedding component to align old and new domain embedding spaces:

$$\mathcal{L}_{EA} = ||\mathcal{G}_A^i(\mathcal{G}_{event}^i(x)) - \mathcal{G}_A^{i-1}(\mathcal{G}_{event}^{i-1}(x))||^2 \quad (5)$$

6 Training

Since our model involves metric learning, hard negative data mining is an essential step for faster convergence and improved discriminative capabilities. However, selecting too hard examples too often makes the training unstable. Therefore, we choose a hybrid negative mining technique where we choose few semi-hard negatives examples (Hermans et al., 2017) and combine it with random negative samples to effectively train our model.

In our work, we define a heuristic objective by weighing samples based on two factors: (i) word overlap or similarity in embedding space of the event text and (ii) intent and emotion free-form text or categories based on STORYCOMMONSENSE data. More specifically, given an event text as anchor and a positive intent text based on a ground

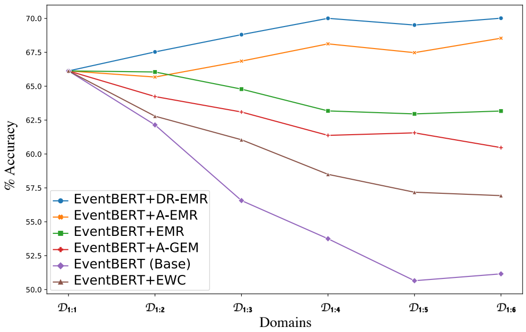

Figure 4: Average accuracy scores (%) of data after 6 permuted runs from domains that have been observed at that point during the continual learning process.

truth motivation category, we mine negative instances for intent as follows: (a) choose random text samples associated with a motivation category that is different from that of the positive example but closer in the embedding space or word overlap, (b) choose random text samples within the same motivation category but with different emotion category. We repeat this process for drawing negative instances related to emotions. For paraphrases, we consider few examples with significant word overlap while the rest are randomly chosen examples. N-pair loss helps alleviate the sensitivity of triplet loss function to the choice of hard triplets. Finally, we pre-train our model with paraphrase data and fine-tune it using the examples obtained from hard negative mining for intents, emotions and paraphrases. For our training, the learning rate is set to 0.0001, the number of training epoch is 20. By default, we use EVENTBERT as our multi-step encoder. We conduct a study by assigning different values for loss coefficients, β_D, β_E, and explain the results of the study in Section 7.1.2.

7 Experiments

We conduct several experiments to study the power of our learned embeddings. Our experiments are designed to answer the following questions:

RQ1: How well does our model perform in comparison to other continual learning approaches for intent-emotion prediction?

RQ2: To what extent do our modeling choices impact the results in predicting intents & emotions?

RQ3: Does our model outperform existing state-of-the-art methods in hard similarity task that evaluates the effectiveness of the learned embeddings?

RQ4: Do the learned embeddings demonstrate transfer capability to downstream tasks – Paraphrase detection & Social IQA reasoning?

7.1 Intent-Emotion Prediction (RQ1)

The continual learning methods evaluated using our *Lifelong EventRep Corpus* are given below.

- **Base**: We simply fine-tune our model on successive tasks from previously trained checkpoint.
- **A-GEM**: This method (Chaudhry et al., 2019) uses a constraint that enables the projected gradient to decrease the loss on older tasks. We randomly choose 2-3% samples from all the previous tasks to form a constraint.
- **EWC**: A regularization-based technique, Online-EWC (Schwarz et al., 2018), is used to address catastrophic forgetting.
- **EMR**: We use randomly stored examples for sparse experience replay.
- **A-EMR**: A variant of our model that uses random samples for experience replay with alignment constraints.
- **DR-EMR**: This is our complete model involving domain representative experience replay and alignment constraints.

7.1.1 Empirical Results

After running six permuted sequence of tasks, we calculate the mean performance on the test set of all observed task domains after time step k, given by $AvgAcc = \frac{1}{k}\sum_{i=1}^{k} Acc^{(i)}$, where $Acc^{(i)}$ is the model accuracy on the test set from the domain $\mathcal{D}_i$. Further, we also compute standard deviation to determine the importance of the order of the tasks during training. Table 1a contains the comparison of last-step $AvgAcc$ scores and standard deviation for predicting intents and emotions. Figure 4 plots the $AvgAcc$ at every step where $\mathcal{D}_{1:i}$ indicates that the model has seen data from i domains to evaluate our continual learning process.

In the absence of any lifelong learning strategies, the performance drops significantly for *Base* model while emphasizing the importance of task order as indicated by the high standard deviation value. Compared to the *Base* model, our results show some improvement in intent and emotion prediction as we introduce methods like *A-GEM* and *EWC*. However, we observe a significant performance gain with *EMR*-based techniques. Our complete model (*DR-EMR*) outperforms all the other methods, thereby demonstrating the importance of

Models	Intents		Emotions	
	AvgAcc	Std	AvgAcc	Std
EVENTBERT (Base)	51.16	10.41	62.27	9.74
EVENTBERT + A-GEM	60.47	6.75	69.44	6.12
EVENTBERT + EWC	56.93	8.86	66.89	7.55
EVENTBERT + EMR	63.17	4.20	72.04	4.66
EVENTBERT + A-EMR	68.54	2.85	73.42	3.10
EVENTBERT+ DR-EMR	**70.02**	**0.38**	**78.48**	**0.65**

(a) Lifelong EventRep Dataset

Models	% Acc.
KGEB (Ding et al., 2016)	50.09

(b) Hard Similarity Dataset

Table 1: Evaluation results on: (a) held-out Lifelong EventRep test set and (b) combined hard similarity dataset.

domain-representative sampling and alignment constraints towards learning representations that help effective prediction of intents and emotions. Moreover, we assess the domain sequences that cause a performance drop. For example, whenever SB-SCK is trained at the end, the model shows reduced accuracy. The reason can be ascribed to the effect of interference of noisy knowledge over the previously trained cleaner domains. Training this noisy source ahead leads to positive knowledge transfer and hence produces sharpened performance outcomes. Despite these odds, our *DM-EMR* model records the least standard deviation implying reduced sensitivity to training order. Figure 3 (Right) shows the dynamics of our continual learning mode. It contains accuracy scores of a single run and displays the lower-triangular values. We see that our approach allows positive backward transfer, i.e., model performance in previous domains gradually increases with new domain knowledge. Our model achieves the best performance (see the bold-faced accuracy scores in Figure 3(Right)) in most domains after observing all the data ($\mathcal{D}_{1:6}$).

7.1.2 Ablation Study (RQ2)

We analyze different model configurations related to: (a) encoding: EVENTGRU, EVENTBERT, (b) pooling: attribute-augmented input (CLS), Mean Pooling (MP) and Attentive Pooling (AP) and (c) sampling: K-Means, CURE. Results of the study are given in Figure 5(Left). We evaluated different combinations of these strategies but only report the average accuracy scores of configurations having the best strategy at each category combined with the variants in the following category, i.e., for pooling strategies, we only report scores with EVENTBERT encoding strategy and so on. From the results, we ascertain that the best configuration comprises an EVENTBERT encoder supported by attentive pooling and CURE-based sample selection.

Methods	Intents	Emotions
Encoding Strategy		
EVENTGRU	60.92	70.61
EVENTBERT	**68.56**	**78.48**
Pooling Strategy		
MP	65.50	76.13
AP	67.28	76.69
CLS	**68.56**	**78.48**
Sampling Strategy		
K-Means	66.45	75.88
CURE	**68.56**	**78.48**

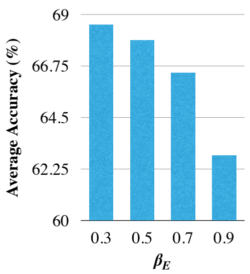

Figure 5: Results of our ablation study on a held-out validation set. **Left:** ***AvgAcc*** scores (%) on intent-emotion prediction task using different encoding, pooling & sampling strategies. **Right:** ***AvgAcc*** scores (%) to measure the effect of β_E in predicting intents.

Additionally, we measure the effect of β_E in the prediction of intents. As shown in Figure 5 (Right), the model performs significantly better for lower values β_E as more weight is assigned for the disentanglement of pragmatic aspects. However, we observe that a balanced loss function with $\beta_E = 0.5$ allows for consistently good performance in both intent-emotion prediction (Figure 5 (Right)) and hard similarity tasks (see Section 7.2). Despite other hyperparameters, changes to β_E determine the importance of incorporating semantic or pragmatic information in the ensuing event embedding.

7.2 Hard Similarity Task (RQ3)

By following the work of Ding et al. (Ding et al., 2019), we evaluate our social event representation on an extended dataset of event pairs containing: (a) similar event pair having minimum lexical overlap (e.g., people admired president / citizens loved leader) (b) dissimilar event pair with high lexical overlap (e.g., people admired president / people admired nature). A good performance in this task will ensure that similar events are pulled closer to each other than dissimilar events. Combining hard similarity datasets from (Ding et al., 2019) and (Weber et al., 2018), the total size of this balanced dataset is 2,230 event pairs. Using our joint embedding h_C for an event text and triplet loss setup, we compute a similarity score between similar and dissimilar pairs. The baselines include: Knowledge-graph based embedding model (KGEB) (Ding et al., 2016), Neural Tensor Network (NTN) and its variants augmented with ATOMIC dataset based embeddings (Int, Senti) (Ding et al., 2019). We report the model's accuracy in assigning a higher similarity score for similar pairs than dissimilar pairs. Table 1b shows that our model outperforms the state-of-the-art method for this task.

7.3 Paraphrase Detection (RQ4)

Given a sentence pair, the objective is to detect whether they are paraphrases or not. For each sentence pair (s_1, s_2), we pass them through our model and obtain their respective h_C, given by vectors (u, v). We concatenate these vectors (u, v) with the element-wise difference $|u - v|$ and feed to a feed-forward layer. We optimize binary cross-entropy loss. For evaluation purposes, we compare our model against baselines like BERT and ESIM (Chen et al., 2016). Trained on a subset of dataset explained in Section 4.2, we choose an out-of-domain test dataset where samples stem from a dissimilar input distribution. To this end, Twitter URL paraphrasing corpus (Lan et al., 2017), referred to as TwitterPPDB, is selected. Table 2b contains results of our evaluation. The results testify the efficacy of our embeddings.

7.4 Social IQA Reasoning (RQ4)

We determine the quality of our latent social event representations by evaluating on a social commonsense reasoning benchmark – SocialIQA dataset (Sap et al., 2019b). Given a context, a question and three candidate answers, the goal is to select the right answer among the candidates. Following Sap et al.(Sap et al., 2019b), the context, question, and candidate answer are concatenated using separator tokens and passed to the BERT model. Additionally, we feed the context to our EventBERT model to obtain three embeddings h_I, h_R, h_C. While the original work computed a score l using the hidden state of $[CLS]$ token, we introduce a minor modification to this step as: $l = W_5 tanh(W_1 h_{CLS} + W_2 h_I + W_3 h_R + W_4 h_C)$, where $W_{1:4} \in \mathcal{R}^{d_H \times d_H}$ and $W_5 \in \mathcal{R}^{1 \times d_H}$ are learnable parameters. Similar to (Sap et al., 2019b), triple with the highest normalized score is used as the model's prediction. We fine-tune BERT models using our new scoring function with social event embedding (denoted as "w/") and compare against baselines (like GPT (Radford et al., 2018)) without our event embeddings (denoted as "w/o"). Results in Table 2a indicate that a simple enhancement procedure at the penultimate step can offer significant performance gains. Our findings also suggest that our enhanced model performed well for question types like 'wants' and 'effects' that weren't explicitly modeled in our embedding model. This confirms that our pragmatics-enriched embeddings lead to improved reasoning capabilities.

Models	**Dev**	**Test**
w/o Social Event Embeddings

8 Conclusion

Humans rely upon commonsense knowledge about social contexts to ascribe meaning to everyday events. In this paper, we introduce a lifelong learning approach to effectively embed social events with the help of a growing set of social commonsense knowledge assertions acquired from different domains. First, we leverage social commonsense knowledge to sharpen social event embeddings with semantic and pragmatic attributes. Next, we employ domain-representative episodic memory replay (DR-EMR) to overcome catastrophic forgetting and enable positive knowledge transfer with the emergence of new domain knowledge. By evaluating on a corpus of social events aggregated from multiple sources, we establish that our model is able to outperform several baselines. Experimental results on downstream tasks like event similarity, reasoning, and paraphrase detection demonstrate the capabilities of our social event embeddings. We hope that our work will motivate further exploration into lifelong representation learning of social events and advance the research in inferring pragmatic dimensions from texts.

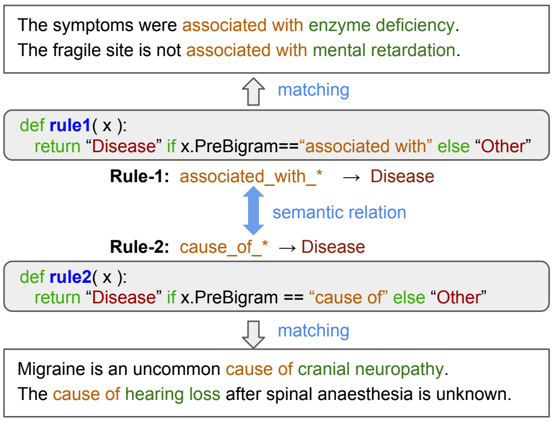
Abstract

Instead of using expensive manual annotations, researchers have proposed to train named entity recognition (NER) systems using heuristic labeling rules. However, devising labeling rules is challenging because it often requires a considerable amount of manual effort and domain expertise. To alleviate this problem, we propose GLaRA, a graph-based labeling rule augmentation framework, to learn new labeling rules from unlabeled data. We first create a graph with nodes representing candidate rules extracted from unlabeled data. Then, we design a new graph neural network to augment labeling rules by exploring the semantic relations between rules. We finally apply the augmented rules on unlabeled data to generate weak labels and train a NER model using the weakly labeled data. We evaluate our method on three NER datasets and find that we can achieve an average improvement of +20% F1 score over the best baseline when given a small set of seed rules.

1 Introduction

Named entity recognition (NER) models often need to be trained with many manual labels to perform well. Due to the high cost of manual annotations, collecting labeled data to train NER models is challenging for real-world applications. Recently, researchers have proposed to collect weak labels using heuristic rules, which are called labeling rules (Bach et al., 2017; Fries et al., 2017; Ratner et al., 2020; Safranchik et al., 2020). This kind of methods typically first ask domain experts to write labeling rules for a NER task, then use these manual rules to generate labeled data and train a NER model with the weakly labeled data. The advantage of these methods is that they do not require manual annotations. However, during our study, we find that writing labeling rules is also challenging for domain-specific tasks. Devising accurate rules often demands a significant amount of manual effort because it requires developers to have deep domain expertise and a thorough understanding of the target data.



The symptoms were associated with enzyme deficiency.
The fragile site is not associated with mental retardation.

```
def rule1( x ):
    return “Disease” if x.PreBigram==“associated with” else “Other”
```

Rule-1: associated_with_* → Disease

Rule-2: cause_of_* → Disease

```
def rule2( x ):
    return “Disease” if x.PreBigram == “cause of” else “Other”
```

Migraine is an uncommon cause of cranial neuropathy.
The cause of hearing loss after spinal anaesthesia is unknown.

Figure 1: Two examples of rules for recognizing `Diseases`. `PreBigram` means the 2 tokens on the left of a candidate entity.

To alleviate manual effort on writing labeling rules, we propose GLaRA, a **G**raph-based **La**beling **R**ule **A**ugmentation framework to automatically learn new rules from unlabeled data with a handful of seed rules. Our work is motivated by the intuition that if two rules can accurately label the same type of entities, then they are semantically related via the entities matched by them. Therefore, we can acquire new labeling rules based on their semantic relatedness with the rules that we have already known. For example, Figure 1 shows two example rules for labeling `Disease` entities. If we know that `rule1` “`associated with` $*\rightarrow$`Disease`” is an accurate rule for labeling diseases, and `rule1` is semantically related to `rule2` “`cause of` $*\rightarrow$`Disease`”, then we can derive that `rule2` can be another accurate rule for labeling diseases.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3636–3649
April 19 - 23, 2021.

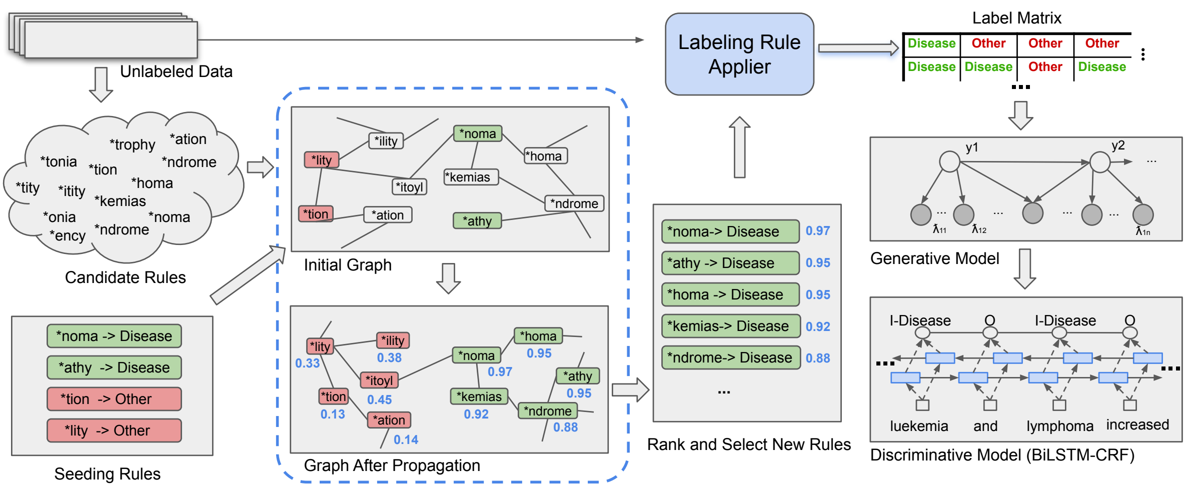


Figure 2: An example workflow of GLaRA framework that using `suffix rules` to recognize `Diseases`. Given unlabeled data and seeding rules, (1) we first extract candidate rules from unlabeled data, (2) then build a graph of rules and learn new rules by propagating the labeling information from seeding rules to other rules. (3) Next we apply selected rules on unlabeled data and obtain a label matrix. (4) Finally, we estimate the noisy labels using a generative model, and (5) train a final NER model with noisy labels. "$*$`noma` → `Disease`" denotes that if a word's suffix is "`noma`" then it will be labeled as `Disease`.

To augment labeling rules, we first define six types of rules and extract all possible rules from unlabeled data as candidate rules. Then, for each rule type, we build a graph by connecting rules of this type based on their semantic similarities. In our work, we compute a rule's embedding as the average of contextual embeddings of entities matched by the rule, and compute the similarities between rules using their embeddings. We learn new rules using a graph neural network model from a small set of seed rules. Next, we train a discriminative NER model using the weak labels generated by both the seeding and learned rules. To obtain weak training labels, we first obtain a label matrix by applying all the augmented rules on each token in unlabeled data. Then, we estimate the labels of unlabeled instances using the LinkedHMM model (Safranchik et al., 2020). We evaluate our framework on three datasets. In our experiments, we first show that our method can achieve better results than baselines when abundant rules are available. We also demonstrate that we can achieve an average improvement of +20% F1 when only a small set of rules are available.

We summarize our major contributions as:

- We propose a new Graph-based Rule Labeling Rule Augmentation (GLaRA)[1] framework, which can effectively learn new labeling rules from unlabeled data automatically.

- We propose a new graph neural network to estimate rules' labeling confidence with a new class distance-based loss function.

- We define six types of labeling rules, which have been proven to be effective on three named entity recognition tasks.

2 The GLaRA Framework

Our goal is to build a NER system with a small set of manually selected seeding rules and unlabeled data. Our key idea is to first augment labeling rules using graph neural networks, based on the hypothesis that semantically similar rules should have similar abilities to recognize entities. Then, we train a NER model using the weak training data labeled by the augmented rules.

Overview Figure 2 shows an example workflow of GLaRA framework using `suffix` rules to recognize `Disease` entities. Our framework consists of five major components. (1) *Rule extractor*: We define six types of rules and extract all possible rules from unlabeled data as candidate rules. (2) *Rule augmentation*: For each rule type, we first build a graph of rules by connecting rules based on their semantic similarities. Given a small set of

---

[1] The code is available at `https://github.com/zhaoxy92/GLaRA`.

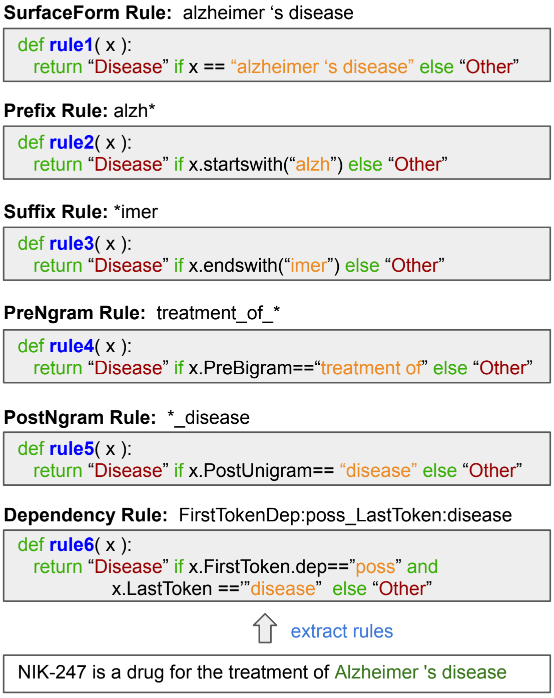
manual seeding rules, we learn new rules by propagating the labeling confidence from seeding rules to other rules. (3) *Rule Applier*: We obtain a label matrix by applying all the augmented rules on each token in the unlabeled data. (4) *Generative Model*: We estimate the labels of unlabeled instances using a generative model. (5) *Discriminative Model*: We train a final discriminative NER model using the weak labels produced by the generative model.

2.1 Candidate Rule Extraction

As demonstrated in previous work on NER (Zhou and Su, 2002), lexical and contextual clues are strong indicators for entity recognition. Therefore, we define and extract six types of rules: `SurfaceForm`, `Prefix`, `Suffix`, `PreNgram`, `PostNgram`, and `DependencyRule` to recognize entities by considering their lexical, contextual, and syntax information.

Given an unlabeled sentence, we first extract all noun phrases (NPs) using a set of Part-of-Speech (POS) patterns, as candidate entity mentions. The POS patterns include "JJ? NN+" (JJ denotes an adjective, and NN denotes a noun) and top 15 most frequent POS patterns of the entity mentions in the development sets. Then, we extract all six types of rules from the unlabeled data as candidate rules for each candidate entity mention. Specifically, we extract the surface form of each candidate entity mention as a `SufraceForm` rule. If the mention is a single token, we extract its first and last m characters as `Prefix` and `Suffix` rules, respectively. For `PreNgram` rule, we extract leading n words of a candidate entity as `inclusive PreNgram` rule; meanwhile, we also extract n words on the left of candidate as `exclusive PreNgram` rule. `PostNgram` rules are created similarly from the right context. Also, for each multi-token entity candidate, we first extract the dependency relations of the first token and the second last token, respectively, and then each dependency is combined with the last token as `Dependency` rules of this mention. We treat m and n as hyperparameters in our work.

Figure 3 show some example rules that extracted for the candidate entity mention "*Alzheimer 's disease*" and how they are used for labeling entities.



SurfaceForm Rule: alzheimer 's disease

```
def rule1( x ):
  return "Disease" if x == "alzheimer 's disease" else "Other"
```

Prefix Rule: alzh*

```
def rule2( x ):
  return "Disease" if x.startswith("alzh") else "Other"
```

Suffix Rule: *imer

```
def rule3( x ):
  return "Disease" if x.endswith("imer") else "Other"
```

PreNgram Rule: treatment_of_*

```
def rule4( x ):
  return "Disease" if x.PreBigram=="treatment of" else "Other"
```

PostNgram Rule: *_disease

```
def rule5( x ):
  return "Disease" if x.PostUnigram== "disease" else "Other"
```

Dependency Rule: FirstTokenDep:poss_LastToken:disease

```
def rule6( x ):
  return "Disease" if x.FirstToken.dep=="poss" and
            x.LastToken =="disease"  else "Other"
```

NIK-247 is a drug for the treatment of Alzheimer 's disease

Figure 3: Example rules extracted for an entity mention, and how these rules will be used to label entities.

2.2 Labeling Rule Augmentation

We aim to learn new labeling rules from seed rules by exploiting the semantic relations between rules. Specifically, we first build a graph with rules as nodes. Then, we initialize the graph with both manually selected positive and negative seeding rules. Positive seeding rules are those that can be used to predict a target entity type. Negative ones are used to predict instances of the "*Other*" class. Next, we estimate the representations of rules by optimizing a graph neural network model. Finally, we compute the distances of a rule to the centroids of positive and negative seeding rules, respectively, and then select rules close to positive centroid as new labeling rules.

Graph of Rules For each type rules, we create a graph $G = (\mathcal{V}_u, \mathcal{V}_s^{pos}, \mathcal{V}_s^{neg}, \mathcal{A})$ with this type of rules as nodes, where $\mathcal{V}_u$ denotes the candidate rules extracted in the previous step, $\mathcal{V}_s^{pos}$ and $\mathcal{V}_s^{neg}$ denotes the positive and negative seeding rules, respectively. $\mathcal{A}$ is the adjacency matrix of nodes. In our graph, each node (i.e., rule) is connected with the top 10 semantically similar nodes. The similarity between two rules is computed as the cosine similarity using their embeddings.

Rule Embeddings We estimate semantic relatedness between rules with their embeddings, which are computed using pre-trained contextual embedding models. Specifically, we first apply the pre-trained ELMo (Peters et al., 2018) model on all unlabeled sentences to obtain contextual embeddings of candidate entity mentions. Then, we compute the embedding of a rule as the average of the embeddings of all the candidate entities that can be matched by this rule. For example, the embedding of the prefix rule "*noma" is calculated as the average of the embeddings of all candidate mentions that ends with "noma".

Graph Propagation Model Given a graph of rules and seeding rules, we formulate the problem of learning new labeling rules (i.e., positive rules) as a graph-based semi-supervised node classification task that aims to classify candidate rules (which could be treated as unlabeled nodes in the graph) as positive or negative.

Based on the intuition that semantically similar rules should predict entity labels similarly. We propose a graph neural network model to propagate labeling information from seeding nodes to other nodes based on the recent work on Graph Attention Network (Veličković et al., 2017). Specifically, given the input embedding h_i of node i and its neighbors $\mathcal{N}_i$, we first compute an attention weight for each connected pair (i, j) as,

$$\alpha_{ij} = \frac{exp(f(A^T[Wh_i, Wh_j]))}{\sum_{k \in N_i} exp(f(A^T[Wh_i, Wh_k]))} \tag{1}$$

where W is a parameter matrix, and f is the LeakyReLU activation function. We then recompute the embedding of i:

$$h_i^* = \alpha_{i,i} Wh_i + \sum_{j \in N_i} Wh_j \tag{2}$$

To keep model stable, we apply multi-head attention mechanism to obtain K attentional states for each node, the average of which is used as final node representation, i.e., $h_i^{*T} = \frac{1}{K} \sum_k h_i^{kT}$.

The objective of our model is defined as follows:

$$\mathcal{L}_{total} = \mathcal{L}_{sup} + \mathcal{L}_{reg} + \mathcal{L}_{dist} \tag{3}$$

where $\mathcal{L}_{sup} = -(y_i \log(p_i)) + (1 - y_i) \log(1 - p_i)$
$\mathcal{L}_{reg} = \sum_{i,j \in N_i} \|h_i - h_j\|_2$
$\mathcal{L}_{dist} = dist(h_{pos}, h_{neg})$

where $\mathcal{L}_{sup}$ is the supervision loss computed on both positive and negative seeding rule nodes, $\mathcal{L}_{reg}$ is the regularization that encourages connected nodes to share similar representations, and $\mathcal{L}_{dist}$ aims to maximize the distance between positive and negative seeding nodes. $dist(\cdot)$ computes the cosine similarity between the centroids of the positive and negative seeds. p_i is the probability of a node being classified as positive, and h_{pos} and h_{neg} are the average embeddings of positive and negative nodes, respectively.

When the learning process is finished, each rule is associated with a new embedding representation, i.e., h_i^{*T}. For each rule, we first compute its cosine distances to the centroids of positive and negative seeding nodes using their embeddings, respectively. Then, we rank all rules by the difference of two distances and select the top M rules closest to the centroid of the positive seeding rules as new labeling rules.

2.3 Generative Model for Label Estimation

After the rule learning process, we apply both the newly learned rules and the seeding rules on unlabeled data to produce a matrix of labels.[2] Since one token can be potentially matched by several different rules, the resulting labels can have conflicts. Therefore, we use the LinkedHMM (Safranchik et al., 2020) model to combine these labels into one label for each token. Briefly, the main idea of LinkHMM is to treat the true label of a token as a latent random variable and estimate its value by relating it to the label outputs from different labeling rules. The estimated labels can be used to train final discriminative NER models.

2.4 Discriminative NER Model

After the training of the generative model (i.e., the LinkedHMM in our work) is completed, each token in the unlabeled data is associated with a weak label. Each weak label is a probability distribution over all entity classes, which can be used to train a discriminative NER model. One advantage of training a discriminative NER model is that it can use other token features while the generative model can only use labeling rules' outputs as inputs. Therefore, even if a token is not matched by any labeling rules, it can still be predicted correctly by the discriminative model.

In our work, we use BiLSTM-CRF (Huang et al., 2015) as our discriminative model. The model first uses BiLSTM to generate a state representation for each token in a sequence. The CRF layer then predicts each token by maximizing the expected likelihood of the entire sequence based on the estimated labels.

---

[2] In our work, we also applied the linking rules developed by (Safranchik et al., 2020) on unlabeled data, so the label matrix also contains the results from linking rules.

3 Experimental Setup

In this section, we present the details of our experimental setup. First, we evaluate our method on three NER datasets, which we refer to `NCBI`, `BC5CDR`, and `LaptopReview`. Then, we describe the baseline methods compared in our experiments. We also give a detailed description of the seed rules used in our experiments.

3.1 Datasets

We evaluated our method on three datasets. Details of each dataset are described below.

`NCBI` (Doğan et al., 2014) contains 793 PubMed abstracts with 6,892 `Disease` mentions and is split into 593 train, 100 dev and 100 test data.

`BC5CDR` (Li et al., 2016) has 1,500 PubMed articles with 5,818 `Disease` and 3,116 `Chemical` mentions. It is split into train, dev, and test sets with 500 articles each.

`LaptopReview` (Pontiki et al., 2016) contains sentences regarding laptop `AspectTerms`, including 3,048 training and 800 test sentences. Following (Safranchik et al., 2020), we hold out 20% of training data as dev set.

Note that we use all training data as our unlabeled data by removing the manual annotations.

3.2 Compared Methods

We compare our method with state-of-the-art weakly supervised methods using dictionaries or heuristic rules as supervision. In this section, we briefly describe these baseline methods.

AutoNER (Shang et al., 2018) is a distantly supervised method, which automatically builds a neural named entity recognition model using dictionaries as weak supervision.

Snorkel (Ratner et al., 2020) is a general machine learning framework that can train classifiers using heuristic rules. By default, it uses a Naive Bayes generative model to denoise labeling rules by predicting each token's label independently.

SwellShark (Fries et al., 2017) is an extension of Snorkel that was developed for biomedical NER. Same as Snorkel, it uses a naive Bayes generative model to denoise manual labeling rules. It also requires a special entity candidate generator to detect entity spans accurately before predicting their entity labels. In our experiments, we report both results using simple noun phrases as candidates, and that generated using extra expert effort.

LinkedHMM (Safranchik et al., 2020) is a framework for training sequence tagging models using weak supervision from manual rules. Besides using labeling rules, it can also use linking rules that indicate whether two consecutive tokens have the same label.

Table 1: Number of positive and negative seed rules for each dataset. `S` denotes the number of seed rules by (Safranchik et al., 2020) and `M` denotes the rules we manually selected. † denotes that corresponding rule type includes both `inclusive` and `exclusive` rules.

3.3 Seed Rules

In our experiments, we used all the labeling rules[3] developed by Safranchik et al. (2020) as part of positive seeding rules. Besides, we manually selected another small set of labeling rules as our input because: (1) we defined six types of rules as described in Section 2.1, but some types of rules were not used in Safranchik et al. (2020) (e.g., prefix rules are not used in NCBI), (2) our method requires negative seed rules, which are used to identify terms that are not entities, to initiate its learning process. To automatically learn new labeling rules, we use both labeling rules from (Safranchik et al., 2020) and our manually selected rules as seeding rules. Numbers of both positive and negative seeding rules used in our experiments are shown in Table 1.[4] Our manually selected seed rules are

---

[3] In our experiments, we used the linked rules from (Safranchik et al., 2020) to obtain weak labels, which are another type of rules that can be used to vote if the two consecutive tokens have the same label, to train our LinkedHMM model. However, our work only focused on augmenting labeling rules, and did not augment linking rules.

[4] Note that in previous work a whole lexicon or dictionary is counted as one rule. However, in our work we count each term in a lexicon or dictionary as one surface form rule.

included in Appendix C.

3.4 Implementation Details

In our experiments, we create a graph for each type of rules for each dataset and learn new rules independently with the same setup. `Prefix` and `Suffix` candidate rules are generated by considering the first and last 3 to 6 characters, and `PreNgram` and `PostNgram` candidate rules are extracted with the windows of 1 to 3 tokens.

We use a two-layer graph attention network to train our graph model. After training, we select M new rules for each type of rules, where the value of M is searched between 20 and 500 on dev sets.

For different datasets, our discriminative NER models used different pre-trained contextual models. Since NCBI and BC5CDR datasets are in the biomedical domain, we finetuned our NER model on the pretrained SciBERT embedding (Beltagy et al., 2019), while for LaptopReview data, the NER model is finetuned on the pretrained BERT_{base} (Devlin et al., 2018) embedding. More details are provided in Appendix A.

4 Experimental Results

In this section, we first compare our method with state of the art methods using all available manual rules. Then, we evaluate our method under scenarios when only limited seeding rules are available, which are very common in real-world applications. Next, we conduct an ablation study to investigate the effectiveness of different types of rules and our newly proposed loss function based on centroid distance. Finally, we also perform a quality analysis of the automatically learned labeling rules.

4.1 Results with Abundant Seeding Rules

In this subsection, we report both the result of our *generative* model with augmented rules in Table 2 and the result of our *discriminative* NER model that is trained using weak labels from the generative model in Table 3.

Table 2 shows the performance of our generative model with augmented rules and baseline generative models[5]. The *Supervised* line is the performance of the LinkedHMM model trained on fully labeled training data. The results show that our method with augmented labeling rules performed best on BC5CDR and LaptopReview datasets. We also achieved a comparative F1 score of 80.2 on NCBI with SwellShark (F1 80.8). Note that SwellShark used lots of manual effort from experts to carefully tune a particular candidate generator for a given dataset. We also notice that, with augmented rules, our method outperforms LinkedHMM by an average of 2.0 F1 points, which demonstrates the effectiveness of augmented rules.

WeakSupervision	NCBI	BC5CDR	Laptop
Snorkel	73.4±1.7	82.2±.5	63.5±1.7
LinkedHMM	79.0±.4	83.0±.2	69.0±1.1
GLARA	**80.8**±.3	**83.5**±.6	**72.3**±1.0

Table 3: Results of discriminative models using weak labels generated by different methods. Our results are the average of five runs.

Table 3 shows the performance of our discriminative NER model (BiLSTM-CRF) trained on weak labels from our GLARA with augmented rules and baseline discriminative models using weak labels from LinkedHMM and Snorkel without augmented rules (Safranchik et al., 2020). The results show

---

[5] Some scores were reported in (Safranchik et al., 2020)

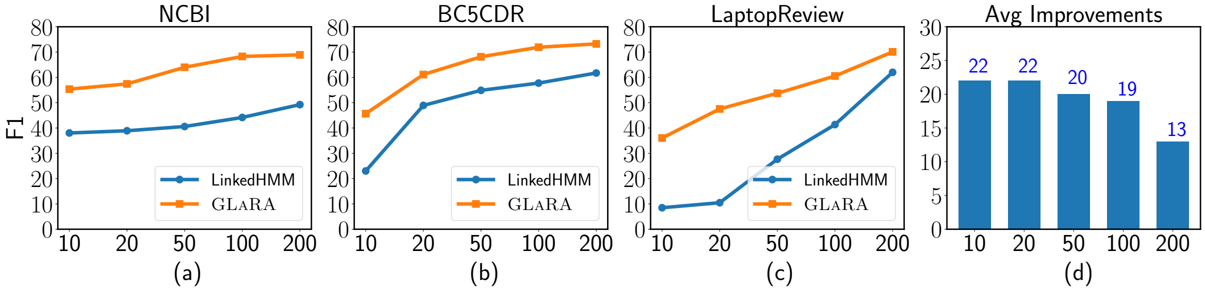

Figure 4: Results of LinkedHMM with only seeding rules and augmented rules by our GLaRA method. The bottom numbers are the numbers of seeding rules used.

that our method achieved a +1.9 F1 point improvement over the second-best system. We also notice that our discriminative model performs slightly better on `NCBI` and `Laptop`, but worse on `BC5CDR` than the generative model, which is consistent with that from (Safranchik et al., 2020).

4.2 Results with Limited Seeding Rules

Though weakly supervised state-of-the-art methods reported in Table 2 achieved relatively good performance, they require a significant amount of manual effort from domain experts for designing and tuning labeling rules. Well-performing methods that require less manual effort are often more desirable. Therefore, we also evaluate our method with little manual effort (i.e., limited seeding rules). We conducted experiments by randomly select at most k rules for each rule type from our seed rules (Section 3.3), where $k \in \{10, 20, 50, 100, 200\}$. When a rule type has less than k seeding rules, we use all of them. Figure 4 shows the performance of the LinkedHMM model using only seeding rules and our GLaRA method with augmented rules on three datasets. Figure 4(d) shows that, with automatically learned rules, our method can obtain average F1 gains of +22 points when using 10 seeding rules and +13 points when there are 200 seeding rules.

4.3 Impact of Different Types of Rules

To investigate the effectiveness of different types of labeling rules, we conducted ablation experiments to evaluate our generative model with augmented rules (i.e., GLaRA) by adding each type of rules cumulatively. Results are shown in Table 4. Empty cells denote that the corresponding type of rules are not used. Results show that `Prefix` rules are most effective on the Laptop dataset, producing +1.5 F1 point improvement. All other rules except `PostNgram` can improve the performance by +0.4 to +0.6 F1 points.

	NCBI	CDR	Laptop	Δ
LinkedHMM	78.7	85.9	68.2	
GLaRA				
+DepRule	79.3	-	-	+0.6
+PostNgram	-	86.0	-	+0.1
+PreNgram	79.6	86.2	69.3	+0.5
+Prefix	-	-	70.8	+1.5
+Suffix	79.8	86.3	71.7	+0.4
+Surface	80.2	-	72.2	+0.5

Table 4: Impact of each type of rules used in our generative model. Δ denotes the average improvement achieved by adding rules cumulatively.

4.4 Effectiveness of Distance Loss $\mathcal{L}_{dist}$

In this work, we proposed a new graph neural network model with a new loss function, i.e., $\mathcal{L}_{dist}$ in Eq. 3. This loss function measures the distance between the centroids of positive and negative seeding rules by computing their cosine similarity. The motivation is that the model should keep positive rules distant from negative ones during the learning process. Table 5 shows the performance of our generative model with and without the distance loss. We find that our method can obtain an average F1 gain of 1.2 points across three datasets with this new loss function.

