where both losses use either the original pretrained name and concept embeddings, or their CCA projections. While the proportion of both losses could be tuned using coefficients, our experiments prove this to be redundant, since both losses systematically converge to zero or near-zero values in all experiments.

4 Data

4.1 Disorder names

4.1.1 SNOMED-CT

Following Kartsaklis et al. (2018) and Phan et al. (2019), we use SNOMED-CT[1] disorder names as biomedical synonym sets. However, since this data is of a diverse nature and quality, we try to select the most natural and coherent data by matching it with a large target domain of processed MEDLINE articles released by Hakala et al. (2016) containing 76M sentences with 120M unique noun phrases scraped from 4K articles. We match disorder names with our target domain in 4 consecutive steps. Firstly, we only retain disorder names of which all tokens appear in the vocabulary of our target domain. Secondly, many disorder names have duplicates with a small set of redundant metatags such as *(disorder)* and *(finding)* added to the name, which very rarely appear as natural language in our target domain (we list these metatags in Appendix A). Since they do not reflect relevant synonymy, we leave out such duplicates. Thirdly, we only retain disorder names of up to 6 tokens, since this is the maximum length of the 20K disorder names which directly match noun phrases from our target domain. This is also similar to the length distribution in disorder normalization benchmarks as the NCBI Disease corpus (Doğan et al., 2014) and the ShARe/CLEF eHealth 2013 corpus (Pradhan et al., 2015). Lastly, we leave out all disorder names which belong to more than one concept identifier.

4.1.2 ICD-10

The SNOMED-to-ICD-10 mapping, which has been officially provided by the U.S. National Library of Medicine[2], groups multiple SNOMED-CT concepts together under more coarse-grained ICD-10 codes, using concept unique identifiers (CUIs) from the UMLS[3] ontology which encompass those SNOMED-CT concepts. We fuse the synonym sets of SNOMED-CT concepts belonging to the same ICD-10 concept into a single set of semantically related terms. Table 1 gives some examples of the SNOMED-to-ICD-10 mappings. These examples show how ICD-10 concepts introduce a broader range of synonymy. While many of the SNOMED-CT synonyms can be resolved using word-level analogies (e.g. *myocardial $\underline{\text{depression}}$* vs. *myocardial $\underline{\text{dysfunction}}$*), the ICD-10 related terms that bridge different SNOMED-CT concepts require more domain-specific semantics to be linked (e.g. for matching *myocardial dysfunction* with *muscular degeneration of heart*).

4.2 Heterogeneous names: MedMentions

The recently released MedMentions corpus (Mohan and Li, 2019) enables training and testing of biomedical name encoders on a larger scale and over a wider variety of semantic types than previous benchmarks. It maps a vast amount of biomedical names mentioned in PubMed abstracts to their corresponding concept unique identifier (CUI) in the UMLS ontology. The annotated subcorpus *MedMentions ST21pv* annotates names belonging to UMLS concepts covering 21 different semantic

	Disorder		Heterogeneous
	ICD-10	SNOMED-CT	MedMentions
train concepts	5,136	20,140	18,417
train mentions	31,610	29,517	38,445
train synonym pairs	120,768	26,214	118,300
validation mentions	4,802	1,355	42,924
test mentions	7,142	2,752	43,544
zero-shot concepts	1,000	1,485	1,098
zero-shot mentions	6,490	4,199	4,705

Table 2: An overview of all the data used in our experiments.

types. We fuse these textual mentions of names into synonym sets. Since they are all verified to occur in existing biomedical free-text, we don't perform any preselection at all. This also means that there are words which are out-of-vocabulary for our fastText model: 10% of the MedMentions names contain such words, which constitute 15% of the total MedMentions vocabulary. As a result, the MedMentions data can show how reliable our approach is in cases where the vocabulary of the word embeddings does not perfectly overlap with the target domain.

5 Experiments and results

5.1 Ranking tasks and data distributions

Ranking tasks We evaluate the usefulness of biomedical name representations for synonym retrieval and concept mapping by applying 3 different performance metrics to a single ranking task. Given a mention *m* of a biomedical name which belongs to the concept identifier *c*, we have to rank a set of biomedical names *S* which includes $C_{syn} \subset S$, a set of names which belong to the same concept identifier *c* as the mention *m*. To rank the biomedical names according to their similarity to the mention, we first encode both the mention *m* as well as every name $n \in S$, and then rank every name n using the cosine similarity between the encoded mention $f(m)$ and the encoded name $f(n)$.

The aim of this task is to rank every correct synonym or semantically related name $syn \in C_{syn}$ as high as possible. We measure the synonym retrieval and concept mapping performance for this task using different metrics. For synonym retrieval, we report **Mean average precision (mAP)** over all synonyms. For concept mapping, we report **Accuracy (Acc)**, the proportion of instances where the highest ranked name *n* is a correct synonym $syn \in C_{syn}$, and **Mean reciprocal rank (MRR)** of the highest ranked correct synonym.

Data distributions Table 2 gives an overview of the data distributions after splitting. For MedMentions, we take our train, validation, test, and zero-shot data from the data splits provided by *MedMentions ST21pv*. For SNOMED-CT and ICD-10, we devise our own sampling method. Firstly, we randomly divide the synonym sets in training concepts and zero-shot test concepts. Secondly, to hold out test mentions from the training data, we randomly sample a single name from each concept which has at least two names (as to avoid empty training concepts), and repeat this procedure to get more test data. We then carry out the same procedure to sample validation data which we use to calculate the stopping criterion during training.

We calculate synonym retrieval and concept mapping performance for the test and validation mentions by ranking for a test mention *m* all names *S* present in the training data, including the synonyms C_{syn} which are present in the training data for the concept identifier *c* of the test mention. The performance of the encoders for the training data is calculated by treating a single training name at a time as test item.

The zero-shot test concepts are used to observe how well our encoders can extrapolate to previously unobserved concepts, for which the encoder has not specifically learned conceptual grounding. We frame the zero-shot setup as a way of testing transfer learning within the same domain, by not including any training names at all. This setup can show that our encodings are robust enough to be used out-of-the-box in entirely novel settings. For this setup, we treat a single zero-shot name at a time as test item, and rank all correct synonyms C_{syn} present in the zero-shot data among all names *S* from the zero-shot data.

5.2 Reference model and baselines

Reference model: BNE We compare our DAN model against the Biomedical Name Encoder (BNE) by Phan et al. (2019), which we train using the exact same data. To have a direct comparison with their model, we leave out the character embeddings from their encoder architecture and only use our fastText word embeddings as input embeddings. This results in a bidirectional LSTM (BiLSTM) (Graves and Schmidhuber, 2005) with

max pooling and a linear transformation:

$$\begin{aligned} h_n &= max(BiLSTM(u_{t1},..,u_{tn})) \\ f(n) &= W(h_n) + b \end{aligned} \tag{6}$$

We also include the publicly released BNE model with skipgram word embeddings, BNE + SG_w, [4] which was trained on approximately 16K synonym sets of disease concepts in the UMLS, containing 156K disease names. We don't include this model for the disorder data, since it was trained on at least part of that data, and we want to avoid that data leakage affects the fairness of the model comparisons.

Baselines As baseline encoder we use the 300-dimensional **fastText** name embeddings which are used as input for the DAN (defined in Equation 1 in Section 3.1). This encoder is an example of a Simple Word-Embedding Model (SWEM) with average pooling, which has been proven to be a strong baseline for various NLP tasks (Shen et al., 2018). We also include two other pretrained baselines among our comparison of encoders: 600-dimensional **Sent2Vec** (Pagliardini et al., 2018) embeddings with word unigram and bigram representations, trained on the same MEDLINE data as our fastText embeddings; and averaged 728-dimensional context-specific token activations extracted from the publicly released **BioBERT** model (Lee et al., 2019).

5.3 Training details

We fit the CCA for the linear constraint using all training names and their corresponding concept prototypes constructed from the same training names. The encoder architectures of our own DAN model and the BNE reference model are implemented in PyTorch (Paszke et al., 2019). Both the input and output dimensionality are 300 (which is the dimensionality of the input fastText embeddings described in Section 3.1). All encoder architectures for which we report results performed best with a single hidden layer.

We tuned the hidden size of the DAN to 38,400 dimensions using a grid search over 300×2^n, with n starting at 1 and being increased until performance declined again. We tuned the BiLSTM for the BNE model to 4,800 dimensions using the same grid search, to make sure the architecture

	anterior pleuritic pain	*breathing painful*	*breathing painful*
	pleuritic pain	back pain worse on sneezing	disorder characterized by back pain
	breathing painful	disorder characterized by back pain	disorder characterised by back pain
	pleural pain	disorder characterised by back pain	back pain worse on sneezing
	chest pain	*anterior pleuritic pain*	distress from pain in labor
	chronic chest pain	pain in heart	persistent pain following procedure
	pain in heart	*pleuritic pain*	chronic mouth breathing
	upper chest pain	precordial pain	chronic chest pain
	parasternal pain	chronic chest pain	dermatitis caused by sweating and friction

Table 6: A comparison of the synonym retrieval by various encoders for the ICD-10 test mention *pain provoked by breathing*. While fastText is already good at matching a few semantically related terms at the top, it retrieves no further names in its top ranks. The BNE ranking picks up on more specific biomedical semantics, but still has a limited coverage. In contrast, the conceptually grounded CCA+DAN ranks all 5 target names at the top.

was compared fairly to our model. At that point, the DAN has ±23M trainable parameters, whereas the BiLSTM already has ±200M trainable parameters. This allows us to empirically confirm that our proposed DAN model is more computationally efficient than the BNE BiLSTM.

Adam optimization (Kingma and Ba, 2015) is performed on a batch size of 64, using a learning rate of 0.001 and a dropout rate of 0.5. Input strings are first tokenized using the Pattern tokenizer (Smedt and Daelemans, 2012) and then lowercased. We use a triplet margin of 0.1 for the siamese triplet loss L_{syn} defined in Equation 3. For the prototypical constraint L_{proto} defined in Equation 4, we use a synonym dropout rate of 0.5. As stopping criterion we use the mAP of synonym retrieval for held-out validation names: we stop training once this score for the current epoch is worse than for the previous epoch.

5.4 Results and discussion

We compare the 3 baselines and the BNE reference model against 3 variants of our model. The CCA fastText model only applies the learned CCA mapping to the pretrained fastText embeddings. The CCA+DAN model applies the linear CCA constraint before training, while the DAN model leaves out the linear constraint.

ICD-10 & SNOMED-CT Table 3 and 4 show the concept mapping and synonym retrieval performance of the different encoders for the ICD-10 and SNOMED-CT data. We see that the fastText baseline consistently outperforms the other baselines. Applying the CCA transformation to the fastText baseline improves performance for every metric, including zero-shot cases. In other words, applying this linear constraint for conceptual grounding already leads to better extrapolation. The DAN model, which combines the siamese triplet loss

	biofilm formation	pellicle formation	dental plaque

Table 7: A comparison of the synonym retrieval by various encoders for the MedMentions test mention *cariogenesis*. While the BNE model does not improve over the fastText baseline, the conceptually grounded CCA+DAN already has complete coverage of all 5 target synonyms at rank 8.

with only the prototypical grounding loss, is able to fit the training data to near perfection without overfitting, since it generalizes well across both test and zero-shot data. Applying the CCA constraint before training increases the performance even more. These observations support the hypothesis of this paper that increasing the effectiveness of conceptual grounding can improve trained encoders.

The results also clearly confirm the robustness of our approach: synonym retrieval is dramatically improved for the test data, without any performance loss for concept mapping. In other words, the representations have encoded more domain-specific semantics while retaining the relevant lexical information. Table 6 gives an example of the impact of our conceptual grounding constraints for ICD-10 test data: the model is able to encode domain-specific semantics beyond word-level analogies for the semantically related names of the test mention *pain provoked by breathing*. Not only does the CCA+DAN model rank all semantically related names at the top: all the following top-ranked names, such as *chest pain*, also have clear semantic links to the mention. In contrast, the BNE model ranks less related names such as *back pain worse on sneezing* and *disorder characterized by back pain* higher than correct synonyms such as *pleuritic pain*.

MedMentions Table 5 shows the performance of the different encoders for the MedMentions data. Table 7 gives an example of how, similar to the disorder data, our CCA+DAN encoder is able to encode specific semantics that the BNE model is lacking: the conceptual grounding constraints have allowed our encoder to represent the semantic similarity between *cariogenesis*, *tooth decay* and *cavities*, while the BNE model does not improve over the fastText baseline.

Despite showing similar trends to the disorder data, the relative improvements of our CCA+DAN encoder over the reference BNE model are less dramatic. Interestingly, the publicly released BNE + SG_{w} model trained by Phan et al. (2019) performs worse out-of-the-box than our pretrained fastText embeddings. This highlights the difficulty of achieving true robustness of biomedical name encoding.

5.5 Semantic relatedness benchmarks

We also evaluate our name encoders on two biomedical benchmarks of semantic similarity, which allow to compare cosine similarity between name embeddings with human judgments of relatedness. MayoSRS (Pakhomov et al., 2011) contains multi-word name pairs of related but different concepts, and can indicate how much generalized domain knowledge has been captured by our conceptual grounding constraints. UMNSRS (Pakhomov et al., 2016) contains only single-word pairs, which also stem from different concepts. This benchmark makes a distinction between *similarity* and *relatedness*.

The correlations in Table 8 confirm the robustness of our conceptually grounded biomedical name representations. While the correlations for the BNE models barely improve over those of the fastText embeddings, our CCA+DAN encoder improves substantially over all 3 benchmarks, regard-

	MayoSRS (rel)	UMNSRS (rel)	UMNSRS (sim)
fastText	0.443	0.473	0.479
CCA+DAN, ICD-10	**0.666**	0.556	0.561
CCA+DAN, SNOMED-CT	0.648	0.537	0.540
CCA+DAN, MedMentions	0.600	0.526	0.543
Phan et al. (2019)	0.626	**0.580**	**0.606**
BNE, ICD-10	0.492	0.472	0.503
BNE, SNOMED-CT	0.415	0.510	0.527
BNE, MedMentions	0.506	0.467	0.500

Table 8: Spearman's rank correlation coefficient between cosine similarly scores of name embeddings and human judgments, reported on semantic similarity (sim) and relatedness (rel) benchmarks. The highest score is denoted in bold, the second highest is underlined.

less of the data source it was trained on. Remarkably, while the publicly released BNE model of Phan et al. (2019) was trained on 156K disease names, the CCA+DAN encoder already outperforms it on MayoSRS when trained on the ICD-10 and SNOMED-CT subsets, which contain only 30K disease names. This proves that Deep Averaging Networks can be effective even for large-scale encoding of biomedical names. Moreover, this finding suggests that future work on biomedical name encoders should not take complex neural architectures for granted. On the contrary, enforcing more relevant constraints such as our conceptual grounding constraints can boost even lightweight encoder architectures.

6 Conclusion and future work

In this paper, we have shown how two conceptual grounding constraints for biomedical name encoders can infuse name representations with more domain-specific semantics without losing robustness. These representations can help with retrieving literal synonyms as well as semantically related terms, and can be sufficiently expressed by a Deep Averaging Network, which is a feedforward neural network that only takes averaged word embeddings as input.

We believe future work can include a comparison of neural encoding architectures with a wider range of complexity. Decreasing the complexity of neural architectures can allow for including more comprehensive training objectives which target more effective encoding of domain-specific semantics.

Acknowledgments

We would like to thank the anonymous reviewers for their feedback. This research was carried out in the framework of the Accumulate VLAIO SBO project, funded by the government agency Flanders Innovation Entrepreneurship (VLAIO). We also like to thank Madhumita Sushil and Nicolae Banari for their comments.

A Redundant metatags

In section 4.1.1, we mention that many names from our SNOMED-CT data are duplicates of other names, with the only difference being that they also contain the following redundant metatags (in order of frequency):

- (disorder)
- (finding)
- (nos)
- (morphologic abnormality)
- (situation)
- (event)
- (observable entity)
- (qualifier value)
- (context-dependent category)
- (procedure)
- (function)
- (attribute)
- (clinical)

Adaptive Mixed Component LDA for Low Resource Topic Modeling

Suzanna Sia **Kevin Duh**
Johns Hopkins University
Baltimore, MD, USA
ssia1@jhu.edu kevinduh@cs.jhu.edu

Abstract

Probabilistic topic models in low data resource scenarios are faced with less reliable estimates due to sparsity of discrete word co-occurrence counts, and do not have the luxury of retraining word or topic embeddings using neural methods. In this challenging resource constrained setting, we introduce an automatic trade-off between the discrete and continuous representations via an adaptive mixture coefficient, which places greater weight on the discrete representation when the corpus statistics are more reliable. The adaptive mixture coefficient takes into account global corpus statistics, and the uncertainty in each topic's continuous distribution. Our approach outperforms the fully discrete, fully continuous, and static mixture model on topic coherence in low resource monolingual and multilingual settings.

1 Introduction

In topic modeling, the goal is to learn key themes in a corpus for exploratory document analysis (Boyd-Graber et al., 2017). Latent Dirichlet Allocation (LDA; Blei et al. (2003)) has been the bedrock for topic modeling and remains a hard to beat baseline for the general scenario which models with only words and documents.

We examine topic modeling in a low resource data setting (Hao et al., 2018), which has seen little attention but is commonly encountered in the digital humanities where document collections are potentially small (Jockers and Mimno, 2013; Schöch, 2017; Navarro-Colorado, 2018). [1] In such scenarios, word co-occurence statistics are less reliable due to sparsity of discrete counts.

With the rise of neural word embeddings (Mikolov et al., 2013), the defacto approach to improving over discrete models has been to utilise continuous representations (regardless of whether the setting is low resource). Early work by Liu et al. (2015) introduced topic dependent word embeddings, while others subsequently use embeddings to influence the discrete topic-word distribution (Zhao et al., 2017; Dieng et al., 2019). However, the low resource scenario constrains us to existing pre-trained embeddings, as the number of train documents is limited to several thousands and thus prohibitively small to train neural models (Srivastava and Sutton, 2017; Zhu et al., 2018; Liu et al., 2019; Hu et al., 2020; Zhu et al., 2020).

We therefore consider approaches that do not require further tuning of embeddings, and operate within the well established LDA probabilistic inference framework in the continuous space. There have been multiple attempts to replace discrete words with pre-trained embeddings (replacing the multinomial topic-word distribution with a continuous topic-word distribution), doing away with discrete words completely (Das et al., 2015; Batmanghelich et al., 2016; Xun et al., 2017). Given the dominance of pre-trained word embeddings in modern NLP, would continuous representations outperform discrete representations even in low resource settings? Surprisingly, we find that discrete LDA outperforms its fully continuous counterpart on topic coherence measures which correlate with human judgement (Lau et al., 2014).

How then can we utilise pre-trained continuous representations for learning better topics? A natural direction is hybrid models based on statistical counts and pre-trained neural representations (Neubig and Dyer, 2016). Early work by Nguyen et al. (2015) used a mixture of discrete and continuous topic-word distributions with static mixture coefficients. However we find that this does not improve over discrete LDA, which motivates a more

---

[1] This differs from the short text setting which has a large number of train documents, that has been addressed by multiple work (Li et al., 2016a; Qiang et al., 2020).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2451–2469
April 19 - 23, 2021.

nuanced treatment of the mixture coefficient.

In this work, we introduce an adaptive mixture coefficient specific to each word and each topic, which is updated at every step of Collapsed Gibbs Sampling (Griffiths and Steyvers, 2004). The intuition is as follows, topic anchor words (Lund et al., 2017) which have stronger signal from corpus statistics should rely more on the discrete distribution, while infrequent words should rely more on their embeddings (pre-trained on a large external corpus). Crucially, we do not assume any prior knowledge of the corpus used to train the word embeddings, and our parameterisation depends on the uncertainty of the continuous topic distributions at the current state of the Markov Chain during Gibbs Sampling. Our contributions are as follows:

1. By using adaptive mixed representations for the observed word with a data-dependent parameterisation, we provide an automatic trade-off between continuous and discrete representations during inference. Our method requires no additional tuning and relies purely on corpus statistics and statistics gathered from the current state of the Markov Chain.

2. We illustrate the extensibility of our approach to LDA variants with a combined topic model; Cross-lingual Adaptive LDA, and showed that adaptive mixing can balance between both discrete and continuous representations for better topic coherence on both monolingual and multilingual datasets.

2 Background

2.1 Unsupervised Learning with LDA

Discrete LDA (Blei et al., 2003) describes a generative probabilistic model of a corpus with latent topics. Formally we can define a corpus with D documents and K topics, where each document has a multinomial distribution over topics, $\Theta = \{\theta_1, \cdots, \theta_D\}$, and each topic has a multinomial distribution over words, $\Phi = \{\phi_1, \cdots, \phi_K\}$. Θ and Φ are the set of document-topic and topic-word distributions respectively. LDA relies on discrete counts and co-occurrence statistics, and therefore has poorer estimates in low resource scenarios due to data sparsity.

Gaussian LDA (Das et al., 2015) proposes a variant of LDA which operates on the continuous vector space rather than on discrete words. Each word is represented by an M-dimensional vector $\mathbf{v} \in \mathbb{R}^M$ and is drawn from a multivariate Gaussian for that topic. That is, for K topics, there are K Gaussian distributions. While there have been extensions to more complex continuous distributions such as von Mises-Fisher (Batmanghelich et al., 2016; Li et al., 2016b)), we opted to work with a simpler distribution to demonstrate the approach, which can subsequently be extended in future work.

Polylingual LDA (Mimno et al., 2009) studies LDA across more than two languages using parallel corpora. The model assumes that the document-topic distribution θ_d, is shared across languages, and that each language specific topic has a multinomial topic-word distribution, $\Phi^{\ell_1}, \Phi^{\ell_2}$ due to the discrete nature of words. Mimno et al. (2009); Ni et al. (2009) showed that Polylingual topic models can infer topic structure in multilingual corpora.

Latent Feature Topic Models A natural extension to discrete only or continuous only representations, is to model a word as being sampled with some probability from its discrete or continuous component. Nguyen et al. (2015) introduced an interpolation between the continuous and discrete representations, but convert the continuous representations back into discrete probability over word types by learning latent feature weights.

3 Discrete-Continuous Mixture LDA

We first establish an incremental extension to the Latent Feature Topic model using mixture of discrete categorical and continuous Gaussian distributions. We adopt a mixture model where each word has some probability of either coming from its categorical (discrete) or Gaussian (continuous) distribution. The **generative process** for this model with K topics is as follows:

For topic $k = 1$ to K
1. Draw covariance $\Sigma_k \sim \mathcal{W}^{-1}(\Psi, \nu_0)$
2. Draw mean $\mu_k \sim \mathcal{N}(\mu_0, \frac{1}{\kappa}\Sigma_k)$
3. Draw topic-word distribution $\phi_k \sim Dir(\lambda)$

For each document d in corpus C
1. Draw a topic distribution $\theta_d \sim Dir(\eta)$
2. For each word $w_{d,i}$
   (a) Draw topic $z_{d,i} \sim Multin(\theta_d)$
   (b) Draw $\pi \sim Beta(\alpha, \beta)$
   (c) With π, draw $w_{d,i} \sim Multin(\phi_{z_{d,i}})$
   (d) With $(1-\pi)$, draw $\mathbf{v}_{d,i} \sim \mathcal{N}(\mu_{z_{d,i}}, \Sigma_{z_{d,i}})$

where $\mathcal{W}^{-1}$ is the Inverse Wishart distribution, Ψ is the normalised Precision matrix, ν_0 is degrees of freedom, μ_0 is the prior mean for each Gaussian topic, and π is a mixture coefficient.

3.1 Gibbs Sampling for Posterior Inference

Given a corpus, our goal is to infer the posterior distribution over Θ and Φ and latent topic assignments $\mathbf{z}$, given the observations $\mathbf{x}$. We perform inference with collapsed Gibbs sampling (Griffiths and Steyvers, 2004) which can be derived by analytically integrating out Θ and Φ.

The key step in Gibbs sampling[2] samples a new topic $z_{d,i}$ assignment for each word, $w_{d,i}$ at index i in document d based on the conditional distribution where the previous assignment is ignored (denoted with $\backslash$):

$$\begin{aligned} & p(z_{d,i}{=}k|\mathbf{z}_{\backslash d,i}, \mathbf{x}, \eta, \varphi) \\ & \propto p(x_{d,i}|z_{d,i}{=}k, \varphi, \mathbf{z}_{\backslash d,i}, \mathbf{x}) \\ & \times p(z_{d,i}{=}k|\eta, \mathbf{z}_{\backslash d,i}, \mathbf{x}) \end{aligned} \tag{1}$$

η is the corresponding parameters of a Dirichlet prior for the document-topic distribution θ, and φ are parameters associated with the topic-word distribution. This is either λ for the Dirichlet prior for multinomial ϕ, or $\mu_0, \Sigma_0, \nu_0, \kappa$ for the Gaussian. In our proposed model (section 5), φ consists of both Dirichlet and Gaussian parameters.[3]

The first term on the right in Equation 1 expresses the probability of the i^{th} word in document d under topic k, while the second term expresses the probability of topic k in document d (Griffiths and Steyvers, 2004). Gaussian LDA modifies the first term to use continuous representations instead of discrete, while cross-lingual models focus on the second term which reflects document level sharing.

We focus on the first term to incorporate adaptive mixed representations in section 5.

Mixture Models Let f_1 be a discrete probability mass function with parameters φ_1 and f_2 be a continuous density function with parameters φ_2. The density can be expressed as a convex combination:

$$f(x|\varphi_1, \varphi_2) = \pi f_1(w|\varphi_1){+}(1{-}\pi) f_2(\mathbf{v}|\varphi_2) \tag{2}$$

Then, the second term in Equation 3 can be expressed as the density of $\mathbf{v}_{d,i}$ under the multivariate t distribution[4] parameterised by mean μ_k and covariance $\frac{\kappa_k+1}{\kappa_k}\Sigma_k$, with ν_k degrees of freedom. κ is a prior confidence on μ_k and Σ_k (Murphy, 2012). $\varphi = \{\lambda, \nu_0, \mu_0, \Sigma_0, \kappa\}$, including parameters of both the Dirichlet and Gaussian priors, with the subscript $_0$ indicating parameters of the conjugate prior. N indicates counts; for the first term in the RHS of Equation 3, $N_{k,w_{d,i}}$ are the counts of that particular word type (for the token $w_{d,i}$) assigned to topic k, and $N_{k,w'}$ is the number of counts of word type w' assigned to topic k, with V being the vocabulary.[5]

$$\begin{aligned} & p(x_{d,i}|z_{d,i} = k, \varphi, \mathbf{z}_{\backslash d,i}, \mathbf{x}) \\ & \propto \pi \frac{N_{k,w_{d,i}}{+}\lambda_{w_{d,i}}}{\sum_{w'}^{|V|} N_{k,w'}{+}\lambda_{w'}} \\ & + (1{-}\pi) t_{\nu_k}(\mathbf{v}_{d,i}|\mu_k, \frac{\kappa_k{+}1}{\kappa_k}\Sigma_k) \end{aligned} \tag{3}$$

Table 1 summarises current and previous work with respect to Equation 1.

4 Perspectives on Mixture Coefficient π

4.1 Perspectives on Static π

There are several ways to interpret the mixture coefficient π which interpolates between the discrete and continuous representations. Both the discrete and Gaussian LDA can be viewed as special cases of a two component mixture model, where the mixture coefficient π is either 1 or 0 respectively. π can also be viewed as a tunable hyperparameter that emphasises either representation depending on the availability of discrete word units or quality of embeddings (Nguyen et al., 2015).

4.2 Perspectives on π as a Static Random Variable Informed by Observations

From a Bayesian perspective, the mixture coefficient, $\pi \in [0, 1]$, can be modelled as a random variable following a $Beta$ distribution. This provides a distribution over component proportions (discrete or continuous) with useful conjugate properties. By Bayes Rule, posterior inference of π is proportional to prior times likelihood: $p(\pi|o) \propto p(\pi)p(o|\pi)$.

---

[2] We refer readers to Resnik and Hardisty (2010) for a detailed explanation or refresher of this process.

[3] Hyperparameters are not crucial to understanding our method, and we expand on the notation for them in Table 1.

[4] The multivariate t distribution arises in Bayesian Inference when the variance of a normally distributed random variable is unknown (Gelman et al., 2013).

[5] When $w_{d,i}$, w' are subscripts of N or λ, they are integers that index a count vector or Dirichlet parameter vector λ. e.g, when used in the context of $N_{k,w_{d,i}}$, $w_{d,i}$ is the index of the word type, for the token of i^{th} word of document d.

LDA types	Topic-Word	$p(x_{d,i}^{\ell_1} \mid z_{d,i}^{\ell_1} = k, \varphi, \mathbf{z}_{\backslash d,i}, \mathbf{x}) \propto$	$p(z_{d,i}^{\ell_1} = k \mid \eta, \mathbf{x}) =$
Discrete	Discrete	$\mathbb{D} = \frac{N_{k,w_{d,i}} + \lambda_{w_{d,i}}}{\sum_{w'}^{\lvert V \rvert} N_{k,w'} + \lambda_{w'}}$	$\frac{N_{k \backslash d,i}^{d} + \eta_k}{\sum_{k'} N_{k' \backslash d,i}^{d} + \eta - 1}$
Gaussian	Continuous	$\mathbb{C} = t_{\nu_k}(\mathbf{v}_{d,i} \mid \mu_k, \frac{\kappa_k + 1}{\kappa_k} \Sigma_k)$	
Static π	Mixture	$(1 - \pi) \cdot (\mathbb{C}) + \pi \cdot (\mathbb{D})$	
Adaptive π	Mixture	$(1 - \pi_{k,j}) \cdot (\mathbb{C}) + \pi_{k,j} \cdot (\mathbb{D})$	
Polylingual	Discrete	$\mathbb{L} = \frac{N_{k,w_{d,i}}^{\ell_1} + \lambda_{w_{d,i}}^{\ell_1}}{\sum_{w'}^{\lvert V^{\ell_1} \rvert} N_{k,w'}^{\ell_1} + \lambda_{w'}^{\ell_1}}$	$\frac{N_{k \backslash d,i}^{\ell_1,d} + N_{k}^{\ell_2,d} + \eta_k}{\sum_{k'} N_{k' \backslash d,i}^{\ell_1,d} + \sum_{k'} N_{k'}^{\ell_2,d} + \eta - 1}$
ℓ-Adapt	Mixture	$(1 - \pi_{k,j}^{\ell_1}) t_{\nu_k^{\ell}}(\mathbf{v}_{d,i}^{\ell_1} \mid \mu_k, \frac{\kappa_k + 1}{\kappa_k} \Sigma_k) + \pi_{k,j}^{\ell_1} \cdot (\mathbb{L})$	

Table 1: **Comparison of various LDA models.** For topic k, language ℓ_1, $N_k^{\ell_1,d}$ are counts of topic k in document d, $N_{k,w_{d,i}}^{\ell_1}$ are counts of the word type for the i^{th} word in document d, $w_{d,i}$ in topic k. j indexes the word type for the token $w_{d,i}$ or $v_{d,i}$, and t_{ν_k} is the probability density function of the multivariate t distribution parameterised by ν_k degrees of freedom, mean μ_k and covariance Σ_k. $\kappa_k = \kappa + \sum_{w'}^{\lvert V \rvert} N_{k,w'}$, where κ represents the belief on the prior of the multivariate Gaussian. For the cross-lingual model, ν^{ℓ} and κ_k^{ℓ} sum counts in ℓ_1 and ℓ_2. "\" denotes counts when excluding that variable. $\lambda \in \mathbb{R}^{\lvert V \rvert}$ and $\eta \in \mathbb{R}^{K}$ are hyperparameters of the Dirichlet prior distribution on topic-word and document-topic distribution respectively.

Here the observations o correspond to the discrete and continuous representations.

It can be shown due to conjugacy of the beta-binomial distribution that when the prior $p(\pi)$ is $Beta(\alpha_0, \beta_0)$, the posterior $p(\pi|o)$ is also a Beta distribution, where α' and β' are counts of words that have a discrete and continuous representation available, and α_0 and β_0 are set to 1 in the absence of any information.

$$\pi \sim Beta(\alpha_0 + \alpha', \beta_0 + \beta') \tag{4}$$

Note that with modern word embeddings such as FastText,[6] and Byte Pair Encoding methods, both discrete and continuous representations are mostly always observed together and $|V| = \alpha' \approx \beta'$, when $|V|$ is large, $\mathbb{E}[\pi] = 0.5$ with $Var[\pi] \approx 0$. Unfortunately, this view is overly "naive" as the continuous representations are not true observations, but learned representations which should not constitute full observation counts. We refer to this setting as "Static Mixing (SMIX)" in section 8, where we directly adopt $\pi = 0.5$. [7]

5 Adaptive Mixture Coefficient $\pi_{k,j}$

We recommend a more pragmatic view for balancing between (noisy) learned word embeddings and discrete counts by modeling the mixture coefficient as a topic k and word type indexed by j, $\pi_{k,j}$ specific random variable. At inference time, we sample $\pi_{k,j} \in [0, 1]$ from a $Beta$ distribution that is specific to each word type and each topic for the α parameter, and topic specific for the β parameter to compute Equation 3.

$$\pi_{k,j} \sim Beta(\alpha_{k,j}, \beta_k) \tag{5}$$

The parameter $\alpha_{k,j}$ represents the concentration on the discrete representation, while β_k represents the concentration on the continuous representation. As we do not assume any knowledge of the external corpus used to train the continuous representations, the β parameter is agnostic to the word type. On each Gibbs sampling update, $\alpha_{k,j}$ is updated by discrete counts for the categorical distribution, and β_k is updated based on the uncertainty in the t distribution as measured by the trace of the covariance matrix Σ_k.

5.1 Adaptive $\alpha_{k,j}$ Based on Counts

We specify corpus specific 'α' priors, α_j^0 for each word type indexed by j in the vocabulary as the number of word counts $N_{k,j}$ normalised by K, the number of topics, and the relative proportion of number of documents D to number of unique vocabulary words $|V|$.

$$\alpha_j^0 = \frac{D}{|V|} + \frac{\sum_k N_{k,j}}{K} \tag{6}$$

Intuitively, we expect that if a word has a higher frequency in the corpus, its statistics based on

---

[6] FastText can generate a representation for previously unseen vocabulary words based on their character Ngrams.

[7] For a vocabulary size of just 1000, $Var[\pi] = 0.00026$.

discrete counts are more reliable. However, if $|V| >> D$, count statistics become less reliable. The $\alpha_{k,j}$ parameter at each step where $N_{k,j}$ is the number of times word type at vocabulary index j was assigned to topic k is

$$\alpha_{k,j} = \alpha_j^0 + N_{k,j} \tag{7}$$

which takes a similar form to the regular closed-form conjugate posterior update in Equation 4 for discrete counts.

5.2 Adaptive β_k Based on Topic Uncertainty

Recall that while counts are appropriate for the discrete case, continuous representations are learned from an external corpus and should not constitute full observation counts. Hence there is *no closed form update for the membership of the continuous representations* (Koller and Friedman, 2009). Instead we let β_k be a random variable which reflects our current confidence in the multivariate t distribution indexed by topic k.

We approximate the uncertainty of the k topic distribution, as measured by the sum of eigenvalues of the square root of the topic covariance matrix Σ_k, equivalently written as $tr(\sqrt{\Sigma_k})$. We formulate β_k as depending on the constant terms $\frac{M}{K}$, M is the number of dimensions of the multivariate Gaussian, and (non-constant) Σ_k which is updated at every step of Gibbs Sampling:

$$\beta_k = \frac{M}{K}(tr(\sqrt{\Sigma_k}))^{-1} \tag{8}$$

The intuition for the inverse relationship between $tr(\sqrt{\Sigma_k})$ and β_k is as follows. If the topic has high variance, then β_k should be smaller as we have less confidence in its density function. The square root is a computational convenience for working with the Cholesky decomposition $L_k^T L_k = \Sigma_k$, where the last step assumes most of the variance is contained along the diagonals[8] of L_k. In the following equation, we simplify the notation of L_k to L.

$$\begin{aligned}(tr(\sqrt{\Sigma_k}))^{-1} &= (tr(\sqrt{L^T L}))^{-1} \approx (||\sqrt{L}||_F^2)^{-1} \\ &= (\sum_{i,j} L_{ij})^{-1} \approx (\sum_i L_{ii})^{-1}\end{aligned} \tag{9}$$

We elaborate on the the interpretation of B_k in Appendix C.

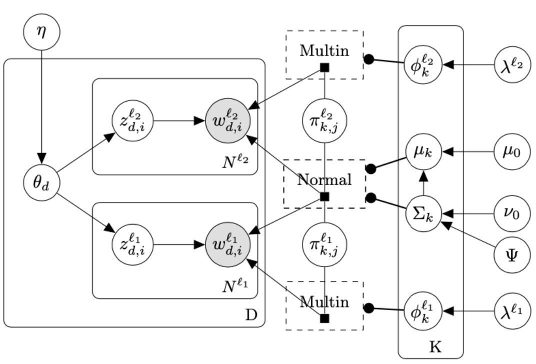

Figure 1: Cross-Lingual Adaptive LDA, with shared continuous parameters μ_k, Σ_k across languages and adaptive $\pi_{k,j}$ for every word type j and topic k. The word type j corresponds to the i^{th} token of document d. $w_{d,i}$ indicates a token when it is not being used as a subscript.

6 Computational Complexity

We consider the computational cost for every Gibbs Sampling step. The main source of computational complexity comes from inverting Σ_k which takes $O(M^3)$ when computing the probability density of $\mathbf{v}_{d,i}$ in row 2 of Table 1.

Since the covariance matrix Σ_k is symmetric and positive semi-definite, we can utilise the Cholesky decomposition where Σ_k can be decomposed as a product of upper and lower triangular matrices, $\Sigma_k = L_k^T L_k$. Although this takes $O(M^3)$, we pay this cost only once during initialisation. L_k is maintained by performing rank-1 updates and downdates (Seeger, 2004) at every step of Collapsed Gibbs Sampling.

As shown in Das et al. (2015), calculating the probability density takes $O(M^2)$ instead of $O(M^3)$. Our proposed prior for β_k sum the diagonals of L_k which takes $O(M)$ with little to no constant time overhead.

Therefore each Gibbs Sampling step takes $O(KM^2)$ where K is the number of topics whose $p(\mathbf{v}_{d,i}|z_{d,i} = k, \varphi, \mathbf{x})$ we need to compute. This is parallelisable to $O(M^2)$ as each term can be computed independently.

7 Cross-lingual Adaptive LDA

The following section describes the extension of our work from the monolingual to the cross-lingual setting. To test the robustness of our proposed model and extensibility to other models, we study the topic coherence in multilingual settings where the quality of word embeddings is thought to be

---

[8] We verified this assumption by inspecting L_k, and found that the off-diagonals tended to be smaller by a factor of 3.

worse than monolingual embeddings. We introduce a new topic model for continuous multilingual representations building on our adaptive sampling scheme, Cross-lingual Adaptive LDA in (Figure 1).

Modeling Assumptions Following Mimno et al. (2009), we assume that the document-topic distribution θ_d is shared across paired language documents, and follow a bag-of-words assumption, i.e., they need not be sentence or word-aligned. We additionally assume that multilingual word embeddings $\mathbf{v}^{\ell_1}, \mathbf{v}^{\ell_2}$ have been mapped to the same embedding space, by adopting shared Gaussian mean μ_k and covariance Σ_k across languages. This reduces the number of parameters and importantly ensures a continuous mapping across languages. Although this does not necessarily affect topic-coherence when measured within in each language, this would results in very poor cross-lingual document-topic representations. We checked this assumption by inspecting the learned topics without parameter sharing and found that topic indexes were mismatched across languages. Topic 5 in English may be about sports but Topic 5 in French may be about medicine.

7.1 Adaptive Mixing for Cross-lingual LDA

For the cross-lingual setting, our parameterisation of Equation 5 takes into account language $\ell \in \mathcal{L}$ for word type j and topic k:

$$\alpha^{\ell}_{k,j} = \frac{D}{|V^{\ell}|} + \frac{\sum_{k'}^{K} N^{\ell}_{k',j}}{K} + N^{\ell}_{k,j}$$
$$\beta^{\ell}_{k} = (\frac{M}{K \cdot |\mathcal{L}|})(tr(\sqrt{\Sigma_k}))^{-1} \qquad (10)$$

Similar to the low resource monolingual setting, our approach relies on existing pre-trained multilingual word embeddings. Note that each language may have different vocabulary size.

8 Experiments

8.1 Experimental Setup

We conduct experiments on a standard monolingual dataset and multilingual wikipedia dataset, reflecting a resource constrained setting by reducing the number of train documents. Our experiments[9] investigate the following:

- Does an adaptive mixture coefficient perform better than the fully continuous, fully discrete, and static mixture coefficient?
- How do the various mixture models perform across different number of training documents?

We compare the following models in Table 2, ℓ- indicates the cross-lingual case in Table 3 and **SMIX** is as described in subsection 4.2:

- **DISC**: Discrete LDA ($\pi = 1$)
- **GAUS**: Gaussian LDA ($\pi = 0$)
- **SMIX**: Static Mix ($\pi = 0.5$)
- **ADAP**: Adaptive Mix (adaptive π)

8.2 Datasets

We use the **20 newsgroup dataset (20NG)** which is a common text analysis dataset containing around 18000 documents and 20 categories.[10] We perform stratified shuffled sampling, using 7000 docs as holdout test and varying the number of training documents from 1000 to 8000. For each model and each training size, we present the results averaged across 5 random splits of the dataset.

Since the goal is to model the present corpora, our main results are evaluated on a held-out test set based on the same corpora. We additionally evaluate on a held-out test set following (Röder et al., 2015). GAUSS performs better in this setting, and we discuss possible reasons in Appendix F.

Wikipedia paired document corpus. For the multilingual scenario, we utilised a Wikipedia dataset (Sasaki et al., 2018) that was automatically constructed by inter-language link to the most relevant foreign language document. For the multilingual setting 1000 test pairs were standardized across all languages, and training data consisted of 8000 randomly selected document pairs for each language. We performed shuffled samping on the training data for 5 random splits of 1000 and 7000 training document pairs.

Note that *low resource topic modeling is not equivalent to low resource languages*. A language can be considered high resource but the collection of documents that we are modeling could be small.[11]

---

[9] Code made available at `https://github.com/suzyahyah/adaptive_mixture_topic_model`

[10] The dataset can be obtained at `http://qwone.com/~jason/20Newsgroups/`

[11] An example of this is the modeling of Golden Age Spanish Sonnets (Navarro-Colorado, 2018) which has a corpus size of around 5000 documents.

Table 3: Performance of various models on languages *ro:*Romanian, *fr:*French, *pl:*Polish, *es:*Spanish on 1000 and 7000 documents. Each NPMI score reported was averaged across 5 random train-test splits. $^*p < 0.05$ significant difference for paired t-test against the strongest baseline (DISC).

Preprocessing Standard text preprocessing steps were applied. Stopwords, digits, punctuations, words that appeared less than 5 times and the top 10 most frequent words were removed for efficiency. Wikipedia articles were restricted to the first 200 words and document titles were removed.

Model Settings All experiments (both 20NG and the multilingual experiments) were conducted with pre-trained multilingual word embeddings from the MUSE library (Conneau et al., 2017). We trained for up to 100 iterations and checked for convergence by inspecting mixing of the posterior topic-word distributions.

Hyperparameters We initialised the prior mean μ_0 and covariance Σ_0 to the empirical mean and sample covariance respectively based on random assignment of words to topics. Following Das et al. (2015), we initialise κ to 1, ν_0 to the embedding size M of 300. Parameters of the Dirichlet prior η and λ are set to 1 and 0.01 respectively, and $K = 20$. The same hyperparameter settings were used in the multilingual setting.

All parameters of our proposed approach are based on corpus statistics, and existing parameters such as number of topics, and embedding size.

8.3 Topic Coherence Measure

Topic models are often evaluated based on the likelihood of held-out documents. However the likelihood of words from the discrete probability mass function and continuous probability density function is not directly comparable. Instead, we compute the coherence score S_k of topic k using the normalised point-wise mutual information (NPMI; Bouma (2009)) which has been found to correlate with human judgement of topic quality (Lau et al., 2014). We also evaluate on the 'C_v' metric, which is closely related (see Appendix F) from Röder et al. (2015).

NPMI ranges from $[-1, 1]$, where -1 indicates no co-occurences and 1 indicates 100% co-occurences. [12] The score of each topic S_k is computed from word pair combinations of the top T words returned by that topic.

$$S_k = \sum_{i=2}^{T} \sum_{j=1}^{i-1} NPMI(w_i, w_j) \tag{11}$$

$$NPMI(w_i, w_j) = \frac{log \frac{p(w_i, w_j) + \epsilon}{p(w_i) \cdot p(w_j)}}{-log(p(w_i, w_j) + \epsilon)} \tag{12}$$

We extract word co-occurrence statistics of the held-out documents to compute $p(w_i)$ and $p(w_i, w_j)$, and set ϵ to $1e^{-12}$ to avoid logarithm of 0. NPMI averaged across all topics are reported as $\frac{1}{K} \sum_k S_k$ in Table 2 and 3.

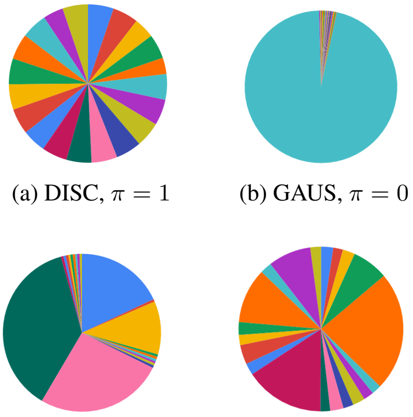
Note that the standard metric in Equation 12 will encounter division by 0 for the case where $p(w_i) \cdot p(w_j) = 0$, which is a case which frequently occurs in our low resource setting. We elaborate on this in Appendix D.

8.4 Results and Discussion

Finding 1: Adaptive Mixing performs best in resource constrained settings. We see that in Table 2, the adaptive mixture coefficient performs better under more resource scarce settings, and

---

[12] Hao et al. (2018) introduced a multilingual NPMI for low resource languages and proposed the bible as a held-out test set, but note that it is "archaic" - good at evaluating topics such as family and religion but poor at evaluating modern topics such as biology. We use regular NPMI for consistency with the monolingual setup.



(a) DISC, $\pi = 1$ (b) GAUS, $\pi = 0$

(c) SMIX, Static π (d) ADAP dynamic π

Figure 2: Topic proportions for various mixture coefficients (π) in the 20NG dataset using $K = 20$. Slices do not correspond to ground truth, and only illustrate relative proportions. Although DISC can recover a similar proportion to the ground truth, the quality of topics are not as good as ADAP.

after a certain point, is nearly equivalent to the Discrete LDA. These results are in the direction that we expect, the discrete model performs increasingly well with larger corpus sizes.

Gaussian LDA (GAUS) performs poorly with increasing number of training documents. The authors report better performance using Pointwise Mutual Information (PMI) which assigns high scores to rare words such as human names such as "scott, graham, walker.."[13] which are not representative of themes. In this work, we evaluate using normalized PMI (Bouma, 2009) which corrects for this. This is somewhat suprising given the dominance of neural methods in modern NLP, and motivates our analysis (see **Observation 1** and **Observation 2**) in the next section.

Interestingly, even with a less optimal continuous distribution, the adaptive method is able to balance between both representations with low number of training documents, and has a 'jump-start' using embeddings. We note that ADAP performs slightly less convincingly in the multilingual setting in terms of achieving statistical significance (not poorer in absolute terms), which could be due to poorer quality of multilingual embeddings.

Finding 2: Static mixture coefficient of $\pi = 0.5$ performs poorly, and while this could potentially be tuned for better performance, our adaptive method requires no tuning at all. This is discussed further in subsection 8.6.

No. train docs = 1000		No. train docs = 7000

Table 4: Top topic words on 20NG, bolded words are common across both topics. ADAP (Adaptive π) is able to construct topics with little training data (1000 docs), and correctly assigns human names to their ground truth topic.

One might expect that SMIX should not be worse than DISC or GAUSS, since it has access to both discrete and continuous distributions. However, the results suggest that equally weighting both the continuous and discrete topic representations, causes the model to not be able to learn effectively if they are in conflict, for e.g, continuous topic prefers topic 15 and the discrete topic prefers topic 3, and if weighted in equal proportions, this hinders the updates in Gibbs Sampling.

8.5 Analysis

Observation 1: GAUS produces narrow topics which are oddly narrow based on names (Table 4), American Cities, directions (North, South, East, West) etc. This phenomena is present in both the monolingual and multilingual models. While these groups of words may be semantically close, they are not representative 'themes' in a corpus.

This may be attributed to pre-training via skip-gram loss to predict neighbouring words (Mikolov et al., 2013). Words which are used in similar contexts have similar embeddings, and the more unique the context is, the narrower the word clusters. To verify this, we compared word clusters from the Gaussian Mixture Model (with same K) (Bishop, 2006), which uses no corpus information. We observe a high word overlap with the topics from GAUS (see Appendix E), indicating that the continuous representations dominate the corpus co-occurence statistics.

Observation 2: GAUS has a rich-get-richer phenomena. Figure 2 shows the size of topics produced by different models on the 20NG. With the exception of very narrow clusters of words,

---

[13] See Table 1 of Das et al. (2015)

most words collapse onto a single topic for GAUS (Figure 2b).[14] If many words have been assigned to one topic, that topic covariance Σ_k becomes much larger than the others, leading to subsequent $\mathbf{v}_i$ then having a higher relative density under that topic during Gibbs Sampling.

Our proposed adaptive π (Figure 2d) counteracts this effect better than the static π (Figure 2c). If Σ_k is large, to balance the effect of words having a higher density under topic k, the algorithm samples a larger π, thereby placing less weight on the continuous representation.

Observation 3: ADAP is flexible and produces reasonable topics. Discrete LDA does not perform well with low training data due to sparsity of word co-occurences. Table 4 shows that ADAP does not suffer from this and can make up for the lack of training data to produce a topic about 'government' and 'law'. Next, we observe that while GAUS clusters all human names together based on their embedding space, ADAP is not overly reliant on embeddings and can correctly assign 'Paul' and 'Mary' to its ground truth topic of christianity. Additional topics and NPMI coherence scores are available in Appendix G.

8.6 Stability of Mixture Coefficient

As our experiments were conducted with a fixed number of topics, we study the expectation of α, β, π under a varying number of topics (K from 20 to 200).

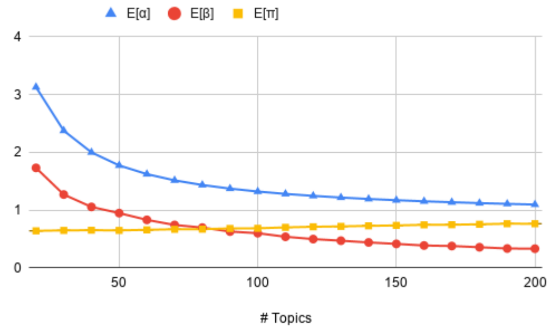

Figure 3: Stability of adaptive mixture coefficient $\pi_{i,k}$ with increasing number of topics in 20NG using 7000 documents. All α, β, π are expected values across all vocabulary words and all topics. We observe that the expected values vary smoothly with increasing K.

We approximate the expectation by the arithmetic average: $\mathbb{E}[\alpha] = \frac{1}{K}\frac{1}{|V|}\sum_k^K \sum_j^{|V|} \alpha_{k,j}$ for a fixed K, where $\mathbb{E}[\pi]$ and $\mathbb{E}[\beta]$ are calculated in the same manner. We verified that as K increases, the variance of π increases as expected, as reflected by the smoothly decreasing $\mathbb{E}[\alpha]$ and $\mathbb{E}[\beta]$.

Note that α and β take on different values for each word and topic during Gibbs Sampling. We observe that while $\mathbb{E}[\pi]$ is close to 0.5 for $K = 20$ for ADAP, it significantly outperforms SMIX ($\pi = 0.5$) in Table 2. This lends confidence to the interpretation that the adaptive mixture coefficient $\pi_{k,j}$ contributes to the better performance, as opposed to simply having a better static π.

9 Conclusion

Low resource scenarios present an interesting challenge to topic modeling due to sparsity of counts and a lack of data to train neural models. Our work proposes an automatic trade-off between externally trained continuous representations and traditional co-occurrence count-based statistics that is specific to each word and topic. The method accounts for variations in number of topics and embedding dimensions, and requires no additional tuning beyond existing methods.

Importantly, it requires no additional retraining of word embeddings or learning of topic embeddings, allowing us to rely solely on pre-trained representations and existing corpus statistics. We showed the efficacy and extensibility of our approach on a monolingual and a multilingual dataset, while introducing a new Cross-lingual Adaptive LDA topic model in the process. In future work, we aim to study the different scenarios of low resource (e.g., when there are a lot of infrequent words such as named entities) and their interaction with different embedding methods.

A Pseudocode for Crosslingual Adaptive LDA Inference

Algorithm 1: Adaptive Mixing LDA Inference

```
Data: Documents $\mathscr{D} = \{doc_1, \cdots, doc_D\}$,
      Vocab $V = \{w_1, \cdots, w_{|V|}\}$,
      Embeddings $\{\mathbf{v}_1, \cdots, \mathbf{v}_{|V|}\}, \mathbf{v} \in \mathbb{R}^M$
Result: $\Phi = \{\phi_1, \cdots, \phi_K\}, \Theta = \{\theta_1, \cdots, \theta_D\}$
Initialization:
$\mu_0 \leftarrow \frac{1}{|V|} \sum_{j=1}^{|V|} \mathbf{v}_j$ (prior mean)
$\Sigma_0 \leftarrow \frac{1}{|V|-1} \sum_{j=1}^{|V|} (\mathbf{v_j} - \mu_0)(\mathbf{v_j} - \mu_0)^T$ (prior cov)
for doc $d \in \{1, \cdots, D\}$, word $i$ do
    $z_{d,i} \leftarrow k$ uniform sample from $\{1, \cdots, K\}$
for topic $k \in \{1, \cdots, K\}$ do
    $N_k \leftarrow |\{z_{d,i} = k | \forall i \in |d|, \forall doc_d \in \mathscr{D}\}|$
    $\mu_k \leftarrow \frac{\kappa \mu_0 + N_k \bar{\mathbf{v}}_k}{\kappa_k}$
    $\Sigma_k \leftarrow \frac{\Psi_k}{\nu + N_k - M + 1}$
    $L_k^T L_k \leftarrow \Sigma_k$ (cholesky decomposition)
    $N_{k,j} \leftarrow |\{z_{d,i} = k | \forall doc_d \in \mathscr{D}\}|$ for each $w_j \in V$, $j$ is word type of token $w_{d,i}$
    $N_k^d \leftarrow |\{z_{d,i} = k | \forall\ w_i$ in $doc_d\}|$ for each $doc_d \in \mathscr{D}$
while iter<maxiter or not converged do
    for doc $d \in \{1, \cdots, D\}$, word $i$ in doc do
        $z_{old} \leftarrow z_{d,i}$
        Decrement by 1, $N_{z_{old}}, N_{z_{old},j}, N_{z_{old}}^d$
        Update $\alpha_{z_{old},j}, \beta_{z_{old}} (Eq : 7, 9)$
        Update $\mu_{z_{old}}, L_{z_{old}}$
        for topic $k \in \{1, \cdots, K\}$ do
            Sample $\pi_{k,j} \sim Beta(\alpha_{k,j}, \beta_k)$
            Compute $\_p(z_{d,i} = k | \varphi, \mathbf{x})(Eq : 1, 3$
        )
    Sample $z_{new} \sim p(z_{d,i} | \varphi, \mathbf{x})$
    Increment by 1, $N_{z_{new}}, N_{z_{new},j}, N_{z_{new}}^d$
    Update $\alpha_{z_{new},j}, \beta_{z_{new}} (Eq : 6, 8)$
    Update $\mu_{z_{new}}, L_{z_{new}}$
```

The full inference algorithm is given in Algorithm 1. For details on the parameterisation of the multivariate t, update of μ_k and computation of Ψ_k, we refer readers to Murphy (2012). For update and downdates of L_k, we refer readers to Seeger (2004) and Das et al. (2015).

B Accounting for Uncertainty in the Multivariate t Distribution

We present a small modification when calculating the density of the word vector $\mathbf{v}_{d,i}$ for each topic (row 2 of Table 1). At each step of Gibbs Sampling, the model samples a topic based on the relative likelihood of a $\mathbf{v}_{d,i}$ drawn from a t-distribution of topic k.[15] We observe that in Equation (1), the second term is dominated by the first term, where $x_{d,i}$ is a word vector representation, $\mathbf{v}_{d,i}$.

In high dimensions, $p(\mathbf{v}_{d,i}^{\ell_1} | z_{d,i}^{\ell_1} = k, \varphi, \mathbf{z}_{\setminus d,i}, \mathbf{x})$ becomes highly skewed towards a certain topic, such that the influence of the document structure becomes negligent. This motivates a correction in the first term, as the embeddings are pre-trained rather than a *true* signal. We correct the degrees of freedom ν_k to better account for uncertainty in the embedding representations.

B.1 Rescaling the Degrees of Freedom ν_k

As given by Murphy (2012), $\nu_k = \nu_0 + N_k - M + 1$, where N_k is the number of words assigned to topic k and M is the embedding dimensions. Upon initialisation, under random assignment of words to topics, $\mathbb{E}[N_k] = \frac{|\tilde{V}|}{K}$, where $|\tilde{V}|$ are all the (non-unique) words in the corpus. Since for a typical corpus $|\tilde{V}|$ is very large and $\frac{|\tilde{V}|}{K} >> M$, the degrees of freedom ν_k are very large resulting in an approximate normal distribution which is over-confident in its posterior predictions. This effectively dominates the priors for Σ_0, ν_0 or μ_0. Hence, we rescale ν_k to $\hat{\nu_k}$ from 1 to 30[16] to account for inherent uncertainty over $\mathbf{v}_i$ belonging to any particular topic.

The effect of rescaling ν_k results in a heavier-tail distribution which results in higher density for $\mathbf{v}$ which are further from μ_k. This encourages better mixing during Gibbs Sampling.

Comparison with the fully Bayesian treatment. We found this heuristic to be numerically and em-

---

[15] Readers are referred Murphy (2012) for an exposition on the form for posterior inference under a Gaussian Prior.

[16] As the degrees of freedom increase, the t distribution approaches the normal distribution. $\nu \geq 30$ is a rule of thumb for when the difference between the t distribution and normal distribution becomes negligible.

pirically more stable than a fully Bayesian treatment which encodes a higher variance in the t distribution by having a larger prior on the covariance matrix Σ_0.

First, re-estimating the covariance matrix at every step of Gibbs Sampling is numerically unstable with a large Σ_0. Next, rescaling ν_k guarantees that we maintain a heavy-tailed t distribution at every iteration of Gibbs Sampling resulting in better mixing of the Markov Chain. By adopting the rescaling heuristic, we can directly set the prior covariance Σ_0 to its sample covariance, removing one adhoc parameter choice. Since both setting a large prior Σ_0 and scaling ν_k are modeling decisions, we adopt the approach that is numerically and empirically more stable.

C Interpretation of β_k

Note that β_k can be interpreted as a random variable drawn from a Gamma distribution, with shape parameter $\frac{1}{K}$, and rate parameter $\frac{tr(\sqrt{\Sigma_k})}{M}$.

$$\beta_k \sim Gamma(\frac{1}{K}, \frac{tr(\sqrt{\Sigma_k})}{M}) \qquad (13)$$

Then, Equation 8 is the point estimate of β_k obtained from the expectation of the Gamma distribution, where $\beta_k \in (0, \infty)$ can be interpreted as real-valued 'counts' for observing the continuous representation. The rate parameter is scaled by $\frac{1}{M}$ to make the numerator robust to dimension size. Since Σ_k is positive semi-definite, and square root is a monotonically increasing function, as M increases, the trace of Σ_k increases ($\sum_i^M \sigma_i, \sigma_i \geq 0, \forall i$) and β_k decreases.

D NPMI when $p(w_i) \cdot p(w_j) = 0$

In our implementation of NPMI, we do not consider the pair if either $p(w_i)$ is $p(w_j)$ is 0, as this simply indicates a "mismatch" between training and test corpus. However if they are non-zero, and $p(w_i) \cdot p(w_j) = 0$, then the model has predicted a poor word pair that never co-occurs despite them individually appearing in the test corpus, and the score for $NPMI(w_i, w_j) = -1$.

This differs from many online implementations of NPMI which will simply set $NPMI(w_i, w_j) = 0$ if $p(w_i) \cdot p(w_j) = 0$, and 'does not penalise very poor word pairs of this nature.

8000	0.4090	0.4298	0.3936	0.4072

Table 6: C_v score on held-out wikipedia dataset.

We believe the main reason for $GAUSS$ to score highly on this measure is most likely due to the scoring of word pairs as described in Appendix D. This is supported by the observation that with some very rare words, the effect of ϵ in the NPMI score in C_v is large, resulting in higher scores than expected. This is described in `https://github.com/dice-group/Palmetto/issues/12`.

Abstract

We evaluate neural model robustness to adversarial attacks using different types of linguistic unit perturbations – character and word, and propose a new method for strategic sentence-level perturbations. We experiment with different amounts of perturbations to examine model confidence and misclassification rate, and contrast model performance with different embeddings BERT and ELMo on two benchmark datasets SQuAD and TriviaQA. We demonstrate how to improve model performance during an adversarial attack by using ensembles. Finally, we analyze factors that affect model behavior under adversarial attack, and develop a new model to predict errors during attacks. Our novel findings reveal that (a) unlike BERT, models that use ELMo embeddings are more susceptible to adversarial attacks, (b) unlike word and paraphrase, character perturbations affect the model the most but are most easily compensated for by adversarial training, (c) word perturbations lead to more high-confidence misclassifications compared to sentence- and character-level perturbations, (d) the type of question and model answer length (the longer the answer the more likely it is to be incorrect) is the most predictive of model errors in adversarial setting, and (e) conclusions about model behavior are dataset-specific.

1 Introduction

Deep neural models have recently gained popularity, leading to significant improvements in many Natural Language Understanding (NLU) tasks (Goldberg, 2017). However, the research community still lacks in-depth understanding of how these models work and what kind of linguistic information is actually captured by neural networks (Feng et al., 2018). Evaluating model robustness to manipulated inputs and analyzing model behavior during adversarial attacks can provide deeper insights into how much language understanding models actually have (Hsieh et al., 2019; Si et al., 2020). Moreover, as has been widely discussed, models should be optimized not only for accuracy but also for other important criteria such as reliability, accountability and interpretability (Lipton, 2018; Doshi-Velez and Kim, 2017; Ribeiro et al., 2016; Goodman and Flaxman, 2017).

Context: One of the most famous people born in Warsaw was Maria Skłodowska-Curie, who achieved international recognition for her research on radioactivity and was the first female recipient of the <u>Nobel Prize</u>.
Question: What was Maria Curie the first female recipient of?
Answer: Nobel Prize

Table 1: Example MC question from SQuAD.

In this work, we evaluate neural model robustness on machine comprehension (MC), a task designed to measure a system's understanding of text. In this task, given a *context* paragraph and a *question*, the machine is tasked to provide an *answer*. We focus on *span-based* MC, where the model selects a single contiguous span of tokens in the context as the answer (Tab. 1). We (1) quantitatively measure when and how the model is robust to manipulated inputs, when it generalizes well, and when it is less susceptible to adversarial attacks, (2) demonstrate that relying on ensemble models increases robustness, and (3) develop a new model to predict model errors during attacks. Our novel contributions shed light on the following questions:

- Which embeddings are more susceptible to noise and adversarial attacks?
- What types of text perturbation lead to the most high-confidence misclassifications?
- How does the amount of text perturbation effect model behavior?
- What factors explain model behavior under perturbation?
- Are the above dataset-specific?

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2470–2481
April 19 - 23, 2021.

Broader Implications We would like to stress the importance of this type of work to ensure diversity and progress for the computational linguistics community. We as a community know how to build new models for language understanding, but we do not fully understand how these models work. When we deploy these models in production, they fail to perform well in real-world conditions, and we fail to explain why they fail; the reason being we have not performed through evaluation of model performance under different experimental conditions. Neural model evaluation and thorough error analysis, especially for tasks like machine comprehension, are critical to make progress in the field. We have to ensure our research community goes beyond F1 scores and incremental improvements and gains deeper understanding of models decision making processes to drive revolutionary research rather than evolutionary.

2 Background

There is much recent work on adversarial NLP, surveyed in Belinkov and Glass (2019) and Zhang et al. (2019). To situate our work, we review relevant research on the black-box adversarial setting, in which one does not have access or information about the model's internals, only the model's output and its confidence about the answer.[1]

In an adversarial setting, the adversary seeks to mislead the model into producing an incorrect output by slightly tweaking the input. Recent work has explored input perturbations at different linguistic levels: character, word, and sentence-level. For *character-level perturbations*, NLP systems generally do not take into account the visual characteristics of characters. Researchers have explored the effects of adding noise by randomizing or swapping characters and examining its effect on machine translation (MT) (Heigold et al., 2018; Belinkov and Bisk, 2018), sentiment analysis and spam detection Gao et al. (2018), and toxic content detection Li et al. (2018). Eger et al. (2019) replaced with similar looking symbols, and developed a system to replace characters with nearest neighbors in visual embedding space. For *word-level perturbations*, Alzantot et al. (2018) used a genetic algorithm to replace words with contextually similar words, evaluating on sentiment analysis and textual entailment. For *sentence-level perturbations*, Iyyer et al. (2018) generated adversarial paraphrases by controlling the syntax of sentences and evaluating on sentiment analysis and textual entailment tasks. Hu et al. (2019) found that augmenting the training data with paraphrases can improve performance on natural language inference, question answering, and MT. Niu and Bansal (2018) use adversarial paraphrases for dialog models.

Other related work includes Zhao et al. (2018); Hsieh et al. (2019), who generated natural looking adversarial examples for image classification, textual entailment, and MT. Specifically for MC, Jia and Liang (2017) added a distractor sentence to the end of the context, Ribeiro et al. (2018) extracted sentence perturbation rules from paraphrases created by translating to and then from a foreign language and then manually judged for semantic equivalence, and (Si et al., 2020) focused on evaluating model robustness for MC.

Unlike earlier work, we empirically show how neural model performance degrades under multiple types of adversarial attacks by varying the amount of perturbation, the type of perturbation, model architecture and embedding type, and the dataset used for evaluation. Moreover, our deep analysis examines factors that can explain neural model behavior under these different types of attacks.

Concurrent with the development of our paper, there has also been a slew of relevant work tackling robustness in neural NLP models, including Adversarial Robustness Toolbox (Nicolae et al., 2018), Advertorch (Ding et al., 2019), Foolbox (Rauber et al., 2020), Advbox (Goodman et al., 2020), OpenAttack (Zeng et al., 2020), TEAPOT (Michel et al., 2019), TextAttack (Morris et al., 2020), TextFooler (Jin et al., 2020), and Robustness Gym (Goel et al., 2021).

3 Methods

We perform comprehensive model evaluation for machine comprehension over several dimensions: the amount of perturbation, perturbation type, model and embedding variation, and datasets.

3.1 Perturbation Type

We examine how changes to the context paragraph (excluding the answer span) affect the model's performance using the following perturbations:

- **Character-level**. In computer security, this is known as a homograph attack. These attacks have been investigated to identify phishing

---

[1] For other settings (e.g. white-box), we refer the reader to the above surveys.

Original	The connection between macroscopic nonconservative forces and microscopic conservative forces is described by detailed treatment with statistical mechanics.
Character	**The** **c**onn**e**ct**io**n b**e**twe**e**n macr**o**scopi**c** nonc**o**nservat**ive** force**s** an**d** micro**s**co**pic** con**s**ervative f**orc**es is de**s**crib**e**d by detailed tre**a**tm**e**nt with st**ati**st**i**cal m**ec**hanic**s**.
Word	The connection between macroscopic nonconservative forces and **insects** conservative **troops** is **referred** by detailed treatment with statistical mechanics.
Sentence	The **link** between macroscopic **non-conservative** forces and microscopic conservative forces is described **in detail by** statistical mechanics.

Table 2: Examples of character, word and sentence-level perturbations (bold indicates perturbed text).

and spam (Fu et al., 2006b,a; Liu and Stamm, 2007) but to our knowledge have not been applied in the NLP domain. We replace 25% of characters in the context paragraph with deceptive Unicode characters[2] that to a human are indistinguishable from the original.

- **Word-level**. We randomly replace 25% of the words in the context paragraph with their nearest neighbor in the GLoVe (Pennington et al., 2014) embedding space.[3]
- **Sentence-level**. We use Improved ParaBank Rewriter (Hu et al., 2019), a machine translation approach for sentence paraphrasing, to paraphrase sentences in the context paragraph. We perform sentence tokenization, paraphrase each sentence with the paraphraser, then recombine the sentences.

For character and word perturbations, we use 25% as this is where the performance curve in Heigold et al. (2018) flattens out.[4] Regardless of the type of perturbation, we do not perturb the context that contains the answer span, so that the answer can always be found in the context unperturbed. Because paraphrasing is per sentence, we only modify sentences that do not contain the answer span. An example of each perturbation type is shown in Tab. 2.

3.2 Amount of Perturbation

For each perturbation type, we experiment with perturbing the training data at differing amounts. All models are tested on fully perturbed test data.

- **None**: clean training data.
- **Half**: perturb half the training examples.
- **Full**: perturb the entire train set.
- **Both**: append the entire perturbed data to the entire clean data.[5]
- **Ens**: ensemble model that relies on none, half and full perturbed data; we rely on ensemble voting and only include the word in the predicted answer if any two models agree.

3.3 Model Architecture and Embeddings

BiDAF model with ELMo (Seo et al., 2017; Peters et al., 2018). ELMo is a deep, contextualized, character-based word embedding method using a bidirectional language model. The Bi-Directional Attention Flow model is a hierarchical model with embeddings at multiple levels of granularity: character, word, and paragraph. We use pre-trained ELMo embeddings in the BiDAF model implemented in AllenNLP (Gardner et al., 2018).

BERT (Devlin et al., 2019). BERT is another contextualized embedding method that uses Transformers (Vaswani et al., 2017). It is trained to recover masked words in a sentence as well as on a next-sentence prediction task. The output layer of BERT is fed into a fully-connected layer for the span classification task. Pre-trained embeddings can be fine-tuned to a specific task, and we use the Huggingface PyTorch-Transformers package, specifically *bert-large-cased-whole-word-masking-finetuned-squad* model. We fine-tune for two epochs in each experimental settings.

3.4 Benchmark Datasets

We experiment on two benchmark MC datasets:

SQuAD (Rajpurkar et al., 2016). The Stanford Question Answering Dataset is a collection of over 100K crowdsourced question and answer pairs. The context containing the answer is taken from Wikipedia articles.

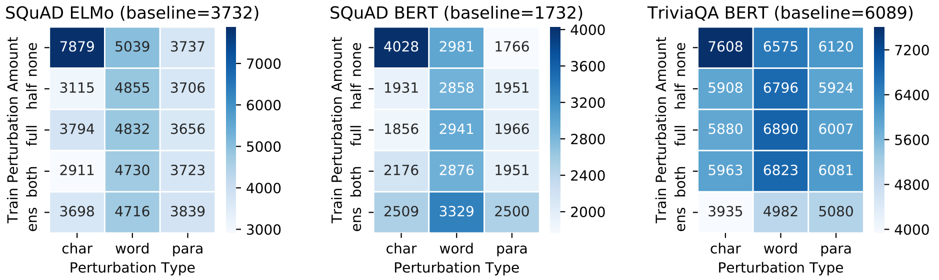
---

[2] From `https://www.unicode.org/Public/security/12.1.0/intentional.txt`

[3] Several alternative embedding techniques could be used to find the nearest neighbors e.g., Word2Vec or FastText. We use GLoVe for consistency with previous work (Li et al., 2018).

[4] Belinkov and Bisk (2018) perturbed text at 100% while Heigold et al. (2018) experimented with 5–30% perturbations.

[5] This has twice the amount of data as other settings so is not directly comparable, but many papers show that doing this can improve a model's performance.



(a) SQuAD, ELMo (b) SQuAD, BERT (c) TriviaQA, BERT

Figure 1: Number of errors by perturbation type and amount of perturbation (higher = worse model performance, or more successful attacks). *Baseline* indicates model errors whose training and testing data were not perturbed. For cross-model/embedding comparison, compare (a) and (b). For cross-dataset comparison, compare (a) and (c). The *ens* training setting is an ensemble of results from the none, half, and full settings.

TriviaQA (Joshi et al., 2017). A collection of over 650K crowdsourced question and answer pairs, where the context is from web data or Wikipedia. The construction of the dataset differs from SQuAD in that question answer pairs were first constructed, then evidence was found to support the answer. We utilize the Wikipedia portion of TriviaQA, whose size is comparable to SQuAD. To match the span-based setting of SQuAD, we convert TriviaQA to the SQuAD format using the scripts in the official repo and remove answers without evidence.

4 Evaluation Results

Fig. 1 summarizes our findings on how model behavior changes under noisy perturbations and adversarial attacks. Here, we briefly discuss how perturbation type, perturbation amount, model, and embeddings affect model misclassification rate. In addition, we contrast model performance across datasets and report how to mitigate model error rate using ensembling. Detailed analyses are presented in Sec. 5. Key findings are *italicized*.

The effect of perturbation type To assess whether perturbations changed the meaning, we ran a human study on a random sample of 100 perturbed contexts from SQuAD. We found (as expected) that the two annotators we employed could not distinguish char-perturbed text from the original. For word perturbations, the meaning of the context remained in 65% of cases, but annotators noted that sentences were often ungrammatical. For sentence-level perturbations, the meaning remained in 83% of cases.

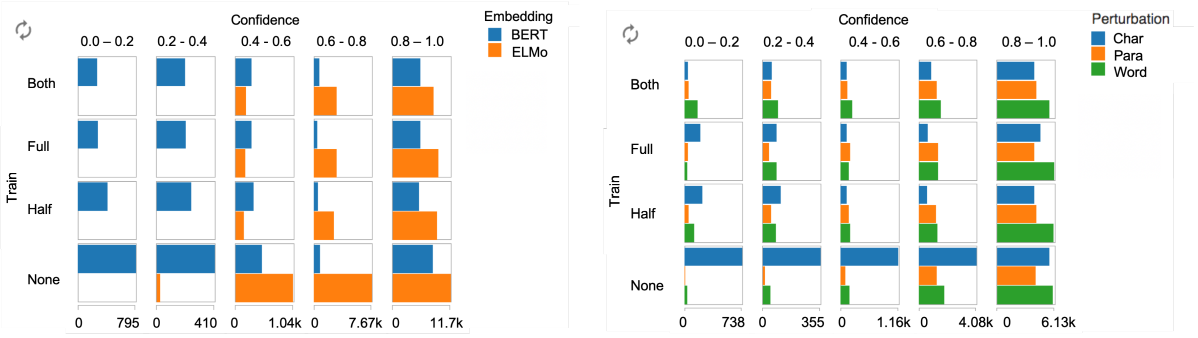
For a model trained on clean data, character perturbations affect the model the most, followed by word perturbations, then paraphrases. To a machine, a single character perturbation results in a completely different word; handling this type of noise is important for a machine seeking to beat human performance. Word perturbations are context independent and can make the sentence ungrammatical.[6] Nevertheless, the context's meaning generally remains coherent. Paraphrase perturbations are most ideal because they retain meaning while allowing more drastic phrase and sentence structure modifications. In Sec. 4.2, we present a more successful adversarially targeted paraphrasing approach.

The effect of perturbation amount Perturbed training data improves the model's performance for character perturbations (1st column of Fig. 1a), likely due to the models' ability to handle unseen words: BiDAF with ELMo utilizes character embeddings, while BERT uses word pieces. Our results corroborate Heigold et al. (2018)'s findings (though on a different task) that *without adversarial training, models perform poorly on perturbed test data, but when models are trained on perturbed data, the amount of perturbed training data does not make much difference.* We do not see statistically significant results for word and paraphrase perturbations (2nd and 3rd columns in each heatmap in Fig. 1). We conclude that perturbing 25% of the words and the non-strategic paraphrasing approach were not aggressive enough.

The effect of model and embedding As shown in Fig. 1a and b, the BERT model had less errors than the ELMo-based model regardless of the perturbation type and amount on SQuAD data. While

---

[6] Future work will address this with language models.



(a) Across models and embedding

(b) Across perturbation types

Figure 2: The effect of perturbation types and embeddings on model behavior measured as high vs. low confidence misclassifications. More robust models should have less high-confidence error or rate (x-axis).

Train	Test	Model Answer
none	char	here”
half	char	Orientalism
full	char	Orientalism
none	word	Orientalism
half	word	behaviourism identities
full	word	The discourse of Orientalism
none	char	Orientalism
half	char	. . . the East as a negative
full	char	Orientalism

Table 3: Example result from response ensembling under the SQuAD ELMo setting. The question is “What was used by the West to justify control over eastern territories?” The answer is “Orientalism”, and in all three settings, the ensemble was correct.

the two models are not directly comparable, our results indicate that the *BERT model is more robust to adversarial attacks compared to ELMo.*

The effect of the data Holding the model constant (Fig. 1b and c), experiments on TriviaQA resulted in more errors than SQuAD regardless of perturbation amount and type, indicating that TriviaQA may be a harder dataset for MC and may contain data bias, discussed below.

4.1 Adversarial Ensembles

Ensemble adversarial training has recently been explored (Tramèr et al., 2018) as a way to ensure robustness of ML models. For each perturbation type, we present results ensembled from the none, half, and full perturbed settings. We tokenize answers from these three models and keep all tokens that appear at least twice as the resulting answer (Tab. 3). Even when all three model answers differ (e.g. in the word perturbation case), ensembling can often reconstruct the correct answer. Nevertheless, we find that this ensembling only helps for TriviaQA, which has an overall higher error rate (bottom row of each figure in Fig. 1).

4.2 Strategic Paraphrasing

We did not observe a large increase in errors with paraphrase perturbations (Fig. 1), perhaps because paraphrasing, unlike the char and word perturbations, is not a deliberate attack on the sentence. Here we experiment with a novel strategic paraphrasing technique that targets specific words in the context and then generates paraphrases that exclude those words. We find the most important words in the context by individually modifying each word and obtaining the model’s prediction and confidence, a process similar to Li et al. (2018). Our modification consists of removing the word and examining its effect on the model prediction. The most important words are those which, when removed, lower the model confidence of a correct answer or increase confidence of an incorrect answer. The Improved ParaBank Rewriter supports constrained decoding, i.e. specifying positive and negative constraints to force the system output to include or exclude certain phrases. We specify the top five important words in the context as negative constraints to generate strategic paraphrases.[7]

We experimented on 1000 instances in the SQuAD dev set as shown in Tab. 4. Our results indicate that *strategic paraphrasing with negative constraints is a successful adversarial attack*, lowering the F1-score from 89.96 to 84.55. Analysis shows that many words in the question are important and thus excluded from the paraphrases. We also notice that paraphrasing can occasionally turn an incorrect prediction into a correct one. Perhaps

---

[7] The number of constraints does not necessarily indicate the number of words that are changed in the context.

Original Paragraph	Strategic Paraphrase
. . . Veteran receiver Demaryius Thomas led the team with 105 receptions for 1,304 yards and six touchdowns, while Emmanuel Sanders caught 76 passes for 1,135 yards and six scores, while adding another 106 yards returning punts.	. . . The veteran earman Demaryius Thomas was leading a team of 1,304 yards and six touchdowns, while Emmanuel Sanders caught 76 passes for 1,135 yards and six scores while he added another 106 yards of punts back.
Question: Who led the Broncos with 105 receptions? **Answer**: Demaryius Thomas (correct) → Emmanuel Sanders (incorrect)	

Table 4: Example of strategic paraphrasing: red indicates the important words, which were used as negative constraints in the paraphrasing; blue indicates changed words in the paragraph.

paraphrasing makes the context easier to understand by removing distractor terms; we leave this for future investigation.

4.3 Model Confidence

In a black-box setting, model confidence is one of the only indications of the model's inner workings. The models we employed do not provide a single confidence value; AllenNLP gives a probability that each word in the context is the start and end span, while the BERT models only give the probability for the start and end words. We compute the model's confidence using the normalized entropy of the distribution across the context words, where n is the number of context words, and take the mean for both the start and end word: $1 - \frac{H_n(\mathbf{s})+H_n(\mathbf{e})}{2}$, where $\mathbf{s}$ and $\mathbf{e}$ are probability distributions for the start and end words, respectively. Low entropy indicates certainty about the start/end location. Since the BERT models only provide probabilities for the start and end words, we approximate the entropy by assuming a flat distribution, dividing the remaining probability equally across all other words in the context.

Comparing confidence across models (Fig. 2a), the *BERT model has lower confidence for misclassifications*, which is ideal. A model should not be confident about errors. Fig. 2b compares confidence across perturbation type. In the *none* training setting, character perturbations introduce the most uncertainty compared to word or paraphrase perturbations. This is expected, since character perturbations result in unknown words. In the adversarial training, word perturbations lead to the highest number of high-confidence errors. Thus, *to convincingly mislead the model to be highly confident about errors, one should use word perturbations.*

5 Robustness Analysis

Here, we do a deeper dive into why models make errors with noisy input. We investigate data characteristics and their association with model errors by utilizing CrossCheck (Arendt et al., 2020), a novel interactive tool designed for neural model evaluation. Unlike several recently developed tools for analyzing NLP model errors (Agarwal et al., 2014; Wu et al., 2019) and understanding ML model outputs (Lee et al., 2019; Poursabzi-Sangdeh et al., 2018; Hohman et al., 2019), CrossCheck is designed to allow rapid prototyping and cross-model comparison to support experimentation.[8]

5.1 The Effect of Question Type, Question and Context Lengths

We examine if models make more errors on specific types of questions in adversarial training, i.e., some questions could just be easier that others. We first examine **question type**:[9] who, what, which, when, where, why, how, and other. The majority of SQuAD questions are *what* questions, while most TriviaQA questions are *other* questions, perhaps indicating more complex questions (Fig. 4a). We see that models usually choose answers appropriate for the question type; even if they are incorrect, answers to *when* questions will be dates or time word spans, and answers to *how many* questions will be numbers. Fig. 4a presents key findings on differences in model misclassifications between two datasets given specific question types. *On the SQuAD dataset, the model finds certain question types, e.g. when and how, easiest to answer regardless of the perturbation type*. Responses to these questions, which generally expect numeric answers, are not greatly affected by perturbations. For TriviaQA, in general we observe more errors across question types compared to SQuAD, i.e. more errors in what, which and who questions.

---

[8] To reproduce our findings, we will release the tool and interactive notebooks upon publication.

[9] Computed as the first word of the question. Many *how* questions are *how many* or *how much*, rather than how in the "in what manner" sense.

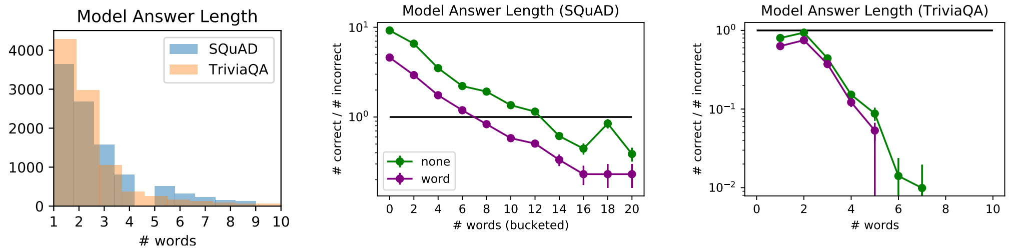


Figure 3: (Left) shows distribution of answer length. (Center) and (Right) show the ratio of correct errors to incorrect errors (log scale y-axis). BERT models were trained on clean data and tested on perturbed data.

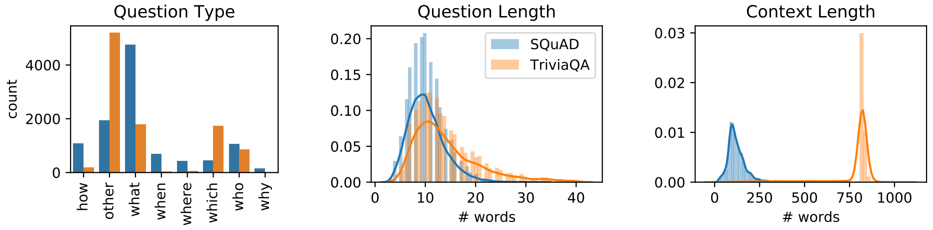
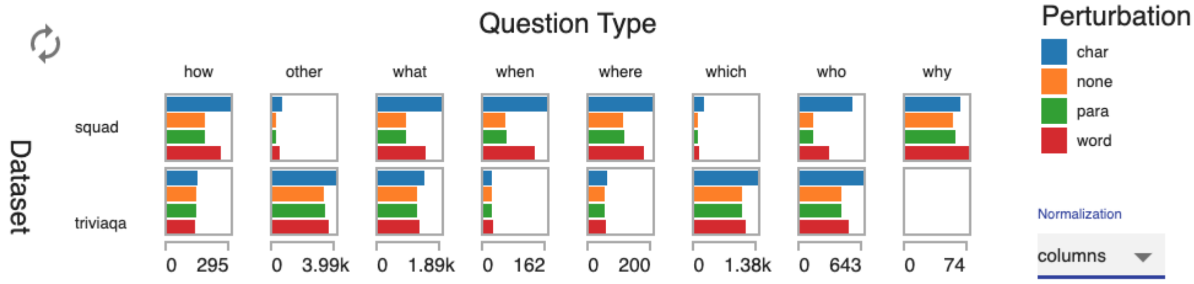


(a) Question type distribution (b) Quest. length norm. density (c) Context length norm. density



(d) Error distribution in BERT models across different perturbations and question types

Figure 4: Contrasting MC model errors by question type, and question and context length across datasets.

Regarding **question length**, SQuAD and TriviaQA have similar distributions (Fig. 4b). Both datasets have a mode answer length around 10 words; TriviaQA has a slightly longer tail in the distribution. We did not find question length to impact the error. Regarding **context length**, SQuAD and TriviaQA have vastly differing context length distributions (Fig. 4c), partly due to how the two datasets were constructed (see Sec. 3.4 for details). For both datasets, the error distribution mirrors the context length distribution, and we did not find any relation between model errors and context length.

5.2 The Effect of Answer Length

Our analysis shows that *the length of the model's answer is a strong predictor of model error in the adversarial setting*: the longer the answer length, the more likely it is to be incorrect. Fig. 3 plots the proportion of correct to incorrect answers. We notice a downward trend which is mostly consistent across experimental settings. For both SQuAD and TriviaQA, the models favored shorter answers, which mirrors the data distribution.

5.3 The Effect of Complexity: Annotator Agreement and Reading Level

Here, we examine the effect of task complexity on model performance under adversarial training, using inter-annotator agreement as a proxy for *question* complexity and paragraph readability as a proxy for *context* complexity.

Inter-annotator agreement represents a **question's complexity**: low agreement indicates that annotators did not come to a consensus on the correct answer; thus the question may be difficult to answer. We examine SQuAD, whose questions have one to six annotated answers. In Fig. 5, we present inter-annotator agreement (human confidence) plotted against model confidence over the four training perturbation amounts, looking only at the incorrect predictions. The setting is SQuAD BERT with character perturbation. We observe

Data	Correct	Errors
SQuAD	12.9	13.0
TriviaQA	17.1	17.5

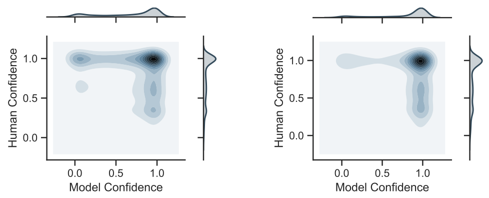
Table 5: Contrasting median readability scores for paragraphs with and without errors across datasets.

that the models are generally confident even when the humans are not, which is noticeable across all perturbation amounts. However, we see interesting differences in model confidence in adversarial training: models trained in the none and half settings have confidence ranging between 0 and 1 compared to the models trained in full and both setting with confidence above 0.8, indicating *training with more perturbed data leads to more confident models*.

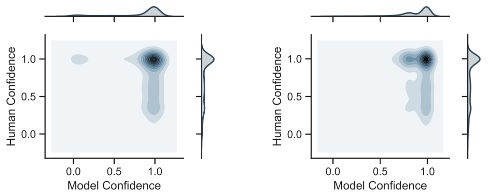
To evaluate the effect of **context complexity**, we use the Flesch-Kincaid reading level (Kincaid et al., 1975) to measure readability. For questions the model answered incorrectly, the median readability score was slightly higher than the median score for correct responses (Tab. 5), indicating that *context with higher reading level is harder for the model to understand*. TriviaQA contexts have higher reading levels than SQuAD.

6 Predicting Model Errors

Our in-depth analysis reveals many insights on how and why models make mistakes during adversarial training. Using the characteristics we analyzed above, we developed a binary classification model to predict whether the answer would be an error, given the model's answer and attributes of the context paragraph. We one-hot-encode categorical features (training amount, perturbation type, question type) and use other features (question length, context length, answer length, readability) as is. For each setting of embedding and perturbation type on SQuAD, we train an XGBoost model with default settings with 10-fold cross validation (shuffled).



(a) None perturbed (b) Half perturbed



(c) Full perturbed (d) Both

Figure 5: The effect of task complexity on model behavior measured as a joint distribution of errors from BERT model on SQuAD using varied amounts of char perturbations (none, half, full and both).

Embedding	Pert.	Majority	F1 score
ELMo	char	0.58	0.70 ± 0.003
ELMo	word	0.54	0.56 ± 0.004
ELMo	para	0.65	0.65 ± 0.008
BERT	char	0.76	0.77 ± 0.008
BERT	word	0.72	0.73 ± 0.006
BERT	para	0.82	0.82 ± 0.006

Table 6: MC error prediction across datasets, embeddings, and perturbation types.

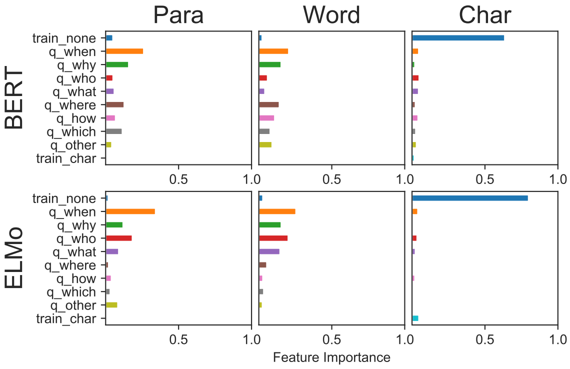


Figure 6: Feature importance when predicting model errors during adversarial attacks.

We present the model's average F1 scores (Tab. 6) and feature importance as computed by the XGBoost model (Fig. 6). We see that performance (micro F1) is better to slightly better than a majority baseline (picking the most common class), indicating that certain features are predictive of errors. Specifically, we find that: *for character perturbations, the fact that the training data is clean is a strong predictor of errors; a model trained on clean data is most disrupted by character perturbations; for word and paraphrase perturbations, question types are important predictors of errors.*

7 Conclusion and Future Work

Our in-depth analysis of neural model robustness sheds light on how and why MC models make errors in adversarial training, and through our error prediction model, we discovered features of the data e.g., question types that are strongly predictive of when a model makes errors during adversarial attacks with noisy inputs. Our results on evaluating the effect of the data e.g., questions and context length will not only explain model performance in context of the data, but will also allow to build future neural models more resilient to adversarial attacks and advance understanding of neural model behavior across a variety of NLU tasks and datasets and its strengths and weaknesses.

For future work, we see many avenues for extension. We plan to experiment with more aggressive and more natural perturbations, and deeper counterfactual evaluation (Pearl, 2019). While recent research has made great strides in increasing model performance on various NLP tasks, it is still not clear what linguistic patterns these neural models are learning, or whether they are learning language at all (Mudrakarta et al., 2018).

More broadly, as AI becomes more entrenched in our lives, AI models need to be held to higher standards including but not limited to accountability (e.g. Wang et al., 2018, 2019, GENIE[10]), fairness (e.g. Saleiro et al., 2018; Bellamy et al., 2018; Bird et al., 2020; Ahn and Lin, 2020, [11];[12];[13]), and transparency (e.g. Lundberg and Lee, 2017; Nori et al., 2019; Hooker et al., 2018; Kokhlikyan et al., 2020; Lundberg et al., 2019; Tenney et al., 2020).

Abstract

Automatic unreliable news detection is a research problem with great potential impact. Recently, several papers have shown promising results on large-scale news datasets with models that only use the article itself without resorting to any fact-checking mechanism or retrieving any supporting evidence. In this work, we take a closer look at these datasets. While they all provide valuable resources for future research, we observe a number of problems that may lead to results that do not generalize in more realistic settings. Specifically, we show that selection bias during data collection leads to undesired artifacts in the datasets. In addition, while most systems train and predict at the level of individual articles, overlapping article sources in the training and evaluation data can provide a strong confounding factor that models can exploit. In the presence of this confounding factor, the models can achieve good performance by directly memorizing the site-label mapping instead of modeling the real task of unreliable news detection. We observed a significant drop (>10%) in accuracy for all models tested in a clean split with no train/test source overlap. Using the observations and experimental results, we provide practical suggestions on how to create more reliable datasets for the unreliable news detection task. We suggest future dataset creation include a simple model as a difficulty/bias probe and future model development use a clean non-overlapping site and date split.[1]

1 Introduction

The proliferation of unreliable news is widely acknowledged (Del Vicario et al., 2016; Lazer et al., 2018; Vosoughi et al., 2018), and its identification is a socially important problem. In this work we use the label unreliable news as a broad term for all unverifiable and misleading news content, regardless of whether the content is malicious (targeted misinformation) or not. Accordingly, while specific definitions vary in different datasets used in this work, we refrain from using the term "fake" since identifying the intent of the author(s) is beyond the scope of this work. To mitigate the problem of surfacing unreliable news content, various websites (e.g., PolitiFact[2], Media Bias/Fact Check (MBFC)[3], GossipCop[4], etc.) determine the reliability of news by manually fact-checking the important claims in given news articles. Beyond requiring investigative expertise, manual fact-checking is time-consuming and is thus limited to only a small set of selected news articles.

Recent research has explored automating this process using machine learning methods to automatically determine news veracity (Pérez-Rosas et al., 2018; Baly et al., 2018; Nie et al., 2019; Wright and Augenstein, 2020). These efforts were made possible due to the availability of large-scale unreliable news detection datasets (Horne et al., 2018b; Shu et al., 2017; Wang, 2017). In our work, we examine if these datasets accurately reflect the real difficulty of this task or if there are any hidden biases in the datasets. Specifically, we study different methods of dataset construction (e.g., how the data was collected, how the data was split, etc.) and show that the assessed difficulty of the task is sensitive to how carefully different factors are considered when building and using these datasets.

Our investigation begins with data collection procedures: we look at the source of news stories (news outlets, social media, fact-checking websites, etc.) as well as the annotation process (number of

Data Collection	Dataset Construction	Experiment Design
1. Collect from less biased or unbiased resources (e.g. original news outlets). (Sec. 3.2)	1. Examine the most salient words to check for biases in the datasets. (Sec. 3.2)	1. Apply debasing techniques when developing models on biased datasets. (Sec. 3.2)
2. Collect from diverse resources (in terms of sources, topics, time, etc.). (Sec. 3.2, 4)	2. Run simple BoW baselines to check how severe the bias is. (Sec. 4)	2. Check the performance on sources/dates not in your training set. (Sec. 4.2, Sec. 4.3)
3. Collect precise article-level labels if possible. (Sec. 3.1)	3. Provide train/dev/test splits with non-overlapping source/time. (Sec. 4.2, 4.3)	3. Check the performance on sources with limited examples. (Sec. 4.4)
		4. Test your model on multiple complementary datasets (e.g. with different domains, styles, etc.). (Sec. 3.2, 4.4)

Table 1: Suggestions for data collection, dataset construction and experiment design for unreliable news research.

labels, granularity of labels, article- or site-level annotation). We discuss the pros and cons of each approach and point out some hidden pitfalls. Using FakeNewsNet (Shu et al., 2017) as an example, we demonstrate how selection biases in data collection can lead to undesired biases in the created datasets.

Moving beyond data collection, we examine two commonly applied ways of splitting the dataset for training and testing that help the model achieve high performance without correctly modeling the task. Specifically, we show that using a disjoint set of sites/news outlets for training and test data significantly decreases the models' performance (>10%) and that the drop in performance is related to how similar (or dissimilar) the sites in both sets are (reflected by various site-level distributional distance metrics including L2, cos, EMD, etc.). Additionally, we also examine the effect of time overlap between both train and test sets. We observe that different news outlets are likely to have similar content in a small time window (i.e., the same story gets covered by multiple outlets within a day or a few days period). While we do not find any evidence that the studied models exploit this factor, we nevertheless suggest that future datasets are split both by time and site/news outlet.

In summary, our main contributions are: (1) showing how data collection procedures can lead to systematic biases in unreliable news datasets, (2) demonstrating how confounding factors——such as site/news outlet and time——in these datasets can degrade their quality and lead to underestimating the difficulty of the task, and finally (3) suggesting possible mechanisms to avoid these biases and confounding factors when building new datasets. To facilitate future research, we also provide a list of practical suggestions for data collection, dataset construction, and experiment design in Table 1.

2 Related Work

Unreliable News Detection. Unreliable news detection and other news veracity related tasks have been receiving an increasing focus as news sources have become more accessible in recent years. A lot of effort has been put into collecting high-quality datasets. Wang (2017); Shu et al. (2017) collected manually labeled statements or news articles from fact-checking websites. The NELA datasets (Horne et al., 2018b; Nørregaard et al., 2019; Gruppi et al., 2020) scrape news articles directly from news outlets and use the manually annotated labels from Media Bias/Fact Check (MBFC) as site-level annotations. Social media is also a popular resource for collecting news stories (Nakamura et al., 2020; Santia and Williams, 2018; Mitra and Gilbert, 2015). Researchers have also collected datasets for various related topics, such as rumor detection (Kwon et al., 2017; Ma et al., 2016), and propaganda detection (Da San Martino et al., 2020; Barrón-Cedeno et al., 2019). Besides classifying the veracity of news articles, researchers have also explored related problems, such as predicting the reliability of news sites (Baly et al., 2018), identifying fact-check worthy sentences (Wright and Augenstein, 2020), among other tasks. Several recent papers also focus on measuring the trustworthiness of single statements (Wang, 2017; Pomerleau and Rao, 2017; Alhindi et al., 2018). In this work, we focus on article-level classification because of its relevance to applications, like news feeds, that operate at the article level.

Dataset	Size	Article Source	Label Type
NELA[5]	136K/713K/1.12M	News outlets	Site-level
FakeNewsNet[6]	603K	Fact-checking websites	Article-level
r/Fakeddit[7]	1.06M	Social Media (Reddit)	Site-level

Table 2: Statistics and properties of three recent large-scale unreliable news datasets. The three statistics of NELA dataset sizes correspond to its three versions released in 2017, 2018 and 2019, respectively.

Pitfalls in Data Collection. Datasets collected through crowd-sourcing or scraping the Internet have the advantage of much better scalability compared to expert-annotated datasets. However, these automatic processes are prone to hidden pitfalls. Gururangan et al. (2018); Poliak et al. (2018) show that crowd-sourcing "Natural Language Inference" datasets leads to various dataset biases. Similar observations have been made for "Fact Verification" datasets (Schuster et al., 2019). Splitting data—for training, testing, and validation——is another important procedure in creating datasets that can lead to several problems. For example, Geva et al. (2019) show that models may just learn the patterns of certain annotators in a random split. Lewis et al. (2020b) demonstrated a significant overlap in current open-domain QA datasets. When present, these unexpected biases or overlaps in datasets can significantly undermine the utility of a dataset and lead to deceptively promising results that are in part due to artifacts of flaws in the dataset rather than successfully modeling the intended task.

Automated Fact Checking for Statements. Automated fact checking is an important task closely related to unreliable news detection, yet is constructed in a more controlled manner. This task focuses on strictly judging the factuality of one single statement instead of an entire article. Vlachos and Riedel (2014) first constructed a dataset with 106 claims from fact-checking websites with paired labels. FEVER (Thorne et al., 2018) is currently the largest scale fact-verification dataset, where 185,445 claims were generated by modifying sentences from Wikipedia. Both the altered claims and the ground truth supporting evidence are included in the dataset. Existing effective approaches for fact-verification include self-attention based networks (Nie et al., 2019), large-scale pretrained transformers (Soleimani et al., 2020), neural retrieval methods (Lewis et al., 2020a), and reasoning on semantic-level graphs (Zhong et al., 2020).

3 Unreliable News Datasets

Collecting high-quality datasets plays an important role in automatic unreliable news detection research. Here we review dataset collection strategies used in constructing recent datasets and point out some hidden pitfalls in these procedures.

3.1 Data Collection Strategies

Unreliable news detection is usually formalized as a classification task. Accordingly, constructing a dataset requires collecting pairs of news articles and labels.

News Articles: Each individual news outlet has its own website where news articles are published. The easiest way to collect a large number of these articles is to simply scrape these websites. Manual annotation or some other mechanism must then be incorporated in order to collect the corresponding labels for each article. Another common way to collect articles is through fact-checking websites. While this approach provides both articles and article-level labels, it normally only provides a limited set of articles. Additionally, scraping these fact-checking websites can lead to additional selection bias in the dataset as highlighted in Section 3.2.

One other recent trend is collecting posts and corresponding labels from social media (Nakamura et al., 2020; Santia and Williams, 2018; Mitra and Gilbert, 2015). While large-scale datasets can be collected through such an approach, they are often noisier than those collected through traditional news sources, due to a more casual use of language, and a heavier dependency on the context.

News Labels: The largest challenge in collecting these datasets lies in collecting labels. Manually checking the factuality (or reliability) and bias of a single article is time-consuming and requires non-trivial expertise. Modeling such a task through a crowd-sourcing framework is diffi-

Article	Failed Senate candidate Roy Moore is suing comedian Sacha Baron Cohen for \$95 million for tricking him into appearing on his Showtime program 'Who is America?' Moore, whose bid for the Alabama failed in the wake of claims he molested a 14-year-old, filed the lawsuit in Washington DC on Wednesday...

Table 4: An example showing a reliable news article from the "*Daily Mail*" site which has a "Low" factual reporting rate on MBFC. Despite coming from a source with low reliability score, the shown article is reliable and very similar to the content on sites with high reliability scores (such as *"BBC"* and *"The Week UK"*) on the same date.

cult. As such, current research datasets almost exclusively rely on existing resources. As discussed earlier, these resources either provide article-level or site-level labels. **Article-level** labels are only available through a few fact-checking websites such as PolitiFact, GossipCop, etc., but the scale is limited since generating these labels is time-consuming and costly. **Site-/Outlet-level** labels, on the other hand, available through websites such as MBFC, provide manual labels for each site/outlet. These websites often assign reliable/unreliable or biased/unbiased labels to each news outlet. Many datasets for unreliable news detection assign these site-level labels to all articles in a given site. While these weak or distant labels are not always accurate (one example is shown in Table 4) , they provide an easy way to create large-scale datasets. In Table 2, we highlight three recent large-scale unreliable news datasets along with their data collection procedure.

3.2 Dataset Selection Biases

Datasets annotated without expert verification (e.g., through crowdsourcing, automatic web scraping, etc.) can have some undesired properties that undermine their quality (Gururangan et al., 2018; Poliak et al., 2018; Schuster et al., 2019). In the following analysis, we choose the FakeNewsNet dataset (Shu et al., 2017) as a representative example.

We first examine the most salient features in the dataset. To achieve this, we train a Logistic Regression (LR) model on the titles of FakeNewsNet using Bag-of-Words features and show the word features with the highest weights for each class in Table 3.[8] The features in the table show clear patterns: the top-features for the reliable (positive) class are either stop words (e.g., 'at', 'the', etc.) or words presumably carrying neutral semantics (e.g. 'season', '2018', 'awards', etc.) while the top features for the unreliable news (negative) class are mostly celebrity names. Using this basic model, we achieve an accuracy of $\sim$78% , while using a BERT-based model that uses both the article and title as input only achieves an incremental improvement yielding an accuracy of 81% (see Sec. 4.1 for detailed model descriptions). By examining the articles in the dataset, we attribute this to the selection bias exhibited by fact-checking websites. Most unreliable (negative) articles contain click-bait titles mentioning celebrities, while reliable sources usually have less sensational titles with fewer mentions of celebrities and more diverse keywords.

Another potential problem is the articles' retrieval framework. FakeNewsNet uses Google search to retrieve the original news article (Shu et al., 2017). Internet search engines have proprietary news ranking and verification processes, which means that even when using the original title and source of a given article, the search results

---

[8] We also calculated the PMI between the label and word features as suggested by Gururangan et al. (2018) and found the two lists to be very similar.

Label Resource	GossipCop
Title	NYC terror attack: Celebrities react on social media
Article	Celebrities are sending their love and support to New York on social media following a terror attack that left eight people dead Tuesday when a truck plowed down pedestrians on a bicycle path near the World Trade Center in Lower Manhattan...
Label	Unreliable
News URL	`tinyurl.com/yxhvdne6`

Table 5: One example from the FakeNewsNet dataset where it is difficult for the article content to support the label. This article contains celebrities' reactions after a terrorist attack. While the article itself does not look like a standard news piece, the reactions in the article are all paired with tweets, so the unreliable label seems to be inconsistent.

might prioritize specific sites over others leading to inaccurate data collection. While Shu et al. (2017) propose several heuristics to handle these problems, it is unlikely that this noisy process is completely fixed. As a result, we find a few mis-matched title-content pairs where the retrieved article cannot support the label, hence making the example confusing. We show one example with a questionable label in Table 5, where we suspect the inconsistency is due to the noisy retrieval step.

Finally, the informal nature of user-generated content on social media may be the source of additional biases. In our preliminary experiments, we found that in r/Fakeddit dataset, a simple Bag-of-Words(BoW)-based logistic regression model can reach equal—or even better—performance than the reported BERT-based models (86.91% vs. 86.44% in the text-only two-way classification setting), hinting at the strong correlation between the label and lexical inputs. This is also reflected in the equally confusing most salient features in this dataset shown in Table 3.

Since different collection procedures and data resources will lead to different problems, there is no uniform solution to producing a completely bias-free dataset. However, one good test is to check the performance of a simple model such as a BoW-based linear model. By analyzing the features learned by the simple model as well as measuring the gap between the performance of a state-of-the-art system and the simple model, one can get a hint of the dataset quality. Unreasonable features, together with small performance gaps, may reveal unwanted biases in the dataset. In practice, we also suggest that when developing models using biased datasets to use debiasing techniques (e.g. Schuster et al. (2019)).

4 Dataset Split Effect

In this section, we study the effect of time and site/outlet overlap between the training and the evaluation set on the model's performance and show how these confounding factors can impact it.

4.1 Baseline Models & Experimental Setup

In the following experiments, we use two models: a logistic regression baseline and a state-of-the-art large-scale pretrained Transformer-based model (RoBERTa; Liu et al. (2019)).

Logistic Regression (LR): We use scikit-learn's (Pedregosa et al., 2011) implementation of Logistic Regression along with TFIDF-based Bag-of-Words features. We add L2 regularization to the model with a regularization weight of 1.0 and train the model using L-BFGS. In our experiments, the LR model uses only the title (and not the article body) as the input.

RoBERTa: Our implementation is based on the Transformers library (Wolf et al., 2019) and AllenNLP (Gardner et al., 2017). We use RoBERTa in two different ways, one takes only the title as the input, the other takes both the title and the article content as the input and formalizes the task as pairwise sentence classification. Specifically, we concatenate the title and the article content with a `[SEP]` token in the middle and use different token type embeddings to differentiate between the title and the content. Articles are truncated to fit the 512-token length limit. In the title-only setting, the batch size is set to 32, the learning rate is set to 5e-5, and the model is trained for 3 epochs. In the article+title setting, the batch size is set to 8, the learning rate is set to 2e-5, and the model is trained for 10 epochs. These hyperparameters are set empirically, and our preliminary experiments show that the results are not sensitive to different settings of these hyperparameters.

Datasets: Here, our analysis focuses on the 2018 version of the NELA dataset (Horne et al., 2018b). Unlike FakeNewsNet, NELA gathers news directly from news outlets, so the influence of selection bias is insignificant. Thus we focus our analysis on

Model	Input	Random Split	Source Split (Article)	Source Split (Site)
Majority	/	50	50	69.29 (0.56)
LR	Title	77.45	67.18 (4.13)	79.28 (5.27)
RoBERTa	Title	85.22	70.40 (4.28)	87.83 (10.44)
RoBERTa	Title+Article	96.94	80.36 (11.91)	85.14 (8.00)

Table 6: Accuracy on validation sets with different split strategies. For “Source Split’, we report the mean and standard deviation (in parentheses) of five different runs. The last column shows the aggregated site-level accuracy.

other potentially confounding factors in the dataset. We use the latest aggregated site-level labels provided in NELA-GT-2019 (Gruppi et al., 2020) and report both the article- and site-level accuracy. For article-level accuracy, we assign the site-level label to all articles from that news outlet and calculate per-article accuracy. For the Source (Site) Split setting (with no overlap between training and evaluation sites), we also report the site-level accuracy: we aggregate the predictions over individual articles for a given outlet and use the majority prediction as the site-level prediction. We use a balanced label distribution for all dataset splits.

The results in the third column of Table 6 show the models’ performance on the random split, which is the default split method used in most papers, e.g. (Nakamura et al., 2020; Horne et al., 2018a). As the results show, even the simplest logistic regression model achieves an accuracy of over 77% whereas the RoBERTa model using both title and the news article as the input reaches almost 97% accuracy.

4.2 Effect of Split by Source

For this experiment, instead of using the standard random split of all the news articles in the dataset, we first randomly split all the sites in the dataset into three disjoint sets (train/dev/test) before adding all articles from each site to their assigned set (train, dev or test). We believe this setup is closer to real-world tasks. For instance, in order to block all unreliable news sources, one simple—yet useful—approach is to maintain a list of questionable sources. All the news from those sources will be automatically blocked. In this setting, the only remaining task is classifying sources with no or very few annotated examples. As the results in Table 6 show, there is a significant drop in performance for all the models when compared to the random split. The logistic regression model’s performance drops from 77.5 to 67.2%, and even the more powerful RoBERTa model with both title and article as input drops from 96.9 to 80.4%, demonstrating the task’s significantly increased difficulty. While aggregating article-level results to site-levels can significantly improve the accuracy, we also see a plateauing trend of the performance where adding the article as additional input brings no further improvement to the RoBERTa model. Since we subsample the original dataset and balance the number of news articles for each label, the majority baseline (at the article level) is always 50%. But the site-level majority baseline is well above random (69.29%). While a new 50% majority baseline can be achieved by re-subsampling the dataset, the current number also indicates a severe imbalance of dataset size between reliable/unreliable sites which can—potentially—be exploited by the models.

Model	Input	Gold Label	Rand. Label
Majority	/	50	50
LR	Title	77.45	66.29
RoBERTa	Title	85.22	74.37
RoBERTa	Title+Article	96.94	95.04

Table 7: Article-level accuracy for the random label experiments compared to gold site labels.

Random Label Experiments: For this experiment, we use the original random split strategy. However, we permute all the site-level labels randomly. Hence each label no longer represents the reliability of the site, and is just an arbitrary feature of the site itself. Therefore, the only way for the models to achieve good performance on this task is to memorize the arbitrary site-label mapping. The results in Table 7 show that the models achieve very high accuracy with the more powerful RoBERTa model with both title and article showing only ~2% accuracy loss when compared to the true labels. These results demonstrate the models’ ability to memorize random site-labels, and the similarity between these results and the results on the random splits suggest that the models are bypassing the real task of reliable/unreliable news classification and are just memorizing the site identities.

Distance	Top 10 Sites	Bottom 10 Sites
l2	11.59	5.79
cosine	210.72	82.91
MMD	7.78	4.20
CORAL	29.07	14.95

Table 8: Average similarity score between sites in the evaluation and training sets.

Performance Variance and Site Similarity Analysis: Another interesting observation from the results in Table 6 is that while the performance on every random split is fairly stable, the performance is much more unstable with respect to splitting by source. For example, the RoBERTa (Title+Article) model results have a standard deviation larger than 10 points, with the highest accuracy reaching over 90% and the lowest one below 60%.