GLaRA	NCBI	BC5CDR	LaptopReview
w/ $\mathcal{L}_{dist}$	$80.2_{\pm .2}$	$86.3_{\pm .3}$	$72.2_{\pm 1.2}$
w/o $\mathcal{L}_{dist}$	$79.3_{\pm 1.2}$	$86.1_{\pm .1}$	$69.7_{\pm .8}$

Table 5: Results of our generative model using augmented rules learned by our graph neural network model with and without distance loss.

RuleType	**Top 5 learned rules**
`Surface`	neurologic_disease, spherocytic_hemolytic_anemia, episodic_hemolytic_anemia, choroid_plexus_carcinoma, sporadic_human_renal_cell_carcinoma

Table 6: Examples of learned new rules for recognizing diseases on NCBI data. "_" denotes the space character.

4.5 Quality Analysis of Learned New Rules

In Table 6, we present top 5 learned rules for each rule type that we automatically learned on the NCBI data set. Each rule is formatted in the way described in Section 2.1.

Table 7 shows the analysis results of the number of new rules (#Rule) and their accuracy (ACC) on the dev sets, which were learned during the experiments presented in Section 4.1. Results show that all the learned rules have accuracy ≥64% with an average of 76%, which justifies the quality of these new rules.

RuleType	**Dataset**	**#Rule**	**ACC**
Surface	NCBI	301	78%
	Laptop	154	69%
Suffix	NCBI	64	100%
	CDR(Dis)	138	90%
	Laptop	25	66%
Prefix	Laptop	16	78%
PreNgram	NCBI	156	65%
	CDR(Dis)	19	64%
	Laptop	17	71%
PostNgram	CDR(Chem)	37	82%
DepRule	NCBI	47	70%

Table 7: Quality analysis of learned new rules.

Besides, we also manually analyzed why some learned rules are not helpful to improve recognition performance. First, some of the learned rules can be overlapping. For example, both "`∗demia→Disease`" and "`∗edemia→Disease`" can be used to recognize `Diseases`. However, if `∗demia` is learned first, then learning `∗edemia` rule will not help because the entities matched by these two rules have large overlaps. Second, some of the rules learned from unlabeled data may not be applied to testing data due to the mismatch between two datasets. For example, though the PostNgram rule "`∗_dystonia→Disease`" is an accurate rule to label diseases such as "oromandibular dystonia" and "responsive dystonia". However, we do not find any matches on test data.

5 Related Work

Training reliable NER systems usually requires large annotation efforts, which is often considered expensive and impractical in certain domains. Therefore, previous studies have been trying to reduce the manual efforts required for annotation while producing comparable performance in NER tasks by utilizing manually designed rules that are cheap and accurate.

Studies have shown that human-defined rules (i.e dictionaries) can greatly aid NER tasks, especially in the domains where the identification of entities needs domain knowledge (Cohen and Sarawagi, 2004; Savova et al., 2010; Xu et al., 2010; Eftimov et al., 2017), and they can also be used to distantly create labeled data set to benefit machine learning models (Mann and McCallum, 2010; Neelakantan and Collins, 2015; Giannakopoulos et al., 2017).

While distantly labeled data sets can be created at a low cost to boost NER tasks, the models still suffer from the noise introduced by the imperfect rules. Therefore, denoising models have been proposed to allow the model to better tolerate the imperfect annotations created by rules. Shang et al. (2018) proposed AutoNER that trains NER systems using only lexicons with a tie-or-break tagging denoising model. Similarly, some recent work (Liu et al., 2019; Yang et al., 2018; Cao et al., 2019) have used a partial matching module to denoise the noisily labeled data sets.

Recently, weak supervision is proposed as another form of denoising framework without using any labeled data. Weakly supervised systems use handcrafted labeling rules to create weak training instances from unlabeled data and then use a denoising generative model to approximate the posteriors of the rules. In this process, the unknown gold label is treated as latent variable by the generative model. The performance of the labeling rules could be further enhanced by training a neural network-based discriminative model by treating the posteriors as soft labels. Related studies such as Snorkel (Ratner et al., 2020), SwellShark (Fries et al., 2017), LinkedHMM (Safranchik et al., 2020), and (Lison et al., 2020) have demonstrated great success with carefully curated labeling rules.

However, manually designing those high-quality rules often require domain expertise and easy to have a low sensitivity on identifying entities. In (Lison et al., 2020), the weak training data is created by broadly collecting available labeling rules from multiple sources, which demonstrates the importance of being able to automatically find new heuristics missed by human efforts. To find new heuristic rules on the basis of a relatively limited number of manually designed rules, previous studies have tried bootstrapping by relying on the co-occurrence, context and pattern features (Thelen and Riloff, 2002; Riloff et al., 2003; Yangarber, 2003; Shen et al., 2017; Tao et al., 2015; Berger et al., 2018; Yan et al., 2019).

Recent studies on graph neural networks has opened up another possibility for learning new rules. By internally infusing the semantics of the neighboring nodes, the popular Graph Convolutional Network (GCN) (Kipf and Welling, 2016) and Graph Attention Network (GAT) (Veličković et al., 2017) have shown great success in semi-supervised node classification when the number of labeled nodes is limited. Graph neural networks have been applied for many NLP tasks such as text classification (Yao et al., 2019; Zhang et al., 2019a; Hu et al., 2019), semantic role labeling (Marcheggiani and Titov, 2017), machine translation (Beck et al., 2018), question answering (Song et al., 2018; Saxena et al., 2020), information extraction (Liu et al., 2018; Vashishth et al., 2018; Nguyen and Grishman, 2018; Sahu et al., 2019; Sun et al., 2019; Fu et al., 2019; Zhang et al., 2019b), etc. In our work, we proposed to use graph neural networks to learn new labeling rules. Based on Graph Attention Network (Veličković et al., 2017), we designed a new graph network model with a new loss function. Experimental results demonstrated that our model performed better than the original graph attention network on learning accurate labeling rules.

6 Conclusion

In this work, we proposed a weakly supervised NER framework that automatically learns high-quality new rules from only a handful of manually designed rules with a graph-based labeling rule augmentation method (GLARA). Experiments on three NER datasets demonstrate that our model outperforms baseline systems and achieves substantially better performance when the number of manual rules is limited. In addition, we also defined six types of rules that have been demonstrated useful for recognizing entities. In the future, we plan to improve GLARA by investigating more complex rule types and rule representation methods for weakly supervised NER.

A Hyperparameter configuration

Graph Propagation Model We use the same graph architecture to train propagation for all types of rules. The model contains 2 graph attention layers each with 3 attention heads and dropout rate is set to be 0.5. The hidden size of each layer is set as 64. We use Adam optimizer with a learning rate of 0.0001. Other hyperparameters (training epoch and number of selected new rules) are presented in Table 8.

Hyperparam	NCBI		BC5CDR		Laptop	
	epoch	#rules	epoch	#rules	epoch	#rules
SurfaceForm	50	50	50	-	50	25
Prefix	50	-	50	-	50	15
Suffix	50	25	50	25(`D`)	50	25
PreNgram$_{\text{inclusive}}$	50	25	30	-	30	
PreNgram$_{\text{exclusive}}$	50	-	50	25(`D`)	30	
PostNgram$_{\text{inclusive}}$	50	-	30		50	
PostNgram$_{\text{exclusive}}$	50	-	50	30(`C`)	50	
Dependency	50	25	50	-	50	25

Table 8: Summary of hyperparameters for propagation. In BC5CDR data. "`D`" denotes the number of selected rules for Disease and "`C`" denotes the that for Chemical for the corresponding rule type. "-" means the corresponding type of propagated rules are not used on our final model.

Generative Model Table 9 presents the hyperparameters used for tuning our LinkedHMM generative model, including "Initial Accuracy (estimated initial accuracy of the rules)", "Accuracy Prior (regularization for initial accuracy)", and "Balance Prior (the entity class distribution)". We used grid search to find the best hyperparameters. The search ranges are created around the default settings of the LinkedHMM model on the three data sets. For training epoch, we use the default setting, 5, for all three datasets. For more details about the hyperparameters, please refer to (Safranchik et al., 2020).

Hyperparam		NCBI	CDR	Laptop
Init Acc	Search	[0.75-0.95]	[0.75-0.95]	[0.75-0.95]
	Best	0.85	0.85	0.9
Acc Prior	Search	[45-65]	[0-15]	[0-5]
	Best	55	5	1
Bal Prior	Search	[440, 460]	[440, 460]	[0, 20]
	Best	450	450	10

Table 9: Summary of hyperparameters for training the LinkedHMM generative model on each data set. The search steps for `InitialAccuracy`, `AccuracyPrior`, and `BalancePrior` are 0.05, 5, and 5, respectively.

Discriminative Model Table 10 presents the hyperparameter configuration for training discriminative model (BiLSTM-CRF). BERT$_{base}$ is used to extract word embeddings and fine-tuned with BiLSTM-CRF. All discriminative models are trained on a 11G 1080Ti GPU with training time being up to ∼20s/epoch. All models have ∼110M parameters.

B Performance on Development Data

In Table 11, we present the performance of the LinkedHMM model on developement sets, with the additional seeding rules manually selected by us, referred as LinkedHMM-M, the performance of the following discriminative model, referred as LinkedHMM-M-D. Also, we report the performance of our models, GLARA and GLARA-D (with discriminative model) on development sets.

Hyperparam		NCBI	BC5CDR	Laptop
BERT		SciBERT	SciBERT	BERT
BiLSTM	Hidden Dim	256	256	256
	Dropout	0.1	0.1	0.1
CRF		yes	yes	no
AdamW	Learning Rate	1e-4	1e-4	1e-4
	Epoch	30	30	30
Batch size		8	8	8
Max sent length		128	128	128

Table 10: Summary of hyperparameters for training discriminative model on each data set.

Model	**NCBI**	**BC5CDR**	**Laptop**
LinkedHMM-M	82.3	87.5	70.1
LinkedHMM-M-D	82.8$\pm$.3	84.5$\pm$.2	71.5$\pm$.8
GLARA	83.1$\pm$.2	87.4$\pm$.3	72.3$\pm$.8
GLARA-D	83.4$\pm$.3	84.5$\pm$.1	72.6$\pm$.6

Table 11: Micro F1 performance on each development data set. $\mathtt{LinkedHMM-M}$ denotes the baseline LinkedHMM model trained with the extra manually selected seeding rules. $\mathtt{LinkedHMM-M-D}$ denotes the discriminative mode (LSTM-CRF) trained based on $\mathtt{LinkedHMM-M}$. Similarly, GLARA$-\mathtt{D}$ denotes the LSTM-CRF model trained based on GLARA.

C Manually Selected Seeds for propagation

As mentioned in the paper, the baseline LinkedHMM does not have seeding rules for all types of rules. For example, negative seeding rules are missing from the baseline LinkedHMM model, except that `SurfaceForm` rules uses a list of stopwords as negative seeding rules. For some types of seeding rules, there are only a few available that are not good enough for training the propagation model. Therefore, for the rule types that do not have enough seeds, we manually select a small set of additional rules as seeds. Note that we keep the total number of seeding rules (including the ones from baseline system) less than 15. We report the manually selected seeding rules for NCBI, BC5CDR-Disease, BC5CDR-Chemical, and LaptopReview in Table 12, Table 13, Table 14, and Table 15, respectively.

An End-to-end Model for Entity-level Relation Extraction using Multi-instance Learning

Markus Eberts **Adrian Ulges**
RheinMain University of Applied Sciences
Wiesbaden, Germany
`{markus.eberts, adrian.ulges}@hs-rm.de`

Abstract

We present a joint model for entity-level relation extraction from documents. In contrast to other approaches – which focus on local intra-sentence mention pairs and thus require annotations on mention level – our model operates on entity level. To do so, a multi-task approach is followed that builds upon coreference resolution and gathers relevant signals via multi-instance learning with multi-level representations combining global entity and local mention information. We achieve state-of-the-art relation extraction results on the DocRED dataset and report the first entity-level end-to-end relation extraction results for future reference. Finally, our experimental results suggest that a joint approach is on par with task-specific learning, though more efficient due to shared parameters and training steps.

1 Introduction

Information extraction addresses the inference of formal knowledge (typically, entities and relations) from text. The field has recently experienced a significant boost due to the development of neural approaches (Zeng et al., 2014; Zhang and Wang, 2015; Kumar, 2017). This has led to two shifts in research: First, while earlier work has focused on sentence level relation extraction (Hendrickx et al., 2010; Han et al., 2018; Zhang et al., 2017), more recent models extract facts from longer text passages (document-level). This enables the detection of inter-sentence relations that may only be implicitly expressed and require reasoning across sentence boundaries. Current models in this area do not rely on mention-level annotations and aggregate signals from multiple mentions of the same entity.

The second shift has been towards multi-task learning: While earlier approaches tackle entity mention detection and relation extraction with separate models, recent joint models address these tasks at once (Bekoulis et al., 2018; Nguyen and Verspoor, 2019; Wadden et al., 2019). This does not only improve simplicity and efficiency, but is also commonly motivated by the fact that tasks can benefit from each other: For example, knowledge of two entities' types (such as *person+organization*) can boost certain relations between them (such as *ceo_of*).

The **Portland Golf Club** is a private golf club in the northwest **United States**, in suburban Portland, Oregon. The **PGC** is located in the unincorporated **Raleigh Hills** area of eastern Washington County, southwest of downtown Portland and east of Beaverton. **PGC** was established in the winter of **1914**, when a group of nine businessmen assembled to form a new club after leaving their respective clubs. The **golf club** hosted the Ryder Cup matches of 1947, the first renewal in a decade, due to World War II. The **U.S.** team defeated Great Britain 11 to 1 in wet conditions in early November.

Figure 1: Our goal is to perform end-to-end entity-level relation extraction on whole documents. We extract entity mentions ("PGC"), entity clusters ({Portland Golf Club, PGC, golf club}), their types (ORG) and relations to other entities in the document, such as ({Portland Golf Club, PGC, golf club}$_{ORG}$, *inception*, {1914}$_{TIME}$), with a single, joint model. Note that document-level relation extraction requires the aggregation of relevant information from multiple sentences, such as in ({Raleigh Hills}$_{LOC}$, *country*, {United States, U.S.})$_{LOC}$). Other entities in the example document are omitted for clarity.

We follow this line of research, and present JEREX[1] ("**J**oint **E**ntity-Level **R**elation **Ex**tractor"),

---

April 19 - 23, 2021. ©2021 Association for Computational Linguistics

a novel approach for joint information extraction. JEREX is to our knowledge the first approach that combines a multi-task model with entity-level relation extraction: In contrast to previous work, our model jointly learns relations and entities without annotations on mention level, but extracts document-level entity clusters and predicts relations between those clusters using a *multi-instance learning* (MIL) (Dietterich et al., 1997; Riedel et al., 2010; Surdeanu et al., 2012) approach. The model is trained jointly on mention detection, coreference resolution, entity classification and relation extraction (Figure 1).

While we follow best practices for the first three tasks, we propose a novel representation for relation extraction, which combines global entity-level representations with localized mention-level ones. We present experiments on the DocRED (Yao et al., 2019) dataset for entity-level relation extraction. Though it is arguably simpler compared to recent graph propagation models (Nan et al., 2020) or special pre-training (Ye et al., 2020), our approach achieves state-of-the-art results.

We also report the first results for end-to-end relation extraction on DocRED as a reference for future work. In ablation studies we show that (1) combining a global and local representations is beneficial, and (2) that joint training appears to be on par with separate per-task models.

2 Related Work

Relation extraction is one of the most studied natural language processing (NLP) problems to date. Most approaches focus on classifying the relation between a given entity mention pair. Here various neural network based models, such as RNNs (Zhang and Wang, 2015), CNNs (Zeng et al., 2014), recursive neural networks (Socher et al., 2012) or Transformer-type architectures (Wu and He, 2019) have been investigated. However, these approaches are usually limited to local, intra-sentence, relations and are not suited for document-level, inter-sentence, classification. Since complex relations require the aggregation of information distributed over multiple sentences, document-level relation extraction has recently drawn attention (e.g. Quirk and Poon 2017; Verga et al. 2018; Gupta et al. 2019; Yao et al. 2019). Still, these models rely on specific entity mentions to be given. While progress in the joint detection of entity mentions and intra-sentence relations has been made (Gupta et al., 2016; Bekoulis et al., 2018; Luan et al., 2018), the combination of coreference resolution with relation extraction for entity-level reasoning in a single, jointly-trained, model is widely unexplored.

Document-level Relation Extraction Recent work on document-level relation extraction directly learns relations between entities (i.e. clusters of mentions referring to the same entity) within a document, requiring no relation annotations on mention level. To gather relevant information across sentence boundaries, multi-instance learning has successfully been applied to this task. In multi-instance learning, the goal is to assign labels to bags (here, entity pairs), each containing multiple instances (here, specific mention pairs). Verga et al. (2018) apply multi-instance learning to detect domain-specific relations in biological text. They compute relation scores for each mention pair of two entity clusters and aggregate these scores using a smooth max-pooling operation. Christopoulou et al. (2019) and Sahu et al. (2019) improve upon Verga et al. (2018) by constructing document-level graphs to model global interactions. While the aforementioned models tackle very specific domains with few relation types, the recently released DocRED dataset (Yao et al., 2019) enables general-domain research on a rich relation type set (96 types). Yao et al. (2019) provide several baseline architectures, such as CNN-, LSTM- or Transformer-based models, that operate on global, mention averaged, entity representations. Wang et al. (2019) use a two-step process by identifying related entities in a first step and classifying them in a second step. Tang et al. (2020) employ a hierarchical inference network, combining entity representations with attention over individual sentences to form the final decision. Nan et al. (2020) apply a graph neural network (Kipf and Welling, 2017) to construct a document-level graph of mention, entity and meta-dependency nodes. The current state-of-the-art constitutes the CorefRoBERTa model proposed by Ye et al. (2020), a RoBERTa (Liu et al., 2019) variant that is pre-trained on detecting co-referring phrases. They show that replacing RoBERTa with CorefRoBERTa improves performance on DocRED.

All these models have in common that entities and their mentions are both assumed to be given. In contrast, our approach extracts mentions, clusters them to entities, and classifies relations jointly.

Joint Entity Mention and Relation Extraction Prior joint models focus on the extraction of mention-level relations in sentences. Here, most approaches detect mentions by BIO (or BILOU) tagging and pair detected mentions for relation classification, e.g. (Gupta et al., 2016; Zhou et al., 2017; Zheng et al., 2017; Bekoulis et al., 2018; Nguyen and Verspoor, 2019; Miwa and Bansal, 2016). However, these models are not able to detect relations between overlapping entity mentions. Recently, so-called span-based approaches (Lee et al., 2017) were successfully applied to this task (Luan et al., 2018; Eberts and Ulges, 2019): By enumerating each token span of a sentence, these models handle overlapping mentions by design. Sanh et al. (2019) train a multi-task model on named entity recognition, coreference resolution and relation extraction. By adding coreference resolution as an auxilary task, Luan et al. (2019) propagate information through coreference chains. Still, these models rely on mention-level annotations and only detect intra-sentence relations between mentions, whereas our model explicitly constructs clusters of co-referring mentions and uses these clusters to detect complex entity-level relations in long documents using multi-instance reasoning.

3 Approach

JEREX processes documents containing multiple sentences and extracts entity mentions, clusters them to entities, and outputs types and relations on entity level. JEREX consists of four task-specific components, which are based on the same encoder and mention representations, and are trained in a joint manner. An input document is first tokenized, yielding a sequence of n byte-pair encoded (BPE) (Sennrich et al., 2016) tokens. We then use the pre-trained Transformer-type network BERT (Devlin et al., 2019) to obtain a contextualized embedding sequence $(\mathbf{e}_1, \mathbf{e}_2, ...\mathbf{e}_n)$ of the document. Since our goal is to perform end-to-end relation extraction, neither entities nor their corresponding mentions in the document are known in inference.

3.1 Model Architecture

We suggest a multi-level model: First, we localize all entity mentions in the document (a) by a *span-based* approach (Lee et al., 2017). After this, detected mentions are clustered into entities by *coreference resolution* (b). We then classify the type (such as *person* or *company*) of each entity cluster by a fusion over local mention representations (*entity classification*) (c). Finally, relations between entities are extracted by a reasoning over mention pairs (d). The full model architecture is illustrated in Figure 2.

(a) Entity Mention Localization Here our model performs a search over all document token subsequences (or *spans*). In contrast to BIO/BILOU-based approaches for entity mention localization, span-based approaches are able to detect overlapping mentions. Let $s := (\mathbf{e}_i, \mathbf{e}_{i+1}, ..., \mathbf{e}_{i+k})$ denote an arbitrary candidate span. Following Eberts and Ulges (2019), we first obtain a span representation by max-pooling the span's token embeddings:

$$\mathbf{e}(s) := \text{max-pool}(\mathbf{e}_i, \mathbf{e}_{i+1}, ..., \mathbf{e}_{i+k}) \qquad (1)$$

Our *mention classifier* takes the span representation $\mathbf{e}(s)$ as well as a span size embedding $\mathbf{w}^s_{k+1}$ (Lee et al., 2017) as meta information. We perform binary classification and use a sigmoid activation to obtain a probability for s to constitute an entity mention:

$$\hat{y}^s = \sigma\Big(\text{FFNN}^s(\mathbf{e}(s) \circ \mathbf{w}^s_{k+1})\Big) \qquad (2)$$

where $\circ$ denotes concatenation and FFNN^s is a two-layer feedforward network with an inner ReLu activation. Span classification is carried out on all token spans up to a fixed length L. We apply a filter threshold α^s on the confidence scores, retaining all spans with $\hat{y}^s \geq \alpha_s$ and leaving a set $\mathcal{S}$ of spans supposedly constituting entity mentions.

(b) Coreference Resolution Entity mentions referring to the same entity (e.g. "Elizabeth II." and "the Queen") can be scattered throughout the input document. To later extract relations on entity level, local mentions need to be grouped to document-level entity clusters by coreference resolution. We use a simple mention-pair (Soon et al., 2001) model: Our component classifies pairs $(s_1, s_2) \in \mathcal{S}\times\mathcal{S}$ of detected entity mentions as coreferent or not, by combining the span representations $\mathbf{e}(s_1)$ and $\mathbf{e}(s_2)$ with an edit distance embedding $\mathbf{w}^c_d$: We compute the Levenshtein distance (Levenshtein, 1966) between spans $d := D(s_1, s_2)$ and use a learned embedding $\mathbf{w}^c_d$. A mention pair representation $\mathbf{x}^c$ is constructed by concatenation:

$$\mathbf{x}^c := \mathbf{e}(s_1) \circ \mathbf{e}(s_2) \circ \mathbf{w}^c_d \qquad (3)$$

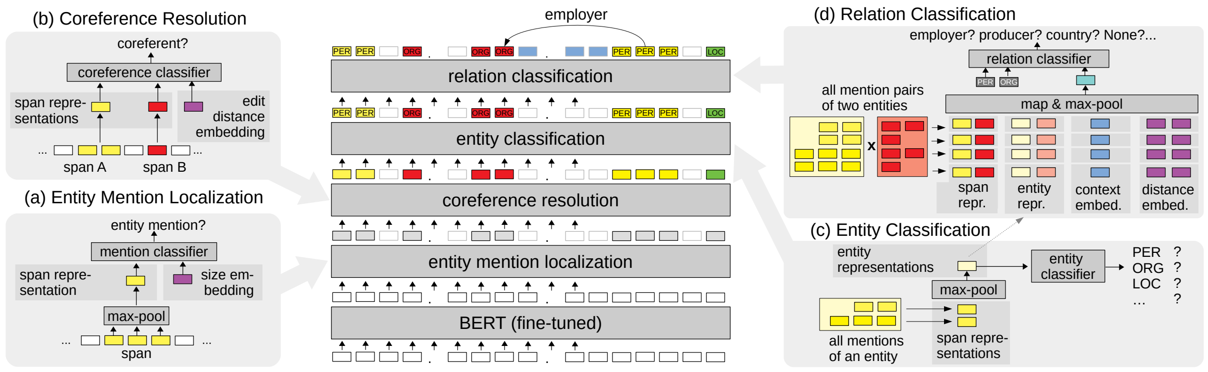

Figure 2: Our approach combines entity mention localization (a), coreference resolution (b), entity classification (c) and relation classification (d) within a joint multi-task model, which is trained jointly on entity-level relation extraction. The sub-components share a single BERT encoder for document encoding. Each input document is only encoded once (*single-pass*) to speed-up training/inference, with sub-components operating on the contextualized embeddings. Both entity classification and relation classification use multi-instance learning to synthesize relevant signals scattered throughout the input document.

Similar to span classification, we conduct binary classification using a sigmoid activation, obtaining a similarity score between the two mentions:

$$\hat{y}^c := \sigma\Big(\text{FFNN}^c(\mathbf{x}^c)\Big) \tag{4}$$

where FFNN^c follows the same architecture as FFNN^s. We construct a similarity matrix $C \in \mathbb{R}^{m \times m}$ (with m referring to the document's overall number of mentions) containing the similarity scores between every mention pair. By applying a filter threshold α^c, we cluster mentions using complete linkage (Müllner, 2011), yielding a set $\mathcal{E}$ containing clusters of entity mentions. We refer to these clusters as *entities* or *entity clusters* in the following.

(c) Entity Classification Next, we map each entity to a type such as $location$ or $person$: We first fuse the mention representations of an entity cluster $\{s_1, s_2, ..., s_t\} \in \mathcal{E}$ by max-pooling:

$$\mathbf{x}^e := \text{max-pool}(\mathbf{e}(s_1), \mathbf{e}(s_2), ..., \mathbf{e}(s_t)) \tag{5}$$

Entity classification is then carried out on the entity representation $\mathbf{x}^e$, allowing the model to draw information from mentions spread across different parts of the document. $\mathbf{x}^e$ is fed into a softmax classifier, yielding a probability distribution over the entity types:

$$\hat{y}^e := \text{softmax}\Big(\text{FFNN}^e(\mathbf{x}^e)\Big) \tag{6}$$

We assign the highest scored type to the entity.

(d) Relation Classification Our final component assigns relation types to pairs of entities. Note that the directionality, i.e. which entity constitutes the head/tail of the relation, needs to be inferred, and that the input document can express multiple relations between different mentions of the same entity pair. Let $\mathcal{R}$ denote a set of pre-defined relation types. The relation classifier processes each entity pair $(e_1, e_2) \in \mathcal{E} \times \mathcal{E}$, estimating which, if any, relations from $\mathcal{R}$ are expressed between these entities. To do so, we score every candidate triple (e_1, r_i, e_2), expressing that e_1 (as head) is in relation r_i with e_2 (as tail). We design two types of relation classifiers: A *global relation classifier*, serving as a baseline, which consumes the entity cluster representations $\mathbf{x}^e$, and a *multi-instance classifier*, which assumes that certain entity mention pairs support specific relations and synthesizes this information into an entity-pair level representation.

Global Relation Classifier (GRC) The global classifier builds upon the max-pooled entity cluster representations $\mathbf{x}_1^e$ and $\mathbf{x}_2^e$ of an entity pair (e_1, e_2). We further embed the corresponding entity types ($\mathbf{w}_1^e$ / $\mathbf{w}_2^e$), which was shown to be beneficial in prior work (Yao et al., 2019), and compute an entity-pair representation by concatenation:

$$\mathbf{x}^p := \Big(\mathbf{x}_1^e \circ \mathbf{w}_1^e\Big) \circ \Big(\mathbf{x}_2^e \circ \mathbf{w}_2^e\Big) \tag{7}$$

This representation is fed into a 2-layer FFNN (similar to FFNN^s), mapping it to the number of relation types $\#\mathcal{R}$. The final layer features sigmoid activations for multi-label classification and assigns any relation type exceeding a threshold α^r:

$$\hat{y}^r := \sigma\Big(\text{FFNN}^p(\mathbf{x}^p)\Big) \tag{8}$$

Multi-instance Relation Classifier (MRC) In contrast to the global classifier (GRC), the multi-instance relation classifier operates on mention level: Since only entity-level labels are available, we treat entity mention pairs as latent variables and estimate relations by a fusion over these mention pairs. For any pair of entity clusters $e_1 {=} \{s_1^1, s_2^1, ..., s_{t_1}^1\}$ and $e_2 {=} \{s_1^2, s_2^2, ..., s_{t_2}^2\}$, we compute a mention-pair representation for any $(s_1, s_2) {\in} e_1 {\times} e_2$. This representation is obtained by concatenating the global entity embeddings (Equation (5)) with the mentions' local span representations (Equation (1))

$$\mathbf{u}(s_1, s_2) := \Big(\mathbf{e}(s_1) \circ \mathbf{x}_1^e\Big) \circ \Big(\mathbf{e}(s_2) \circ \mathbf{x}_2^e\Big) \tag{9}$$

Further, as we expect close-by mentions to be stronger indicators of relations, we add meta embeddings for the *distances* d_s,d_t between the two mentions, both in sentences (d_s) and in tokens (d_t). In addition, following Eberts and Ulges (2019), the max-pooled context between the two mentions ($\mathbf{c}(s_1, s_2)$) is added. This *localized context* provides a more focused view on the document and was found to be especially beneficial for long, and therefore noisy, inputs:

$$\mathbf{u}'(s_1{,}s_2){:=}\mathbf{u}(s_1{,}s_2) \circ \mathbf{c}(s_1{,}s_2) \circ \mathbf{w}_{d_s}^r \circ \mathbf{w}_{d_t}^{r'} \tag{10}$$

This mention-pair representation is mapped by a single feed-forward layer to the original token embedding size (768):

$$\mathbf{u}''(s_1, s_2) := \text{FFNN}^p(\mathbf{u}'(s_1, s_2)) \tag{11}$$

These focused representations are then combined by max-pooling:

$$\mathbf{x}^r {=} \text{max-pool}(\{\mathbf{u}''(s_1, s_2) | s_1 {\in} e_1{,} s_2 {\in} e_2\}) \tag{12}$$

Akin to GRC, we concatenate $\mathbf{x}^r$ with entity type embeddings $\mathbf{w}_1^e/\mathbf{w}_2^e$ and apply a two-layer FFNN (again, similar to FFNN^s). Note that for both classifiers (GRC/MRC), we need to score both (s_1, r_i, s_2) and (s_2, r_i, s_1) to infer the direction of asymmetric relations.

3.2 Training

We perform a supervised multi-task training, whereas each training document features ground truth for all four subtasks (mention localization, coreference resolution, as well as entity and relation classification). We optimize the joint loss of all four components:

$$\mathcal{L} := \beta_s \cdot \mathcal{L}^s + \beta_c \cdot \mathcal{L}^c + \beta_e \cdot \mathcal{L}^e + \beta_r \cdot \mathcal{L}^r \tag{13}$$

$\mathcal{L}^s$, $\mathcal{L}^c$ and $\mathcal{L}^r$ denote the binary cross entropy losses of the span, coreference and relation classifiers. We use a cross entropy loss ($\mathcal{L}^e$) for the entity classifier. A batch is formed by drawing positive and negative samples from a single document for all components. We found such a *single-pass approach* to offer significant speed-ups both in learning and inference:

- Entity mention localization: We utilize all ground truth entity mentions $\mathcal{S}^{gt}$ of a document as positive training samples, and sample a fixed number N_s of random non-mention spans up to a pre-defined length L_s as negative samples. Note that we only train and evaluate on the full tokens according to the dataset's tokenization, i.e. not on byte-pair encoded tokens, to limit computational complexity. Also, we only sample intra-sentence spans as negative samples. Since we found intra-mention spans to be especially challenging ("New York" versus "New York City"), we sample up to $\frac{N_s}{2}$ intra-mention spans as negative samples.

- Coreference resolution: The coreference classifier is trained on all span pairs drawn from ground truth entity clusters $\mathcal{E}^{gt}$ as positive samples. We further sample a fixed number N_c of pairs of random ground truth entity mentions that do not belong to the same cluster as negative samples.

- Entity classification: Since the entity classifier only receives clusters that supposedly constitute an entity during inference, it is trained on all ground truth entity clusters of a document.

- Relation classification: Here we use ground truth relations between entity clusters as positive samples and N_r negative samples drawn from $\mathcal{E}^{gt} {\times} \mathcal{E}^{gt}$ that are unrelated according to the ground truth.

Each component's loss is obtained by averaging over all samples. We learn the weights and biases of sub-component specific layers as well as the

		Joint Model*			**Pipeline**

(c)	Entity Classification	79.84	80.36	80.10	79.00	79.52	79.26
(d)	Relation Classification	42.76	38.25	40.38	43.61	37.50	40.32
	Relation Classification (GRC)	38.69	37.32	37.98	39.07	36.44	37.70

Table 1: Test set evaluation results of our multi-level end-to-end system JEREX on DocRED (using the end-to-end split). We either train the model jointly on all four sub-components (left) or arrange separately trained models in a pipeline (right) (* joint results are for MRC except for the last row).

meta embeddings during training. BERT is fine-tuned in the process.

4 Experiments

We evaluate JEREX on the DocRED dataset (Yao et al., 2019). DocRED ist the most diverse relation extraction dataset to date (6 entity and 96 relation types). It includes over 5,000 documents, each consisting of multiple sentences. According to Yao et al. (2019), DocRED requires multiple types of reasoning, such as logical or common-sense reasoning, to infer relations.

Note that previous work only uses DocRED for relation extraction (which equals our relation classifier component) and assumes entities to be given (e.g. Wang et al. 2019; Nan et al. 2020). On the other hand, DocRED is exhaustively annotated with mentions, entities and entity-level relations, making it suitable for end-to-end systems. Therefore, we evaluate JEREX both as a relation classifier (to compare it with the state-of-the-art) and as a joint model (as reference for future work on joint entity-level relation extraction).

While prior joint models focus on mention-level relations (e.g. Gupta et al. 2016; Bekoulis et al. 2018; Chi et al. 2019), we extend the strict evaluation setting to entity level: A mention is counted as correct if its span matches a ground truth mention span. An entity cluster is considered correct if it matches the ground truth cluster exactly and the corresponding mention spans are correct. Likewise, an entity is considered correct if the cluster as well as the entity type matches a ground truth entity. Lastly, we count a relation as correct if its argument entities as well as the relation type are correct. We measure precision, recall and micro-F1 for each sub-task and report micro-averaged scores.

Split	#Doc.	#Men.	#Ent.	#Rel.
Train	3,008	78,677	58,708	37,486
Dev	300	7,702	5,805	3,678
Test	700	17,988	13,594	8,787
Total	4,008	104,367	78,107	49,951

Table 2: DocRED dataset split used for end-to-end relation extraction.

Dataset split The original DocRED dataset is split into a train (3,053 documents), dev (1,000) and test (1,000) set. However, test relation labels are hidden and evaluation requires the submission of results via Codalab. To evaluate end-to-end systems, we form a new split by merging train and dev. We randomly sample a train (3,008 documents), dev (300 documents) and test set (700 documents). Note that we removed 45 documents since they contained wrongly annotated entities with mentions of different types. Table 2 contains statistics of our end-to-end split. We release the split as a reference for future work.

Hyperparameters We use BERT$_{\text{BASE}}$ (cased)[2] for document encoding, an attention-based language model pre-trained on English text (Devlin et al., 2019). Hyperparameters were tuned on the end-to-end dev set: We adopt several settings from (Devlin et al., 2019), including the usage of the Adam Optimizer with a linear warmup and linear decay learning rate schedule, a peak learning rate of 5e-5[3] and application of dropout with a rate of 0.1 throughout the model. We set the size of meta embeddings ($\mathbf{w}^s$, $\mathbf{w}^c$, $\mathbf{w}^e$, $\mathbf{w}^r_{d_s}$, $\mathbf{w}^{r'}_{d_t}$) to 25 and the number of epochs to

---

[2] We use the implementation from (Wolf et al., 2019).

[3] We performed a grid search over [5e-6, 1e-5, 5e-5, 1e-4, 5e-4].

Model	Ign F1	F1
CNN (Yao et al., 2019)	40.33	42.26
LSTM (Yao et al., 2019)	47.71	50.07
Ctx-Aware (Yao et al., 2019)*	48.40	50.70
BiLSTM (Yao et al., 2019)	48.78	51.06
Two-Step (Wang et al., 2019)*	-	53.92

JEREX (MRC)*	**58.44**	**60.40**

Table 3: Comparison of our relation classification component (GRC/MRC) with the state-of-the-art on the DocRED relation extraction task. We report test set results on the original DocRED split. Ign F1 ignores relational facts also present in the train set. Models marked with $*$ use a Transformer-type model for document encoding.

	JM*	**SM**
Task	F1	F1
Mention Localization	92.99	92.66
Coreference Resolution	90.54	90.46
Entity Classification	95.66	95.29
Relation Classification	59.46	59.76
Relation Classification (GRC)	56.45	56.55

Table 4: Single-task performance of the joint model (left) and separate models (right) on the end-to-end split (* joint results are for MRC except for the last row).

20. Performance is measured once per epoch on the dev set, out of which the best performing model is used for the final evaluation on the test set. A grid search is performed for the mention, coreference and relation filter threshold (α^s=0.85, α^c=0.85, α^r(GRC)=0.55, α^r(MRC)=0.6) with a step size of 0.05. The number of negative samples (N_s=N_c=N_r=200) and sub-task loss weights (β_s=β_c=β_r=1, β_e=0.25) are manually tuned. Note that some documents in DocRED exceed the maximum context size of BERT (512 BPE tokens). In this case we train the remaining position embeddings from scratch.

4.1 End-to-End Relation Extraction

JEREX is trained and evaluated on the end-to-end dataset split (see Table 2). We perform 5 runs for each experiment and report the averaged results. To study the effects of joint training, we experiment with two approaches: (a) All four sub-components are trained jointly in a single model as described in Section 3.2 and (b) we construct a pipeline system by training each task separately and not sharing the document encoder.

Table 1 illustrates the results for the joint (left) and pipeline (right) approach. As described in Section 3, each sub-task builds on the results of the previous component during inference. We observe the biggest performance drop for the relation classification task, underlining the difficulty in detecting document-level relations. Furthermore, the multi-instance based relation classifier (MRC) outperforms the global relation classifier (GRC) by about 2.4% F1 score. We reason that the fusion of local evidences by multi-instance learning helps the model to focus on appropriate document sections and alleviates the impact of noise in long documents. Moreover, we found the multi-instance selection to offer good interpretability, usually selecting the most relevant instances (see Figure 3 for examples). Overall, we observe a comparable performance by joint training versus using the pipeline system.

This is also confirmed by the results reported in Table 4, where we evaluate the four components independently, i.e. each component receives ground truth samples from the previous step in the hierarchy (e.g. ground truth mentions for coreference resolution). Again, we observe the performance difference between the joint and pipeline model to be negligible. This shows that it is not necessary to build separate models for each task, which would result in training and inference overhead due to multiple expensive BERT passes. Instead, a single neural model is able to jointly learn all tasks necessary for document-level relation extraction, therefore easing training, inference and maintenance.

4.2 Relation Extraction

We also compare our model with the state-of-the-art on DocRED's relation extraction task. Here, entity clusters are assumed to be given. We train and test our relation classification component on the original DocRED dataset split. Since test set labels are hidden, we submit the best out of 5 runs on the development set via CodaLab to retrieve the test set results. Table 3 includes previously reported results from current state-of-the-art models. Note that our global classifier (GRC) is similar to

Queequeg is a fictional character in the 1851 novel Moby-Dick by American author **Herman Melville**. The son of a South Sea chieftain who left home to explore the world, **Queequeg** is the first principal character encountered by the narrator, Ishmael. The quick friendship and relationship of equality between the tattooed cannibal and the white sailor shows **Melville**'s basic theme of shipboard democracy and racial diversity...

Shadowrun:Hong Kong is a turn-based tactical role-playing video game set in the Shadowrun universe. It was developed and published by **Harebrained Schemes**, who previously developed **Shadowrun Returns** and its standalone expansion. It includes a new single - player campaign and also shipped with a level editor that lets players create their own Shadowrun campaigns and share them with other players. In January 2015, **Harebrained Schemes** launched a Kickstarter campaign in order to fund additional features and content they wanted to add to the game, but determined would not have been possible with their current budget. The initial funding goal of US $ 100,000 was met in only a few hours. The campaign ended the following month, receiving over $ 1.2 million. The game was developed with an improved version of the engine used with **Shadowrun Returns** and Dragonfall. **Harebrained Schemes** decided to develop the game only for Microsoft Windows, OS X, and Linux, ...

Figure 3: Two example documents of the DocRED dataset. Highlighted are relations "creator" between "Queequeg" and "Herman Melville" (top) and "developer" between "Shadowrun Returns" and "Harebrained Schemes" (bottom). Bordered pairs are the top selections of the multi-instance relation classifier.

the baseline by (Yao et al., 2019). However, we replace mention span averaging with max-pooling and also choose max-pooling to aggregate mentions into an entity representation, yielding considerable improvement over the baseline. Using the multi-instance classifier (MRC) instead further improves performance by about 4.5%. Here our model also outperforms complex methods based on graph attention networks (Nan et al., 2020) or specialized pre-training (Ye et al., 2020), achieving a new state-of-the-art result on DocRED's relation extraction task.

4.3 Ablation Studies

We perform several ablation studies to evaluate the contributions of our proposed multi-instance relation classifier enhancements: We remove either the global entity representations $\mathbf{x}_1^e, \mathbf{x}_2^e$ (Equation 5) (a) or the localized context representation $\mathbf{c}(s_1, s_2)$ (Equation 10) (b). The performance drops by about 0.66% F1 score when global entity representations are omitted, indicating that multi-instance reasoning benefits from the incorporation of entity-level context. When the localized context representation is omitted, performance is reduced by about 0.90%, confirming the importance of guiding the model to relevant input sections. Finally, we limit the model to fusing only intra-sentence mention pairs (c). In case no such instance exists for an entity pair, the closest (in token distance) mention pair is selected. Obviously, this modification reduces computational complexity and memory consumption, especially for large documents. Nevertheless, while we observe intra-sentence pairs to cover most relevant signals, exhaustively pairing all mentions of an entity pair yields an improvement of 0.67%.

Model	F1
Relation Classification (MRC)	59.76
- (a) Entity Representations	59.10
- (b) Localized Context	58.85
- (c) Exhaustive Pairing	59.09

Table 5: Ablation studies for the multi-level relation classifier (MRC) using the end-to-end split. We either remove global entity representations (a), the localized context (b) or only use intra-sentence mention pairs (c). The results are averaged over 5 runs.

5 Conclusions

We have introduced JEREX, a novel multi-task model for end-to-end relation extraction. In contrast to prior systems, JEREX combines entity mention localization with coreference resolution to extract entity types and relations on an entity level. We report first results for entity-level, end-to-end, relation extraction as a reference for future work. Furthermore, we achieve state-of-the-art results on the DocRED relation extraction task by enhancing multi-instance reasoning with global entity representations and a localized context, outperforming several more complex solutions. We showed that training a single model jointly on all subtasks instead of using a pipeline approach performs roughly on par, eliminating the need of training separate models and accelerating inference. One of the remaining shortcomings lies in the detection of false positive relations, which may be expressed according to the entities' types but are actually not expressed in the document. Exploring options to reduce these false positive predictions seems to be an interesting challenge for future work.

WER–BERT: Automatic WER Estimation with BERT in a Balanced Ordinal Classification Paradigm

Akshay Krishna Sheshadri* **Anvesh Rao Vijjini*** **Sukhdeep Kharbanda**

Samsung R&D Institute India - Bangalore
`{a.sheshadri,a.vijjini,sukhdeep.sk}@samsung.com`

Abstract

Automatic Speech Recognition (ASR) systems are evaluated using Word Error Rate (WER), which is calculated by comparing the number of errors between the ground truth and the transcription of the ASR system. This calculation, however, requires manual transcription of the speech signal to obtain the ground truth. Since transcribing audio signals is a costly process, Automatic WER Evaluation (e-WER) methods have been developed to automatically predict the WER of a speech system by only relying on the transcription and the speech signal features. While WER is a continuous variable, previous works have shown that positing e-WER as a classification problem is more effective than regression. However, while converting to a classification setting, these approaches suffer from heavy class imbalance. In this paper, we propose a new balanced paradigm for e-WER in a classification setting. Within this paradigm, we also propose WER-BERT, a BERT based architecture with speech features for e-WER. Furthermore, we introduce a distance loss function to tackle the ordinal nature of e-WER classification. The proposed approach and paradigm are evaluated on the Librispeech dataset and a commercial (black box) ASR system, Google Cloud's Speech-to-Text API. The results and experiments demonstrate that WER-BERT establishes a new state-of-the-art in automatic WER estimation.

1 Introduction

ASR systems are ubiquitous now. They are available across applications such as Voice Assistants, Assisted Living or Hands free device usage. However, with the widespread usage of ASR systems, there comes a heavy need for ASR Evaluation as well - to select, compare or improve alternate ASR systems. WER is widely considered as the standard metric for ASR evaluation. A higher WER means a higher percentage of errors between the ground truth and the transcription from the system. WER is calculated by aligning the two text segments using string alignment in a dynamic programming setting. The formula is as follows:

$$WER = \frac{ERR}{N} \tag{1}$$

where ERR is the sum of errors (Insertions, Deletions or Substitutions) between the transcription and the ground truth. N is number of words in ground truth. As evident from this equation, the presence of ground truth is necessary for the calculation of errors, and hence, for WER. However, manual transcription of speech at word level is a expensive and dilatory process. Hence, the need for an automatic ASR evaluation is important but few attempts have addressed this. Furthermore, for effectively training, evaluating and judging the performance of an ASR system, WER calculation needs to be done on adequate hours of data. As this test set increases, a more accurate estimation of WER is possible. Since automatic WER evaluation does not have the bottleneck of manual transcription, it can be calculated over large test sets leading to more accurate estimates. Because of the immense popularity of attention based architectures for text classification (Madasu and Rao, 2019, 2020a; Rao et al., 2020; Madasu and Rao, 2020b), we propose the transformer (Vaswani et al., 2017) encoder architecture — Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018) for . BERT is pretrained on huge amounts of open domain language and is extensively used for its effectiveness in natural language understanding tasks. By pretraining on such data, the model gains knowledge of general domain language structure which aids in predicting

April 19 - 23, 2021.

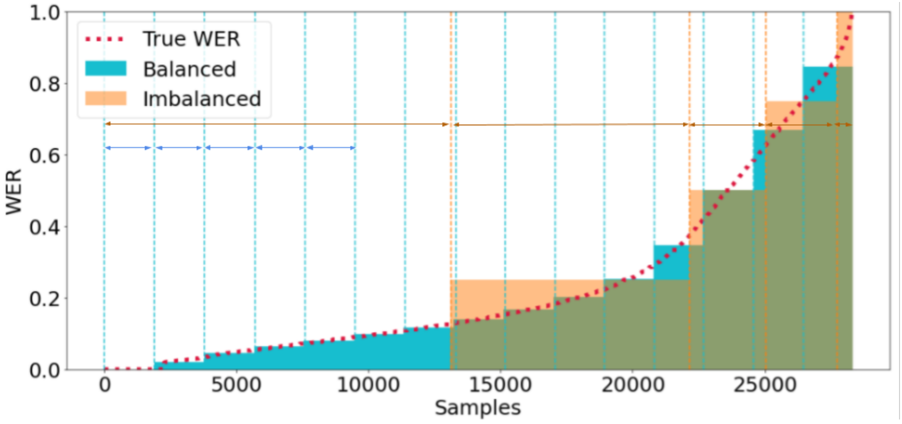

Figure 1: Distribution of WER classes of the 100 hr dataset, using proposed Balanced approach and using the Elloumi et al. (2018) imbalanced approach. The space between two consecutive vertical lines indicates the size of a respective class. The blue lines are evenly spaced, whereas the orange lines are spaced irregularly, indicating an imbalanced distribution.

speech errors which are typically observed as a deviation from the general syntax and semantics of a sentence. While previous approaches address e-WER (Ali and Renals, 2018; Elloumi et al., 2018, 2019) in classification settings, their models suffer with gross imbalance in the WER classes. To address this issue, we present a training framework which will always consist of training on equal sized classes no matter the true WER distribution. Additionally, these previous e-WER classification tasks assume that there is no inherent relative ordering to the classes. However, this is not the case with WER classification since a misclassification closer to the ground truth will lead to a lower mean absolute error (MAE) in the WER prediction. Such classification tasks are called Ordinal classification(Frank and Hall, 2001).

The overall contributions of our paper can be summarized follows:

(i) A new balanced paradigm for training WER as a classification problem which addresses the label imbalance issue faced by previous works.

(ii) WER-BERT - We find that language model information is helpful in predicting WER and hence propose a BERT based architecture e-WER.

(iii) Distance Loss to address the ordinal nature of WER classification which penalizes misclassifications differently based on how far off the predicted class is when compared to the real class.

2 Related Work

While the importance of an automatic WER prediction system is immense, there have not been many works directly addressing it. Related works such as exploring the word-level confidence in ASR prediction are abundant (Seigel and Woodland, 2011; Huang et al., 2013). There have also been works predicting the errors or error estimates as well in some form (Ogawa and Hori, 2015, 2017; Seigel and Woodland, 2014; Yoon et al., 2010). These approaches either predict some of the errors described in WER prediction or alternate metrics to rate ASR systems such as accuracy or error type classification. However, they lack calculation of the complete WER score. Transcrater (Jalalvand et al., 2016) was one of the first works which aim at predicting WER directly. They propose a neural network in a regression setting trained on various features such as parts of speech, language model, lexicon, and signal features. However, more recent approaches(Ali and Renals, 2018; Elloumi et al., 2018, 2019) phrase WER prediction as a classification approach. Ali and Renals (2018) propose two types of models based on the input available — the glassbox model which uses internal features of the target ASR system such as its confidence in transcribing the audio clip; and the black box model which only uses the transcripts and other features generated from the transcript such as the word and the grapheme count. They propose a bag-of-words model along with additional transcription features such as duration for e-WER.

The black box setting is a harder task since ASR model features such as the average log likelihood and the transcription confidence can give a good indication on how many errors may have occurred during the automatic transcription. However, the black box approach is not specific to the architectural design of an ASR system and can be used with any ASR system without access to its internal metrics such as the aforementioned confidence. Thus our proposed approach is trained in a black box setting.

Elloumi et al. (2018, 2019) build a CNN based model for WER classification. We built models based on them as baselines to evaluate WER-BERT's performance. They are further explained in the Sections 4 and 6.

ASR errors often make a transcription ungrammatical or semantically unsound. Identifying such constructs is also reflected in the dataset of Corpus of Linguistic Acceptability(CoLA) (Warstadt et al., 2019b,a). CoLA is a dataset intended to gauge at the linguistic competence of models by making them judge the grammatical acceptability of a sentence. CoLA is also part of the popular GLUE benchmark datasets for Natural Language Understanding (Wang et al., 2018). BERT (Devlin et al., 2018) is known for outperforming previous GLUE state-of-the-Art models, including the CoLA dataset.

3 Dataset

For our experiments, we have used the Librispeech dataset (Panayotov et al., 2015) which is a diverse collection of audio book data along with the ground text. It has around 1000 Hours of audio recordings with different levels of complexity. We pass these audio clips through an ASR system to get its transcripts and the WER is calculated by comparing it with the ground text. This paper reports findings in the experiments run with Google Cloud's Speech-to-Text API. We chose this commercial ASR system, rather than reporting results on an internal ASR system, since it's easily accessible through the google-api and the results are reproducible. For our experiments, we have used the 10 and 100 hour datasets and made a 60:20:20 split into train, dev and test sets for each dataset. As can be seen in Table 1 of Section B of the Appendix, the characteristics of the 100 and 10 hour datasets are quite different. However, within a dataset, the train, dev and test sets have similar distributions of WER and other characteristics. Table 1 lists a few examples with each row having the ground text, the transcript obtained from Google Cloud's Speech-to-Text API, the True WER and the WER predicted by our proposed model.

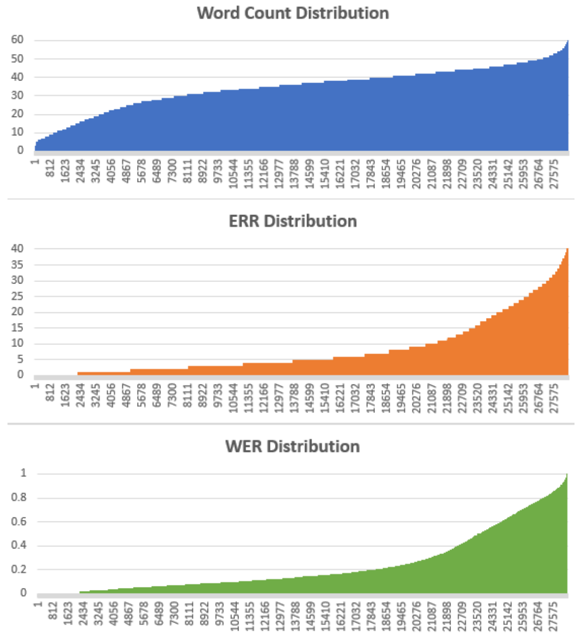

Figure 2: Distribution of WER, ERR and Word Count on our Training (Train 100hr) set.

4 Single Task and Double Task for WER Estimation

As shown in Equation 1, the WER of an utterance is the fraction obtained by the division of 2 integers — Errors per sentence (ERR), which is the total number of insertions, deletions and substitutions needed to convert an ASR's transcript to the ground text, and the word count of the ground text (N). Since the WER of a sentence is a continuous variable between 0 and 1 (mostly), a common way to model this is through a regression model. Elloumi et al. (2018, 2019) instead present a way to turn this into a classification problem for e-WER. They experiment with various combinations of text and audio signal inputs and show that a classification approach outperforms its corresponding regression approach trained on the same inputs. Elloumi et al. (2018)'s approach estimates WER directly with a 6 class classification model (with classes corresponding to $0\%, 25\%, 50\%, 75\%, 100\%$ and 150%). Once the model is trained, the predictions are calculated as follows:

$$WER_{Pred}(s) = P_{softmax}(s) \cdot WER_{fixed} \quad (2)$$

where s is a sample, WER_{Pred} is the predicted WER for s, $P_{softmax}(s)$ is the softmax probability distribution output by the classification model, $WER_{fixed} = [0, 0.25, 0.5, 0.75, 1.0, 1.5]$ is the fixed vector and '$\cdot$' is the dot product operator. We

---

https://cloud.google.com/speech-to-text.

call this approach as the Single Task method for e-WER. Alternatively, Ali and Renals (2018) present another classification approach for e-WER. They argue that the calculation of WER relies on two distinct calculations — ERR and N. Since both of them are discrete integers, they propose two independent classification problems to the estimate errors in the sentence $ERR_{est.}$ and to estimate the Word Count of the ground text $N_{est.}$. The predicted WER is then calculated as $(ERR_{est.}/N_{est.})$. We call this approach as the Double Task method for e-WER.

4.1 The Problem of Class Imbalance

While these approaches had good results, both of them suffer from the problem of imbalanced classes. As we can seen from Figure 2, the ERR and the WER are highly imbalanced. The nature of WER is such that it is very less likely for this task to be balanced for any data and any ASR system. This imbalance leads to poor performance due to certain WER or ERR classes having very few samples in them. With Elloumi et al. (2018), all the true WER's are 'cast' to the nearest multiple of 0.25. It can be seen from Figure 2 that the number of samples belonging to a class varies tremendously in this imbalanced setting. This leads to the model having poor performance, especially in the higher WER ranges. Moreover, different ASR systems will have their own distributions and some may be relatively well balanced in some ranges while other may be much worse. This approach is not scalable and it fails to generalize a method for creating balanced class distributions, irrespective of the ASR system.

4.2 Proposed Balanced Division

We propose an alternate paradigm for creating WER class distributions. We extend the single task setting for e-WER to a balanced WER class distribution irrespective of the dataset and ASR system. Instead of fixing a list of WER values based on a factor such as 0.25 to represent the classes, the total number of classes desired K is decided. Let $w_1, w_2, w_3, ...w_D$ be the WERs of individual samples ordered in an ascending manner where D is the total number of samples in the corpus. Then the number of samples in each of the K classes when divided uniformly will be $n_s = (D/K)$. A class C_i will be defined as the samples with WER in the range: $[w_{(i-1)*n_s}, w_{(i)*n_s}]$ where $i \in \{1, 2, ...K\}$. This is shown in Figure 1 where $K = 15$ classes are made with equal number of samples in each. The WER value WER_{Fixed_i} associated with each class C_i is defined as the mean WER of that class:

$$WER_{Fixed_i} = \sum_{j=(i-1)*n_s}^{(i)*n_s} \frac{w_j}{n_s} \qquad (3)$$

Once WER_{Fixed} is calculated, we use Equation 2 to compute the predicted WER of a sample using $P_{softmax}$ calculated from a neural network model. Apart from being balanced, this approach also has the benefit of generating classes which fits the true WER curve better than the previous approach as show in Figure 1. It's important to understand that while the ERR estimation in the Double Task setting of Ali and Renals (2018) is also imbalanced, it can't be mapped into arbitrary classes based on ordering. Since WER is a continuous variable, unlike ERR, it is possible to decide the boundary for a WER class arbitrarily to create balanced sets.

5 WER-BERT

In this section we explain our proposed architecture WER-BERT, which is primarily made of four sub-networks. Our architecture is shown with details in Figure 3.

Signal Sub-network: Elloumi et al. (2018) use the raw signal of the audio clip to generate features such as MFCC and Mel Spectrogram. They are features commonly used in the design of ASR systems, particularly systems which use an acoustic model and furthermore these features aid their model performance. These signal features are passed through the m18 architecture (Dai et al., 2017). m18 is a popular deep convolutional neural network (CNN) used for classification with audio signal features. This CNN model has 17 convolutional+max pooling layers which is followed by global average pooling. L2 Regularization of $1e-4$ and Batch Normalization are added after each of the convolutional layers.

Numerical Features Sub-network: Ali and Renals (2018) black box models had two major components — text input and numerical features. These numerical features are important to the model as they contain information regarding the number of errors. For instance, in ASR systems, there are errors if a user speaks too fast or too slow and this is directly reflected in the du-

---

Refer to Section A.2 of the appendix for tuning of the class hyperparameter K

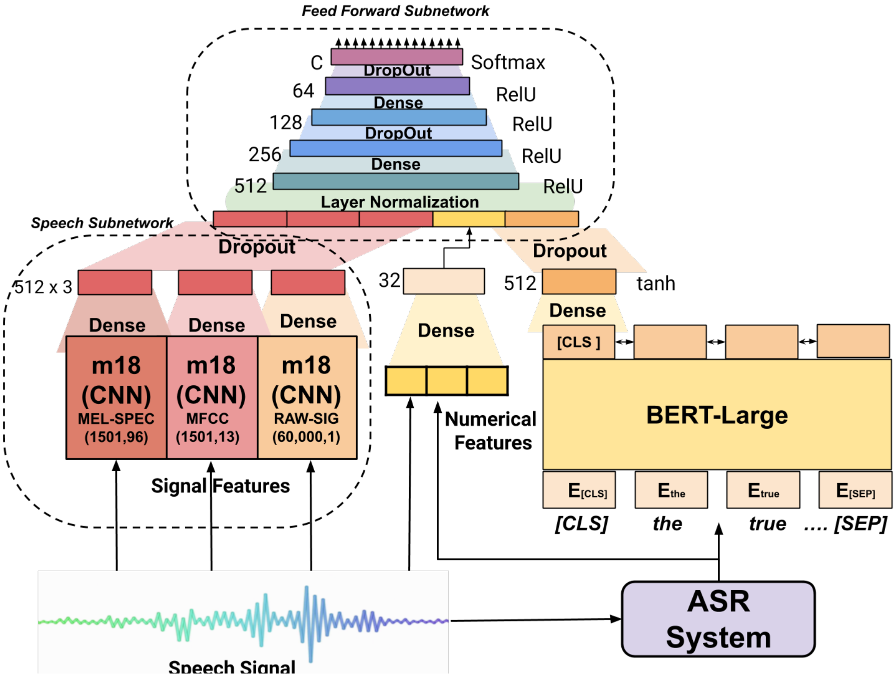

Figure 3: Proposed WER-BERT

ration and word count features. The numerical features we have used are Word Count, Grapheme Count and Duration. These features are concatenated and passed through a simple feed forward network which is used to upscale the numerical features fed into the model (from 3 to 32).

BERT: Bi-directional Encoder Representations (BERT) (Devlin et al., 2018) is a pre-trained unsupervised natural language processing model. It is a masked language model which has been trained on a large corpus including the entire Wikipedia corpus. The transcription samples from the ASR system, are passed through the associated tokenizer which gives a contextual representation for each word. It also adds 2 special tokens — the [CLS] token at the beginning and the [SEP] token at the end of the sentence. We have used the BERT-Large Uncased variant. The large variant has 24 stacked transformer Vaswani et al. (2017) encoders. It gives an output of the shape (Sequence Length X 1024) of which only the 1024 shaped output corresponding to the [CLS] token is used. In WER-BERT, BERT weights are fine tuned with rest of architecture during training.

Feed Forward Sub-Network: This sub-network is a deep fully connected network which is used to concatenate and process the features generated by the sub-networks predating it (BERT, numerical sub-network and the signal sub-network). It has 4 hidden layers (512, 256, 128 and 64 neurons) followed by the output softmax layer. Dropout regularization is added to prevent overfitting considering the large amount of parameters. To account for outputs from the eclectic sub-networks with disparate distributions, we further add Layer Normalization (Ba et al., 2016) before concatenation. Normalization is important to lessen the impact of any bias the network may learn towards one or the other representations.

Distance Loss for Ordinal Classification: Typical classification problems deal with classes which are mutually exclusive and independent such as sentiment prediction or whether an image is a cat or a dog. In such a setting, classification accuracy is the most important metric and there is no relation or relative ordering between the classes. However, e-WER in a classification setting is an ordinal classification problem (Frank and Hall, 2001). Previous approaches which propose WER estimation as classification tasks ignore this idea (Elloumi et al., 2018; Ali and Renals, 2018; Elloumi et al., 2019). While the classification accuracy is important, it is more important that given a sample is misclassified, the predicted label is close to the true label. For instance, if the true label corresponds to the WER class of 0.1, a prediction of 0.2 and a prediction of 0.7 are treated the same in the current classification scenario. Since we want the prediction to be as close as possible, if not exactly the same, we introduce a “distance” loss which is

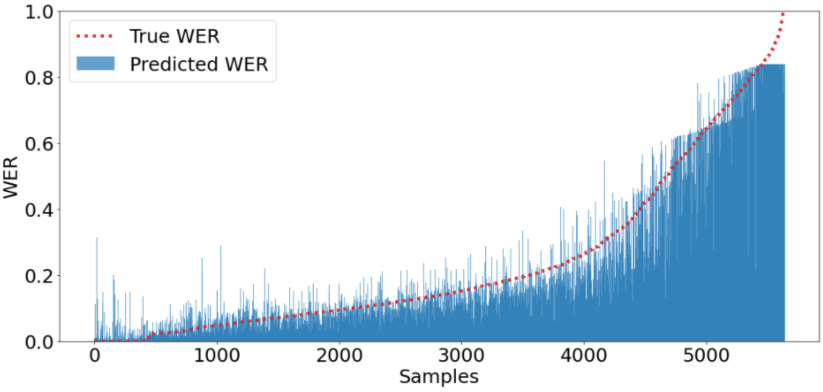

Figure 4: WER Predicted by WER-BERT SOTA model as compared to the True WER of all samples (Test 100hr)

$L_{custom}(s) = L_{\theta}(s) + \alpha * \gamma$ and γ is as follows

$$|y_{pred}(s) \cdot WER_{fixed} - y_{true}(s) \cdot WER_{fixed}| \tag{4}$$

where s is a sample, α is a hyperparameter (we have used $\alpha = 50$ in our experiments), $L_{\theta}(s)$ is the cross entropy loss, $y_{true}(s)$ is a one hot vector representing the true WER class of s and y_{pred} is the estimated probability distribution of s over all the classes output by the softmax of the classification model.

6 Experiments And Baselines

For each of the experiments below, the training is repeated for 10 runs and we report the average performance of all the runs on the test set. For all the experiments, we use Crossentropy as the loss function and MAE of WER as the evaluation metric.

6.1 BOW

Bag of Words + Num. Feat.(Black Box): Following (Ali and Renals, 2018), we build a black box model for the double task estimation of ERR and word count.The word count estimation task was treated as a 46 class classification model with class 1 corresponding to word count of 2, class 46 with word count of 47 (90^{th} percentile). Similarly, the ERR estimation task was modelled as a 20 class classification problem with class 0 corresponding to no errors and class 19 corresponding to 19 errors(90^{th} percentile). Both of these tasks are handled by logistic regression models which use Bag of Words features for both the words present in the sentence as well as the graphemes (monograms

---

Refer to Section A.1 of the appendix for tuning of the Distance Loss hyperparameter α

and bigrams) of the sentence. These features are concatenated with numerical features such as word count, grapheme count and the duration and then fed to a feedforward network. Dropouts are also added after each layer to prevent overfitting.

6.2 CNN

Following, Elloumi et al. (2018) for e-WER. These CNN models use ASR transcript and signal features (Raw signal, MFCC and Mel Spectrogram) as inputs and CNN for learning features from the textual transcription itself.

Text Input: The text input is padded to T words (where T was taken as 50, the 95^{th} percentile of the sentence length) and was transformed into a matrix $Embeddings$ of the size NXM where M is the embedding size (300). These embeddings were obtained from GloVe (Pennington et al., 2014). The CNN architecture is Kim (2014).

Signal Inputs:

RAWSIG: This input is obtained by sampling the audio clip at 8KHz and max duration was set to 15s; shorter audio clips were padded while the longer ones were clipped. While using this with the M18 architecture, it was further down-sampled to 4KHz due to memory constraints and its dimension is $60000X1$.

MELSPEC: This input was calculated with 96 dimensional vectors, each of which corresponds to a particular Mel frequency range. They were extracted every 10ms with an analysis window of 25ms and its dimension is $1501X96$.

MFCC: This input was calculated by computing 13 MFCCs every 10ms and its dimension is $1501X13$.

These signal features are used as an input to the M18 architecture Dai et al. (2017) (refer to Section 5: Signal sub-network). For joint use of both text and signal inputs, the outputs of the text and signal sub-networks are followed by a hidden layer (512 processing units) whose outputs are concatenated (with a dropout regularization of 0.1 being applied between the hidden layer and the concatenation layer). This is followed by 4 hidden layers (of 512, 256, 128 and 64 neurons) and the output layer with Dropout regularization added to prevent overfitting due to the large amount of parameters

CNN-text (balanced): While Elloumi et al. (2018) show that just CNN-text isn't enough to get good results. This experiment provides a baseline to compare against Bert-large since that does not have signal features as well. This model is trained in our balanced class setting with 15 classes explained in Section 4.2.

CNN-text + RAWSIG (Double Task): The best architecture in Elloumi et al. (2018) was trained in the double task setting proposed by (Ali and Renals, 2018). The ERR estimation was modelled as a 20 class task and the word count estimation was modelled as a 46 class task.

CNN-text + RAWSIG (Elloumi et al., 2018): This was the best architecture proposed by Elloumi et al. (2018). This is a single task approach which uses the imbalanced WER class distribution (classes corresponding to WER of 0, 0.25...1.5 WER).

CNN-text + RAWSIG (Balanced): Same model as CNN-text + RAWSIG but trained in our balanced class setting with 15 classes explained in Section 4.2.

CNN-text + MFCC + MELSPEC + RAWSIG (Balanced): Instead of using only RAWSIG input, we pass all 3 signal features into their respective m18 models. The outputs of the KIM CNN model (for the text input) and each of these m18 models are concatenated and processed in same fashion as WER-BERT explained in Section 5.

6.3 BERT architectures

Experiments are carried with the architecture described in Section 5. We carry out Ablation studies to identify important input features in isolation. We start with the full architecture shown in section 5 and subsequently remove sub-networks to compare performance. All the experiments except for the distance loss one are carried out with Crossentropy as the loss and MAE of WER as the evaluation metric and are trained with the balanced classes paradigm.

7 Results and Discussion

Table 2 captures the results of proposed approach with previous approaches along with ablation studies for the proposed approach. While the WER of the 10 hour dataset is low (≈10) and the 100 hour dataset is high (≈20), we see that the proposed approach models both effectively. Figure 4 shows that WER-BERT's estimation of WER closely follows the true WER curve. Furthermore, due to the proposed balanced paradigm, it is able to predict well in the mid-high WER classes even with less samples in this region. Figure 5 shows the com-

	Model	MAE WER 100 hour	RMSE WER 100 hour	MAE WER 10 hour	RMSE WER 10 hour

Table 2: Performance Comparison.

parison of Balanced and Imbalanced class setting. Comparing Figure 4 and 5, we see that the WER-BERT models much better in the lower and mid regions compared to the CNN balanced model.

7.1 Effectiveness of WER-BERT and Ablation Studies

The best WER-BERT model, with all Num., Signal feats. and distance loss outperforms other models in both MAE and RMSE metrics. In particular, we see that a BERT model outperforms the corresponding CNN model with the same inputs - 14.44 v/s 12.04 & 13.08 v/s 11.19 for the CNN-text and BERT-large model in the 100 hour and 10 hour data respectively (and similar results for the CNN-text + signal feat and BERT-large + signal feat models). We credit effectiveness of BERT at its language model information and ability to identify improbable word sequences which often correlate with transcription errors. Models such as CNN, while being effective, lack the backing of a language model and hence fail to do the same. While this is important, it alone fails to beat the earlier approaches which utilise signal features i.e. Making a WER prediction from just the transcription is not enough. Signal features tells us how an utterance was spoken along with background noise. This contains valuable information such as signal noise which correlates with higher WER. The effectiveness of WER-BERT is particularly evident in Table 1 where we see that it is able to predict WER which is very close to the True WER. We hypothesize this is due to irregular word sequences such as "..when is dorian says.." or "..the man i can steadily." being identified by BERT's language model. Furthermore, even when our model predicts a far off WER, it does so in a justified manner. The transcription "1724" and "st james 7" give a high True WER score whereas WER-BERT identifies these sequences as correct and probable and gives low scores. Since WER matches strings exactly, it ends up giving a 100% error in this case due to library's text processing limitations. Note that while we use BERT, the language model itself can be any transformer, since they all have the common idea that LM backing helps identifying speech errors in ways CNN models can't.

7.2 Effectiveness of proposed balancing setting

We use the best architecture reported by Elloumi et al. (2018): CNN-text + RAWSIG for comparing the three paradigms. Balanced outperforms the Double Task approach of Ali and Renals (2018) and Single Task approach Elloumi et al. (2018) (9.65 v/s 11.34 v/s 14.09 for the 100 Hour set). The class imbalance in their approach causes bias towards the largest classes during training, where most of the predictions end up. This especially harms the WER prediction in higher ranges where number of samples are less. Figure 5 shows the performance difference between CNN + RAWSIG models in the new balanced paradigm and the imbalanced Elloumi et al. (2018) setting. Since the model encounters heavily imbalanced labels in the later setting, its predictions also reflect the same. There are only two kinds of predictions - one corresponding to the lowest WER class (also largest in number as seen in Figure 1) and another in the range of second largest class. The information of

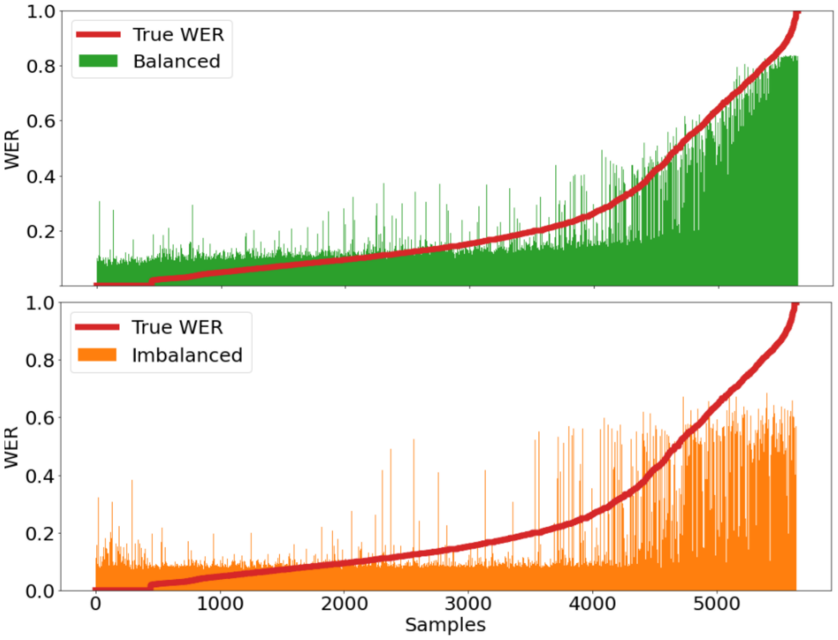

Figure 5: WER Predicted by the CNN + RAWSIG (Balanced) and CNN + RAWSIG (Elloumi et al., 2018) (Imbalanced) as compared to True WER for all samples (Test 100hr)

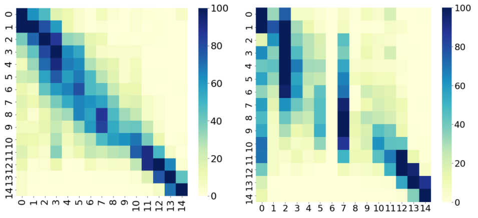

(a) with Distance Loss (b) w/o Distance Loss

Figure 6: Confusion Matrices of the BERT-*large* + All Features model

the other classes are mostly ignored due to being present in low numbers. Meanwhile, the balanced paradigm fits the slope of the curve after 40 WER well. The range of > 40 WER is tough for the model to predict as the number of samples available in this region is lesser than samples in < 40 WER (almost 70% of data). Despite this, balanced paradigm effectively divides this area into adequate number of classes for good performance. While the performance in the mid region (20-40 WER) is poor for this model, custom loss and BERT model in WER-BERT take care of this as seen in Figure 4.

7.3 Effectiveness of Distance loss

Addition of Distance loss to WER-BERT certainly improves the performance. In Figure 6 we see the confusion matrix of WER classification visualized with and without the custom loss. Due to the custom loss the models predicted class is much closer to the ground truth class represented by the diagonal of the matrix. This is due to distance loss' ability to penalize far off predictions which is lacking in typical classification loss functions such as crossentropy. We see an improvement of nearly 1 MAE with this.

8 Conclusion

We propose WER-BERT for Automatic WER Estimation. While BERT is an effective model, addition of speech signal features boosts the performance. Phrasing WER classification as a ordinal classification problem by training using a custom distance loss encodes the information regarding relative ordering of the WER classes into the training. Finally, we propose a balanced paradigm for training WER estimation systems. Training in a balanced setting allows proposed model to predict WER adequately even in regions where samples are scarce. Furthermore, this balanced paradigm is independent of WER prediction model, ASR system or the speech dataset, making it efficient and scalable.

A Hyperparameter Tuning Details

In this section we explain the tuning and selection procedure of the proposed experiments' hyperparameters, namely the distance loss weight α and number of classes K. Furthermore, we also attempt to explain the behaviour of these variables on the performance in terms of MAE.

A.1 Tuning Distance Loss Hyperparameter α

Figure 7 shows the effect of varying α with effect on performance on the 100hr dataset with the WER-BERT model with and without custom loss. As evident, we get the lower MAE and RMSE for $\alpha = 50$. Lower or higher α leads to decrement in performance. Recalling Equation 4 from the main paper:

$$L_{custom}(s) = L_{\theta}(s) + \alpha * \gamma \tag{5}$$

where γ is:

$$|y_{pred}(s) \cdot WER_{fixed} - y_{true}(s) \cdot WER_{fixed}| \tag{6}$$

For low values of α (0.0001 to 0.001), in the above equations $L_{custom}(s)$ becomes equal to just $L_{\theta}(s)$ which the classification cross entropy loss. Hence, essentially low α performance tends to the line of No custom loss WER-BERT performance. On the other hand, higher α values weight the custom loss too much more than the cross entropy loss. While the decrement in performance isn't very high, moderate adverse effects still show that, regular classification cross entropy loss is required for WER-BERT training.

A.2 Tuning Class Hyperparameter K

Figure 8 shows the effect on performance of the CNN + RAWSIG model for varying MAE. We get the minimum MAE and RMSE at $K = 15$. Largely speaking, for lower K, RMSE and MAE suffer because the new classes no more accurately depicts the true WER. For example, in Figure 1 of main paper, we can see that if $K = 3$ or 4, WERs in a wide range from 40 to 100 will be clubbed into a single class despite their huge differences. This

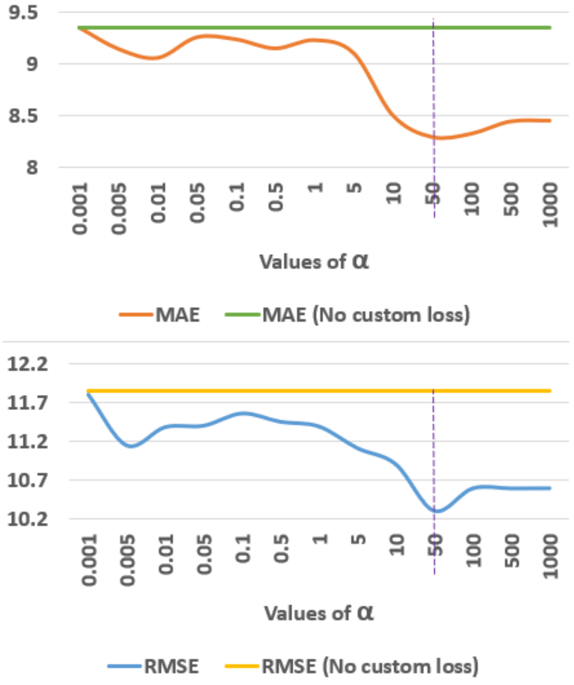

Figure 7: Distribution of MAE and RMSE for different values of α against no custom loss in WER-BERT. The values here are presented for the 100hr dataset.

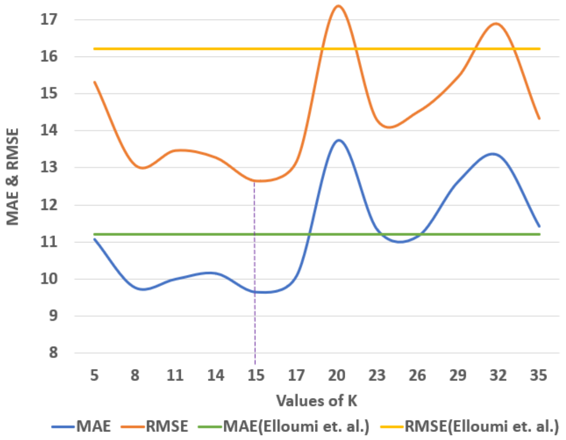

Figure 8: Distribution of MAE and RMSE for different values of K against Elloumi et al. (2018) approach. The values here are presented for the CNN + RAWSIG model on the 100hr dataset.

Datasets	ERR	Duration	Length	True WER
Train 100hr	8.16	12.74	34.84	23.42
Dev 100hr	8.13	12.70	34.64	23.47
Test 100hr	8.18	12.61	34.50	23.70
Train 10hr	2.65	7.29	20.44	12.97
Dev 10hr	2.28	7.15	19.96	11.40
Test 10hr	2.41	7.18	20.25	11.91

Table 3: Averaged Statistics regarding the Train 100hr and Test 100hr dataset.

will further make it hard for the model to predict WERs in this range.

On the other hand, higher K yields new classes accurate to true WER especially in the higher ranges(50 to 100), but at the cost of class size. For example at K=30, each class will have about 900 (28000/30) samples.Furthermore, since True WER is a highly imbalanced variable, there exists a long tail in the lower WER regions in Figure 1 of main paper. This WER region is divided into many classes, despite the WER range being largely small. For example for $K > 30$ the model will be forced to distinguish between nearly four classes with arbitrary samples of all 0 True WER. Just for $K = 15$, model encounters two classes which are actually both 0 WER. This number of redundant classes with arbitrary samples will only increase as K increases.