One potential factor behind the varying performance is the heterogeneity of different news sources (sites). News sites that are similar to those in the training set could be much easier to classify than sites with completely different styles or content. In this case, even when splitting by site, correlations between the content of similar sites in the training and evaluation sets may drive the generalization performance. To assess this hypothesis, we measure the dependence on the distances between sites in the training and evaluation sets and the model performance at the site level in the evaluation set. Given a set s in the evaluation set, we measure its similarity to all the sites in the training set $t \in S_{train}$. Below we show that higher accuracy on the site s is associated with a higher similarity between s and sites in the training set with the same label $t \in S_{same}$, providing evidence in favor of our hypothesis.

In order to measure the similarity between different sites, we take the representation learned by the RoBERTa model as the representation of the article with a focus on its reliability. Since the RoBERTa model feeds the whole sentence into the multi-layer transformer architecture and feeds the representation of `[CLS]` token to the downstream classifier (Devlin et al., 2019; Liu et al., 2019), we use the same `[CLS]` representation as the representation for the whole title+article input.

For similarity-metrics between sites, we follow Guo et al. (2020) and calculate the l2-distance, cosine distance, MMD (maximum mean discrepancy) distance (Gretton et al., 2012; Li et al., 2015) and the CORAL (correlation alignment) distance (Sun and Saenko, 2016; Sun et al., 2016). Following Guo et al. (2020), the l2 and cosine distances are calculated by first averaging all the example representations to get the site representation and calculating the distance between site representations; the MMD distance is calculated using an unbiased finite sample estimate from Li et al. (2015); and the CORAL distance is calculated by $D_{CORAL} = \frac{1}{4d^2}\|C_s - C_t\|_F^2$, where d is the feature dimension, C_s and C_t are the co-variance of two sets and $\|\cdot\|_F^2$ is the squared matrix Frobenius norm. To simplify our analysis, we filter out all the sites containing less than 100 examples (assuming the articles from these sites are too few to significantly influence the model). For every site in the evaluation set s, we calculate its distance with respect to every different site t in the training set, and then compare its minimum distance w.r.t the subset of sites with the same gold label S_{same} and the subset of sites with the opposite label S_{oppo},

$$sim\_score_s = \frac{\min\limits_{t \in S_{oppo}} \{dist(s,t)\}}{\min\limits_{t \in S_{same}} \{dist(s,t)\}}$$

We compute this ratio using all four distances above for the top and bottom 10 sites in the evaluation datasets (ranked based on their accuracy with RoBERTa) and report the mean over all the sites and over all five different random splits in Table 8. The top 10 sites always have a much larger similarity score than the bottom 10 sites, indicating that they have a much larger similarity with sites in the training sets with the same label. This trend holds across all of the distance metrics. The sensitivity of performance on the site similarity raises additional concerns about how the results in Table 6 may generalize in real-life. As newly emerged unreliable sites are likely to behave differently from old sites, the model's performance may be on the lower end of the variance.

As a natural extension, we also explored building a model that directly optimizes these site-level distance metrics in order to have better site-level generalization performance. However, in our preliminary results, our model does not show significant improvement from the baseline models. This can also hint at the fact that it is very difficult for these models to extract features that are useful to the task of reliable/unreliable news classification itself and instead learn site-specific features.

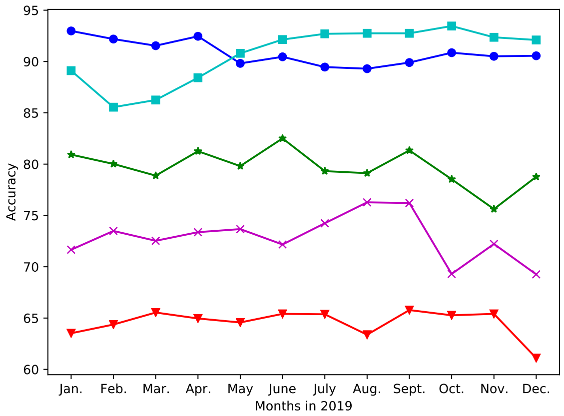

Figure 1: Accuracy of RoBERTa models trained on NELA-GT-2018 and tested on articles from the 12 months covered in the NELA-GT-2019 dataset. The five different lines in the figure represent models trained using five different random site splits.

4.3 Effect of Split By Time

Another potentially important factor to consider while creating train/test/dev splits for a news-based dataset is time. As news-worthy events happen everyday, multiple news articles from different outlets can report the same event. For example, in the NELA 2018 dataset (Nørregaard et al., 2019), within a period of two days (from 2018/10/01 to 2018/10/02), there are more than 100 news articles from over 60 sources about the US-Canada-Mexico trade accord. Therefore, by remembering the content of the event from one article, the model can easily predict the label for any related news article.

To test the effect of time, we examine the model's performance on news articles from a temporally disjoint dataset. Specifically, since all our models are trained on the NELA-GT-2018 (Nørregaard et al., 2019), we use the NELA-GT-2019 (Gruppi et al., 2020) as the evaluation dataset. We split the news articles in 2019 into twelve months and plot the performance trend in Figure 1. We can see that, unlike the significant performance drop in the source split experiments, we do not observe a clear correlation between the performance and the length of the time gap. Therefore, at least for the current models and datasets, splitting by time does not significantly influence the current results. This finding may result from that the fact that the model is not memorizing the exact events in the training set (this is not limited to the unreliable news domain), or it could be attributed to the noise in the training set (similar events can be reported both in reliable and unreliable sources). However, we do have to point out that our current observation only holds for the current models, and it is possible for more powerful models to memorize all events. In addition, the widest time gap tested here is still within a couple of years, which is still a relatively short time in terms of news events. A longer time gap (or a major event such as COVID-19) may lead to different behavior by the models. So in practice, we nonetheless suggest splitting datasets by time to avoid these issues.

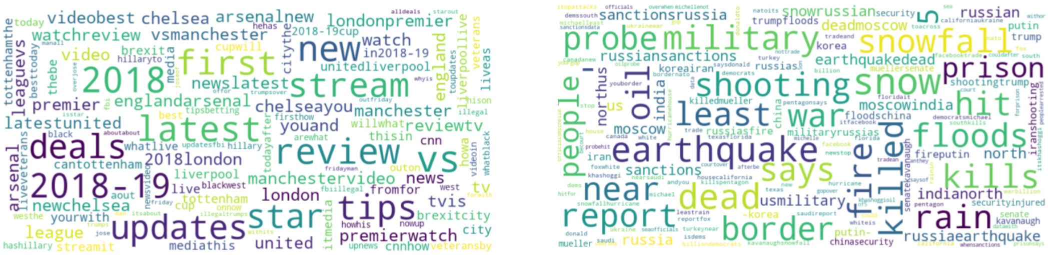
4.4 Error Analysis

Here, we conduct an error analysis to see how the model performs with respect to the variation of some other factors of practical interest, such as topic and site size.

The Influence of Topic in Article-Level Prediction: In order to gain better insight on the performance drop in the source split experiments, we perform a deeper investigation of the numbers in Table 6. We first check whether the models show different performance on different topics. To get a high-level understanding of what the topics are, we look at the titles of articles in the evaluation set and calculate words with the highest PMI with the accuracy of prediction of the RoBERTa model. We then use these PMI values as weights and plot the word cloud figures in Figure 2. In the word cloud of correct predictions, we observe many words related to sports events, while words in the incorrect predictions cloud mostly appear in political news. This is not surprising since there is much more of an incentive to interfere with political news than sports news — making the need for more robust models even more pressing for real-world applications.

The Influence of Size in Site-Level Prediction: Finally, we examine the effect of prediction aggregation from article-level to site-level. Unlike in current datasets where most sites can have hundreds or even thousands of articles, a newly-emerged news outlet waiting for classification may only have a very limited number of articles. Accordingly, while in Table 6, we see a general improvement of the aggregation, it is also important to check the aggregation effect when the number of articles in a given site is small.

In Figure 3 we plot the performance of 5 different runs of the RoBERTa (Title+Article) model



(a) Word cloud of article titles with correct predictions.

(b) Word cloud of article titles with incorrect predictions.

Figure 2: Word cloud of article titles. The words with highest PMI to the prediction correctness of the RoBERTa model are selected.

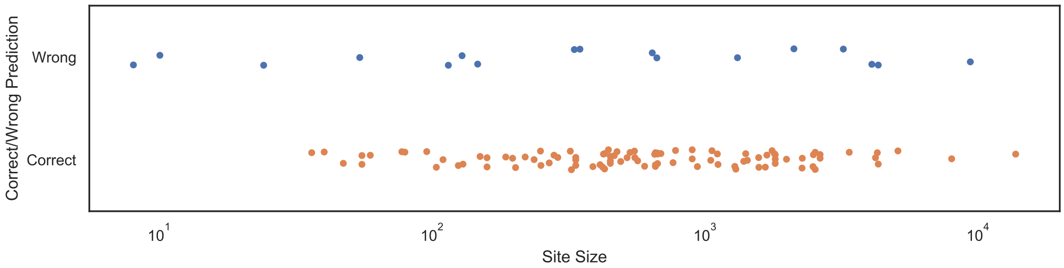


Figure 3: Site-level prediction accuracy of the RoBERTa (Title+Article) model vs. numbers of article in the site (in all five random runs). Blue circles denote wrong predictions and red circles denote correct predictions.

against the number of articles on a given site. We can see that the performance is worse when the size of the site is less than 100, demonstrating the difficulty of predicting the reliability of a site given limited resources. It is also surprising to see a significant number of errors even when the site size is over 1000. This indicates the limitation of simply aggregating the site-level prediction at test-time. Capturing the article-site hierarchy in a better way is a potential future research direction.

5 Conclusion

In this paper, we took a closer look at current large-scale unreliable news detection datasets. We studied their collection procedures and dataset split strategies, and pointed out important flaws in the current approaches. Specifically, we demonstrated that selection bias in dataset collection that often leads to undesired and significant artifacts in these datasets; highlighting confounding factors (e.g., article source, time) in news datasets that can lead to underestimating the difficulty of the task. Finally we provide suggestions on how to better create and process such datasets in the future. We hope our work leads to more high-quality news datasets and that it inspires further work in this direction.

Abstract

Significant memory and computational requirements of large deep neural networks restrict their application on edge devices. Knowledge distillation (KD) is a prominent model compression technique for deep neural networks in which the knowledge of a trained large teacher model is transferred to a smaller student model. The success of knowledge distillation is mainly attributed to its training objective function, which exploits the soft-target information (also known as "dark knowledge") besides the given regular hard labels in a training set. However, it is shown in the literature that the larger the gap between the teacher and the student networks, the more difficult is their training using knowledge distillation. To address this shortcoming, we propose an improved knowledge distillation method (called Annealing-KD) by feeding the rich information provided by the teacher's soft-targets incrementally and more efficiently. Our Annealing-KD technique is based on a gradual transition over annealed soft-targets generated by the teacher at different temperatures in an iterative process, and therefore, the student is trained to follow the annealed teacher output in a step-by-step manner. This paper includes theoretical and empirical evidence as well as practical experiments to support the effectiveness of our Annealing-KD method. We did a comprehensive set of experiments on different tasks such as image classification (CIFAR-10 and 100) and NLP language inference with BERT-based models on the GLUE benchmark and consistently got superior results.

1 Introduction

Despite the great success of deep neural networks in many challenging tasks such as natural language processing (Vaswani et al., 2017; Liu et al., 2019), computer vision (Wong et al., 2019; Howard et al., 2017), and speech processing (Chan et al., 2016; He et al., 2019), these state-of-the-art networks are usually heavy to be deployed on edge devices with limited computational power (Bie et al., 2019; Lioutas et al., 2019). A case in point is the BERT model (Devlin et al., 2018) which can be comprised of more than a hundred million parameters.

The problem of network over-parameterization and expensive computational complexity of deep networks can be addressed by neural model compression. There are abundant of neural model compression techniques in the literature (Prato et al., 2019; Tjandra et al., 2018; Jacob et al., 2018), among which knowledge distillation (KD) is one of the most prominent techniques (Hinton et al., 2015). KD is tailored a lot to serve different applications and different network architectures (Furlanello et al., 2018; Gou et al., 2020). For instance, patient KD (Sun et al., 2019), TinyBERT (Jiao et al., 2019), and MobileBERT (Sun et al., 2020) are designed particularly for distilling the knowledge of BERT-based teachers to a smaller student.

The success of KD is mainly attributed to its training objective function, which exploits the soft-target information (also known as "dark knowledge") besides the given regular hard labels in the training set (Hinton, 2012). Previous studies in the literature (Lopez-Paz et al., 2015; Mirzadeh et al., 2019) show that when the gap between the student and teacher models increases, training models with KD becomes more difficult. We refer to this problem as KD's *capacity gap problem* in this paper. For example, Mirzadeh et al. (2019) show that if we gradually increase the capacity of the teacher, first the performance of student model improves for a while, but after a certain point, it starts to drop. Therefore, although increasing the capacity of a teacher network usually boosts its performance, it does not necessarily lead to a better teacher for the student network in KD. In other words, it would

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2493–2504
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

be more difficult for KD to transfer the knowledge of this enhanced teacher to the student. A similar scenario happens when originally the gap between the teacher and student network is large.

Mirzadeh et al. (2019) proposed their TAKD solution to this problem which makes the KD process more smooth by filling the gap between the teacher and student networks using an intermediate auxiliary network (referred to as "teacher assistant"). The size of this TA network is between the size of the student and the teacher; and it is trained by the teacher first. Then, the student is trained using KD when the TA network is playing the role of its teacher. This way, the training gap (between the teacher and the student) would be less significant compared to the original KD. However, TAKD suffers from the high computational complexity demand since it requires training the TA network separately. Moreover, the training error of the TA network can be propagated to the student during the KD training process.

In this paper, we want to solve the KD *capacity gap problem* from a different perspective. We propose our Annealing-KD technique to bridges the gap between the student and teacher models by introducing a new KD loss with a dynamic temperature term. This way, Annealing-KD is able to transfer the knowledge of the teacher smoothly to the student model via a gradual transition over soft-labels generated by the teacher at different temperatures. We can summarize the contributions of this paper in the following:

1. We propose our novel Annealing-KD solution to the KD *capacity gap problem* based on modifying the KD loss and also introducing a dynamic temperature function to make the student training gradual and smooth.

2. We provide a theoretical and empirical justification for our Annealing-KD approach.

3. We apply our technique to ResNET8 and plain CNN models on both CIFAR-10 and CIFAR-100 image classification tasks, and the natural language inference task on different BERT based models such as DistilRoBERTa, and BERT-Small on the GLUE benchmark and achieved the-state-of-the art results.

4. Our technique is simple, architecture agnostic, and can be applied on top of different variants of KD.

2 Related Work

2.1 Knowledge Distillation

In the original Knowledge distillation method by Hinton et al. (2015), which is referred to as KD in this paper, the student network is trained based on two guiding signals: first, the training dataset or *hard labels*, and second, the teacher network predictions, which is known as *soft labels*. Therefore, KD is trained based on a linear combination of two loss functions: the regular cross entropy loss function between the student outputs and hard labels, and the KD loss function to minimize the distance between the output predictions of the teacher and student networks at a particular temperature, $\mathcal{T}$, on training samples:

$$\begin{aligned}
&\mathcal{L} = (1-\lambda)\mathcal{L}_{CE} + \lambda\mathcal{L}_{KD} \\
&\mathcal{L}_{CE} = H_{CE}\Big(y, (\sigma(z_s(x))\Big) \\
&\mathcal{L}_{KD} = \mathcal{T}^2 KL\Big(\sigma(\frac{z_t(x)}{\mathcal{T}}), \sigma(\frac{z_s(x)}{\mathcal{T}})\Big)
\end{aligned} \tag{1}$$

where $H_{CE}(.)$ and $KL(.)$ are representing the cross entropy and KL divergence respectively, $z_s(x)$ and $z_t(x)$ are the output logits from the student and teacher networks, $\mathcal{T}$ is the temperature parameter, $\sigma(.)$ is the softmax function and λ is a coefficient between [0,1] to control the contribution of the two loss functions. The above loss function minimizes the distance between the student model and both the underlying function and the teacher model assuming the teacher is a good approximation of the underlying function of the data.

A particular problem with KD, that we would like to address in this paper, is that the larger the gap between the teacher and the student networks, the more difficult is their training using knowledge distillation (Lopez-Paz et al., 2015; Mirzadeh et al., 2019).

2.2 Teacher Assistant Knowledge Distillation (TAKD)

To address the capacity gap problem between the student and teacher networks in knowledge distillation, TAKD (Mirzadeh et al., 2019) proposes to train the student (of small capacity) with a pre-trained intermediate network (of moderate capacity) called teacher assistance. In this regard, we first train the TA with the guidance of the teacher network by using the KD method. Then, we can use the learned TA network to train the student network. Here, since the capacity of the TA network is between the capacity of the teacher and the student networks, therefore it can fill the gap between the teacher and student and enhance the complexity of the teacher and transfer its knowledge to the student network.

As it is mentioned in (Mirzadeh et al., 2019), a better idea could be using TAKD in a hierarchical way. So in this case, we can have several TAs with different levels of capacity from large capacities close to the teacher model to small capacities close to the student model. Then we could train these TAs consecutively from large capacities to small capacities in order to have a more smooth transfer of teacher's knowledge to the student model. But it will be difficult. Because, first, since we need to train a new model each time, it is computationally expensive. Second, in this way we will have additive error in each step. Each TA after training will have an approximation error and these errors will accumulate and transfer to the next TA. In the next section, we will propose a simple method to realize this idea and avoid the mentioned problems.

2.3 Annealing in Knowledge Distillation

Clark et al. (2019) proposed an annealing idea in their Born-Again Multi-task (BAM) paper , to train a multitask student network using distillation from some single-task teachers. They introduce a so-called teacher annealing scheme to distill from a dynamic weighted mixture of the teacher prediction and the ground-truth label. In this regard, the weight of teacher's prediction is gradually reduced compared to the weight of ground-truth labels during training. Therefore, early in training, the student model mostly learns from the teacher and later on, it learns mostly from target labels. However, our Annealing-KD is different from Clark et al. (2019) in different aspects. First, the introduced annealing term in BAM is conceptually different from our annealing. While in BAM, teacher annealing controls the contribution of the teacher dark knowledge compared to the ground-truth labels during training, our Annealing-KD is only applied to the teacher output in the KD loss to solve the capacity gap problem between the teacher and student networks. Second, the way we do annealing in our technique is through the temperature parameter and not by controlling the contribution of the teacher and ground-truth labels. Third, BAM falls into another category of knowledge distillation which focuses on improving the performance of the student model and not compressing it. Our method is described in the next section.

3 Method: Annealing Knowledge Distillation

In this section, we describe our Annealing-KD technique and show the rationale behind it. First, we start by formulating the problem and visualizing our technique using an example for a better presentation. Then, we use VC-dimension theory to understand why our technique improves knowledge distillation. We wrap up this section by visualizing the loss landscape of Annealing KD for a ResNet network in order to investigate the impact of our method on the KD loss function.

KD defines a two-objective loss function (i.e. the $\mathcal{L}_{KD}$ and $\mathcal{L}_{CE}$ terms in Equation 1) to minimize the distance between student predictions and soft labels and hard labels simultaneously. Without adding to the computational needs of the KD algorithm, our Annealing-KD model breaks the KD training into two stages: Stage I, gradually training the student to mimic the teacher using our Annealing-KD loss $\mathcal{L}_{\text{KD}}^{\text{Annealing}}$; Stage II, fine-tuning the student with hard labels using $\mathcal{L}_{CE}$. We can define the loss function of our method as following.

$$\mathcal{L} = \begin{cases} \mathcal{L}_{\text{KD}}^{\text{Annealing}}(i), & \textbf{Stage I: } 1 \leq \mathcal{T}_i \leq \tau_{\text{max}} \\ \mathcal{L}_{CE}, & \textbf{Stage II: } \mathcal{T}_n = 1 \end{cases} \tag{2}$$

In the above equation, i indicates the epoch index in the training process with the max epoch number of n for stage I, $\mathcal{T}_i$ represents the temperature value at i^{th} epoch, $\mathcal{L}_{CE}$ is unchanged from Equation 1, and at each epoch (i), $\mathcal{L}_{\text{KD}}^{\text{Annealing}}(i)$ is defined as following:

$$\begin{aligned} &\mathcal{L}_{\text{KD}}^{\text{Annealing}}(i) = ||z_s(x) - z_t(x) \times \Phi(\mathcal{T}_i)||_2^2 \\ &\Phi(\mathcal{T}) = 1 - \frac{\mathcal{T}-1}{\tau_{\text{max}}}, 1 \leq \mathcal{T} \leq \tau_{\text{max}}, \mathcal{T} \in \mathbb{N} \end{aligned} \tag{3}$$

In Equation 2, $\mathcal{L}_{\text{KD}}^{\text{Annealing}}$ is defined as an MSE loss between the logits of the student ($z_s(x)$) and an annealed version of the teacher logits ($z_t(x)$), obtained by multiplying the logits by the *annealing function* $\Phi(\mathcal{T})$. The annealing function $\Phi(\mathcal{T})$ can be replaced with any monotonically decreasing function $\Phi : [1, \tau_{\text{max}}] \in \mathbb{N} \rightarrow [0, 1] \in \mathbb{R}$. In stage I of our training, initially we set $\mathcal{T}_1 = \tau_{\max}$ (which leads to the most softened version of the teacher outputs because $\Phi(\mathcal{T}_1) = \frac{1}{\tau_{\max}}$) and decrease the temperature during training as the epoch number grows (that is $\mathcal{T} \rightarrow 1$ while $i \rightarrow n$). Training in stage I continues until $i = n, \mathcal{T} = 1$, for which $\Phi(\mathcal{T}_n) = 1$ and we get the sharpest version of z_t without any softening. The intuition behind using the MSE loss in stage I is that matching the logits of the teacher and student models is a regression task and MSE is one of the best loss functions for this task. We also did an ablation study to compare the performance of MSE and KL-divergence loss function in stage I, and the results of this study support our intuition. For more details, please refer to table 10 of the appendices.

Therefore, our Annealing-KD bridges the gap between the student and teacher models by introducing the dynamic temperature term (that is the annealing function $\Phi(\mathcal{T})$) in the stage I of training. This way our Annealing-KD method is able to smoothly transfer the teacher's knowledge to the student model via a gradual transition over soft-labels generated by the teacher at different temperatures.

To summarize, our Annealing-KD technique is different from KD in following aspects:

- Annealing-KD does not need any λ hyper-parameter to weigh the contribution of the soft and hard lable losses, because it does the training of each loss in a different stage.
- Our Annealing-KD loss $\mathcal{L}_{\text{KD}}^{\text{Annealing}}$ uses $||.||_2^2$ loss instead of the KL divergence.
- Moreover, our technique uses a dynamic temperature by defining the annealing function $\Phi(\mathcal{T})$ in the Annealing-KD loss instead of using a fixed temperature in KD.
- Our empirical experiments showed that it is best to take the network logits instead of the softmax outputs in $\mathcal{L}_{\text{KD}}^{\text{Annealing}}$. Furthermore, in contrast to KD, we do not add the temperature term to student output.

Algorithm 1 explains the proposed method in more detail.

In this section, we proposed an approach to alleviate the gap between the teacher and student models as well as reducing the sharpness of the KD loss function. In our model, instead of pushing the student network to learn a complex teacher function from scratch, we start training the student from a softened version of the teacher and we gradually move toward the original teacher outputs through our annealing process.

Algorithm 1

```
function ANNEALING-KD($S$,$T$,$X$, $k$, $\mathcal{T}_{max}$, $n$)

                                                    ▷ stage I
    for $\mathcal{T} = \tau_{max}$ to 1 do
        $\Phi \leftarrow 1 - \frac{\mathcal{T}-1}{\tau_{\max}}$
        for $i = 1$ to $k$ do
            TRAIN-ANNEALING($S$,$T$, $X$,$\Phi$)

    end for
    $S \leftarrow$ LOAD-BEST-CHECKPOINT  ▷ stage II
    for $i = 1$ to $n$ do
        TRAIN-FINE-TUNE($S$, $X$)
        SAVE-BEST-CHECKPOINT($S$)
    end for
    $S \leftarrow$ LOAD-BEST-CHECKPOINT
    return $S$
end function
```

3.1 Example

For better illustration of our proposed method, we designed a simple example to visualize different parts of our Annealing-KD algorithm. In this regard, we defined a simple regression task using a simple 2D function. This function is a liner combination of three sinusoidal functions with different frequencies $f(x) = sin(3\pi x) + sin(6\pi x) + sin(9\pi x)$. We randomly sample some points from this function to form our dataset (Figure 2-(a)). Next, we fit a simple fully connected neural network with only one hidden layer and the sigmoid activation function to the underlying function of the defined dataset. The teacher model is composed of 100 hidden neurons and trained with the given dataset. After training, the teacher is able to get very close to training data (see the green curve in Figure 2-(a)). We plot the annealed output of the teacher function in 10 different temperatures in Figure. 2-(b). Then, a student model with 10 hidden neurons is trained once with regular KD (Figure 2-(f)) and once with our Annealing-KD (Figures. 2-(c, d, e) depicts the student output at temperatures 10,

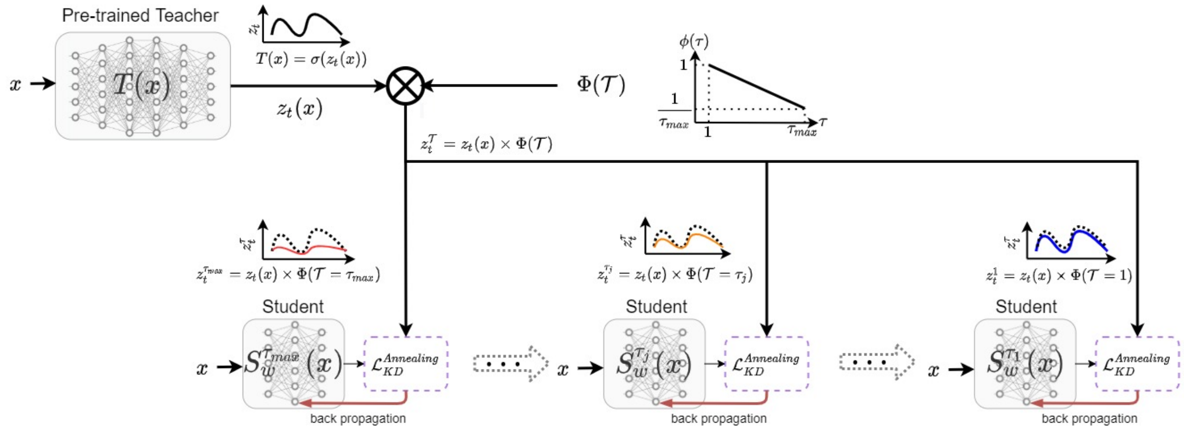

Figure 1: Illustrating the Stage I of the Annealing-KD technique. Given a pre-trained teacher network, we can derive the annealed output of the teacher at different temperature using the annealing function $\Phi(\mathcal{T})$. We start training of the student from $\mathcal{T} = \tau_{max}$ and go to $\mathcal{T} = 1$.

5, and 1 during the Annealing-KD training). As it is shown in these figures, Annealing-KD guides the student network gradually until it gets to a good approximation of the underlying function and it can match the teacher output better than regular KD.

3.2 Rationale Behind Annealing-KD

Inspired by (Mirzadeh et al., 2020), we can leverage the VC-dimension theory and visulaizing loss landscape to justify why Annealing-KD works better than original KD.

3.2.1 Theoretical Justification

In VC-dimension theory (Vapnik, 1998), the error of classification can be decomposed as:

$$R(f_s) - R(f) \leq O(\frac{|\mathcal{F}_s|_c}{N^{\alpha_s}}) + \varepsilon_s \qquad (4)$$

where $R(.)$ is the expected error, $f_s \in \mathcal{F}_s$ is the learner belongs to the function class $\mathcal{F}_s$. f is the underlying function. $|.|_c$ is some function class capacity measure. $O(.)$ is the estimation error of training the learner and ε_s is the approximation error of the best estimator function belonging to the $\mathcal{F}_s$ class (Mirzadeh et al., 2019). Moreover, N is the number of training samples, and $\frac{1}{2} \leq \alpha \leq 1$ is a parameter related to the difficulty of the problem. α is close to $\frac{1}{2}$ for more difficult problems (slow learners) and α is close to 1 for easier problems or fast learners (Lopez-Paz et al., 2015).

In knowledge distillation, we have three main factors: the student (our learner), the teacher, and the underlying function. Based on (Lopez-Paz et al., 2015; Mirzadeh et al., 2019), we can rewrite Equation 4 for knowledge distillation as following:

$$R(f_s) - R(f_t) \leq O(\frac{|\mathcal{F}_s|_c}{n^{\alpha_{st}}}) + \varepsilon_{st} \qquad (5)$$

where the student function f_s is following f_t. To define similar inequality for our Annealing-KD technique, we need to consider the effect of the temperature parameter on the three main functions in KD first. For this purpose, we can define $f_s^{\mathcal{T}}$, $f_t^{\mathcal{T}}$, and $f^{\mathcal{T}}$ as the annealed versions of student, teacher, and underlying functions. Furthermore, let $R_{\mathcal{T}}(.)$ to be the expected error function w.r.t the annealed underlying function at temperature $\mathcal{T}$. Hence, for Annealing-KD we have

$$R_{\mathcal{T}}(f_s^{\mathcal{T}}) - R_{\mathcal{T}}(f_t^{\mathcal{T}}) \leq O(\frac{|\mathcal{F}_s|_c}{n^{\alpha_{st}^{\mathcal{T}}}}) + \varepsilon_{st}^{\mathcal{T}}. \qquad (6)$$

Note that in $\mathcal{T} = 1$, $f_t^1 = f_t$, $f_s^1 = f_s$, $f^1 = f$, and $R_1(.) = R(.)$. Therefore, we can rewrite Equation 6 at $\mathcal{T} = 1$ as:

$$R_1(f_s^1) - R_1(f_t^1) \leq O(\frac{|\mathcal{F}_s|_c}{n^{\alpha_{st}^1}}) + \varepsilon_{st}^1. \qquad (7)$$

That being said, to justify that our Annealing-KD is working better than original KD, we can compare Equations 7 and 5 to show the following inequality holds.

$$O(\frac{|\mathcal{F}_s|_c}{n^{\alpha_{st}^1}}) + \varepsilon_{st}^1 \leq O(\frac{|\mathcal{F}_s|_c}{n^{\alpha_{st}}}) + \varepsilon_{st} \qquad (8)$$

Since in Annealing-KD, the student network at each temperature is initialized with the trained student network at $f_s^{\mathcal{T}-1}$, the student is much closer to the teacher compared with the original KD method, where the student starts from random a initialization. In other words, in annealing KD, the student

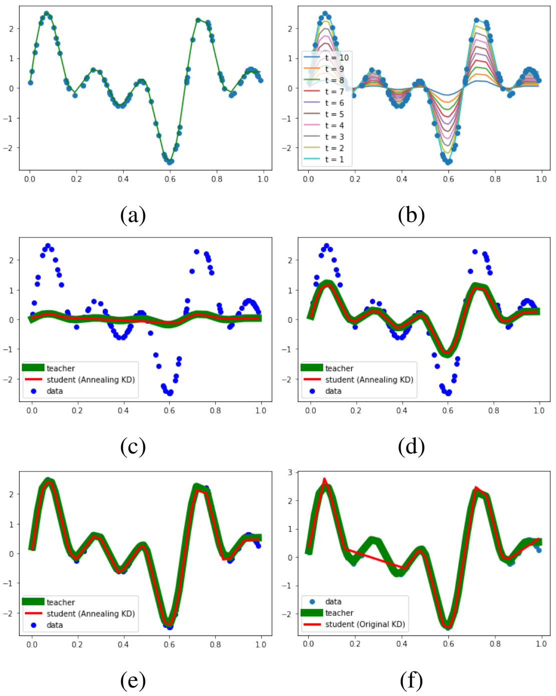

Figure 2: (a) Data samples and trained teacher. (b) Annealed teacher in different temperatures. (c) Student after matching to annealed teacher in $\mathcal{T} = 10$. (d) Student after matching to annealed teacher in $\mathcal{T} = 5$. (e) Student after matching to $\mathcal{T} = 1$. (f) Student trained without KD.

network can learn the annealed teacher at temperature $\mathcal{T}$ faster than the case it starts from a random initial point. Therefore, we can conclude that $\alpha_{st} \leq \alpha_{st}^{\mathcal{T}}$. This property also holds for the last step of annealing KD where $\mathcal{T} = 1$. It means we have $\alpha_{st} \leq \alpha_{st}^{1}$. Furthermore, bear in mind that since the approximation error depends on the capacity of the learner and in annealing KD we do not change the structure of the student, then we expect to have $\varepsilon_{st} = \varepsilon_{st}^{\mathcal{T}}$. Therefore, based on these two evidence ($\alpha_{st} \leq \alpha_{st}^{\mathcal{T}}$ and $\varepsilon_{st} = \varepsilon_{st}^{\mathcal{T}}$), we can conclude that Equation 8 holds.

3.2.2 Empirical Justification

Because of the non-linear nature of neural networks, the loss functions of these models are non-convex. This property might prevent a learner from a good generalization. There are some beliefs in the community of machine learning, this phenomena can be harsher in the sharp loss functions than the flat loss functions (Chaudhari et al., 2019; Hochreiter and Schmidhuber, 1997). Although, there are some arguments around this belief (Li et al., 2018), for the case of knowledge distillation it seems flatter loss functions are related to higher accuracy (Mirzadeh et al., 2019; Zhang et al., 2018; Hinton et al., 2015). One of the advantages of annealing the teacher function during training is reducing the sharpness of annealing loss function in the early steps of stage I. In other words, the sharpness of the loss function in annealing KD changes dynamically. In the early steps of annealing when the temperature is high, the loss function is flatter. This helps the student to train the teacher network's behaviour faster and easier.

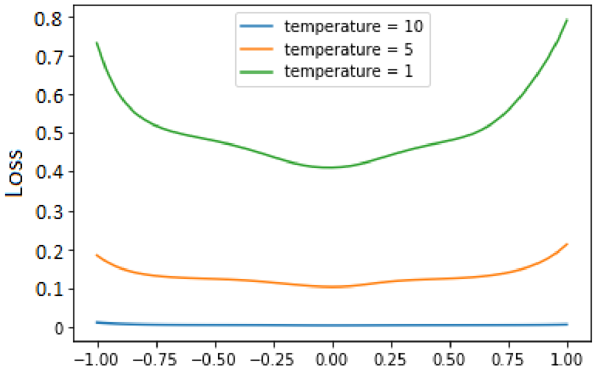

Figure 3: Visualization of annealing KD loss function in stage I for ResNet 8 student during the training on CIFAR-10 dataset in different temperatures

In order to compare the effect of different temperatures, the loss landscape visualization method in (Li et al., 2018) is used to plot the loss behaviour of CIFAR-10 experiment with ResNet 8 student in Figure. 3. Here as it is shown, by decreasing the temperature during the training, the sharpness of the loss function increases. So the student network can avoid many of the bad local minimums in the early stages of the algorithm when the temperature is high. Then in the final stages of the algorithm, when the loss function is sharper, the network starts from a much better initialization.

4 Experiments

In this section, we describe the experimental evaluation of our proposed Annealing KD method. We evaluate our technique on both image classification and natural language inference tasks. In all of our experiments, we compare the annealing KD results with TAKD, standard KD, and training student without KD results.

4.1 Datasets

For image classification, we assess Annealing-KD on CIFAR-10 and CIFAR-100 datasets (Krizhevsky et al., 2009) which are image datasets containing

32 × 32 color images with 10 and 100 classes respectively. For the natural language inference task, we employ the General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2018), which is a collection of nine different tasks for training, evaluating, and analyzing natural language understanding models. GLUE consists of Multi-Genre Natural Language Inference (MNLI) (Williams et al., 2017), Quora Question Pairs (QQP) (Chen et al., 2018), Question Natural Language Inference (QNLI) (Rajpurkar et al., 2016), Stanford Sentiment Treebank (SST-2) (Socher et al., 2013), Corpus of Linguistic Acceptability (COLA) (Warstadt et al., 2019), Semantic Textual Similarity Benchmark (STS-B) (Cer et al., 2017), Microsoft Research Paraphrase Corpus (MRPC) (Dolan and Brockett, 2005), Recognizing Textual Entailment (RTE) (Bentivogli et al., 2009), Winograd NLI (WNLI) (Levesque et al., 2012).

4.2 Experimental Setup for Image Classification Tasks

For image classification experiments, we used CIFAR-10 and CIFAR-100 datasets with the same experimental setup in the TAKD method (Mirzadeh et al., 2020). In these experiments, we used ResNet and plain CNN networks as the teacher, student, and also the teacher assistant for the TAKD baseline. For the ResNet experiments, we used ResNet-110 as the teacher and ResNet-8 as the student. For plain CNN experiments, we used CNN network with 10 layers as teacher and 2 layers as the student according to TAKD. Also, for the TAKD baseline, we used ResNet-20 and CNN with 4 layers as the teacher assistant. Tables 1 and 2 compare the annealing KD performance with other baselines over CIFAR-10 and CIFAR-100 datasets respectively. For the ResNet experiments in both tables 1 and 2, the teacher ResNet-110 is trained from scratch and a ResNet-20 TA is trained by the teacher using KD. Then we would like to train a ResNet-8 student using different techniques and compare their performance against our Annealing KD method. In this regard, we evaluate the performance of training the student from scratch, training with the large ResNet-110 teacher using KD, training with TA as the teacher and using our Annealing-KD approach. The results of this experiment with ResNet show that our Annealing-KD outperforms all other baselines and TAKD is the second-best performing student without significant distinction compared to KD. More details about the training hyper-parameters are added to the appendix A.

Table 1: Comparing the test accuracy of annealing KD, TAKD, regular KD, and student without teacher on CIFAR-10 dataset with both ResNet and CNN models

Model	Type	Training method	Accuracy
ResNet	Teacher(110)	from scratch	93.8
	TA(20)	KD	92.39
	Student(8)	from scratch	88.44
	Student(8)	KD	88.45
	Student(8)	TAKD	88.47
	Student(8)	**Annealing KD (ours)**	**89.44**
CNN	Teacher(10)	from scratch	90.1
	TA(4)	KD	82.39
	Student(2)	from scratch	72.75
	Student(2)	KD	72.43
	Student(2)	TAKD	72.62
	Student(2)	**Annealing KD (ours)**	**73.17**

Table 2: Comparing the test accuracy of annealing KD, TAKD, regular KD, and student without teacher on CIFAR-100 dataset with both ResNet and CNN models

Model	Type	Training method	Accuracy
ResNet	teacher(110)	from scratch	71.92
	TA(20)	KD	67.6
	student(8)	from scratch	61.37
	student(8)	KD	61.41
	student(8)	TAKD	61.82
	student(8)	**Annealing KD (ours)**	**63.1**
CNN	Teacher(10)	from scratch	64.89
	TA(4)	KD	60.73
	student(2)	from scratch	51.35
	student(2)	KD	51.62
	student(2)	TAKD	51.85
	student(2)	**Annealing KD (ours)**	**53.35**

4.3 Experimental setup for GLUE tasks

For these set of experiments, we use the GLUE benchmark which consists of 9 natural language understanding tasks. In the first experiment (Table 3), we use RoBERTa-large (24 layers) as teacher, DistilRoBERTa (6 layers) as student, and RoBERTa-base (12 layers) as the teacher assistant for the TAKD baseline. For Annealing KD, we use a maximum temperature of 7, learning rate of 2e-5, and train for 14 epochs in phase 1, and 6 epochs in phase 2. In table 3 the Annealing KD and the other baselines performances on dev set of GLUE tasks are compared. Also, we compared the performances of these methods on test set based on the GLUE benchmark's leaderboard results in table 4. In the second experiment (Table 5), we use

Table 3: DistilRoBERTa results for Annealing KD on dev set. F1 scores are reported for MRPC, pearson correlations for STB-B, and accuracy scores for all other tasks.

KD Method	CoLA	RTE	MRPC	STS-B	SST-2	QNLI	QQP	MNLI	WNLI	Score
Teacher	68.1	86.3	91.9	92.3	96.4	94.6	91.5	90.22/89.87	56.33	85.29
From scratch	59.3	67.9	88.6	88.5	92.5	90.8	90.9	84/84	52.1	79.3
Vanilla KD	60.97	71.11	90.2	88.86	92.54	91.37	91.64	84.18/84.11	56.33	80.8
TAKD	61.15	71.84	89.91	88.94	92.54	91.32	**91.7**	83.89/84.18	56.33	80.85
Annealing KD	**61.67**	**73.64**	**90.6**	**89.01**	**93.11**	**91.64**	91.5	**85.34/84.6**	56.33	**81.42**

Table 4: Performance of DistilRoBERTa trained by annealing KD on the GLUE leaderboard compared with Vanilla KD and TAKD. We applied the standard tricks to all 3 methods and fine-tune RTE, MRPC and STS-B from trained MNLI student model.

KD Method	CoLA	MRPC	STS-B	SST-2	MNLI-m	MNLI-mm	QNLI	QQP	RTE	WNLI	Score
Vanilla KD	**54.3**	86/80.8	85.7/84.9	93.1	83.6	82.9	90.8	71.9/89.5	74.1	65.1	78.9

Annealing KD	54	**88.0/83.9**	**87.0/86.6**	**93.6**	**83.8**	**83.9**	90.8	**72.6/89.7**	73.7	65.1	**79.5**

Table 5: BERT-Small results for Annealing KD on dev set. F1 scores are reported for MRPC, pearson correlations for STS-B, and accuracy scores for all other tasks.

KD Method	CoLA	RTE	MRPC	STS-B	SST-2	QNLI	QQP	MNLI	WNLI	Score
Teacher	65.8	71.48	89.38	89.2	92.77	92.82	91.45	86.3/86.4	60.56	82.19
Vanilla KD	33.5	57	86	72.3	88.76	**83.15**	**87**	72.62/73.19	54.92	70.58
TAKD	34.24	59.56	85.23	71.1	89.1	82.62	87	72.32/72.45	54.92	70.76
Annealing KD	**35.98**	**61**	**86.2**	**74.54**	**89.44**	83.14	86.5	**73.85/74.84**	54.92	**71.68**

BERT-large (24 layers) as teacher, BERT-small (4 layers) as student, and BERT-base (12 layers) as the teacher assistant of TAKD. We use a maximum temperature of 7 for MRPC, SST-2, QNLI, and WNLI, and 14 for all other tasks. The number of epochs in phase 1 is twice the maximum temperature, and 6 in phase 2. We use the learning rate of 2e-5 for all tasks except RTE and MRPC which use 4e-5. Table 5 compares the performance of annealing KD and other baselines on dev set for small-BERT experiments. For more details regarding other hyper-parameters, refer to the appendix. We also perform ablation on the choice of loss function in phase 1, and choice of different max temperature values, both of which can be found in the appendix.

4.4 GLUE Results

We present our results in Tables 3, 4, and 5. We see that Annealing KD consistently outperforms the other techniques both on dev set as well as the GLUE leaderboard. Furthermore, in table 5, when we reduce the size of the student to a 4 layer model (BERT-Small), we notice almost twice as big of a gap in the average score over Vanilla KD when compared with DistilRoBERTa (Table 3). We can also observe TAKD improving slightly over Vanilla KD, with the improvement being more significant in the case of the smaller student (BERT-Small).

5 Discussion

In image classification experiments, the improvement gap between the annealing KD results and the other baselines in CIFAR-100 experiments is larger than CIFAR-10 ones. We can observe similar conditions for the NLP experiments between BERT-small and DistilRoBERTa students (the performance gap of BERT-small is larger). In both of these cases, the problem for the student was more difficult. CIFAR-100 dataset is more complex than CIFAR-10 dataset. So the teacher has learned a more complex function that should be transferred to the student. In NLP experiments, on the other hand, the tasks are the same but BERT-small student has a smaller capacity in compare with DistilRoBERTa. Therefore the problem is more difficult for BERT-small. From this observation, we can conclude, whenever the gap between the teacher and student is larger, the annealing KD performs better than the other baselines and leverage the acquired knowledge by the teacher to train the student.

6 Conclusion and Future Work

In this work, we discussed that the difference between the capacity of the teacher and student models in knowledge distillation may hamper its performance. On the other hand, in most cases, larger neural networks can be trained better and get more accurate results. If we consider better teachers can train better students, then larger teachers with better accuracy would be more favourable for knowledge distillation training. In this paper, we proposed an improved knowledge distillation method called annealing KD to alleviate this problem and leverage the knowledge acquired by more complex teachers to guide the small student models better during their training. This happened by feeding the rich information provided by the teacher's soft-targets incrementally and more efficiently. Our Annealing-KD technique was based on a gradual transition over annealed soft-targets generated by the teacher at different temperatures in an iterative process; and therefore, the student was trained to follow the annealed teacher output in a step-by-step manner.

A Experimental parameters of the image classification tasks

In this section, we include more detail of our experimental settings of section 4.2 in the paper. For the baseline experiments, we used the same experimental setup as (Mirzadeh et al., 2019). We performed two series of experiments based on ResNet and plain CNN neural networks on CIFAR-10 and CIFAR-100 datasets. Table 6 illustrates the hyper-parameters used in these experiments. (BS = batch size, EP1= number of epochs in phase 1 (for the baselines, this is the number of training epochs), EP2 = number of epochs in phase 2, LR = learning rate, MO = momentum, WD = weight decay, τ_{max} = maximum temperature)

Table 6: Hyper-parameters of CIFAR-10 and CIFAR-100 experiments

Model	Type	Training method	BS	EP1	EP2	LR	MO	WD	τ_{max}

B BERT Experiments

In these experiments, RoBERTa-large (24 layers) and DistilRoBERTa (6 layers) are used as the teacher and student models respectively. Also, RoBERTa-base (12-layer) is used as the teacher assistant for the TAKD baseline. For Annealing KD, we use the maximum temperature of 7 and the learning rate of 2e-5 for all the tasks. We trained the student model for 14 epochs in phase 1, and 6 epochs in phase 2. Table 8 illustrates the details of the hyper-parameters of the experiments. Also, Table 11 illustrates the hyper-parameter values of BERT-small experiments in detail. Also, we did two ablation studies. In the first one, we tried to fine-tune the maximum temperature in annealing KD and check the performance improvement compared with using the general value of 7. As it is illustrated in Table 9, we can get more improvement with selecting the maximum temperature parameter more carefully. The second ablation is about comparing the effect of mean square error and KL-divergence loss functions on the final results of the experiments when they are used as the loss function of the first phase. Table 10 shows the results of this ablation.

Unsupervised Extractive Summarization using Pointwise Mutual Information

Abstract

Unsupervised approaches to extractive summarization usually rely on a notion of sentence importance defined by the semantic similarity between a sentence and the document. We propose new metrics of relevance and redundancy using pointwise mutual information (PMI) between sentences, which can be easily computed by a pre-trained language model. Intuitively, a relevant sentence allows readers to infer the document content (high PMI with the document), and a redundant sentence can be inferred from the summary (high PMI with the summary). We then develop a greedy sentence selection algorithm to maximize relevance and minimize redundancy of extracted sentences. We show that our method outperforms similarity-based methods on datasets in a range of domains including news, medical journal articles, and personal anecdotes.

1 Introduction

Modern neural network-based approaches to summarization require a large amount of document-summary pairs that are usually unavailable outside of the news domain. For example, summarization datasets of personal narratives and office meetings contain only a few hundred examples (Ouyang et al., 2017; Carletta et al., 2005). In this work, we tackle the problem of unsupervised extractive summarization which aims to select important sentences from the document. While there exists extensive prior work (Radev et al., 2000; Mihalcea and Tarau, 2004; Liu and Lapata, 2019; Zheng and Lapata, 2019), most approaches rely on the assumption that important sentences are *similar* to other sentences in the document. However, it is unclear if similarity-based features lead to meaningful content selection (Kedzie et al., 2018).

Inspired by recent work on formalizing the notion of importance in summarization (Peyrard, 2019), we propose metrics for *relevance* and *redundancy* based on pointwise mutual information (PMI). Intuitively, a relevant summary allows the reader to maximally infer the document content, and a summary has minimal redundancy if each sentence in it provides additional information. Therefore, we measure the relevance of a summary by its PMI with the document. High relevance means that the probability of the document increases conditioning on the summary. Similarly, we measure redundancy by PMI of sentence pairs *within the summary*. A sentence is redundant if seeing other sentences significantly increases its probability.

Based on the new metrics, we design a simple sentence extraction algorithm. We estimate the PMI of sentence pairs by a pre-trained language model fine-tuned on in-domain documents. We then use a simple sequential sentence selection algorithm for extractive summarization, which greedily maximizes relevance and minimizes redundancy.

Experimental results show that our algorithm outperforms similarity-based methods across multiple domains, including news, personal stories, and medical articles.[1]

2 Relevance and Redundancy

We begin by formalizing relevance and redundancy for summarization. Consider a document of n sentences $D = \{d_1, \ldots, d_n\}$ and a summary of m sentences $S = \{s_1, \ldots, s_m\}$. We would like to measure the relevance of S to D and the redundancy of S.

Relevance. Relevance measures how well the summary condenses the original text such that we can infer its key content. Specifically, a summary

---

[1] Our code and pretrained models are available at `https://github.com/vishakhpk/mi-unsup-summ`.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2505–2512
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

sentence is relevant if observing it reduces our uncertainty about (unseen) sentences in the document. For example, the summary may contain the main link in the thread of conversation in the document. We thus quantify the relevance of a summary sentence s to a document sentence d by their PMI:

$$\text{Rel}(s, d) \overset{\text{def}}{=} \text{pmi}(s; d), \tag{1}$$

which measures the dependence between s and d. A positive score means that s and d are very likely to co-occur, thus seeing one implies the other. A zero score means that s and d are independent. A negative score means that s and d are unlikely to co-occur, e.g. contradicting sentences, thus such a summary sentence is discouraged. We further define the relevance of a summary S to the document D by the sum of sentence-level relevance:

$$\text{Rel}(S, D) \overset{\text{def}}{=} \sum_{s \in S} \sum_{d \in D} \text{Rel}(s, d). \tag{2}$$

Redundancy. Redundancy measures how much overlap exists among the summary sentences. It is typically measured by the semantic similarity between two sentences. However, even if two sentences express different meanings, there is redundancy if one is entailed by the other. For example, consider:

1. *"Michelle, of South Shields, Tyneside, says she feels like a new woman after dropping from dress size 30 to size 12."*
2. *"Michelle weighed 25st 3lbs when she joined the group in April 2013 and has since dropped to 12st 10lbs."*

Though expressing different information, both imply Michelle's weight loss.

Given a summary sentence, we want to assign a score proportional to the amount of information in the sentence which is already present in the rest of the summary. Therefore, we quantify the redundancy of a sentence s given another sentence s' by their dependence in terms of PMI:

$$\text{Red}(s, s') \overset{\text{def}}{=} \text{pmi}(s; s'). \tag{3}$$

Similarly, the redundancy of a summary S is defined by the total redundancy of all sentence pairs:

$$\text{Red}(S) \overset{\text{def}}{=} \sum_{i=1}^{m} \sum_{j=i+1}^{m} \text{pmi}(s_i; s_j). \tag{4}$$

Estimate PMI. By definition, $\text{pmi}(s; d) = \log \frac{p(s|d)}{p(d)} = \log \frac{p(d|s)}{p(s)}$. Since both s and d are sentences, we use a language model, p_{LM}, to estimate the probabilities. Conditional probabilities are comoputed by considering the condition sentence as the prefix.

Note that while PMI can be computed in two equivalent ways according to the definition, the estimates from a language model do not guarantee that $\frac{p_{\text{LM}}(d|s)}{p_{\text{LM}}(d)} = \frac{p_{\text{LM}}(s|d)}{p_{\text{LM}}(s)}$. Thus we choose to condition on the summary sentence:

$$\text{pmi}(s; d) \overset{\text{def}}{=} \log \frac{p_{\text{LM}}(d \mid s)}{p_{\text{LM}}(d)}. \tag{5}$$

This is consistent with our definition of relevance: *seeing the summary*, how well we can estimate the document content. For redundancy, we condition on the earlier sentence:

$$\text{pmi}(s_i; s_j) \overset{\text{def}}{=} \begin{cases} \log \frac{p_{\text{LM}}(s_j|s_i)}{p_{\text{LM}}(s_j)} & \text{if } i < j \\ \text{pmi}(s_j; s_i) & \text{otherwise} \end{cases}, \tag{6}$$

since a sentence is redundant if it can be inferred from previous sentences.

3 Sequential Sentence Extraction

Given relevance and redundancy defined above, we aim to select important sentences from the document that maximize relevance and minimizes redundancy. We consider a weighted combination of the two criteria:

$$\max_{S \subseteq D} \lambda_1 \text{Rel}(S, D) + \lambda_2 \text{Red}(S) \text{ s.t. } |S| \leq k, \tag{7}$$

where $|S|$ denotes the number of sentences in the summary. This is a combinatorial problem that is expensive to solve when k is large. Therefore, we solve it approximately by selecting sentences sequentially in a greedy fashion. Given the previously selected sentences, we select the next sentence from the document that maximally improves the objective (7) until k sentences are selected. Our full algorithm is shown in Algorithm 1, where $\Delta(s)$ denotes the change incurred by the new summary $S \cup \{s\}$.

4 Experiments

Datasets. We evaluate on a diverse range of domains: (i) news articles: CNN-Dailymail (CNN-DM) (See et al., 2017) and XSum (Narayan et al., 2018); (ii) personal anecdotes: Reddit (Ouyang

Algorithm 1: ExtractSentences(D, k)

```
$S := \emptyset$
for $j \leftarrow 1$ to $k$ do
    for $s \in D \setminus S$ do
        $\Delta(s) := \lambda_1 \text{Rel}(\{s\}, D) + \lambda_2 \sum_{s' \in S} \text{Red}(s', s)$
    end
    $s_j := \text{argmax}_{s \in D \setminus S} \Delta(s)$
    $S := S \cup \{s_j\}$
end
return $S$
```

et al., 2017) and Reddit-TIFU (Kim et al., 2019); (iii) scientific articles: PubMed (Kedzie et al., 2018). Further, these datasets allow us to evaluate on highly abstractive summarization (XSum), small data (Reddit), and long documents (PubMed). Details of the datasets are shown in Appendix A.

Baselines. We compare our approach against the following unsupervised extraction methods: (i) **heuristic**: lead-k which selects the first k sentences. (ii) **similarity-based**: TextRank (Barrios et al., 2016; Mihalcea and Tarau, 2004) and PacSum (Zheng and Lapata, 2019) which use graph-based selection with similarity metrics based on tf-idf sentence vectors and BERT embeddings, respectively.[2]

To ablate the contribution of PMI, we also include a variant of our algorithm which uses cosine similarity of tf-idf sentence representations to measure redundancy and relevance of sentence pairs. Additionally, we include two **reference** methods: oracle extraction[3] and the state-of-the-art supervised approaches: For CNN-Dailymail, XSum, Reddit-TIFU and Pubmed the results are from Zhang et al. (2019) and for Reddit from Ouyang (2019).

Language model fine-tuning. For our method, we use the pre-trained GPT-2 large model (Radford et al., 2019) to calculate the PMI. To adapt the language model to specific domains, we fine-tune it on the training documents (excluding the gold summaries) in each dataset. To make it better fit our task of estimating the probability of one sentence given another, as described in Section 2, we fine-tune GPT-2 on two-sentence segments (as opposed to a long stream of tokens). Each segments consist of a pair of sentences from the document.[4]

Implementation details. We preprocess the documents with spaCy (Honnibal and Montani, 2017) to split the text into sentences. All hyperparameters are tuned on 200 randomly sampled document-summary pairs selected from the validation set to optimize the Rouge-1 F-measure, including λ_1 and λ_2 in our method which balances relevance and redundancy scores in Equation (7), the number of keywords in TextRank and the number of sentences to select for all extractive methods.

To select the values of λ_1 and λ_2 we run a grid search at intervals of 0.1 from -2 to 2 for both. For all datasets, the best weighting was 2 for relevance and -2 for redundancy.[5] The weights are intuitive because we want to maximize relevance (λ_1) and minimize redundancy (λ_2). For the Lead-k baselines, k was 3 for CNN-Dailymail, Reddit-TIFU and XSum, 4 for Reddit and 9 for PubMed.

4.1 Results

We evaluate all methods on the five datasets using the Rouge-1/2/L (Lin and Rey, 2004) F-measure. Table Table 1 shows our main results.