Furthermore, for a range of values of K, we see that the balanced CNN + RAWSIG model still outperforms the CNN + RAWSIG (Elloumi et al., 2018)'s performance. This further reinforces the efficacy of the balanced paradigm even with its senstivity to a hyperparameter.

B Dataset

Additional dataset details are present in Table 3.

Two Training Strategies for Improving Relation Extraction over Universal Graph

Abstract

This paper explores how the Distantly Supervised Relation Extraction (DS-RE) can benefit from the use of a Universal Graph (UG), the combination of a Knowledge Graph (KG) and a large-scale text collection. A straightforward extension of a current state-of-the-art neural model for DS-RE with a UG may lead to degradation in performance. We first report that this degradation is associated with the difficulty in learning a UG and then propose two training strategies: (1) Path Type Adaptive Pretraining, which sequentially trains the model with different types of UG paths so as to prevent the reliance on a single type of UG path; and (2) Complexity Ranking Guided Attention mechanism, which restricts the attention span according to the complexity of a UG path so as to force the model to extract features not only from simple UG paths but also from complex ones. Experimental results on both biomedical and NYT10 datasets prove the robustness of our methods and achieve a new state-of-the-art result on the NYT10 dataset. The code and datasets used in this paper are available at `https://github.com/baodaiqin/UGDSRE`.

1 Introduction

Relation Extraction (RE) is an important task in Natural Language Processing (NLP). RE aims to turn unstructured texts into structured Knowledge Graph (KG), which is typically stored as (e_1, r, e_2) triplets, where e_1 is a *head entity*, r is a relation and e_2 is a *tail entity*, such as (*aspirin*, *may_treat*, *pain*) and (*Guy Maddin*, *place_lived*, *Winnpeg*). RE can be formulated as a classification task to predict a predefined relation r from entity pair (e_1, e_2) annotated evidences.

One obstacle that is encountered when building a RE system is the generation of a large amount of manually annotated training instances, which is expensive and time-consuming. For coping with this difficulty, Mintz et al. (2009) propose Distant Supervision (DS) to automatically generate training samples via linking KGs to texts. They assume that if (e_1, r, e_2) is in a KG, then all sentences that contain (e_1, e_2) (hereafter, *sentence evidences*) express the relation r. It is well known that the DS assumption is too strong and inevitably accompanies the wrong labeling problem, such as the sentence evidences (1b and 2) below, which fail to express *may_treat* and *place_lived* relation respectively.

(1) a. ***Aspirin***$_{e_1}$ *is widely used for short-term treatment of* ***pain***$_{e_2}$*, fever or colds.*

b. *The tumor was remarkably large in size, and* ***pain***$_{e_2}$ *unrelieved by* ***aspirin***$_{e_1}$.

(2) *He is now finishing a documentary about* ***Winnipeg***$_{e_2}$*, the final installment of a personal trilogy that began with "Cowards Bend the Knee" (a 2003 film that also featured a hapless hero named* ***Guy Maddin***$_{e_1}$*).*

Recently, neural network models with attention mechanism have been proposed to alleviate the wrong labeling problem and attend informative sentence evidences such as (1a) (Lin et al., 2016; Ji et al., 2017; Du et al., 2018; Jat et al., 2018; Han et al., 2018a,b). However, there can be a large portion of entity pairs that lack such informative sentence evidences that explicitly express their relation. This makes Distantly Supervised Relation Extraction (DS-RE) further challenging (Sun et al., 2019).

For compensating the lack of informative sentence evidences, Dai et al. (2019) utilize multi-hop paths connecting a target entity pair (hereafter, *path*) over a KG as extra evidences for DS-RE. An example of such multi-hop KG path can be seen in Figure 1, where p_1 depicts a multi-hop KG path

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3673–3684
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

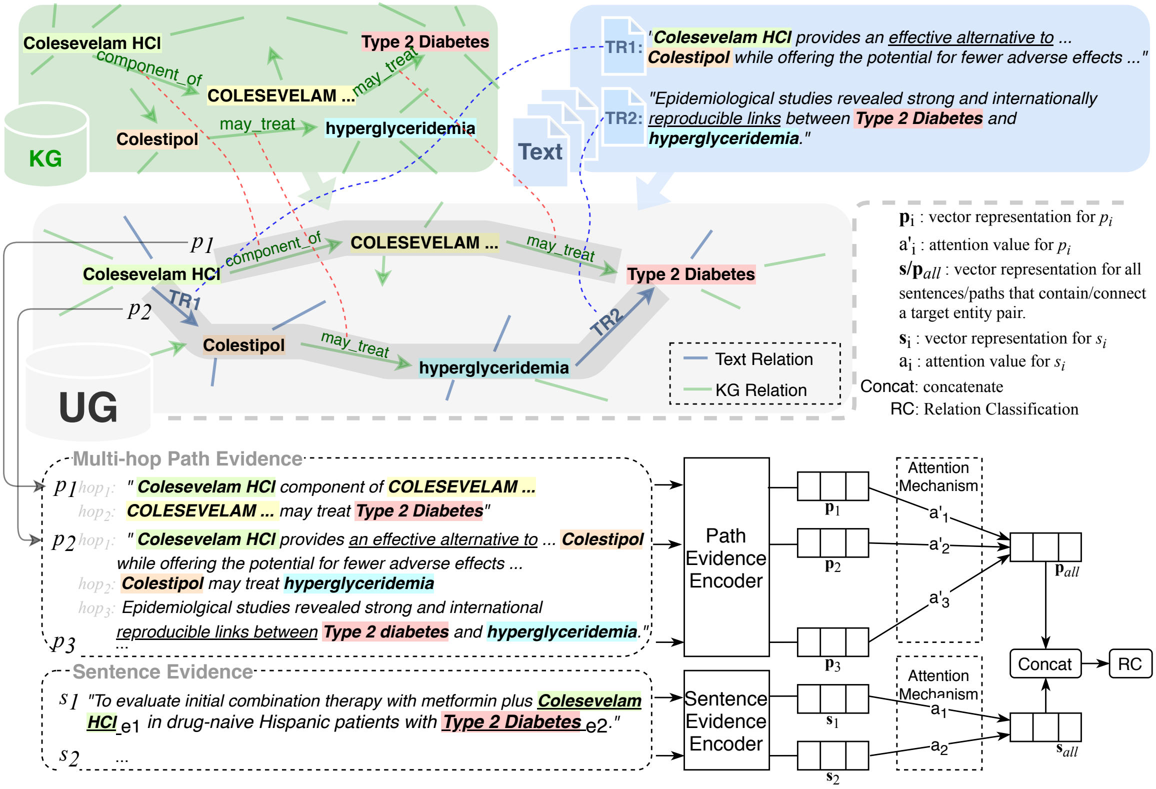

Figure 1: Overview of our UG-based framework, where **Colesevelam HCl** and **Type 2 Diabetes** are the target entities, **COLESEVELAM ...**, **Colestipol** and **hyperglyceridemia** are intermediate entities, each UG path consists of multiple hops and each hop represents a KG relation (such as "*Colestipol may treat hyperglyceridemia*") or Text (or Textual) relation (such as TR1 and TR2), which is the sentence containing two (target or intermediate) entities.

of the form of $e_1 \xrightarrow{component\_of} e_3 \xrightarrow{may\_treat} e_2$. The model of Dai et al. (2019) uses such multi-hop paths as additional features for predicting the relation between a given target entity pair (e_1, e_2), which is reported effective for performance improvement. However, KGs are often highly incomplete (Min et al., 2013) and may be too sparse to provide enough informative paths in practice, which may hamper the effectiveness of multi-hop paths.

Given this background, in this study, we take one step further, aiming for inducing maximal signals of distant supervision from both a KG and a large text collection (hereafter, *Text*). For this purpose, we consider using multi-hop paths over a Universal Graph (UG) as extra features for DS-RE. Here, we define a UG as a joint graph representation of both KG and Text, where each node represents an entity from KG or Text, and each edge indicates a KG relation or Textual relation, as shown in Figure 1. The path p_2 in the figure is an example of UG path, comprising a textual edge TR1, a KG edge *may_treat*, and another textual edge TR2. By augmenting the original KG with textual edges, one can expect far more chances to find informative path evidences between any given target entity pairs, because the number of such textual edges is likely to be much larger than the number of KG edges (Note that one can collect as many textual edges as needed from a raw text corpus with an entity linker). Extending a KG to a UG, therefore, may allow a DS-RE model to learn richer distant supervision signals.

The idea of using multi-hop paths over a UG is not necessarily new on its own. For example, Toutanova et al. (2015) propose to use a UG for knowledge graph completion, and Das et al. (2017b) propose a model trained to reason over a UG for question answering. However, there is no prior study that has explored the effective way to use a UG for the task of DS-RE from text. In fact, finding an effective way of using a UG for DS-RE is not as simple as it may seem. As we report in this paper, a straightforward extension of the Dai et al. (2019) model to the UG setting may result in performance degradation.

Motivated by this, in this paper, we address how one can make effective use of UG for DS-RE. We first report our observation that a straightforward extension of the Dai et al. (2019) model to the UG setting tends to allocate the majority of attention to only a limited set of UG paths such as short KG paths and miss out the learning from a wide range of UG paths (§4.1), which hinders performance gain. In order to alleviate the negative effect of the attention bias and realize the potential of UG paths, we propose two training (or debiasing) strategies: (1) Path Type Adaptive Pretraining (§4.2), which aims to improve the adaptability of the model to various UG paths; and (2) Complexity Ranking Guided Attention mechanism (§4.3), which enables the model to learn from both simple and complex UG paths. Experimental results on both biomedical and NYT10 (Riedel et al., 2010) datasets prove that: (1) UG paths have the potential to bring performance gain for DS-RE as compared with KG paths; (2) the proposed training methods are effective to fully exploit the potential of UG paths for DS-RE because the proposed methods significantly and consistently outperform several baselines on both datasets and especially achieve a new state-of-the-art result on the NYT10 dataset.

2 Related Work

To improve the performance of a DS-RE model, recently, researchers introduce various attention mechanisms. Lin et al. (2016) propose a relation vector based attention mechanism. Jat et al. (2018); Du et al. (2018) propose multi-level (e.g., word-level and sentence-level) structured attention mechanism. Ye and Ling (2019) apply both intra-bag and inter-bag attention for DS-RE. Han et al. (2018b) propose a relation hierarchy based attention mechanism. Han et al. (2018a) propose a joint model that adopts a KG embeddings based attention mechanism. Jia et al. (2019) propose an attention regularization framework to select informative sentence evidences for DS-RE. However, these models rely only on noisy sentence evidences from DS, neglecting the rich UG paths for DS-RE.

Besides the sentence evidences from DS, researchers also leverage external evidences for DS-RE. Ji et al. (2017) apply entity descriptions generated from Freebase and Wikipedia as extra evidences, Lin et al. (2017) utilize multilingual text as extra evidences and Vashishth et al. (2018) use multiple extra evidences including entity types, dependency and relation alias information for DS-RE. Alt et al. (2019) utilize pretrained language model as background information for DS-RE. Sun et al. (2019) apply relational table extracted from Web as supplementary evidences for DS-RE.

To apply DS-RE beyond sentence boundary, Quirk and Poon (2017) utilize syntactic information to extract relation from neighboring sentences. Zeng et al. (2017) apply two-hop KG paths identified from two-hop textual paths as extra evidences for DS-RE. Different from this work, we directly use the rich UG paths as extra evidences. Dai et al. (2019) extend the framework of Han et al. (2018a) by introducing multiple KG paths as extra evidences for DS-RE. Neelakantan et al. (2015); Das et al. (2017a) use multiple reasoning paths over Text and KG for relation prediction in the paradigm of Knowledge Graph Completion. Our work differs from the ones mentioned above in two ways: (i) We utilize the UG paths as extra evidences for the task of DS-RE from text, (ii) We take into account the factor of attention bias while encoding UG paths and propose two effective debiasing methods to exploit the potential of UG paths for DS-RE.

3 Base Model

We select the DS-RE model proposed by Dai et al. (2019) as our base model and extend it into our UG setting. Given a target entity pair (e_1, e_2), a bag of corresponding sentence evidences $S_r = \{s_1, ..., s_n\}$ and a bag of UG paths $P_r = \{p_1, ..., p_m\}$, the base model aims to measure the probability of (e_1, e_2) having a predefined relation r (including the empty relation NA). The base model consists of four main modules: KG Encoder, Sentence Evidence Encoder, Path Evidence Encoder and Relation Classification Layer, as shown in Figure 2.

3.1 KG Encoder

Suppose we have a KG containing a set of fact triplets $\mathcal{O} = \{(e_1, r, e_2), ...\}$, where each fact triplet consists of two entities $e_1, e_2 \in \mathcal{E}$ and their relation $r \in \mathcal{R}$. Here $\mathcal{E}$ and $\mathcal{R}$ stand for the set of entities and relations respectively.

The KG Encoder then encodes $e_1, e_2 \in \mathcal{E}$ and their relation $r \in \mathcal{R}$ into low-dimensional vectors $\mathbf{h}, \mathbf{t} \in R^d$ and $\mathbf{r} \in R^d$ respectively, where d is the dimensionality of the embedding space. The KG Encoder adopts TransE (Bordes et al., 2013) to score a given triplet. Specifically, given a triplet (e_1, r, e_2), TransE evaluates its plausibility

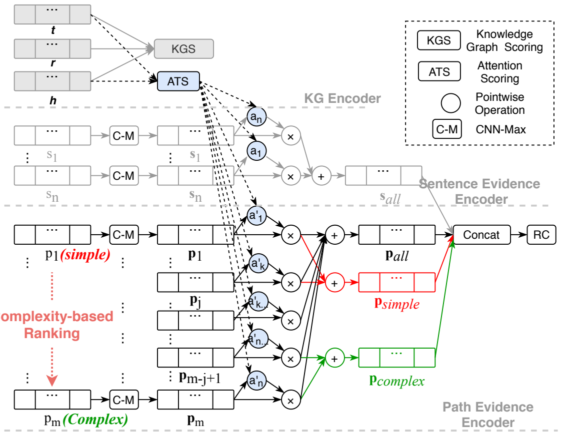

Figure 2: Overview of the base model and our proposed Complexity Ranking Guided Attention mechanism (§4.3). The base model takes the sentence evidences (e.g., s_1, ...) containing a target entity pair and the UG paths (e.g., p_1, ...) connecting the entity pair as input for predicting their relation. The KG embeddings of the entity pair (i.e., $\mathbf{h}$ and $\mathbf{t}$) are used for calculating the attention over these sentences and paths. The Complexity Ranking Guided Attention mechanism is proposed to force the model to attend both simple UG paths (e.g., $p_1 \sim p_j$) and complex ones (e.g., $p_{m-j+1} \sim p_m$).

via Equation 1:

$$f_r(e_1, e_2) = b - \|\mathbf{r}_{ht} - \mathbf{r}\|, \tag{1}$$

$$\mathbf{r}_{ht} = \mathbf{t} - \mathbf{h}, \tag{2}$$

where b is a bias constant and $\mathbf{r}_{ht}$ is a latent relation embedding for (e_1, e_2). The conditional probability can be formalized over all fact triplets $\mathcal{O}$ as follows:

$$P(e_1, r, e_2|\theta_{\mathcal{E}}, \theta_{\mathcal{R}}) = \frac{\exp(f_r(e_1, e_2))}{\sum_{r' \in \mathcal{R}} \exp(f_{r'}(e_1, e_2))} \tag{3}$$

where $\theta_{\mathcal{E}}$ and $\theta_{\mathcal{R}}$ are parameters for entities and relations respectively.

3.2 Sentence Evidence Encoder

Given a bag of sentence evidences $S_r = \{s_1, ..., s_n\}$, the Sentence Evidence Encoder applies CNN-Max (see Appendix §A.1) on each sentence, namely $\mathbf{s}_i = \text{CNN-Max}(s_i)$, to derive the sentence representations $\{\mathbf{s}_1, ..., \mathbf{s}_n\}$. The encoder then calculates the bag-level vector representation $\mathbf{s}_{\text{all}}$ via Equation 4:

$$\mathbf{s}_{\text{all}} = \sum_{i=1}^{n} a_i \mathbf{s}_i, \tag{4}$$

$$a_i = \frac{\exp(\langle \mathbf{r}_{ht}, \mathbf{x}_i \rangle)}{\sum_{k=1}^{n} \exp(\langle \mathbf{r}_{ht}, \mathbf{x}_k \rangle)},$$

$$\mathbf{x}_i = \tanh(\mathbf{W}\mathbf{s}_i + \mathbf{b})$$

where $\mathbf{r}_{ht}$ is from Equation 2, $\mathbf{W}$ is the weight matrix, $\mathbf{b}$ is the bias vector, a_i is the weight for the i-th sentence in S_r.

3.3 Path Evidence Encoder

Given a bag of UG paths $P_r = \{p_1, ..., p_m\}$ connecting an entity pair of interest (e_1, e_2), the Path Evidence Encoder encodes them into a bag-level vector representation $\mathbf{p}_{\text{all}}$. Since we represent a path as a sequence of words (or a long sentence), as shown in Figure 1, analogously to the Sentence Evidence Encoder, we apply a CNN-Max (see Appendix §A.1) to encode each path p_i, namely $\mathbf{p}_i = \text{CNN-Max}(p_i)$. The bag-level path representation $\mathbf{p}_{\text{all}}$ for P_r is then calculated via Equation 5:

$$\mathbf{p}_{\text{all}} = \sum_{i=1}^{m} a'_i \mathbf{p}_i, \tag{5}$$

$$a'_i = \frac{\exp(\langle \mathbf{r}_{ht}, \mathbf{x'}_i \rangle)}{\sum_{k=1}^{m} \exp(\langle \mathbf{r}_{ht}, \mathbf{x'}_k \rangle)},$$

$$\mathbf{x'}_i = \tanh(\mathbf{W}\mathbf{p}_i + \mathbf{b})$$

where a'_i is the weight for the i-th path in P_r.

3.4 Relation Classification Layer

The conditional probability of (e_1, e_2) having a relation r is formulated via Equation 6:

$$P(e_1, r, e_2|S_r, P_r, \theta_S, \theta_P) = \frac{\exp([\mathbf{o}]_r)}{\sum_{c=1}^{n_r} \exp([\mathbf{o}]_c)} \tag{6}$$

where $\mathbf{o} = \mathbf{M}[\mathbf{s}_{\text{all}}; \mathbf{p}_{\text{all}}] + \mathbf{d}$, θ_S, θ_P are the parameters in Sentence Evidence Encoder and Path Evidence Encoder, $\mathbf{M}$ is the representation matrix of relations, $\mathbf{d}$ is a bias vector, $\mathbf{o}$ is the output vector containing the prediction scores of all predefined relations, $[\mathbf{o}]_c$ is the prediction score for the relation c, and n_r is the total number of relations.

Given a training dataset consisting of triplets $\mathcal{O} = \{(e_1^1, r^1, e_2^1), (e_1^2, r^2, e_2^2), ...\}$, we minimize the objective function as follows:

$$J(\theta) = -\frac{1}{|\mathcal{O}|} \sum_{i=1}^{|\mathcal{O}|} \log P(e_1^i, r^i, e_2^i|\theta_{\mathcal{E}}, \theta_{\mathcal{R}}) + \log P(e_1^i, r^i, e_2^i|S_{r^i}, P_{r^i}, \theta_S, \theta_P) \tag{7}$$

The base model is optimized with Stochastic Gradient Descent (SGD). Following (Han et al., 2018a), we optimize $P(e_1^i, r^i, e_2^i|\theta_{\mathcal{E}}, \theta_{\mathcal{R}})$ and $P(e_1^i, r^i, e_2^i|S_i, P_i, \theta_S, \theta_P)$ in parallel.

4 Proposed Training Method

4.1 Problem of Attention Bias

While extending the base model into our UG setting, we observe that the base model tends to allocate more attention to KG or linguistically simple paths as compared to Textual paths (i.e., the path comes form Text), Hybrid paths (i.e., the path comes from both Text and KG), or linguistically complex ones, as shown in Figure 3a and Figure 3b. We consider that this would be because paths including Textual relations (i.e., Textual and Hybrid paths) or complex paths are comparatively noisier than KG or simple paths, but which does not necessarily mean the former is not useful. For instance, in Figure 1, the complex Hybrid path p_2 is useful for predicting (**Colesevelam_HCl**, *may_treat*, **Type_2_Diabetes**), because p_2 implies a plausible line of reasoning " ***Colesevelam_HCl*** $\xrightarrow{\textit{alternative\_to}}$ *Colestipol* $\xrightarrow{\textit{may\_treat}}$ *hyperglycemia* $\xrightarrow{\textit{strong\_link\_to}}$ ***Type_2_Diabetes***". However, due to the attention bias mentioned above, the base model allocates low attention ($a'_2 \approx 8.0 \times 10^{-36}$) on the informative path, and thus fails to learn from such complex but useful evidences.

To reduce the negative effect of the attention biases and make full use of the UG path, we propose the following two training (or debiasing) strategies: Path Type Adaptive Pretraining (§4.2) and Complexity Ranking Guided Attention (§4.3).

4.2 Path Type Adaptive Pretraining

As shown in Figure 3a, the base model tends to bias toward KG paths. This indicates that the base model mainly relies on KG paths so that it is incapable of capturing informative features from Textual and Hybrid paths. This bias will decrease the flexibility and adaptability of the base model to different types of paths.

To address this issue, we propose a debiasing strategy called Path Type Adaptive Pretraining. In this strategy, we pretrain the base model sequentially using Textual, Hybrid, and KG Paths as path evidences, and then finetune it with all types of paths as illustrated in Figure 4. We hypothesize that this strategy can prevent the reliance on a single type of UG path and improve the capacity of extracting features from the entire UG paths, and thereby increase the performance.

4.3 Complexity Ranking Guided Attention

Similar to the bias towards KG paths, the base model also focuses on linguistically simple paths, as shown in Figure 3b, even though complex ones are informative (e.g. p_2 in Figure 1). We hypothesize that restricting the attention span to the complex (simple) paths can force the model to pay attention to the complex (simple) paths, thereby effectively utilize them. Under this hypothesis, we propose a Complexity Ranking Guided Attention mechanism, as illustrated in Figure 2.

Specifically, given a bag of paths $P_r = \{p_1, ..., p_m\}$, we rank them according to their complexity scores (κ), which are calculated via $\kappa = \lambda_1\tau_1 + \lambda_2\tau_2 + ...$, where τ denotes the feature for capturing linguistic complexity (e.g., path length) and λ is a corresponding weight, which is a hyperparameter. Sentence length (i.e., the number of tokens in a sentence) and lexical richness (i.e., the number of token types) are commonly used features for evaluating sentence complexity (Brunato et al., 2018). Therefore, this work adopts them to calculate the complexity for a given path.

Then, we group top j most and least complex paths into a set of complex and simple paths respectively, where j is a hyperparameter[1]. The set level representation is calculated via the Equation 8.

$$\mathbf{p}_{\text{complex} \textit{ or } \text{simple}} = \sum_{i \in \textit{top\_j} \textit{ or } i \in \textit{last\_j}} a'_i \mathbf{p}_i \tag{8}$$

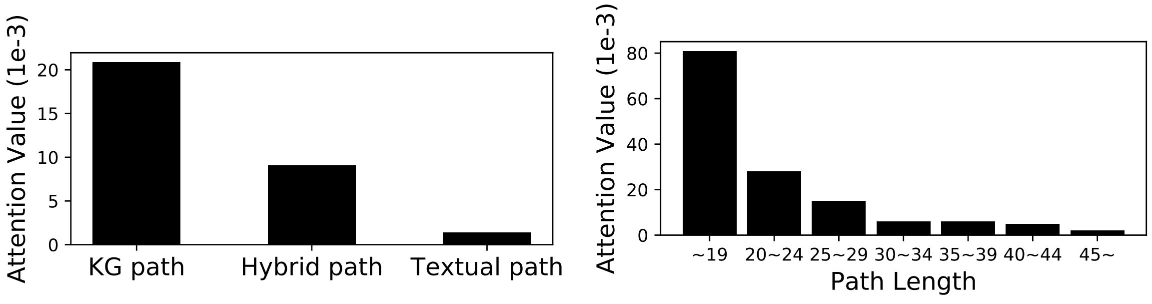
$$a'_i = \frac{\exp(\langle \mathbf{r}_{ht}, \mathbf{x'}_i \rangle)}{\sum_{k \in \textit{top\_j} \textit{ or } k \in \textit{last\_j}} \exp(\langle \mathbf{r}_{ht}, \mathbf{x'}_k \rangle)},$$
$$\mathbf{x'}_i = \tanh(\mathbf{W}\mathbf{p}_i + \mathbf{b})$$

Finally, we concatenate the resulting representation $\mathbf{s}_{\text{final}}$, $\mathbf{p}_{\text{final}}$, $\mathbf{p}_{\text{simple}}$ and $\mathbf{p}_{\text{complex}}$ as the input to the relation classification layer. The conditional probability $P(e_1, r, e_2|S_r, P_r, \theta_S, \theta_P)$ is formulated via Equation 9, where $\mathbf{o} = \mathbf{M}[\mathbf{s}_{\text{all}}; \mathbf{p}_{\text{all}}; \mathbf{p}_{\text{complex}}; \mathbf{p}_{\text{simple}}] + \mathbf{d}$.

$$P(e_1, r, e_2|S_r, P_r, \theta_S, \theta_P) = \frac{\exp([\mathbf{o}]_r)}{\sum_{c=1}^{n_r} \exp([\mathbf{o}]_c)} \tag{9}$$

---

[1] In our experiments, we set j as 30 for NYT10 dataset and 50 for Biomedical dataset.



(a) Path type and attention

(b) Path complexity and attention

Figure 3: (**Left**) Average attention weights across different path types. (**Right**) Average attention weights across different length range of paths. Here, we use path length as an indicator of path complexity, which denotes the number of words in a path.

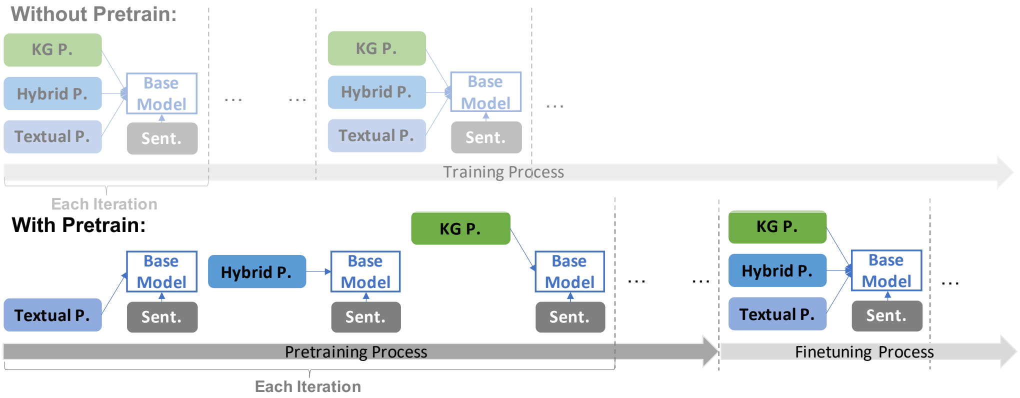


Figure 4: Path Type Adaptive Pretraining strategy, where "Textual/Hybrid/KG P." represent Textual, Hybrid, and KG paths respectively, and "Sent." represents the sentence evidences. In this strategy (**Pretrain**), instead of using all types of paths to train the base model in all iterations, we sequentially train the model with Textual, Hybrid and KG paths, and then finetune it with all types of paths.

5 Experiments

5.1 Data

We evaluate our proposed framework on a biomedical dataset and NYT10 dataset (Riedel et al., 2010). The statistics of both datasets is summarized in Table 1. We will detail both datasets as follows.

Biomedical Dataset. This datatset is created by linking biomedical KG with biomedical Text. We choose UMLS[2] and Medline corpus as the biomedical KG and Text respectively. UMLS is a frequently used biomedical knowledge base, while Medline corpus is a large collection of biomedical abstracts, both are developed and maintained by the U.S. National Library of Medicine[3]. For identifying UMLS entity mentions in the Medline corpus, we use a state-of-the-art UMLS Named Entity Recognizer (NER), ScispaCy (Neumann et al., 2019). The NER identifies UMLS concepts and annotates them by their corresponding UMLS Concept Unique Identifier (CUI) and entity types.

From the UMLS KG and the entity linked Medline corpus, we extract fact triplets (i.e., (e_1, r, e_2)) and corresponding sentence evidences containing (e_1, e_2) under the restriction that: (1) each entity pair should be connected by a RO (RO stands for "has Relationship Other than synonymous, narrower, or broader") relationship; (2) each entity should belong to the following entity types: Protein, Gene, Disease or Syndrome, Enzyme, Chemical, Sign or Symptom and Pharmacologic Substance. Then we divide the collected triplets and sentence evidences into training and testing set according to the year when the source abstract of sentence evidence was published. The former is aligned to the years until 2008 and the latter to the years 2009 $\sim$ 2018, ensuring the testing set only contains the

unobserved triplets.

To simulate the noise in the real world, besides the "related" triplets, we also extract the "unrelated" triplets and sentence evidences based on a closed world assumption: pairs of entities not listed in a KG are regarded to have NA relation and sentences containing them are considered to be the NA sentence evidences. We divide the NA triplets and NA sentence evidences in the same way mentioned above. We use a subset of UMLS (see Appendix §A.3) and the Medline abstracts published until 2008 as the KG and Text respectively to create the UG for path retrieval. In addition, we use the same subset of UMLS triplets mentioned above to train the KG Encoder introduced in §3.

NYT10. The dataset is created by aligning Freebase relational facts with the New York Times Corpus. Sentence evidences from the year 2005 $\sim$ 2006 are used for training and the evidences from 2007 are used for testing. NYT10 dataset has been widely used by (Lin et al., 2016; Ji et al., 2017; Du et al., 2018; Jat et al., 2018; Du et al., 2018; Han et al., 2018a,b; Vashishth et al., 2018; Ye and Ling, 2019; Alt et al., 2019). We use Freebase[4] and ClueWeb12 with Freebase entity mention annotations (Gabrilovich et al., 2013) as the KG and Text to create the UG for path searching. In addition, following (Han et al., 2018a), we use FB60K for training the KG Encoder.

UG path search. Given an entity pair (e_1, e_2), the UG path set P_r is obtained by performing random walks over the UG from e_1 till e_2 with maximum step[5].

5.2 Settings

We follow (Lin et al., 2016) and conduct the held-out evaluation, in which the model for DS-RE is evaluated by comparing the fact triplets identified from evidences (i.e., the bag of sentence evidences S_r and the bag of UG path evidences P_r) with those in KG. Following the evaluation of previous works, we draw Precision-Recall curves and report the Area Under Curve (AUC) and Precision@N (P@N) metrics, which gives the percentage of correct triplets among top N ranked candidates. The parameter settings of our experiments are detailed in Appendix §A.2.

To demonstrate the effectiveness of our framework, we choose the model proposed by Dai et al. (2019) as the baseline model, because this is the closest model in terms of incorporating multiple paths for DS-RE. Henceforth, "Sent+KG" is the baseline model, which uses both sentence evidences and KG paths. "Sent+UG" represents the base model in §3 which takes UG paths instead of KG paths as path evidences. "Sent+UG+Pretrain" and "Sent+UG+Ranking" denote the base model trained with Path Type Adaptive Pretraining strategy and the base model with Complexity Ranking Guided Attention mechanism, respectively. "Sent+UG+Ranking+Pretrain" means the base model trained with both strategies.

5.3 Results and Discussion

Precision-Recall Curves. The Precision-Recall (PR) curves of each model on the biomedical and NYT10 datasets are shown in Figure 5 and Figure 6, respectively. The results show that: (1) "Sent+UG" does not have obvious advantages than "Sent+KG", illustrating that due to the biases discussed in §4.1, simply applying UG paths on the base model has limited effect on improving the performance of DS-RE. (2) "Sent+UG+Pretrain" and "Sent+UG+Ranking" achieve better overall performance than "Sent+KG" on both datasets, especially when the recall is greater than 0.3, demonstrating that UG has the potential to enhance the performance and the two proposed debiasing strategies are effective for exploiting the potential of UG for DS-RE. (3) "Sent+UG+Ranking+Pretrain" achieves the highest precision over the (almost) entire recall range on both datasets, proving that the two proposed strategies have a mutual complementary relationship on exploiting UG for DS-RE. This is understandable because the two proposed strategies deal with different types of biases, in addition, "Pretrain" helps the base model adapt to UG paths by effectively tuning its weights, while "Ranking" enhances the base model by adjusting its attention mechanism. (4) The consistent improvement on

---

[4] From the entire Freebase, we only collect the triplets with the relations that are mentioned in NYT10 dataset for UG creation, ensuring not to overlap with testing set.

[5] We manually set the maximum step as 3.

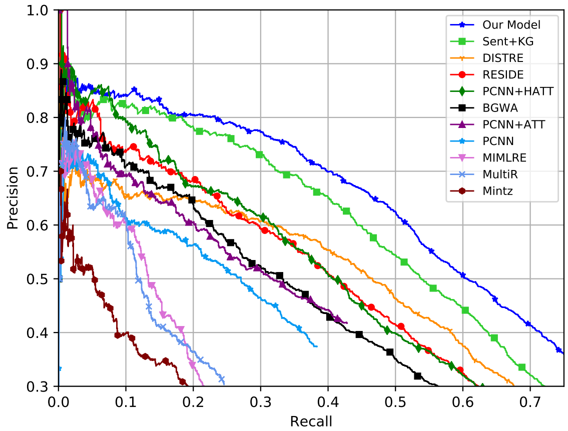

Figure 7: PR curves of previous state-of-the-art methods and our proposed model on NYT10 dataset.

two datasets from different domains further proves the validity of our proposed methods.

AUC and P@N Evaluation. Table 2 further presents the results in terms of AUC and P@N. From them, we have similar observation to the PR curves. We also observe that the effectiveness of UG paths is more pronounced on Biomedical dataset than on NYT10 dataset. We speculate that compared to the generic NYT10 dataset, further Background Knowledge (BK) is needed to identify relations from Biomedical dataset, and UG paths could be utilized as the BK to facilitate the scientific DS-RE.

Comparison with State-of-the-art Baselines on NYT10. To demonstrate the effectiveness of our proposed model, we also compare it against the following baselines on NYT10 dataset: Mintz (Mintz et al., 2009), MultiR (Hoffmann et al., 2011), MIMLRE (Surdeanu et al., 2012), PCNN (Zeng et al., 2015), PCNN+ATT (Lin et al., 2016), BGWA (Jat et al., 2018), PCNN+HATT (Han et al., 2018b), RESIDE (Vashishth et al., 2018), DISTRE (Alt et al., 2019) and Sent+KG (Dai et al., 2019). The results shown in Figure 7 and Table 3 indicate that: (1) our selected base model, "Sent+KG", is a strong baseline because it signif-

System	AUC	P@0.1k	P@0.2k	P@0.3k	P@0.5k	P@1k	P@2k
Mintz†	10.7	52.3	50.2	45.0	39.7	33.6	23.4

Our Model	**55.0**	**86.0**	**84.0**	**83.3**	**80.4**	**71.9**	**54.5**

Table 3: P@N and AUC from previous state-of-the-art DS-RE models and our proposed model on NYT10 dataset, where †represents that these results are quoted from (Alt et al., 2019) and ‡indicates the results using the pretrained model from (Han et al., 2018b).

icantly outperforms other state-of-the-art models; and (2) our model can effectively take advantage of the rich UG paths for DS-RE because it beats the strong baseline and achieves a new state-of-the-art result on the commonly used DS-RE dataset.

Base	Prop.	**Biomedical Triplet**
✗	✓	(Beta-2...Gene , gene_associated_with_disease, Asthma)
		Multi-hop Path
Low	**High**	*hop*$_1$: *"The human Beta-2...Gene is responsible for the binding of endogenous Catecholamine and their ..."* *hop*$_2$: *" Catecholamine chemical structure of Epinephrine "* *hop*$_3$: *" Epinephrine may treat Asthma ".*
Base	Prop.	**NYT10 Triplet**
✗	✓	(San_Francisco , /location/contains, Noe_Valley)
		Multi-hop Path
Low	**High**	*hop*$_1$: *" San_Francisco /location/contains Fort_Point "* *hop*$_2$: *"Surf spots and surfing regions include Northern CA, the Bay_Area , San Francisco, Ocean Beach and Fort Point "* *hop*$_3$: *" Bay_Area /location/contains Noe_Valley "*

Table 4: Some examples of attention distribution over paths from "Sent+UG" (Base) and "Sent+UG+Ranking+Pretrain" (Prop.), where ✓(or ✗) represents the correct (or incorrect) prediction of the target relation.

Case Study. Table 4 shows the UG path examples that are scored with highest ("High") or lowest (or lower than 1.0×10^{-3}) ("Low") attention by the base model and our proposed framework. The paths in the table generally mean "*Beta-2... Gene* $\xrightarrow{is\_responsible\_for}$ *Catecholamine* $\xrightarrow{is\_the\_chemical\_class\_of}$ *Epinephrine* $\xrightarrow{may\_treat}$ *Asthma*" and "*San_Francisco* $\xrightarrow{contains}$ *Fort_Point* $\xrightarrow{equal\_status}$ *Bay_Area* $\xrightarrow{contains}$ *Noe_Valley*", and thus can be seen as the useful path evidences for identifying *gene_associated_with_disease* and */location/contains* relation respectively. These examples indicate that our proposed training strategies could help the base model attend such informative UG paths so that it can correctly identify the target relation.

6 Conclusion and Future Work

We have introduced UG paths as extra evidences for the task of DS-RE from text. In order to fully take advantage of the rich UG paths, we have proposed two training (or debiasing) strategies: Path Type Adaptive Pretraining and Complexity Ranking Guided Attention mechanism. We have conducted experiments on both biomedical and NYT10 datasets. The results show that the two proposed methods are effective for exploiting the potential of UG paths for improving the performance of DS-RE.

In the future, we plan to carry out the following steps: (1) we further investigate how the proposed training methods influence the performance via manual analysis so as to better the efficiency; and (2) instead of random walk, we may collect UG paths by adopting more sophisticated mechanisms such as training a path searching agent via reinforcement learning to prevent redundant and noisy paths.