PMI vs similarity. We first compare PMI and tf-idf in our framework. The results (Ours (PMI) vs Ours (tf-idf)) show that measuring relevance and redundancy using PMI is better than word overlap, especially on narratives (Reddit). The Reddit writing style is less reporting facts like in news and more describing a sequence of events, thus it is helpful to capture the dependence between events. We show an example contrasting the two metrics in Table 2. Further, our method achieves better or comparable results across all datasets compared to other similarity-based methods. The oracle extraction is predictably the best result across all datasets. Our extractive approach outperforms the supervised baseline on the smallest dataset, Reddit, demonstrating the utility of unsupervised approaches in this setting. More examples are shown in Appendix B.

---

[2] For TextRank, Zheng and Lapata (2019) showed that tf-idf works better than BERT embeddings so we follow the same.

[3] We select sentences greedily to optimize the Rouge-1 score against the reference (Nallapati et al., 2017).

[4] Our preliminary results show that this works slightly better than standard LM fine-tuning.

[5] Note that there are multiple optimal values, e.g. 1 and -1, the selected values are based on tie-breaking in our algorithm.

Table 1: Rouge-1/2/L F-Measure scores of unsupervised extractive methods, oracle extraction, and SOTA results using surpervised learning on CNN-DM, XSum, Reddit, Reddit-TIFU and PubMed. The best results among unsupervised methods are in bold. Our PMI-based extractor outperforms similarity-based methods on non-news domains, and is comparable on news domains. (PacSum results on non-news domains are not reported as the released model is fine-tuned only on the news domain.)

Gold Summary	Ours(PMI)	PacSum
Cillian McCann was filmed by his mother Toni at seven weeks old. In the clip, the little boy can clearly be seen trying to speak to his family. After several attempts he manages to say "hello". The average child can say six words by the time they reach 18 months.	Whose adorable son Cillian said his first word at just seven weeks old. **In the video Cillian is seen struggling to get his word out, but with a bit of encouragement from his mother he finally says hello.** Toni says that Cillian was very alert from a young age and had been trying to make out words since he was just five weeks old .	Most parenting advice says you don't have to worry if your baby doesn't start speaking until around 18 months. The tiny tot, who is now nine weeks old, was filmed by his 36-year-old mother who says that she knew he had been trying to communicate for a while. **Cillian has three older sisters, Toni revealed that her little girls, Sophie(bottom right), Eva(bottom left) and Ellie(top), did not start talking at such an early age.**

Table 2: Example of summaries selected by PMI vs PacSum. PacSum selected the sentence (bolded) about the child's siblings. It mentions talking at an early age which is the main theme of the article. However, it does not inform us how the child started talking in the video. Our method using PMI selected sentences focusing on the content of the video and the child.

Extraction algorithm. Another important component in extractive methods is the sentence selection/decoding algorithm. The most common approach is to select sentence greedily according to certain objective. TextRank uses a graph-based method inspired by PageRank. However, in Table 1 we see that TextRank and Ours (tf-idf) (using greedy selection) achieve similar results, showing that the selection algorithm does not have a large impact, which is also found by Zheng and Lapata (2019).

Ablation study. To understand the contribution of relevance and redundancy in the proposed metric, we conducted an ablation study on CNN/DM and Reddit-TIFU. In Table 3, we see that relevance alone does well, but augmenting it with redundancy obtains the best performance across all metrics. Minimizing redundancy alone works poorly because it cannot identify important content.

Position bias in PacSum. One may wonder why PacSum and lead-k significantly outperform other extractive methods on CNN-DM. We hypothesize that they take advantage of the lead bias on CNN/DM. Figure 1 shows histograms of the positions of summary sentences selected by our method and PacSum on CNN/DM. Notably, 82.3% of sentences selected by PacSum were in the first three, and this value drops to 21.4% in our method. This provides an empirical explanation as to why PacSum is so far ahead of the other extractive approaches on CNN-DM. The authors (Zheng and Lapata, 2019) also noted a drop in performance when positional information was removed in PacSum. In addition, their performance degrades on XSum (which doesn't suffer from lead bias). A

Table 3: Ablation Results on CNN-DM and Reddit-TIFU. We observe that the combination of relevance and redundancy yields the best performance across all metrics.

concurrent work (Xu et al., 2020) performed a similar analysis, observing the reliance on position information of PacSum in the news domain.

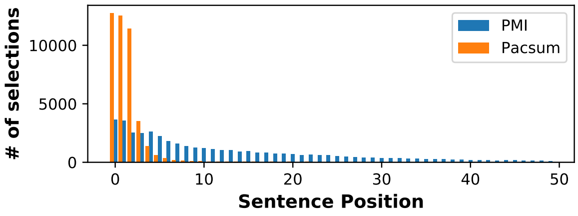

Figure 1: Histogram of the position of sentences selected by our method and PacSum on CNN/DM. PacSum uses position information which allows it to take advantage of the lead bias. In contrast, our method is position-agnostic but still captures the fact that earlier sentences are more important in news articles.

5 Related Work

Similarity-based summarization. Most unsupervised extractive summarization methods rely on sentence pair similarity as a proxy for importance (Zheng and Lapata, 2019; Mihalcea and Tarau, 2004; Barrios et al., 2016; Erkan and Radev, 2004) and use variants of the Pagerank (Page et al., 1999) algorithm to perform selection. We propose PMI as an alternative and compare it to a concurrent similarity based approach.

Leveraging pretrained language models. Scoring a sentence on its ability to predict subsequent sentences using a language model has been adapted for sentence summarization. (West et al., 2019). Zhou and Rush (2019) use two language models, a generic pretrained language model for contextual matching and a task specific one to enforce fluency. A concurrent work (Xu et al., 2020) used sentence level transformer self-attentions and probabilities to rank sentences for unsupervised extractive summarization. We use the language model to compute PMI, which then scores sentences on relevance and redundancy as criteria for selection.

Diversity in content selection. Maximal Marginal Relevance (Goldstein and Carbonell, 1998) has been used to produce summaries that prioritize diversity in selected content. A similarity metric is used to produce summaries based on similarity to a query while maintaining diversity among selected sentences in various domains (Chandu et al., 2017). This can be seen as analogous to our comparison to our approach tf-idf based selection.

6 Conclusion and Discussion

We propose metrics for relevance and redundancy in summarization based on pointwise mutual information, and an unsupervised extractive summarization algorithm using pre-trained language models. We demonstrate the effectiveness of our method on both news and non-news domains. Supervised models often learn the lead bias in the datasets and degrade significantly when such hues are absent (Kedzie et al., 2018). Furthermore, even human evaluation of content selection has large variance (Nenkova et al., 2007; Chaganty et al., 2018). Our work is a first step towards formalizing a notion of importance that informs algorithm design in summarization. We believe it is important to have a better formalization of content importance in terms of both task definition/evaluation and modeling. We hope our results will spur more work in this direction.

A Dataset Details

CNN/DM is known to have a very strong extractive Lead-3 baseline as is common in the news domain. XSum contains summaries of BBC news articles but is highly abstractive in nature. The Reddit dataset is a small corpus of around 500 personal stories shared on Reddit with abstractive and extractive summaries. For Reddit-TIFU, we use the TIFU-long subset as used in Zhang et al. (2019). The Reddit-TIFU didn't come with a train split and since we look at unsupervised methods, we used 200 pairs as validation data to decide parameters and report test results on the rest. The PubMed dataset contains longer medical journal articles with the corresponding abstracts functioning as the groundtruth summaries.

Dataset	Train	Validation	Test
CNN-DM	287,113	13,368	11,490
XSum	204,045	11,332	11,334
Reddit	404	24	48
Reddit-TIFU	-	200	41139
PubMed	21,250	1,250	2,500

Table 4: Size of train, validation and test splits of datasets used

B Analysis of Examples

Table 5 shows some example summaries from the CNN-Dailymail validation set in comparison to extractive candidate summaries obtained for the correponding documents using the baseline Lead-3 approach, our Interpolated PMI based approach and the PacSum approach (Zheng and Lapata, 2019) that uses sentence similarity to obtain state-of-the-art Rouge results on the dataset. These are shown to highlight the difference between using PMI and similarity for sentence selection. In the first example, the gold summary details about how medical information regarding two patients was leaked to sales representatives. The similarity based approach selects all three sentences associated with only one of the patients whereas the PMI based approach yields a summary that contains information about both. Once the first sentence concerning the first patient is selected, all sentences associated with it are penalised by a corresponding amount resulting in a more well rounded selection of information. Similarly, in the second example the sentence that details how the child overcame his initial struggles to speak after some encouragement from his parent was only selected by the PMI approach. This summarises exactly what happens in the video clip being spoken about and the same point is highlighted even in the gold summary. The contents of the paragraph can be easily understood when the information about the clip is used as a context. The rest of the paragraph talks goes into how the child spoke faster than his siblings which explains the selection made by PacSum. The third example highlights the issue of PacSum being identical to the Lead-3 baseline by modelling position information present in the dataset. In the fourth example, the PacSum based approach selects two sentences with quotes that have negative connotations while the one selected by PMI about how the protagonist could not forgive himself could serve to better explain the need for an intervention on the Dr. Phil show.

The purpose of this is to highlight that the intangible nature of the definition of relevance. The content selected varies between PMI and sentence similarity and each might find an application in the right setting. It again highlights the need to consider what one expects from the summarisation task.

Abstract

It is crucial to provide an inter-sentence context in Neural Machine Translation (NMT) models for higher-quality translation. With the aim of using a simple approach to incorporate inter-sentence information, we propose **m**ini-**b**atch **e**mbedding (MBE) as a way to represent the features of sentences in a mini-batch. We construct a mini-batch by choosing sentences from the same document, and thus the MBE is expected to have contextual information across sentences. Here, we incorporate MBE in an NMT model, and our experiments show that the proposed method consistently outperforms the translation capabilities of strong baselines and improves writing style or terminology to fit the document's context.[1]

1 Introduction

Current standard neural machine translation (NMT) models (Sutskever et al., 2014; Bahdanau et al., 2015; Luong et al., 2015; Vaswani et al., 2017) translate sentences in a sentence-by-sentence manner. However, some have argued that it is critical to consider the inter-sentence context in handling discourse phenomena (Hardmeier, 2012), which include coherence, cohesion, coreference (Bawden et al., 2018; Nagata and Morishita, 2020), and writing style (Yamagishi et al., 2016). To correctly translate these linguistic features, some works provide additional context information to an NMT model by concatenating the previous sentence (Tiedemann and Scherrer, 2017), applying a context encoder (Bawden et al., 2018; Miculicich et al., 2018; Voita et al., 2018), or using a cache-based network (Tu et al., 2018; Kuang et al., 2018).

Most of the previous studies have considered only a few previous context sentences. Several methods, such as the cache-based network, consider long-range context but heavily modify the standard NMT models and require additional training/decoding steps. Our goal is to make a simple but effective context-aware NMT model, which does not require heavy modification to standard NMT models and can handle a wider inter-sentence context. To this end, we propose a method to create an embedding that represents the contextual information of a document. To create this embedding, we focused on the mini-batch, which is commonly used in NMT training and decoding for efficient GPU computation. We modified the mini-batch creation algorithm to choose sentences from a single document and created an embedding that represents the features of the mini-batch. We call this embedding **mini-batch embedding (MBE)** and incorporate it in the NMT model to exploit contextual information across the sentences in the mini-batch.

Our main contributions can be summarized as follows: (i) We introduce mini-batch embedding to represent the features of sentences in a mini-batch. (ii) We incorporate mini-batch embedding in NMT to achieve simple context-aware translation and find that our approach improves translation performance by up to 1.9 BLEU points.

2 Neural Machine Translation

The current NMT model $f(\cdot)$ generates a sequence of target sentence tokens $\boldsymbol{y} = (y_1, \ldots, y_t)$ given a sequence of source sentence tokens $\boldsymbol{x} = (x_1, \ldots, x_s)$: $\boldsymbol{y} = f(\boldsymbol{x}; \theta)$, where θ is a set of model parameters and s and t are the numbers of source and target sentence tokens. The model parameters are trained by minimizing the loss function:

$$\mathcal{L}_{\mathrm{NMT}}(\theta) = -\sum_{(\boldsymbol{x},\boldsymbol{y})\in\mathbb{D}} \log P(\boldsymbol{y}|\boldsymbol{x}; \theta), \quad (1)$$

---

[1] Our implementation is publicly available: `https://github.com/nttcslab-nlp/mbe-nmt`

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2513–2521
April 19 - 23, 2021.

where $\mathbb{D}$ is a set of bilingual sentence pairs. Since the model only uses a single sentence as its input, it does not consider the inter-sentence context.

3 Context-aware NMT with Mini-batch Embedding

To exploit the inter-sentence context in NMT with a simple modification, we propose **m**ini-**b**atch **e**mbedding (MBE) to represent the features of sentences in the mini-batch. Figure 1 shows an overview of how we create mini-batch embedding and incorporate it in the NMT model.

3.1 Mini-batch Embedding

Let $\boldsymbol{B} = \{(\boldsymbol{x}_1, \boldsymbol{y}_1), \ldots, (\boldsymbol{x}_n, \boldsymbol{y}_n)\}$ be a mini-batch, where $(\boldsymbol{x}_i, \boldsymbol{y}_i)$ is a pair of source/target sentences. Normally, we randomly select them from all of the training data to create a mini-batch $\boldsymbol{B}$. However, for our method, we choose sentence pairs from the same document to create a mini-batch.

Let $g_{\text{enc}}(\cdot)$ be a single Transformer encoder layer. We first compute sentence-wise contextualized embeddings $\boldsymbol{E}_i = (\boldsymbol{e}_{i,1}, \ldots, \boldsymbol{e}_{i,s_i})$ as $\boldsymbol{E}_i = g_{\text{enc}}(\boldsymbol{x}_i; \phi)$, where s_i is the number of tokens in $\boldsymbol{x}_i$ and ϕ are the model parameters. MBE $\boldsymbol{z} \in \mathbb{R}^e$ is computed:

$$\boldsymbol{z} = \frac{1}{n} \sum_{i=1}^{n} \boldsymbol{v}_i, \quad \boldsymbol{v}_i = \frac{1}{s_i} \sum_{j=1}^{s_i} \boldsymbol{e}_{i,j}, \tag{2}$$

where e is a hidden dimension of the NMT model. We use mean pooling[2] to make both sentence embeddings $\boldsymbol{v}_i$ and MBE $\boldsymbol{z}$. By adopting this procedure, we expect MBE $\boldsymbol{z}$ to have inter-sentence context features, which is desirable for a context-aware NMT.

Note that we ignore the order of sentences in a document. This is a beneficial trait because this method is also applicable to corpora with document boundaries but without in-document sentence order, such as ParaCrawl (Esplà et al., 2019).

3.2 Learning NMT with Mini-batch Embedding

To use inter-sentence information, we modify the NMT model by adding MBE to the input:

$$\boldsymbol{y} = f(\boldsymbol{x}, \boldsymbol{z}; \theta). \tag{3}$$

We concatenated MBE to the input word embeddings, and the model uses MBE as the first input token (Fig. 1). Now the encoder/decoder takes $s+1$ and $t+1$ embeddings.

The Transformer encoder layer for MBE was jointly trained with the NMT model by modifying the loss function in Eq. (1):

$$\mathcal{L}_{\text{NMT}}(\theta, \phi) = -\sum_{\boldsymbol{B} \in \mathbb{D}'} \sum_{(\boldsymbol{x},\boldsymbol{y}) \in \boldsymbol{B}} \log P(\boldsymbol{y}|\boldsymbol{x}, \boldsymbol{B}; \theta, \phi), \tag{4}$$

where $\mathbb{D}'$ is a set of mini-batches created from $\mathbb{D}$.

3.3 Mini-batch Embedding Gate

The MBE may degrade the translation performance when the NMT model does not need any context information to translate the mini-batch or the MBE fails to contain important information for translation. To deal with such cases, we aim to make the model estimate how important MBE is for each mini-batch. Thus we added a mini-batch embedding gate to determine MBE's importance.

In this setting, we prepared two types of mini-batches for training: (i) sentences from the same document and (ii) sentences from different documents. Then we trained a binary classifier that predicts whether the sentences in the mini-batch are selected from the same document:

$$P(d|\boldsymbol{z}) = \text{softmax}(\boldsymbol{W}\boldsymbol{z}), \tag{5}$$

where $\boldsymbol{W} \in \mathbb{R}^{2 \times e}$ is a parameter matrix and d is a binary value that takes 1 if the sentences in the mini-batch are selected from the same document.

To train the classifier, we minimize the loss function:

$$\mathcal{L}_{\text{MB}}(\psi) = -\sum_{(d,\boldsymbol{B}) \in \mathbb{D}'} \log P(d|\boldsymbol{B}; \psi), \tag{6}$$

where ψ is a set of parameters for the classifier. For training, we mix the two types of mini-batches at the same ratio.

Concretely, we jointly minimize the NMT and the classifier loss functions:

$$\mathcal{L}(\theta, \phi, \psi) = \mathcal{L}_{\text{NMT}}(\theta, \phi) + \lambda \mathcal{L}_{\text{MB}}(\psi), \tag{7}$$

where λ is a hyperparameter used to control the weight of the classifier loss. We use the value predicted by the classifier as a gate. Our new weighted MBE is

$$\tilde{\boldsymbol{z}} = \alpha \boldsymbol{z}, \tag{8}$$

where $\alpha = P(d = 1|\boldsymbol{z})$, and we change $\boldsymbol{z}$ in Eqs. (3) to $\tilde{\boldsymbol{z}}$.

---

[2] This approach was inspired by Reimers and Gurevych (2019), who successfully created sentence embeddings from BERT embeddings (Devlin et al., 2019) by mean pooling.

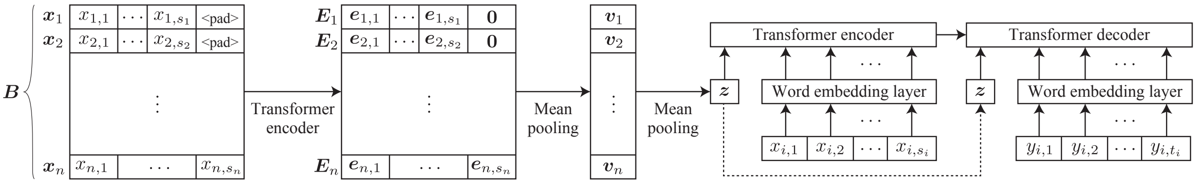

Figure 1: Overview of context-aware NMT with mini-batch embedding. $\boldsymbol{x}_i$ is a sequence of source tokens, $\boldsymbol{B}$ is a mini-batch that has n sentences, $\boldsymbol{E}_i$ is sentence-wise contextualized embeddings computed by a Transformer encoder, $\boldsymbol{v}_i$ is a sentence vector, and $\boldsymbol{z}$ is mini-batch embedding. We pad short sentences with a special <pad> token to adjust their length to the longest sentence in the mini-batch.

4 Experiments

4.1 Compared Models

We used four settings as baselines:

Baseline 6 Enc-Layers is the original Transformer NMT model with six encoder-decoder layers.

Baseline 7 Enc-Layers resembles Baseline 6 Enc-Layers, but the number of encoder layers was changed to seven. Since our MBE model requires an additional Transformer encoder layer, this model has a comparable number of parameters as the following MBE models.

2-to-1 is the context-aware translation model proposed by Tiedemann and Scherrer (2017) that translates a pair of previous and current source sentences into a target sentence. Two source sentences are concatenated with a special sentence boundary token. This method is known as a strong baseline for context-aware NMT (Bawden et al., 2018; Voita et al., 2018). Other settings are identical to those of Baseline 6 Enc-Layers[3].

DocRepair is another recent context-aware translation model, which uses two-step decoding (Voita et al., 2019). The first step generates 1-best translation with a sentence-level NMT model given a single sentence. The second step generates document-level translation given 1-best translations of four consecutive sentences concatenated with a special token.

We compared our proposed methods with the following settings:

MBE Enc resembles Baseline 6 Enc-Layers but uses MBE in the encoder.

MBE Enc w/o Gate resembles MBE Enc, but it does not use the MBE gate described in Section 3.3.

MBE Dec uses MBE in the decoder.

MBE Enc/Dec uses MBE in both the encoder and the decoder.

4.2 Experimental Settings

Datasets/Evaluation We trained Japanese-English NMT models. As training data, we used the JParaCrawl corpus (Morishita et al., 2020). JParaCrawl was created by crawling the web and aligning parallel sentences, and each sentence-pair has a URL from which the sentences were taken. In this experiment, we regarded the sentences from the same URL as a document.

We used several test sets with document boundaries: (i) scientific paper excerpts (ASPEC (Nakazawa et al., 2016)), (ii) news (newsdev2020 from WMT20 news translation shared task[4]), and (iii) TED talks (tst2012 from IWSLT translation shared task (Cettolo et al., 2012)). As a dev set to tune the NMT model, we used the ASPEC dev split. See Section A.1 in the Appendix for corpus statistics and detailed preprocessing steps.

To evaluate the translation performance, we used `sacreBLEU`[5] (Post, 2018) and report the BLEU scores (Papineni et al., 2002).

Model Configurations We used the Transformer model as an NMT model (Vaswani et al., 2017). Our hyperparameters were based on the "big" settings defined by Vaswani et al. (2017). For the MBE experiments, we set λ in Eq. (7) to 1.0. We set the mini-batch size to 3,000 tokens. If the tokens in a document were larger than this size, we

---

[3] Since our training data have document boundaries but the in-document sentence orders were shuffled, we randomly selected one in-document sentence and used it as previous context. For dev/test sets, we used the original sentence order.

[4] We used newsdev2020 as a test set because no official test set for English-Japanese was available at the time of writing. Since we did not use newsdev2020 for tuning the model, there is no problem with using it as a test set.

split the document into several mini-batches[6]. If the tokens in a document are smaller, we put all tokens into a single mini-batch[7]. See Section A.2 in the Appendix for detailed hyperparameters and training settings.

4.3 Experimental Results and Analysis

Translation Performance Table 1 summarizes the model performance on several test sets. See Table 3 in the Appendix for the dev set performance. The results show that the scores of the proposed methods surpass the baseline as well as the stronger baselines that used seven encoder layers or the existing context-aware models.

Translation Examples Figure 2 shows an example translation of a sentence from the scientific paper excerpts (ASPEC test set). In this example, the word "mentions" is translated in two ways. The baseline system translated the word as "言及しています", which is a colloquial expression. In contrast, the proposed method translated it as "述べる", which suits usage in scientific papers. This shows that MBE could change the writing style to one that is more appropriate for scientific papers compared to the baseline.

Figure 3 shows another example, which is from TED talks (tst2012). This example shows how our model could change the translation of the word "you". Our method translated this word as "君", which is friendlier than the baseline output "あなた". In this document, "he" is a friendly old man, and thus the MBE output is more appropriate for this context.

These examples show that our method improved the writing style to fit the context and chose the appropriate word for the context. This indicates that MBE helped the NMT model by providing context information across the mini-batch.

Effect of Decoding Batch-size In the previous section, we discussed the translation performance given a document, which means that the sentences in the entire document are in a mini-batch. However, in practice, we sometimes have to translate a part of the document. To check the robustness of the model in such situations, we decoded the test set by limiting the number of sentences in a mini-batch.

Figure 4 shows the experimental results. The baseline model scores are identical to those in Table 1, since the model is immune to mini-batch size. Our MBE models achieve better performance when given a larger context. It reach comparable or better scores than the baseline model when given a single sentence or a smaller context. However, the model without using MBE gate (MBE Enc w/o Gate) showed a drastic drop in performance when translating a single sentence. This shows that the gate properly works to weigh the importance of MBE and improve performance.

5 Related Work

Context-aware NMT Tiedemann and Scherrer (2017) proposed a 2-to-1 (or 2-to-2) method that concatenates two source sentences and generates one (or two) target sentences. This is a simple model, but it only considers a previous sentence, while our method can make use of larger contexts. Junczys-Dowmunt (2019) extended the 2-to-2 method to document-to-document by concatenating all sentences in a document. Although they showed that the method is effective, it requires heavy computational cost since the NMT model

---

[6] We sorted the sentences in a document by their length when splitting the document into several mini-batches to maintain the training efficiency. Since the method focuses more on writing style and wording, we do not keep the original order of the sentences.

[7] In this case, the mini-batch size could be smaller than 3,000 tokens, since we did not want to mix up the sentences from different documents.

has to process very long context. Miculicich et al. (2018) proposed a model that uses a hierarchical attention network to use previous context embeddings. However, their work can only use a few previous sentences as context, in contrast to our work that can use a larger context. Tu et al. (2018) and Kuang et al. (2018) proposed a cache-based approach to store longer context, while our work uses a much simpler architecture. Voita et al. (2019) proposed a method called DocRepair, one of the most recent context-aware NMT methods, that employs two decoding steps. It first translates a sentence by sentence-level NMT, and then the concatenated output is fed to a document-level model that outputs document-level translation. Although this is a promising method, it requires training of three sequence-to-sequence models to translate a single direction and needs two decoding steps, which slows down the translation. Our method has an advantage in that it only trains a single model and uses single-step decoding, which requires only a small computational cost.

NMT with Tags We used an MBE as the first input of the encoder/decoder. Our approach is similar to the work that uses special tags to control or provide additional information to NMT (Johnson et al., 2016; Takeno et al., 2017; Caswell et al., 2019). Johnson et al. (2016) added tags to a source sentence for indicating the target language in multilingual NMT models. Takeno et al. (2017) proposed a method that controls the target length or the domain by adding a tag to the decoder inputs. Caswell et al. (2019) used a tag to indicate the synthetic corpus (Sennrich et al., 2016). Our work, which automatically generates a tag (MBE) with the sentence in a mini-batch and uses a gate to control the importance of MBE, is different from the previous studies.

6 Conclusion

We proposed mini-batch embedding (MBE), which is a simple but effective method to represent contextual information across documents. We incorporated MBE in the NMT model, which enabled it to outperform competitive baselines. We found that our NMT model could choose the appropriate word and writing style to match the document context. An analysis showed that our model’s performance improves with a large context, but it still achieves comparable or even better performance than that of the baseline when translating a single sentence. Our future work includes applying MBE to other applications and improving the method to generate embeddings from a mini-batch.

Table 2: Number of sentences and documents in train/dev/test sets

A Detailed Experimental Settings

In this section, we describe more detailed experimental settings.

A.1 Data/Evaluation

The number of sentences and documents contained in the train/dev/test sets are shown in Table 2. We tokenized the sentences into subwords with `sentencepiece` (Kudo, 2018; Kudo and Richardson, 2018) and set the vocabulary size to 32k for each language. For the training set, we removed sentences whose length exceeded 250 subword tokens. For the DocRepair method, we used the JParaCrawl corpus as data for both monolingual and bilingual document-level application.

A.2 Model Configurations

We used the Transformer model as an NMT model (Vaswani et al., 2017). Our hyperparameters are based on "big" settings defined by Vaswani et al. (2017) and have six encoder/decoder layers, 16 attention heads, and 1,024 dimensions for all of the hidden states except the feed-forward network hidden states that have 4,096 dimensions. We used a dropout with a probability of 0.3 (Srivastava et al., 2014). As an optimizer, we used Adam with $\alpha = 0.001$, $\beta_1 = 0.9$, and $\beta_2 = 0.98$ (Kingma and Ba, 2015). A root-square decay learning rate schedule was used with a linear warm-up of 4,000 steps (Vaswani et al., 2017). We clipped the gradients to avoid exceeding their norm of 1.0. For the MBE experiments, we set λ in Eq. (7) to 1.0 and set the per-GPU-batch-size to 3,000 tokens. Since large-batch training can reduce training time (Ott et al., 2018), we accumulated about 280k tokens for an update. Based on dev set perplexity, we trained the model for 24,000 iterations. We saved the model every 200 iterations and averaged the last eight model parameters for decoding. We normalized the candidate translation scores by dividing their length and carried out a beam search with a size of six. Our implementation is based on `fairseq` (Ott et al., 2019). We used mixed-precision training (Micikevicius et al., 2018) to reduce memory consumption and training time. All experiments were run on eight NVIDIA Tesla V100 GPUs with 32-GB memory. Since we did not conduct a hyperparameter search, almost all of the settings were borrowed from (Morishita et al., 2020).

DocRepair requires the training of three sequence-to-sequence models: (1) an NMT model that translates language X to Y; (2) an NMT model that translates in reverse direction to make round-trip translation; and (3) a sequence-to-sequence model that converts 1-best translations to document-level translation. We used "Baseline 7 Enc-Layers" models for both (1) and (2), and newly trained the Transformer model for (3).

B Additional Experimental Results

Table 3 shows the number of parameters for each model, training speed, and BLEU scores on the dev set. The scores show the same tendency as the test set (Table 1).

The DocRepair method requires two translation models (English-to-Japanese and Single-to-Document), and thus the number of model parameters is larger than that for the other models. Although it also requires a Japanese-to-English translation model for creating round-trip translation data for training, these model parameters are not included in the table.

Since our MBE implementation was still in the experimental phase, the training speed was slower than that of the baselines, which were fully optimized by `fairseq` developers. We can further improve our implementation for faster computation, but we leave this for future work.

Abstract

We investigate how Multilingual BERT (mBERT) encodes grammar by examining how the high-order grammatical feature of *morphosyntactic alignment* (how different languages define what counts as a "subject") is manifested across the embedding spaces of different languages. To understand if and how morphosyntactic alignment affects contextual embedding spaces, we train classifiers to recover the subjecthood of mBERT embeddings in transitive sentences (which do not contain overt information about morphosyntactic alignment) and then evaluate them zero-shot on intransitive sentences (where subjecthood classification depends on alignment), within and across languages. We find that the resulting classifier distributions reflect the morphosyntactic alignment of their training languages. Our results demonstrate that *mBERT representations are influenced by high-level grammatical features that are not manifested in any one input sentence*, and that this is robust across languages. Further examining the characteristics that our classifiers rely on, we find that features such as passive voice, animacy and case strongly correlate with classification decisions, suggesting that mBERT does not encode subjecthood purely syntactically, but that subjecthood embedding is continuous and dependent on semantic and discourse factors, as is proposed in much of the functional linguistics literature. Together, these results provide insight into how grammatical features manifest in contextual embedding spaces, at a level of abstraction not covered by previous work.[1]

1 Introduction

Our goal is to understand whether, and how, large pretrained models encode abstract features of the grammars of languages. To do so, we analyze the notion of subjecthood in Multilingual BERT (mBERT) across diverse languages with different **morphosyntactic alignments**. Alignment (how each language defines what classifies as a "subject") is a feature of the grammar of a language, rather than of any single word or sentence, letting us analyze mBERT's representation of language-specific high-order grammatical properties.

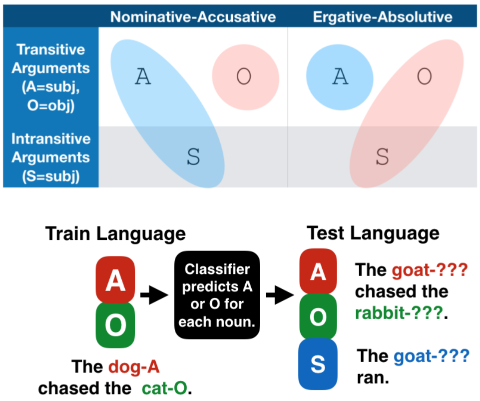

Figure 1: **Top**: Illustration of the difference between alignment systems. A (for agent) is notation used for the **transitive subject**, and O for the *transitive object*: "**The lawyer** chased *the dog*." S denotes the intransitive subject: "The lawyer laughed." The blue circle indicates which roles are marked as "subject" in each system.
Bottom: Illustration of the training and test process. We train a classifier to distinguish A from O arguments using the BERT contextual embeddings, and test the classifier's behavior on intransitive subjects (S). The resulting distribution reveals to what extent morphosyntactic alignment (above) affects model behavior.

Recent work has demonstrated that transformer models of language, such as BERT (Devlin et al., 2019), encode sentences in structurally meaningful ways (Manning et al., 2020; Rogers et al., 2020; Kovaleva et al., 2019; Linzen et al., 2016;

Gulordava et al., 2018; Futrell et al., 2019; Wilcox et al., 2018). In Multilingual BERT, previous work has demonstrated surprising levels of multilingual and cross-lingual understanding (Pires et al., 2019; Wu and Dredze, 2019; Libovický et al., 2019; Chi et al., 2020), with some notable limitations (Mueller et al., 2020). However, these studies still leave an open question: are higher-order abstract grammatical features — features such as morphosyntactic alignment, which are not realized in any one sentence — accessible to deep neural models? And how are these allegedly discrete features represented in a continuous embedding space? Our goal is to answer these questions by examining grammatical subjecthood across typologically diverse languages. In doing so, we complicate the traditional notion of the grammatical subject as a discrete category and provide evidence for a richer, probabilistic characterization of subjecthood.

For 24 languages, we train small classifiers to distinguish the mBERT embeddings of nouns that are subjects of transitive sentences from nouns that are objects. We then test these classifiers on out-of-domain examples *within* and *across* languages. We go beyond standard probing methods (which rely on classifier accuracy to make claims about embedding spaces) by (a) testing the classifiers out-of-domain to gain insights about the shape and characteristics of the subjecthood classification boundary and (b) testing for awareness of morphosyntactic alignment, which is a feature of the grammar rather than of the classifier inputs.

Our main experiments are as follows. In Experiment 1, we test our subjecthood classifiers on out-of-domain *intransitive subjects* (subjects of verbs which do not have objects, like "The man slept") in their training language. Whereas in English and many other languages, we think of intransitive subjects as grammatical subjects, some languages have a different morphosyntactic alignment system and treat intransitive subjects more like objects (Dixon, 1979; Du Bois, 1987). We find evidence that a language's alignment is represented in mBERT's embeddings. In Experiment 2, we perform successful zero-shot cross-linguistic transfer of our subject classifiers, finding that higher-order features of the grammar of each language are represented in a way that is parallel across languages. In Experiment 3, we characterize the basis for these classifier decisions by studying how they vary as a function of linguistic features like animacy, grammatical case, and the passive construction.

Taken together, the results of these experiments suggest that mBERT represents subjecthood and objecthood robustly and probabilistically. Its representation is general enough such that it can transfer across languages, but also language-specific enough that it learns language-specific abstract grammatical features.

2 Background: Morphosyntactic alignment

In transitive sentences, languages need a way of distinguishing which noun is the transitive subject (called A, for agent) and which noun is the transitive object (O). In English, this distinction is marked by word order: "The dog$_\text{A}$ chased the lawyer$_\text{O}$" means something different than "the lawyer$_\text{A}$ chased the dog$_\text{O}$". In other languages, this distinction is marked by a morphological feature: case. Case markings, usually affixes, are attached to nouns to indicate their role in the sentence, and as such in these languages word order is often much freer than in English.

Apart from A and O, there is also a third grammatical role: intransitive subjects (S). In sentences like "The lawyer laughed", there is no ambiguity as to who is doing the action. As such, cased languages usually do not reserve a third case to mark S nouns, and use either the A case or the O case. Languages that mark S nouns in the same way as A nouns are said to follow a Nominative–Accusative case system, where the nominative case is for A and S, and the accusative case is for O. [2] Languages that mark S nouns like O nouns follow an Ergative–Absolutive system, where the ergative case is used to mark A nouns, and the absolutive case marks S and O nouns. For example, the Basque language follows this system. A visualization of the two case systems is shown in Figure 1.

The feature of whether a language follows a nominative-accusative or an ergative-absolutive system is called *morphosyntactic alignment*. Morphosyntactic alignment is a high-order grammatical feature of a language, which is not usually inferable from looking at just one sentence, but from

---

[2] English pronouns follow a Nominative–Accusative system. For example, the pronoun "she" is nominative and is used both for A and S (as in "she laughed"). The pronoun "her" is accusative and is used only for O.

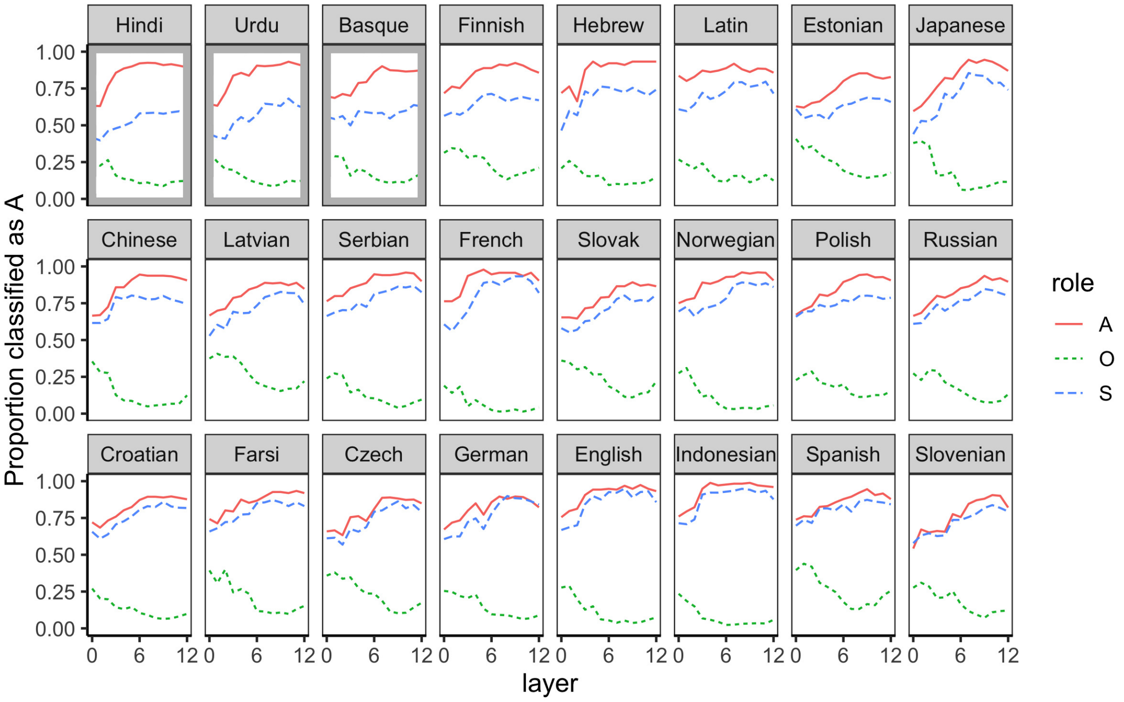

Figure 2: Results of Experiment 1: the behavior of subjecthood classifiers across mBERT layers (x-axis). For each layer, the proportion of the time that the classifier predicts arguments to be A, separated by grammatical role. In higher layers, A and O are reliably classified correctly, and S is mostly classified as A. When the source language is Basque (ergative) or Hindi or Urdu (split-ergative) S is less likely to pattern with A. The figure is ordered by how close the S line is to A, and ergative and split-ergative languages are highlighted with a gray box.

the system with which different sentences are encoded. As such, examining the way that individual contextual embeddings express morphosyntactic alignment gets to the question of how mBERT encodes abstract features of grammar. This is a question that is not answered by work that looks at the contextual encoding of the features that are realized in sentences, like part of speech or sentence structure.

3 Methods

Our primary method involves training classifiers to predict subjecthood from mBERT contextual embeddings, and examining the decisions of these classifiers within and across languages. We train a classifier to distinguish A from O in the mBERT embeddings of one language, and we examine its performance on S embeddings in its training language, and on A, S, and O mBERT embeddings in other languages.

Data To train a subjecthood classifier for one language, we use a balanced dataset of 1,012 transitive subject (A) mBERT embeddings, and 1,012 transitive object (O) mBERT embeddings. We test our classifiers on test datasets of A, S, and O embeddings. Our data points are extracted from the Universal Dependencies treebanks (Nivre et al., 2016): we use the dependency parse information to determine whether each noun is an A or an O, and if it is either we pass the whole sentence through mBERT and take the contextual embedding corresponding to the noun. We run experiments on 24 languages; specifically, all the languages that are both in the mBERT training set[3] and have Universal Dependencies treebanks with at least 1,012 A occurences and 1,012 O occurences.[4]

Labeling Since UD treebanks are not labeled for sentence role (A, S and O), we extract these labels using the dependency graph annotations. We only include nouns and proper nouns, leaving pronouns

---

[3] `https://github.com/google-research/bert/blob/master/multilingual.md`

[4] Our datasets for all languages are the same size. We have set them all to be the size of the largest balanced A-O dataset we can extract from the Basque UD corpus, since Basque is one of the only represented ergative languages and we wanted it to meet our cutoff.

for future work. [5] We label a noun token as:

- **O** if it has a verb as a head and its dependency arc is either `dobj` or `iobj`.
- **A** if it has a verb as a head and its dependency arc is `nsubj` and it has a sibling O.
- **S** if it has a verb as a head and its dependency arc is `nsubj` and it has no sibling O.

Finally, we exclude the subjects of passive constructions (where the object of an action is made the grammatical subject) to analyze separately, as including these examples would confound grammatical subjecthood with semantic agency. We also exclude the siblings of expletives (e.g., “There are many goats”), as these are grammatical objects which appear without subjects as the only argument of the verb, and we also exclude the children of auxiliaries (“The goat can swim”), looking only at the arguments of verbs.

Because we use embeddings and are limited by the Universal Dependencies annotation scheme, there are some cross-linguistic differences in how arguments are handled. For instance, our system is not able to handle null subjects or null objects, even though those are prominent parts of many languages.

Classifiers For each language, and for each mBERT layer ℓ, we train a classifier to classify mBERT contextual embeddings drawn from layer ℓ as A or O. The classifiers are all two-layer perceptrons with one hidden layer of size 64. We train each classifier for 20 epochs on a dataset of the layer-ℓ contextual embeddings of 1,012 A nouns and 1,012 O nouns. In total, we train 24 languages × 13 mBERT layers = 312 total classifiers.

4 Experiment 1: Subjecthood in mBERT

In our first experiment, we train a classifier to predict the grammatical role of a noun in context from its mBERT contextual embedding, and examine its behavior on intransitive subjects (S), which are out-of-domain.

This experimental setup lets us ask two questions about subjecthood encoding in mBERT. Firstly, do contextual word embeddings reliably encode subjecthood information? Secondly, how do our classifiers act when given S arguments (intransitive subjects), which crucially do not appear in the training data? If S arguments are mostly classified as A, that would suggest mBERT is learning a nominative-accusative system, where A and S pattern together. If S patterns with O, that would suggest it has an ergative-absolutive system. If S patterns differently in different languages, that would suggest that it learns a language-specific morphosyntactic system and expresses it in the encoding of nouns in transitive clauses (which are unaffected by alignment), so that the A-O classifiers can pick it up.

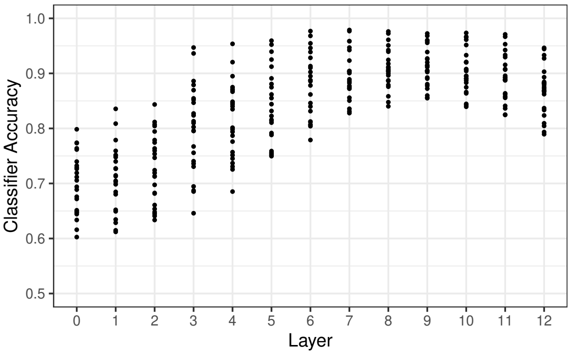

Figure 3: Accuracy of A-O classifiers for every language, by mBERT layer. For all languages, accuracy is highest in layers 7-10

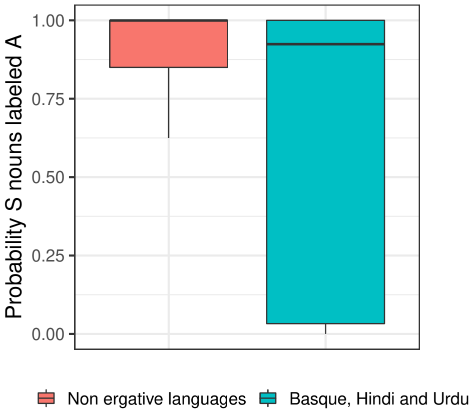

Figure 4: Distribution of layer 10 classifier probabilities for S nouns in the test set. When trained on non-ergative languages, the classifiers mostly predict S nouns to be A. When trained on ergative and split-ergative languages, the classifier predictions for S are much more spread out (towards being classified as O), suggesting that the ergative nature of the languages is expressed in the contextual embeddings of the A and O nouns, influencing the classifier.

4.1 Results

Our results show that the classifiers can reliably perform A-O classification of contextual embed-

---

[5] For an example of how pronouns complicate how subjecthood is defined, see Fox (1987).

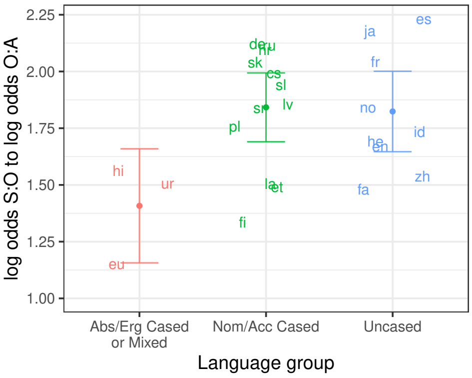

Figure 5: For layer 10, the log odds ratio of S:A relative to O:A, by source language. This is a measure of how close S is to A, relative to O. The ergative languages skew lower than the others, although some other languages (like Finnish and Estonian) also skew low.

dings with relatively high accuracy, especially in the higher layers of mBERT. As shown in Figure 3, performance peaks at around mBERT layers 7-10, where for the majority of languages classifier accuracy surpasses 90%. This is consistent with previous work showing that syntactic information is most well represented in BERT's later middle layers (Rogers et al., 2020; Hewitt and Manning, 2019; Jawahar et al., 2019; Liu et al., 2019). For the rest of this paper, we will focus mainly on the behavior of the classifiers in the high-performance higher layers to assess the properties in these highly contextual spaces that define subjecthood within and across languages.

Performance across layers on the test sets of all 24 languages is shown in Figure 2. When we break the classifiers' behavior down across roles, we see that S nouns mostly pattern with A, though they are consistently less likely to be classed as A than transitive A nouns.

The separation between the A and the S lines is not constant for all languages: it is the largest for Basque, which is an ergative language, and Hindi and Urdu, which have a split-ergative case system (De Hoop and Narasimhan, 2005). This difference is highlighted in Figure 4, where we show the classifiers' probabilities of classifying S nouns as A across the test sets of Basque, Hindi and Urdu versus the test sets for all other 21 languages. In Figure 5, we plot the log odds ratio of classifying S as A versus classifying S as O, and show that for ergative languages this is significantly lower. The fact that classifiers trained on ergative and split-ergative languages are more likely to classify S nouns as O indicates that the ergativity of the language is encoded in the A and O embeddings that the classifiers are trained on.

Note, however, that the A-O classifiers for the ergative languages do not deduce a fully ergative system for classifying S nouns, but a greater skew towards classifying S as O than nominative languages. This suggests that, even though properties of ergativity are encoded in mBERT space, the prominence of nominative training languages has influenced the contextual space to be biased towards encoding a nominative subjecthood system. The difficulty of training the classifier in Basque seems consistent with Ravfogel et al. (2019)'s finding that learning agreement is harder in Basque than in English.

In Experiment 2, we test the zero-shot performance of these A-O classifiers across languages, to ask: is there a parallel, interlingual notion of subjecthood in mBERT contextual space, and do language-specific morphosyntactic alignment biases transfer interlingually?

5 Experiment 2: Transferring across languages

We can learn only so much about mBERT's general subjecthood representations by training and testing in the same language, since many languages in our data set have case-marking and therefore have surface forms that reflect their grammatical roles. To test whether representations of subjecthood in mBERT are language-general, we can do a similar analysis to Experiment 1 but with zero-shot cross-lingual transfer.

That is, we train a classifier to distinguish A and O in Language X (just as in Experiment 1), but then we test in Language Y by seeing how the classifier classifies A, O, and S arguments in Language Y.

By training a classifier on one language and testing on others, we can ask: *is subjecthood encoded in parallel ways across languages in mBERT space?* If a classifier trained to distinguish A from O in a source language can then use the same parameters to successfully classify A from O in another language, this would indicate that the difference between A and O is encoded in similar ways in mBERT space for these two languages.

Secondly, we can examine the classification of S nouns (which are out of domain for the classifiers) in the zero-shot cross-lingual setting. By ob-

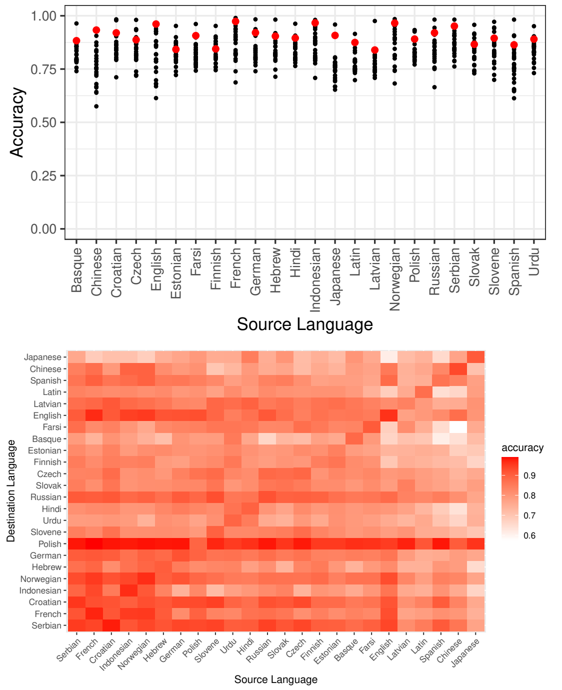

Figure 6: Experiment 2 Results: Cross-lingual transfer accuracies (accuracies shown are for BERT layer 10). **Top:** For each classifier trained to distinguish A and O nouns in a source language (labeled on the x-axis), we plot the accuracy that classifier achieves when tested zero-shot on all other languages. Zero-shot transfer is surprisingly successful across languages, indicating that subjecthood is encoded cross-lingually in mBERT. Each black point represents the accuracy of a classifier tested on a particular destination language, and the red points represent the within-language accuracy.
Bottom: Analytical performance of classifiers for every language pair. The x-axis sorted by average transfer accuracy, so that the source whose classifier performs the best on average is on the left. Despite the general English bias that mBERT often exhibits, in our experiments English is neither a standout source nor destination.

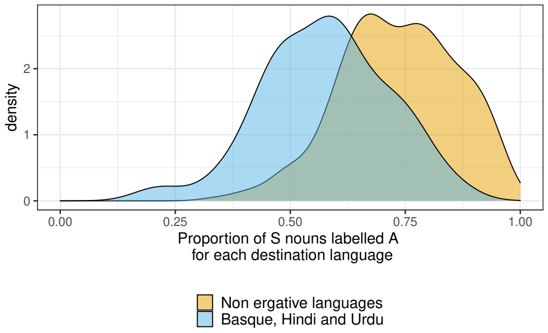

Figure 7: Classifiers trained on ergative languages are more likely to label S nouns in other languages as O. For BERT layer 8, the proportion of S nouns in each destination language test set labeled as A for the classifiers trained on (1) ergative and split-ergative languages (blue) or (2) the rest of the languages.

serving the test behavior of classifiers on S nouns in other languages, we can ask: *is morphosyntactic alignment expressed in cross-lingually generalizable and parallel ways in mBERT contextual embeddings?* If a classifier trained to distinguish Basque A from O is more likely to classify English S nouns as O, this means that information about morphosyntactic alignment is encoded specifically enough to represent each language's alignment, but in a space that generalizes across languages.

5.1 Results

Zero-shot transfer of subjecthood classification is effective across languages, as shown in Figure 6. The average accuracy across all source-destination pairs for a high-performing mBERT layer (layer 10) is 82.61%, and there are several pairs for which zero-shot transfer of the sentence role classifier yields accuracies above 90%. The consistent success of zero-shot transfer across different source and destination pairs indicates that mBERT has parallel, interlingual ways of encoding grammatical and semantic relations like subjecthood. We would expect there to be some extent of joint learning in mBERT: different languages wouldn't exist totally independently in the contextual embedding space, both due to mBERT's multilingual training texts and to successful regularization. It is nevertheless surprising that zero-shot transfer of subjecthood classification between languages is so successful out of the box, and that for all classifiers, within-language accuracy (the red dots in Figure 6) is not an outlier compared to transfer accuracies. Our results show not just that there is mutual entanglement between the contextual embedding spaces of many languages, but that syntactic and semantic information in these spaces is organized in largely parallel, transferable ways.

We can then look at how S is classified: does the subjecthood of S, and the degree of ergativity within each language that we saw expressed in Experiment 1 generalize across languages? Classifiers trained on ergative languages are significantly more likely to classify S nouns in other languages as O, as illustrated in Figure 7 (the source language's case system is a significant predictor of the probability of S being an agent, in a mixed effect regression with a random intercept for language $\beta = .11$, $t = 2.63$, $p < .05$). Our results show that the ergative nature of these languages is encoded in the contextual embeddings of transitive nouns (where ergativity is not realized), and that this encoding of ergativity transfers coherently across languages.

6 Experiment 3: Syntactic and semantic factors of continuous subjecthood

To explore the nature of mBERT's underlying representation of grammatical role, we ask which arguments are most likely to be classified as subjects or objects. This is of particular interest when the classifier gets it wrong: what kinds of subjects get erroneously classified as objects?

The functional linguistics literature offers insight into these questions. It has been frequently claimed that grammatical subjecthood is actually a multi-factor, probabilistic concept (Keenan and Comrie, 1977; Comrie, 1981; Croft, 2001; Hopper and Thompson, 1980) that cannot always be pinned down as a discrete category. Some subjects are more subject-y than others. Comrie (1988) argues that a subject can be thought of as the intersection of that which is high in **agency** (subjects *do* things) and **topicality** (subjects are the topics of sentences). Thus, in English, a prototypical subject is something like “He kicked the ball.” since in such a sentence, the pronoun “he” is a clear agent and the topic of the sentence. But, in a sentence like “The lake, which Jack Frost visited, froze,” the subject is still “lake.” But it is less subject-y: it is not the clear topic of the sentence and it is not an agent.

A probabilistic notion of grammatical role lends itself naturally to the continuous embedding spaces of computational models. So, in a series of experiments, we explored what factors in mBERT contextual embedding space predict subjecthood.

In these experiments, we examine how the decisions and probabilities of the A-O classifiers from Experiment 2 relate to other linguistic features known to contribute to the degree of subjecthood. In particular, we look at whether nouns appear in *passive constructions*, as well as the *animacy* and *case* of nouns. In seeing how passives, animacy, and case interact with our subjecthood classifiers, we can assess if mBERT's representation of subjecthood in continuous space is consistent with functional analyses, and better understand the continuous space in which mBERT encodes syntactic and semantic relations.

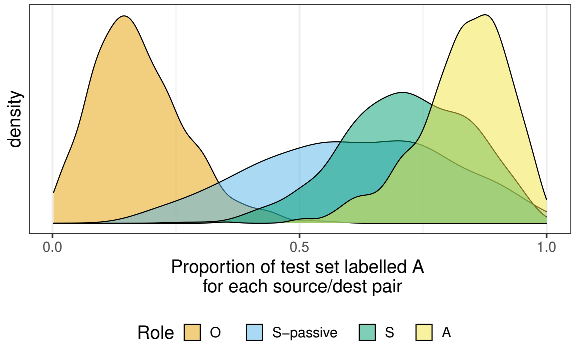

Figure 8: Passive subjects are hard to classify. The distribution of average classifier probabilities in layer 10 for all source-destination language pairs, separated by role. While the layer 10 classifier separates A and S from O, passive subjects remain largely ambiguous in their classification. These plots indicate that, in mBERT space, the grammatical subjects of passive constructions are less subject-y.

We choose these three factors as they are well-studied in the functional literature, as well as readily available to extract from UD corpora. Passive subjects are marked with a separate dependency arc label, the animacy of nouns is annotated directly in some UD treebanks, and in case-marked languages, nouns are annotated with their case. Future work on a more complete examination of the functional nature of contextual embeddings would include other factors not readily available in UD, like the discourse and information structure (topicality) of nouns in context.

6.1 Results

The first area that we look at are passive constructions. In passive constructions such as “The lawyer was chased by a cat”, the grammatical subject is not the main actor or agent in the sentence. As such, while a purely syntactic analysis of subjecthood would classify passive subjects (S-passive) as subjects, an understanding of subjecthood as continuous and reliant on semantics would be more prone to classify passive subjects as objects. As shown in Figure 8, subjecthood classifiers across languages are ambivalent about how they classify passive subjects, even in layers where they have the acuity to successfully separate A and S from O. This indicates that the classifiers do not learn a purely syntactic separation of A and O: the subjecthood encoding that they learn from mBERT space is largely dependent on semantic information.