A Appendix

A.1 CNN-Max

Convolutional Neural Network with Max pooling layer (CNN-Max) is adopted to derive the sentence representation $\mathbf{s}$ and path representation $\mathbf{p}$. Specifically, vector representation $\mathbf{v}_t$ for each word w_t is calculated via Equation 10, where $\mathbf{W}^{w}_{emb}$ is a word embedding projection matrix (Mikolov et al., 2013), $\mathbf{W}^{wp}_{emb}$ is a word position embedding projection matrix (Zeng et al., 2014), $\mathbf{x}_t^{w}$ is a one-hot word representation and $\mathbf{x}_t^{wp}$ is a one-hot word position representation, which indicates the relative distance between the current word and the target entity pair.

$$\begin{aligned} \mathbf{v}_t &= [\mathbf{v}_t^{w}; \mathbf{v}_t^{wp1}; \mathbf{v}_t^{wp2}], \\ \mathbf{v}_t^{w} &= \mathbf{W}^{w}_{emb}\mathbf{x}_t^{w}, \\ \mathbf{v}_t^{wp1} &= \mathbf{W}^{wp}_{emb}\mathbf{x}_t^{wp1}, \\ \mathbf{v}_t^{wp2} &= \mathbf{W}^{wp}_{emb}\mathbf{x}_t^{wp2} \end{aligned} \tag{10}$$

The sentence representation $\mathbf{s}$ and path representation $\mathbf{p}$ are formulated via the Equation 11, where $\mathbf{W}^{sent}$ (or $\mathbf{W}^{path}$) is the convolution kernal, $\mathbf{b}^{sent}$ (or $\mathbf{b}^{path}$) is the corresponding bias vector, $\mathbf{v}_t^{sent}$ (or $\mathbf{v}_t^{path}$) is the vector for each word w_t in a sentence (or path), $[vec]_i$ is the i-th value of vec, ν is the dimensionality of $\mathbf{s}$ and $\mathbf{p}$, and k is the convolutional window size.

$$\begin{aligned} [\mathbf{s}]_i &= \max_t\{[\mathbf{h}_t^{sent}]_i\},\ \forall i = 1, ..., \nu \\ [\mathbf{p}]_i &= \max_t\{[\mathbf{h}_t^{path}]_i\},\ \forall i = 1, ..., \nu \end{aligned} \tag{11}$$

$$\begin{aligned} \mathbf{h}_t^{sent} &= \tanh(\mathbf{W}^{sent}\mathbf{z}_t^{sent} + \mathbf{b}^{sent}), \\ \mathbf{h}_t^{path} &= \tanh(\mathbf{W}^{path}\mathbf{z}_t^{path} + \mathbf{b}^{path}), \\ \mathbf{z}_t^{sent} &= [\mathbf{v}^{sent}_{t-(k-1)/2}; ...; \mathbf{v}^{sent}_{t+(k-1)/2}], \\ \mathbf{z}_t^{path} &= [\mathbf{v}^{path}_{t-(k-1)/2}; ...; \mathbf{v}^{path}_{t+(k-1)/2}] \end{aligned}$$

A.2 Parameter Settings

All of the hyperparameters used in our experiments are listed in Table 5. Most of them follow the hyperparameter setting in (Dai et al., 2019) and (Han et al., 2018a). We use a Word2Vec model[6] to train the word embeddings on the UMLS entity linked corpus for the biomedical dataset, and adopt the word embeddings released by (Lin et al., 2016) for NYT10 dataset. We apply Stochastic Gradient Descent (SGD) to optimize the proposed DS-RE model.

Hyperparameter	**Biomedical**	**NYT10**
word embedding dimension	50	50
KG embedding dimension	50	50
position embedding dimension	5	5
CNN window size	3	3
CNN filter number	100	230
dropout rate	0.5	0.5
learning rate (for sentences and paths)	0.02	0.05
learning rate (for KG)	0.05	0.001
batch size	50	160

Table 5: Hyperparameters used in our experiments.

Selected Entity Types
Antibiotic, Biologically Active Substance, Bacterium, Organ, Cell Component, Cell Function, Cell, Clinical Drug, Ion, Eukaryote, Food, Genetic Function Hazardous or Poisonous Substance, Hormone, Immunologic Factor, Inorganic Chemical, Organic Chemical, Pathologic Function, Receptor, Steroid, Virus and Vitamin.

Table 6: List of selected UMLS entity types.

A.3 Subset of UMLS

Besides the 7 entity types mentioned above, we also use other 22 entity types, as listed in Table 6, to collect the UMLS triplets that are connected by RO relationship, ensuring all testing triplets are removed. The main reasons to manually restrict the entity type is because (1) we observe that most of the Medline abstracts discuss the relationship among these entity types; (2) these concrete entities could prevent semantic drift while searching UG paths.

Abstract

Automatic Post-Editing (APE) aims to correct errors in the output of a given machine translation (MT) system. Although data-driven approaches have become prevalent also in the APE task as in many other NLP tasks, there has been a lack of qualified training data due to the high cost of manual construction. eSCAPE, a synthetic APE corpus, has been widely used to alleviate the data scarcity, but it might not address genuine APE corpora's characteristic that the post-edited sentence should be a minimally edited revision of the given MT output. Therefore, we propose two new methods of synthesizing additional MT outputs by adapting back-translation to the APE task, obtaining robust enlargements of the existing synthetic APE training dataset[1]. Experimental results on the WMT English-German APE benchmarks demonstrate that our enlarged datasets are effective in improving APE performance.

1 Introduction

src	Manipulates the shape of an item .
mt	**Bearbeitet** die Form eines Elements **an** .
pe	**Verändert** die Form eines Elements .

Table 1: An example of APE triplets from the WMT dataset (Bojar et al., 2017). **Boldface** words are either incorrect words in *mt* or post-edited words in *pe*.

Automatic Post-Editing (APE) seeks to automatically correct errors included in the output of a black-box machine translation (MT) system to improve the final translation quality, thereby reducing the effort required for manual post-editing (Allen and Hogan, 2000; Chatterjee et al., 2015; Bojar et al., 2016; Chatterjee et al., 2018). In general, APE can be considered as a task of sequence-to-sequence supervised learning, which requires a considerable amount of human-annotated data. However, constructing an APE corpus—a set of triplets (Table 1), each of which includes a source text (*src*), a machine-translated text (*mt*), and a manually post-edited text (*pe*)—is labor-intensive work because post-editors should create *pe* in principle by **minimally editing** *mt* while preserving the meaning of *src*. In fact, the sizes of currently available 'genuine' APE corpora provided by WMT (Bojar et al., 2016, 2017; Chatterjee et al., 2018, 2019, 2020) are too small to train deep APE models effectively.

To overcome the lack of genuine APE corpora, several previous studies have proposed methods to construct synthetic training datasets (Junczys-Dowmunt and Grundkiewicz, 2016; Negri et al., 2018; Lee et al., 2020), and they appear to be partially helpful in mitigating the data scarcity problem. One such study is eSCAPE (Negri et al., 2018), which has been shown to be effective in training deep models and adopted in a number of APE works (do Carmo et al., 2020). Utilizing parallel corpora, which comprise pairs of a source sentence (*src*) and a reference sentence (*ref*), eSCAPE was constructed as a set of synthetic APE triplets in the form of (*src*, *mt*, *ref*) where *mt* is a machine translation of *src*, and *ref* serves as an alternative to *pe* of a genuine APE triplet.

Despite the effectiveness of eSCAPE, we argue that it may have two major drawbacks: (1) eSCAPE's method relies heavily on parallel resources, so its scalability is restricted to the quantity of available parallel resources and can be even more limited in low-resource scenarios; (2) the relation between *mt* and *ref* may not thoroughly reflect the actual relation between *mt* and *pe* because *ref* is not guaranteed to be a minimally edited revision of *mt*, potentially leading to the discrepancy between

---

(a) PBSMT dataset

(b) NMT dataset

Figure 1: (a) and (b) are categorical distributions that indicate the proportion y [%] of samples belonging to a specific TER interval x for each of the two APE data types classified according to the type of the target MT system. Here, TER is a metric that presents the distance (error ratio) between *mt* and its target (*pe* or *ref*).

the distribution of translation errors in genuine data and that of translation errors in the synthetic data (Figure 1).

In this paper, we propose two automatic methods that are inspired by back-translation from the MT task (Sennrich et al., 2016), employing the APE process in the forward direction and the backward direction with applying the eSCAPE resource to them to create additional synthetic *mt*. Our approach not only extends the existing resource, but also aims to better simulate the characteristics of real APE data by making our synthetic *mt* better approximate the error distribution of the WMT APE benchmark dataset.

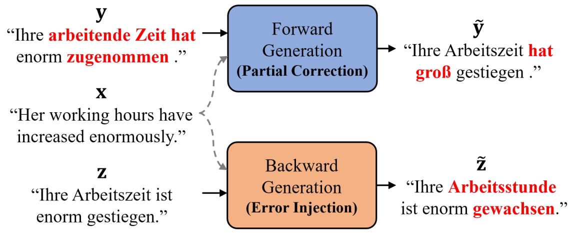

Figure 2: An illustration of our two synthetic data generation methods. $\mathbf{x}$, $\mathbf{y}$, and $\mathbf{z}$ are examples of *src*, *mt*, and *ref*, respectively. $\tilde{\mathbf{y}}$ and $\tilde{\mathbf{z}}$ are expected outputs that the proposed methods will produce. **Boldface** words indicate incorrect words.

2 Background and Related Work

Back-translation. Back-translation is a method to create synthetic source texts from clean target texts by using an MT system that is trained in the target–to–source direction. Back-translation has allowed many MT studies to use monolingual data to generate additional parallel data so that they alleviate data scarcity; moreover, it has also been successfully adopted by other NLP tasks such as summarization (Parida and Motlicek, 2019; Jernite, 2019) and grammatical error correction (Xie et al., 2018).

Learning Objective of APE. Given that APE aims to revise *mt* to *pe* while preserving the meaning of *src*, each one of the two sources (*src*, *mt*) plays a distinct and critical role: *src* is treated as an auxiliary source, not only offering intact semantic and contextual information but also being helpful in identifying mistranslation; *mt*, meanwhile, serves as the primary source, which needs to be corrected. In this perspective, the multi-source approach: (*src*, *mt*) $\mapsto$ *ref*, is commonly used to take both *src* and *mt* into account (Chatterjee et al., 2018, 2019). Specifically, considering *src*, *mt*, and *pe* as $\mathbf{x} = \{x_i\}_{i=1}^{T_x}$, $\mathbf{y} = \{y_j\}_{j=1}^{T_y}$, and $\mathbf{z} = \{z_k\}_{k=1}^{T_z}$ with the sequence lengths T_x, T_y, and T_z, respectively, the APE model learns to predict *pe* with the following conditional probability:

$$p(\mathbf{z}) = \prod_{k=1}^{T_z} p(z_k|\mathbf{x}, \mathbf{y}, z_{<k}; \theta), \tag{1}$$

where θ is a set of model parameters.

3 Method

Beyond the eSCAPE corpus, to yield a more convincing error distribution as well as to supply APE models with more APE resources made out of limited parallel resources, we propose synthetic-data generation methods that can be seen as adaptations of back-translation to the APE task in terms of creating synthetic *mt*, which is one of the two sources of APE.

We produce new synthetic *mt* so that *ref* can better act as its minimally post-edited text, whereas this *ref* may not do so for the original *mt*. Specifically, we suggest two strategies, both of which apply the APE process: '**forward generation**' and '**backward generation**'; each one of them performs APE in the forward direction and the backward direction, respectively. As described in Figure 2, the former partially corrects *mt* to reduce the distance between *mt* and *ref*, while the latter injects the right quantity of translation errors into *ref*.

3.1 Forward Generation

The '**F**orward **G**eneration' (FG) method lets an APE model take *src* and *mt* as input to produce mt_{FG} as output by partially correcting *mt* through the forward path of APE; the training objective of an FG model is identical to that of a normal APE model (Eq. 1). The output mt_{FG} then forms a new synthetic triplet (*src*, mt_{FG}, *ref*) together with *src* and *ref*. We use such triplets to construct a new set of synthetic triplets $\mathrm{eSCAPE}_{\mathrm{FG}}$.

Considering that *mt* generally requires a lot of excessive correction to match *ref*, this approach's motivation is that mt_{FG}, in itself a product of the APE process, will generally be closer to *ref* than the original *mt*. However, if the distance between mt_{FG} and *ref* is excessively small, indicating that the two texts are almost identical, APE models trained on $\mathrm{eSCAPE}_{\mathrm{FG}}$ may not learn error-correction patterns sufficiently. Thus, unlike the standard training procedure, we force the FG model's training process to stop earlier before convergence, making the remaining errors in its output mt_{FG} ample. We therefore use simple arrangements (§4) to find one optimal value for this stop point.

3.2 Backward Generation

Borrowing the idea of back-translation, the '**B**ackward **G**eneration' (BG) method reverses the APE process during training by moving *mt* to the position of *ref* and vice versa; hence, a BG model is trained on (*src*,*ref*) $\mapsto$ *mt* to maximize the following conditional probability:

$$p(\mathbf{y}) = \prod_{j=1}^{T_y} p(y_j|\mathbf{x}, \mathbf{z}, y_{<j}; \theta). \tag{2}$$

In other words, the model learns to generate mt_{BG} to contain translation errors that occur in *mt* conditioned on a pair of *src* and *ref*. The output mt_{BG} then composes a new synthetic triplet (*src*, mt_{BG}, *ref*) together with *src* and *ref*. We use such triplets to construct another set of synthetic triplets $\mathrm{eSCAPE}_{\mathrm{BG}}$.

Dataset		# Triplets

	Dev	1,000
	Test2016	2,000
	Test2017	2,000
	Test2018	2,000
`WMT-NMT`	Train	13,442
	Dev	1,000
	Test2018	1,023
`eSCAPE-PBSMT`		7,258,533
`eSCAPE-NMT`		7,258,533

Table 2: Statistics of the WMT and eSCAPE datasets on the PBSMT and NMT subtasks.

In contrast to FG, the concept of BG is to corrupt a clean text (*ref*) by learning until the distance between the BG output and *ref* becomes similar to the edit distance of real APE data. However, if we let the BG model fully converge, the output mt_{BG} may not have a big difference from the original *mt*; on the other hand, if the model has been barely trained, mt_{BG} would be almost the same as *ref*. In both instances, APE models trained on $\mathrm{eSCAPE}_{\mathrm{BG}}$ may not learn error-correction patterns sufficiently. We use the same arrangements (§4) as in FG to find an optimal value for the BG model's stop point.

4 Experiments

Metric. Following the evaluation setting used in the WMT APE shared task, we adopt TER (Snover et al., 2006) as the primary metric to measure the distance between the model's prediction and the reference text; and BLEU (Koehn et al., 2007) as the secondary metric to measure the degree of n-gram match. In addition, all evaluations in our experiments are case-sensitive.

Dataset. We use two kinds of APE datasets: human-made APE datasets, which are provided by WMT, and eSCAPE. Both are English–German (EN–DE) APE corpora; they are further categorized according to their subtask depending on whether the target MT system is a phrase-based statistical MT (PBSMT) system or a neural MT (NMT) system. The WMT datasets are in the IT domain, whereas eSCAPE was made out of domain-general parallel corpora. Detailed data statistics are presented in Table 2. We tokenized all words in our datasets into sub-word units by using Senten-

'*' represents that our model's improvement is significant enough compared to the eSCAPE baseline in the second row with $p < 0.05$. The best result among our models in each column is in **bold** type. The three models at the bottom are current state-of-the-art models.

cePiece (Kudo and Richardson, 2018).

Model Configuration. We implemented a Transformer-based APE model, the "sequential" model proposed by Lee et al. (2019), which is one of the best performing models. We use this model both as generation models that create synthetic *mt* with our two proposed methods and also as the final APE models to examine the effectiveness of those synthesized data as additional training data. We follow the hyperparameter setting described in Lee et al. (2019), which again follows almost the same setting of the "base" Transformer described in the original paper Vaswani et al. (2017). However, we adjust the warm-up rate to 15,000 and the batch size to 25,000. We used OpenNMT-py[2] to implement and execute all models.

Synthetic Data Generation. To prevent our data generation model from generating what it has already seen during the training phase, we adopt the n-fold jack-knifing technique, which splits the whole dataset into $n-1$ folds for training and 1 left-out fold for generation and validation, into our data generation process. Specifically,

1. Split eSCAPE into $n = 8$ folds: $\{f_i\}_{i=1}^{8}$.
2. Construct a training set, $\mathcal{D}_i = \text{Append}\left(\{f_j\}_{j=1}^{8} \setminus \{f_i\}\right)$.
3. Train a data generation model (FG or BG) $\mathcal{M}_i$ on $\mathcal{D}_i$ and use 2,000 randomly extracted held-out samples from f_i for validation.
4. At a given model checkpoint, generate $\widetilde{mt}_i$ with $\mathcal{M}_i$ by supplying it with the pair of two sources in f_i.
5. Construct $mt_{FG/BG} = \text{Append}\left(\{\widetilde{mt}_i\}_{i=1}^{8}\right)$.

To examine the optimal stop point (§3.1, §3.2), we saved a model checkpoint every 25K training steps up to 150K steps, where the model converges with respect to its validation perplexity; thus, we obtained 6 sets of synthetic *mt* for each one of the two methods. Finally, for each method, we trained 6 APE models by using each new set of triplets including synthetic *mt*; and choose one set of synthetic *mt* that reports the best performance on the WMT validation dataset.

Evaluation With assistance from the FG and BG methods, we have a set of synthetic APE triplets $\mathcal{S} = \{\text{eSCAPE}, \text{eSCAPE}_{FG}, \text{eSCAPE}_{BG}\}$ available for training. In our experiments, we trained several APE models on various combinations of synthetic triplets in $\mathcal{S}$ together with the WMT training datasets and then compared the evaluation results to investigate how each data configuration affects the model's APE performance. Finally, after training the models until their perplexities on the WMT development dataset converge, we evaluated them on the WMT test datasets. We considered two baselines: (1) TER between *mt* and *pe* of the test datasets and (2) the performance of the APE model that is trained only on eSCAPE; the former

implies that no post-editing has occurred yet, and it is used as the official baseline for the WMT APE shared task.

5 Results and Discussion

Table 3 shows the evaluation results. We observed that when eSCAPE$_{\text{FG}}$ or eSCAPE$_{\text{BG}}$ is used instead of eSCAPE, the APE model's performance does not make a big difference from the eSCAPE baseline. One possible reason that we expect is the gap between those synthetic *mt* and *mt* in the WMT dataset; in other words, synthetic *mt* is not produced by an existing MT system.

Nevertheless, we found that when we augment eSCAPE with eSCAPE$_{\text{FG}}$ and/or eSCAPE$_{\text{BG}}$, the trained APE model shows consistent improvements in its APE performance and most of the improvements upon the eSCAPE baseline are statistically significant. Moreover, the results also surpass current state-of-the-art (except the ensemble models) APE models (Correia and Martins, 2019; Lopes et al., 2019), which are built on top of BERT (Devlin et al., 2019), thus contain more model parameters, and exploit a huge amount of monolingual data. We expect that these results are because, in addition to an increase in the total quantity of training samples, the integration of multiple synthetic datasets, each of which focuses on different aspects of APE from the other—eSCAPE contains actual MT outputs; on the other hand, synthetic triplets better satisfy the minimal-edit criterion—appears to have an effect on the models' APE performance.

We found that our proposed methods derive a large number of new *mt* (Table 4) from eSCAPE and also yield a more similar TER distribution to that of WMT data than that of eSCAPE in terms of not only the mean TER (Table 4) but also the decrease in KL-divergence (Figure 3).

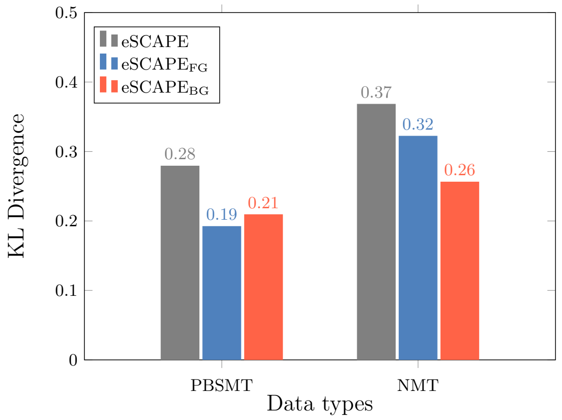

Figure 3: Presentation of $D_{KL}(P \parallel Q)$ (with base-10 logarithms) where P and Q are TER categorical distributions; P is for the WMT data, and Q is for each kind of synthetic triplets. The TER categorical distributions are plotted in the same manner as in Figure 1.

6 Conclusion and Future Work

In this paper, we tried to alleviate the drawbacks of eSCAPE by suggesting two new methods that adapt back-translation to the APE task, consequently increasing the data quantity and address the minimum editing characteristic. According to our experimental results, although APE models trained on each one of our two synthetic datasets show just comparable performances to the eSCAPE baseline, those trained on integrations of multiple synthetic datasets show consistent improvements over the baseline, implying that our new synthetic datasets are beneficial enlargements of eSCAPE. However, we manually selected the optimal stop points for both of our proposed generation schemes, so we will automate these selection processes in our future work.

Abstract

Unsupervised image captioning is a challenging task that aims at generating captions without the supervision of image–sentence pairs, but only with images and sentences drawn from different sources and object labels detected from the images. In previous work, *pseudo-captions*, *i.e.*, sentences that contain the detected object labels, were assigned to a given image. The focus of the previous work was on the alignment of input images and pseudo-captions at the sentence level. However, pseudo-captions contain many words that are irrelevant to a given image. In this work, we investigate the effect of removing mismatched words from image–sentence alignment to determine how they make this task difficult. We propose a simple gating mechanism that is trained to align image features with only the most reliable words in pseudo-captions: the detected object labels. The experimental results show that our proposed method outperforms the previous methods without introducing complex sentence-level learning objectives. Combined with the sentence-level alignment method of previous work, our method further improves its performance. These results confirm the importance of careful alignment in word-level details.[1]

1 Introduction

Image captioning is a task to describe images in natural languages. This is a fundamental challenge with regard to automatically retrieving and summarizing the visual information in a human-readable form. Recently, considerable progress has been made (Vinyals et al., 2015; Xu et al., 2015; Anderson et al., 2018b) owing to the development of neural networks and a large number of annotated image–sentence pairs (Young et al., 2014; Lin et al., 2014; Krishna et al., 2017). However, these pairs are limited in their coverage of scenes[2], and scaling them is difficult owing to the cost of manual annotation.

Unsupervised image captioning (Feng et al., 2019) aims to describe scenes that have no corresponding image–sentence pairs, without requiring additional annotation of the pairs. The only available resources are images and sentences drawn from different sources and object labels detected from the images. Although it is highly challenging, unsupervised image captioning has the potential to cover a broad range of scenes by exploiting a large number of images and sentences that are not paired by expensive manual annotation.

To train a captioning model in this setting, previous work (Feng et al., 2019; Laina et al., 2019) employed sentences that contained the object labels detected from given images. We refer to these sentences as *pseudo-captions*. However, pseudo-captions are problematic in that they are likely to contain words that are irrelevant to the given images. Assume that an image contains two objects *cat* and *girl* (Figure 1). This situation could give rise to various possible pseudo-captions, *e.g.*, “a girl is holding a cat,” “a cat is sleeping with a girl,” “a girl is running with a cat.” When the first sentence is the correct caption of the image, the words *sleeping* and *running* of the other sentences are irrelevant to the image. As the detected object labels provide insufficient information to judge which sentence corresponds to the image, many pseudo-captions containing such mismatched words can be produced.

---

[1] Code will be available at `https://github.com/ukyh/RemovingSpuriousAlignment`

[2] For example, the standard captioning dataset MS COCO (Lin et al., 2014) covers only approximately 100 object categories out of 500 object categories defined in an object detection dataset (Agrawal et al., 2019). In addition to objects, attributes and relations are also not covered well owing to the small vocabulary size, 8791 (Karpathy and Fei-Fei, 2015).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3692–3702
April 19 - 23, 2021.

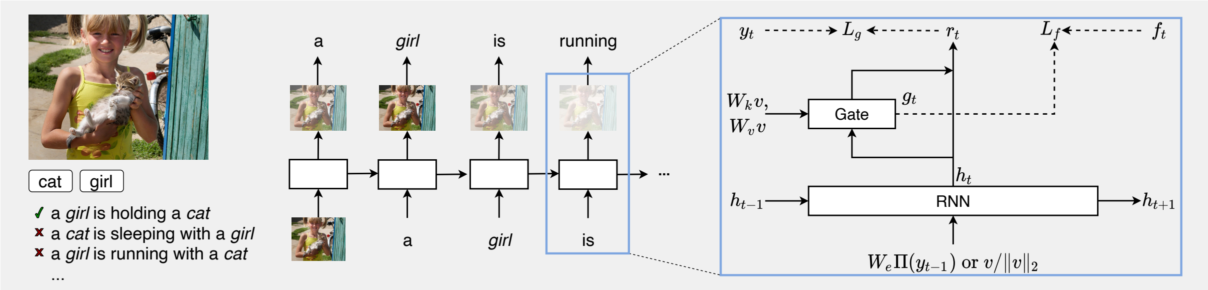

Figure 1: Overview of our model. The input is listed on the left-hand side: an image, its detected object labels, and its pseudo-captions. The model learns to generate the pseudo-captions while considering the correspondence between the image and each word being generated. The detailed process is shown in the blue box on the right-hand side. The base encoder–decoder model output $\boldsymbol{h}_t$, a gate value g_t, and a pseudo-label f_t on the gate are described in Sections 2.1, 2.2, and 2.3, respectively. The dashed arrows indicate the processes conducted only during training.

Regardless of the problem in pseudo-captions, previous work (Feng et al., 2019; Laina et al., 2019) did not explicitly remove word-level mismatches. They tried aligning the features of images and their pseudo-captions at the sentence level. Although this line of approach can potentially align the images and sentences correctly if there are sentences that exactly describe each image, it is not likely to hold for the images and sentences retrieved from different sources.

To shed light on the problem of word-level spurious alignment in the previous work, we focus on removing mismatched words from image–sentence alignment. To this end, we introduce a simple gating mechanism that is trained to exclude image features when generating words other than the most reliable words in pseudo-captions: the detected objects. The experimental results show that the proposed method outperforms previous methods without introducing complex sentence-level learning objectives. Combined with the sentence-level alignment method of previous work, our method further improves its performance. These results confirm the importance of careful alignment in word-level details.

2 Method

Our model comprises a sequential encoder–decoder model, a gating mechanism on the encoder–decoder model, a pseudo-label on the gating mechanism, and a decoding rule to avoid the repetition of object labels, as presented in Figure 1.

2.1 Base Encoder–Decoder Model

Typical supervised, encoder–decoder captioning models maximize the following objective function during training:

$$\boldsymbol{\theta}^* = \arg\max_{\boldsymbol{\theta}} \sum_{(\boldsymbol{I},\boldsymbol{y})} \log p(\boldsymbol{y}|\boldsymbol{I};\boldsymbol{\theta}), \tag{1}$$

where $\boldsymbol{\theta}$ are the parameters of the models, $\boldsymbol{I}$ is a given image, and $\boldsymbol{y} = y_1, ..., y_T$ is its corresponding caption, the last token y_T is a special end-of-sentence token.

However, in unsupervised image captioning, the corresponding caption $\boldsymbol{y}$ is not available. Instead, object labels in given images are provided by pretrained object detectors. Previous work utilized the detected object labels to assign a roughly corresponding caption $\hat{\boldsymbol{y}}$, *i.e.*, a pseudo-caption, to the given image. Following the previous work, we define pseudo-captions of an image as sentences containing the object labels detected from the image. Given the pseudo-caption $\hat{\boldsymbol{y}}$, our base encoder–decoder model maximizes the following objective function:

$$\boldsymbol{\theta}^* = \arg\max_{\boldsymbol{\theta}} \sum_{(\boldsymbol{I},\hat{\boldsymbol{y}})} \log p(\hat{\boldsymbol{y}}|\boldsymbol{I};\boldsymbol{\theta}). \tag{2}$$

In encoder–decoder captioning models, the probability $p(\boldsymbol{y}|\boldsymbol{I})$[3] is auto-regressively factorized as $p(\boldsymbol{y}|\boldsymbol{I}) = \prod_{t=1}^{T} p(y_t|y_{<t}, \boldsymbol{I})$ and each $p(y_t|y_{<t}, \boldsymbol{I})$ is computed by a single step of recurrent neural networks (RNNs). The encoder encodes the given image $\boldsymbol{I}$ to an image representation $\boldsymbol{v} \in \mathbb{R}^{d'}$ that is fed to the decoder as an initial input to generate a sequence of words auto-regressively. The detailed

---

[3] Hereafter, we omit the model parameter $\boldsymbol{\theta}$ for brevity.

computation of $p(\hat{y}_t|\hat{y}_{<t}, \boldsymbol{I})$ is as follows:

$$p(\hat{y}_t|\hat{y}_{<t}, \boldsymbol{I}) = \frac{\exp(\boldsymbol{h}_t^\top \boldsymbol{W}_o \Pi(\hat{y}_t))}{\sum_{y' \in \mathcal{Y}} \exp(\boldsymbol{h}_t^\top \boldsymbol{W}_o \Pi(y'))}, \quad (3)$$

$$\boldsymbol{h}_t = \begin{cases} \mathrm{Dec}\left(\frac{\boldsymbol{v}}{\|\boldsymbol{v}\|_2}, \boldsymbol{h}_0\right), & \text{if } t = 1; \\ \mathrm{Dec}(\boldsymbol{e}_t, \boldsymbol{h}_{t-1}), & \text{otherwise}, \end{cases} \quad (4)$$

$$\boldsymbol{v} = \boldsymbol{W}_a \mathrm{Enc}(\boldsymbol{I}), \quad (5)$$

$$\boldsymbol{e}_t = \boldsymbol{W}_e \Pi(\hat{y}_{t-1}), \quad (6)$$

where Enc$(\cdot)$ is a pre-trained image encoder with a linear transformation matrix $\boldsymbol{W}_a \in \mathbb{R}^{d \times d'}$ on top of it, Dec$(\cdot)$ is an RNN decoder, $\Pi(\cdot)$ is the one-hot encoding function, $\boldsymbol{h}_0 \in \mathbb{R}^d$ is a zero vector, $\mathcal{Y}$ is the whole vocabulary to use, and $\boldsymbol{W}_e, \boldsymbol{W}_o \in \mathbb{R}^{d \times |\mathcal{Y}|}$ are the word embedding matrices. Details of the encoder and decoder are provided in Section 3.2.

2.2 Gating Mechanism to Consider Word-Level Correspondence

As indicated in Eq. 2, our base encoder–decoder model decodes all of the words in pseudo-captions from the images. However, pseudo-captions are highly likely to contain words that are irrelevant to the given images. Thus, forcing a model to decode the pseudo-captions in their entirety from the images might be more disadvantageous than beneficial for training precise captioning models.

To enable our model to handle word-level mismatches, we introduce a simple gating mechanism. Our model, which is equipped with this gating mechanism, takes an image representation at each t-th time step. The gate is designed to control the amount of image representation used to generate the t-th word. In other words, the gate is expected to determine the extent to which the given image corresponds to the t-th word. With a slight modification to Eq. 3, our model with the gating mechanism is defined as follows:

$$p(\hat{y}_t|\hat{y}_{<t}, \boldsymbol{I}) = \frac{\exp(\boldsymbol{r}_t^\top \boldsymbol{W}_o \Pi(\hat{y}_t))}{\sum_{y' \in \mathcal{Y}} \exp(\boldsymbol{r}_t^\top \boldsymbol{W}_o \Pi(y'))}, \quad (7)$$

$$\boldsymbol{r}_t = g_t \frac{\boldsymbol{W}_v \boldsymbol{v}}{\|\boldsymbol{W}_v \boldsymbol{v}\|_2} + (1 - g_t)\boldsymbol{h}_t, \quad (8)$$

$$g_t = \mathrm{sigmoid}(\tanh(\boldsymbol{W}_k \boldsymbol{v})^\top \boldsymbol{h}_t), \quad (9)$$

where $\boldsymbol{W}_k, \boldsymbol{W}_v \in \mathbb{R}^{d \times d}$ are the linear transformation matrices for computing the gate value $g_t \in [0, 1]$ and the output of the gate $\boldsymbol{r}_t \in \mathbb{R}^d$. When g_t is close to one, it forces the model to use more information from the image ($\boldsymbol{v}$) to generate the t-th word; when g_t is close to zero, it forces the model to do the opposite.

The fed image representation $\boldsymbol{W}_v \boldsymbol{v}$ is kept constant at every time step t. Thus, even when the t-th word is correctly pictured in the image $\boldsymbol{I}$, $\boldsymbol{W}_v \boldsymbol{v}$ itself cannot determine which specific object in the image should be generated according to the current context in the output caption. Therefore, we apply L2 normalization to the image representation in Eq. 8 to ensure that a relatively greater amount of the contextual information ($\boldsymbol{h}_t$) is used.

To train our model with the gating mechanism, we minimize the following cross-entropy loss for each pair of images and their pseudo-captions:

$$\mathcal{L}_g = -\frac{1}{T} \sum_{t=1}^{T} \log p(\hat{y}_t|\hat{y}_{<t}, \boldsymbol{I}). \quad (10)$$

2.3 Pseudo-Labels on Gate to Remove Word-Level Spurious Alignment

The above gate is expected to reflect the correspondence between images and words in pseudo-captions. However, learning to reflect the correspondence correctly is difficult for the gate under the noisy and weak supervision of pseudo-captions.

In this work, our focus is to remove the spurious alignment between images and words in pseudo-captions. Consequently, we apply the following rule to the gate that largely suppresses image representations to use: g_t should be close to one if the t-th word to generate is a detected object label; otherwise, it should be close to zero. This is based on the assumption that, given an image and its pseudo-caption, the reliable words in the pseudo-caption are only the detected object labels, and the others are likely to be irrelevant to the image.

We assign a pseudo-label $f \in \{0, 1\}$ on the gate: $f_t = 1$ if the word $\hat{y}_t$ corresponds to any of the object labels detected from a given image; otherwise, $f_t = 0$. The gate then learns the correspondence by minimizing the following loss function:

$$\mathcal{L}_f = -\frac{1}{T} \sum_{t=1}^{T} \Big[\alpha f_t \log g_t + (1 - f_t) \log(1 - g_t)\Big], \quad (11)$$

where α is the weight to emphasize the loss when $f_t = 1$. A relatively large value is recommended for α to prevent g_t from always being zero because the number of detected object labels (where $f_t = 1$)

	Training Text	Object Detector	Image Encoder	Text Decoder
A (Feng et al., 2019)	SS	Faster-RCNN trained on OpneImages-v2	Inception-v4	1-layer LSTM of 512 dimensions
B (Laina et al., 2019)	GCC	Faster-RCNN trained on OpneImages-v4	ResNet-101	1-layer GRU of 200 dimensions

Table 1: Summary of the difference in the experimental settings.

in pseudo-captions is generally smaller than the number of the other words (where $f_t = 0$).

Combined with the loss function of Eq. 10, the final loss function is defined as follows:

$$\mathcal{L} = \mathcal{L}_g + \mathcal{L}_f. \tag{12}$$

2.4 Unique-Object Decoding

An evaluation of our model revealed that it tends to repeat words in object categories. Although repetition is common in encoder–decoder models, this repetition was generated owing to a different cause. As mentioned in Section 2.2, the image representation $\boldsymbol{v}$ cannot correctly predict the word $\hat{y}_t$ without the context representation $\boldsymbol{h}_t$; if the gate value g_t is exactly one, the model always outputs the most salient object label in the given image.

To avoid ignoring contextual information, we applied a simple decoding rule during the evaluation. Given that the model generates a word y_t at t-th time step, our decoding rule checks whether y_t is in predefined object categories, *i.e.*, object categories defined for object detectors. If y_t is found in the object categories, the rule forces the probability of generating y_t to be zero in the subsequent time steps.

3 Experiments

We ran the experiments under two different settings, Feng et al. (2019) and Laina et al. (2019), for a fair comparison with each. For brevity, we refer to the settings in Feng et al. (2019) and Laina et al. (2019) as setting A and B, respectively. The difference of the settings is clarified in Table 1.

3.1 Datasets

Evaluation Set. To evaluate our proposed method, we used the MS COCO dataset (Lin et al., 2014) with the validation/test split defined by Karpathy and Fei-Fei (2015). Each split has 5,000 images and five reference captions for each image.

Training Images. We used the images (without their captions) in the remaining training split of MS COCO (113,286 images), and a pre-traind object detector (Huang et al., 2017) to retrieve the object labels found in the images[4]. The detector is a publicly available Faster-RCNN model[5] (Ren et al., 2015). The training data of the object detector differs depending on the previous work; thus, we used the object detector trained on OpenImages-v2 (Krasin et al., 2017) to compare with Feng et al. (2019) and that trained on OpenImages-v4 (Kuznetsova et al., 2020) to compare with Laina et al. (2019). Note that these object detectors were not trained on MS COCO images. Following the previous work, we refrained from using the detected bounding boxes and their features.

Training Text. Following the previous work, we used the Shutterstock image description corpus (SS) (Feng et al., 2019) and the training split captions (without images) of Google's Conceptual Captions (GCC) (Sharma et al., 2018) for comparison with Feng et al. (2019) and Laina et al. (2019), respectively. SS consists of 2.3M image descriptions crawled from Shutterstock, an online stock photography website; GCC consists of 3.3M image descriptions crawled from the web. Note that these sentences are not the descriptions of the images in MS COCO.

3.2 Implementation Details

Image Encoder. For a fair comparison with the previous work, we employed different image encoders depending on the compared method: Inception-v4 (Szegedy et al., 2017) in the settings of Feng et al. (2019) and ResNet-101 (He et al., 2016a,b) in the settings of Laina et al. (2019). Both image encoders were pre-trained on ImageNet (Russakovsky et al., 2015) and are publicly available[6]. The parameters of the image encoder were fixed during training and prediction.

Text Decoder. Similar to the image encoder, we

---

[4] Although this pre-trained object detector requires bounding box and semantic label annotations, it can be replaced with any multi-label image classifier, which can be trained on image-tag pairs that are largely and freely available on the web. To ensure this compatibility, bounding box features are not used in unsupervised image captioning.

Table 2: Comparison with the state-of-the-art results on the experimental settings A and B. The scores of our model are the *mean* $\pm$ *standard deviation* of five runs. The scores obtained for BLEU-1 to 3 and SPICE are not provided in the original paper of Laina et al. (2019).

used a different RNN as our decoder: LSTM (Hochreiter and Schmidhuber, 1997) and GRU (Cho et al., 2014) to enable us to compare our results with those of Feng et al. (2019) and Laina et al. (2019), respectively. Following the previous work, the number of hidden layers' dimensions was set to 512 for LSTM and 200 for GRU. The number of the RNN layer was set to one. Word embeddings were randomly initialized and had the same dimensions as the RNN hidden layer.

Pseudo-Captions. Captions tend to describe salient objects, not all detected objects. For example, the frequent object *person* often co-occurs with *face* and *clothing* in images, but these three are not always the salient objects to be described in a caption. To avoid collecting the pseudo-captions that only contain these frequent objects, we picked up each detected object and their pairs to retrieve pseudo-captions, rather than using all detected objects. In this retrieval, we converted object labels to their plural forms using a dictionary used in Feng et al. (2019) so that the pseudo-captions could also cover the plural forms of the objects.

Pseudo-Caption Preprocessing. For each pair of objects, we selected sentences where fewer than four words existed between the objects. This is to pick up the sentences likely to describe the relations of the target objects. We then removed the sentences wherein the target objects were adjacent to avoid collecting the objects' compound words. For each object, we selected sentences wherein fewer than two words were in between the object and its dependent adjective to pick up the sentences likely to describe the object in detail. We used spaCy[7] en_core_web_lg model for parsing.

Value of α. As described above, each pseudo-caption contains only one or two detected objects, which is very few compared with the average sentence lengths of the text corpora (12.0 in SS and 10.7 in GCC). To balance the label imbalance of f_t, we searched the value for α (Eq. 11) at a power of 2 and found that $\alpha = 16$, which roughly equals the quotient of $\frac{\text{Sentence Length}}{\text{Detected Objects}}$, worked well across the settings.

Training Iteration. After collecting the pseudo-captions, we created a set of the objects and pairs that were used to collect the pseudo-captions. The training is iterated over the pairs in this set, rather than over each image, to avoid overfitting for the most frequent object labels. On each iteration of the pairs of objects, we randomly sampled the image and pseudo-caption, wherein both of the objects were contained. Likewise, we did the same sampling on each object in the pairs. The number of the object pairs was 11,607 and 10,612 in the settings A and B, respectively. We set the batch size to eight and terminated the training when the best validation score (specifically, the CIDEr score) did not exceed for 20 epochs. For the optimizer, we used Adam with the recommended hyperparameters (Kingma and Ba, 2015).

Evaluation. In the evaluation, we set the maximum decoding length to 20. Our model decoded captions by using greedy search and unique-object decoding, described in Section 2.4. The evaluation metrics we used were BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Denkowski and Lavie, 2014), CIDEr (Vedantam et al., 2015) and SPICE (Anderson et al., 2016).

3.3 Comparison with the State-of-the-Art Results

Table 2 lists the results of our model compared with the previous state-of-the-art results. To avoid evaluating cherry-picked scores, we computed the mean and standard deviation of five results obtained with different seeds[8]. Our method outperforms the previous approaches in terms of all evaluation metrics. These results confirm the effectiveness of our simple method.