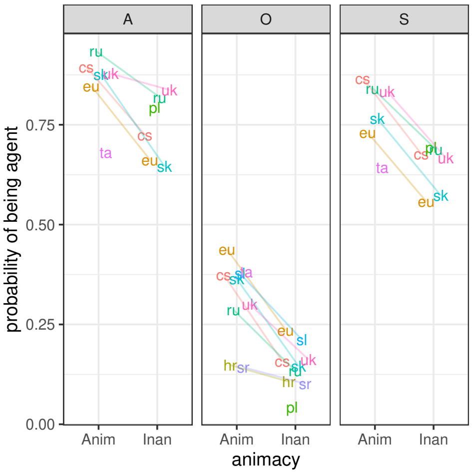

Figure 9: The influence of animacy on classification (within and across languages). For a high-performing layer (Layer 10), the average probability of classifiers in all languages classifying nouns in languages with animacy distinctions as A. For all three roles, animates are more likely to be classified as agents. The labels are two-letter codes for the languages.

We also find that *animacy is a strong predictor of subjecthood*. Our results presented in Figure 9 demonstrate that when we control by role, animacy is a significant factor in determining the probability of being classified as A. Classifiers in all languages, when zero-shot evaluated on a corpus marked for animacy, are more likely to classify animate nouns as A than inanimate nouns. For Layer 10, a mixed effect regression predicting each destination language's probability of assigning an argument to being an agent shows that both role and animacy are significant predictors (with a main effect of animacy corresponding to a 16% increase in the probability of being an agent, $p < .01$). These results indicate that, in learning to separate A from O, the classifiers did not learn a purely syntactic separation of the space (though it is possible to distinguish A and O using only strictly structural syntactic features). Instead, we see that subjecthood information is entangled with semantic notions such as animacy, giving credence to the hypothesis that subjecthood BERT space is encoded in a way concordant with the multi-factor manner proposed by Croft, Comrie, and others.

Lastly, we find that classifier probabilities also vary with case, even when we control for sentence role. As demonstrated in Figure 10, across grammatical roles, classifiers are significantly more likely to classify nouns as A if they are in more agentive cases (nominative and ergative). In a mixed effect regression predicting Layer 10 probability of being an agent based on role and whether the case is agentive (nominative/ergative), there was a 15% increase associated with being nominative/ergative across categories ($t = 2.74, p < .05$).

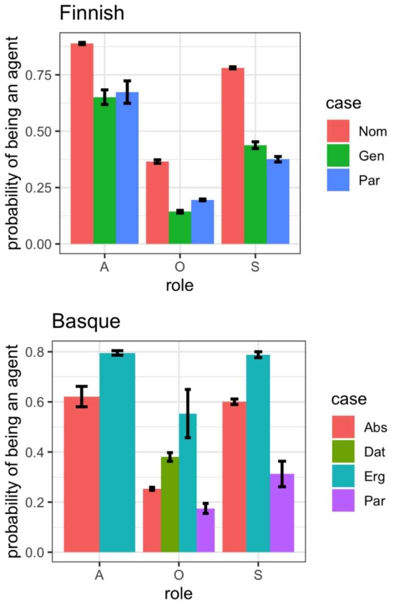

Figure 10: Average probability of being an agent, in layer 10, with 95% confidence intervals, for Finnish and Basque broken up by case.

7 Discussion

Our experimental results constitute a way to begin understanding how general knowledge of grammar is manifested in contextual embedding spaces, and how discrete categories like subjecthood are reconciled in continuous embedding spaces. While most previous work analyzing large contextual models focuses on extracting their analysis of features or structures present in specific inputs, we focus on morphosyntactic alignment, a feature of grammars that is not explicitly realized in any one sentence.

We find that, when tested out of domain, classifiers trained to predict transitive subjecthood in mBERT contextual space robustly demonstrate decisions which reflect (a) the morphosyntactic alignment of their training language and (b) continuous encoding of subjecthood influenced by semantic properties.

There has been much recent work pointing out the limitations of the probing methodology for analyzing embedding spaces (Voita and Titov, 2020;

Pimentel et al., 2020; Hewitt and Liang, 2019), a methodology that is very similar to ours. The main limitation pointed out in this literature is that the power of classifiers is a confounding variable: we can't know if a classifier's encoding of a feature is due to the feature being encoded in BERT space, or to the classifier figuring out the feature from surface encoding.

In this paper, we address these issues by proposing two ways to use classifiers to analyze embedding spaces that go beyond probing, and avoid the limitations of arguments based only around the accuracy of probes. Firstly, our results rely on testing the classifiers on *out-of-domain zero-shot transfer*: both to S arguments and to different languages. As such, we focus on linguistically defining the type of classification boundary which our classifiers learn from mBERT space, rather than their accuracy, and in using transfer we avoid many of the limitations of probing, as argued in Papadimitriou and Jurafsky (2020). Secondly, we examine a feature (morphosyntactic alignment) which is *not inferable from the classifiers' training data*, which consists only of transitive sentences. We are asking if mBERT contextual space is organized in a way that encodes the effects of morphosyntactic alignment for tokens that do not themselves express alignment. Especially in the cross-lingual case, a classifier would not be able to spuriously deduce this from the surface form, whatever its power.

A limitation of our experimental setup is that both our Universal Dependencies training data and the set of mBERT training languages are heavily weighted towards nominative-accusative languages. As such, we see a clear nominative-accusative bias in mBERT, and our results are somewhat noisy as we only have one ergative-absolutive language and two semi-ergative languages

Future work should examine the effects of balanced joint training between nominative-accusative and ergative-absolutive languages on the contextual embedding of subjecthood. And we hope that future work will continue to ask not just *if* deep neural models of language represent discrete linguistic features, but how they represent them probabilistically.

Streaming Models for Joint Speech Recognition and Translation

Abstract

Using end-to-end models for speech translation (ST) has increasingly been the focus of the ST community. These models condense the previously cascaded systems by directly converting sound waves into translated text. However, cascaded models have the advantage of including automatic speech recognition output, useful for a variety of practical ST systems that often display transcripts to the user alongside the translations. To bridge this gap, recent work has shown initial progress into the feasibility for end-to-end models to produce both of these outputs. However, all previous work has only looked at this problem from the consecutive perspective, leaving uncertainty on whether these approaches are effective in the more challenging streaming setting. We develop an end-to-end streaming ST model based on a re-translation approach and compare against standard cascading approaches. We also introduce a novel inference method for the joint case, interleaving both transcript and translation in generation and removing the need to use separate decoders. Our evaluation across a range of metrics capturing accuracy, latency, and consistency shows that our end-to-end models are statistically similar to cascading models, while having half the number of parameters. We also find that both systems provide strong translation quality at low latency, keeping 99% of consecutive quality at a lag of just under a second.

1 Introduction

Speech translation (ST) is the process of translating acoustic sound waves into text in a different language than was originally spoken in.

This paper focuses on ST in a particular setting, as described by two characteristics: (1) We desire models that translate in a streaming fashion, where users desire the translation before the speaker has finished. This setting poses additional difficulties compared to consecutive translation, forcing systems to translate without knowing what the speaker will say in the future. (2) Furthermore, the speaker may want to verify that their speech is being processed correctly, intuitively seeing a streaming transcript while they speak (Fügen, 2008; Hsiao et al., 2006). For this reason, we consider models that produce both transcripts and translation jointly.[1]

Previous approaches to streaming ST have typically utilized a cascaded system that pipelines the output of an automatic speech recognition (ASR) system through a machine translation (MT) model for the final result. These systems have been the preeminent strategy, taking the top place in recent streaming ST competitions (Pham et al., 2019; Jan et al., 2019; Elbayad et al., 2020; Ansari et al., 2020). Despite the strong performance of these cascaded systems, there are also some problems: error propagation from ASR output to MT input (Ruiz and Federico, 2014); ASR/MT training data mismatch and loss of access to prosodic/paralinguistic speech information at the translation stage (Sperber and Paulik, 2020); and potentially sub-optimal latencies in the streaming context. End-to-end (E2E) models for ST have been proposed to remedy these problems, leveraging the simplicity of a single model to sidestep these issues. E2E models are also appealing from computational and engineering standpoints, reducing model complexity and decreasing parameter count.

Although initial research has explored E2E models for joint speech recognition and translation, no previous works have examined them in the streaming case, a crucial step in using them for many real-world applications. To understand this area more fully, we develop an E2E model to compare

*Work done during an internship with Apple

[1] This corresponds to the *mandatory transcript* case in the proposed categorization by Sperber and Paulik (2020).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2533–2539
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

with its cascading counterpart in this simultaneous joint task. We build off the models proposed by Sperber et al. (2020) in the consecutive case, extending them for use in the streaming setting. We also use the re-translation technique introduced by Niehues et al. (2018) to maintain simplicity while streaming. To reduce model size, we introduce a new method for E2E inference, producing both transcript and translation in an interleaved fashion with one decoder.

As this task requires a multi-faceted evaluation along several axes, we provide a suite of evaluations to highlight the differences of these major design decisions. This suite includes assessing translation quality, transcription quality, lag of the streaming process, output flicker, and consistency between the transcription and translation. We find that our E2E model performs similarly to the cascaded model, indicating that E2E networks are a feasible and promising direction for streaming ST.

2 Proposed Method

Network Architecture In the ST survey provided by Sperber et al. (2020), they introduce several E2E models that could be used for the joint setting. As our work focuses on providing a simple but effective approach to streaming ST, we focus on the *CONCAT* model, which generates both the transcript and translation in a concatenated fashion. We compare this E2E model against the standard cascading approach, following the architecture and hyperparameter choices used in Sperber et al. (2020). All audio input models use the same multi-layer bidirectional LSTM architecture, stacking and downsampling the audio by a factor of three before processing. We note that although bidirectional encoders are unusual with standard ASR architectures, re-translation makes them possible. The cascaded model's textual encoder follows the architecture described in Vaswani et al. (2017) but replaces self-attention blocks with LSTMs. Decoder networks are similar, but use unidirectional LSTMs. More implementation details can be found in Appendix A.

In order to reduce model size and inference time for E2E networks, we introduce a novel method for interleaving both transcript and translation in generation, removing the need to use separate decoders. This method extends the *CONCAT* model proposed by Sperber et al. (2020) to jointly decode according to the ratio given by the parameter γ (Figure 1).

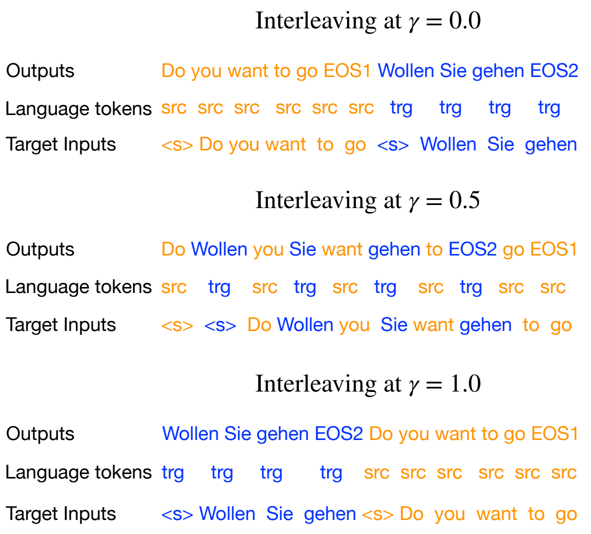

Figure 1: Example token representations (En→De) for three different interleaving parameters (Section 2). Language tokens indicate whether the data corresponds to the source transcript or the target translation and are used with a learned embedding that is summed with the word embeddings, as described in Sperber et al. (2020).

When $\gamma = 0.0$, we generate the transcript tokens until completion, followed by the translation tokens (vice versa for $\gamma = 1.0$). At $\gamma = 0.0$, our model is equivalent to the previously proposed model. Defining $\mathrm{count_i}$ as the count of i tokens previously generated, transcription tokens as *st* and translation tokens as *tt*, we generate the next token as a transcription token if:

$$(1.0 - \gamma) * (1 + \mathrm{count_{tt}}) > \gamma * (1 + \mathrm{count_{st}})$$

This approach enables us to produce tokens in an interleaving fashion, given the hyperparameter γ.

Re-translation We use the re-translation method (Niehues et al., 2018; Arivazhagan et al., 2020a,b) as it provides a simple way to handle the streaming case. This method works by simply re-translating the utterance as new data arrives, updating its former prediction. As we are generating both transcript and translation, this avoids the challenging issue of combining the requirements for both components: streaming speech models need to manage the audio signal variability across time while streaming translation models need to overcome issues with reordering and lack of future context.

Alternative strategies to the re-translation approach include the chunk-based strategy explored by Liu et al. (2020), which commits to all previous output chunks and Ren et al. (2020) who utilize an additional segmenter model trained via CTC

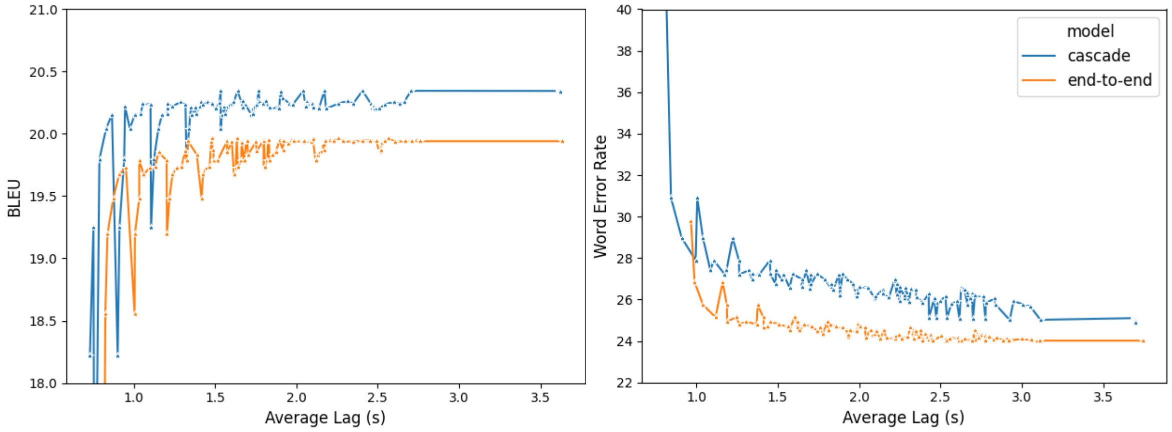

Figure 2: Left: average lag in seconds vs BLEU score. Right: average lag in seconds vs WER score. All points are the mean of each configuration's score across the eight target languages. Configurations are the cross product of the values for K and F, see Section 2: Inference. Note that points near 1.0 AL have appx. 99% of the unconstrained BLEU score. Results for the E2E model use $\gamma = 0.5$.

Table 1: BLEU and WER scores for models trained on different target languages. Bold scores indicate results that are statistically similar to the best score using a bootstrap permutation test with $\alpha = 0.05$.

(Graves et al., 2006) to create segments that are translated via wait-k (Ma et al., 2019). Although these approaches show effective results, they add additional complexity without addressing issues particular to streaming transcription.

Inference In order to generate quality-latency curves, we use several techniques to reduce latency and flicker at the cost of quality. The first is the mask-*k* method proposed by Arivazhagan et al. (2020b), masking the last K output tokens. The second method is a form of constrained decoding: we define a hyperparameter F that sets the number of free tokens allowed to change in the next re-translation. Thus, we constrain future output to match the first $len(tokens) - F$ tokens of the current output. All models use values $\{0, 1, 2, 3, 4, 5, 7, 10, 100\}$ for K and $\{0, 1, 2, 3, 4, 5, 7, 10, 15, 20, 25, 100\}$ for F. For interleaving models, we set K and F on both transcript and translation tokens.

3 Experimental Settings

Data We use the MuST-C corpus (di Gangi et al., 2019) since it is the largest publicly available ST corpus, consisting of TED talks with their English transcripts and translations into eight other language pairs. The dataset consists of at least 385 hours of audio for each target language.

We utilize the log Mel filterbank speech features provided with the corpus as input for the ASR and E2E models. To prepare the textual data, we remove non-speech artifacts (e.g. "(laughter)" and speaker identification) and perform subword tokenization using SentencePiece (Kudo and Richard-

Model	En→De Incr.	En→De Full	En→Es Incr.	En→Es Full	Mean Incr.	Mean Full

Table 2: Consistency scores for En→De, En→Es, and average results over all languages; lower is better (see Sperber et al. (2020)). *Incr.* stands for the incremental consistency score, or the average consistency throughout retranslation. Bold scores indicate results that are statistically similar to the best score using a bootstrap permutation test with $\alpha = 0.05$.

son, 2018) on the unigram setting. Following previous work for E2E ST models, we use a relatively small vocabulary and share transcription and translation vocabularies. We use MuST-C dev for validation and report results on tst-COMMON, utilizing the segments provided (Appendix D).

Prefix Sampling We implement techniques developed by Niehues et al. (2018); Arivazhagan et al. (2020b) for improving streaming ST, sampling a random proportion of each training instance as additional data to teach our models to work with partial input. See Appendix C for implementation details.

Metrics We evaluate these models on a comprehensive suite of metrics: sacrebleu (*BLEU*, Post (2019)) for translation quality, word error rate (*WER*, (Fiscus, 1997)) for transcription quality, average lag (*AL*, Ma et al. (2019)) for the lag between model input and output, and normalized erasure (*NE*, Arivazhagan et al. (2020a)) for output flicker. Measuring consistency is a nascent area of research; we use the robust and simple lexical consistency metric defined by Sperber et al. (2020), which uses word-level translation probabilities. To show how consistent these results are while streaming, we compute an incremental consistency score, averaging the consistency of each re-translation.

4 Results

Results for the quality-latency curves created by the use of constrained decoding and mask-*k* (Section 3) are shown in Figure 2. Unconstrained settings are used for all results in table form. For convenience, bold scores indicate the highest performing models in each metric according to a bootstrap permutation test.

Translation Quality We see in Table 1 that the cascaded model slightly outperforms some E2E models, while achieving statistically similar performance to the $\gamma = 1.0$ model. We note however, that the cascaded model has nearly twice as many parameters as the E2E models (217M vs 107M). When we examine these models under a variety of different inference conditions (using constrained decoding and mask-*k* as in Arivazhagan et al. (2020a)), we further see this trend illustrated through the quality vs latency trade-off (left of Figure 2), with both models retaining 99% of their BLEU at less than 1.0 AL.

Transcription Quality Conversely, Table 1 and the right of Figure 2 show that the $\gamma = 1.0$ E2E model performs similarly or slightly better than the cascaded model across all inference parameters and all target languages. With an AL of 1.5, the E2E model loses only 3% of its performance.

Consistency The E2E models perform worse than the cascaded on consistency, with the best models being approximately 18% less consistent (Table 2). The cascaded model also maintains better scores through each re-translation (*Incr.*).[2]

Flicker We note that the flicker scores for cascade and E2E models are similar, with both having normalized erasure scores of less than 1 and the majority of inference settings having less than the "few-revision" threshold of 0.2 (proposed by Arivazhagan et al. (2020a)). More NE details are found in Appendix B.

Interleaving Rate Table 1 also shows us the overall results for different interleaving rates. We see that interleaving at a rate of 1.0 has the best

---

[2] Initial experiments indicate that the triangle E2E architecture (Sperber et al., 2020) model may perform better on consistency in our streaming setting, but due to time constraints we were not able to explore this further. Future work exploring alternative architectures or decoding techniques (Le et al., 2020) may provide fruitful avenues of research.

quality scores (0.7 less WER than the next best rate, the base $\gamma = 0.0$ model) but the worst consistency (Table 2). Conversely, $\gamma = 0.3$ has the worst quality scores but the best consistency.

5 Conclusion

We focus on the task of streaming speech translation, producing both a target translation and a source transcript from an audio source. We develop an end-to-end model to avoid problems that arise from the use of cascaded models for streaming ST. We further introduce a new method for joint inference for end-to-end models, generating both translation and transcription tokens concurrently. We show that our novel end-to-end model, with only half the number of parameters, is comparable to standard cascaded models across a variety of evaluation categories: transcript and translation quality, lag of streaming, consistency between transcript and translation, and re-translation flicker. We hope that this will spur increased interest in using end-to-end models for practical applications of streaming speech translation.

A Model Details

In this section we will describe implementation details of the model architectures (shown in Figure 3) and training processes.

Model Architectures Unless otherwise noted, the same hyperparameters are used for all models. Weights for the speech encoder are initialized based on a pre-trained attentional ASR task that is identical to the ASR part of the direct multitask model. Other weights are initialized according to Glorot and Bengio (2010). The speech encoder is a 5-layer bidirectional LSTM with 700 dimensions per direction. Attentional decoders consist of 2 Transformer blocks (Vaswani et al., 2017) but use 1024-dimensional unidirectional LSTMs instead of self-attention, except for the *CONCAT* model, which uses 3 layers.

For the cascade's MT model, encoder/decoder both contain 6 layers with 1024-dimensional LSTMs. Subword embeddings are size 1024. We regularize using LSTM dropout with $p = 0.3$, decoder input word-type dropout (Gal and Ghahramani, 2016), and attention dropout, both $p = 0.1$. We apply label smoothing with strength $\epsilon = 0.1$.

Training We optimize using Adam (Kingma and Ba, 2014) with $\alpha = 0.0005$, $\beta_1 = 0.9$, $\beta_2 = 0.98$, 4000 warm-up steps, and learning rate decay by using the inverse square root of the iteration of each instance. We set the batch size dynamically based on the sentence length, such that the average batch size is 128 utterances. The training is stopped when the validation score has not improved over 10 epochs, where the validation score is corpus-level translation BLEU score (for the E2E and MT models) and corpus-level WER for the cascade's ASR model.

For decoding and generating n-best lists, we use beam size 5 and polynomial length normalization with exponent 1.5. Our implementation is based on PyTorch (Paszke et al., 2019) and XNMT (Neubig et al., 2018), and all models are trained in single-GPU environments, employing Tesla V100 GPUs with 32 GB memory. Most E2E and ASR models converged after approximately 30 epochs or 5 days of training. MT models converged after approximately 50 epochs or 2 days of training.

B Normalized Erasure (Output Flicker)

We see similar curves for both the cascaded model and the E2E model when comparing normalized erasure in Figure 4. We see that most settings have an NE score of less than 0.2, while virtually all settings are less than 1. We note that a proportion of 0.2 for NE means that, on average, 1/5 of the tokens change once before they settle to their final state.

C Prefix Training

We used prefix training to increase stability and reduce flickering in the streaming setting. We conducted this by utilizing each training instance twice in each epoch: one as normal and the other with only the prefix. The length of the prefixes were randomly sampled from [0, 1]. We found that this additional data augmentation was particularly helpful; without it, the models would hallucinate the rest of a partial sentence.

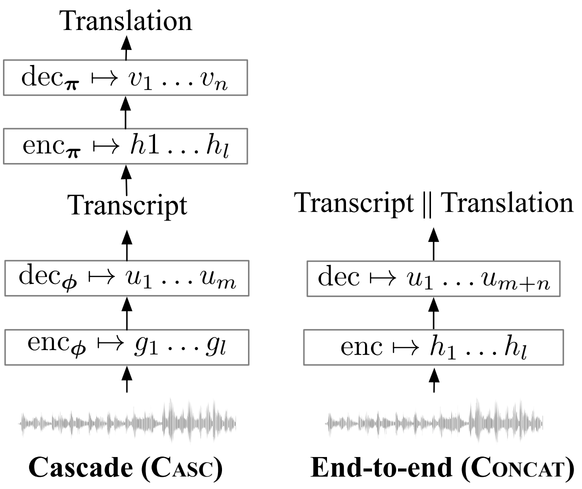

Figure 3: Architectures of the cascade and concatenated (E2E) model

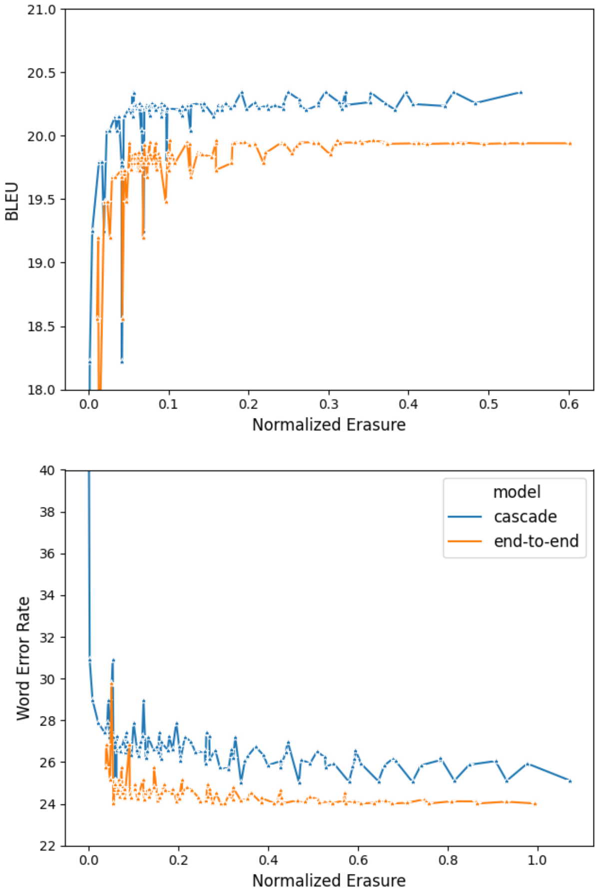

Figure 4: Left: average lag in seconds vs NE score. Right: NE vs WER score. All values are the mean of the results from the eight target languages.

We further found that starting the prefix sampling data augmentation too late in training was also negative. After testing initial models on the dev set, we found that starting this additional augmentation 15 epochs after training was best.

D Utterance Segmentation

We follow the audio segments provided in the MuST-C corpus, created through a use of human alignment and XNMT (Neubig et al., 2018). We note that there exist a variety of methods for creating segments for such models, however, we leave additional exploration of E2E alignment methods as future work.

Abstract

This paper explores learning rich self-supervised entity representations from large amounts of associated text. Once pre-trained, these models become applicable to multiple entity-centric tasks such as ranked retrieval, knowledge base completion, question answering, and more. Unlike other methods that harvest self-supervision signals based merely on a local context within a sentence, we radically expand the notion of context to include *any* available text related to an entity. This enables a new class of powerful, high-capacity representations that can ultimately distill much of the useful information about an entity from multiple text sources, without any human supervision.

We present several training strategies that, unlike prior approaches, learn to *jointly* predict words and entities—strategies we compare experimentally on downstream tasks in the TV-Movies domain, such as MovieLens tag prediction from user reviews and natural language movie search. As evidenced by results, our models match or outperform competitive baselines, sometimes with little or no fine-tuning, and can scale to very large corpora.

Finally, we make our datasets and pre-trained models publicly available[1]. This includes *Reviews2Movielens*, mapping the ∼1B word corpus of Amazon movie reviews (He and McAuley, 2016) to MovieLens tags (Harper and Konstan, 2016), as well as Reddit Movie Suggestions with natural language queries and corresponding community recommendations.

1 Introduction

Much of the online information describing entities in domains such as music, movies, venues or consumer products, is only available as unstructured text—a format that is human-readable but not machine-understandable (yet). Consider online reviews—a rich source of mostly user-generated about a vast number of entities. Our key research question is: *Can we learn strong models for entity understanding tasks such as vertical search and question answering, solely from text?* In other words, given a large and noisy collection of documents about an entity, can we distill all the useful information therein into a dense entity representa-

Review 1: *"This movie develops its power best if you don't try to look out for the "real" and "true" events behind the four versions of the narration... shown in a very intelligent and artistic way, no silly plot-twists, no explanation in the end — it is open to your fantasy... "$MOVIE" is an important piece of cinematic storytelling and a really interesting way to reflect on the origin of tales... Some scenes even remind me of Andrej Tarkovskijs intensive style..".*
Review 2: *"Just rented this, and at first I didn't like very much, but then it starts to sink in for how good it is, the acting is great especially Toshiro Mifune, it was shot very good for an older movie... it's #62 on the top 250"*
Review 3: *"Saw this movie at my local video store... was placed on a waiting list, but when I returned to check it out the video store had closed down over night. Actually whent out of business"*
... More reviews ...
Summary tags: [nonlinear] [multiple storylines] [japan] [black and white] [surreal] [cerebral] [imdb top 250], ...

Table 1: *Reviews2Movielens* task, illustrated. Here are sample review snippets for a certain classic film which is summarized using MovieLens tags. Notice that the tags may not appear in the input verbatim and can be thought of as boolean questions about the film. Note also that Review 3 has zero relevant signal—a common challenge of low SNR in this dataset. Bonus teaser: can you guess the $MOVIE from these snippets? This little quiz alludes to a key learning task in our approach.

tion, so as to benefit multiple downstream tasks?

Traditionally, learning entity representations required supervised signals such as clicks, "likes" and consumption behavior (Agichtein et al., 2006; Huang et al., 2013; Koren et al., 2009; Vig et al., 2012a), which are generally expensive and time consuming to obtain at scale. To leapfrog these limitations, we draw inspiration from the recent progress in unsupervised learning of text, particularly contextualized representations via techniques such as ELMo (Peters et al., 2018), CoVe (McCann et al., 2017) and BERT (Devlin et al., 2019). Many of these representations are learned by predicting a missing word from its context. More recently, Sun et al. (2019) showed that extending word masking strategies to entities can lead to superior language models. Even more recent entity linking methods such as RELIC (Ling et al., 2020) and others, detailed in Section 6, were shown to produce explicit encodings applicable to entity understanding tasks.

We start with RELIC-like approaches and generalize them into a family of models, collectively called DocEnt, that jointly embed text and entities (Section 2) via self-supervised tasks. The first one, DocEnt-Dual, is essentially RELIC, but trained with a much broader context to include any and all sentences potentially related to an entity. Importantly, DocEnt-Dual/RELIC only optimizes a single task, namely *entity prediction* given an associated sentence, effectively modeling $P(Entity|Sentence)$.

Another natural way of jointly modelling entities and text is by directly tapping the cross-attention mechanism in BERT, simply by extending the BERT vocabulary to include entity tokens V_E. Each entity-related sentence can then be augmented with a corresponding token from V_E. We call this method DocEnt-Full and, despite (or perhaps because of) its conceptual simplicity, it proves surprisingly effective in semi-supervised tasks.

Finally, DocEnt-Hybrid aims to capture the best of both models by extending DocEnt-Dual with an additional task of predicting words in a sentence, conditioned on its associated entity. This task encourages the latter to "remember" salient phrases in its sentences.

We empirically evaluate these methods by learning entity representations for movies from a TV-Movies portion of the Amazon Reviews Corpus (He and McAuley, 2016). To this end, we consider several movie-oriented tasks for downstream evaluation, i.e. Reddit Movie Suggestions and MovieLens Tag Prediction (Harper and Konstan, 2016), which we study in both zero-shot, supervised and few-shot settings. We join the MovieLens dataset with the reviews corpus (He and McAuley, 2016) obtaining a mapping from movie reviews to user-generated tags. On the supervised tag prediction task, our text-based model demonstrates SOTA performance, despite not using powerful user signals (Vig et al., 2012a). In fact, we are able to match or outperform baselines on all tasks where they are available.

1.1 Contributions

1. First, we propose a family of methods to train deep self-supervised entity representations purely from related text documents, with strong zero-shot results on ranked retrieval with natural language queries.

2. Secondly, we show that these pre-trained representations are amenable to fine-tuning on new tasks such as MovieLens tag prediction, where we show state-of-the-art results. They are also effective few-shot learners, which we demonstrate on a harder *open-vocabulary*[2] task akin to Boolean Question Answering (Clark et al., 2019).

3. Next, we propose *Reviews2Movielens*—a new Text Based Entity Understanding task. The requisite dataset, which we release publicly, effectively joins the Amazon Movie Reviews Corpus and MovieLens into a large, sparsely supervised set with approximately 1B words and 470K movie-tag pairs.

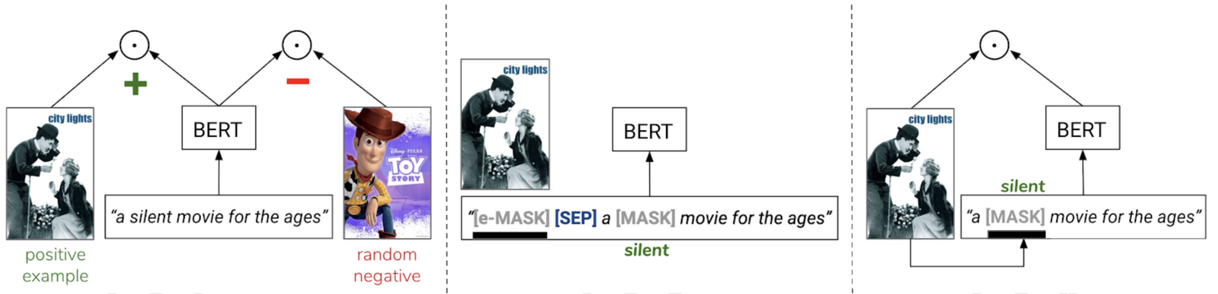
4. Finally, we also release a dataset of user-generated Reddit Movie Suggestions, a benchmark for natural language search and recommendation scenarios.

2 Self-Supervised Entity Representations

Inspired by the success of self-supervised language models, we seek to extend them to jointly compute text and entity representations. Recall that our input is a set of entities $\mathcal{E}$ where for every entity $e \in \mathcal{E}$, we have a collection of sentences, denoted by $\mathcal{S}_e$, from all documents related to e. Intuitively, we want the representation of e to be influenced by each associated sentence $s \in \mathcal{S}_e$, and vice versa.

---

[2] An open vocabulary allows any phrase to be a label.



DocEnt-Dual (RELIC) DocEnt-Full DocEnt-Hybrid

Figure 1: Models in the DocEnt family. Left: a baseline dual encoder model called DocEnt-Dual a.k.a. RELIC, maximizing $P(e|s)$ but not $P(s|e)$. Center: DocEnt-Full—a model maximizing the joint sentence-entity probability using full cross-attention. Right: DocEnt-Hybrid, designed to capture the best of both worlds.

To that end, we explore two (self-) supervision signals: $P(e \mid s)$ and $P(s \mid e)$.

2.1 DocEnt-Dual, Known as RELIC

At the core of DocEnt-Dual is a RELIC model that co-encodes an entity e and an associated sentence $s \in \mathcal{S}_e$ so as to maximize their compatibility score, defined as the cosine similarity between the two encodings:

$$\mathbf{s}(e, s) = \frac{g(e)^T f_{CLS}(s)}{\|g(e)\| \|f_{CLS}(s)\|},$$

where $g(e)$ is an embedding of e and $f(s)$ is a BERT-based encoding of s, with its special $[CLS]$ token whose output representation is denoted by f_{CLS}. Then, the conditional probability of e given s is given by a softmax over the set $\mathcal{E}$ [3]:

$$P(e|s) = \frac{\exp(\mathbf{s}(e, s))}{\sum_{e' \in \mathcal{E}} \exp(\mathbf{s}(e', s))}.$$

Finally, RELIC is trained by maximizing $\log P(e|s)$ over all associated pairs $e, s \in \mathcal{S}_e$:

$$\mathcal{L}_E(e, s) = \log P(e|s).$$

Note that both g and f (initialized with a common BERT) are learned during training.

Our sole difference to the original RELIC is in training data: while RELIC only uses sentences containing entity mentions, we allow a radically broader context – all sentences associated with an entity – with the goal of remembering all of its attributes. Crucially, no human labeling is required.

Despite its effectiveness (as demonstrated in Section 5), RELIC has one obvious limitation: it ignores $P(s \mid e)$, leaving a useful signal "on the table". We therefore propose another way of co-encoding sentences and entities by tapping the full cross-attention power of Transformers.

2.2 DocEnt-Full

Before we proceed, let us revisit BERT's Masked Language Model (MLM) training objective. Given a sequence of input tokens $s = [s_1, \ldots, s_n]$, a fraction of tokens s_J at randomly selected positions J is replaced with a special *[MASK]* token. We denote this new sequence by s_{-J}.

Then, BERT predicts masked tokens based on their contextualized representations $f(s_{-J})$. The MLM training objective to maximize is:

$$\mathcal{L}_{MLM} = \log P(s_J \mid s_{-J}).$$

Enter DocEnt-Full. It follows the standard BERT architecture, with a twist. First, we expand the input vocabulary to include all entity tokens in $\mathcal{E}$. Then, during input sequence construction, each sentence $s \in \mathcal{S}_e$ is prepended[4] with the corresponding entity token e, as shown in Figure 1. This way, masking and predicting this token (via softmax) effectively adds our new objective $\mathcal{L}_E$ to BERT. Further, the new e token is now part of a sentence context, augmenting the original $\mathcal{L}_{MLM}$ to

$$\mathcal{L}_{MLM+E}(s, e) = \log P(s_J \mid s_{-J}, e),$$
$$\text{and } \mathcal{L}_{\text{FULL}} = \mathcal{L}_E + \lambda \mathcal{L}_{MLM+E}$$

becomes the combined loss function optimized using nothing but BERT's standard MLM training, with a hyperparameter λ to balance the two terms[5].

---

[3] In practice, only a subset of entities in $\mathcal{E}$ is used in the denominator: the so called "in-batch negatives".

[4] Technically, we replace BERT's standard (s_A, s_B) two-segment input structure with (e, s), for $s \in \mathcal{S}_e$.

[5] The relative masking frequency of entity tokens is another hyperparameter available to balance the two objectives.

This conceptual simplicity and full cross-attention power come with a cost: bundling wordpieces and entities together forces the model to allocate an equal capacity to both types of tokens (e.g., 768D for BERT-base), regardless of the size of $\mathcal{E}$. As a result, a relatively small-sized $\mathcal{E}$ may be prone to overfitting[6] in zero-shot scenarios, as we observe in Section 5.4.2.

2.3 DOCENT-HYBRID

Recall that RELIC avoids the above limitation by decoupling text and entity encoders. To get the best of both worlds, we introduce DOCENT-HYBRID—a third model that sticks with the modular dual encoder architecture while also modeling $P(s \mid e)$. This is achieved by implementing a different variant of $\mathcal{L}_{MLM+E}$ where, for every masked wordpiece token, the output of Transformer layers $f(s_{-J})$ is first concatenated with the associated entity embedding $g(e)$ before feeding into the final MLM prediction layer. By including entity embeddings in the prediction of related text tokens, we get them to "remember" important aspects from the text without sacrificing modularity.

3 Tasks

In this section, we define the three tasks used to evaluate pre-trained entity representations.

3.1 Supervised Task: Movielens Tag Prediction

The original MovieLens Tag Prediction task is to produce movie-tag scores for a set of movies and a canonical vocabulary of tags (see examples in Table 1), based on a collection of crowdsourced (movie, tag, user) votes, as well as (user, movie) star ratings. These tags are often not factual but may refer to plot elements, qualitative aspects or reflect subjective opinions. Since the same can be said about user reviews, and we observe a non-trivial amount of textual entailment between the two sources. We therefore intentionally exclude user ratings from the input. The new challenge is to complete the movie-tag relevance matrix by leveraging movie reviews, hereafter referred to as the *closed-vocabulary tag prediction* task[7]. This is a supervised setup where models are fine-tuneed with tag labels and evaluated on a held-out set subset of movies, as elaborated in Section 5.

3.2 Few-Shot Task: Open Vocabulary Tag Prediction

In reality, the space of tags is not static. Rather, tags are a useful kind of user-generated content that evolves to reflect the zeitgeist, much like human language. Many online platforms (e.g, Twitter and Instagram to name a few) have vibrant online communities that keep inventing new tags. We therefore propose a new *open-vocabulary* formulation of the tag prediction problem where any phrase is allowed to be a tag.

This requires a small change in evaluation. Instead of held-out movies, we hold out a subset of tags and fine-tune on the rest (and on all the movies). Note that this is no longer a classic multi-label classification task as we never get to see the test labels during training. Rather, this open-vocabulary setup is akin to answering boolean questions (about a movie) based on a text document (Clark et al., 2019).

3.3 Zero-Shot Task: Reddit Movie Suggestions

The purpose of this task is to evaluate pre-trained entity representations in the context of vertical search. The classic entity ranking problem is, given a text query and a finite set of entities, to rank them according to their relevance to the query. Recall that DOCENT models are naturally designed to make such relevance predictions via $P(Entity|Sentence)$ — without any fine-tuning, if necessary. We therefore leverage the Reddit Movie Suggestions Dataset (detailed in Section 4.3) as a source of both queries and ground truth to define a zero-shot movie ranking task. To clarify, the notion of *zero shot* implies a pre-trained but not fine-tuned model in our context. This dataset is particularly interesting for its challenging queries, with their distinctly natural, often conversational language (e.g., *"Last week I watched the British cold war movie Threads. I am scarred, but intrigued as well. Any similar deeply disturbing yet realistic movies you can recommend?"*, see Table 2 for more examples). Another challenge is an explicit recommendation intent present in many of the queries (i.e., *"Movies like ..."*), making this task a mixture of Search and Recommendation. The latter typically requires specialized recommendation models of entity-to-entity

---

[6] Conversely, a very large $\mathcal{E}$ may require an optimized implementation of softmax to maintain scalability.

[7] One can also view this as a two-dimensional knowledge base (KB) completion problem, where relation types are not available and the KB is reduced to a 2D matrix.

Query	**Top 5 Results**
Movies like [**Whiplash**] about an artist or a musician chasing an almost impossible dream and nearly or does ruin his life because of it	Inside Llewyn Davis, **Whiplash**, A Young Man with a Horn, Hustle & Flow, Born to Be Blue
Really dark, slow paced movies with minimal story, but incredible atmosphere, kinda like [**Drive**] or [**The Rover**]	**The Rover**, Valhalla Rising, Only God Forgives, Blade Runner, Sicario
Films like [**Mission Impossible**] or [**The Italian Job**] that have big scenes where the characters must break in or infiltrate some place	National Treasure: Book of Secrets, **Mission: Impossible – Rogue Nation**, Ant-Man, **The Italian Job**

Table 2: Qualitative examples illustrating zero-shot movie ranking by DOCENT-FULL, with natural language queries crawled from Reddit. The bracketed greyed-out movie mentions are users' examples of desired recommendations, removed from the queries to probe the model in what resembles a movie guessing game. Those obfuscated entities were correctly guessed by the model based on remaining query terms, making it to the Top 5 in most cases. Other top matches appear to be equally relevant.

similarity, and cannot generally be solved with keyword-based search.

4 Datasets

4.1 Amazon Movie Reviews Corpus

All our models are pretrained on Amazon Product Reviews (He and McAuley, 2016) in the "Movies and TV" category, comprising 4,607,047 reviews for 208,321 movies collected during 1996–2014[8].

4.2 Reviews2Movielens

One of this paper's contributions is *Reviews2Movielens*—a new multi-document multi-label dataset created by joining Amazon Movie Reviews (He and McAuley, 2016; Ni et al., 2019) and MovieLens (Harper and Konstan, 2016), a rich source of crowdsourced movie tags. The key challenge in joining the two datasets is establishing correspondences between their respective movie IDs, which turns out to be a many-to-one mapping[9]. We have identified a subset of high-precision many-to-one correspondences by applying Named Entity Recognition techniques[10] to both Amazon product titles (incl. release years) and their product pages. The resulting mapping consists of 71,077 unique Amazon IDs and 28,918 unique MovieLens IDs. The mapping accuracy was manually verified to be 97% based on 200 random samples. Ultimately, the joined dataset contains nearly 2 million reviews and close to 1B words, significantly more than its IMDB counterpart (Maas et al., 2011).

Since both datasets are widely used as a source of data and academic benchmarks (Miller et al., 2003; Jung, 2012; Anand and Naorem, 2016; He and McAuley, 2016; Ni et al., 2019), we hope that this new mapping[11] will be useful to the community.

4.3 Reddit Movie Suggestions

This user-generated dataset contains a collection of 4765 movie-seeking queries and corresponding recommendations, collectively curated and voted on by the Reddit Movie Suggestions community[12]. Worth noting are (a) the conversational, human-to-human language of the queries; (b) the community-recommended movies that, while sparse and possibly biased, can be used as a source of ground truth. While modest in size, the dataset is well-suited to evaluate zero-shot performance on the movie ranking task defined in Section 3.3.

5 Experiments

5.1 Pre-training

All our experiments start with pre-training models on the Amazon Movie Reviews corpus, followed by optional task-dependent fine-tuning. First, we apply some simple filtering to the input, removing reviews shorter than 5 words and movies with less than 5 reviews [13]. This results in 81,057 Amazon movies, of which 17,131 have MovieLens correspondences, and 4,181,727 reviews in total. Further, we split reviews into individual sentences (or short paragraphs) so as to circumvent the BERT

---

[8] We've used the 2016 version of the dataset from `http://jmcauley.ucsd.edu/data/amazon`.

[9] Each Amazon ID (ASIN) matches a canonical product URL, e.g., `https://www.amazon.com/dp/B06XGG4FFD`. However, these IDs correspond to specific product *editions* (typically DVDs) rather than unique titles, causing duplication issues. Some are collections of several titles.

[10] We use the public Google Cloud Natural Language API – `https://cloud.google.com/natural-language/docs/basics#entity%20analysis`.

[11] See `http://goo.gle/research-docent`

[12] `https://www.reddit.com/r/MovieSuggestions`

[13] This low-count filtering is applied after de-duplication and aggregation.

sequence length limit. Finally, since our goal is to learn non-obvious entity attributes, we remove movie names from their reviews.

All our models use the standard BERT-base configuration with 12 layers, 12 attention heads and a hidden size of 768, and are initialized with a publicly available BERT-base checkpoint[14].

5.2 Tag Prediction: Fine-tuning Strategies

We will now describe the fine-tuning strategies used to transfer pre-trained DOCENT models to downstream tag prediction tasks.

DOCENT-FULL To generate movie-tag relevance scores, we need to predict $P(Tag|Movie)$, which we cast as binary classification. Recall that BERT has a built-in binary classifier (for next-sentence prediction), implemented as a single-layer FFN [15] on top of its *[CLS]* output, with logistic loss. We simply repurpose that layer for our task.

DOCENT-DUAL and DOCENT-HYBRID Recall that, during pre-training, DOCENT-DUAL and DOCENT-HYBRID use softmax cross entropy loss to predict $P(Entity|Sentence)$. However, tag prediction poses the inverse problem: predict tags based on a movie entity. In our dual encoder framework, that can be done simply by computing softmax over all of the encoded tags rather than entities, without any changes to the architecture.

Shared Strategies For fine-tuning, all of the models share the following choices. First, we treat every existing movie-tag pair in the training set as a positive example, weighted proportionally to the number of user votes for that pair (or to the logarithm thereof). Next, for a given movie, about 10% of all vocabulary tags are sampled as negative examples, excluding the known true positives for that movie. To prevent overfitting, we fix entity embedding weights for all models during fine-tuning.

5.3 Entity-less Baselines

To corroborate the utility of explicit entity representations, we set out to evaluate a few baselines that circumvent them by representing each entity as a Bag-of-Sentences (BoS), computed over its related reviews with a sentence encoder of choice. Such a BoS encoder can replace entity embeddings in our architecture, yielding a naïve variant of DOCENT-DUAL. We call these baselines BOS-GLOVE, BOS-BERT and BOS-SENTENCEBERT[16], reflecting their underlying sentence encoders.

Task	Movies	Tags	M-T Pairs
Closed (test)	1000	1128	46359
Closed (dev)	380	1128	17943
Open (test)	6392	500	141618
Open (dev)	3362	100	25274

Table 3: Evaluation datasets sizes for Tag Prediction tasks. Closed / Open stand for the closed and open vocabulary tasks, respectively; M-T Pairs shows the number of corresponding movie-tags pairs. The top two rows describe *movie* holdout sets used in our closed vocabulary experiments; bottom two rows showing *tag* holdouts for open vocabulary experiments.

5.4 Evaluation

5.4.1 Movielens Tag Prediction

The main challenge with evaluating tag prediction is the sparse and noisy nature of user-generated ground truth. For instance, a certain movie tag having zero votes may still be relevant in reality. On the other hand, some entities may have votes for contradictory tags (e.g., both "funny" and "not funny"). The original Tag Genome baseline (Vig et al., 2012b) mitigated this by collecting an additional dataset of unbiased movie-tag relevance scores. Alas, that data has not been released. Instead, we propose two complementary metrics that cast tag prediction either as binary classification or as a ranking problem.

For classification, we binarize labels as follows. Let $\#(m, t)$ be the number of users who assigned a tag t to a movie m. Then its binary counterpart $l(m, t)$ is set to 1 iff $\#(m, t) > T$, a threshold[17].

For the tag ranking formulation, we make the assumption that true movie-tag relevance is correlated with the number of movie-tag votes, and define our movie-tag relevance score as $r(m, t) = \#(m, t)$.

Equipped with this score, we use Precision@k and NDCG metrics (Järvelin and Kekäläinen, 2002) to measure performance.

Tag prediction baselines include

MovielensTopTags— a fixed ordering of tags.

[14] `https://storage.googleapis.com/bert_models/2018_10_18/uncased_L-12_H-768_A-12.zip`

[15] Feed-Forward Neural Network

[16] SENTENCEBERT (Reimers and Gurevych, 2019) fine-tunes BERT on NLI to provide off-the-shelf semantic sentence representations.

[17] We use $T = 2$ to filter out noisy tags.

Model	MAP	AUC
MovielensTopTags	6.2	0.80
TD-IDF	32.3	0.86
BoS-BERT	39.3	0.91
TagGenome	43.9	**0.98**
DocEnt-Full	**44.7**	**0.98**
DocEnt-Dual	38.6	0.96
DocEnt-Hybrid	44.1	**0.98**
Human	76.6	0.99

Table 4: Mean Average Precision and ROC-AUC results on the closed-vocabulary tag prediction task. TagGenome is the original baseline from MovieLens creators (Vig et al., 2012b), trained on multiple additional features and considered SOTA. Despite using fewer features, DocEnt matches TagGenome performance on AUC and outperforms it on precision (MAP).

TF-IDF scores for movie-tag pairs, based on tag frequencies in movie reviews.

BoS-BERT, as defined in Sec. 5.3, is fine-tuned to estimate sentence-to-tag relevance directly[18]. This setup is applicable to both open and closed vocabulary scenarios. During inference, a movie-tag prediction is obtained by averaging over sentence-wise predictions for the movie's reviews.

TagGenome—the original baseline from MovieLens team (Vig et al., 2012b). The comparison is not entirely apt as that model was trained on additional movie-tag relevance data and user ratings, albeit with a smaller corpus of unsupervised reviews. Also, TagGenome was trained on all of MovieLens (no holdouts).

Humans—to simulate human performance, apply cross-validation to ground truth user votes, treating one of the folds as a quasi-model.

All models were evaluated on the same holdout sets, with averaging.

Closed Vocabulary Tag Prediction In this scenario, evaluation is done on a holdout set of movies (with a smaller development set used for hyperparameter tuning; see Table 3 for details).

Results for ranking (MAP) and binary classification (AUC) metrics are shown in Table 4. Collectively, DocEnt models outperform the strong TagGenome baseline on tag ranking (see also Fig. 2 (a) and (b)) and match (or slightly outperform) it in binary classification. It is a strong result, considering that DocEnt had no access to additional features used by TagGenome and employed no feature engineering. Of the three models, DocEnt-Dual scores the lowest on all metrics, likely due to not optimizing for $P(Text \mid Entity)$ in pre-training. Finally, note that all models still score way below humans on the (harder) tag ranking task, indicating considerable headroom.

Model	MRR	Recall, %	
		@50	@100
Lucene (TF-IDF)	0.14	15.3	20.7
BoS-GloVe	0.04	4.1	6.6
BoS-BERT*	0.08	9.6	14.2
BoS-SentenceBert	0.07	7.6	11.7
DocEnt-Full	0.22	21.3	28.4
DocEnt-Dual	0.27	28.0	36.3
DocEnt-Hybrid	**0.31**	**31.9**	**40.9**

Table 5: Zero-shot results for DocEnt models vs several baselines on Reddit Movie Suggestions. MRR stands for Mean Reciprocal Rank.

Open Vocabulary Tag Prediction This task is evaluated by withholding parts of the tag vocabulary so that those tags are never seen in training (consult Table 3 for details). Fig. 2 (c) shows our models' performance on the binary classification task base on the fraction of the vocabulary seen by a model in fine-tuning. The graph shows that training with only 100 of the 1124 tags results in reasonable performance. Of our three models, DocEnt-Full starts below the others but adapts the fastest, reaching a near-closed vocabulary performance with less than 50% of the full tag vocabulary.

5.4.2 Reddit Movie Suggestions

Movie suggestion baselines Since this is a search task, we compare our models to an Apache Lucene[19] baseline, arguably the world's most widely used open-source search engine. For completeness, we also compare to BoS-BERT*[20], BoS-GloVe and BoS-SentenceBert, neural baselines defined in Sec. 5.3, whose query-movie relevance score is given by the maximum cosine similarity among the movie's review sentences[21].

Table 5 shows the Mean Reciprocal Rank (MRR) as well as recall, metrics that suit the noisy ground

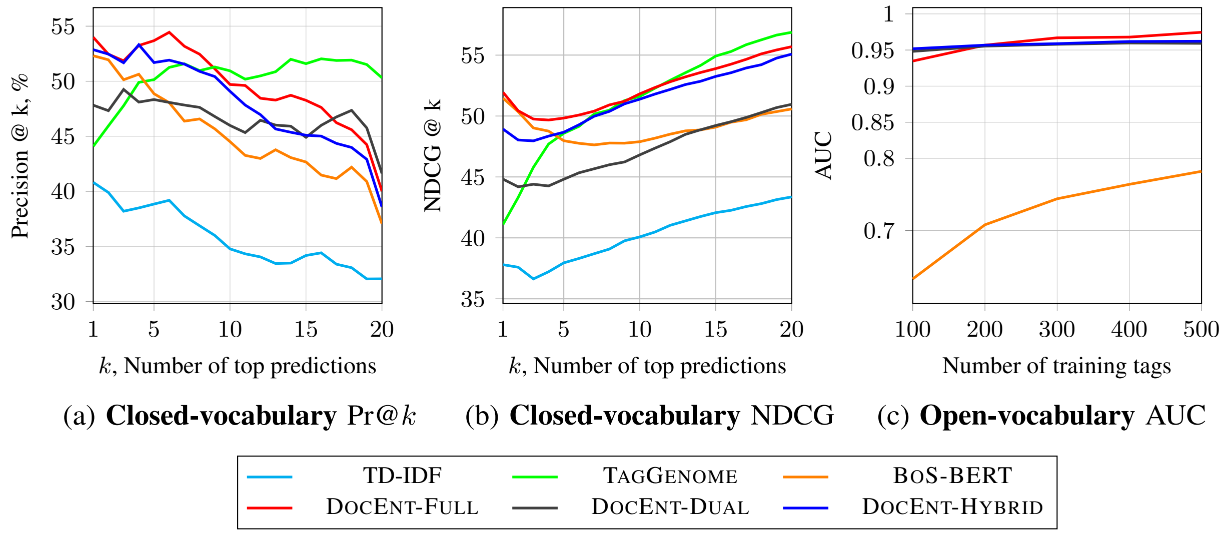
---

[18] We found it is best to encode a review sentence using BERT's *[CLS]* output, while tags are encoded by averaging individual tokens' output vectors.

[19] `https://lucene.apache.org/`

[20] In absence of a fine-tuned *[CLS]* output, this version of BoS-BERT encodes sentences by averaging their individual tokens' output vectors.

[21] In this case, we found that aggregating sentence-wise predictions with L^∞ norm is superior to averaging.



(a) **Closed-vocabulary** Pr@k (b) **Closed-vocabulary** NDCG (c) **Open-vocabulary** AUC

Figure 2: Performance on tag prediction tasks. Left and center: Precision and NDCG @k, with a closed vocabulary. DOCENT-FULL dominates the strong TAGGENOME baseline for smaller values of k, a concentration of gains typical for binary classification models. For perspective, human Precision@k ranges 80-95% for this task. Right: AUC for open vocabulary experiments, with models trained using a variable fraction of the tag vocabulary. DOCENT approaches close-vocabulary AUC after training with only 10-50% of the vocabulary (showing all baselines that were available to us in this setting).

truth (for completeness, see also the qualitative results in Table 2). DOCENT models outperform the Lucene baseline on all metrics, with DOCENT-HYBRID leading by a large margin. Compared to DOCENT-DUAL, its strong performance is not surprising since DOCENT-HYBRID optimizes both $P(Entity \mid Text)$ and $P(Text \mid Entity)$—a combination of tasks that helps avoid overfitting.