---

3.4 Ablation Study

Table 3 lists the results of our model obtained in the ablation studies. We tested the ablation of the gating mechanism (*gate*), pseudo-labels on the gating mechanism (*pseudoL*), unique-object decoding (*unique*), and image features (*image*). The pseudo-labels cannot be implemented without the base gating mechanism. Thus, the model "w/o *gate* w/ *pseudoL*" is not applicable. The model w/o *image* is the same as Ours (full) except that it only uses the word embeddings of detected object labels, rather than image features. It encodes detected object labels into word embeddings and then takes their mean[9] and replaces the image feature $\boldsymbol{v}$ with it. All models here were trained in the same manner as described in Section 3.2.

The results show that the pseudo-labels on the gating mechanism contribute a lot to the performance; the score degrades significantly from Ours (full) to w/o *pseudoL* in all metrics. On the other hand, the base gating mechanism does not function well by itself; not all scores of w/o *gate* are lower than those of w/o *pseudoL*. These results demonstrate that explicitly removing the word-level spurious alignment contributes the most to the relatively high performance of our model. Although it is a relatively low contribution compared with the pseudo-labels, unique-object decoding also enhances performance.

The degraded performance of w/o *image* suggests that object labels themselves are insufficient to describe images correctly. We observed that this model was vulnerable to errors propagated through object detectors. See Section 3.8 for the examples.

3.5 Combining with Previous Methods

Our method focuses on removing word-level spurious alignment between images and pseudo-captions, whereas the previous methods focus on aligning images and pseudo-captions at the sentence level. To utilize the strength of each, we combined our method with the previous methods as a model initialization method.

We first trained our model on the setting A and generated captions for the images in training data. We then paired the captions with the images as their pseudo-captions[10]. With the pairs, the caption generator of Feng et al. (2019) was initialized by learning to generate the pseudo-captions from the images. After the initialization, we trained the previous model using their publicly available code[11]. We used the same hyperparameters as Feng et al. (2019) except for the learning rate of 10^{-5} for the

---

[9] The number of detected objects was 3.0 in setting A and 4.0 in setting B on average. Thus, taking the mean does not break the detected information significantly.

[10] To avoid assigning obviously incorrect pseudo-captions, we omitted the captions that contained fewer than one detected object for the images with more than two detected objects. For the images with fewer than one detected object, we omitted the captions that contained no detected objects.

Table 5: Bag-of-words matching scores with respect to detected object labels and the other words.

generator and 10^{-8} for the discriminator.

Table 4 shows the results. The combined model further improves the performance of our model and Feng et al. (2019). In particular, the improvement from Feng et al. (2019) is much larger than that from our model. These results suggest that removing the word-level spurious alignment is critical for the subsequent sentence-level alignment.

3.6 Negative Effect of Spurious Alignment

To further investigate the effect of removing the spurious alignment, we evaluated our model on *noisier words*: words other than the detected object labels. Our method discourages from aligning them with images because they are likely to be irrelevant to given images, while previous methods force the alignment. We tested the following bag-of-words matching on the MS COCO test set.

Let S be the bag of words of a caption generated from an image $\boldsymbol{I}$ and T^m be the m-th reference caption of $\boldsymbol{I}$. Given a set of detected object labels $\mathcal{O}$ of $\boldsymbol{I}$, we took the intersections $S_{det} = S \cap \mathcal{O}$ and $S_{other} = S \cap \overline{\mathcal{O}}$ for S, as well as for T^m. We define the precision (P), recall (R) and F1 score (F) of S against T^m as follows: $P = \frac{|S \cap T^m|}{|S|}$, $R = \frac{|S \cap T^m|}{|T^m|}$, $F = 2 \cdot \frac{P \cdot R}{P+R}$. Based on this, we define the precision, recall, and F1 score of S_{det} against T^m_{det} by replacing S with S_{det} and T^m with T^m_{det}, and likewise for those of S_{other} against T^m_{other}. We calculated the above scores for each pair of a generated captions and their reference captions and subsequently averaged it across the pairs. The pairs with empty T^m_* were excluded from the calculation.

Table 5 shows the results. Overall, the scores on detected object labels (Detected) are about two times higher than those on the other words (Others), indicating the difficulty of learning the alignment of the latter, noisier words. Our model performs better in predicting the noisier words, outperforming Feng et al. (2019) in all metrics. These results indicate that refraining from the alignment works better than forcing it for the noisier words.

		Word Type	Frequency
Object	Feng et al. (2019)	205	20013
	Ours	306	15052
	Ours + Feng et al. (2019)	239	18226
Others	Feng et al. (2019)	827	24865
	Ours	169	83693
	Ours + Feng et al. (2019)	121	110358

Table 6: Analysis of generated captions with respect to object labels and the other words. Word Type is the number of unique words, and Frequency is the mean of the frequency of the words in the training text corpus.

On the other hand, our model performs worse in predicting detected object labels. This is because our method trusts all detected object labels and aligns them with images without any constraints used in previous work. Combined with the previous method (Ours + Feng et al. (2019)), our model improves the prediction on detected object labels.

3.7 Positive Effect of Frequency

By assigning the pseudo-label f, our method encourages to align detected object labels with the image representation $\boldsymbol{v}$ and the other words with the contextual representation $\boldsymbol{h}$. Thus, our model is likely to predict the latter words mostly based on the previous output sequences, as language models do. If this is the case, then the latter words predicted tend to be the frequent words in the training text corpus.

To verify this tendency, we analyzed the frequency of output words in the training text corpus for object labels and the other words[12]. Table 6 presents the results. In contrast to object labels, our outputs' vocabulary is about five times smaller than that of Feng et al. (2019), and the words tend to be highly frequent in the training text corpus.

The results also show that a model performs better if it has the smaller and more frequent vocabulary of the words other than object labels. This correlation is convincing considering the coverage of frequent words. For example, a general caption such as "a man *with* a bike" can correctly cover various scenes in which a man is riding/sitting on/leaning on/standing near/... a bike. This positive effect of frequency suggests that firstly aligning the frequent words and gradually extending them can

---

[12] As we analyzed each unique word across all output captions in the MS COCO test set, we roughly divided the words into object labels and the others, not into detected object labels and the others.

be a promising approach.

3.8 Qualitative Analysis on Outputs

Figure 2 shows the captions generated by our model, its ablated models, Feng et al. (2019), and the combined model trained on the setting A. Our model generated correct captions for images (a) and (b). It successfully generated object labels that were not even detected by the object detector: *bat* in (a) and *mirror* in (b). On the other hand, errors of the object detector directly propagated to the output captions of w/o *image* model: the model generated an incorrect object *a bottle of wine*, owing to the missing object *bat* in (a).

Captions of the other images are negative results of our model. We observed that our model tended to repeat similar objects: *cat* and *dog* in (c), and *elephant* and *elephants* in (f). Without unique-object decoding, this tendency got worse: w/o *unique* model repeated *cat* in (c) and (e), and *elephant* in (f). Ours + Feng et al. (2019) model did not change much of the prediction of our model, as we set the learning rate low (see Section 3.5). However, it allowed the partial correction seen in (c): the combined model modified *dog* to *suitcase*.

In our outputs, words other than object labels tended to be frequent words and composed short phrases. On the contrary, Feng et al. (2019) tended to generate less frequent words (*savuti* and *kenya* in (f)) and longer phrases (*portrait of a happy young* in (a) and *young couple in love* in (d)), which were incorrect predictions in these examples.

Figure 3 shows output captions of our model and the gate values for each word. Overall, the gate values were high for object labels and low for the other words. Although our model was correct on the words other than object labels in these examples, these words were generated mostly by contextual features, thus heavily relied on contextual frequency. This heavy reliance on contexts resulted in generating the same word after an object label without considering images: *is sitting on* followed *cat* in both (c) and (e).

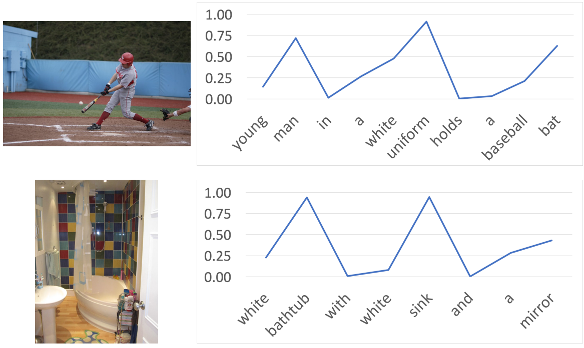

Figure 3: Sample captions with gate values. The plot represents the values of g_t for each predicted word. The value of g_t becomes high when the word is predicted using mainly image representation.

4 Related Work

There has been considerable research with different settings and approaches to describe scenes that have no image–sentence pairs. Novel object captioning (Hendricks et al., 2016; Venugopalan et al., 2017; Anderson et al., 2018a; Agrawal et al., 2019) attempted describing unseen objects in captions.

They incorporated an image classifier or object detector trained on objects not included in image–sentence pairs. Lu et al. (2018) tested captioning models on the generation of unseen combinations of objects, and Nikolaus et al. (2019) extended this to the unseen combinations of objects, attributes, and relations. In both settings, only the combinations were unseen, but each word in the combinations appeared in the training data. Semi-supervised approaches utilized caption retrieval models to automatically collect the corresponding captions for unannotated images to augment image–sentence pairs (Liu et al., 2018; Kim et al., 2019).

The above work was evaluated on the scenes where correct descriptions partially overlapped with those in the training image–sentence pairs. However, there can be scenes with no such overlap due to the limited coverage of the currently available image–sentence pairs. Taking a step further, unsupervised image captioning (Feng et al., 2019; Laina et al., 2019) aims to describe scenes that have no overlap with the image–sentence pairs, without the annotation of the pairs. To test in that situation, the task does not allow to use any image–sentence pairs. The only available resources are images and sentences drawn from different sources and object labels detected from the images.

Feng et al. (2019) first trained an encoder–decoder model that takes object labels in a sentence as its input and outputs the original sentence. After training, this model took the object labels detected from each image and outputted a sentence to pair with the image as its pseudo-caption. These pairs were then used to initialize a caption generator for the subsequent image–sentence alignment: bi-directional (image-to-sentence and sentence-to-image) feature reconstruction and GAN training (Goodfellow et al., 2014) to ensure fluency in generated captions. In the work of Laina et al. (2019), pseudo-captions were sentences that contained object labels detected from a given image. They employed metric learning and GAN training to minimize the difference between images and pseudo-captions in their latent space, as well as to maximize the difference between images and sentences wherein no detected object label was included.

Our approach is different from them in that it focuses on removing the mismatched words of pseudo-captions to take reliable supervision only, rather than forcing the use of the entire pseudo-captions for image–sentence alignment. Although the previous work additionally ensured to align detected object labels to images, they did not prevent the spurious alignment between images and words.

As an eased setting of unsupervised image captioning, unpaired image captioning has also been explored (Feng et al., 2019; Laina et al., 2019; Gu et al., 2019; Liu et al., 2019). The major difference from unsupervised image captioning is that images and sentences are drawn from image–sentence pairs, rather than from different sources. That is, every image has completely matched captions in pseudo-captions, which is not the case in unsupervised image captioning. As correct captions exist for each image, previous approaches focused on matching images and sentences at the sentence level. Contrary to these approaches, we focus on employing unsupervised image captioning and devising a method to remove word-level spurious alignment in the much noisier pseudo-captions.

Another variation of unpaired image captioning is the generation of captions in one language that has no image–sentence pairs, using paired images and captions in another language (Gu et al., 2018; Song et al., 2019). However, this line of research is beyond the scope of our work, as it requires image–sentence pairs to be at least in one language.

Our gating mechanism borrowed the idea of adaptive attention (Lu et al., 2017, 2018). Adaptive attention serves to control when generating words from image representations. Although these methods assume that the control is automatically learned from image–sentence pairs, this is not the case in an unsupervised setting. Our method is different from theirs in that we add heuristic pseudo-labels to train the gate when using image representations.

5 Conclusion

We investigated the importance of removing word-level spurious alignment between images and pseudo-captions in the task of unsupervised image captioning. For this purpose, we introduced a simple gating mechanism trained to align image features with only the most reliable words in pseudo-captions. The experimental results showed that our proposed method outperformed the previous methods without the sentence-level learning objectives used in the previous methods. Moreover, our method improved the performance further by combining with the previous methods. These results confirmed the importance of careful alignment in word-level details.

Towards More Fine-grained and Reliable NLP Performance Prediction

`fujl16@fudan.edu.cn`

Abstract

Performance prediction, the task of estimating a system's performance without performing experiments, allows us to reduce the experimental burden caused by the combinatorial explosion of different datasets, languages, tasks, and models. In this paper, we make two contributions to improving performance prediction for NLP tasks. First, we examine performance predictors not only for holistic measures of accuracy like F1 or BLEU, but also *fine-grained* performance measures such as accuracy over individual classes of examples. Second, we propose methods to understand the *reliability* of a performance prediction model from two angles: confidence intervals and calibration. We perform an analysis of four types of NLP tasks, and both demonstrate the feasibility of fine-grained performance prediction and the necessity to perform reliability analysis for performance prediction methods in the future. We make our code publicly available: `https://github.com/neulab/Reliable-NLPPP`

1 Introduction

Performance prediction (P^2) aims to predict a machine learning system's performance based on features of the underlying problem, dataset, or learning algorithm. While this topic is still relatively unexplored in the NLP context, there are a few examples of predicting performance as: (i) a function of training or model parameters for determining the number of training iterations (Kolachina et al., 2012) or value of hyperparameters (Rosenfeld et al., 2019) and identifying and terminating bad training runs (Domhan et al., 2015). (ii) a function of dataset characteristics to illustrate which factors are significant predictors of system performance (Birch et al., 2008; Turchi et al., 2008), or find a subset of representative experiments to run in order to obtain plausible predictions (Xia et al., 2020). In this paper, we ask two research questions with respect to performance prediction: can we predict performance on a more *fine-grained* level, and can we quantify the *reliability* of performance predictions?

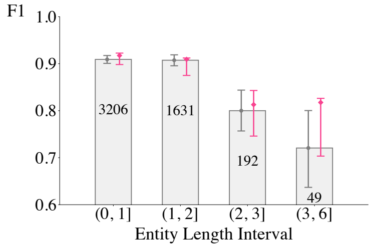

Figure 1: Breakdown of performance over different entity lengths of an NER system. *Actual F1* (gray point) is calculated from actual results while *predicted F1* (red point) is estimated by a performance prediction model. Gray and red lines represent corresponding confidence intervals. Numbers in each bar indicate the number of test samples in each length bucket.

With respect to the first contribution, previous P^2 methods have almost entirely focused on predicting *holistic* measures of accuracy such as entity F1 (Ratinov and Roth, 2009) or BLEU score (Papineni et al., 2002) over the entire dataset (§2.2). However, from a perspective of understanding the workings of our models, work on model analysis has demonstrated the need for more *fine-grained* analysis over a wide variety of tasks (Kummerfeld et al., 2012; Kummerfeld and Klein, 2013; Karpathy et al., 2015; Neubig et al., 2019; Fu et al., 2020a,b,c). These methods calculate separate accuracy scores for different types of examples (e.g. accuracies for entity recognition by entity length). Our first contribution is to examine experimental settings where we predict these fine-grained evaluation scores (§2.3), and also propose performance prediction methods particularly suited to this fine-grained evaluation setting (§3).

Our second contribution is the development of methods for estimating the reliability of performance predictions. While allowing estimation

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3703–3714
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

of experimental results without actually having to run the corresponding experiments may improve efficiency, if the performance predictor is wrong it may lead to missing results of a potentially important experiment. This particularly becomes an issue when developing methods for fine-grained performance prediction, as the number of data points which can be used to predict each performance number decreases as we subdivide datasets into finer-grained categories. Thus, we make methodological steps towards answering two specific questions: (i) how can we define and calculate a confidence interval over performance predictions? (ii) how well does the confidence interval of prediction performance calibrate with the true probability of an experimental result? Fig. 1 is an example of performance prediction and reliability analysis over fine-grained performance estimates (F1 scores over different entity length buckets) of an NER system are obtained in two ways: (i) calculated based on results from the NER system itself (in gray); (ii) estimated based on a performance prediction model, without running an actual experiment (in red). We can observe that: (1) with fewer test samples (e.g. `49`), confidence intervals of both actual and predicted F1 become much wider, suggesting larger uncertainty. (2) in the last bucket, the predicted F1 (red point) is far from the actual F1 (gray point), but with a confidence interval of predicted performance (red bar), the actual F1 still falls within it, indicating the importance of knowing the level of confidence.

In experiments, we investigate the efficacy of different performance prediction models on four typical NLP tasks under both holistic and fine-grained settings, then explore methods for the reliability analysis of these performance prediction models. Major experimental results show: 1) there is no one-size-fits-all model: best-scoring performance prediction systems in different scenarios are diverse. In particular, one of our proposed models achieved the best results on the Part-of-Speech task (§6.1). 2) a better performance prediction model doesn't imply better calibration (§6.2). 3) all four performance prediction models (including previous top-scoring ones) produce confidence intervals over-confidently (§6.2).

2 Performance Prediction: Formulation and Applicable Scenarios

In this section, we will mathematically define performance prediction and its application in the holistic and fine-grained evaluation.

2.1 Formulation

Given a machine learning model $\mathcal{M}$, which is trained over a training set $\mathcal{D}^{tr}$ based on a specific training strategy $\mathcal{S}$, we then test the dataset $\mathcal{D}^{ts}$ under evaluation setting $\mathcal{E}$ and the test result y can be formulated as a function of the following inputs:

$$y = f(\mathcal{M}, \mathcal{D}^{tr}, \mathcal{D}^{ts}, \mathcal{S}, \mathcal{E}), \qquad (1)$$

This we will refer to as the *actual* performance (e.g., F1 score), which requires us to run an actual experiment.

Alternatively, to calculate y, instead of performing a full training and evaluation cycle, one can directly estimate it by extracting features of $\mathcal{M}$, $\mathcal{D}^{tr}$, $\mathcal{D}^{ts}$, $\mathcal{S}$, and running them through a prediction function

$$\hat{y} = g(\Phi_{\mathcal{M}}, \Phi_{\mathcal{D}^{tr}}, \Phi_{\mathcal{D}^{ts}}, \Phi_{\mathcal{S}}, \mathcal{E}; \Theta), \qquad (2)$$

where $\Phi(\cdot)$ represents features of the input, and Θ denotes learnable parameters. We will refer to this as our *predicted* performance. As long as Eq. 2 is fast to calculate and a relatively accurate approximation of Eq. 1, it allows us to get a reasonable idea of expected experimental results much more efficiently than if we had to actually experiment.

In a real scenario, not all inputs in Eq. 2 need to be taken into account, and researchers can adopt different inputs for a particular use. For example, Domhan et al. (2015) define $\hat{y}$ as a function of training strategy $\mathcal{S}$ (e.g., different hyper-parameter settings) so that they can know which training setting can lead to bad performance without running. Dodge et al. (2020) estimate validation performance as a function of computation budget to conduct more robust model comparisons.

Why Performance Prediction matters for NLP tasks Firstly, for some NLP tasks with few resources, it is challenging to build and test systems for all languages or domains. For example, the task of Machine Translation (MT) for low resource languages is hard due to the lack of the large parallel corpora, preventing us from measuring system performance in these scenarios (Xia et al., 2019, 2020). Therefore, performance prediction is useful in that it can efficiently and comprehensively give insights about the workings of models over a wide variety of task settings. Secondly, performance prediction can be used to alleviate the data sparsity problem in fine-grained evaluation, which plays an important role in current NLP task evaluation (Fu et al., 2020a).

In this paper, we consider two performance prediction scenarios, a holistic evaluation setting that most previous works have explored, and a novel setting of predicting fine-grained evaluation metrics. Below, we briefly describe them.

2.2 Holistic Evaluation

Performance prediction in holistic evaluation aims to estimate an overall score (e.g., BLEU) based on dataset characteristics, specifically,

$$\hat{y} = g^{\text{holistic}}(\Phi_{\mathcal{D}^{tr}}, \Phi_{\mathcal{D}^{ts}}; \Theta), \tag{3}$$

where $\Phi(\cdot)$ represents features of input and Θ denotes learnable parameters.

Featurization In practice, we choose a machine translation (MT) task and a Part-of-Speech task (POS) task in this setting. We use the same set of dataset features as (Xia et al., 2020), including the language features and the source and the target, or transfer language.

2.3 Fine-grained Evaluation

In contrast, fine-grained evaluation aims to break down the overall score into different interpretable parts, allowing us to identify the strengths and weakness of learning systems. For example, the accuracy of an NER system with an overall F1 score 90 (%) can be partitioned into four buckets based on different entity lengths l (e.g., $[l = 1, 1 < l \leq 3, 3 < l \leq 5, l > 5]$) of test entities, thereby obtaining fine-grained F1 scores: $[93, 91, 89, 75]$, identifying that the model struggles on longer entities ($l > 5$).

Although fine-grained evaluation is advantageous in interpreting systems' performance, it frequently suffers from the data sparsity problem—a few or no test samples may be included within certain buckets. For example, in the above case it's difficult to calculate the F1 score for entities whose lengths satisfy $l > 7$ since few entities can be found in the whole test set.

With the above dilemma in mind, we define a performance prediction problem in fine-grained evaluation where the paucity of test samples in some buckets leads to an inability to compute performance accurately.

$$\hat{y} = g^{\text{fine}}(\Phi_M, \Phi_{\mathcal{D}^{tr}}, \Phi_{\mathcal{D}^{ts}}; \Theta), \tag{4}$$

where $\Phi(\cdot)$ represents features of input and Θ denotes learnable parameters.

Featurization Performing fine-grained evaluation involves two major steps: (i) partition the test set into different *buckets* based on a certain *aspect* (e.g., `entity length`), (ii) and calculate performance (e.g., `F1 score`) for each bucket. Therefore, data-wise ($\Phi_{\mathcal{D}^{ts}}$), the input of performance prediction function in Eq. 4 ($\mathrm{g}^{fine}(\cdot)$) can be featurized as different types of (i) buckets (ii) aspects (iii) datasets. Additionally, we take (iv) different types of models as input. We present brief descriptions of the above four types of features.

1. *Models*: We choose 12 models for the NER task and 8 models for the Chinese Word Segmentation (CWS) task. The models are built by choosing the different character encoder (e.g., ELMo (Peters et al., 2018) and Flair (Akbik et al., 2018; Akbik et al.)), word embedding (e.g., GloVe (Pennington et al., 2014) and Word2Vec (Mikolov et al., 2013b)), sentence-level encoder (e.g., LSTM (Hochreiter and Schmidhuber, 1997) and CNN (Kalchbrenner et al., 2014)), and decoder (e.g., MLP and CRF (Lample et al., 2016; Collobert et al., 2011)).
2. *Datasets*: We consider 6 (5) datasets for the NER (CWS) task, detailed in appendix.
3. *Attributes*: We consider the interpretable evaluation aspects proposed in works (Fu et al., 2020a). We consider 9 attributes for the NER task and 8 attributes for the CWS task in this paper (e.g, entity length and sentence length).
4. *Buckets*: The test entities (words) of the NER (CWS) task are partitioned into four buckets according to their attribute value. We compute the F1 score for the entities.

3 Parameterized Regression Functions

The performance prediction model takes in a set of features that characterize an experiment's peculiarities and predict performances based on different parameterized regressors $\mathrm{g}(\cdot)$ in Eq. 2. We first describe methods explored by previous works and then present a tensor regression-based approach that is particularly well-suited for fine-grained performance prediction.

3.1 Gradient Boosting Methods

Previous work on performance prediction has used gradient boosted decision tree models (Ganjisaf-

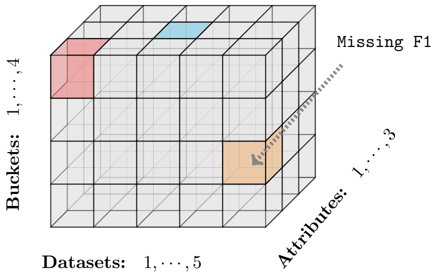

Figure 2: Illustration of performance tensor in the fine-grained evaluation scenario. Colored entries represent missing performances that would be predicted.

far et al., 2011; Chen and Guestrin, 2016), which demonstrate robust performance on the relatively low-data scenarios we often encounter in performance prediction tasks. We specifically explore the following two models:

XGBoost (Chen and Guestrin, 2016) is a tree boosting system widely used to solve problems such as ranking, classification, and regression. We use the same experimental setting as described in (Xia et al., 2020).

LightGBM (Ke et al., 2017) is a gradient boosting framework. Compared with XGBoost, which utilizes a level-wise tree growth in the decision tree, LightGBM uses a leaf-wise splitting method.

3.2 Tensor Regression

Besides gradient boosted trees, we also present tensor regression-based performance prediction models. Tensors are multidimensional arrays that can concisely depict the structure of the data. The order of a tensor is its number of dimensions. For example, in the NER task, the four feature dimensions of a tensor are model, dataset, attribute and bucket, with each slice representing one underlying relationship between the two dimensions. Applying tensor factorization algorithms in the performance prediction setting allows us to determine the interdependencies between multiple aspects of the tasks simultaneously.

Performance Prediction as Tensor Completion To formulate the performance prediction task as a tensor regression problem: (i) we first define a *performance tensor* that each entry stores a performance value under a specific setting determined by input features (described in §2.3); (ii) missing entries in performance tensor can be predicted based on different tensor completion techniques.

Specifically, taking fine-grained evaluation for example, we define a fine-grained performance tensor as $\mathbf{Y} \in \mathbb{R}^{I_1 \times I_2 \times I_3 \times I_4}$, where $\mathbf{Y}_{ijkt}$ denotes the performance (e.g. F1 score) of the i-th model (e.g. `BERT-based Tagger`) on the j-th bucket (e.g. 2_{nd}) that is obtained by partitioning the k-th dataset (e.g. `CoNLL03`) based on the t-th attribute (e.g. `entity length`). I_1, I_2, I_3, I_4 denote the number of models, buckets, datasets, attributes. Fig. 2 elaborates on this, in which three dimensions (buckets, datasets, and attributes) are considered for the sake of presentation.

CP Decomposition The CP decomposition (Hitchcock, 1927) expresses a tensor $\mathbf{Y}$ as a sum of lower rank tensors. For example, an order 4 tensor can be decomposed as the sum of R rank-1 tensors, each being the outer product of four vectors in each dimension.

Robust PCA Robust PCA is a modification of principal component analysis (PCA) (Candès et al., 2009). If a tensor can be conceived as a superposition of low-rank components and a sparse component, Robust PCA attempts to recover the low-rank and sparse components. The sparse components can be considered as the gross, but sparse noise in the dataset.

4 Statistical Preliminaries

Before going into our second contribution to establishing reliability of performance prediction, we describe two relevant concepts from statistics.

4.1 Confidence Interval (CI)

The confidence interval (CI) is a range of possible values for an unknown parameter associated with a *confidence level* of γ (Nakagawa and Cuthill, 2007; Dror et al., 2018) that the actual parameter can fall into the suggested range. Specifically, suppose that we are interested in estimating the underlying true parameter of ω. Given an observed parameter estimate of $\hat{\omega}$, obtained from the data, we aim to compute an interval with a confidence level γ that ω lies in an interval CI.

Commonly, there are two approaches to calculate confidence intervals, depending on our knowledge about the distribution of the statistics of interest. When an analytical form exists and we have reasonable assumptions on the distribution, we can employ the normal theory or use Student's t-distribution to construct a confidence interval.

Regarding data drawn from a completely unknown distribution, a CI can be calculated by a bootstrapping method (Efron, 1992; Johnson, 2001). The main idea behind the bootstrapping method is to simulate the real distribution by sampling with replacement from a distribution that approximates it, thereby allowing us to make inferences about the statistics of interest and construct confidence intervals. Common methods to construct the CI with bootstrap include the percentile method, where after specifying a confidence level γ, we take the range of points that cover the middle γ proportion of bootstrap sampling distribution $\hat{Y}$ as the desired confidence interval, represented by $(Q_{\hat{Y}((1-\gamma)/2)}, Q_{\hat{Y}((1+\gamma)/2)})$, where Q denotes the quantile. Works on establishing confidence for results in NLP tasks using this bootstrap method include Koehn (2004) and Li et al. (2017).

4.2 Model Calibration (MC)

Calibration (Gleser, 1996), also known as reliability, refers to the ability of a model to make good probabilistic predictions. For a discrete distribution over events, a model is said to be well-calibrated if for those events that the model assigns a probability of p, the long-run proportion that the event actually occurs turns out to be p. For example, if a weather forecast model predicts that there is a 0.1 probability of rain at 7 a.m., then when observed on a large number of random trials at 7 a.m., the model is well-calibrated if 0.1 of them actually do result in rain. Similarly, for a classification model matching the probability a model assigns to a predicted label (i.e., *confidence*) and the correctness measure of the prediction (i.e., *accuracy*) (Wang et al., 2020) is desired.

Nonetheless, it is common that a model could have a high predictive accuracy, but poor calibration if the model systematically over- or under-estimates its confidence in the predictions it makes. One way to quantify miscalibration is to use *Expected Calibration Error* (ECE; Nae (2015)), which aims to quantitatively characterize the difference in expectation between confidence and accuracy. To calculate ECE, the predictions should first be partitioned into M buckets based on the confidence of the predictions, where N represents the total number of prediction samples and $|B_m|$ is the number of samples in the m-th bucket. Given these buckets, ECE can be defined as,

$$\mathrm{ECE} = \sum_{m=1}^{M} \frac{|B_m|}{N} |\mathrm{acc}(B_m) - \mathrm{conf}(B_m)|, \quad (5)$$

where $\mathrm{acc}(B_m)$ denotes the accuracy of B_m,

$$\mathrm{acc}(B_m) = \frac{1}{|B_m|} \sum_{i \in B_m} \mathbf{1}(\hat{y}_i = y_i), \quad (6)$$

where $\hat{y}$ and y represent predicted and ground truth labels respectively. $\mathrm{conf}(B_m)$ represents the average confidence of bucket B_m,

$$\mathrm{conf}(B_m) = \frac{1}{|B_m|} \sum_{i \in B_m} \hat{p}_i. \quad (7)$$

where $\hat{p}$ represents the prediction confidence of sample i.

5 On Reliability of P^2 Models

Now we discuss our methodology for predicting the reliability of performance prediction models through confidence intervals and the calibration of those confidence intervals.

5.1 CIs of Predicted Performance

We refer to $y \sim Y$ as an actual observed performance as in Eq. 1 for a specific task (e.g., NER). y is the output of an NLP system learned on a dataset $\mathcal{D} = (\mathcal{D}^{tr}, \mathcal{D}^{ts})$. We refer to $\hat{y} \sim \hat{Y}$ as a predicted performance estimated as Eq. 2. $\hat{y}$ is the output of a performance prediction model learned from a dataset $\Phi(\mathcal{D}) = (\Phi(\mathcal{D}^{tr}), \Phi(\mathcal{D}^{ts}))$, where $\Phi(\cdot)$ represents the input dataset features. Our goal is to compute a confidence interval w.r.t a predicted performance $\hat{y}$, to make inference about Y.

Bootstrap for CI of Predicted Performance One potential challenge is that we cannot make plausible assumptions about the distribution of predicted performances $\hat{Y}$, which prevents us from using popular parametric methods (as mentioned in § 4.1) to calculate the confidence interval. Instead, we resort to a bootstrap resampling method as adopted in (Efron, 1992), to simulate $\hat{Y}$.

To achieve this, we first (i) sample different training sets for the performance prediction model $\Phi(\mathcal{D})_1^{tr}, \Phi(\mathcal{D})_2^{tr}, \cdots, \Phi(\mathcal{D})_K^{tr} \sim \Phi(\mathcal{D})^{tr}$, and then (ii) train K performance prediction models using Eq. 2 on each of the K partitions, and (iii) evaluate K models on $\Phi(\mathcal{D})^{ts}$, thereby obtaining a prediction distribution $\hat{Y}$. From this resampling distribution, we use the percentile method, taking the top $(1-\gamma)/2$ and the bottom $(1+\gamma)/2$ of the distribution as higher and lower bounds for the confidence interval.

5.2 Calibration of CI

Because we calculate confidence intervals of the predicted performance $\hat{y}$, drawn from the distribution of $\hat{Y}$, rather than the actual y from Y, it's still unclear if our predicted CI is reliable enough to cover the actual performance. In other words, "from an infinite number of independent trials, does the true value *actually* lie within the intervals approximately 95% of the times?"

To answer this question, we establish a method to measure calibration for the confidence interval of predicted performance. To check (i) if y could be generally contained in the prediction intervals reasonably well, and (ii) if a prediction model produces predictions that are not over or under-confident, we empirically examine the prediction distributions and establish the reliability of the confidence intervals.

To this end, we extend the definition of calibration in classification setting to our regression problem. Specifically, we formulate confidence level γ as prediction confidence conf defined in Eq. 7, and then the original definition of different M buckets can be instantiated as different confidence levels here: $\gamma_1, \cdots, \gamma_M$. The *accuracy* at each confidence level γ_b defined as follows:

$$\mathrm{acc}(\gamma_b) = \frac{\sum_{i=1}^{N} \mathbb{1}(A < y_i < B)}{N}, \qquad (8)$$

where $i \in [1, N]$, $b \in [1, M]$. N represents the number of test samples. y_i denotes the actual performance for the test sample i. $A = (Q_{\hat{Y}((1-\gamma_b)/2)}$ and $B = Q_{\hat{Y}((1+\gamma_b)/2)})$.

Intuitively, $\mathrm{acc}(\gamma_b)$ represents the relative frequency of the actual value y falling into the predicted confidence interval w.r.t. $\hat{y}$. Fig. 3 illustrates how $\mathrm{acc}(\gamma_b)$ is calculated: given three samples whose performances are to be predicted, the denominator of $\mathrm{acc}(\gamma_b = 0.8)$ is 3 while the numerator tallies how many times (2 in this case) the actual performances (i.e., y_1, y_2, y_3) of three samples fall into the confidence interval (with $\gamma_b = 0.8$) of corresponding bootstrapped distributions.

Based on Eq. 8, we can re-write a calibration error CE as:

$$\begin{aligned} \mathrm{CE} &= \sum_{b=1}^{M} \mid \mathrm{acc}(\gamma_b) - \gamma_b \mid & (9) \\ &= \sum_{b=1}^{M} \mid \frac{\sum_{i=1}^{N} \mathbb{1}(A < y_i < B)}{N} - \gamma_b \mid & (10) \end{aligned}$$

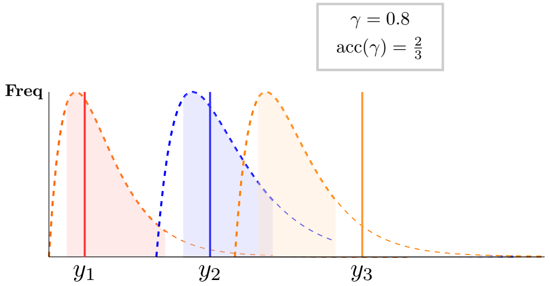

Figure 3: Illustration of calibration on confidence intervals ($\gamma_b = 0.8$) w.r.t. the predicted performance. Solid lines represent actual performances (y) while dashed lines denote resampled predicted performances using bootstrap. Boundaries of shaded areas indicate confidence interval $(Q_{\hat{Y}((1-\gamma_b)/2)}, Q_{\hat{Y}((1+\gamma_b)/2)})$. Intuitively, y_1 and y_2 fall into confidence intervals of corresponding bootstrapped distributions $\hat{Y}_1$ and $\hat{Y}_2$.

6 Experiments

In this section, we break down our experimental results into answering two research questions sections: (1) how well do our underlying performance predictors work, particularly the newly proposed tensor-based predictors and on the newly proposed task of fine-grained performance prediction? (2) how well can we estimate the reliability of our performance predictions?

Models Besides the four performance prediction models (CP, PCA, XGBoost, LGBM) that we have introduced in §3, following Xia et al. (2020), we additionally use a simple mean value baseline model which predicts an average of scores s from the training folds for all test entries in the left-out evaluation fold:

$$\hat{s}^{(i)}_{\text{mean}} = \frac{1}{|\mathcal{D} \setminus \mathcal{D}^{(i)}|} \sum_{s \in \mathcal{D} \setminus \mathcal{D}^{(i)}} s; i \in 1, ...k, \qquad (11)$$

where $\mathcal{D}^{(i)}$ is the left-out data used to evaluate the model performance.

Hyper-parameters Detailed information about the hyper-parameters used in training the performance prediction models in various tasks is provided in the appendix.

Tasks We explore performance prediction on four tasks: (1) Machine Translation (MT) (Schwenk et al., 2019), (2) Part-of-Speech tagging (POS), (3) Named Entity Recognition (NER), (4) Chinese Word Segmentation (CWS). To compare the performance of tensor-based models and gradient boosting models on the same dataset, we convert the datasets used in different prediction tasks to tensors. Statistics of the tensor data are shown in the appendix.

6.1 Evaluation of Performance Prediction

Setup To investigate the effectiveness of the performance prediction models across different tasks, we conduct k-fold cross-validation for evaluation. Specifically, we randomly partition the entire experimental data $\mathcal{D}$ into $k = 5$ folds, use 4 folds for training, and test the model's performance on the remaining fold. To evaluate the result, we calculate the average root mean square error (RMSE) between the predicted scores and the true scores.

Results The RMSE scores of different performance tasks are shown in Tab. 1. Notably, RMSE scores across different tasks should not be compared directly, because the scales of the evaluation metrics are different. We observed that:

(1) Overall, all four models we investigated outperform the baseline by a large margin, indicating their effectiveness on these four performance prediction tasks. (2) Comparing two tensor-based models, PCA consistently outperforms CP. Notably, our proposed tensor regression model (PCA) has surpassed the previous best-performing system (XGBoost (Xia et al., 2020)) on the `POS` dataset and achieved comparable result on the `MT` dataset despite the relatively high sparsity of the tensor (0.346). (3) We observe that CP achieves much worse performance on the `POS` dataset. One potential reason is that: CP is sensitive to datasets (like `POS`) that exhibit large variance along some feature dimensions, which can not be alleviated by feature scaling. (4) There is no one-size-fits-all model: on different datasets, the corresponding best-scoring performance prediction models are diverse, suggesting that we should take dataset's characteristics into account when selecting a model for a specific performance prediction scenario.

Prediction Error Analysis In §1 and Fig. 1, we reveal how entities with different lengths influence the performance prediction, a result of the underlying paucity of data. Here we perform a more detailed error analysis to understand the factors that influence the performance of performance prediction models. Specifically, we perform a case study on the `NER` task using XGBoost and look for feature combinations on which performance predictions show poor results. We use XGBoost to predict F1 scores on all possible combinations of four feature dimensions (models, datasets, attributes, and buckets) to obtain $\hat{y}_{ijkt}$ using the combined test sets from 5-fold cross-validation. For each prediction, we calculate a square residual $(\hat{y}-y)^2$. Then, we group the square residuals by 2 of the 4 dimensions[1] and take their mean value aggregated over the other 2 dimensions. Fig. 4 shows the aggregated mean square residual (MSR) fixed on the model and dataset dimensions, and Fig. 5 shows the result fixed on the attribute and bucket dimensions. In both figures, a high MSR (dark grid) means a poor performance prediction. In Fig. 4, we notice that (1) dataset-wise: `WB` and `WNUT`, and (2) model-wise: *CcnnWgloveLstmMlp* and *CnoneWrandLstmCrf* show poor results. We observe that (1) `WB` is generated from weblogs and `WNUT` is generated from Twitter, both of which are noisy. (2) *CcnnWgloveLstmMlp* does not use a CRF-decoder, and *CnoneWrandLstmCrf* does not encode character-level features, both of which are important characteristics in building an `NER` model. It is plausible that the systems have an unstable performance in those experimental settings and thus make them harder to predict. In Fig. 5, we notice that (1) a lower bucket value along the attributes *entity consistency*, *token consistency*, and *entity density*, (2) a higher bucket value along the attributes *token frequency* or *entity length* lead to poor performance prediction results. In other words, the performance prediction model finds it hard to predict when there is a low label consistency of token or entity, a low entity density, and when token frequency is high and entity is long.

Model	Fine-grained		Holistic	
	NER	**CWS**	**MT**	**POS**
Baseline	0.209	0.137	6.388	29.09
XGBoost	**0.055**	**0.021**	2.463	7.319
LGBM	0.059	0.041	**2.389**	7.673
CP	0.068	0.043	4.065	24.70
PCA	0.057	0.029	2.920	**5.860**

Table 1: Results (RMSE, lower scores indicate better performances) of different performance prediction models on four tasks. The lowest value of each column is bold.

6.2 Evaluation of Reliability

Setup As described in §5.1, we use non-parametric bootstrap to produce confidence intervals for $\hat{y}$. For the holistic evaluation setting, we

---

[1] Readers can refer to this work (Fu et al., 2020a) to get more details.

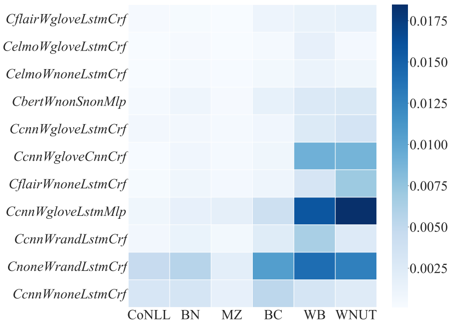

Figure 4: Each grid in the heatmap denotes the mean square residual fixed on the corresponding model (y-axis) and dataset (x-axis) aggregated over all attributes and buckets. The colorbar on the right denotes the value of the mean square residual. Readers can refer to this work (Fu et al., 2020a) to get more details about the information of models and attributes.

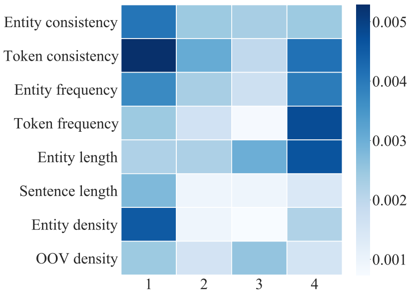

Figure 5: Each grid denotes the mean square residual fixed on the corresponding attribute (y-axis) and bucket (x-axis) aggregated over all models and datasets. Buckets 1 to 4 are ordered in increasing attribute value.

do not include tensor-based models since the property, "*with replacement*", of the bootstrap makes it difficult to construct resampled tensors in the holistic evaluation setting.

When calculating a calibration error as defined in Eq. 10, we set $M = 20$, choosing a range of 20 increasing confidence levels, (i.e. $\gamma_1 = 0.05, \gamma_2 = 0.10 \cdots, \gamma_{20} = 1.00$), to evaluate the correctness of the confidence intervals given by prediction models. Besides using a reliability diagram and a calibration error, to compare the calibration performances of different models more comprehensively, we additionally use the following quantitative metrics: (1) *average width* is the mean range of all the prediction distributions, formally, the difference between the maximum and minimum: $\frac{1}{N}\sum_{i\in[1,N]} \max(\hat{Y}_i) - \min(\hat{Y}_i)$. (2) *coverage* is the value of acc_b evaluated at $\gamma = 1$. (i.e. proportion of y $\hat{y}$ that fall into the distributions $\hat{Y}$, out of all the N prediction entries).

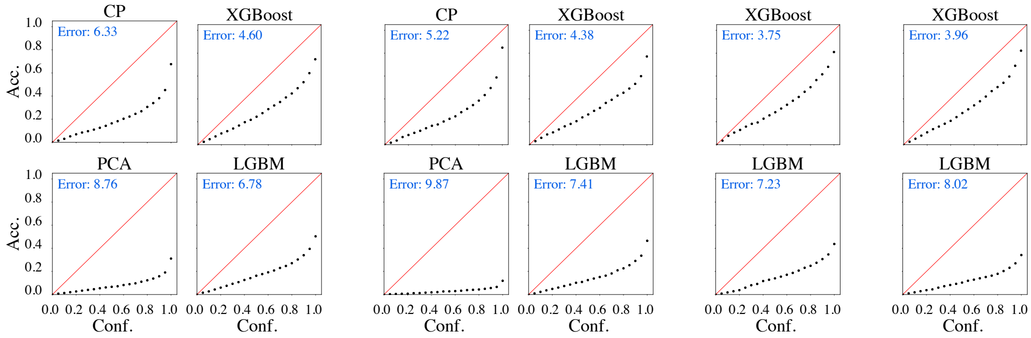
Results The reliability diagram of different models and their corresponding metrics on four tasks are illustrated in Fig. 6 and Tab. 2 respectively. Intuitively, the smaller the CE (calibration error) value is, the more closely the black dotted line becomes diagonal. Ideally, a perfectly calibrated model should have a CE of 0.

Model	CE	Wid.	Cov.	CE	Wid.	Cov.
	NER			CWS		
Baseline	10.47	0.006	0.01	10.50	0.003	0.01
XGBoost	4.60	0.093	0.75	4.38	0.045	0.77
LGBM	6.78	0.093	0.50	7.41	0.029	0.46
CP	6.33	0.110	0.68	5.22	0.099	0.85
PCA	8.76	0.051	0.31	9.87	0.015	0.12
Model	**MT**			**POS**		
Baseline	9.98	1.46	0.08	10.30	3.96	0.03
XGBoost	3.75	5.55	0.81	3.96	17.61	0.82
LGBM	7.23	3.01	0.44	8.02	12.90	0.34

Table 2: Calibration errors (CE), average width (Wid.), coverage (Cov.) of different models over four tasks. (`NER`, `CWS` for fine-grained evaluation setting and `MT`, `POS` for holistic evaluation setting)

From these two tables, we see that: (1) Overall, in both holistic (`MT` and `POS`) and fine-grained settings (`NER` and `CWS`), we see that XGBoost achieves the lowest calibration error together with a higher coverage, especially in the holistic setting. (2) We observe that all of the plots indicate that the intervals produced by the models are over-confident, as the dots lie under the identity function. In other words, given a confidence level γ, the actual accuracy is lower than γ. (3) In Tab. 1, we find that LGBM achieves the lowest RMSE (2.389) in task MT, but its calibration error (7.23) is worse than XGBoost (3.75), implying that a model that predicts accurately is not necessarily well calibrated. This could be explained by the observation that the predicted distribution $\hat{Y}$ of LGBM has a narrower width (3.01). Given a large number of trials predicted by LGBM, we cannot be confident that the true y is contained in the range of values predicted.

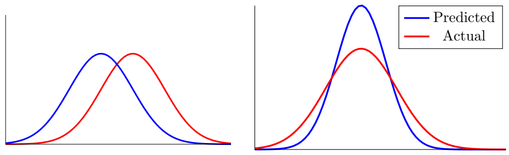
Case Analysis To get a better understanding of how calibration analysis is conducted on different performance models, we perform a case study on `NER` task. Fig. 7(a-b) illustrates two plots that artificially simulate two common relations following Diebold et al. (1997) between actual and predicted distribution: (i) *Bias* (ii) *Over-confidence*. From Tab. 2, we see that XGBoost is better calibrated than LGBM in NER task. To interpret this gap, we (i) first randomly select test samples from NER dataset and then (ii) use two performance prediction models XGBoost and LGBM to produce blue



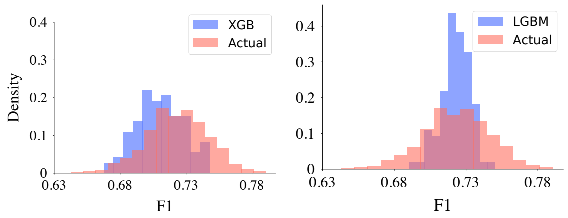
(a) NER (b) CWS (c) MT (d) POS

Figure 6: Calibration of different performance prediction models on four tasks (`NER`, `CWS` for fine-grained evaluation setting and `MT`, `POS` for holistic evaluation setting).

distributions in Fig. 7(c-d) using the bootstrap (as §5.1). A perfectly calibrated model will show a histogram shape that resembles the actual one. We can see that the histogram shape of (d) signifies an over-confidence problem, in which the predicted distribution (in blue) is covered by the actual distribution (in red). By contrast, in (c) the histogram of XGBoost in blue shifts to the left compared with the actual observed distribution, indicating that the prediction on this bucket is biased.



(a) Bias (b) Over-Confident



(c) Bias (d) Over-Confident

Figure 7: The first row of two plots (a,b) artificially simulate two typical relations between actual and predicted distributions. The second row of two plots (c,d) show two real-world distributions of predicted performance w.r.t one test sample from NER task against corresponding actual distributions.

7 Implications and Future Directions

In this work, we not only widen the applicability of performance prediction, extending it to fine-grained evaluation scenarios, but also establish a set of reliability analysis mechanisms to improve its practicality. In closing, we highlight some potential future directions:

Confidence over confidence: Our work provides an idea for reliability analysis of the predicted confidence interval, which could also be explored on other scenarios, e.g., density forecasting (Diebold et al., 1997). Another potentially valuable research topic is to build connections with the probability integral transform (Angus, 1994), which is a typical method of calibration evaluation in financial risks, and our proposed calibration method.

Calibration for automated evaluation metrics: From a broader point of view, the role of existing learnable automatic evaluation metrics for text generation, such as BLEURT (Sellam et al., 2020) and COMET (Rei et al., 2020), is similar to a performance prediction model (i.e., both take features of input data as input and then output an evaluation score). Reliability analysis of these metrics is also an important topic since they determine the direction of model optimization.

A Datasets

Named Entity Recognition (NER) We choose two well-established benchmark datasets: CoNLL-2003 [2] and OntoNotes 5.0. [3] CoNLL-2003 is drawn from Reuters news. OntoNotes 5.0 is collected from newsgroups (`NW`), broadcast news (`BN`), broadcast conversation (`BC`), weblogs (`WB`), magazine genre (`MZ`), and telephone speech (`TC`), in which the first five genres of text are used in this paper.

Chinese Word Segmentation (CWS) We consider five mainstream datasets: `CKIP`, `CTB`, `MSR`, `NCC`, and `SXU`, from SIGHAN2005 [4] and SIGHAN2008 [5]. The traditional Chinese characters in `CKIP` are mapped to simplified Chinese characters in our experiment.

B Models

Our NER (CWS) models can be decomposed into four aspects: 1) character/subword encoders; 2) word (bigram) embeddings; 3) sentence-level encoders; 4) decoders.

The four aspects of NER can be summarized as: 1) character/subword encoder: `ELMo` (Peters et al., 2018), `Flair` (Akbik et al., 2018; Akbik et al.), `BERT` [6] (Peters et al., 2018; Devlin et al., 2018); 2) additional word embeddings: `GloVe` (Pennington et al., 2014); 3) sentence-level encoders: `LSTM` (Hochreiter and Schmidhuber, 1997), `CNN` (Kalchbrenner et al., 2014; Chen et al., 2019); 4) decoders: `MLP` or `CRF` (Lample et al., 2016; Collobert et al., 2011).

The four aspects' setting of CWS: 1) character/subword encoder: `ELMo`, `BERT`; 2) bigram embeddings: `Word2Vec` (Mikolov et al., 2013a), averaging the embedding of two contiguous characters; the settings of 3) the sentence-level encoders and 4) decoders are equal to NER.

Feature	NER	CWS	MT	POS
Sparisity	0.0	0.0	0.346	0.019
Shape	(11,6,9,4)	(5,8,8,4)	(39,39,22)	(26,60,14)

Table 3: Statistics of performance tensors for four tasks. *Sparsity* denotes the percentage of missing values in the tensor

We can also do bootstrap for predictions using regression models. If we consider recovering missing data with CP decomposition as a prediction method, we can construct a CI on the predicted values too.

C Hyper-parameters

For XGBoost, we use squared error as the objective function for regression and set the learning rate as 0.1. We allow the maximum tree depth to be 10, the number of trees to be 100, and use the default regularization terms to prevent the model from overfitting. For LGBM, we set the objective as regression for LGBMRegressor, the number of boosted trees and maximum tree leaves to be 100, adopt a learning rate of 0.1, and use the default regularization terms. For the Robust PCA model, we scale all the datasets, adopt the default regularization parameter of 1 for both the low rank and the sparse tensor, and set the learning rate as 1.1. For CP Decomposition, we do not standardize the features in CWS and NER, but do so for WMT and POS. We adopt a rank $r = 5$ in training and performance prediction, expressing the recovered tensor used for prediction to be a sum of 5 rank-1 tensors.

Statistics of Tensor Tab. 3, where *sparsity* denotes the percentage of missing values in the tensor.

Metrical Tagging in the Wild:
Building and Annotating Poetry Corpora with Rhythmic Features

Thomas Haider

Max Planck Institute for Empirical Aesthetics, Frankfurt am Main
Institute for Natural Language Processing (IMS),
University of Stuttgart
`thomas.haider@ae.mpg.de`

Abstract

A prerequisite for the computational study of literature is the availability of properly digitized texts, ideally with reliable meta-data and ground-truth annotation. Poetry corpora do exist for a number of languages, but larger collections lack consistency and are encoded in various standards, while annotated corpora are typically constrained to a particular genre and/or were designed for the analysis of certain linguistic features (like rhyme). In this work, we provide large poetry corpora for English and German, and annotate prosodic features in smaller corpora to train corpus driven neural models that enable robust large scale analysis.

We show that BiLSTM-CRF models with syllable embeddings outperform a CRF baseline and different BERT-based approaches. In a multi-task setup, particular beneficial task relations illustrate the inter-dependence of poetic features. A model learns foot boundaries better when jointly predicting syllable stress, aesthetic emotions and verse measures benefit from each other, and we find that caesuras are quite dependent on syntax and also integral to shaping the overall measure of the line.

1 Introduction

Metrical verse, lyric as well as epic, was already common in preliterate cultures (Beissinger, 2012), and to this day the majority of poetry across the world is drafted in verse (Fabb and Halle, 2008). In order to reconstruct such oral traditions, literary scholars mainly study textual resources (rather than audio). The rhythmical analysis of poetic verse is still widely carried out by example- and theory-driven manual annotation of experts, through so-called close reading (Carper and Attridge, 2020; Kiparsky, 2020; Attridge, 2014; Menninghaus et al., 2017). Fortunately, well-defined constraints and the regularity of metrically bound language aid the prosodic interpretation of poetry.

However, for projects that work with larger text corpora, close reading and extensive manual annotation are neither practical nor affordable. While the speech processing community explores end-to-end methods to detect and control the overall personal and emotional aspects of speech, including fine-grained features like pitch, tone, speech rate, cadence, and accent (Valle et al., 2020), applied linguists and digital humanists still rely on rule-based tools (Plecháč, 2020; Anttila and Heuser, 2016; Kraxenberger and Menninghaus, 2016), some with limited generality (Navarro-Colorado, 2018; Navarro et al., 2016), or without proper evaluation (Bobenhausen, 2011). Other approaches to computational prosody make use of lexical resources with stress annotation, such as the CMU dictionary (Hopkins and Kiela, 2017; Ghazvininejad et al., 2016), are based on words in prose rather than syllables in poetry (Talman et al., 2019; Nenkova et al., 2007), are in need of an aligned audio signal (Rosenberg, 2010; Rösiger and Riester, 2015), or only model narrow domains such as iambic pentameter (Greene et al., 2010; Hopkins and Kiela, 2017; Lau et al., 2018) or Middle High German (Estes and Hench, 2016).

To overcome the limitations of these approaches, we propose corpus driven neural models that model the prosodic features of syllables, and to evaluate against rhythmically diverse data, not only on syllable level, but also on line level. Additionally, even though practically every culture has a rich heritage of poetic writing, large comprehensive collections of poetry are rare. We present in this work datasets of annotated verse for a varied sample of around 7000 lines for German and English. Moreover, we collect and automatically annotate large poetry corpora for both languages to advance computational work on literature and rhythm. This may include the analysis and generation of poetry, but also more general work on prosody, or even speech synthesis.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3715–3725
April 19 - 23, 2021.

Our main contributions are:

1. The collection and standardization of heterogenous text sources that span writing of the last 400 years for both English and German, together comprising over 5 million lines of poetry.
2. The annotation of prosodic features in a diverse sample of smaller corpora, including metrical and rhythmical features and the development of regular expressions to determine verse measure labels.
3. The development of preprocessing tools and sequence tagging models to jointly learn our annotations in a multi-task setup, highlighting the relationships of poetic features.

2 Manual Annotation

We annotate prosodic features in two small poetry corpora that were previously collected and annotated for aesthetic emotions by Haider et al. (2020). Both corpora cover a time period from around 1600 to 1930 CE, thus encompassing public domain literature from the modern period. The English corpus contains 64 poems with 1212 lines. The German corpus, after removing poems that do not permit a metrical analysis, contains 153 poems with 3489 lines in total. Both corpora are annotated with some metadata such as the title of a poem and the name and dates of birth and death of its author. The German corpus further contains annotation on the year of publication and literary periods.

Figure 1 illustrates our annotation layers with three fairly common ways in which poetic lines can be arranged in modern English. A poetic line is also typically called *verse*, from Lat. *versus*, originally meaning to turn a plow at the ends of successive furrows, which, by analogy, suggests lines of writing (Steele, 2012).

In this work, we manually annotate the sequence of syllables for metrical (meter, met) prominence (+/−), including a grouping of recurring metrical patterns, i.e., foot boundaries (|). We also operationalize a more natural speech rhythm (rhy) by annotating pauses in speech, caesuras (:), that segment the verse into rhythmic groups, and in these groups we assign main accents (2), side accents (1) and null accents (0). In addition, we develop a set of regular expressions that derive the verse measure (msr) of a line from its raw metrical annotation.

In English or German, the rhythm of a linguistic utterance is basically determined by the sequence of syllable-related accent values (associated with pitch, duration and volume/loudness values) resulting from the 'natural' pronunciation of a line, sentence or text by a competent speaker who takes into account the learned inherent word accents as well as syntax- and discourse-driven accents. Thus, lexical material comes with n-ary degrees of stress, depending on morphological, syntactic, and information structural context. The prominence (or stress) of a syllable is thereby dependent on other syllables in its vicinity, such that a syllable is pronounced relatively louder, higher pitched, or longer than its adjacent syllable.

```
msr iambic.pentameter
met −  + | −   + | −   + |  −  +| −  + |
rhy 0  1   0   0   0   2 :  0  1  0  2  :
   My love is like to ice, and I to fire:

msr iambic.tetrameter
met  −   + |−   + | −   + | −   +  |
rhy  0   1  0   2   0   0   0   1  :
    The winter evening settles down

msr trochaic.tetrameter
met  +    − | +   − | +  −  | +
rhy  0    0   1   0   1  0    2  :
    Walk the deck my Captain lies,
```

Figure 1: Examples of rhythmically annotated poetic lines, with meter (+/−), feet (|), main accents (2,1,0), caesuras (:), and verse measures (msr). Authors: Edmund Spenser, T.S. Eliot, and Walt Whitman.

2.1 Annotation Workflow

Prosodic annotation allows for a certain amount of freedom of interpretation and (contextual) ambiguity, where several interpretations can be equally plausible. The eventual quality of annotated data can rest on a multitude of factors, such as the extent of training of annotators, the annotation environment, the choice of categories to annotate, and the personal preference of subjects (Mo et al., 2008; Kakouros et al., 2016).

Three university students of linguistics/literature were involved in the manual annotation process. They annotated by silent reading of the poetry, largely following an intuitive notion of speech rhythm, as was the mode of operation in related work (Estes and Hench, 2016). The annotators additionally incorporated philological knowledge to recognize instances of poetic license, i.e., knowing how the piece is supposed to be read. Especially the annotation accuracy of metrical syllable stress and foot boundaries benefited from recognizing the schematic consistency of repeated verse measures, license through rhyme, or particular stanza forms.

2.2 Annotation Layers

In this paper, we incorporate both a linguistic-systematic and a historically-intentional analysis (Mellmann, 2007), aiming at a systematic linguistic description of the prosodic features of poetic texts, but also using labels that are borrowed from historically grown traditions to describe certain forms or patterns (such as verse measure labels).

We evaluated our annotation by calculating Cohen's Kappa between annotators. To capture different granularities of correctness, we calculated agreement on syllable level (accent/stress), between syllables (for foot or caesura), and on full lines (whether the entire line sequence is correct given a certain feature).

Main Accents & Caesuras: Caesuras are pauses in speech. While a caesura at the end of a line is the norm (to pause at the line break) there are often natural pauses in the middle of a line. In few cases the line might also run on without a pause. As can be seen in Figure 1, punctuation is a good signal for caesuras. Caesuras (csr) are denoted with a colon. We operationalize rhythm by annotating three degrees of syllable stress, where the verse is first segmented into rhythmic groups by annotating caesuras, and in these groups we assign main accents (2), side accents (1) and null accents (0).

	Syllable		Whole Line	
	m.ac	caesura	m.ac	caesura
DE$_{blind}$	.84	.92	.59	.89
EN$_{blind}$	.80	.88	.66	.86

Table 1: Cohen Kappa Agreement for Main Accents and Caesura

Six German and ten English poems were annotated by two annotators to calculate the agreement for rhythm. Table 1 lists the agreement figures for main accents (m.ac) and caesuras. It shows that caesuras can be fairly reliably detected through silent reading in both languages. On the other hand, agreement on main accents is challenging. Figure 2 shows the confusion of main accents for German. While 0s are quite unambiguous, it is not always clear when to set a primary (2) or side accent (1).

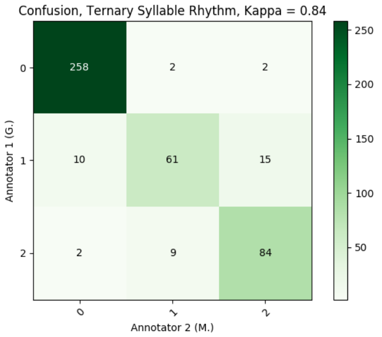

Figure 2: Confusion of German Main Accents

Meter and Foot: In poetry, meter is the basic prosodic structure of a verse. The underlying abstract, and often top-down prescribed, meter consists of a sequence of beat-bearing units (syllables) that are either prominent or non-prominent.Non-prominent beats are attached to prominent ones to build metrical feet (e.g. iambic or trochaic ones). This metrical structure is the scaffold, as it were, for the linguistic rhythm. Annotators first annotated the stress of syllables and in a subsequent step determined groupings of these syllables with foot boundaries, thus a foot is the grouping of metrical syllables. The meter (or measure) of a verse can be described as a regular sequence of feet, according to a specific sequence of syllable stress values.

	Syllable		Whole Line	
	meter	foot	meter	foot
DE$_{corr.}$	.98	.87	.94	.71
DE$_{blind}$	.98	.79	.92	.71
EN$_{blind}$	.94	.95	.87	.88

Table 2: Cohen Kappa Agreement for Metrical Stress and Foot Boundaries. Corr. is the agreement of the first version against the corrected version. Blind means that annotators did not see another annotation.

The meter annotation for the German data was first done in a full pass by a graduate student. A second student then started correcting this annotation with frequent discussions with the first author. While on average the agreement scores for all levels of annotation suggested reliable annotation after an initial batch of of 20 German poems, we found that agreement on particular poems was far lower than the average, especially for foot boundaries. Therefore, we corrected the whole set of 153 German poems, and the first author did a final pass. The agreement of this corrected version with the first version is shown in Table 2 in the row DE$_{corr.}$. To check whether annotators also agree when not exposed to pre-annotated data, a third annotator and the second annotator each annotated 10 diverse German poems from scratch. This is shown in DE$_{blind}$. For English, annotators 2 and 3 annotated 6 poems blind and then split the corpus.

Notably, agreement on syllables is acceptable, but feet were a bit problematic, especially for German. To investigate the sources of disagreement, we annotated and calculated agreement on all 153 poems. Close reading for disagreement of foot boundaries revealed that poems with κ around .8 had faulty guideline application (annotation error). 14 poems had an overall $\kappa < .6$, which stemmed from ambiguous rhythmical structure (multiple annotations are acceptable) and/or schema invariance, where a philological eye considers the whole structure of the poem and a naive annotation approach does not render the intended prosody correctly.

As an example for ambiguous foot boundaries, the following poem, Schiller's 'Bürgschaft', can be set in either *amphibrachic* feet, or as a mixture of *iambic* and *anapaestic* feet. Such conflicting annotations were discussed by Heyse (1827), who finds that in the Greek tradition the *anapaest* is preferable, but a 'weak amphibrachic gait' allows for a freer rhythmic composition. This suggests that Schiller was breaking with tradition.

```
(Foot Boundary Ambiguity) Schiller, 'Die Bürgschaft'

(1) met="-+-|-+-|-+-|"
    Ich lasse |    den Freund   dir | als Bürgen, |
(2) met="-+|--+|--+|-"
    Ich las   | se den Freund | dir   als Bürg | en,
Transl.: I leave this friend to you as guarantor

(1) met="-+-|-+-|-+-|"
    Ihn magst   du, | entrinn'   ich, | erwürgen. |
(2) met="-+|--+|--+|-"
    Ihn magst | du,   entrinn' | ich,   erwür | gen.
Transl.: Him you may strangle if I escape.

(1) (amphibrach)
(2) (iambus / anapaest)
```

Verse Measures: We develop a set of regular expressions to determine the measure of a line from its raw metrical annotation. We orient ourselves with the handbook of Knörrich (1971). The 'verse measure' (msr) is a label for the whole line according to recurring metrical feet. We label the verse according to its dominant foot, i.e., the repetition of patterns like `iambus` (−+), `trochee` (+−), `dactyl` (+−−), `anapaest` (−−+), or `amphibrach` (−+−). Also, the rules determine the number of stressed syllables in the line, where *di-*, *tri-*, *tetra-*, *penta-*, and *hexameter* signify 2, 3, 4, 5, and 6 stressed syllables accordingly. Thus, `+-+-+-` is an example for a trochaic.trimeter and `-+-+-+-+` is a iambic.tetrameter, since the foot boundaries should look like this: `-+|-+|-+|-+|`. Typically, female (unstressed) line endings are optional (cadence). Additionally, we annotate labels for (i) `inversion`, when the first foot is inverted, e.g., the first foot in a iambic line is trochaic: `+--+-+-+`, (ii) `relaxed`, if an unstressed syllable was inserted: `-+-+--+-+` (iambic.tetrameter.relaxed), (iii) and choliambic endings: `-+-+-+--+`. Besides these basic forms, we also implement historically important forms such as a strict `alexandrine`,[1] the `dactylic hexameter`,[2] conventionally known as 'hexameter', and some ode forms like the `asklepiadic` verse (`+-+--++--+-+`).

Table 3 lists the most frequent labels for each language without length, called short measure (smsr). The English data includes all datasets that are used in the experiments, as discussed in section 4.1.3.

English		German	
freq.	smsr	freq.	smsr
2096	iambic	1976	iambic
490	trochaic	793	trochaic
306	anapaest	258	amphibrach
255	amphibrach	206	alexandrine
248	daktylic	76	daktylic
152	hexameter	72	anapaest
91	prosodiakos	26	asklepiade
52	other	17	pherekrateus
35	alexandrine	14	glykoneus

Table 3: Most frequent verse measures in small English and German corpora, without length.

3 Large Poetry Corpora

In order to enable large scale experiments on poetry, we collect and standardize large poetry corpora for English and German. The English corpus contains around 3 million lines, while the German corpus contains around 2 million lines. The corpora and code can be found at `https://github.com/tnhaider/metrical-tagging-in-the-wild`

---

[1] Alexandrine: `-+-+-+-+-+-+-?`
The symbol before ? is optional

[2] Hexameter: `+--?+--?+--?+--?+--+-`

Our resources are designed in a standardized format to sustainably and interoperably archive poetry in both .json and TEI P5 XML. The .json format is intended for ease of use and speed of processing while retaining some expressiveness. Our XML format is built on top of a “Base Format”, the so-called DTA-Basisformat[3] (Haaf et al., 2014) that not only constrains the data to TEI P5 guidelines, but also regarding a stricter relaxNG schema that we modified for our annotation.[4]

3.1 A Large German Poetry Corpus

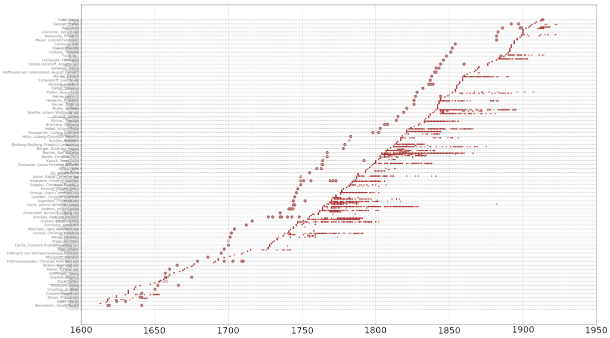

Figure 3: Each dot represents a poem of a German Author (y-axis) over Time (x-axis) from Textgrid (small dots bottom) and DTA (large dots top). 1600–1950. Authors are not aligned, and poems can be on top of each other.

We built a large, comprehensive, and easily searchable resource of New High German poetry by collecting and parsing the bulk of digitized corpora that contain public domain German literature. This includes the German Text Archive (DTA) (`http://deutschestextarchiv.de`) the Digital Library of Textgrid (`http://textgrid.de`), and also the German version of Project Gutenberg (which we omit from our experiments due to inconsistency).[5]

Each of these text collections is encoded with different conventions and varying degrees of consistency. Textgrid contains 51,264 poems with the genre label ‘Verse’, while DTA contains 23,877 poems with the genre label ‘Lyrik’. It should be noted that the whole DTA corpus contains in total 40,077 line groups that look like poems, but without the proper genre label, poems are likely embedded within other texts and might not come with proper meta-data. We implement XML parsers in python to extract each poem with its metadata and fix stanza and line boundaries. The metadata includes the author name, the title of the text, the year it was published, the title and genre of the volume it was published in, and finally, an identifier to retrieve the original source. We perform a cleaning procedure that removes extant XML information, obvious OCR mistakes, and normalize umlauts and special characters in various encodings,[6] particularly in DTA. We use langdetect[7] 1.0.8 to tag every poem with its language to filter out any poems that are not German (such as Latin or French). The corpus finally almost 2M lines in over 60k poems. In Figure 3 we plotted each poem in DTA and Textgrid over time, from 1600 to 1950. The x-axis shows the year of a poem, while the y-axis is populated by authors. One can see that DTA consists of full books that are organized by author (large dots) so that the datapoints for single poems get plotted on top of each other, while Textgrid has a time stamp for most single poems (after 1750), outlining the productive periods of authors.

3.2 A Large English Poetry Corpus

The English corpus contains the entirety of poetry that is available in the English Project Gutenberg (EPG) collection. We firstly collected all files with the metadatum ‘poetry’ in (temporal) batches with the GutenTag tool (Brooke et al., 2015), to then parse the entire collection in order to standardize the inconsistent XML annotation of GutenTag and remove duplicates, since EPG contains numerous different editions and issues containing the same material. We also filter out any lines (or tokens) that indicate illustrations, stage directions and the like. We use langdetect to filter any non-English material.

The github repository of Parrish (2018) previously provided the poetry in EPG by filtering single lines with a simple heuristic (anything that could look like a line), not only including prose with line breaks, but also without conserving the integrity of poems but providing a document identifier per line to find its origin. We offer our corpus in XML with intact document segmentation and metadata, still containing over 2.8 million lines.

---

[3] `http://www.deutschestextarchiv.de/doku/basisformat/`

[4] This schema defines a strict layout of poetic annotation. It allows us to validate XML files regarding their correctness. It is thus useful for manual annotation with the OxygenXML editor, avoiding parsing errors downstream.

[5] `https://www.projekt-gutenberg.org/`

[6] We fix the orthography both on string and bytecode level. We replace the rotunda (U+A75B) and the long s (U+017F), the latter of which is pervasive in DTA.

[7] `https://pypi.org/project/langdetect/`

4 Experiments

In the following, we carry out experiments to learn the previously annotated features and determine their degree of informativeness for each other with a multi-task setup. We include two additional datasets with English meter annotation, and evaluate pre-processing models for syllabification and part-of-speech tagging.

4.1 Preprocessing

Tokenization for both languages is performed with SoMaJo with a more conservative handling of apostrophes (to leave words with elided vowels intact) (Proisl and Uhrig, 2016). This tokenizer is more robust regarding special characters than NLTK. We also train models for hyphenation (syllabification) and part-of-speech (POS) tagging, since syllabification is a prerequisite to analyse prosody, and POS annotation allows us to gauge the role of syntax for prosodic analysis.

4.1.1 Hyphenation / Syllabification

For our purposes, proper syllable boundaries are paramount to determine the segmentation of lines regarding their rhythmic units. The test the following systems:[8] *Sonoripy*,[9] *Pyphen*,[10] *hypheNN*,[11] and a BiLSTM-CRF (Reimers and Gurevych, 2017)[12] with pretrained word2vec character embeddings. These embeddings were trained on the corpora in section 3.

To train and test our models, we use CELEX2 for English and extract hyphenation annotation from wiktionary for German.[13] We evaluate our models on 20,000 random held-out words for each language on word accuracy and syllable count. Word accuracy rejects any word with imperfect character boundaries, while syllable count is the more important figure to determine the proper length of a line. As seen in Table 4, the BiLSTM-CRF performs best for English and does not need any postprocessing. For German, the LSTM model is less useful as it tends to overfit, where over 10% of annotated lines were still rejected even though in-domain evaluation suggests good performance. We therefore use an ensemble with HypheNN, Pyphen and heuristic corrections for German, with only 3% error on the gold data, as seen in Table 5 (the datasets are discussed in section 4.1.3).

	German		English	
	w. acc.	sy. cnt	w. acc.	sy. cnt
SonoriPy	.476	.872	.270	.642
Pyphen	.839	.875	.475	.591
HypheNN	.909	.910	.822	.871
BiLSTM-CRF	**.939**	**.978**	**.936**	**.984**

Table 4: Evaluation of Syllabification Systems on Wiktionary (German) and CELEX (English).

	German	EPG64	FORB	PROS
# correct lines	3431	1098	1084	1564
# faulty lines	58	114	49	173

Table 5: Size of manually annotated corpora. Faulty lines denotes the number of lines where the automatic syllabification failed. Correct lines are used for experiments, since only there the gold annotation aligns.

4.1.2 POS tagging

Since we are dealing with historical data, POS taggers trained on current data might degrade in quality and it has been frequently noted that poetry makes use of non-canonical syntactic structures (Gopidi and Alam, 2019). For German, we evaluate the robustness of POS taggers across different text genres. We use the gold annotation of the TIGER corpus (modern newspaper), and pre-tagged sentences from DTA, including annotated poetry (Lyrik), fiction (Belletristik) and news (Zeitung).[14] The STTS tagset is used. We train and test Conditional Random Fields (CRF)[15] to determine a robust POS model.[16] See Table 7 for an overview of the cross-genre evaluation. We find that training on TIGER is not robust to tag across domains, falling to around .8 F1-score when tested

---

[8] Syllabipy determines boundaries based on the sonority principle, Pyphen uses the Hunspell dictionaries, and HypheNN is a simple feed forward network that is trained on character windows.

[9] `https://github.com/alexestes/SonoriPy` `https://github.com/henchc/syllabipy`

[10] `pyphen.org`

[11] `github.com/msiemens/HypheNN-de`

[12] `https://github.com/UKPLab/emnlp2017-bilstm-cnn-crf`

[13] For German, wiktionary contains 398.482 hyphenated words, and 130.000 word forms in CELEX. Unfortunately, German CELEX does not have proper umlauts, and models trained on these were not suitable for poetry. For English, wiktionary only contains 5,142 hyphenated words, but 160,000 word forms in CELEX.

[14] DTA was tagged with TreeTagger and manually corrected afterwards. `http://www.deutschestextarchiv.de/doku/pos`

[15] From the sklearn crf-suite

[16] As features, we use the word form, the preceding and following two words and POS tags, orthographic information (capitalization), character prefixes and suffixes of length 1, 2, 3 and 4.

POS	Noun	Adj.	Full V.	Adverb	Modal V.	Interj.	Pron.	Prep.	Konj.	Art.
Abr. POS Tag	NN	ADJ	VV	ADV	VM	ITJ	P	AP	KO	AR
Accent Ratio	.97	.89	.84	.75	.73	.55	.4–.015	.27	.23	.06

Table 6: Accent ratio for part-of-speech of German monosyllabic words (ratio of metrical stress).

against poetry and news from DTA. These results suggest that this is mainly due to (historical) orthography, and to a lesser extent due to local syntactic inversions.

Test	Train				
	TIGER	DTA	DTA+TIG.	Belletr.	Lyrik

TIGER	**.971**	.928	.958	.929	.913

Table 7: Evaluation of German POS taggers across genres. F1-scores.

For English, we test the Stanford core-nlp tagger.[17] The tagset follows the convention in the Penn TreeBank. This tagger is not geared towards historical poetry and consequently fails in a number of cases. We manually correct 50 random lines and determine an accuracy of 72%, where particularly the 'NN' tag is overused. This renders the English POS annotation unreliable for our experiments.

4.1.3 Additional Data and Format

The annotated corpora for English include: (1) The for-better-for-verse (FORB) collection[18] with around 1200 lines which was used by Agirrezabal et al. (2016, 2019), and (2) the 1700 lines of poetry against which `prosodic`[19] (Anttila and Heuser, 2016; Algee-Hewitt et al., 2014) was evaluated (PROS). We merge these with our own (3) 1200 lines in 64 English poems (EPG64). The first two corpora were already annotated for metrical syllable stress. However, FORB does not contain readily available foot boundaries, and in PROS foot boundaries are occasionally set after each syllable.[20] Table 5 shows the number of lines in each of our datasets and the number of lines that were incorrectly segmented by our best syllabification systems.