Also expected is the relatively weak performance of DOCENT-FULL. As discussed in Sec. 2, its high-capacity entity representations are prone to overfitting when the number of entities is relatively small. Still, this shortcoming can be remedied by fine-tuning, as evidenced by this model's superior results on tag prediction in Sec. 5.4.1. These results suggest that DOCENT-FULL may be a good choice in semi-supervised scenarios.

6 Related Work

Much of the prior art in text-based entity understanding is motivated by the *Entity Linking* (EL) problem: predict a unique entity from its mention in text, assuming a single right answer. By contrast, tasks like entity retrieval and tag prediction imply multiple valid matches and emphasize understanding entities through the prism of their attributes, expressed in natural language. Still, recent EL works propose dual encoder approaches similar to ours (Yamada et al., 2017; Ling et al., 2020; Cheng and Roth, 2013; Sun et al., 2015; Yamada et al., 2016; Chang et al., 2020; Kobayashi et al., 2016; He et al., 2013; Gupta et al., 2017), with Ling et al. (2020) already discussed in Section 2.1. Dual encoders have also been explored in zero-shot scenarios (Gillick et al., 2019; Logeswaran et al., 2019; Wu et al., 2019; Gupta et al., 2017), with entity embeddings computed dynamically based on metadata such as dictionary definitions, entity name and/or category. Others incorporate entity representations directly in the transformer by retrieving from an external memory (Févry et al., 2020; Peters et al., 2019). While clearly useful for EL, e.g., in sentences with multiple entity mentions, the benefits to our applications are unclear. Finally, there is ERNIE (Sun et al., 2019) – a language model trained with awareness of entity mentions. Alas, the lack of explicit entity representation limits its use in our tasks.

7 Conclusion & Future Work

This paper proposes a family of models to learn self-supervised entity representations from large document collections. We motivate these dedicated representations by contrasting them with naive text-as-a-proxy approaches, with clear gains on entity-centric tasks such as natural language search and movie tag prediction. We then show that achieving superior performance requires optimizing both $P(Entity \mid Text)$ and $P(Text \mid Entity)$—in contrast to the baseline RELIC model (and similar prior dual encoders) having only a single objective. To that end, we propose two novel models and study them in zero-shot, few-shot and supervised settings. We match or outperform competitive baselines, where available, with little or no fine-tuning.

Future Work As shown qualitatively in Sec. 3.3, DOCENT has the potential for being a hybrid approach to bridge entity retrieval and recommendation, an application worth exploring in depth (e.g., on the MovieLens Recommendation task which can be readily integrated with DOCENT thanks to *Reviews2Movielens*). A larger entity retrieval study with heterogeneous entity types is another useful direction. Lastly, extending DOCENT to additional entity understanding tasks such as QA and summarization is yet another promising avenue.

Acknowlegements

Abstract

Evidence plays a crucial role in any biomedical research narrative, providing justification for some claims and refutation for others. We seek to build models of scientific argument using information extraction methods from full-text papers. We present the capability of automatically extracting text fragments from primary research papers that describe the evidence presented in that paper's figures, which arguably provides the raw material of any scientific argument made within the paper. We apply richly contextualized deep representation learning pre-trained on biomedical domain corpus to the analysis of scientific discourse structures and the extraction of "evidence fragments" (i.e., the text in the results section describing data presented in a specified subfigure) from a set of biomedical experimental research articles. We first demonstrate our state-of-the-art scientific discourse tagger on two scientific discourse tagging datasets and its transferability to new datasets. We then show the benefit of leveraging scientific discourse tags for downstream tasks such as claim-extraction and evidence fragment detection. Our work demonstrates the potential of using evidence fragments derived from figure spans for improving the quality of scientific claims by cataloging, indexing and reusing evidence fragments as independent documents.

1 Introduction

Primary experimental articles (i.e., papers that describe original experimental work) provide the crucial raw material for all other subsequent scientific research. However, the drastically growing number of scientific literature makes it increasingly difficult for domain experts to efficiently utilize them. Automatic information extraction from biomedical literature is a crucial step to help researchers to achieve this goal.

Extracting important information from biomedical literature to facilitate and accelerate scientific discovery has been a goal for computational linguistics for some time (Hobbs, 2002), with the focus of identifying relevant entities, relations, and events from text to populate a knowledge base. However, these methods do not take into account the fact that scientific work involves attempting to provide explanations for evidence derived from experiments and is therefore driven principally by authors attempting to convince expert readers that their claims are the "correct" explanations for the experimental evidence. Thus, an important aspect of building machines capable of understanding scientific literature is first recognizing different *rhetorical components* of scientific discourse, with which we will then be able to distinguish the *observations* made in experiments from their *implications* and distinguish between *claims* supported by evidence and *hypotheses* put forward to prompt further research. It is this goal, of being able to distinguish between the different rhetorical components of scientific discourses so that we can build AI systems to facilitate more accurate analysis and understand-

ing of scientific literature, that motivates our work.

Scientific discourse tagging is a task that tags clauses or sentences in a scientific article with different rhetorical components of scientific discourses. Figure 1 shows an example of a paragraph with discourse tags. In this work, we leverage a state-of-the-art contextualized word embedding and a novel word-to-sentence attention mechanism to develop a model for scientific discourse tagging that achieves the state-of-the-art performances on two benchmark datasets SciDT (Dasigi et al., 2017) and PubMed-20k-RCT (Jin and Szolovits, 2018) by 6.9% and 2.3% absolute F1 respectively. [1] More importantly, we show the strong transferability of our scientific discourse tagger to new datasets by beating the baseline (Huang et al., 2020) via zero-shot prediction on CODA-19 dataset (Huang et al., 2020). Furthermore, we demonstrate the effectiveness of scientific discourse tagging on two downstream scientific literature understanding tasks: claim-extraction and evidence fragment detection, and demonstrate the benefit of leveraging scientific discourse tags information. In particular, we outperform the state-of-the-art claim extraction model (Achakulvisut et al., 2019) by 3.8% F1, and outperform figure span detection baseline (Burns et al., 2017) by 5% F1.

2 Background and Related Works

Problem Formulation. We define scientific discourse tagging as a task that labels sentences in a scientific article based on its rhetorical elements of scientific discourse. Formally, a paragraph can be represented as an ordered collection of sequences $\mathbf{S} = [S_1, S_2, ..., S_n]$, and each element S_i is annotated with a discourse label $L_i \in \{L_1, L_2, ..., L_k\}$. Note that S_i may be defined differently in different datasets – e.g., sentences in the PubMed-RCT dataset (Dernoncourt and Lee, 2017), clauses in the SciDT dataset composed by Burns et al. (2016) and Dasigi et al. (2017), and sentence fragments in CODA-19 dataset (Huang et al., 2020). For conciseness, we refer all these variations as *sentences*. The labels also can be slightly different. For example, in PubMed-RCT, $\mathbf{L} = \{$*objective*, *background*, *methods*, *results*, *conclusions*$\}$, in CODA-19 (Huang et al., 2020), $\mathbf{L} = \{$*background*, *purpose*, *method*, *finding/contribution*, *other*$\}$ while in SciDT dataset (Burns et al., 2016; Dasigi et al., 2017), the labels $\mathbf{L} = \{$*goal*, *fact*, *hypothesis*, *problem*, *method*, *result*, *implication*, *none*$\}$ as defined by De Waard and Maat (2012). Table 1 gives more details about the definitions of the tags.

2.1 Prior Works on Scientific Discourse Tagging

Feature-based Scientific Discourse Tagging. There has been a significant amount of work aimed at understanding types of scientific discourse. Teufel and Moens (1999) and Teufel and Moens (2002) described argumentative zoning, which groups sentences into a few rhetorical zones highlighted by important clauses such as "in this paper we develop a method for". Hirohata et al. (2008) used conditional random field (CRF) (Lafferty et al., 2001) with handcrafted features to classify sentences in abstracts into 4 categories: *objective, methods, results*, and *conclusions*. Liakata (2010) defined "zone of conceptualization" which classifies sentences into 11 categories in scientific papers and Liakata et al. (2012) used CRF and LibSVM to identify these "zone of conceptualization". Guo et al. (2010) used Naive Bayes and Support Vector Machine (SVM) (Cortes and Vapnik, 1995) to compare three schema: section names, argumentative zones and conceptual structure of documents. Burns et al. (2016) studied the problem of scientific discourse tagging, which identifies the discourse type of each clause in a biomedical experiment paragraph and composed a dataset for it. They adopted the discourse type taxonomy for biomedical papers proposed by De Waard and Maat (2012). The taxonomy contains eight types including *goal, fact, result, hypothesis, method, problem, implication* and *none* as Table 1 shows. Most recently,

---

[1] `https://github.com/jacklxc/ScientificDiscourseTagging`

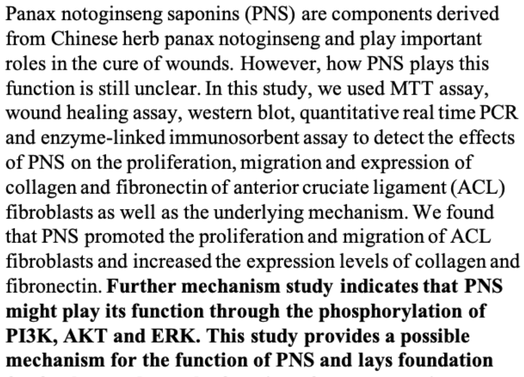
Cox et al. (2017) used the same schema (De Waard and Maat, 2012) by exploring a variety of methods for balancing classes before applying classification algorithms.

Deep Learning for Scientific Discourse Tagging. Due to the prevalence of deep learning, neural sequence labeling approach using bidirectional LSTM (Hochreiter and Schmidhuber, 1997) and CRF (BiLSTM-CRF) (Huang et al., 2015) has been prevailing for classic word-level sequence tagging problems such as named entity recognition (NER), part of speech tagging (POS), and word segmentation (Huang et al., 2015; Peng and Dredze, 2015, 2016; Ma and Hovy, 2016; Chiu and Nichols, 2016; Peng and Dredze, 2017; Wang et al., 2017; Huang et al., 2019). Since scientific discourse tagging, which is a sentence-level sequence tagging problem, has one additional dimension of input comparing to word-level sequence tagging problems, an encoder is required to encode word-level representations to clause/sentence-level representations. While one simple way is to pre-compute sentence embeddings from word embeddings (Arora et al., 2016), there are more sophisticated methods to compute sentence-level embeddings on-the-fly using BiLSTM (Jin and Szolovits, 2018; Srivastava et al., 2019) or attention (Dasigi et al., 2017), before feeding them into a clause/sentence-level sequence tagger. Alternatively, as BERT (Devlin et al., 2018) prevails among various natural language processing (NLP) tasks, a simple baseline method is to directly use a BERT-like model's (e.g. SciBERT (Beltagy et al., 2019)) prefix token ($[CLS]$) representation of each sentence as the sentence representation for classification task (Huang et al., 2020). In this work, we combine these methods to present a state-of-the-art scientific discourse tagger.

2.2 Downstream Applications

Claim Extraction.

Claim extraction has been extensively studied in various domains. In addition to scientific articles (Stab et al., 2014), previous work has analyzed social media (Dusmanu et al., 2017), news (Habernal et al., 2014; Sardianos et al., 2015) and Wikipedia (Thorne et al., 2018; Fréard et al., 2010) for a task called *Argumentation Mining* to extract claims and premises. However, there are less attention and dataset available in the biomedical domain. Achakulvisut et al. (2019) composed a claim-extraction dataset derived from MEDLINE [2] paper abstracts, and proposed a neural network model that significantly outperformed the rule-based method proposed by Sateli and Witte (2015). Figure 2 shows an example abstract with the last two sentences annotated as claims.



Panax notoginseng saponins (PNS) are components derived from Chinese herb panax notoginseng and play important roles in the cure of wounds. However, how PNS plays this function is still unclear. In this study, we used MTT assay, wound healing assay, western blot, quantitative real time PCR and enzyme-linked immunosorbent assay to detect the effects of PNS on the proliferation, migration and expression of collagen and fibronectin of anterior cruciate ligament (ACL) fibroblasts as well as the underlying mechanism. We found that PNS promoted the proliferation and migration of ACL fibroblasts and increased the expression levels of collagen and fibronectin. **Further mechanism study indicates that PNS might play its function through the phosphorylation of PI3K, AKT and ERK. This study provides a possible mechanism for the function of PNS and lays foundation for further study on the function of panax notoginseng.**

Figure 3: An example paragraph of evidence fragment detection. The explicit mention of subfigure codes are underlined. The red lines indicate the borders of the evidence fragments. For each clause, the discourse type as well as the BIO tags indicating "blocks" (see Section 3.2.2) are provided.

In this work, we formulate claim extraction (Achakulvisut et al., 2019) similarly as scientific discourse tagging: **S** contains sentences and $L_i \in \{0, 1\}$ indicates whether the corresponding sentence is a claim or not.

Evidence Fragment detection. Burns et al. (2017) coined the concept of "evidence fragments" as the text section in narrative surrounding a figure reference that directly describes the experimental

---

[2] https://www.nlm.nih.gov/bsd/medline.html

figure. They composed an evidence fragment detection dataset, and proposed the evidence fragment detection task that tags each clause with semantically referred subfigure codes. They further proposed a rule-based method of using these subfigure codes as anchors to link evidence fragments to European Bioinformatics Institute's INTACT (Orchard et al., 2013) data records. As a result, INTACT's preexisting, manually-curated structured interaction data can serve as a gold standard for machine reading experiments.

Burns et al. (2017) formulated the problem into a clause-level tagging problem. Formally, each clause S_i in a paragraph $\mathbf{S} = [S_1, S_2, ..., S_n]$ is annotated with a set of subfigure codes $f^i = \{f_1^i, f_2^i, ..., f_m^i\}$ that each clause is semantically referring to, where the length m can be any non-negative integer. Figure 3 shows an illustration of a paragraph of evidence fragment detection annotation. Each clause in the paragraph is associated with a set of semantically relevant subfigures.

3 Approaches

3.1 Scientific Discourse Tagger

Model Overview. We formulate scientific tagging as a sentence level sequence tagging problem. We develop a deep structured model extending Dasigi et al. (2017), which consists of a contextualized word embedding layer, an attention layer that summarizes word embeddings into sentence embeddings, and a BiLSTM-CRF sequence tagger (Huang et al., 2015) on top of the sentence embeddings for discourse type tagging. Figure 4 gives an overview of the architecture. We detail each component in this section.

Embeddings. We explore pre-trained BioGloVe embedding (Burns et al., 2019), BioBERT (Lee et al., 2019) and SciBERT (Beltagy et al., 2019) embedding, which are GloVe and BERT embeddings trained on the text in biomedical domain.

Sentence Representations via Attention. We observe that only keywords are essential to determine the discourse types, and attention is an appropriate mechanism for emphasizing certain inputs and ignoring others. Dasigi et al. (2017) also explored using an attention mechanism to summarize word representations to sentence representations, however, we propose a new variation of attention mechanism using an LSTM. Specifically, we first encode the sentence using an LSTM to get contextualized hidden vectors of each word h_i, and use them to learn attentions by introducing another trainable vector s of the same dimension of h_i. We then apply the attention to summarize the word embeddings into a clause embedding. Detailed equations are provided in section A.1. The dashed circle in Figure 4 illustrates our LSTM-Attention based clause encoder.

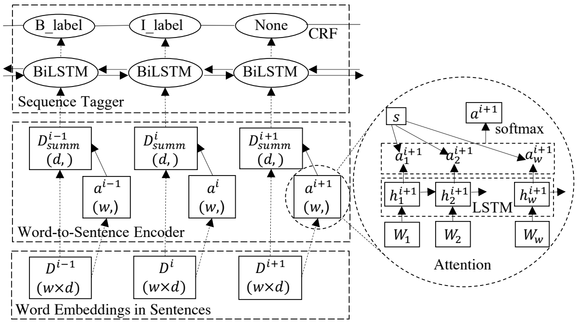

Figure 4: High-level overview of our scientific discourse tagger. Dashed arrows indicate we may apply dropout in those connections.

Sentence-level Sequence Tagging. We observe that the discourse labels have a clear transition of logic flow (e.g. *result* usually followed by *implication*, and *method* usually followed by *hypothesis*). Therefore, we extend LSTM sequence tagger used by Dasigi et al. (2017) to BiLSTM-CRF sequence tagger (Huang et al., 2015) to label discourse types for each sentence in a paragraph.

Labels in BIO Scheme. We use the BIO scheme (Sang and Veenstra, 1999) to train all of our models (Baseline models for SciDT dataset do not use BIO2 scheme). Specifically, we convert the labels into BIO scheme where *none* label represents *O* and all other labels are converted into *B_label* when the previous label type is different from the current label and *I_label* when the previous label is the same as the current label.

3.2 Downstream Applications

3.2.1 Claim Extractor

Due to the similar problem formulation of evidence extraction task (Achakulvisut et al., 2019), we directly employ the discourse tagging model for claim extraction.

3.2.2 Evidence Fragment Detector

Problem Reduction. As Figure 3 shows, since each clause in evidence fragment detection task may refer to more than one subfigure codes, we cannot directly solve it as a standard classification task. Instead, we reduce it to a clause-level sequence tagging problem under a block-based assumption. We treat each paragraph as a single input. During training, we encode the subfigure code reference sequences of the clauses in each paragraph into a single BIO (Sang and Veenstra, 1999) sequence (where *B* indicates the clause is the beginning of a block, *I* indicates the clause is in the same block as the previous clause, and *O* indicates that no subfigure code is being referred to) as demonstrated at the end of each clause in Figure 3. For prediction, we decode the semantic subfigure code references of all clauses from the BIO sequence for each paragraph following the same block-based assumption.

Block-Based Assumption. Most subfigure code reference labels are block-based. We call contiguous clauses that share the same subfigure code reference labels as a block, which is segmented by red lines in Figure 3. We further observe that most blocks explicitly mention all of the semantically referred subfigure codes at least once. Therefore, assuming this property is true for all blocks, we can reconstruct a sequence of semantic subfigure code references for all clauses in a paragraph. We use the explicitly mentioned subfigure codes for each block and a BIO sequence indicating where each block starts and ends for the reconstruction. Consequently, during encoding, we convert annotated semantically referenced subfigure code labels into BIO scheme. During decoding, we first localize the start and end position of each block using BIO predicted tags, then fill each block with all explicitly mentioned subfigure codes.

Clause-level Sequence Tagger. The key part of our sequence tagging-based solution for evidence fragment detection is to determine where a block starts and ends. We apply a clause-level sequence tagger to tag each clause in a paragraph. Due to the small size of the evidence fragment detection dataset, we empirically observe that feature-based CRF sequence taggers outperform neural-network based sequence taggers, we thus adopt the feature-based model. In addition to the scientific discourse tags, we use explicitly mentioned subfigure codes as well as unigram, bigram and trigram words as features. For each clause, we use all features described previously from the current clause in addition to the same sets of features from the adjacent previous and next clauses.

Figure 5: Count of each label in three datasets. The lines correspond to the mappings from SciDT dataset (Burns et al., 2016; Dasigi et al., 2017) and PubMed 20k RCT dataset (Dernoncourt and Lee, 2017) to CODA-19 dataset (Huang et al., 2020) for zero-shot predictions (Section 5.2).

4 Experimental Setup

We evaluate the performance of our scientific discourse tagger on PubMed-RCT dataset (Dernoncourt and Lee, 2017) and SciDT dataset (Burns et al., 2016; Dasigi et al., 2017) (Section 5.1). We also examine the transferablity of our scientific discourse tagger to new datasets using CODA-19 dataset (Huang et al., 2020) (Section 5.2). We further study the efficiency of scientific discourse tags on claim-extraction task via transfer learning as well as evidence fragment detection task in a pipeline fashion (Section 6).

4.1 Datasets

Figure 5 shows the distribution of the labels in the three datasets introduced below as well as their mappings used for zero-shot predictions in Section 5.2.

PubMed-RCT Dataset. We use PubMed-RCT (Dernoncourt and Lee, 2017) as the standard dataset to evaluate our scientific discourse tagger against other strong baselines. PubMed-RCT is derived from PubMed for sequential sentence classification. It has two versions – a smaller PubMed 20k RCT, and a 10 times larger PubMed 200k RCT. Due to our limited availability of computational resources, we only consider PubMed 20k RCT in this work. PubMed 20k RCT is a large dataset that consists of 20k abstracts of randomized controlled trials (RCTs), with vocabulary of 68k across 240k sentences. Each sentence of an abstract is labeled with one of the following roles (section heads) in the abstract: *background*, *objective*, *method*, *result* or *conclusion*.

SciDT Dataset. Similar to PubMed-RCT (Dernoncourt and Lee, 2017), SciDT dataset (Burns et al., 2016; Dasigi et al., 2017) is a clause-based dataset with more fine-grained taxonomy. We further expand SciDT dataset by applying the same clause parsing and annotation pipeline described by Dasigi et al. (2017). This dataset is derived from the Pathway Logic (Eker et al., 2002) and INTACT databases (Orchard et al., 2013). Texts from all sections of each of those papers were pre-processed by parsing each sentence to generate a sequence of main and subordinate clauses using Stanford Parser (Socher et al., 2013). Domain experts were asked to label each of the clauses using the 7-label taxonomy proposed by De Waard and Maat (2012) whose distributions are shown in Figure 5. We apply sequential methods to sequences of clauses in individual paragraphs.

Overall, SciDT dataset has a total of 634 paragraphs and 6124 clauses. We randomly split 570 paragraphs as the training and validation set and the rest as the test set. Each paragraph contains up to 30 clauses and the number of word per clause has a mean of 17.7 and a standard deviation of 12.5. The total vocabulary size is 8563, which is a small dataset for an NLP task. However, we note the difficulties of obtaining such dataset. We further perform a quality assessment of the dataset by re-annotating the test set. We obtain Cohen's kappa coefficient $\kappa = 0.823$, which indicates a high quality of the dataset.

CODA-19 Dataset. CODA-19 (Huang et al., 2020) is a human-annotated dataset on a subset of the abstracts of CORD-19 (Wang et al., 2020), which is a corpus of scholarly articles about COVID-19. Wang et al. (2020) segmented each abstract into sentence fragments by comma (,), semicolon (;), and period (.). Each sentence fragment is labeled with one of the research aspects: *background*, *purpose*, *method*, *finding/contribution* or *other*, which is similar to the label sets of PubMed-RCT (Dernoncourt and Lee, 2017). There are 10966 abstracts in total. We use this dataset to further examine our scientific discourse tagger architecture's applicability to new datasets as well as the transferability of our trained scientific discourse tagger to new datasets.

4.2 Baseline Models

PubMed-RCT Dataset. We compare our discourse tagger against two strong baselines on the PubMed 20k RCT dataset: (1) a hierarchical sequential labeling network (HSLN) proposed by Jin and Szolovits (2018) and (2) the state-of-the-art model (Srivastava et al., 2019) on this dataset. HSLN (Jin and Szolovits, 2018) used bio-word2vec (Moen and Ananiadou, 2013), a word2vec embedding (Mikolov et al., 2013) trained on corpora of Wikipedia, PubMed, and PMC, a convolutional neural network (CNN) (LeCun et al., 2015) (HSLN-CNN) or a BiLSTM (HSLN-RNN) as a sentence encoder, followed by a BiLSTM-CRF architecture (Huang et al., 2015) as a sentence-level sequence tagger. Srivastava et al. (2019) used a similar architecture: bio-word2vec (Moen and Ananiadou, 2013) as word embedding, BiLSTM layer with a special dilation mechanism and a capsule layer (Hinton et al., 2011) as the sentence encoder and BiLSTM-CRF (Huang et al., 2015) as the sentence-level sequence tagger.

Model		**RCT**	**SciDT**

Table 2: Scientific discourse tagging performance measured by test F1 score on PubMed 20k RCT and SciDT dataset.

SciDT Dataset. In addition to the model of Dasigi et al. (2017) trained on our expanded SciDT dataset, we also compare with feature based CRF and SVM with unigram, bigram and trigram words in the previous, current and next clauses as features.

CODA-19 Dataset. Huang et al. (2020) composed the CODA-19 dataset and studied a few baselines for scientific discourse tagging. Their best model is a fine-tuned SciBERT (Beltagy et al., 2019).

5 Experimental Results

5.1 Supervised Learning Results

Table 2 reports the test F1 score of our scientific discourse tagger and its variations against baseline models on PubMed 20k RCT dataset and SciDT dataset. Our best scientific discourse tagger outperforms the state-of-the-art model (Srivastava et al.,

2019) on PubMed 20k RCT dataset by more than 2 % absolute F1 score. Given the large size of PubMed 20k RCT, this result robustly demonstrates the strength of our model. Our model also significantly outperforms Dasigi et al. (2017) with 5% absolute F1 score (per McNemar's test, $p < 0.01$). Based on these performance, we claim our scientific discourse tagger as state-of-the-art. Note that for scientific discourse tagging, the micro F1 performance is equivalent to accuracy.

Ablation Studies. We also perform ablation studies to compare the effect of different word embeddings and attention mechanisms to the performance of our scientific discourse tagger on PubMed-RCT and SciDT dataset in Table 2. All neural network based models discussed for scientific discourse tagging tasks, including ours consist of a word embedding, a word-to-sentence encoder and a sentence-level sequence tagger. As we introduce in Section 3.1, our best model has SciBERT (Beltagy et al., 2019) as our contextualized word embedding, an LSTM-attention structure as our word-to-sentence encoder and BiLSTM-CRF (Huang et al., 2015) as our sentence sequence tagger. Comparing to other baseline models, we improve the model design by adopting the state-of-the-art BERT (Devlin et al., 2018) based language model as our contextualized embedding. Instead of bidirectional LSTM as word-to-sentence encoder used by Jin and Szolovits (2018) and Srivastava et al. (2019), we improve the attention structure proposed by Dasigi et al. (2017). We compare the effect of different embeddings and attention types used in scientific discourse tagger. As Table 2 indicates, our main improvement comes from SciBERT (Beltagy et al., 2019). In addition to BioBERT (Lee et al., 2019) which trains BERT (Devlin et al., 2018) on biomedical domain corpus, SciBERT uses a domain specific vocabulary. BERT as a contextualized embedding also contributes partially to the performance improvement as the BioBERT embedding globally outperforms BioGloVe (Burns et al., 2019), which is a static embedding trained on biomedical domain corpus, on PubMed-RCT dataset. Another source of improvement comes from the attention structure. Our LSTM-attention outperforms the RNN-attention that Dasigi et al. (2017) used.

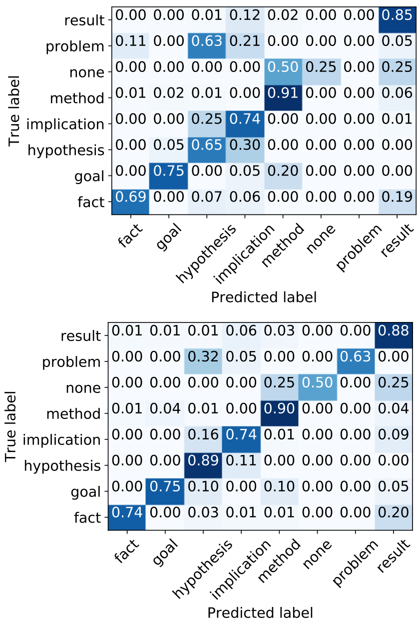

Figure 6: Confusion matrix on SciDT test data. Up: Dasigi et al. (2017). Down: Our scientific discourse tagger.

Error Analysis. Figure 6 compares the confusion matrices of Dasigi et al. (2017) and our best scientific discourse tagger on SciDT test set. As suggested by the overall performance, our model globally predicts the discourse tags more precisely than Dasigi et al. (2017). Specifically, Dasigi et al. (2017) failed to predict *problem* tag, but our model achieved 0.63 accuracy on predicting *problem* tag. Figure 6 also indicates the different difficulties of predicting different discourse labels due to the imbalance of the label distributions, as Table 5 shows.

5.2 Transfer Learning on CODA-19 Dataset

We further demonstrate the strong performance of our scientific discourse tagger by training it on CODA-19 dataset (Huang et al., 2020). As Table 3 shows, our model outperforms the baseline from Huang et al. (2020) by 14.6% absolute F1 on the test set.

More importantly, we use these results as baselines and CODA-19 dataset as an example dataset to show the transferability of our model to new datasets. We first perform zero-shot prediction using our best *trained* scientific discourse taggers on PubMed-RCT (Dernoncourt and Lee, 2017) or SciDT dataset (Dasigi et al., 2017). We map the labels from the original datasets to the target CODA-19 dataset by applying majority vote to the predicted labels on the training set as the lines in Figure 5 show. Then we perform predictions using the best trained scientific discourse taggers on CODA-19 test set and convert the predicted labels from the original label sets to the target CODA-

Model	Test F1
Huang et al. (2020)	0.749
Ours	**0.885**
Zero-shot Prediction from RCT	0.760
Zero-shot Prediction from SciDT	**0.761**
PubMed-RCT pre-train	**0.909**

Table 3: Transfer Learning Performance on CODA-19 Dataset.

Model	Test F1
Achakulvisut et al. (2019)	0.790
Ours (No pre-train)	0.791
Ours (PubMed-RCT pre-train)	**0.828**

Table 4: Claim extraction performance measured by binary F1 score, which regards 0 as negative label.

19 label set. As a result, as Table 3 shows, our zero-shot prediction results are even higher than the baseline from Huang et al. (2020) which was directly trained on the CODA-19 dataset. This result indicates the strong transferability of our trained scientific discourse tagger as a useful tool on new datasets.

Furthermore, we separately perform a standard transfer learning by taking the scientific discourse tagger pre-trained on PubMed-RCT dataset and fine-tuning it on CODA-19 dataset. We replace the last CRF layer with a new one to match the labels of CODA-19 dataset. As a result, we achieved 0.909 test F1, which is another 2.4% absolute F1 improvement on our model directly trained on CODA-19 dataset. This is likely due to the similar label structures between PubMed-RCT and CODA-19 dataset.

6 Downstream Applications

6.1 Claim Extraction

Dataset. Achakulvisut et al. (2019) introduced an expertly annotated dataset for extracting claim sentences from biomedical paper abstracts. They followed the definitions by Sateli and Witte (2015) to annotate a claim as a statement that either declares something is better, proposes something new, or describes a new finding or a causal relationship. Each sentence is tagged with a binary label indicating it is a claim or not. Each abstract may contain multiple claims as Figure 2 shows. The dataset contains 1500 abstracts sampled from MEDLINE database.

Baseline Model. Achakulvisut et al. (2019) constructed claim-extraction dataset and proposed a model using the sentence classification technique presented by Arora et al. (2016) as sentence encoding method, and the standard BiLSTM-CRF (Huang et al., 2015) as the sentence-level sequence tagger. Their best model was pre-trained on PubMed 200k RCT (Dernoncourt and Lee, 2017) for transfer learning and used GloVe (Pennington et al., 2014) as their word embedding.

Model Performance. Table 4 compares the test binary F1 performance of Achakulvisut et al. (2019) with our test performance. We first train our scientific discourse tagger model directly on the claim-extraction dataset. We obtain test binary F1 score of 0.791, which is already higher than Achakulvisut et al. (2019). Then as Achakulvisut et al. (2019) suggested, we pre-train the scientific discourse tagger on PubMed 20k RCT (Dernoncourt and Lee, 2017) and fine-tune it on the claim-extraction dataset. We replace the last CRF layer with a new one to match the binary label structure of claim-extraction dataset. As a result, we obtain test binary F1 score of 0.828, which is another 3.7% absolute F1 improvement on our model without transfer learning. This result demonstrates the benefit of transfer learning from scientific discourse tagging task to it's downstream-tasks.

6.2 Evidence Fragment Detection

Dataset. Burns et al. (2017) introduced evidence fragment detection dataset, which shares the same format and source of clause-based paragraphs with SciDT dataset (Dasigi et al., 2017). As Figure 3 shows, each clause was annotated with subfigure codes that it is semantically referring to. Each clause may not refer to any subfigure code, or simultaneously refer to multiple subfigure codes. The explicit mentions of the subfigure codes were also annotated. All paragraphs are from *Results* section of experimental papers, and most of the paragraphs are from a subset of SciDT dataset (Burns et al., 2016; Dasigi et al., 2017). We further expand evidence fragment detection training set by annotating extra *Results* section paragraphs from SciDT dataset. Overall this small dataset consists of 191 paragraphs as training data and 19 paragraphs as test data.

Baseline Model. Burns et al. (2017) proposed a rule-based method for evidence fragment detection task. The key steps are determining where each evidence fragment begins and ends based on the discourse tags of each clause. They treat *hypothe-*

Model	BIO F1	Test F1
Burns et al. (2017)	N/A	0.75
Ours (W/O Discourse Tags)	0.750	0.742
Ours (W/ Discourse Tags)	**0.821**	**0.807**

Table 5: Evidence fragment detection performance measured by micro F1 score. Our block-based decoding method achieves 0.94 F1 using ground truth BIO sequences.

sis, *problem* and *fact* as indicators of beginning of a evidence fragment, and *result* and *implication* as indicators of the end of a evidence fragment. They also used other features including section headings and whether the references to subfigures are entirely disjoint. Note that their document-level rule-based tagging is across multiple paragraphs in the *Results* section.

Model Performances. We use a feature-based CRF with block-based encoding-decoding method to solve this task as a sequence tagging problem. The decoding method described in Section 3.2.2 achieves 0.94 F1 score given the ground truth BIO sequences. Table 5 compares our feature-based CRF model performance with Burns et al. (2017) We also compare our feature-based CRF model performances trained with or without scientific discourse tags from SciDT dataset. Our feature-based CRF model without scientific discourse tags as inputs does not outperform Burns et al. (2017). However, by adding the scientific discourse tag as a feature, we obtain 5.7% absolute F1 improvement over Burns et al. (2017), reaching 0.807 test F1. This improvement is because of the improvement of the CRF sequence tagger. This result shows the strong benefit of scientific discourse tags as the upstream task of evidence fragment detection.

7 Discussion

We use the claim-extraction task and the evidence fragment detection task as two examples to demonstrate the benefit of leveraging pre-trained scientific discourse taggers and scientific discourse tags to improve the downstream-task performance via transfer learning or in a pipeline fashion. As Burns et al. (2017) proposed, given the output of evidence fragment detection system, we can link subfigure codes with INTACT (Orchard et al., 2013) records to obtain evidence fragments for each experimental figure.

We further suggest that the evidence fragment detection task can help biocurators delineate evidence fragments as independent documents so they can be cataloged, indexed, and reused. Traditionally scientists' arguments are based on relationships between claims and evidences within the same paper and possibly a limited number of cited papers. With the help of evidence fragments, we are able to discard the convention of only linking claims to evidence from a single paper or of following citations, which are often based on linking separate claims from different papers. As a future work, we can surface the evidence fragments combined with figures and captions across multiple papers. Clark et al. (2014) proposed the "Micropublications" semantic model, which is an abstract framework that integrates scientific argument and evidence from scientific documents. Our scientific discourse tagger, claim extractor and evidence fragment detector may serve as the actual implementation of the modules in such a framework. Ultimately, we hope to dramatically increase the amount of primary evidence used to generate individual claims and therefore improve the quality of those claims.

8 Conclusions

We develop a state-of-the-art model for scientific discourse tagging and demonstrate its strong performance on PubMed-RCT dataset (Dernoncourt and Lee, 2017) and SciDT dataset (Burns et al., 2016; Dasigi et al., 2017) as well as its strong transferability on new datasets such as CODA-19 dataset (Huang et al., 2020). We then demonstrate the benefit of leveraging the scientific discourse tags on downstream-tasks by providing claim-extraction task and evidence fragment detection task as two show cases. We further propose a future direction that scientific discourse tagging helps delineate evidence fragments as independent documents so they can be cataloged, indexed, and reused. As a result, we can dramatically increase the amount of primary evidence used to generate individual claims and therefore improve the quality of those claims.

A Appendices

A.1 Sentence Representations via Attention

Each of the word representations in the input tensor D is first reduced from d to d_2 dimensions. Then the word representations are projected from d_2 dimension to p dimension. For attention without context, p dimensional reduced word representations directly perform dot product with a p dimensional vector to obtain attention scores without using RNN. For attention with context, a simple RNN or LSTM with unit size h is used to compute attention scores. After obtaining the summarized matrix D_{summ}, we use bidirectional LSTM with hidden state of size H to tag the clauses.

LSTM-Attention We take the input tensors D of shape $c \times w \times d$ and output a matrix A of shape $c \times w$ which contains the attention weights of all the words in each clause or sentence. We first project each input word into a lower dimensional space using a projection matrix P of shape $d \times p$.

$$D_l = tanh(D \cdot P) \in \mathbb{R}^{c \times w \times d}$$

We score D_l with context that is summarized by an LSTM. Specifically, we score each word in the i^{th} clause in the context of other words in the same clause or sentence using an LSTM. The score for each word is a function of its p dimensional representation W_j and the previous words in the clause represented by the hidden states (h^i_{j-1}) in the LSTM cell. The equations are the following:

$$\begin{aligned} D^i_l &= D_l[i, :, :] \in \mathbb{R}^{w \times p} \\ W_j &= D^i_l[j, :] \in \mathbb{R}^p \\ h^i_j &= LSTM(W_j,\, h^i_{j-1}) \in \mathbb{R}^h \\ h^i &= [h^i_1\, h^i_2 \ldots h^i_w] \in \mathbb{R}^{w \times h} \\ a^i &= softmax(h^i \cdot s) \in \mathbb{R}^w \\ A &= [a^1\, a^2 \ldots a^i \ldots a^c] \in \mathbb{R}^{c \times w} \end{aligned}$$

where $LSTM$ is an LSTM cell with the unit size of h. s is a vector of length h.

Finally like Dasigi et al. (2017), a $c \times d$ shaped weighted sum D_{summ} of the input tensor D is computed, with the weights computed by the attention mechanism, then it is fed to a clause/sentence-level sequence tagger to tag discourse labels.

$$D_{summ}[i, :] = A[i, :] \cdot D[i, :, :] \in \mathbb{R}^d$$

Hyper-Parameter	Used

Batch size	10

Table 6: Optimal hyper-parameters of scientific discourse tagger model

A.2 Implementation and Training Details

The scientific discourse tagging model is implemented using Keras (Chollet et al., 2015) with Tensorflow (Abadi et al., 2015) backend. We use early stopping mechanism with toleration of 2 epochs. We schedule the training by training the model with a learning rate of lr for 20 epochs. We use Adam (Kingma and Ba, 2014) as our optimizer. The optimal hyper-parameters and the attempted range if applicable are listed in Table 6.

Abstract

The performance of natural language generation systems has improved substantially with modern neural networks. At test time they typically employ beam search to avoid locally optimal but globally suboptimal predictions. However, due to model errors, a larger beam size can lead to deteriorating performance according to the evaluation metric. For this reason, it is common to rerank the output of beam search, but this relies on beam search to produce a good set of hypotheses, which limits the potential gains. Other alternatives to beam search require changes to the training of the model, which restricts their applicability compared to beam search. This paper proposes incremental beam manipulation, i.e. reranking the hypotheses in the beam during decoding instead of only at the end. This way, hypotheses that are unlikely to lead to a good final output are discarded, and in their place hypotheses that would have been ignored will be considered instead. Applying incremental beam manipulation leads to an improvement of 1.93 and 5.82 BLEU points over vanilla beam search for the test sets of the E2E and WebNLG challenges respectively. The proposed method also outperformed a strong reranker by 1.04 BLEU points on the E2E challenge, while being on par with it on the WebNLG dataset.

1 Introduction

In natural language generation (NLG), the goal is to generate text representing structured information (e.g. a database record or a meaning representation) that is both fluent and contains the right information. Sequence-to-sequence models (seq2seq) have been effective on many tasks in NLG (for example: Wen et al., 2015; Dušek and Jurčíček, 2016). These systems first create an embedding for the input information. This embedding is used incrementally during decoding, generating one token at a time. Seq2seq models are generally decoded using beam search, to mitigate the effect of locally optimal but globally suboptimal decisions made by greedy search.

The performance of NLG systems can plateau or even decrease when beam sizes larger than 10 are used, which is counter-intuitive since larger beams produce more likely sequences according to the model. For example, Dušek and Jurčíček (2016) used a beam size of 10, and Asghar et al. (2017) found a size of 5 to be optimal. Decreasing performance has been found across a range of tasks including (Cohen and Beck, 2019). Moreover, it and was given by Koehn and Knowles (2017) as one of the six main challenges facing neural machine translation. To investigate this, Stahlberg and Byrne (2019) presented an exact search algorithm to find the most likely output according to a seq2seq model. However, this performed poorly compared to beam search, demonstrating that search errors (from beam search) can mask model errors (from the seq2seq model).

To mitigate the limitations of beam search, it is common practice to apply a reranker to the final set of hypotheses. This can be done by defining a reranking criterion (for example: Kumar and Byrne, 2004; Blain et al., 2017; Borgeaud and Emerson, 2020) or by training a reranker to predict the best hypothesis in a beam (for example: Dušek and Jurčíček, 2016; Agarwal et al., 2018). Training a reranker allows us to take into account information from outside the model and mitigate model errors. However, rerankers can only choose a hypothesis from the final beam, which limits their potential.

To quantify this, we trained the seq2seq model proposed by Dušek and Jurčíček (2016), and applied it to the E2E validation set (Novikova et al., 2017b). For each instance, we recorded the point at which

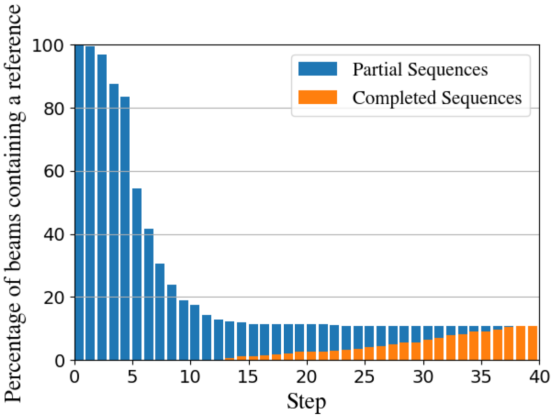

Figure 1: The percentage of beams which contain a reference (orange), or which could still lead to a reference (blue), using the model of Dušek and Jurčíček (2016) with beam size 3 on the E2E validation set.

all gold-standard references fell out of the beam, meaning that none of the partial hypotheses in the beam could be extended to a gold reference. A final beam containing at least one of the references would score optimally with an oracle reranker (providing an upper bound on performance). Figure 1 shows the results for beam size 3.[1] The final beam contained a reference in only 60 out of 547 cases (11%). For the remaining 89% of the cases, even an oracle reranker would be unable to give optimal results. The figure also shows that in over half of the cases, all references fell out in the first 6 steps. In contrast, references that were still in the beam at step 15 were almost certain to stay in the beam until the end. These observations suggest that an *early* manipulation of the beam has a strong potential to improve performance.

In this paper, we propose a method for manipulating which items are pruned from the beam at each stage of decoding. We then present evidence that this is a successful approach: it led to an improvement of 1.93, and 5.82 BLEU points over vanilla beam search on the E2E and WebNLG challenges, respectively. When comparing to a strong reranker, the performance of incremental beam manipulation was similar on the WebNLG dataset, whilst increasing the performance on the E2E challenge by 1.04 points. We also applied beam manipulation on top of length normalisation (Murray and Chiang, 2018), and incremental beam manipulation was able to improve its performance.

2 Related Work

This paper is far from the first to try to improve beam search for natural language generation.

One modification is to use a variable beam size instead of a fixed one (Freitag and Al-Onaizan, 2017). However, this can only improve decoding speed, as the ranking of the hypotheses in the beam remains unchanged, and thus model errors are exposed by the reduction of search errors.

Length normalisation (Murray and Chiang, 2018) is widely used strategy that often improves the performance of a beam search decoder, by mitigating the fact that seq2seq models are biased towards generating shorter sequences. Rather than directly using model probabilities to order the hypotheses in the beam, each probability is normalised according to the length of the hypothesis, so that shorter hypotheses are penalised. However, this only has an impact once the hypotheses within the beam have different lengths. This only occurs towards the end of the decoding process, and we showed in the previous section that the reference hypotheses often fall out of the beam relatively early. Furthermore, Stahlberg and Byrne (2019) showed that the biases causing the deteriorating model performance are more complex than a simple length bias.

Wiseman and Rush (2016) modified the training procedure for seq2seq models. They ran beam search and introduced a loss each time the gold standard sequence fell out of the beam. Goyal et al. (2018) and Collobert et al. (2019) also modified the training procedure. They added a term to the loss function that approximated the loss that the model would receive when generating using a beam search method for each example in the training set. However, one of the reasons that beam search has been so widely used is that it can be applied on top of a language model without changing the training procedure, and this is lost with these approaches.

Gu et al. (2017) manipulated the hidden state of the language model at each step of the decoding. This was achieved via a multi-output regressor that produced a vector that is added to the hidden state used in decoding. The regressor was trained via reinforcement learning, and the training signal was gathered by injecting unstructured noise to the hidden state. Chen et al. (2018) also manipulate the hidden state. For each training instance, they apply beam search and take the hypothesis with the

---

[1] For larger beam sizes, the same general trends were observed. See Appendix A for beam size 10.

highest BLEU score. The manipulator network is trained to encourage a greedy decoder to produce this output. Both of these approaches rely on inferring a better hidden state to be used in the decoding, which is not straightforward to define. We instead manipulate the hypotheses in the beam directly.

Finally, Negrinho et al. (2018) presented a framework for learning a beam search framework via imitation learning. This resulted in a beam aware algorithm which was proved to have no regret guarantees. While this paper makes a compelling argument for this method in theory, putting it into practice requires a number of further engineering decisions. Our work can be seen as a way of applying this general framework using a simple and computationally efficient roll-out strategy.

3 Incremental Beam Manipulation

In order to describe our method for incremental beam search, we first introduce terminology to describe a standard beam search decoder. The decoder produces a sequence iteratively, token by token. At each iteration it performs 3 actions: expand, rank and prune. The expand step generates all possible next step hypotheses. The rank step orders these hypotheses from most likely to least likely. The pruning step then removes the hypotheses that are near the end of this order.

This formulation of the beam search algorithm enables us to view beam manipulation as a ranking problem since expand is determined by the (fixed) decoder and the size of the beam chosen determines the pruning. The rank step determines which hypotheses will not be kept in the next iteration and hence discarded. By modifying the ranking method used, we can choose the partial hypotheses expanded during beam search, taking into account the current state of the beam as well as signals beyond model scores.

It is worth noting that while this paper applies beam manipulation on top of a seq2seq model, the techniques used could be applied without change to any conditional or unconditional neural language model that can be decoded using beam search.

3.1 Ranking via Roll-out

Partial hypotheses are more difficult to rank than complete hypotheses since the rest of the generated text is unknown. For example, consider the following partial hypotheses:

> Loch Fyne is a restaurant located...
>
> There is a family friendly...

Both of these convey some information about a family-friendly restaurant named ‘Loch Fyne’. It is hard to know which partial sequence will lead to a better complete sentence, which is what we would like a ranker to tell us. Existing rerankers often rely on detecting missing information, but some information may still be to come for partial hypotheses.

What we need is a way to rank partial hypotheses based on how the seq2seq model is likely to complete them. We propose ranking partial hypotheses based on a *greedy roll-out*. This is a computationally efficient approximation of how the seq2seq model might complete the partial hypothesis.

In the existing literature, roll-outs are generally used at training time (Chang et al., 2015), for the situation where the model's subsequent decisions influence the loss function for an individual decision. The roll-outs are used to produce an approximation to the final sequence that would be reached if the original action was taken. This enables a value for the loss of the original decision to be predicted.

On the other hand, incremental beam manipulation aims to predict which partial hypotheses will lead to good completed sequences. Similar to traditional roll-outs, this is impacted by the generating model's subsequent decisions. In this case, the difference is that roll-outs are used to provide features in addition to obtaining training signal. It is also worth noting that for incremental beam manipulation we use roll-outs at test time as well as at training time.

Beam manipulation can be applied after any step in the beam search decoding. Figure 2 illustrates a single manipulation. The roll-outs are used to produce approximations to the completed hypotheses that would be produced if the partial hypothesis remained in the beam. These completed sequences are then ranked to define an order of the partial sequences. Since this may result in different hypotheses remaining in the beam, the area of the search space considered during the decoding has been manipulated.

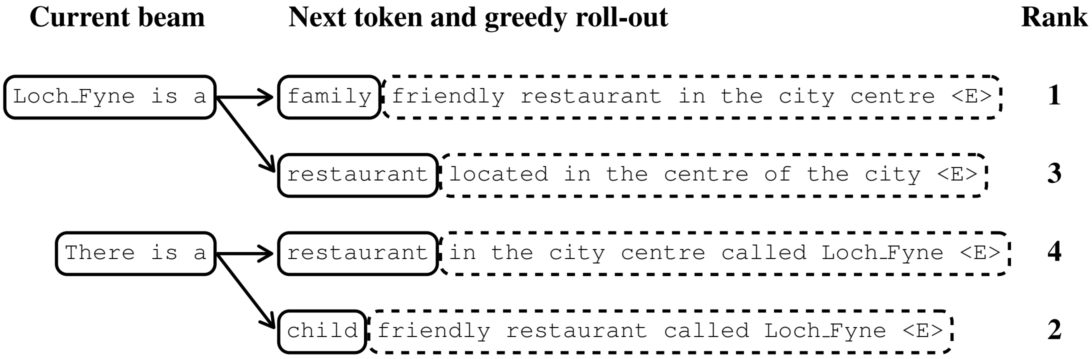

Figure 2: Incremental beam manipulation, for a beam size of 2, when generating the 4th token. Each element of the beam is expanded, and each partial hypothesis is greedily rolled out to a complete hypothesis. The complete hypotheses are ranked and then pruned. The partial hypotheses are then used in the next step of beam search.

3.2 Reranker Architecture

Incremental beam manipulation requires a method to rank completed hypotheses. There are many existing rerankers designed for this task, such as the TGEN reranker (Dušek and Jurčíček, 2016). However, these rerankers are unlikely to be effective when used in incremental beam manipulation. In the latter, the partial hypotheses need to be ranked according to their potential to produce good completed hypotheses. This is a related but different task to that of a traditional reranker that aims to identify the hypotheses that will score best against some metric such as BLEU score. Rerankers of completed hypotheses typically rely on input information missing from the output as the signal; however, this is not necessarily useful when reranking partial hypotheses. For example, it is more useful to identify partial hypotheses which are indicative of model failure at an early stage of decoding.

To rank the partial hypotheses via roll-outs as introduced in the previous section, we explored two commonly used techniques in the field of information retrieval: pointwise ranking and pairwise ranking (Liu, 2009). Pointwise approaches predict a numerical value for each item, and the items are ordered by sorting them according to this value. Pairwise approaches, given a pair of hypotheses, output which of them would rank more highly, and techniques such as the Copeland method (Saari and Merlin, 1996) are then used to produce a total ordering from these pairwise comparisons. In preliminary experiments, the pointwise approach outperformed the pairwise approach. These results are summarised in Appendix B. For the remainder of this paper, we will focus on the pointwise approach.

The inputs to the reranker were:

- The meaning representation (i.e. the structured information input for NLG). This was passed as a sequence.
- The generated text produced by the roll-out of the partial hypothesis. This was passed as a sequence surrounded by the start token `<S>` and end token `<E>`.
- The rank, according to the seq2seq model probability, of the completed sequence in the beam. Since this was a categorical variable, it was passed as a one-hot vector.

The architecture of the reranker is summarised in Figure 3. This model is used to assign a value to each hypothesis individually. The meaning representation and the rolled-out text are each passed through an LSTM,[2] and then all inputs are concatenated and passed through two fully connected layers.

At inference time the reranker is used to identify poorly performing hypotheses so that these can be pruned. This enabled the task of the reranker to be simplified to distinguishing between those hypotheses near the bottom of the beam from the hypotheses in the rest of the beam. Therefore, we used the reranker's scores to split the hypotheses into two groups: those with scores in the bottom quartile

---

[2] For efficient batching, it is common practice to add padding tokens to make sequences the same length. We prepended padding tokens rather than appending them, as this led to better performance in preliminary experiments. This is presumably because prepended tokens have a smaller impact on the final hidden state.

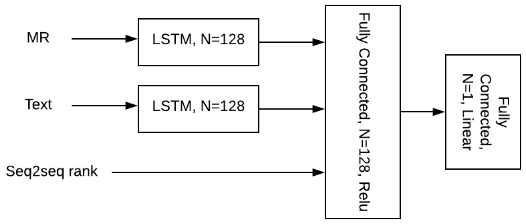

Figure 3: Architecture of the reranker. N is the number of hidden units for the LSTMs and the number of output nodes for the fully connected layers. For the fully connected layers, the activation function is shown.

and those with scores in the top three quartiles. The hypotheses within each group were ordered by the seq2seq model's probability.

In preliminary experiments, we also tried using the reranker to provide a total ordering. However, using it to provide a coarse partial ordering (as described above) gave more promising results.

3.3 Training the Reranker

We trained the reranker on completed hypotheses that were ranked from best to worst. The sequences were produced by generating text sequences using the seq2seq model. A beam search decoding, with a large beam size, was applied to each instance in the training set. [3] The set of hypotheses present in the final beam of the search was ranked from best to worst and recorded.

The notion of the best hypothesis was simplified to the one that received the highest BLEU score (Papineni et al., 2002) against the manually written references. BLEU was chosen due to its wide adoption as an automatic evaluation measure, but any automatic metric could have been used in its place.

As discussed at the end of the previous section, we need the reranker to distinguish between hypotheses that should be pruned from those that should be kept. Furthermore, for the purpose of reranking, only relative differences in BLEU score matter, not absolute values. Therefore, when generating training data, hypotheses in the bottom section of the beam (according to BLEU) were assigned the target value -1, and the rest were assigned the target value 1.

Similarly, it is only the differences in the reranker's scores that matter, and not the absolute values. Therefore, after applying the reranker to each hypothesis in a beam, we normalise the scores to have a mean of 0.

Using the normalised BLEU scores (-1 or 1) and normalised reranker scores (with a mean of 0), we use relative mean absolute error (RMAE) as the training objective, as shown in Equation (1), where b is the set of hypotheses in the beam, x is a hypothesis, $\hat{x}_{\text{ranker}}$ is the normalised score predicted by the reranker, and x_{BLEU} is the normalised target derived from the BLEU score ordering of the beam.

$$\text{RMAE}(b) = \sum_{x \in b} |\hat{x}_{\text{ranker}} - \hat{x}_{\text{BLEU}}| \qquad (1)$$

Several other relative loss functions have been shown to be successful in other situations (Zhang et al., 2019). In preliminary experiments, we evaluated a number of these including log cosh error and mean square error, but they did not outperform RMAE.

3.4 Choosing when to Manipulate

In theory, it would be desirable to manipulate the beam at every step of hypothesis generation, but in practice, the difficulty of ranking partial hypotheses could limit its benefits. While manipulating the beam can avoid certain model errors, it might also introduce other errors, either from the greedy roll-out strategy or the reranker. Reranking at every step may compound such errors. Empirically, we found it was more effective to apply beam manipulation to some rather than all steps.

Choosing when to manipulate is thus an important decision. It is advisable to avoid manipulating the beam too early: not only it is harder to rank hypotheses with very few tokens, but it is also less likely to be beneficial. As shown in Figure 1, in the first few steps even a relatively small beam size can keep hypotheses that could lead to the reference outputs. On the other hand, it is also advisable not to manipulate too late: once hypotheses have fallen out of the beam, they cannot be put back in. As the optimal choice of when to manipulate the beam is dependent on the dataset and the model,

---

[3] In preliminary experiments, we held back a portion of the training set from the seq2seq model's training phase, so that the beam manipulation ranker was trained on outputs that the seq2seq model had not seen. However, the system was unable to recover from the lower performance of the seq2seq model.

we treat this as a hyperparameter to be tuned on the validation set.