Figure 4 shows an example line in the data layout that is used for the experiments, including the 'measure' that was derived with regular expressions from the meter line. 'Syll' is the position of the syllable in a word, 0 for monosyllaba, otherwise index starting at 1. We removed punctuation to properly render line measures, even through punctuation is a good signal for caesuras (see Figure 1).

```
# tok  met ft pos syll csr main smsr    measure    met_line

4.2 Accent Ratio of Part-of-Speech

Previous research has noted that part-of-speech annotation provides a good signal for the stress of words (Nenkova et al., 2007; Greene et al., 2010). To test this, we calculate the pos-accent ratio of monosyllabic words in our German annotation by dividing how often a particular part-of-speech appears stressed (+) in the corpus by how often this part-of-speech occurs in the corpus. We restrict this to monosyllabic words, as polysyllabic words typically have a lexical stress contour. The result is a hierarchy of stress that we report in Table 6. At the ends of the spectrum, we see that nouns are usually stressed, while articles are seldom stressed.

4.3 Learning Meter

To learn the previously annotated metrical values for each syllable, the task is framed as sequence classification. Syllable tokens are at the input and

---

[17] `https://nlp.stanford.edu/software/tagger.shtml`

[18] `https://github.com/manexagirrezabal/for_better_for_verse/tree/master/poems`

[19] `https://github.com/quadrismegistus/prosodic`

[20] Additionally, FORB makes use of a `<seg>` tag to indicate syllable boundaries, so we do not derive the position of a syllable in a word. It also contains two competing annotations, `<met>` and `<real>`. The former is the supposedly proper metrical annotation, while the latter corresponds to a more natural rhythm (with a tendency to accept inversions and stress clashes). We only chose `<real>` when `<met>` doesn't match the syllable count (ca. 200 cases), likely deviating from the setup in (Agirrezabal et al., 2016, 2019).

the respective `met` labels at the output. We test a nominal CRF (see section 4.1.2) and a BERT model as baselines and implement a BiLSTM-CRF[21] with pre-trained syllable embeddings. These embeddings were trained by splitting all syllables in the corpora from section 3, and training word2vec embeddings over syllables. This system uses three layers of size 100 for the BiLSTM and does the final label prediction with a linear-Chain CRF. Variable dropout of .25 was applied at both input and output. No extra character encodings were used (as these hurt both speed and accuracy).

We do a three fold cross validation with 80/10/10 splits and average the results, reporting results on the test set in Table 8. We evaluate prediction accuracy on syllables and the accuracy of whether the whole line was tagged correctly (line acc.). Line accuracy is especially important if we want to classify poetic verse measures.

	English		German	
	syll. acc	line acc	syll. acc	line acc
CRF	.922	.478	.941	.553
BERT	.850	.371	.932	.498
BiLSTM-CRF	**.955**	**.831**	**.968**	**.877**
Agirrezabal (2019)	.930	.614	-	-
Antilla & Heuser (2016)	.894	.607	-	-

Table 8: Best Classifiers for Metrical Syllable Stress

Though not directly comparable (data composition differs), we include results as reported by Agirrezabal et al. (2019) for the English for-better-for-verse dataset. We also test the system '`prosodic`' of Anttila and Heuser (2016) against our gold data (EPG64), resulting in .85 accuracy for syllables and .44 for lines. When only evaluating on lines that were syllabified to the correct length (their syllabifier), 27% of lines are lost, but on this subset it achieves .89 syllable and .61 line accuracy.

Learning the sequence of metrical syllable stress with BERT cannot compete our other models, possibly resulting from an improper syllable representation, as the word-piece tokenizer segments word chunks other than syllables.

We also experiment with framing the task as document (line) classification, where BERT should learn the verse label (e.g., iambic.pentameter) for a given sequence of words. On the small English dataset, BERT only achieves around .22 F1-macro and .42 F1-micro. We then tagged 20,000 lines of the large English corpus with a BiLSTM-CRF model and trained BERT on this larger dataset, reaching .48 F1-macro and .62 F1-micro. In this setup, BERT detects frequent classes like iambic.pentameter or trochaic.tetrameter fairly well (.8), but it appears that this model mainly picks up on the length of lines and fails to learn measures other than iambus and trochee like dactyl or anapaest or irregular verse with inversions. This might limit experiments with transfer learning of verse measure knowledge.

4.4 Pairwise Joint Prosodic Task Learning

	met	feet	syllin	pos	csra	m.ac	emo
single	.964	.871	**.952**	.864	.912	.866	.328

+all	.967	**.930**	.947	.790	.919	.870	.377

Table 9: Accuracy for Pairwise Joint Task Learning.

With the aim of learning the relationships between our different annotation layers, we performed experiments with a multi-task setup. We used the BiLSTM architecture from the previous experiment, where the sequence of syllable embedding vectors is at the input, and the respective sequence of labels at the output. We used the German dataset here, as the annotation is generally more reliable (e.g., POS). In this experiment we also try to learn the annotation of aesthetic emotions that was described for this dataset by Haider et al. (2020). Each line was annotated with one or two emotions from a set of nine emotions. Here, we only used the primary emotion label per line.

First, we trained a single task model for each annotation layer, then all tasks jointly (`+all`), and finally pair-wise combinations (`+<auxiliary task>`). In Table 9, we report the accuracy on syllable level for each main task with their respective auxiliary tasks.

Note that learning syllable-level POS does not benefit from any other task, not even the syllable position in the word, while several tasks like caesuras, main accents and emotions benefit from additional POS information. Predicting meter also degrades from an additional POS task, which possibly interferes with the syllable embeddings. Meter might be also more contextual than suggested in Table 6.

---

[21] `https://github.com/UKPLab/emnlp2017-bilstm-cnn-crf`

However, meter tagging slightly benefits from fine-grained verse measure labels. Interestingly, learning foot boundaries heavily benefits from jointly learning syllable stress. In a single task setup, foot boundaries are learned with .871 accuracy, but in combination with metrical stress, feet are learned with .922 acc. and in combination with main accents at .915. This might be expected, as foot groupings are dependent on the regularity of repeating metrical syllable stresses (though less dependent on main accents). However, our annotators only achieved Kappa agreement of .87 for feet. It is curious then, how the model overcomes this ambiguity. When learning all tasks jointly (`+all`), foot prediction even reaches .930, suggesting that feet are related to all other prosodic annotations.

We observe that the exchange between caesuras and main accents is negligible. However, caesuras benefit from POS (despite the absence of punctuation), syllable position (syllin) and global measures (msr), indicating that caesuras are integral to poetic rhythm and fairly dependent on syntax.

For emotions we find, despite the hard task (line instead of stanza), and only using syllable embeddings rather than proper word embeddings, that the single task setup is already better than the majority baseline. More importantly, we can see that jointly learning POS or verse measure benefits the emotion prediction (slightly the meter prediction itself: .97). This suggests that there might be a systematic relationship between meter and emotion.

5 Related Work

5.1 Annotation of Prosodic Features

Earlier work (Nenkova et al., 2007) already found strong evidence that part-of-speech tags, accent-ratio[22] and local context provide good signals for the prediction of word stress. Subsequently, models like MLP (Agirrezabal et al., 2016), CRFs and LSTMs (Estes and Hench, 2016; Agirrezabal et al., 2019) and transformer models (Talman et al., 2019) have notably improved the performance to predict the prosodic stress of words and syllables. Unfortunately, most of this work only evaluates model accuracy on syllable or word level, with the exception of Agirrezabal et al. (2019).

A digital resource with annotation of poetic meter was missing for New High German. For Middle High German, Estes and Hench (2016) annotated a metrical scheme for hybrid meter. Anttila et al. (2018) annotated main accents in political speeches. Agirrezabal et al. (2016, 2019) used the English *for-better-for-verse* and the dataset of Navarro et al. (2016), who annotated hendecasyllabic verse (11 syllables) in Spanish Golden Age sonnets. Algee-Hewitt et al. (2014) annotated 1700 lines of English poetry to evaluate their system.

5.2 Poetry Corpora & Generation

Several poetry corpora have been used in the NLP community. Work on English has strongly focused on iambic pentameter, e.g., of Shakespeare (Greene et al., 2010) or with broader scope (Jhamtani et al., 2017; Lau et al., 2018; Hopkins and Kiela, 2017). Other work has focused on specific genres like Spanish sonnets (Ruiz Fabo et al., 2020), limericks (Jhamtani et al., 2019), or Chinese Tang poetry (Zhang and Lapata, 2014). There are further resources with rhyme patterns (Reddy and Knight, 2011; Haider and Kuhn, 2018) or emotion annotation (Haider et al., 2020). Truly large corpora are still hard to find, besides the Gutenberg project for English and Textgrid and DTA for German.

6 Conclusion

We created large poetry corpora for English and German to support computational literary studies and annotated prosodic features in smaller corpora. Our evaluation shows that a multitude of features can be annotated through silent reading, including meter, main accents and caesuras, even though foot annotation can be challenging. Finally, we performed first experiments with a multi-task setup to find beneficial relations between certain prosodic tasks. Learning metrical annotation, including feet and caesuras, largely benefits from a global verse measure label, while foot boundaries also benefit from any joint learning with syllable stress and all features alltogether, even surpassing the human upper bound.

Abstract

Aspect-level sentiment analysis (ASA) has received much attention in recent years. Most existing approaches tried to leverage syntactic information, such as the dependency parsing results of the input text, to improve sentiment analysis on different aspects. Although these approaches achieved satisfying results, their main focus is to leverage the dependency arcs among words where the dependency type information is omitted; and they model different dependencies equally where the noisy dependency results may hurt model performance. In this paper, we propose an approach to enhance aspect-level sentiment analysis with word dependencies, where the type information is modeled by key-value memory networks and different dependency results are selectively leveraged. Experimental results on five benchmark datasets demonstrate the effectiveness of our approach, where it outperforms baseline models on all datasets and achieves state-of-the-art performance on three of them.[1]

1 Introduction

Aspect-level sentiment analysis (ASA) determines the sentiment polarity of a given input text on the fine-grained level, where the sentiment towards a particular aspect in the text is predicted instead of the entire input. E.g., the sentiment of an aspect "*bar service*" in the sentence "*Total environment is fantastic although bar service is poor.*" is negative, although the text as a whole conveys a positive sentiment polarity. Due to its high practical value in many scenarios, e.g., product review analysis, social media tracking, etc., ASA attracts much attention in the natural language processing (NLP) community for years (Tang et al., 2016a,b; He et al., 2018a; Sun et al., 2019; Zhang et al., 2019; Song et al., 2019; Huang and Carley, 2019).

In recent studies, neural networks, especially recurrent models with attention mechanism, are widely applied in this task, where many of them (Wang et al., 2016; Tang et al., 2016a; Chen et al., 2017; Ma et al., 2017; Fan et al., 2018; Liang et al., 2019; Tang et al., 2020) model semantic relatedness between context and aspect words to facilitate sentiment analysis on aspects. There are other approaches using additional inputs such as word position (Gu et al., 2018), document information (He et al., 2018b; Li et al., 2018a), commonsense knowledge (Ma et al., 2018). Among all such inputs, dependency results of the input text are proved to be a kind of useful information (He et al., 2018a; Sun et al., 2019; Huang and Carley, 2019; Zhang et al., 2019; Wang et al., 2020; Tang et al., 2020), because they can help the model locate important content that modifies the aspect words and thus further suggests the sentiment towards the aspect words. Previous approaches with attention mechanism (He et al., 2018a; Wang et al., 2020), graph neural networks (GNN) (Sun et al., 2019; Huang and Carley, 2019; Zhang et al., 2019; Wang et al., 2020) and transformer (Tang et al., 2020) are applied in leveraging such information. However, most of them mainly focus on using the dependencies among words and omit to leverage other information such as relation types, which could provide useful cues to predict the sentiment. Also, they model all dependency information instances equally without weighting them according to their contribution to the task, where noisy information from the auto-generated dependency tree may hurt model performance. Therefore, improved methods are expected to comprehensively and efficiently learn dependencies among words to enhance ASA.

To address the aforementioned limitations, in this paper we propose an effective and efficient neural approach to ASA with incorporating word dependencies, which is acquired from off-the-shelf toolkits and modeled by key-value memory net-

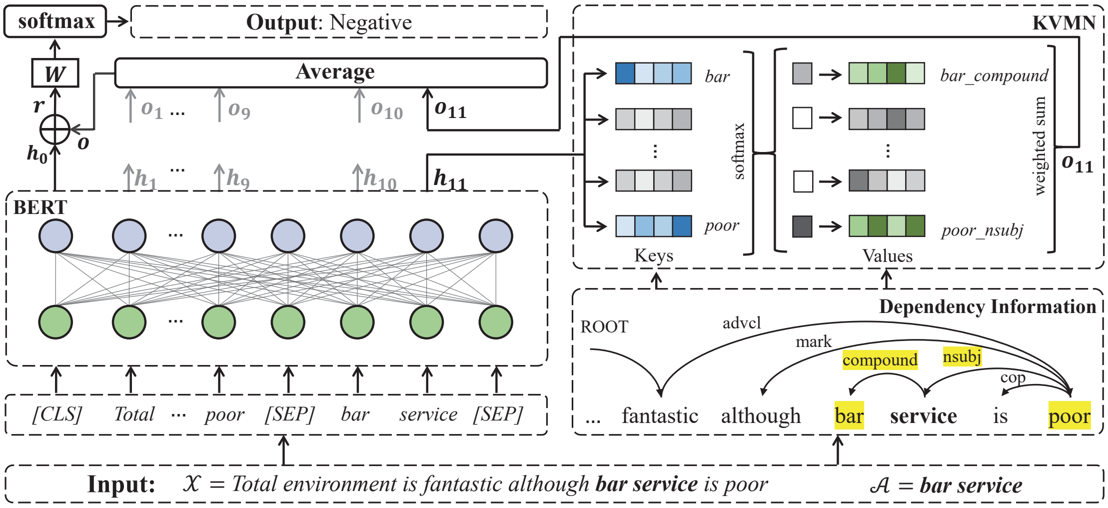

Figure 1: The overall architecture of the proposed model. The left part illustrates the backbone encoder (BERT) and decoder for ASA; the right part demonstrates the key-value memory networks (KVMN) for dependency information incorporation, where we use example word dependencies and their types (highlighted in yellow) of the aspect term "*service*" to show that how they are extracted, weighted and then fed into the left part for ASA.

works (KVMN) (Miller et al., 2016). In detail, for each input text parsed by a dependency parser, we extract its dependency relations and feed them into the KVMN, in which word-word associations and their corresponding dependency types are mapped to keys and values, respectively. Then the KVMN learns and weights different dependency knowledge according to the contribution of their corresponding keys to the ASA task, and provides the resulted representations to a regular ASA model, i.e., a BERT-based classifier, for final aspect-level sentiment predictions. In doing so, the proposed approach not only comprehensively leverages both word relations and their dependency types, but also effectively weights them through the memory mechanism according to their contributions to the ASA task. We evaluate the proposed approach on five benchmark datasets, where our approach outperforms the baselines on all datasets and achieves state-of-the-art on three of them.

2 The Approach

The task of ASA aims to analyze the sentiment of a text towards a specific aspect, which is formalized as a classification task performing on sentence-aspect pairs (Tang et al., 2016b; Ma et al., 2017; Xue and Li, 2018; Hazarika et al., 2018; Fan et al., 2018; Huang and Carley, 2018; Tang et al., 2019; Chen and Qian, 2019; Tan et al., 2019). In detail, each input sentence and the aspect terms in it are denoted by $\mathcal{X} = x_1, x_2, \cdots, x_n$ and $\mathcal{A} = a_1, a_2 \cdots, a_m$, respectively, where $\mathcal{A}$ is the sub-string of $\mathcal{X}$ ($\mathcal{A} \subset \mathcal{X}$), n and m refer to the word-based length of $\mathcal{X}$ and $\mathcal{A}$. Following this paradigm, we design the architecture of our approach in Figure 1, with a BERT-based (Devlin et al., 2019) encoder illustrated on the left to compute the sentence-aspect pair representation $\mathbf{r}$, and enhanced by the word dependency information obtained from the KVMN module on the right, then the result is fed into a softmax decoder to predict the text sentiment towards the aspect. Therefore, ASA through our approach can be formalized as

$$\hat{y} = \underset{y \in \mathcal{T}}{\arg\max}\, p(y|\mathcal{X}, \mathcal{A}, \mathrm{KVMN}(\mathcal{X}, \mathcal{A})) \quad (1)$$

where $\mathcal{T}$ denotes the set of sentiment polarities for y and p computes the probability of predicting $y \in \mathcal{T}$ given $\mathcal{X}$ and $\mathcal{A}$. $\hat{y}$ refers to the predicted sentiment polarity type for $\mathcal{A}$ in the context of $\mathcal{X}$. In the rest of this section, we firstly describe KVMN for leveraging word dependencies, then explain how the resulted representations are integrated into the backbone sentiment classifier.

2.1 KVMN for Word Dependencies

High quality text representations always play a crucial role to obtain good model performance for different NLP tasks (Song et al., 2017; Seyler et al., 2018; Song and Shi, 2018; Song et al., 2018; Babanejad et al., 2020), where contextual features, including n-grams and syntactic information, have been demonstrated to be effective in enhancing text representation and thus leads to improvements on different models (Song et al., 2006, 2009; Song and Xia, 2012; Song et al., 2012; Song and Xia, 2013; Dong et al., 2014; Miller et al., 2016; Seyler et al., 2018; Diao et al., 2019; Sun et al., 2019; Zhang et al., 2019; Huang and Carley, 2019; Tian et al., 2020b,c,d,e; Chen et al., 2020). Among all these features, dependency ones have been widely used, especially for ASA. To incorporate word dependencies into ASA task, there are many options, including attention mechanism (He et al., 2018a) where the information of dependency types among word pairs are omitted, and GNN and Transformer-based methods (Sun et al., 2019; Zhang et al., 2019; Wang et al., 2020; Tang et al., 2020) that require complicated architectures to model the entire dependency structure of an input text. Compared to these options, KVMN, whose variants have been demonstrated to be effective in incorporating contextual features (Miller et al., 2016; Guan et al., 2019; Song et al., 2020; Tian et al., 2020a,f; Nie et al., 2020), not only provides an appropriate way to leverage both word-word relations as well as their corresponding dependency types, but also weights different dependency information according to their contribution to the ASA task.

In detail, to build the KVMN, we firstly collect all word-word relations extracted from the parse results of a corpus via an off-the-shelf toolkit and use them to form the key set, and map their corresponding dependency types to the value set. Then, two embedding matrices, $\mathbf{K}$ and $\mathbf{V}$ are applied to the key and value sets with each vector representing a key or a value in the sets. At training or prediction stage, given an input text, our model obtains its dependency parsing result, i.e., for each w_i in a sentence-aspect pair, where w_i comes from $\mathcal{X}$, $\mathcal{A}$, or both $\mathcal{X}$ and $\mathcal{A}$, we extract words associated with w_i and their corresponding dependency types from the parse results. Note that, for each word, we use its inbound and outbound dependency types to represent its governor and dependent word, respectively. Therefore, for example, as illustrated in Figure 1, the words associated to the aspect word "*service*" are "*poor*" (governor) and "*bar*" (dependent); their corresponding dependency types are thus "*nsubj*" and "*compound*", respectively. Afterwards, we map the associated words and their corresponding dependency types to keys $\mathcal{K}_i = \{k_{i,1}, k_{i,2}, \cdots, k_{i,j}, \cdots, k_{i,q}\}$ and values $\mathcal{V}_i = \{v_{i,1}, v_{i,2}, \cdots, v_{i,j}, \cdots, v_{i,q}\}$ from $\mathbf{K}$ and $\mathbf{V}$ in the KVMN, where each item in $\mathcal{K}_i$ and $\mathcal{V}_i$ has its embedding denoted by $\mathbf{e}^k_{i,j}$ and $\mathbf{e}^v_{i,j}$, respectively. Once the keys and values are placed, we take the hidden vector $\mathbf{h}_i$ for w_i from the encoder (i.e., BERT), and compute the weight assigning to each value $v_{i,j}$ by

$$p_{i,j} = \frac{exp(\mathbf{h_i} \cdot \mathbf{e}^k_{i,j})}{\sum_{j=1}^{q} exp(\mathbf{h_i} \cdot \mathbf{e}^k_{i,j})} \tag{2}$$

We thus use $p_{i,j}$ to activate the corresponding values $v_{i,j}$ and compute the weighted sum by

$$\mathbf{o}_i = \sum_{j=1}^{q} p_{i,j} \mathbf{e}^v_{i,j} \tag{3}$$

where $\mathbf{o}_i$ refers to the output of the KVMN model for w_i and carries its word dependency information.

2.2 Word Dependency Integration for ASA

As shown in Figure 1, the entire model starts from encoding the input text. For the aforementioned sentence-aspect pair for ASA, it is normally organized by concatenating $\mathcal{X}$ and $\mathcal{A}$ to form a special sequence of $[[CLS], \mathcal{X}, [SEP], \mathcal{A}, [SEP]]$, and then feed it into an encoder, i.e., BERT, to obtain the hidden vectors by

$$[\mathbf{h}_0, \mathbf{H}^{\mathcal{X}}, \mathbf{H}^{\mathcal{A}}] = BERT(\mathcal{X}, \mathcal{A}) \tag{4}$$

where $\mathbf{h}_0$ denotes the hidden vector for the text-initial symbol $[CLS]$, and $\mathbf{H}^{\mathcal{X}}$, $\mathbf{H}^{\mathcal{A}}$ the embedding matrices of words in $\mathcal{X}$ and $\mathcal{A}$, respectively.

Upon the modeling of word dependencies for each w_i, different $\mathbf{o}_i$ are obtained and averaged, then concatenated with $\mathbf{h}_0$ by

$$\mathbf{r} = \mathbf{h}_0 \oplus \frac{1}{l} \cdot \sum_{i=1}^{l} \mathbf{o}_i \tag{5}$$

where $\mathbf{r}$ is the representation for the input sentence-aspect pair enhanced by word dependencies, and the value of l equals to n, m, or $n+m$ if all w_i come from $\mathcal{X}$ only, $\mathcal{A}$ only, or $\mathcal{X}+\mathcal{A}$, respectively.[2] Then, we use a dense layer with a trainable matrix $\mathbf{W}$ and vector $\mathbf{b}$ to align $\mathbf{r}$'s dimension to the output space by $\mathbf{u} = \mathbf{W} \cdot \mathbf{r} + \mathbf{b}$, with each dimension of $\mathbf{u}$ corresponding to a sentiment type. Finally, a softmax function is applied to $\mathbf{u}$ to predict the output sentiment $\hat{y}$ for the aspect $\mathcal{A}$ in $\mathcal{X}$:

$$\hat{y} = \arg\max \frac{exp(u^t)}{\sum_{t=1}^{|\mathcal{T}|} exp(u^t)} \tag{6}$$

where u^t is the value at dimension t in $\mathbf{u}$.

---

[2] Figure 1 illustrate the case that w_i comes from $\mathcal{X} + \mathcal{A}$, where $i \in [1, 11]$ for all $\mathbf{h}_i$.

[3] For all datasets, the sum of aspect samples under three sentiment polarities is larger than the total sentence numbers,

Table 1: The statistics of the five benchmark datasets, where the number of aspects on three sentiment polarities and sentences are reported.[3] We also report the number and percentage of the contrastive cases (DIFF.) where in a sentence the sentiments on aspect(s) are different from the entire sentence.

3 Experimental Settings

3.1 Datasets

Five benchmark datasets, i.e., LAP14 and REST14 (Pontiki et al., 2014), REST15 (Pontiki et al., 2015), REST16 (Pontiki et al., 2016), TWITTER (Dong et al., 2014), are used in our experiments. Specifically, LAP14 is a dataset consists of laptop computer reviews; REST14, REST15, and REST16 consist of restaurant reviews from online users; TWITTER includes tweets collected by querying the Twitter API. For all datasets, we use their official train/test splits and follow Tang et al. (2016b) to clean them by filtering out the aspects with the conflict label[4] as well as the sentences without an aspect. The statistics of the processed five datasets are reported in Table 1, where the numbers of aspects with positive, neutral, and negative polarities are reported. Note that in some datasets, e.g., LAP14 and REST14, there are rather high percentages of sentences (e.g., the sentence in Figure 1) that contain different sentiments towards aspects, as shown in the DIFF. rows in Table 1, which indicates a bigger challenge on ASA comparing to sentiment analysis on an entire sentence.

3.2 Word Dependency Extraction

Similar to previous studies (Wang et al., 2020; Tang et al., 2020) that also require dependency information, we employ the English version of SAPar[5] (Tian et al., 2020e), which is the most effective constituency parser trained on English Pen Tree-Bank (PTB) (Marcus et al., 1993), to obtain the constituency trees of the input text and then convert them into dependency trees by Stanford converter[6]. Therefore, when a dependency tree is built on the entire input text, for each word in the text, one can find its dependent words and types according to the dependency paths on the tree. Consequently, the dependency relations of each word to others can be extended along with the dependency paths and it is not restricted that only one-hop (first-order) relations can be considered in our model. One could easily extend the coverage of word dependencies with two- or three-hop relations from a given word, which are known as second- and third-order dependencies, e.g., "*poor* $\rightarrow$ *service* $\rightarrow$ *bar*" in Figure 1 is a second-order dependency relation.

As described in §2.1, extracting first-order word dependencies is straightforward; to extend it with higher order ones, we follow the same principle to extract word dependencies and assign dependency types as follows: (1) for the governor w_g of the target word w, we collect all its governor and dependents (except for w) associated with w_g's inbound and outbound dependency types, respectively; (2) for each dependent w_d of w, we find all dependents of w_d and use outbound dependency types to represent w_d's dependent words; (3) we include all context words and their corresponding dependency types collected in (1) and (2) as the input to KVMN for w and repeat the process for further higher order word dependencies.

For example, in the input text in Figure 1, the second-order word dependencies and types for "*service*" are started from its governor "*poor*" and dependent "*bar*". Then for "*poor*", we collect its governor "*fantastic*" with an inbound dependency type of "*advcl*", and dependents "*although*" and "*is*" with the outbound dependency types of "*mark*" and "*cop*", respectively. For "*bar*", it is not able to expand because it has no dependent,

---

because that many sentences have more than one aspect and such aspects usually have contrastive sentiment polarities.

[4] The "*conflict*" label is used in LAP14, REST14/16 to identify aspects that have conflict sentiment polarities.

Table 2: Experimental results (accuracy and F1 scores) of using different encoders (BERT-base and BERT-large) with and without KVMN on five benchmark datasets, where $\mathcal{X}$, $\mathcal{A}$, and $\mathcal{XA}$ refer to that KVMN models word dependencies from $\mathcal{X}$ only, $\mathcal{A}$ only, and $\mathcal{X} + \mathcal{A}$, respectively.

the collection thus stops here. Therefore, the resulted words (keys) in second-order dependencies and their corresponding dependency types (values) for "*service*" are $\mathcal{K}_{11} = \{bar, poor, fantastic, although, mark\}$, and $\mathcal{V}_{11} = \{bar\_compound, poor\_nsubj, fantastic\_advcl, although\_mark, is\_cop\}$, respectively.

3.3 Implementation Details

We adopt BERT-base-uncased and BERT-large-uncased[7] as the encoders in our approach, which are demonstrated to be the most effective encoders for many NLP tasks (Straková et al., 2019; Baldini Soares et al., 2019; Xu et al., 2019). In our experiments, we use their default settings for the two BERT encoders (i.e., for BERT-base-uncased, we use 12 layers with 768 dimensional hidden vectors; and for BERT-large-uncased, we use 24 layers with 1024 dimensional hidden vectors). For all experiments, we use Adam optimizer (Kingma and Ba, 2014) and try different combinations of learning rates, dropout rates, and batch size.[8] In addition, we apply Xavier initialization (Glorot and Bengio, 2010) on all trainable parameters including the embeddings for keys and values in the KVMN. Moreover, we use the cross-entropy loss function to optimize our model and follow the convention to evaluate our models via accuracy and macro-averaged F1 scores over all sentiment polarities, i.e., positive, neutral and negative.

4 Experimental Results

4.1 Effect of Using Word Dependencies

In the main experiments, we test our model with and without integrating word dependencies by KVMN, where both the base and large BERT encoders are used. In detail, when leveraging word dependencies, we run experiments on our proposed model to explore the effect of learning from different parts of the input, i.e., we try word dependencies from three sources: $\mathcal{X}$ only, $\mathcal{A}$ only, and both $\mathcal{X}$ and $\mathcal{A}$ (see §2.2). Experimental results are reported in Table 2 with the prefixes of KVMN denoting which part is encoded from.

There are several observations. First, KVMN works well with both the base and large BERT. Although BERT baselines have already achieved good performance, improvements of our proposed model over the baselines are observed on all datasets with respect to both accuracy and F1 scores. Second, among the three settings of encoding from different parts of the input (i.e., $\mathcal{X}$, $\mathcal{A}$, $\mathcal{X}$+$\mathcal{A}$) in KVMN, in most datasets (except for Twitter), the highest performance is observed on "$\mathcal{A}$-KVMN". These results comply with the intuition where extracting and learning word dependencies from $\mathcal{A}$ ensures KVMN only incorporates the information from the content directly associated with the aspect words, thus focuses the model on the words that are most likely to be helpful on ASA for a particular aspect in a sentence. Third, although the overall performance of $\mathcal{X}$-KVMN and $\mathcal{XA}$-KVMN are not as good as that of $\mathcal{A}$-KVMN, they are still better than the baselines without using word dependencies. Especially for $\mathcal{X}$-KVMN, where word dependencies are extracted from the entire sentence, in this case,

---

[7] We obtain the BERT models from `https://github.com/huggingface/pytorch-pretrained-BERT`.

(b) BERT-large

Table 3: Experimental results of our models with the best setting (i.e., using base and large BERT with $\mathcal{A}$-KVMN) of using dependency relations on different (i.e., 1st, 2nd and 3rd) orders. Average percentage of words in a sentence covered by word dependencies on different orders are also reported in the Cvge. column.

the dependency information also helps ASA even though it introduces some noise to the task when the entire sentence possesses a different sentiment polarity (as shown in the Diff. rows in Table 1), while such noise contributes to its inferior performance to the $\mathcal{A}$-KVMN setting. Therefore, for the case that the sentiment is agreed between the entire sentence and its aspect (e.g., Twitter dataset is in this case according to Table 1), $\mathcal{X}$-KVMN and $\mathcal{A}$-KVMN have similar performance.

4.2 Effect of Different Dependency Orders

Previous experiments showed the effectiveness of our model with KVMN on first-order word dependencies. In this experiment, we use the best setting (i.e., models using $\mathcal{A}$-KVMN) for base and large BERT and run them with encoding higher-order dependencies to further investigate the effectiveness of our model with more dependency information. Particularly, we try second- and third-order word dependencies and compare their results with the previous first-order ones. The results on all datasets, as well as average coverage (%) of words in each sentence with respect to different dependency orders,[9] are reported in Table 3, where (a) and (b) show the results of models with BERT-base and BERT-large encoders, respectively. From the results, it is found that in most cases (e.g., for both base and large BERT), models using second-order word dependencies achieve the overall highest performance, which can be explained by that first-order dependency for aspect words is not enough to cover enough salient information helping ASA. This is a common phenomenon when negation is included in a sentence. For example, in "*the pizza is not good*", for its aspect "*pizza*", whose first-order dependencies only link "*pizza*" with "*good*", the classifier is thus misled to predict a positive sentiment polarity. Compared to using second-order word dependencies, third-order dependencies in general do not provide further improvement to ASA, which owes to the reason that more irrelevant information is introduced to the encoder thus distract the model for final prediction. In fact, third-order dependencies lead to that around 75% words in each sentence are fed into KVMN, which could severely affect ASA by sentence-level sentiment polarities, and eventually harm model performance especially when an aspect-level sentiment differs from the sentence-level sentiment.

4.3 Comparison with Previous Studies

To further demonstrate the effectiveness of our approach, we compare our best-performing model, i.e., the BERT-large encoder with second-order word dependencies incorporated through $\mathcal{A}$-KVMN, with previous studies, where the comparisons on all datasets are reported in Table 4, where the results of BERT-large baseline, as well as the ones using BERT-base, are also reported for references. It is observed that, our model consistently outperforms the BERT-large baseline on all datasets and achieves state-of-the-art on three of them (i.e., Lap14, Rest15, Rest16) in terms of

---

[9] This metric is used to present how many words in each input sentence are involved when different orders are applied for extracting word dependencies, so as to illustrate how much information in a sentence is helpful for ASA.

Table 4: Performance Comparison (on accuracy and F1 scores) of our best model (BERT-LARGE + $\mathcal{A}$-KVMN with second-order word dependencies) with previous studies on all datasets. The results of BERT-large baseline are also reported for references. Models that use BERT-large as the encoder are marked by "†". The results marked by "*" indicate that our model is significantly better than the corresponding baseline model (t-test with $p < 0.05$).

both accuracy and F1 scores. Specifically, compared with previous studies that also leverage dependency information, our approach outperforms He et al. (2018a); Sun et al. (2019); Huang and Carley (2019); Zhang et al. (2019) on all dataset and outperforms Wang et al. (2020) and Tang et al. (2020) on most datasets. This observation is valid because, in previous models, they are weighting or averaging hidden vectors of the (aspect related) words rather than on the relations, and omitting dependency types which provide guidance to emphasize some useful relations, e.g., the "*amod*" (i.e., adjectival modifier) type identifies that an adjectival modifier could be the sentiment words of a corresponding aspect. Therefore, the superiority of our model comes from two aspects, weighting word-word relations and leveraging dependency types. KVMN highlights salient dependency relations and learns from them and their dependency types, which alleviates the influence of noisy dependency information. In addition, we note that our approach achieves inferior results on TWITTER dataset compared with Tang et al. (2020). One possible explanation is that a dependency parser trained in the general domain can get inferior parsing results on TWITTER texts from the social media domain, which makes it harder for our approach to improve the BERT-large baseline compared to other datasets. Nevertheless, the effectiveness of our approach is still valid given that our approach outperforms Tang et al. (2020) on all other datasets.

5 Analyses

5.1 Ablation Study

To confirm the validity of using both word relations (keys) and their corresponding dependency types (values) for ASA, we conduct an ablation study by learning from either part of the two types of dependency information. We choose the models using BERT-base and BERT-large with our best setting (i.e., models with second-order word dependencies and $\mathcal{A}$-KVMN) for this study and adapt the KVMN module to key-only or value-only input. The experimental results on all benchmark datasets are reported in Table 5, where keys or values are ablated. It is clearly indicated in the table that, for models with different encoders (i.e., base and large BERT), the model performance drops on all datasets if either keys or values are excluded. Specifically, in most cases, the drop of performance (especially on accuracy) is higher when keys are ablated ("– KEYS"), comparing with the ablation of values ("– VALUES"). This phenomenon indicates the context words, which attracts much attention from previous studies (He et al., 2018a; Sun et al., 2019; Zhang et al., 2019; Huang and Carley, 2019), play a more important role compared with their

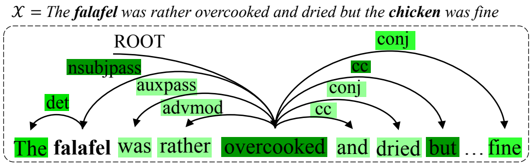
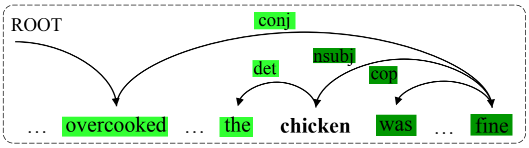
(b) BERT-large

Table 5: Results on five datasets from our full models (base and large BERT with $\mathcal{A}$-KVMN and second-order word dependencies) and its variants where keys ("− Keys") and values ("− Values") are ablated. Δ refers to the drop of accuracy and F1 score when keys or values are excluded from the full model.

dependency types. Still, one cannot deny the contribution of dependency types because the drop is still significant if values are excluded, where even on some datasets (e.g., Rest15 and Rest16) higher drops are observed on F1 than Key ablation. The results for this ablation study demonstrate that dependency type is of high importance to improve ASA if they are appropriately encoded.



(a): $\mathcal{A}$ = ***falafel*** y^* = *negative*



(b): $\mathcal{A}$ = ***chicken*** $y*$ = *positive*

Figure 2: Illustration of an example sentence with two aspects in different sentiment polarities. For each aspect, weights (from our best model) assigned to dependent words and dependency types are visualized with colors, where darker color refers to higher weights.

5.2 Case Study

To illustrate the effect of KVMN module on weighting salient word dependencies and thus improve ASA, we conduct a case study on the sentence "*The falafel was rather overcooked and dried but the chicken was fine*" shown in Figure 2, in which it contains two aspects with contrast sentiment polarities, i.e., *negative* towards "*falafel*" and *positive* towards "*chicken*". For each aspect, we run our best model (BERT-large + $\mathcal{A}$-KVMN with second-order word dependencies), and visualize the weights ($p_{i,j}$ in Eq. (2)) assigned to all associated dependency types and their corresponding words, where darker color refers to higher weights.

For the first aspect "*falafel*" (Figure 2(a)), although there are some adjectives carrying opposite sentiment polarities within its second-order relations, KVMN successfully distinguishes "*overcooked*" is more important to it and assigns a relatively higher weight. This is because that the corresponding type ("*nsubjpass*", passive nominal subject) to "*overcooked*" is intensively highlighted so that the model identifies it as the main sentiment carrier for the aspect word "*falafel*" where other adjectives (i.e., "*dried*" and "*fine*") share the "*conj*" (conjunction) type and are distantly related to the aspect words, making them less important.

For the other aspect "*chicken*" (Figure 2(b)), similar to the first one, both "*overcooked*" and "*fine*" are included in its associated context words. In this case, "*fine*" is more closely dependent on "*chicken*" than "*overcooked*", where it has a "*nsubj*" (noun subject) type showing a predicate role thus receives higher weight from KVMN, resulting in a positive sentiment polarity prediction towards "*chicken*". Overall, this case study perfectly explains the effectiveness of our model, where two aspects share the same context and the only change is the dependency information ($\mathbf{o_i}$) comes from KVMN. Therefore, the different prediction results for the two aspects suggest that KVMN appropriately learns from salient dependency relations and types for each aspect, where different types have their own capabilities to enhance ASA accordingly (e.g., "*nsubj*" may contribute more than "*conj*").

6 Related Work

Different from sentiment analysis for large granular texts, such as document and sentences, ASA focuses on processing sentiment polarities for a specific aspect (e.g., "*pizza*") or category (e.g., "*food*") in a piece of text. To address this task, early approaches (Jiang et al., 2011; Dong et al., 2014) followed the sentence classification paradigm and recent studies enhanced it as a mission of sentence-aspect pair classification with applying neural approaches (Wang et al., 2016; Tang et al., 2016a; Ma et al., 2017; Chen et al., 2017; Xue and Li, 2018; Li et al., 2018b; Hu et al., 2019; Xu et al., 2019) such as recurrent models (e.g., bi-LSTM) and pre-trained encoders (e.g., BERT) for effectively capturing contextual information. In addition to improving the input form, advanced models such as memory networks (Tang et al., 2016b; Chen et al., 2017; Wang et al., 2018; Zhu and Qian, 2018; Mao et al., 2019), attention mechanism (Wang et al., 2016; Ma et al., 2017; Hazarika et al., 2018), capsule networks (Du et al., 2019; Chen and Qian, 2019; Jiang et al., 2019), GNN (Huang and Carley, 2019; Sun et al., 2019; Zhang et al., 2019; Wang et al., 2020), and transformer (Tang et al., 2020) are applied to this task, with other studies leveraging external resources, including position information (Gu et al., 2018), document information (He et al., 2018b), commonsense knowledge (Ma et al., 2018), etc. Among all resources, syntactic information was proved to be the most effective one and successfully adopted in recent studies with GNN (Huang and Carley, 2019; Sun et al., 2019; Zhang et al., 2019). Compared with previous studies, our approach offers an alternative way to use KVMN and syntactic information for ASA. Consider those studies using memory networks where their memories are represented by contextual features of the aspect terms, dependency information was not leveraged in their work. In addition, compared with those approaches leveraging word dependencies (i.e., using attention mechanism or GNN), where they not only omitted useful dependency information such as relation types, but also demanded a complicated model structure in doing so, our approach ensures comprehensively encoding from both word-word relations and their dependency types, and models them in an efficient way by KVMN.

7 Conclusion

In this paper, we propose an effective neural approach to improve ASA with word dependencies by KVMN, where for each aspect term, we firstly extract the words associated to it according to the dependency parse of the input sentence and their corresponding dependency relation types, then use KVMN to encode and weight such information to enhance ASA accordingly. In our approach, not only word-word relations but also their dependency types are leveraged in a KVMN, which to our best knowledge are the first attempts in all related syntax-driven studies for ASA. Experimental results on five widely used benchmark datasets demonstrate the effectiveness of our approach, and shows that second-order word dependency is the best choice for ASA, where the new state-of-the-art results are achieved on three datasets. Moreover, further analyses illustrate the validity of applying KVMN on both dependency relation and type information, especially the effectiveness of dependency types, which are often omitted in previous studies.

Appendix

A. Model Size and Running Speed

Table 6 reports the number of trainable parameters and inference speed (sentences/second)[10] of baseline (i.e., the ones without using KVMN and the dependency information) and our best performing models (i.e., the ones with $\mathcal{A}$-KVMN and the second-order dependencies) on all datasets.

B. Hyper-parameter Settings

Table 7 reports the hyper-parameters we used for tuning our models. For each dataset, we try all combinations of the hyper-parameters and report the one with the highest accuracy score in our paper.

---

[10] The test is performed on a Quadro RTX 6000 GPU.

MODELS	LAP14		REST14		REST15		REST16		TWITTER	
	PARA.	SPEED	PARA.	SPEED	PARA.	SPEED	PARA.	SPEED	PARA.	SPEED
BERT-BASE	109.5M	37.1	109.5M	38.1	109.5M	37.3	109.5M	38.5	109.5M	38.2