4 Experiments

In this section we will present results on the E2E (Novikova et al., 2017b) and WebNLG challenges (Gardent et al., 2017). We evaluate the systems using the BLEU implementation used in the original E2E challenge.[4] For all the experiments reported we use the seq2seq architecture from Dušek and Jurčíček (2016) for the underlying model that we are trying to manipulate.[5]

It is well-known that BLEU is not a completely reliable method for predicting human perceptions of the quality of individual NLG outputs (for example: Callison-Burch et al., 2006; Novikova et al., 2017a). However, in this case, we are comparing outputs from variants of the same system, and thus BLEU is more likely to provide reasonable estimates of their felicity to the references, as argued by both Callison-Burch et al. and Novikova et al..

To support the idea behind our approach, i.e. manipulating the beam during decoding instead of only at the end, we compare against existing rerankers applied to the beam at the end of decoding. These include the TGEN reranker, proposed by Dušek and Jurčíček (2016), that has achieved state-of-the-art BLEU scores on NLG tasks, as well as the same reranker architecture defined in Section 3.2. Both architectures are trained to perform reranking of the final beam only. When comparing between these two methods of reranking the final beam, no significant difference in performance was found. In this section, we report results for the architecture defined in Section 3.2. For completeness, results for both rerankers are included in Appendix C.

By using the same architecture both for the final-beam reranker and for beam manipulation, we can be more confident that any difference in results is due to the beam manipulation strategy (reranking during decoding, not just at the end).

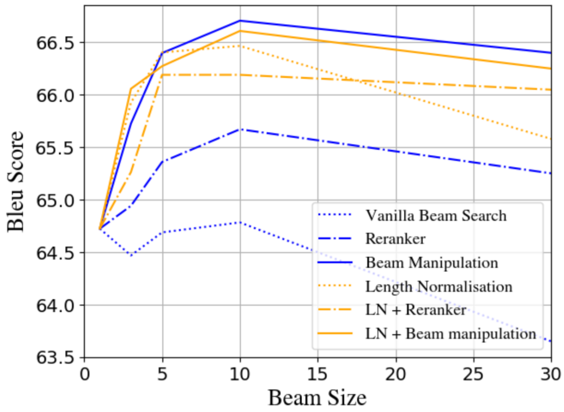

Figure 4: Results on the test set of the E2E challenge. LN = Length Normalisation.

In our experiments, we also consider length normalisation (Murray and Chiang, 2018), which is a well-known technique that often increases the BLEU score of the resulting sequences since it addresses the bias of language models to favour short sequences, as discussed in Section 2. Although the values assigned to a sequence when using length normalisation are no longer probabilities, it still performs the expand, rank and prune steps at each iteration of the decoding. Hence, we can apply beam manipulation in tandem with length normalisation. Finally, we also considered nucleus sampling (Holtzman et al., 2020) as a baseline. However, it was found to decrease performance even when compared to vanilla beam search.

In what follows, we will not only comment on test results when the beam size is tuned on the validation sets, but we will also comment on test results across all beam sizes. The reason for doing this is that considering all beam sizes assesses whether the technique is robust to changes in beam size. In our opinion, this makes for a more convincing result then just indicating a difference in performance at a single beam size. This is especially pertinent since a well-documented issue of beam search is that larger beam sizes can lead to deteriorating performance. The results table in Appendix C indicates the validation set's optimal beam size for each of the systems.

4.1 E2E BLEU Results

Figure 4 indicates the results on the E2E test set. The first thing to note is that increasing the beam size did not lead to any considerable gain in performance for the vanilla beam search strategy. For all beam sizes except 10, the performance is worse than greedy decoding, while using a beam size of 10 only increased performance by 0.06 points.

---

[4] `https://github.com/tuetschek/e2e-metrics`

[5] The source code for this paper is at `https://github.com/jamesHargreaves12/incremental_beam_manipulation`

Compared to vanilla beam search, reranking was an effective strategy, increasing the performance at all beam sizes. Similarly, applying incremental beam manipulation was able to outperform both methods at all beam sizes. Using the validation set to tune the beam size, the BLEU scores are 0.89 and 1.93 BLEU points higher for the reranker and incremental beam manipulation, respectively. The difference in BLEU scores between incremental beam manipulation and reranker methods was found to be significant (using a permutation test with significance level 0.01).

Length normalisation was the strongest baseline increasing the BLEU score of vanilla by 1.69 points. Adding the reranker on top of length normalisation decreases performance for all beam sizes less than 30. The strong performance of length normalisation is likely due to the fact that the E2E test set contained longer, and more complex inputs (and hence references) than the training and validation set (Dušek et al., 2020). Nevertheless, applying incremental beam manipulation on top of length normalisation was able to increase the BLEU score for all beam sizes except 5.

It is worth pointing out that while incremental beam manipulation improved both vanilla beam search and length normalisation, the overall BLEU score for the combination with the latter was lower for all sizes other than size 3. This is surprising considering that vanilla beam search performed worse than length normalisation when not combined with incremental beam manipulation. This could be due to the fact that the greedy roll-out approximation is less accurate for length normalisation than vanilla beam search since length normalisation only has an impact once some items in the beam have been completed.

4.2 WebNLG BLEU results

Figure 5 indicates the results on the WebNLG test set. As in the results for E2E, we can see that increasing the beam size of vanilla beam search was not an effective way to increase BLEU score. A greedy decode outperformed it at all beam sizes. Reranking the final beam was more effective, increasing the BLEU score by 5.83 points. Applying incremental beam manipulation had a very similar performance to reranking, increasing the performance at beam sizes 3 and 10 but reducing it at size 5.

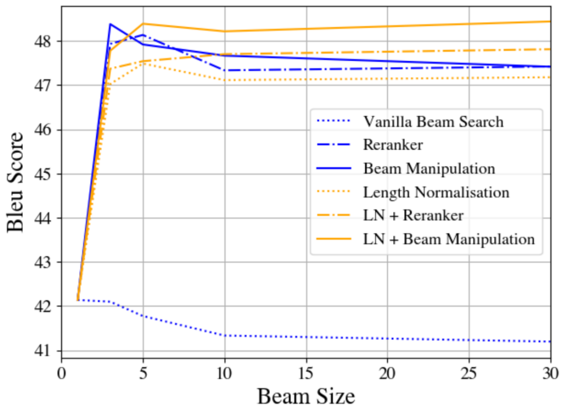

Figure 5: Results on the test set of the WebNLG challenge. LN = Length Normalisation.

The length normalisation baseline improved upon the vanilla baseline, increasing the BLEU score by 5.01 points. Reranking the final beam of the length normalised beam search was more effective on the WebNLG dataset than the E2E dataset; applying the reranker outperformed length normalisation at every beam size. Focusing on the beam sizes that performed optimally on the validation set, the BLEU score on the test set was increased by 0.43 points. Applying incremental beam manipulation on top of length normalisation received a yet higher BLEU score than reranked length normalisation for all beam sizes. Increasing the BLEU score by 1.33 points compared to the length normalisation. The improvement in BLEU scores achieved by applying incremental beam manipulation to the length normalised beam search was found to be significant when compared to length normalisation (with or without final beam reranking).

Unlike the E2E dataset, beam manipulation had higher performance when applied on top of length normalisation rather than vanilla beam search, outperforming it for all beam sizes except 3. The BLEU score was 0.52 points higher when taking the values at the beam sizes with the highest performances on the validation set.

4.3 Fallout with Beam Manipulation

In Section 1, we explained that references often fall out a beam relatively early during decoding, and reported results on the E2E task. We repeated the same experiment for when applying incremental beam manipulation. A beam size of 3 was used so that the results could be directly compared to those for vanilla beam search in Figure 1.

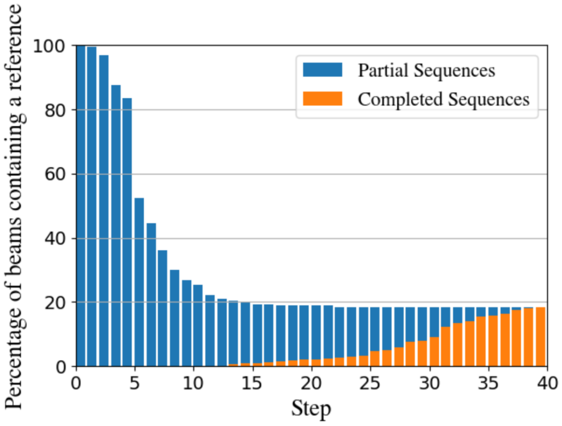

Figure 6: The percentage of beams which contain a reference (orange), or which could still lead to a reference (blue), using Incremental Beam Manipulation with beam size 3 on the E2E validation set. This improves on vanilla beam search, shown in Fig. 1.

The results are shown in Figure 6. The graph indicates that beam manipulation indeed ameliorates this issue. The final beam contains a (correct) reference in 100/547 cases (approx 18%), a large increase from the 60 of vanilla beam search. This is mainly due to reducing the number of references that fall out in steps 5 to 15, which is consistent with the fact that we are manipulating at steps 5, 10, 15 and 20. We also observed that most of the retention gain is due to earlier manipulation steps.

4.4 Human Evaluation

To further investigate the differences between the systems, we conducted a human evaluation comparing the incremental beam manipulation system's output against the output of the strongest baseline on the E2E dataset – length normalisation.

The human evaluation was performed by the second and third authors of the paper. While the annotators had been involved in the design of the system, they had not seen textual outputs from the system prior to the annotation. The outputs were presented in a random order, without indicating which output came from which system. The systems were compared in terms of both fluency and adequacy.

For fluency, each annotator compared the system outputs for the same meaning representation input (without seeing it) and indicated their preference. Both annotators annotated 50 examples from the E2E test set.

Little difference between the outputs was found. The systems were labelled as equally fluent in 76% of cases (incremental beam manipulation was preferred in 12% of all cases).

To judge the adequacy of the generations, human raters were presented with the meaning representation input and the text generated by a system. They were asked to label any hallucinations and any repetitions. They were asked to ignore missing information as the human references that the system had been trained on contained frequent examples of missing information (Dušek et al., 2020), so for this dataset, missing information is better seen as content selection. Between the annotators, a combined total of 524 examples were labelled for both for hallucination and repetition.

Once again, the results were not conclusive in support of either system, with no statistically significant difference between them. The overall performance was very high: for 95% of the inputs, both systems exhibited no signs of hallucination or repetition. This error analysis did, however, highlight that some errors are repeated multiple times, almost word for word. For example, all 5 cases of repetition for the incremental beam manipulation system had the following form: "There is a pub called X located near Y. It is a pub."

It is worth re-iterating that the system was optimised for BLEU, and not fluency or adequacy. The fact that an improvement in BLEU has not led to an improvement in a human evaluation suggests that BLEU may not be an accurate enough metric for this task, even when comparing similar systems. Therefore, BLEU may be even more limited in usefulness than Callison-Burch et al. (2006) and Novikova et al. (2017a) suggested.

4.5 Example outputs

We now present a couple of examples where manipulating the beam during decoding led to an improvement in the quality of the output. These were selected from the set of examples for which the output of the beam manipulator was preferred by the human annotators in terms of adequacy. The examples are given in Figure 7.

In the first example, we can see that length normalisation leads to a repetition of the fact that The Cricketers had an 'average customer rating', showing the downsides of a technique that just favours longer outputs. Neither the output from the beam

Input: name = The Cricketers | eat type = restaurant | food = English | price range = cheap | rating = average | area = city centre | family friendly = yes | near = Café Rouge
BM: The Cricketers serves cheap English food in the city centre near Café Rouge. It has an average customer rating and is family-friendly. **LN:** The Cricketers is a cheap, family-friendly, English restaurant with an average customer rating. It is located in the city centre near Café Rouge and has an average customer rating. **RR:** The Cricketers is a cheap, family-friendly restaurant located in city centre near Café Rouge.

Input: name = The Phoenix | eat type = pub | food = French | price range = £20-25 | rating = 3 out of 5 | area = riverside | family friendly = no | near = Café Sicilia
BM: The Phoenix is a French restaurant in riverside near Café Sicilia. It has a moderate price range and a customer rating of 3 out of 5. It is not kid friendly. **LN:** The Phoenix is a restaurant providing French food in the £20-25 price range. It is located in the riverside. It is near Café Sicilia. Its customer rating is 5 out of 5. **RR:** The Phoenix is a restaurant providing French food in the £20-25 price range. It is located in the riverside. It is near Café Sicilia. Its customer rating is high.

Figure 7: Example outputs for different systems. BM = Incremental beam manipulation system, LN = Vanilla beam search with length normalisation, RR = Vanilla beam search with reranking applied to the final beam.

manipulator nor the reranked approach contain repetitions, although we can see that more of the input information is realised in the case of the beam manipulator.

The second example contains a hallucination for both the length normalised and reranked systems – the input clearly states that the customer rating was '3 out of 5'. In contrast, whereas these systems claim that it was '5 out of 5' and 'high' respectively. The beam manipulation system avoided this issue.

5 Conclusions

Rerankers are commonly used to increase the performance of NLG systems decoded by beam search, by modifying which hypothesis from the final beam is chosen. This means that rerankers are dependent on good hypotheses reaching the final beam. However, this is often not the case; on the validation set of E2E challenge, only 11% of references were present in the final beam when the seq2seq model from (Dušek and Jurčíček, 2016) was decoded with a beam size of 3.

To address this limitation, we proposed incremental beam manipulation, which modifies the ranking of partial hypotheses within the beam at intermediate steps of the decoding, and hence chooses which are pruned. We evaluated this method on both the E2E and WebNLG challenges. The results showed that applying beam manipulation, instead of a reranker, was able to increase the BLEU score by 1.04 on the E2E challenge. We further showed that incremental beam manipulation was able to increase performance when applied on top of length normalisation.

The optimal reranker for incremental beam manipulation may differ at each step of generation (for example, token 5 vs. token 20). In future work, we intend to refine our method further by conditioning the reranker on how far through the beam search we are.

A Fallout experiment with larger beam size

Figure 1 indicates the step at which the reference sentences drop out of the beam (for a beam size of 3). Figure 8 indicates the same results for a larger beam size of 10.

The figure indicates that the number of references that were contained in the final beam was higher for a beam size 10. For the early iterations of the decoding the number of references that fell out of the beam was far lower for a beam size of 10. A larger beam size meant that the beam contained more hypotheses and so has more chances to match against a reference.

However the shape of the graphs is very similar. The majority of references that fell out did so relatively early in the process. 54% of references fell out by step 7, increasing to 79% by step 9. At step 21 the final last reference fell out of the beam despite the fact that the beam contained partially references up to step 40.

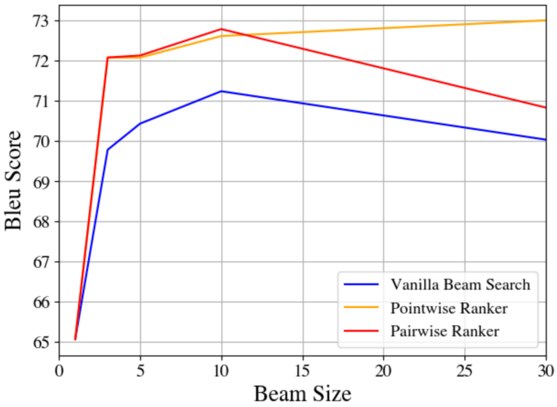

Figure 9: Comparison between the performance of the pointwise and pairwise rankers when used as rerankers on the E2E validation set.

B Pointwise vs Pairwise rerankers

This paper required a method of ranking completed hypotheses from worst to best. During preliminary experiments we implemented rerankers based on the Pairwise and Pointwise strategies from the Information Retrieval field. See Section 3.2 for more details.

To evaluate the performance of the different rankers we applied each of the rankers as a reranker of the final beam of a vanilla beam search over the E2E validation set. The BLEU scores for each of the rerankers were calculated for each beam size. The results are shown in Figure 9.

We can see that there was very little difference in performance for the two methods of reranking for the beam sizes up to 10. However, for beam size 30 the pointwise reranker significantly outperforms the pairwise reranker. The larger the beam size the greater the number of hypotheses that the reranker can pick as top and hence the greater the impact of the reranker.

The pointwise reranker requires O(k) runs of the reranker to produce a total ordering. On the other hand the Copeland method to produce a total ordering from the pairwise comparisons requires $O(k^2)$ number of pairwise Comparisons.

These factors lead us to choose the Pointwise ranker over the pairwise ranker for the experiments in the results section.

Beam size	Vanilla	Rerank	TGEN	LN	LN+Rerank	BM	LN+BM

C Numerical results

This section will present the numerical results for the E2E and WebNLG datasets so that they can be more readily compared in future works. The results are given in Table 1 and Table 2.

D Hyperparameters

Throughout this paper a number of hyperparameters were introduced. The values used for each of the models in this paper are summarised bellow. Note that the search for these values was far from exhaustive so there is a good chance that the results of this paper could be improved upon through a better optimisation procedure.

In Section 3.3, the beam is split into two sections, bottom and rest. For all beam manipulation models the bottom of the beam was set to the bottom (i.e. lowest scoring) quarter of the beam. We also say a large beam is used to generate the data for training the beam. For all experiments in this paper we use a beam size of 50.

A key hyperparameter for performance of the incremental beam manipulation was the steps of the beam search at which the beam was manipulated. This hyperparameter varied for the 4 separate beam manipulation models. The values are summarised as follows:

- E2E, Incremental Beam Manipulation on top of vanilla beam search: 5, 10, 15, 20 and final.
- E2E, Incremental Beam Manipulation on top of length normalised beam search: 5, 7 and 10.
- WebNLG, Incremental Beam Manipulation on top of vanilla beam search: 4, 12 and final.
- WebNLG, Incremental Beam Manipulation on top of length normalised beam search: 5 and 12.

It is worth noting that manipulating the final step is the same as reranking the beam according to the ranker used in beam manipulation (i.e. no rollouts are performed).

StructSum: Summarization via Structured Representations

Abstract

Abstractive text summarization aims at compressing the information of a long source document into a rephrased, condensed summary. Despite advances in modeling techniques, abstractive summarization models still suffer from several key challenges: (i) *layout bias*: they overfit to the style of training corpora; (ii) *limited abstractiveness*: they are optimized to copying n-grams from the source rather than generating novel abstractive summaries; (iii) *lack of transparency*: they are not interpretable. In this work, we propose a framework based on document-level structure induction for summarization to address these challenges. To this end, we propose incorporating *latent and explicit dependencies across sentences in the source document* into end-to-end single-document summarization models. Our framework complements standard encoder-decoder summarization models by augmenting them with rich structure-aware document representations based on implicitly learned (latent) structures and externally-derived linguistic (explicit) structures. We show that our summarization framework, trained on the CNN/DM dataset, improves the coverage of content in the source documents, generates more abstractive summaries by generating more novel n-grams, and incorporates interpretable sentence-level structures, while performing on par with standard baselines.[1]

1 Introduction

Text summarization aims at identifying important information in long source documents and expressing it in human readable summaries. Two prominent methods of generating summaries are *extractive* (Dorr et al., 2003; Nallapati et al., 2017), where important sentences in the source article are selected to form a summary, and *abstractive* (Rush et al., 2015; See et al., 2017), where the model restructures and rephrases essential content into a paraphrased summary.

State of the art approaches to abstractive summarization employ neural encoder-decoder methods that encode the source document as a sequence of tokens producing latent document representations and decode the summary conditioned on the representations. Recent studies suggest that these models suffer from several key challenges. First, since standard training datasets are derived from news articles, model outputs are strongly affected by the layout bias of the articles, with models relying on the leading sentences of source documents (Kryscinski et al., 2019; Kedzie et al., 2018). Second, although they aim to generate paraphrased summaries, abstractive summarization systems often copy long sequences from the source, causing their outputs to resemble extractive summaries (Lin and Ng, 2019; Gehrmann et al., 2018). Finally, current methods do not lend themselves easily to interpretation via intermediate structures (Lin and Ng, 2019), which could be useful for identifying major bottlenecks in summarization models.

To address these challenges, we introduce *StructSum*: a framework that incorporates structured document representations into summarization models. StructSum complements a standard encoder-decoder architecture with two novel components: (1) a *latent-structure attention* module that adapts structured representations (Kim et al., 2017; Liu and Lapata, 2017) for the summarization task, and (2) an *explicit-structure attention* module that incorporates an external linguistic structure (e.g., coreference links). The two complementary components are incorporated and learned jointly with the encoder and decoder, as shown in Figure 1.

Encoders with induced latent structures have been shown to benefit several tasks including document classification, natural language inference

(Liu and Lapata, 2017; Cheng et al., 2016), and machine translation (Kim et al., 2017). Our latent structure attention module builds upon Liu and Lapata (2017) to model the dependencies between sentences in a document. It uses a variant of Kirchhoff's matrix-tree theorem (Tutte, 1984) to model such dependencies as non-projective tree structures(§2.2). The explicit attention module is linguistically-motivated and aims to incorporate inter-sentence links from externally annotated document structures. We incorporate a coreference based dependency graph across sentences, which is then combined with the output of the latent structure attention module to produce a hybrid structure-aware sentence representation (§2.3).

We test our framework using the CNN/DM dataset (Hermann et al., 2015) and show in §4.1 that it outperforms the base pointer-generator model (See et al., 2017) by up to 1.1 ROUGE-L. We find that the latent and explicit structures are complementary, both contributing to the final performance improvement. Our modules are also orthogonal to the choice of an underlying encoder-decoder architecture, rendering them flexible to be incorporated into other advanced models.

Quantitative and qualitative analyses of summaries generated by StructSum and baselines (§4), reveal that structure-aware summarization mitigates the news corpora layout bias by improving the coverage of source document sentences. Additionally, StructSum reduces the bias of copying large sequences from the source, inherently making the summaries more abstractive by generating $\sim$15% more novel n-grams than a competitive baseline. We also show examples of the learned interpretable sentence dependency structures, motivating further research for structure-aware modeling.

2 StructSum Framework

Consider a source document $\boldsymbol{x}$ consisting of n sentences $\{\boldsymbol{s}\}$ where each sentence $\boldsymbol{s}_i$ is composed of a sequence of words. Document summarization aims to map the source document to a target summary $\boldsymbol{y}$ of m words $\{y\}$. A typical neural abstractive summarization system is an attentional sequence-to-sequence model that encodes the input sequence $\boldsymbol{x}$ as a continuous sequence of tokens $\{w\}$ using a standard encoder (Hochreiter and Schmidhuber, 1997; Vaswani et al., 2017). The encoder produces a set of hidden representations $\{\mathbf{h}\}$. A decoder maps the previously generated token y_{t-1} to a hidden state and computes a soft attention probability distribution $p(\mathbf{a}_t \mid \boldsymbol{x}, \boldsymbol{y}_{1:t-1})$ over encoder hidden states. A distribution p over the vocabulary is computed at every time step t and the network is trained using the negative log likelihood loss: $\text{loss}_t = -\log p(y_t)$.

StructSum modifies the above architecture as follows. We aggregate the token representations from the encoder to form sentence representations as in hierarchical encoders (Yang et al., 2016). We then use implicit- and explicit-structure attention modules to augment the sentence representations with sentence dependency information, leveraging both a learned latent structure and an external structure from other NLP modules. The attended vectors are then passed to the decoder, which produces the output abstractive summary. In the rest of this section, we describe our framework architecture, shown in Figure 1, in detail.

2.1 Sentence Representations

We consider an encoder which takes a sequence of words in a sentence $\boldsymbol{s}_i = \{w\}$ as input and produces contextual hidden representation for each word $\mathbf{h}_{w_{ik}}$, where w_{ik} is the k^{th} word of the i^{th} sentence, $k = 1 : q$ and q is the number of words in the sentence $\boldsymbol{s}_i$. The word hidden representations are max-pooled at the sentence level and passed through a sentence-encoder, which produces new hidden sentence representations for each sentence $\mathbf{h}_{\boldsymbol{s}_i}$. The sentence hidden representations are then passed as inputs to the latent and explicit structure attention modules.

2.2 Latent Structure (LS) Attention

We model the latent structure of a source document as a non-projective dependency tree of sentences and force a pairwise attention module to automatically induce this tree. We denote the marginal probability of a dependency edge as $a_{ij} = p(z_{ij} = 1)$ where z_{ij} is the latent variable representing the edge from sentence i to sentence j. We parameterize the unnormalized pairwise scores between sentences with a neural network and use the Kirchoff's matrix tree theorem (Tutte, 1984) to compute the marginal probability of a dependency edge between any two sentences.

Specifically, we decompose the representation of a sentence $\boldsymbol{s}_i$ into a *semantic* vector $\mathbf{g}_{\boldsymbol{s}_i}$ and *structure* vector $\mathbf{d}_{\boldsymbol{s}_i}$ as $\mathbf{h}_{\boldsymbol{s}_i} = [\mathbf{g}_{\boldsymbol{s}_i}; \mathbf{d}_{\boldsymbol{s}_i}]$. Using the structure vectors $\mathbf{d}_{\boldsymbol{s}_i}, \mathbf{d}_{\boldsymbol{s}_j}$, we compute a score f_{ij} between sentence pairs (i, j) (where sentence i is

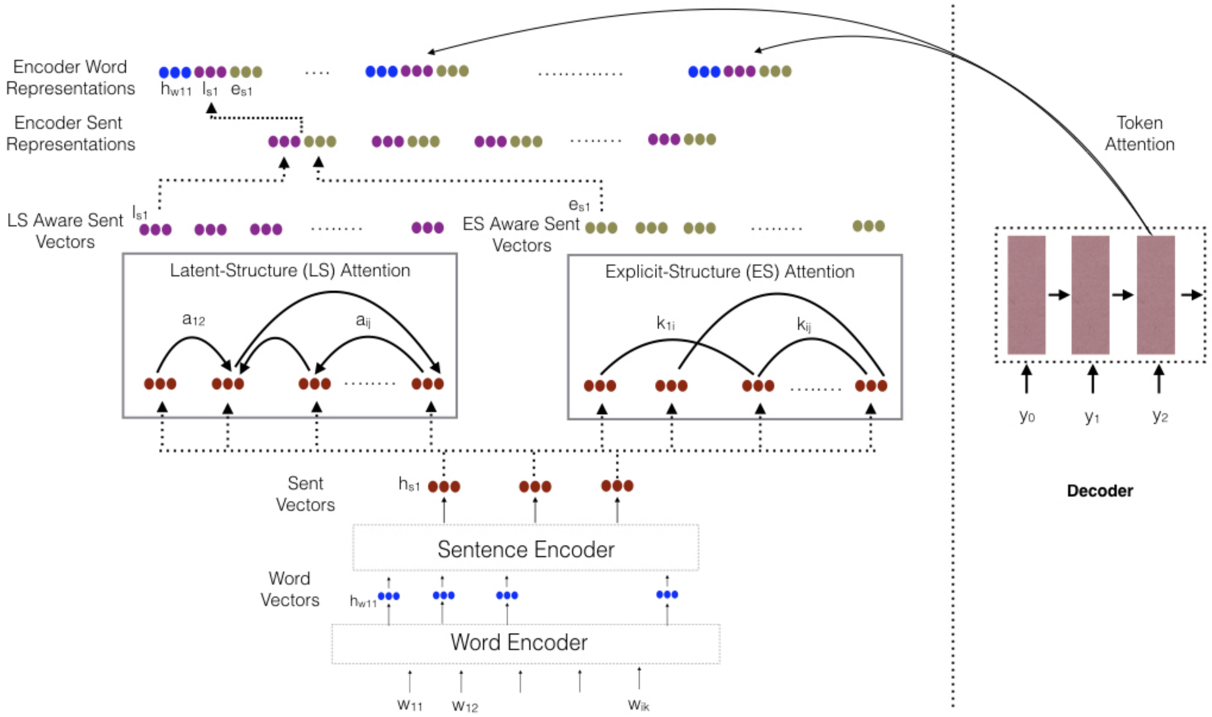

Figure 1: StructSum incorporates Latent Structure (LS) §2.2 and Explicit Structure (ES) §2.3 Attention to produce structure-aware representations. Here, StructSum augments the Pointer-Generator model, but the methodology that we proposed is general, and it can be applied to other encoder-decoder summarization systems

the parent node of sentence j) and a score r_i (where the sentence $\boldsymbol{s}_i$ is the root node):

$$f_{ij} = F_p(\mathbf{d}_{\boldsymbol{s}_i})^T W_a F_c(\mathbf{d}_{\boldsymbol{s}_j}) \text{ and } r_i = F_r(\mathbf{d}_{\boldsymbol{s}_i})$$

where F_p, F_c and F_r are linear-projection functions that build representations for the parent, child and root nodes respectively, and W_a is the weight for bilinear transformation. Here, f_{ij} is the edge weight between nodes (i, j) in a weighted adjacency graph $\mathbf{F}$ and is computed for all pairs of sentences. Using f_{ij} and r_i, we compute normalized attention scores a_{ij} and a_i^r using a variant of Kirchhoff's matrix-tree theorem where a_{ij} is the marginal probability of a dependency edge between sentences (i, j) and a_i^r is the probability of sentence i being the root.

Using these probabilistic attention weights and the semantic vectors $\{\mathbf{g}_{\boldsymbol{s}}\}$, we compute the attended sentence representations as:

$$\mathbf{p}_{\boldsymbol{s}_i} = \sum_{j=1}^{n} a_{ji}\mathbf{g}_{\boldsymbol{s}_j} + a_i^r \mathbf{g}_{root}$$

$$\mathbf{c}_{\boldsymbol{s}_i} = \sum_{j=1}^{n} a_{ij}\mathbf{g}_{\boldsymbol{s}_i}$$

$$\mathbf{l}_{\boldsymbol{s}_i} = \tanh(W_r[\mathbf{g}_{\boldsymbol{s}_i}, \mathbf{p}_{\boldsymbol{s}_i}, \mathbf{c}_{\boldsymbol{s}_i}])$$

where $\mathbf{p}_{\boldsymbol{s}_i}$ is the context vector gathered from possible parents of sentence i, $\mathbf{c}_{\boldsymbol{s}_i}$ is the context vector gathered from possible children, and $\mathbf{g}_{root}$ is a special embedding for the root node. Here, the updated sentence representation $l_{\boldsymbol{s}_i}$ incorporates the implicit structural information.

2.3 Explicit Structure (ES) Attention

Following Durrett et al. (2016), who showed that modeling coreference knowledge through anaphora constraints leads to improved clarity or grammaticality, we incorporate cross-sentence coreference links as the source of explicit structure. First, we use an off-the-shelf coreference parser[2] to identify coreferring mentions. We then build a coreference based sentence graph by adding a link between sentences $(\boldsymbol{s}_i, \boldsymbol{s}_j)$, if they have any coreferring mentions. This graph is converted into a weighted graph by incorporating a weight on the edge between two sentences that is proportional to the number of unique coreferring mentions between them. We normalize these edge weights for every sentence, effectively building a weighted adjacency matrix $\mathbf{K}$ where k_{ij} is given by:

---

[2] `https://github.com/huggingface/neuralcoref/`

$$k_{ij} = P(z_{ij} = 1) \tag{1}$$

$$= \frac{count(m_i \bigcap m_j) + \epsilon}{\sum_{v=1}^{n} count(m_i \bigcap m_v)} \tag{2}$$

where m_i denotes the set of unique mentions in sentence $\boldsymbol{s}_i$, $(m_i \bigcap m_j)$ denotes the set of co-referring mentions between the two sentences, and z is a latent variable representing a link in the coreference sentence graph. $\epsilon = 5e^{-4}$ is a smoothing hyperparameter.

Given contextual sentence representations $\{\mathbf{h}_{\boldsymbol{s}}\}$ and our explicit coreference-based weighted adjacency matrix $\mathbf{K}$, we learn an explicit structure-aware representation as follows:

$$\mathbf{u}_{\boldsymbol{s}_i} = \tanh(F_u(\mathbf{h}_{\boldsymbol{s}_i}))$$

$$\mathbf{t}_{\boldsymbol{s}_i} = \sum_{j=1}^{p} k_{ij}\mathbf{u}_{\boldsymbol{s}_j}$$

$$\mathbf{e}_{\boldsymbol{s}_i} = \tanh(F_e(\mathbf{t}_{\boldsymbol{s}_i}))$$

where F_u and F_e are linear projections and $\mathbf{e}_{\boldsymbol{s}_i}$ is an updated sentence representation which incorporates explicit structural information.

Finally, to combine the two structural representations, we concatenate the latent and explicit sentence vectors as: $\mathbf{h}_{\boldsymbol{s}_i} = [\mathbf{l}_{\boldsymbol{s}_i}; \mathbf{e}_{\boldsymbol{s}_i}]$ to form encoder sentence representations of the source document. To provide every token representation with the context of the entire document, the token representations are concatenated with their corresponding structure-aware sentence representation: $\mathbf{h}_{w_{ij}} = [\mathbf{h}_{w_{ij}}; \mathbf{h}_{\boldsymbol{s}_i}]$ where $\boldsymbol{s}_i$ is the sentence to which the word w_{ij} belongs. The resulting structure-aware token representations can be used to directly replace previous token representations as input to the decoder.

3 Experiments

Dataset: We evaluate our approach on the CNN/Daily Mail corpus[3] (Hermann et al., 2015; Nallapati et al., 2016) and use the same preprocessing steps as shown in See et al. (2017). The CNN/DM has 287226/13368/11490 train/val/test samples respectively. The reference summaries have an average of 66 tokens ($\sigma = 26$) and 4.9 sentences. Differing from See et al. (2017), we truncate source documents to 700 tokens instead of 400 in training and validation sets to model longer documents with more sentences. All our experiments were trained on Nvidia GTX Titan X GPUs.

Base Model: Although StructSum framework can be incorporated in any encoder-decoder framework with structure-aware representations, for our experiments we chose the pointer-generator model (See et al., 2017) as the base model, due to its simplicity and ubiquitous usage as a neural abstractive summarization model across different domains (Liu et al., 2019; Krishna et al., 2020). The word and sentence encoders are BiLSTM and the decoder is a BiLSTM with a pointer based copy mechanism. We re-implement the base pointer-generator model and augment it with the StructSum modules described in §2 and hence our model can be directly compared to it.

Baselines: In addition to the base model, we compare StructSum with the following baselines:
Tan et al. (2017): This is a graph-based attention model that is closest in spirit to the method we present in this work. A graph attention module is used to learn attention between sentences, but it cannot be easily used to induce interpretable document structures, since its attention scores are not constrained to learn structure. On top of latent and interpretable structured attention between sentences, StructSum introduces an explicit structure component to inject external document structure, which distinguishes it from Tan et al. (2017).
Gehrmann et al. (2018): This work introduces a separate content selector which tags words and phrases to be copied. The DiffMask variant is an end-to-end variant like ours and hence is included in our baselines. We compare StructSum with the DiffMask experiment.[4]

Hyperparameters: Our encoder uses 256 hidden states for both directions in the one-layer BiLSTM, and 512 for the single-layer decoder. We use the Adagrad optimizer (Duchi et al., 2011) with a learning rate of 0.15 and an initial accumulator value of 0.1. We do not use dropout and use

---

[3] `https://cs.nyu.edu/~kcho/DMQA/`

[4] The best results from Gehrmann et al. (2018) outperform DiffMask experiment, but they use inference-time hard masking which can be applied on ours. Our baselines also exclude Reinforcement Learning (RL) based systems as they are not directly comparable, but our approach can be introduced in an encoder-decoder based RL system. Since we do not incorporate any pretraining, we do not compare with recent contextual representation based models (Liu and Lapata, 2019).

Table 1: Evaluation of summarization models on the CNN/DM dataset. Published abstractive summarization baseline scores are on top. The bottom section shows re-implementations of See et al. (2017)[5] and StructSum results that incorporate latent and explicit document structure into the base models. StructSum's utility is on par with the base models, while introducing additional benefits of better abstractiveness and intrepretability shown in §4.

gradient-clipping with a maximum norm of 2. We selected the best model using early stopping based on the ROUGE score on the validation dataset as our criteria. We also used the coverage penalty during inference as shown in Gehrmann et al. (2018). For decoding, we use beam-search with a beam width of 3. We did not observe significant improvements with higher beam widths.

4 Evaluation

A standard ROUGE metric does not shed meaningful light into the quality of summaries across important dimensions. As a recall-based metric it is not suitable for assessing the abstractiveness of summarization; it is also agnostic to layout biases and does not facilitate intrepretability of model decisions. We thus adopt automatic metrics tailored to evaluating separately each of these aspects. We compare StructSum to our base model, the pointer-generator network with coverage (See et al., 2017) and the reference.

4.1 Automatic Metrics

We first conduct a standard comparison of generated summaries with reference summaries using ROUGE-1,2 and L (Lin, 2004) F1[6] metric. Table 1 shows the results. We first observe that introducing the latent structures and explicit structures independently improves our performance on ROUGE-L. It suggests that modeling dependencies between sentences helps the model compose better long sequences compared to baselines. We see small improvements in ROUGE-1 and ROUGE-2, hinting that we retrieve similar content words as the baseline but compose them into better contiguous sequences. As both ES and LS independently get similar performance, the results show that LS attention induces good latent dependencies that make up for pure external coreference knowledge.

Finally, our combined model which uses both Latent and Explicit structure performs the best with an improvement of **1.08 points** in ROUGE-L and **0.6 points** in ROUGE-1 over base pointer-generator model (statistically significant for 11490 samples at p=0.05 using Wilson Confidence Test). It shows that the latent and explicit information are complementary and a model can jointly leverage them to produce better summaries. Additionally, we find that structural inductive bias helps a model to converge faster. The combined LS+ES Attention model converges in 126K iterations in comparison to ∼230K iterations required for the pointer-generator network.

While ROUGE is a popular metric used for evaluating summarization models, it is limited to only evaluating n-gram overlap while ignoring semantic correctness. Hence, we compared our method with the baseline Pointer-Generator model using the BERTScore metric (Zhang et al., 2020). We observe that our model improves BERTScore by 9 points (12.3 for Pointer-Generator v/s 21.7 for StructSum) showing that our model is able to generate semantically correct content.

4.2 Abstractiveness

Despite being an abstractive model, the pointer-generator model tends to copy very long sequences of words including whole sentences from the

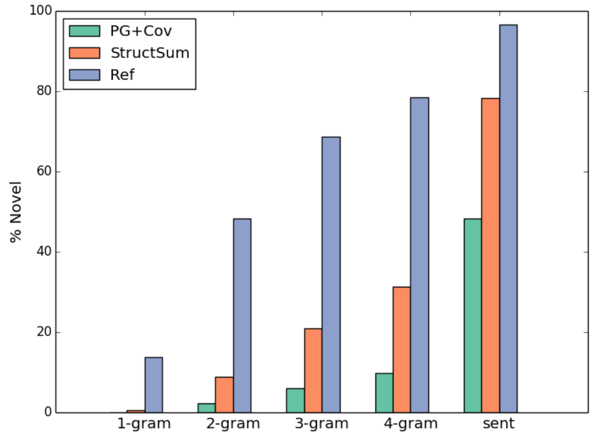

Figure 2: Comparison of % Novel n-grams between StructSum, Pointer-Generator+Coverage and the Reference. Here, "sent" indicates full novel sentences.

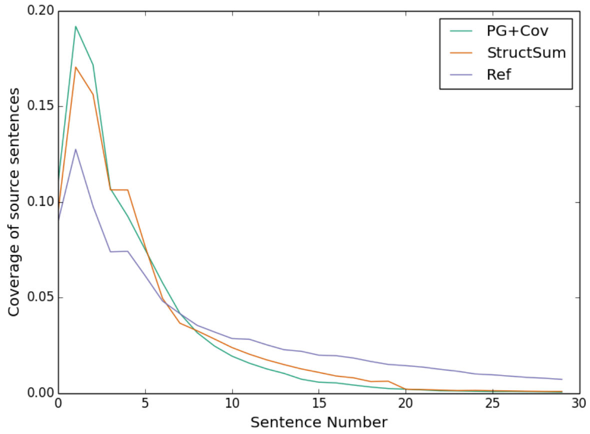

Figure 3: Coverage of source sentences in summary. Here the x-axis is the sentence position in the source article and y-axis shows the normalized count of sentences in that position copied to the summary.

source document (also observed by Gehrmann et al. (2018)). We use two metrics to evaluate the abstractiveness of the model:

Copy Length: Table 2 shows a comparison of the average length (Copy Len) of contiguous copied sequences from the source document (greater than length 3). We observe that the pointer-generator baseline on average copies 16.61 continuous tokens from the source which shows the extractive nature of the model. This indicates that pointer networks, aimed at combining advantages from abstractive and extractive methods by allowing to copy content from the input document, tend to skew towards copying, particularly in this dataset. A consequence of this is that the model fails to interrupt copying at desirable sequence length. In contrast, modeling document structure through StructSum reduces the length of copied sequences to 9.13 words on average reducing the bias of copying sentences entirely. This average is closer to the reference (5.07 words) in comparison, without sacrificing task performance. StructSum learns to stop when needed, while still generating coherent summaries.

Novel N-Grams: The proportion of novel n-grams generated has been used in the literature to measure the degree of abstractiveness of summarization models (See et al., 2017). Figure 2 compares the percentage of novel n-grams in StructSum as compared to the baseline model. Our model produces novel trigrams 21.0% of the time and copies whole sentences only 21.7% of the time. In comparison, the pointer-generator network has only 6.1% novel trigrams and copies entire sentences 51.7% of the time. This shows that StructSum on average generates 14.7% more novel n-grams in comparison to the pointer-generator baseline.

4.3 Coverage

A direct outcome of copying shorter sequences is being able to cover more content from the source document within given length constraints. We observe that this leads to better summarization performance. We compute coverage by computing the number of source sentences from which contiguous sequences greater than length 3 are copied in the summary. Table 2 shows a comparison of the coverage of source sentences in the summary content. While the baseline pointer-generator model only copies from 12.1% of the source sentences, StructSum copies content from 24.0% of the source sentences. Additionally, the average length of the summaries produced by StructSum remains mostly unchanged at 66 words on average compared to 61 of the baseline model. This indicates that StructSum produces summaries that draw from a wider selection of sentences from the original article compared to the baseline models.

4.4 Layout Bias

Neural abstractive summarization methods applied to news articles are typically biased towards selecting and generating summaries based on the first few sentences of the articles. This stems from the structure of news articles, which present the salient information of the article in the first few sentences

	Copy Len	Coverage
PG+Cov	16.61	12.1 %
StructSum	9.13	24.0 %
Reference	5.07	16.7 %

Table 2: Results of analysis of copying and coverage distribution over the source sentences on CNN/DM test set. Copy Len denotes the average length of copied sequences; Coverage – coverage of source sentences.

	Coref	NER	Coref+NER
precision	0.29	0.19	0.33
recall	0.11	0.08	0.09

Table 3: Precision and recall of ES and LS shared edges

and expand in the subsequent ones. As a result, the LEAD 3 baseline, which selects the top three sentences of an article, is widely used in the literature as a strong baseline to evaluate summarization models applied to the news domain (Narayan et al., 2018). Kryscinski et al. (2019) observed that the current summarization models learn to exploit the layout biases of current datasets and offer limited diversity in their outputs.

To analyze whether StructSum also holds the same layout biases, we compute a distribution of source sentence indices that are used for copying content (copied sequences of length 3 or more are considered). Figure 3 shows the distributions of source sentences covered in the summaries. The coverage of sentences in the reference summaries shows a high proportion of the top 5 sentences of any article being copied to the summary. Additionally, the reference summaries have a smoother tail end distribution with relevant sentences in all positions being copied. It shows that a smooth distribution over all sentences is a desirable feature. We notice that the pointer-generator framework have a stronger bias towards the beginning of the article with a high concentration of copied sentences within the top 5 sentences of the article. In contrast, StructSum improves coverage slightly having a lower concentration of top 5 sentences and copies more tail end sentences than the baselines. However, although the modeling of structure does help, our model has a reasonable gap compared to the reference distribution. We see this as an area of improvement and a direction for future work.

Depth	2	3	4	5+
StructSum	29.3%	53.7%	14.4%	2.6%

Table 4: Distribution of latent tree depth.

5 Analysis of Induced Document Structures

Similar to Liu and Lapata (2017), we also look at the quality of the intermediate structures learned by the model. We use the Chu-Liu-Edmonds algorithm (Chu and Liu, 1965; Edmonds, 1967) to extract the maximum spanning tree from the attention score matrix as our sentence structure. Table 4 shows the frequency of various tree depths. We find that the average tree depth is 2.9 and the average proportion of leaf nodes is 88%, consistent with results from tree induction in document classification (Ferracane et al., 2019). Further, we compare latent trees extracted from StructSum with undirected graphs based on coreference, on NER, or on both. These are constructed similarly to our explicit coreference based sentence graphs in §2.3 by linking sentences with overlapping coreference mentions or named entities. We measure the similarity between the learned latent trees and the explicit graphs through precision and recall over edges. The results are shown in Table 3. We observe that our latent graphs have low recall with the linguistic graphs showing that our latent graphs do not capture the coreference or named entity overlaps explicitly, suggesting that the latent and explicit structures capture complementary information.

Figure 4 shows qualitative examples of induced structures along with summaries from the StructSum. The first example shows a tree with sentence 3 chosen as root, which was the key sentence mentioned in the reference. In both examples, the sentences in the lower level of the dependency tree contribute less to the generated summary. Similarly, in the examples source sentences used to generate summaries tend to be closer to the root node. In the first summary, all source content sentences used in the summary are either the root node or within depth 1 of the root node. In the second example, 4 out of 5 source sentences were at depth=1 in the tree. In both examples, generated summaries diverged from the reference by omitting certain sentences used in the reference. These sentences are in the lower section of the tree, providing insights on which sentences were preferred for the

summary generation. We also see in example 1 that the latent structures cluster sentences based on the main topic of the document. Sentences 1,2,3 differ from sentences 5,6,7 in the topic discussed and our model clustered the two sets separately.

6 Related Work

Data-driven neural summarization falls into *extractive* (Cheng et al., 2016; Zhang et al., 2018) or *abstractive* (Rush et al., 2015; See et al., 2017; Gehrmann et al., 2018; Chen and Bansal, 2018). Pointer-generator See et al. (2017) learns to either generate novel in-vocabulary words or copy from the source. It has been the foundation for much work on abstractive summarization (Gehrmann et al., 2018; Hsu et al., 2018; Song et al., 2018). Our model extends it by incorporating latent/explicit structure, but these extensions are applicable to any other encoder-decoder architecture. For example, a follow-up study has already shown benefits of our method in multi-document summarization (Chowdhury et al., 2020).

In pre-neural era, document structure played a critical role in summarization (Leskovec et al., 2004; Litvak and Last, 2008; Liu et al., 2015; Durrett et al., 2016; Kikuchi et al., 2014). More recently Song et al. (2018) infuse source syntactic structure into the pointer-generator using word-level syntactic features and augmenting them to decoder copy mechanism. In contrast, we model sentence dependencies as latent structures and explicit coreference structures; we do not use heuristics or salient features. Li et al. (2018) propose structural compression and coverage regularizers incorporating structural bias of target summaries while we model the structure of the source document. Fremann and Klementiev (2019) induce latent structures for aspect based summarization, Cohan et al. (2018) focus on summarization of scientific papers, Isonuma et al. (2019) reviews unsupervised summarization, Mithun and Kosseim (2011) use discourse structures to improve coherence in blog summarization and Ren et al. (2018) use sentence relations for multi-document summarization. These are complementary directions to our work. To our knowledge, StructSum is the first to jointly incorporate latent and explicit document structure in a summarization framework.

7 Conclusion and Future Work

In this work, we propose the framework StructSum for incorporating latent and explicit document structure in neural abstractive summarization. We introduce a novel explicit-attention module which incorporates external linguistic structures, instantiating it with coreference links. We show that our framework improves the abstractiveness and coverage of generated summaries, and helps mitigate layout biases associated with prior models. We present an extensive evaluation of StructSum along abstractiveness, coverage, and layout quantitatively. Future work will investigate the role of document structures in pretrained language models (Lewis et al., 2019; Liu and Lapata, 2019).

Project-then-Transfer: Effective Two-stage Cross-lingual Transfer for Semantic Dependency Parsing

Hiroaki Ozaki, Gaku Morio, Terufumi Morishita, Toshinori Miyoshi

Abstract

This paper describes the first report on cross-lingual transfer for semantic dependency parsing. We present the insight that there are two different kinds of cross-linguality, namely surface level and semantic level, and try to capture both kinds of cross-linguality by combining annotation projection and model transfer of pre-trained language models. Our experiments showed that the performance of our graph-based semantic dependency parser almost achieved the approximated upper bound.

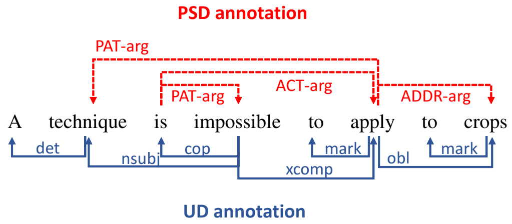

Figure 1: Example dependency annotations. Above: Semantic dependency (PSD). Below: Syntactic dependency (UD). Semantic dependency focuses more on meaning relationship between words.

1 Introduction

Cross-lingual dependency parsing attracted much attention for its powerful representational capability in grammatical and semantic lexical relations (Zhang and Barzilay, 2015; Guo et al., 2015; Ammar et al., 2016; Zeman et al., 2017, 2018; de Lhoneux et al., 2018; Schuster et al., 2019). Several remarkable contributions have been made in *syntactic* dependency parsing, especially on universal dependencies (UD; Nivre et al. 2016). For example, Kondratyuk and Straka (2019) showed that a single multilingually fine-tuned neural model utilizing a pre-trained language model could successfully parse 75 languages in UD with comparable performances to state-of-the-art parsers.

However, cross-lingual *semantic* dependency parsing (Oepen et al., 2014, 2015, 2016), which is totally different dependency structure from syntactic dependencies (shown in Figure 1), has not been explored as far as we know. A reason for this is the lack of parallel graphbanks that cover many languages with consistent annotation policies. One exception is Prague Semantic Dependencies (PSD; Mikulová 2009), which is a treebank of bi-lexical semantic graphs and contains over 30,000 pairs of parallel annotated sentences from the Wall Street Journal in English and Czech.

Considering these circumstances, we propose to train semantic dependency parsers by capturing commonalities across languages as a remedy for the absence of massive multilingual graphbanks. Our work draws on the intuition that cross-linguality exists in both superficial level and semantic level. Accordingly, we leverage a two-stage fashion involving treebank-based transfer and model-based transfer.

Treebank-based transfer, often called annotation projection, is a method of projecting source language annotations to a target language by using a mapping function such as word alignment. The annotation projection has been reported as a promising approach under truly low-resource settings for UD parsing (Rosa and Mareček, 2018). However, annotation projection often suffers from noise in word alignment (Damonte and Cohen, 2018). For the model-based transfer, several studies on transferring contextualized word vectors have reported that it improves the parsing performance (Mulcaire et al., 2019; Kondratyuk and Straka, 2019).

Our experiments on PSD graphbank indicate that the optimal performance can be achieved by incorporating the two-stage transfer. Surprisingly, we observed improvement even when the projected treebank was erroneous. Furthermore, the two-

April 19 - 23, 2021.

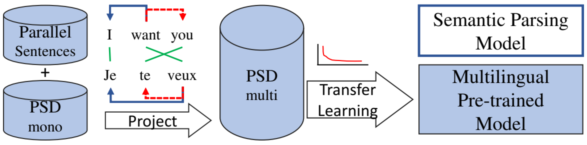

Figure 2: Project-then-Transfer approach.

stage transfer method achieved almost upper-bound performance, which was approximated by evaluating the cross-linguality of PSD annotation through the projection. We also provide detailed analyses from both perspectives of cross-linguality.

2 Related Work

Semantic Dependency Parsing: The topic of semantic dependency parsing has spurred enduring interest (Peng et al., 2017, 2018; Dozat and Manning, 2018; Wang et al., 2019; Kurita and Søgaard, 2019). Much of the current interest lies in higher-level interactions between relations. In parallel with our study, Aminian et al. (2020) shows improvement of PSD parsing trained on cross-lingually projected graphbank with multitask training of UD parsing as an auxiliary task. Unlike their work, we perform a zero-shot training with UDify pretrained model to validate the hypothesis of the two different cross-linguality.

Utilizing Models across Different Graphbanks: Parsing semantic graphs in different semantic abstraction levels was introduced as CoNLL shared task 2019 (Oepen et al., 2019). Candidate teams tackled this problem with methods such as transition-based parsers (Hershcovich et al., 2018; Bai and Zhao, 2019; Lai et al., 2019) and graph-based parsers (Zhang et al., 2019; Koreeda et al., 2019). Small improvements were reported in both approaches, but improving semantic parsing on different semantic graphs remains a difficult problem.

3 Transfer Strategies

To enable cross-lingual semantic parsing, we focused on two different types of cross-linguality, namely *cross-linguality on surface* and *cross-linguality in semantics*. *Cross-linguality on surface* lies on our hypothesis of typological correspondences among most of languages. For example, annotation projection, which is a treebank-based transfer, assumes *cross-linguality on surface* and projects source language annotations to a target language. On the other hand, *cross-linguality in semantics* is based on the assumption that lexical-, phrase-, or sentence-level meaning correspondences may exist among most of languages. Recently, multilingual BERT (Devlin et al., 2019; Pires et al., 2019) directly captures *cross-linguality in semantics* beyond lexicons by large-scaled language model training on parallel corpora.

Though both annotation projection and multilingual pre-trained model can handle either *cross-linguality on surface* or *in semantics*, we argue that they could not utilize both cross-linguality in effective way. Hence, we propose two-stage transfer which incorporates both methods, to capture the two kinds of cross-linguality as possible. We firstly introduce the two transfer methods for applying them to PSD graphbank, and then we explain our two-stage transfer method; Project-then-Transfer.

Annotation Projection: As aforementioned, this is the approach focuses on *cross-linguality on surface*. We trained word alignment model on PSD graphbank, and then projected all annotations in a monolingual graphbank to the other language.

Zero-shot Model Transfer: In this study, we transferred only pre-trained language models, because we aimed to focus on *cross-linguality in semantics* more.We trained PSD parsers with multilingual pre-trained model on a monolingual graphbank in PSD, and then apply the monolingually trained parsers to the other language.

Project-then-Transfer: We incorporate both transfer methods by applying them in two-stage fashion as shown in Figure 2. Firstly, we prepared multilingually projected PSD graphbanks. We automatically generated PSD annotations on English sentences in a multilingual parallel corpus by the previously introduced English PSD parser which was created in the zero-shot approach. By utilizing bi-lingual word alignment, we projected PSD annotations on English to other languages. We finally trained Project-then-Transfer models on a concatenated graphbank of both original and projected PSD.

4 Experiments

4.1 Setup and Implementations

To perform word alignment, we used an IBM2 aligner *fast_align*[1] (Dyer et al., 2013).

Li et al. (2019) (English monolingual training)			93.	92.	92.5	82.	81.	81.7	88.3

Table 1: SDP scores for each model and approach. U and L stand for "unlabeled" and"labeled" respectively. P, R, and F stand for "precision", "recall" and "F1-score" respectively. LF/UF is a proxy metric of label prediction accuracy. Bold values represent the best scores. Li et al. (2019) is the best PSD parser at CoNLL 2019 shared task.

To perform model-based transfer, we used mainly graph-based parsers, but we also used a transition-based parser for a comparison purpose. Our graph-based PSD parser employed UDify architecture[2] (Kondratyuk and Straka, 2019). We replaced activation function of biaffine attention layers in UDify with sigmoid activation (Dozat and Manning, 2018). We trained two variances of graph-based parsers, and a transition-based parser:

Graph-BERT: We trained it with mulitilinugal BERT as Kondratyuk and Straka (2019) did.

Graph-UDify: We trained it with UDify's pre-trained language model[3] instead of multilingual BERT. Since UDify is pre-trained on many languages in UD, we expect that it capture more *cross-linguality on surface* than BERT.

Transition-BERT: We used an architecture introduced by Che et al. (2019)[4], which was the best transition-based parser in the CoNLL 2019 shared task (Oepen et al., 2019). We trained it from scratch with the same hyperparameters given by the source code.

The pre-trained multilingual BERT[5] was downloaded via the above parser implementations. We used mtool[6] to evaluate SDP scores (Oepen et al., 2014) as metrics for parsing performance. A list of the best hyperparameters is available in Appendix. We added "tag_loss_w", which is a constant multiplied by the loss of relation label predictions.

We divided PSD graphbank into three splits, namely train-set (30,000 pairs), dev-set (2000 pairs), and test-set (3653 pairs). We selected the best models by monitoring the labeled F1-score of SDP on the dev-set of the target language and evaluated the scores on the test-set of the target language. We chose Parallel Universal Dependencies (PUD; Zeman et al. 2017) as additional multilingual parallel corpora for Project-then-Transfer, because they contain 1,000 parallel sentences for 18 languages, with mostly consistent UD annotations. Further details are in Appendix.

4.2 Results and Discussion

Table 1 shows the SDP scores for each model in each approach. Firstly, we focus on the cross-linguality of PSD annotations by the annotation projection. Unlabeled scores of projection models were within a range of 0.4 - 0.5. Since alignment error rate (AER) of English-Czech reported around 0.25 (Legrand et al., 2016), edge projection accuracy could be estimated as $(1 - \mathrm{AER})^2 \approx 0.56$ [7]. Annotation agreement rate of relations[8] between the two languages was estimated to fluctuate between 0.7 to 0.9 according to the mitigation efficacy of alignment error. Annotation agreement rate of relation labels was estimated as about 0.75 by comparing unlabeled and labeled scores (LF/UF of fast_align model). These rates could be upper bounds of performances.

By comparing monolingual training (Li et al.,

Graph-UDify + PUD_Czech	en2cs	80.6	57.8

Table 2: Unlabeled and labeled scores trained on English PSD with projected PUD_Czech.

2019), unlabeled-F of Project-then-Transfer (UDify) was about 85% of that of monolingual training. This ratio is in the range of estimated annotation agreement rate of relations.

Models and Approaches Comparison: As we can see from Table 1, the graph-based models outperformed the Transition-BERT, especially, graph-based UDify models demonstrated superiority to the other models. Graph-UDify of Project-then-Transfer approach, which is the best model, achieved an unlabeled F1-score of 82.5, that is close to the upper-bounds estimated above. In additions, there were few differences in LF/UF scores, which are also close to the upper-bound of relation label prediction. Thus, our best model achieved high performance, which is close to theoretical upper bounds. This indicates that bi-lexical relations captured by syntactic dependency are also helpful for parsing semantic dependency, yet there remaining information that were not captured in the UDify. We claim that the missing information was related to *cross-linguality on surface*, then we perform a deeper analysis on this in the following paragraph.

What is NOT captured by Pre-trained Models?: Figure 3 shows examples of gold and Graph-UDify (cs2en) outputs. The annotation projection had managed completely project *unlabeled* relations in the source language, but a swapping had happened between two relations, namely "REG" and "PAT-arg", which had been caused by alignment errors.

We observed that parsers based on the model-based transfer often failed to parse relations which contain functional words. This phenomenon can be observed in Figure 3c. Those relations containing functional words tended to be successfully converted by the annotation projection. Hence, we obtained better results with the Project-then-Transfer approach as shown in Figure 3d. This implies that pre-trained models including UDify represent rather *semantic* bi-lexical relations than grammatical ones.

We performed a further analysis on cross-linguality of UDify model. Figure 4 shows relation accuracy for each of four UPOS, namely *noun*, *verb*, *num* and *adp*. We calculated conditional "unlabeled" relation accuracy, which measures whether source or target word belongs to the specific UPOS type. By focusing on the accuracy of *num* (numeric) and *adp* (adposition), which are considered to be hard-to-contextualize examples, the annotation projection outperformed the zero-shot approach. The Project-then-Transfer approach improved the accuracy for almost all UPOS types including *num* and *adp*.

Cross-linguality on Surface: Table 5 shows SDP scores trained on English PSD with projected PUD_Czech. The performances were comparable to the zero-shot approach, but less than those of the Project-then-Transfer approach. Hence, multilingually projected treebank is significant to improve the performances. This implies that *cross-linguality on surface* can be captured by training on multilingually projected treebank.

5 Conclusion

This paper described transfer methods for cross-lingual semantic dependency parsing. We showed that both *cross-linguality on surface* and *in semantics* were necessary to improve the performance. Consequently, we achieved almost the upper bound performance approximated by the annotation projection. The results encouraged us to develop cross-lingual semantic dependency parser for many languages. We will further conduct explore these models, and evaluations on cross-linguality across languages broadly.

Acknowledgments

Computational resource of AI Bridging Cloud Infrastructure (ABCI) provided by the National Institute of Advanced Industrial Science and Technology (AIST) was used. We would like to thank the anonymous reviewers for their helpful comments. We also thank Dr. Masaaki Shimizu for the convenience of the computational resources.

Table 4: SDP scores on the dev-set for each model and approach.

Model	language	UF	LF
Graph-BERT + PUD_Czech	en2cs	69.0	50.7
Graph-UDify + PUD_Czech	en2cs	80.9	58.0

Table 5: Unlabeled and labeled dev-set scores of models trained on English PSD with projected PUD_Czech.

eters. We tuned hyperparamters in zero-shot approach, then we reused the best hyperparameters in Project-then-Transfer approach. We trained all models with NVIDIA V100 on Ubuntu 18.04. Our GPU environment is a mixture of both 32GB and 64GB memories.

We obtained PSD treebank from the Linguistic Data Consortium (LDC) [9]. We converted original SDP format data to MRP format before the training. This SDP to MRP graph conversion is a loss-less conversion.

A.2 Performances on Dev-set

Figure 5 shows *expected validation performances*. Table 4 and Table 5 show performances on the dev-set. Most of scores were consistent with the performances on the test-set. Only transition-based model is an exceptional case. Though over-fitting seemed to happen, its performances are still lower than those of graph-based models.

A.3 Full Results of Relation Accuracy

Figure 6 shows relation accuracy for all UPOS types. We can see that zero-shot performances of eleven types, namely *noun*, *verb*, *propn* (proper noun), *conj* (conjunction), *pron* (pronoun), *adv* (adverb), *punct* (punctuation), *det* (determiner), *part* (particle), *cconj* (coordinating conjunction), and *x* (other), are outperformed those of annotation projection, and all content words are included in this group. Zero-shot performances of the other five types, *num*, sym (symbol), *adp*, *sconj* and *intj* (interjection), are comparable or underwhelmed to those of annotation projection. Because the words categorized as *intj* only appeared a few times in this analysis, we could not make a discussion regarding *intj*.

A.4 Multi-Task Learning

We argue that it is natural to perform multi-task learning (MTL) of UD and PSD dependencies when both annotations are available, since UDify's pre-train model, which is trained on UD annotations, improved the performances. Firstly, we added UD annotation on PSD treebank by existing UD parser UDPipe[10]. Our MTL setting is to share only BERT layers, but higher layers including scalar-mix layers are distinct. We used UDify "as is" for UD prediction. A Loss function to perform MTL is a simple linear combination of that of UDify and our PSD model. We show the MTL results in Table 6. Performances were degraded by comparing to those of non-MTL models. This could be because UD and PSD annotations are contradictive to perform MTL.

Abstract

Open Information Extraction (OIE) systems seek to compress the factual propositions of a sentence into a series of n-ary tuples. These tuples are useful for downstream tasks in natural language processing like knowledge base creation, textual entailment, and natural language understanding. However, current OIE datasets are limited in both size and diversity. We introduce a new dataset by converting the QA-SRL 2.0 dataset to a large-scale OIE dataset (LSOIE). Our LSOIE dataset is 20 times larger than the next largest human-annotated OIE dataset. We construct and evaluate several benchmark OIE models on LSOIE, providing baselines for future improvements on the task. Our LSOIE data, models, and code are made publicly available.[1]

1 Introduction

Open Information Extraction (OIE) (Banko et al., 2007) aims to automatically extract all factual propositions of a sentence into a series of n-ary tuples. For example, the sentence "the cook baked and ate the cake" would produce two extractions representing the two basic propositions of the sentence: (the cook, **ate**, the cake) and (the cook, **baked**, the cake). In OIE, extraction arguments are required to be contiguous spans from the sentence and the resulting tuple should be intelligible as natural text when read in order. The schema-free nature of OIE provides a flexible framework in which to capture semantic relations between entities in natural language text. Open Information Extraction tuples are useful to a variety of downstream tasks including knowledge base creation (Zhang et al., 2019), textual entailment (Levy et al., 2014), and other natural language understanding tasks (Mausam, 2016).

	Domains	#Sent.	#Ext.	Ext. / Sent.	Vocab	Ordered
OIE2016	Wiki, Newswire	3,180	8,477	2.7	13,863	
AW-OIE	Wiki, Wikinews	3,300	17,165	5.2	15,853	
LSOIE-wiki	Wiki, Wikinews	24,296	56,662	2.3	46,617	✓
LSOIE-sci	Science	47,998	97,550	2.0	51,668	✓

Table 1: OIE dataset metrics. Our new dataset LSOIE has substantially more text available than prior work, and includes a new science domain. Our dataset conversion process leverages the scope of the QA-SRL 2.0 bank and improves upon previous methodology.

Open Information Extraction relations may be explicitly stated by verbal predicates, or implicitly stated through nominalizations. In this paper, we focus only on explicit extractions. With the original goal of OIE as web scale information extraction (Banko et al., 2007), an OIE system can focus solely on explicit extractions because the redundancy of language will inevitably display implicit information elsewhere.

The interest in OIE has grown: both in terms of the types of models that can be applied to tackle OIE (Cui et al., 2018; Stanovsky et al., 2018; Jiang et al., 2019), and in terms of the downstream applications to which OIE can be applied (Mausam, 2016; Zhang et al., 2019). As the interest in OIE grows, however, so too should the scale of the corpora available for training and evaluating OIE models.

In this paper, we expand the reach and quality of OIE data by developing a new dataset, LSOIE, which is built by converting the QA-SRL BANK 2.0 dataset (FitzGerald et al., 2018) to the task of OIE. Our new dataset contains almost ten times as many extractions and about 20 times as many sentences as previous OIE datasets built from human anno-

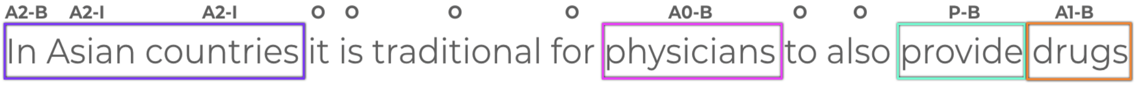

Figure 1: An example annotated sentence from QA-SRL 2.0 (FitzGerald et al., 2018). In this case, the annotations are derived from the question and answers: - Where does someone **provide** something? **In Asian countries**. Who **provides** something? **physicians**. What is being **provided**? **drugs**. The extracted tuple in our new LSOIE dataset is (physicians, **provide**, drugs, in Asian countries).

tations (see Table 1). We benchmark LSOIE with several models, providing baseline results for future research. Our LSOIE dataset, models, and code are publicly available.

2 Background

2.1 OIE Datasets

Available OIE corpora fall into three categories: (1) converted from crowdsourcing, (2) model-derived, and (3) directly crowdsourced.

Converted from crowdsourcing: Stanovsky and Dagan (2016) created the OIE2016 dataset by converting the crowd-annotated QA-SRL (He et al., 2015) dataset's question-answer pairs to OIE extraction relations. Similarly, Stanovsky et al. (2018) generated the AW-OIE dataset by converting the crowd-annotated Question Answer Meaning Representation (QAMR) dataset's question-answer pairs.

The OIE2016 and AW-OIE datasets were the first datasets used for supervised OIE. These datasets provided the basis for supervised approaches in NLP, but they are small and extractions lack accuracy, as they are converted in the order that question answer pairs appear in the base dataset.

Model-derived: Cui et al. (2018) and Jia et al. (2018) generate large derivative training datasets by running rules-based models and keeping high confidence extractions for downstream tasks. Similarly, Gashteovski et al. (2019) introduce the largest OIE dataset to date (over 340M triples) by deriving extractions from `MinIE` Gashteovski et al. (2017) with the goal of automatically constructing a knowledge base. While model-derived datasets are useful for knowledge base construction, using them for downstream tasks teaches the new model to replicate the behavior of the original, often noisy, base model.

Directly crowdsourced: Bhardwaj et al. (2019) point out that the evaluation framework used in Stanovsky and Dagan (2016) is rather noisy and the tuple matching algorithm is overly lenient because it only looks at lexical overlap for the whole extraction, ignoring the ordering of arguments. Bhardwaj et al. (2019) provide an alternative evaluation set that has been crowdsourced specifically for OIE, annotating 1,282 sentences. While this dataset is useful for the evaluation of OIE systems, its format differs from other work in OIE - the predicate entry in CARB (Bhardwaj et al., 2019) tuples contains context that is often broken into separate tuples by other OIE systems.

2.2 The QA-SRL Bank 2.0

In QA-SRL, each predicate-argument relationship in a sentence is labeled manually with a question-answer pair. FitzGerald et al. (2018) design a large-scale crowdsourcing annotation pipeline to incentivize extensive and accurate coverage. Relative to the original QA-SRL annotations (He et al., 2015), which were collected from 10 hired freelance workers, the new QA-SRL dataset achieves similar precision (95.7% versus 97.5%) and lower recall (72.4% versus 86.6%). Relative to Propbank (Palmer et al., 2005), an expert annotation system designed to capture all semantic roles in a sentence. the QA-SRL 2.0 authors find that their work 95% precision and 85% recall. FitzGerald et al. (2018) then build a supervised QA-SRL parser and extend the reach of their dataset by over-generating new candidate question-answer pairs and passing them through their validation process.

The QA-SRL paradigm is well-suited to be a precursor to OIE extractions, as it captures predicate-argument relations in a schema-free way.

3 The LSOIE Dataset

Our work expands upon and addresses the shortcomings present in Stanovsky and Dagan (2016) and Stanovsky et al. (2018). We apply a similar conversion processes used for OIE2016 on the QA-SRL BANK 2.0 dataset. In addition, we implement novel conversion heuristics to ensure data quality and order arguments. The result is LSOIE, an OIE dataset that is much larger and diverse than prior work.

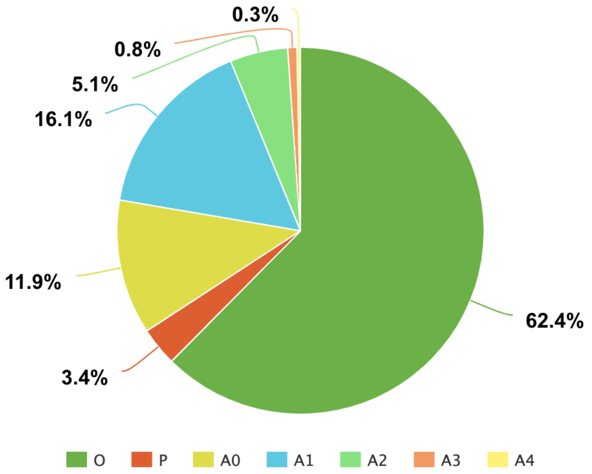

Figure 2: The distribution of token level tags (listed clockwise) in the LSOIE dataset. P denotes the extraction's predicate, A_0-A_N denote the extraction's arguments, and O denotes that a given token does not belong to the extraction.

3.1 LSOIE Conversion Process

We produce LSOIE via conversion from QA-SRL in the same manner as Stanovsky and Dagan (2016), with several important changes to adapt their method to the QA-SRL BANK 2.0.

A QA-SRL annotation for a predicate p consists of a list of questions $Q = \{q_0, \dots, q_n\}$, and a set of answer spans $A_i = \{a_{i0}, \dots, a_{in_i}\}$ for each question q_i. For each tuple $(a_0, \dots, a_k)$ in the Cartesian product $\bigtimes_i^n A_i$, we produce the extraction tuple $(a_0, p, a_1, \dots, a_k)$.

In our example extraction in Figure 1, the target predicate p is *provide*. The list of questions Q is [*Where does someone provide something?*, *Who provides something?*, *What is being provided?*] The list of arguments A is [*In Asian countries*, *physicians*, *drugs*]. The converted extraction tuple is (*physicians*, *provide*, *drugs*, *in Asian countries*).

To ensure data quality and as a result of differences between the original QA-SRL dataset and the QA-SRL BANK 2.0, we had to make two important changes to the algorithm:

Answer Filtering: The original QA-SRL dataset has a single set of mutually-exclusive answer spans for each question, written by a single annotator. In contrast, the QA-SRL BANK 2.0 has answer judgments from three annotators for each question, some providing answer sets and others marking the questions as invalid. To consolidate these, we only include questions marked as valid by all three annotators. Then, for each question, we iteratively draw the longest remaining answer span that does not overlap with a previously drawn answer span, until there are none left.

*Bats are the only mammals that can truly **fly**.* (Bats, **fly**)
*Greece moved up three to be **ranked** tenth.* (Greece, **ranked**, tenth)
*A popular student, in 1915 Mao was **elected** secretary of the Students Society.* (Mao, **elected**, secretary of the Students Society, in 1915)
*The proposed amendment already **passed** both houses in 2011.* (The proposed amendment, **passed**, both houses, in 2011)
*In polygynous species, males try to **monopolize** and mate with multiple females.* (males, **monopolize**, multiple females)
*Animals **adapted** to live in the desert are called xerocoles.* (Animals, **adapted**, to live in the desert)

Table 2: Example sentences with example extractions. Note that only one example extraction is shown here, though a sentence can yield multiple extractions.

In answer filtering, our primary motivation was to clean the raw version of crowd workers' answer responses in the QA-SRL 2.0 dataset, where questions can be posed that are not valid or the answer to them is ambiguous. We found it advantageous for dataset quality to require a strict agreement between all annotators. In choosing the longest answer span, we were motivated to not miss relevant portions of the argument, as individual crowd workers occasionally annotated a limited portion of the answer span that did not encapsulate the whole semantic meaning of the derived argument.

Argument Ordering: Stanovsky and Dagan (2016)'s original algorithm relies on the original, annotator-written order of QA-SRL questions, which may or may not produce a sensible argument ordering. Furthermore, in the QA-SRL BANK 2.0, the original order in which the questions were written is unavailable.

So, to determine argument order, we use a heuristic based on the relative order between answer spans for each question in their source text. We consider the abstract form of questions, which includes verb tense without information about its lemma. For a given question q_i in an extraction, let q_{i_x} represent the percentage of predicates in the QA-SRL BANK 2.0 where the answer span to the generalized version of q_i appears in the x^{th} place relative to other answer spans, according to the natural order of the sentence. For each argument slot in the derived extraction, the answer to the question with the highest probability q_{i_x} of naturally occurring in that slot is chosen as the argument.

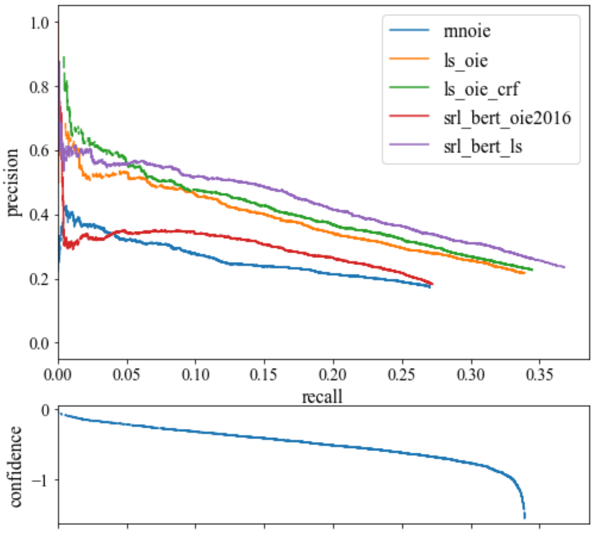

Figure 3: Top: performance of Supervised OIE systems on the LSOIE-wiki test set. Bottom: `ls_oie` estimated confidence at each extraction.

In our example extraction in Figure 1, the question *Who* `[predicate]` *something?* precedes *What is being* `[predicate]`*?* which precedes *Where does someone* `[predicate]` *something?*, enabling our algorithm to accurately extract argument ordering, which is not available from the natural ordering of the sentence or the ordering of crowd annotations in FitzGerald et al. (2018).

3.2 Dataset Statistics

We run our updated dataset conversion process over the directly crowdsourced portion of the train, development, and test partitions of the QA-SRL BANK 2.0. Stratifying the resulting data by domain, we present the new LSOIE corpus in two sections, LSOIE-wiki and LSOIE-sci. Dataset statistics are shown in Table 1. Example extractions are shown in Table 2. We provide the distribution of argument, predicate, and null tag labels in Figure 2. The LSOIE corpus expands the scope of OIE2016 and AW-OIE in size, textual diversity, and domain.

4 Benchmark Evaluation

Models: We evaluate several models on our new LSOIE dataset. Following Stanovsky et al. (2018), we model OIE as a supervised learning problem and format it as BIO tagging with tunable thresholding on extractions. We benchmark several model variants:

- **`rnnoie`** is a replication of the model in Stanovsky et al. (2018), based on a bidirectional LSTM transducer over GloVe embeddings (Pennington et al., 2014) and learned part-of-speech embedding features.

	LSOIE-wiki		LSOIE-sci	
Model	F_1	**AUC**	F_1	**AUC**
`rnnoie`	.22	.07	.26	.10
`ls_oie`	.28	.13	.33	.18
`ls_oie_crf`	.29	.14	.33	.19
`srl_bert_oie2016`	.23	.08	.29	.13
`srl_bert_ls`	**.31**	**.16**	.37	.21
`ls_oie_sci`	-	-	.34	.19
`ls_oie_crf_sci`	-	-	.35	.20
`srl_bert_ls_sci`	-	-	**.38**	**.22**

Table 3: Modeling results on the LSOIE test sets.

- **`ls_oie`** is a replication of `rnnoie` trained on LSOIE.
- **`ls_oie_crf`** is the same as `ls_oie`, but trained end-to-end with a Conditional Random Field on top to capture BIO transition constraints and trained to maximize the likelihood of the gold BIO sequence.
- **`srl_bert_ls`** is based on `ls_oie`, but uses BERT (Devlin et al., 2019) as the bidirectional encoder and the Sentence A / Sentence B embedding feature as the predicate indicator, inspired by Shi and Lin (2019).
- **`srl_bert_oie2016`** is the same architecture as `srl_bert_ls` but applied to the OIE2016 data.
- **`⋆_sci`** models were trained with the same architectures applied only to the LSOIE-sci training set.

Experiments and Evaluation: We use the AllenNLP framework (Gardner et al., 2018) built on PyTorch (Paszke et al., 2019) to implement, train, and test our models. We train `rnnoie` and `srl_bert_oie2016` on OIE2016 and `ls_oie` and `srl_bert_ls` on LSOIE-wiki. We also focus the series of models by only training on LSOIE-sci. We do not evaluate `⋆_sci` models on LSOIE-wiki. We limit our evaluation to supervised OIE systems.

We evaluate our system's performance against the gold test data in LSOIE-wiki and LSOIE-sci by considering extractions to be a match if they contain the same predicate as the gold extraction and contain the syntactic head of each gold argument. Syntactic heads are extracted with the Stanford CoreNLP dependency parser (Chen and Manning, 2014). Although it would be ideal to have the gold syntactic head, this method is preferable to taking the lexical overlap of the entire extraction

Stanovsky and Dagan (2016), ignoring argument tags and ordering as pointed out in Lechelle et al. (2019).

We then assign a confidence score to each extraction to allow for tuning the precision-recall tradeoff. For the non-CRF models, we use the mean log probability assigned to the tag labels in the extraction as the confidence score. For the CRF model, we use the log probability assigned to the entire sequence. We differ from Stanovsky et al. (2018) where confidence was calculated as the product of the inverse of the model's estimate probability for each tag label, preferring longer extractions which were more likely to get a 50% lexical match, outweighing the deficit of swimming upstream against the model's estimated confidence and still producing a downward sloping precision recall curve.

We use Viterbi decoding to extract the most likely valid BIO tagging sequence given the model's probability output for each BIO tag. We import the Viterbi algorithm functionality from the AllenNLP library (Gardner et al., 2018).

5 Discussion

Figure 3 shows precision and recall curves on the LSOIE-wiki test set, accompanied by the `ls_oie` model's estimated confidence. Table 3 shows F_1 and AUC scores for the benchmark models on the LSOIE-wiki and LSOIE-sci test sets.

The OIE modeling task is difficult. Results on both evaluation sets show that the BERT model and the CRF output layer improve over the baseline model. Training with the LSOIE improves model performance. When science is the target domain, the `*_sci` models are preferable, as they have slightly higher in-domain performance, showing the value of the domain split in LSOIE.

5.1 Error Analysis

We conduct a manual error analysis of the `ls_oie` model, where we find that our baseline models could benefit from more careful extractions.

Incorrect predicate: At minimum confidence, 53% of the model's precision errors come from verbs that are not present in the gold dataset. Half of these are legitimate predicates that are missing from the gold dataset and the other half are auxiliary verbs, that should not be present in the gold dataset. Depending on the deployment environment, the model could be improved with predicate filtering heuristics at prediction time.

Argument Concatenation: We examined 500 incorrect extractions by `ls_oie`. We found that 36% of unmatched extractions were semantically similar to the gold extraction. These extractions either concatenated arguments A_1-A_N into A_1 while gold did not, split these arguments apart while gold did, or dropped a non-material argument. For future modeling, this is an argument to drop A_2 and beyond from the dataset and only model OIE with extraction triples.

True Errors: Among the extraction errors, 2/3 involve errors in argument ordering, often following the natural order of the sentence. The other 1/3 of errors involved the model making nonsensical extractions or not making extracting arguments beyond A_0, presumably because of lack of confidence and defaulting to the O label.

LSOIE Modeling Improvements: We also manually examined 100 extractions where `ls_oie` chose the right extraction over `rnnoie`. In these cases, we found improved argument ordering, increased confidence on relevant A_1 objects, and better accuracy identifying subjects that are distant from the predicate.

6 Conclusion

In this paper, we introduced the LSOIE dataset as a resource for supervised OIE. We have algorithmically re-purposed the QA-SRL BANK 2.0 into a new OIE dataset, LSOIE, which contains over 70,000 sentences and over 150,000 extraction tuples. To benchmark the new dataset, we trained and evaluated a series of supervised OIE models, providing baselines for future research on the OIE modeling task.

The code and datasets introduced in this paper can be found at `https://github.com/Jacobsolawetz/large-scale-oie`.

Acknowledgments

A special thanks to Julian Michael and Gabriel Stanovsky for providing much needed guidance and feedback for our research. This project would not have been possible without their insight and previous progress on the topic. We also thank the anonymous reviewers for their feedback.

Changing the Mind of Transformers
for Topically-Controllable Language Generation

Abstract

Large Transformer-based language models can aid human authors by suggesting plausible continuations of text written so far. However, current interactive writing assistants do not allow authors to guide text generation in desired topical directions. To address this limitation, we design a framework that displays multiple candidate upcoming topics, of which a user can select a subset to guide the generation. Our framework consists of two components: (1) a method that produces a set of candidate topics by predicting the centers of word clusters in the possible continuations, and (2) a text generation model whose output adheres to the chosen topics. The training of both components is self-supervised, using only unlabeled text. Our experiments demonstrate that our topic options are better than those of standard clustering approaches, and our framework often generates fluent sentences related to the chosen topics, as judged by automated metrics and crowdsourced workers.

1 Introduction

Recently, Transformer-based language models (LMs) have achieved impressive performance in language generation tasks (Radford et al., 2019; Dai et al., 2019) such as open-domain story generation (See et al., 2019a). When writing with the LM, users often desire an intuitive and effective way to control what a LM is going to generate (Keskar et al., 2019). To address this need, interactive writing assistants provide options to reveal possible developments of the story and generate continuations guided by the user-selected options.

Interactive writing assistants have wide applications in creative writing (Roemmele and Gordon, 2015; Clark et al., 2018; Akoury et al., 2020), education (Luo et al., 2015), and gaming (Walton, 2020). Nevertheless, the existing systems' options usually do not provide fine-grained control and/or require substantial human labor. In some prior work (Keskar et al., 2019; Tu et al., 2019), users choose among a static set of predefined attributes (e.g., sentiment) that only provide coarse-grained control. Other work (Roemmele and Gordon, 2015; Clark et al., 2018) presents users with multiple generated continuations, which requires substantial reading effort and might not contain topics that users want to see. Finally, options could be nodes in a plot graph that are handcrafted (Luo et al., 2015) or derived from a collaboration between humans and machine (Li et al., 2013), but such choices are usually limited due to the high cost of preparing the options.

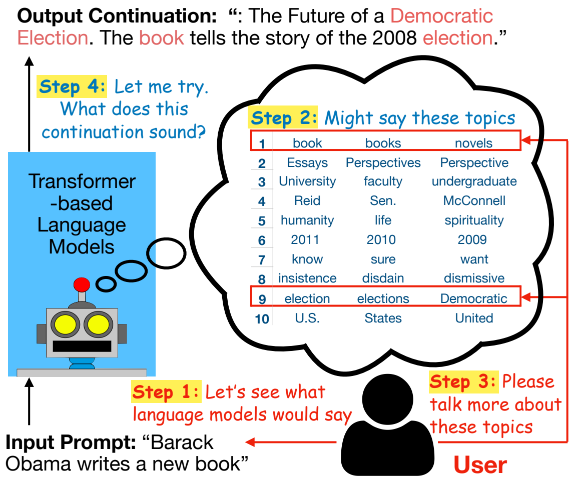

Figure 1: Given an input prompt, the Transformer-based LM provides $K = 10$ topics that might be mentioned next and each topic is represented by $M = 3$ words. The user could guide the generation process by choosing a subset of topics.

To address these limitations, we propose an interactive writing framework that provides a set of topics and guides the text generation by the user-chosen topics. The topic options are generated dynamically based on the input prompt to pro-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2601–2611

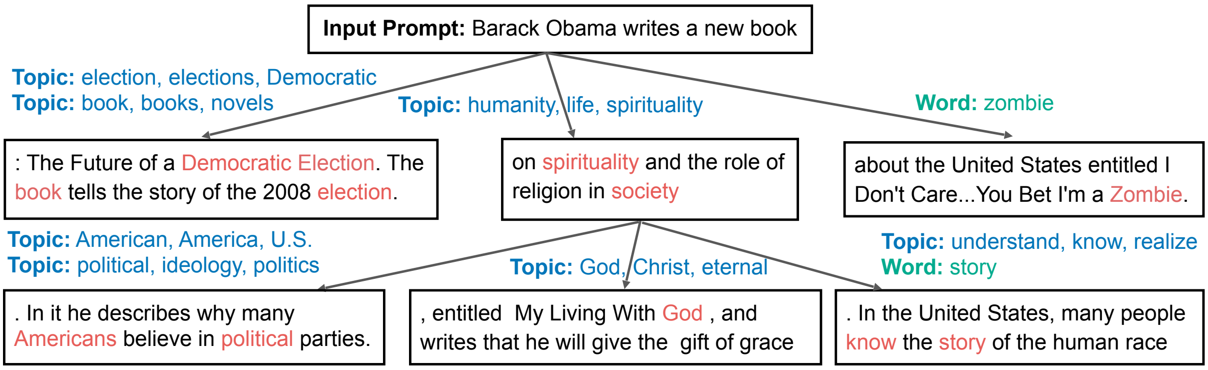

Figure 2: Examples of our generated options and continuations. We highlight the words in the continuation that are related to the chosen topics or to the specified word.

vide fine-grained control, and our models are self-supervised without the need to define the attributes or collect annotations. As depicted in Figure 1, a user can peek at the most probable K topics (shown as bags of words) appearing after the input prompt and control the generation by choosing the topics.

In Figure 2, we compare multiple generated sentences conditioned on different chosen topic(s) or specified word(s). For example, if the user chooses a topic about *humanity*, *life*, and *spirituality*, our system continues the input prompt "*Barack Obama writes a new book*" with "*on spirituality and the roles of religion in society*". Then, we can use the generated text as the new input prompt and update the set of topics to include other more relevant topics such as *God*, *Christ*, and *eternal*. The process can be repeated to create a plot tree.

A user can also control the generation by specifying word(s) if the user wants to see the words that are not in the topic list or seeks a transition to a word that is not directly related to the input prompt. For example, a user can ask our system to generate a sentence about *zombie*. Consequently, the continuation of *"Barack Obama writes a new book"* becomes *"about the United States entitled I Don't Care...You Bet I'm a Zombie"*.

The system is realized by two components: an option generator and a conditional text generator. Given a prompt, the option generator suggests a set of K topics. After a user chooses a subset of the topics and specifies some words, the embedding of every word or topic will guide the conditional text generator to produce the continuation that is both consistent with the existing prompt and relevant to the chosen topics and words.

Both components are self-supervised and use pretrained GPT2 models (Radford et al., 2019) to encode the input prompt. During training, the option generator predicts the cluster centers of future words, which are in the continuation of the prompt, based on the contextualized embeddings from GPT2. The conditional text generator fine-tunes GPT2 to predict the next words given the prompt and a few subsequent words. Since both components' input and output only come from the prompt and its continuation, training the system only requires a raw corpus, word tokenizers, and a list of stop words. This makes the proposed method suitable for open-domain story generation and easily being fine-tuned for a specific domain.

In experiments, we demonstrate that our system recommends high-quality topics and often generate sentences that follow the chosen topics. We compare our option generator with global topic models such as LDA (Blei et al., 2001) or local topic models such as clustering the words in the input prompt. The results show that the proposed method generates significantly more topics that are plausible and promote the narrative. Moreover, we compare our conditional text generator with PPLM (Plug and Play Language Models) (Dathathri et al., 2020) and demonstrate that our generation is more fluent and relevant to the chosen topics. Our code is available at `https://github.com/iesl/interactive_LM`.

2 Method

The proposed framework consists of two components: option generator and conditional text generator. In Figure 3, we illustrate the two components and their interaction. First, given the prompt $x_1, ..., x_I$ inputted by a user, the option generator at the bottom of the figure outputs K topics. After the user chooses two topics about *book* and *election* and specifies one extra word *story*, the topics

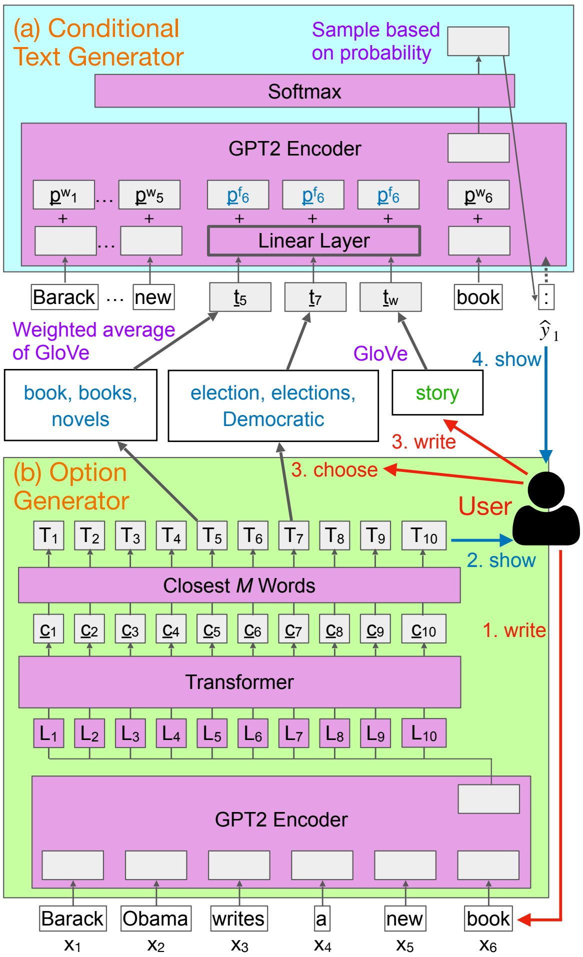

Figure 3: Our model architectures for (a) conditional text generator and (b) option generator. During testing, the information flows from the bottom to the top.

and word are passed to our text generator as the generation guidance. Accordingly, the generator continues to write the next token $\hat{y}_1$.[1]

In the following subsections, we introduce our model designs and the way to train each component. More implementation details are described in the appendix.

2.1 Option Generator

When we do not have labeled attributes in a corpus, we can create options by clustering all the words in a corpus into topics (Tu et al., 2019). The clustering could be done by topic modeling approaches such as LDA (Blei et al., 2001). The resulting topics are static (i.e., the clustering is performed globally without considering the prompt). However, the prompt might have a narrow focus and the related words of interest are all clustered into a single topic.

A simple remedy is to cluster only the words in the prompt rather than all the words in the corpus. The topics are created dynamically and locally given a prompt and can capture more fine-grained aspects in the continuations. However, the topics derived from the prompt might provide less inspiration because the users have seen the prompt. Another major drawback of the approach is that the generated topics might encourage the LM to generate repetitive sentences or make a narrative circle inside a loop.

Motivated by the challenges, we propose an option generator that predicts the cluster centers based on the prompt instead of clustering the words in the prompt during testing.

2.1.1 Model Prediction

The goal of our option generator is to predict the K cluster centers of words in the possible continuations and use the cluster centers as the topics user could choose from. As in Figure 3 (b), the option generator uses GPT2 to encode the input prompt $x_1, ..., x_I$ and passes the output embedding to K different linear layers $L_1, ..., L_K$. To model the dependency of clusters, a Transformer (Vaswani et al., 2017) takes the K embeddings as input and predicts the cluster centers $\underline{c}_1, ...\underline{c}_K$ in GloVe (Pennington et al., 2014) space. During testing, each predicted cluster center is normalized by its L2 norm, and we use the M closest words in the normalized GloVe space to represent the topic T_i, which users can choose.

We choose to learn the cluster centers in GloVe space rather than GPT2 or BERT (Devlin et al., 2019) space because the non-contextualized word embeddings are easier to visualize. Users can easily understand the meaning of a cluster center by seeing nearby words. We normalize GloVe space in this work to make the squared L2 distance equal to twice the cosine distance between two embeddings.

Our architecture is similar to the one in Chang et al. (2021), but we use a pretrained GPT2 encoder rather than train a BERT-like Transformer from scratch. Another difference is that we ignore the connection between the second Transformer and the output of GPT2 to save GPU memory for handling a longer input prompt.

---

[1] The framework is flexible. For example, the GPT2 encoders in the two components could be shared. Besides topics, the option generator could be extended to predict likely attributes in the continuation such as positive sentiment and event frames (Tu et al., 2019) if the corresponding label data are available in the training corpus.

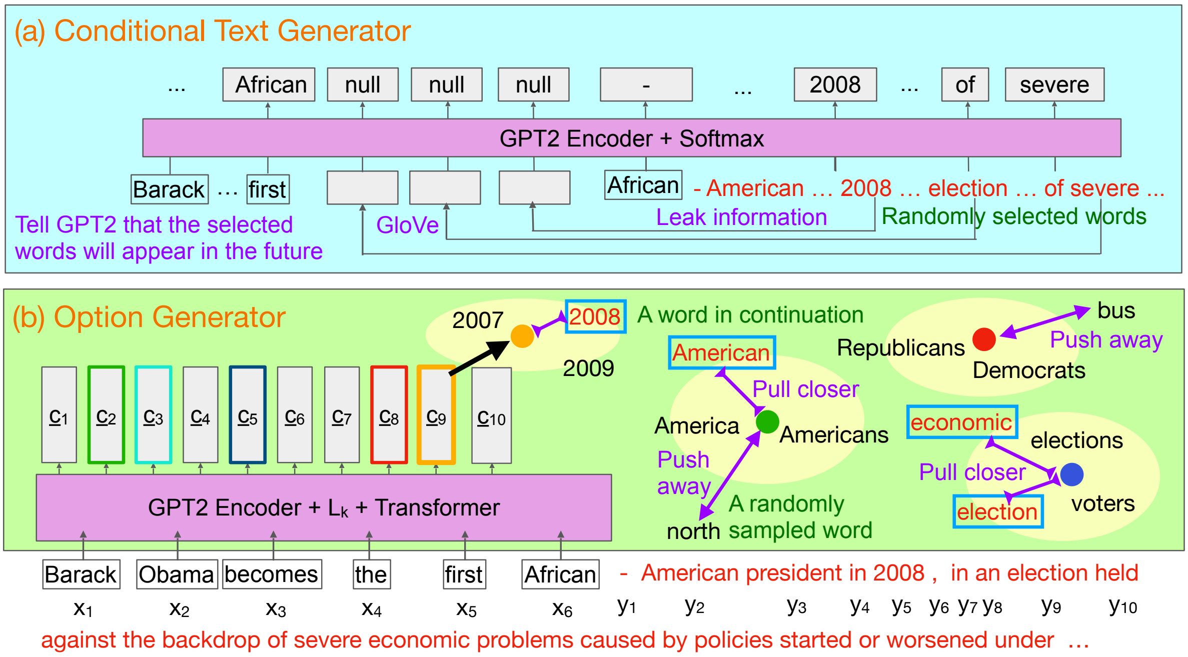

Figure 4: Training our two components using the same sentence. (a) We randomly pick $n = 3$ words in the actual continuation as our conditions for the text generator, and the null labels mean their predicted probabilities are ignored in our loss. (b) We visualize 5 out of $K = 10$ generated topics in a normalized GloVe space. Red words are the ones that appear in the continuation and pull the nearby cluster centers closer during training.

2.1.2 Model Training

In Figure 4 (b), we visualize our training procedure. For each input prompt in the training corpus, we run a forward pass through the Transformers and get predicted cluster centers $\underline{c}_1, ...\underline{c}_K$. Next, we collect 50 words in the continuation (except stop words) as positive examples and match the words with cluster centers as in the E-step of the EM algorithm (Dempster et al., 1977). We minimize the distances between the centers and their nearby positive examples by backpropagating the gradients through the matching and updating our Transformer models. Furthermore, we randomly sample some words as negative examples and maximize the distances between the cluster centers and their nearby embeddings from negative examples.

Using Figure 4 (b) as an example, the orange cluster center is pulled closer toward the embedding of *2008*, which appears in the continuation. The green cluster center is pushed away from the embedding of *north*, a randomly sampled word. Since each output embedding $\underline{c}_k$ is pulled by only the nearby embeddings of words in the continuation, the output embedding will naturally become the cluster center of the nearby continuation word embeddings. Notice that the related topics like *Democrats* and *Republicans* are not observed in the prompt and continuation, but our model can predict a red cluster center close to them because the model can learn from other similar input prompts whose continuation mentions words like *Democrats*.

Chang et al. (2021) discover that non-negative sparse coding (NNSC) (Hoyer, 2002) could encourage the Transformers to predict more diverse and relevant topics compared with Kmeans, so we adopt NNSC as our clustering loss, and its formulation could be found in Chang et al. (2021).

2.2 Conditional Text Generator

After the user chooses topic(s) or specifies word(s), each topic or word is converted to a GloVe embedding. The component aims to generate the text given the input prompt and the GloVe embeddings of the topics or words we prefer to see in the continuation.

Users only see the M words closest to the kth predicted cluster center $\underline{c}_k$ from our option generator, so we compute the kth topic embedding as

$$\underline{t}_k = \frac{\sum_{m=1}^{M} \cos(\underline{e}^w_m, \underline{c}_k)\underline{e}^w_m}{|| \sum_{m=1}^{M} \cos(\underline{e}^w_m, \underline{c}_k)\underline{e}^w_m ||}, \qquad (1)$$

where $\underline{e}^w_m$ is the normalized GloVe embedding of the mth closet word and $\cos(\underline{e}^w_m, \underline{c}_k)$ is the cosine similarities between the mth word embedding and the embedding $\underline{c}_k$.

2.2.1 Model Prediction

During testing, the topic embeddings $\underline{t}_k$ or embedding of the specified words are inserted into GPT2 encoder before x_I, the last word piece in the prompt. The inserted embeddings nudge the GPT2 to generate the sentences containing the desired words with a higher probability.

As Figure 3 (a) shows, the GloVe embeddings are first passed through a linear layer to make their dimension become the same as the hidden state size of GPT2. Then, the transformed embeddings are added with special positional embeddings $\underline{p}_I^f$, which are different from those for the prompt $\underline{p}_i^w$. The special positional embedding tells GPT2 that the inserted embeddings have a different meaning and where the conditional generation starts.

The GPT2 encoder's output goes through a softmax layer, which computes the probability of each token being observed as the first word piece in the continuation y_1. We adopt top-k sampling (Fan et al., 2018), which reduces the chance of sampling words with low probability, to pick the next word, and autoregressively sample one token $\widehat{y}_o$ at a time to generate the continuation $\widehat{y}_1, ..., \widehat{y}_O$.

2.2.2 Model Training

We train the generator using the continuation of a prompt and some randomly selected non-stop words in the continuation as its generation conditions. Since the continuation contains the randomly-selected words, the generator would be heavily penalized if it ignores the conditions by assigning low probabilities to the selected words in all the continuation positions.

An example is illustrated in Figure 4 (a). Given an input prompt in the training set, we randomly pick a number n from 0 to K and sample n words from the next $O = 25$ words (except stop words). Next, the normalized GloVe embeddings of n words are inserted to the GPT2 encoder before the last word piece in the prompt, and we ignore the output probabilities corresponding to the inserted positions during training. To speed up the training, we conduct the future word insertion in multiple positions of each training text sequence.

We insert the future words just before the text that might contain the words rather than at the beginning as in the classic seq2seq model, because we do not want the model to learn to generate the continuation based on the future topics that have not yet be specified by the users (e.g., The GPT2 should not know that it will see *election* in the future when it learns to generate *Barack Obama ...* during training).

By allowing the LM to see the upcoming words earlier, we leak partial label information to the LM input. Consequently, GPT2 learns to utilize the information and generate the sentence containing the desired words to achieve a lower perplexity loss. Notice that the training method allows us to specify our topical preference without significantly scarifying generation efficiency and fluency, but it cannot guarantee to generate all the desired topics, especially when we specify multiple ones.

One concern of the method is that the LM cannot see all possible sets of topics or words users might specify during training. Besides, each GloVe embedding used to supervise LM comes from a single word, but we ask the LM to condition on average GloVe embedding of the top M words during testing. Nevertheless, we observe that the LM is often able to generalize well in our experiments because similar words have similar GloVe embeddings, lots of training instances could be easily prepared by the self-supervised method, and our option generator usually provides the topics mentioned in the continuation in our training corpus.

3 Experiments

We evaluate two components separately, and both evaluations include automated metrics and human judgment. Throughout the evaluation, the number of topics $K = 10$ and the length of generations is 50 word pieces. We find that fixing $K = 10$ works well in our experiments. If the possible continuations cover more than 10 topics, our option generator tends to output the important topics. If they cover fewer topics, our option generator tends to output the related topics that are not explicitly mentioned in the prompt or the duplicated topics. More experiment setup details could be found in the appendix.

3.1 Datasets

We use 90% of English Wikipedia 2016 as our training set for both components, 5% as our validation set to determine the hyperparameters such as the number of epochs, and the remaining 5% as our test set to perform the automated evaluation.

For human evaluation, we collect labels from Amazon Mechanical Turk (MTurk). We randomly sample sentences from the training set of STS benchmark (STSb) (Cer et al., 2017) as our input prompts. Compared with Wikipedia, the sentences from STSb are easier to understand for annotators because a large portion of sentences in Wikipedia involves terminologies, depends on a longer context, or might even just be a list of names.

In STSb, we sample 24 sentences as our prompts, and each method generates one continuation for each input prompt. Each generated continuation or topics will be scored by three different workers.

3.2 Option Generator Evaluation

We evaluate the topics from different option generators by judging whether the topics will appear in the continuation and whether the topics would promote the narrative. The goal is to have topics that are relevant and provide new information. The topics that are too similar to the prompt words might be redundant and not helpful because the users have already seen the prompt.

3.2.1 Automatic Evaluation Metrics

- **Sim**: If the generated topics T can help users to write the continuation, the embedding of every non-stop word in the actual continuation should be similar to the embeddings of a generated topic. Thus, we compute

  $$\mathrm{Sim}(\bar{Y}, T) = \sum_{o=1}^{O'} \max_{k=1}^{K} (\underline{t}_k)^T \underline{e}_o^{\bar{y}}, \qquad (2)$$

  where $\bar{Y} = \{\bar{y}_o\}_{o=1}^{O'}$ is a set of non-stop words in the continuation and $O' = 25$. $\underline{t}_k$ is the normalized embedding of kth topic in T from equation 1 and $\underline{e}_o^{\bar{y}}$ is the oth word in $\bar{Y}$.
- **Sim Short**: When computing Sim, we use the input prompts containing around 180 words on average. To examine the topic quality at the start of writing, where the authors might need assistance the most, we also report $\mathrm{Sim}(\bar{Y}, T)$ on short input prompts (with 35 words on average).
- **Sim Diff**: The options that are helpful to users should be sufficiently different from the words in the input prompt to promote the narrative and avoid generating repeated content. Thereby, we also evaluate methods using Sim Diff = $\mathrm{Sim}(\bar{Y}, T)$ - $\mathrm{Sim}(\bar{X}, T)$, where $\bar{X} = \{\bar{x}_i\}_{i=1}^{I'}$ are the non-stop words in the input prompt.

3.2.2 Human Evaluation

Our questionnaire shows the prompt and asks which generated topics are likely to appear in a reasonable continuation and which topics promote the narrative. For each method, we report the average number of its topics that are likely to appear (L), promote the topic (TP), and both (L&TP). For example, an MTurk worker is shown three topics generated by a method given a prompt: ABC. The worker thinks A is likely to appear in the continuation and AB promote the topic. Then, L=$|\{A\}|$=1, TP=$|\{AB\}|$=2, and L&TP=$|\{A\} \cap \{AB\}|$=$|\{A\}|$=1 for this prompt.

Scope	Method	Sim	Sim Short	Sim Diff
Global	Sample	14.63	14.42	**0.16**

	Ours	7.85 ± 0.25	**6.96** ± 0.26	**6.75** ± 0.28

Table 2: Comparison of option generators using human judgment (mean ± standard error). L and TP refer to likelihood and topic promotion, respectively.

3.2.3 Option Generator Baselines

We compare our generator with two types of methods.[2] The first type performs the clustering globally and selects the most relevant topics to the input prompt from the static set of clusters. We cluster all the words into $J = 150$ topics by LDA (Blei et al., 2001) (**LDA-global**) and into $J = 1000$ topics by Kmeans on the normalized GloVe embedding space (Tu et al., 2019) (**Kmeans-global**). We also randomly sample K words from the whole vocabulary as our cluster centers (**Sample-global**).

Similar to equation 1, we find the M words with the closest embeddings to each cluster center to represent the topic and compute the topic embedding $\underline{t}_j$ as the weighted average embedding of M words in the jth topic. Among all J cluster centers, we pick the K topics with the closest $\underline{t}_j$ to the

---

[2] Another alternative is to generate many continuations and cluster the words in the generation. However, the method takes time, which might be prohibited by limited computational resources and the real-time interaction requirement.

prompt embedding, where the prompt embedding is the average embedding of all words in the input prompt.

The second type of methods discovers the K topics from the input prompt. We cluster non-stop words in the prompt using non-negative sparse coding (Hoyer, 2002) (**NNSC-local**) and Kmeans (**Kmeans-local**). We also sample K non-stop words from the prompt and call it **Sample-local**. Similar to equation 1, we represent each topic using M words and compute the weighted average of their embeddings $\underline{t}_k$ as the input of our text generator. Notice that the locally clustering methods produce similar results when the prompts come from STSb due to their short lengths, so we only test **Kmeans-local** in our human evaluation.

3.2.4 Results

In Table 1, we show that local methods generate the options more relevant to the input prompt than the global methods due to significantly higher Sim and Sim Short. Our method performs better compared to other local methods, especially in Sim Diff, which highlights the high novelty of our generated topics. The improvement on Sim Short is larger than that on Sim because our method could suggest the related topics that are not explicitly mentioned in the short prompt (e.g., *U.S.* in Figure 1).

The human evaluation results are presented in Table 2. Our method wins in terms of generating relevant topics that promote the narrative. The **Kmeans-local** performs better in L because most of the words in the input prompts could be mentioned again in the next sentence. However, it often leads to the redundant topics that are too similar to the prompt.

Table 3 compares the options generated by different methods while Table 4 compares the text generated using different option generators and text generators. More examples are presented in the appendix. In Table 3, we can see that most topics in **Kmeans-local** do not promote the narrative, which makes the generated continuation become a copy of the input prompt in Table 4. We will quantitatively evaluate the generated continuations using different option generators in the appendix. Notice that the high redundancy problem is hard to be solved by a conditional text generator because the relatedness between the prompt and the generated text is hard to be controlled (See et al., 2019b).

3.3 Conditional Text Generator Evaluation

To demonstrate our text generator's effectiveness, we use our option generator to prepare the topic embeddings and randomly select n topics as our conditions to simulate the user's choice, where n is a random number from 1 to K. The sentences generated by different methods are compared.

3.3.1 Automatic Evaluation Metrics

We match the union of $M \times K$ top words in the chosen topics with the words in the generated continuations and count the number of tokens that are matched exactly (token), the number of matched word types (word), and the number of topics that contain at least one matched word (topic) to measure the relevancy between the continuations and the chosen topics. Notice that the scores are underestimated because the generation might mention words in different morphological variations or other

Text Generation Method	Automatic Metrics						Inference Time	Human Judgement		
	Relevancy Hit			Quality				Relevancy		Fluency
	Token	Word	Topic	PPL (↓)	Dist-1	Dist-2	s (↓)	Recall	Precision	Score
PPLM	1.48	0.99	0.77	18.49	**40.29**	**80.83**	17.74	30.56 ± 2.96	56.01 ± 4.41	3.83 ± 0.13
Ours	**2.36**	**1.79**	**1.40**	**16.39**	37.98	79.65	**1.02**	**41.46** ± 3.47	**56.41** ± 4.41	**4.07** ± 0.10
GPT2	1.27	0.84	0.64	14.24	39.80	80.22	1.00	24.49 ± 2.77	48.69 ± 4.61	4.15 ± 0.11

Table 5: Comparison of conditional text generators. The numbers in Dist-1, Dist-2, Recall, and Precision are percentages. Lower perplexity (PPL) and inference time are better. The better performances between PPLM and our method are highlighted. In human evaluation, we report the mean ± standard error of each method.

words related to the topics.

The fluency of the generated text is measured using the perplexity (Serban et al., 2016) of the original GPT2 (with 345M parameters) without being fine-tuned on Wikipedia. Dist-n (Li et al., 2016) is the ratio between the number of unique n-grams and the number of all n-grams in the continuations, where n=1 or 2. Higher Dist-n implies more diverse generations. The average inference time per input prompt is also presented.

3.3.2 Human Evaluation

We present the prompt and the generated continuation and ask the worker to score the generation's fluency from 1 (not fluent at all) to 5 (very fluent). Next, we show K topics and ask which topics are mentioned in the generation. Treating the worker's choices as prediction and the topics our model conditions on as ground truth, we report the average precision and recall of the prediction.

3.3.3 Conditional Text Generator Baselines

We compare our method with **PPLM** (Plug and Play Language Models) (Dathathri et al., 2020) due to its strong performance against the weighted decoding approach from Ghazvininejad et al. (2017) when the condition is a bag of words.

The condition for **PPLM** is the union of the top M words in the chosen topics and each word's weight is neglected. We use our generation model without conditioning on any word (i.e., $n = 0$) during testing[3] as the base model of **PPLM**. We also present the performance of the base model itself as a reference to know the significance of our improvement (denoted as **GPT2**).

3.3.4 Results

Table 5 indicates that our model outperforms **PPLM** in all metrics except in Dist-1 and Dist-2. We suspect that our model generates slightly less diverse sentences in order to make the generation more relevant to the given topics.

The generation might mention a topic even if it is not chosen as a condition, so we achieve similar precision compared to **PPLM** in human evaluation. The recall of **PPLM** means that only around 30% of given topics are mentioned. The low recall indicates the difficulty of mentioning multiple randomly selected topics in the next 50 word pieces while keeping the sentence fluent. By contrast, achieving 40% on recall demonstrates the effectiveness of our conditional text generator.

Compared with **PPLM**, our model requires an additional training step but achieves low inference time and high relevancy to the given topics/words once the training is finished. The benefits make it preferable in our interactive writing application.

4 Related Work

Different interactive writing assistants provide different forms of options to let users express their preferences. The options could be manually defined classes (e.g., sentiment) (Keskar et al., 2019; Dathathri et al., 2020), semantic frames (Tu et al., 2019), or event structures such as (subject, verb, object, modifier) (Martin et al., 2018; Tambwekar et al., 2019; Ammanabrolu et al., 2020). The forms of options allow users to control the attributes of the generated text but require labels or classifiers that map the text to the attributes/options.

The options could also be a single query word at the beginning (Austin, 2019), the article title (Yan, 2016), politeness (Niu and Bansal, 2018) or specificity (See et al., 2019b) of the text, or the length of the generated sentence (Tu et al., 2019). However, the options cannot provide fine-grained control on topical directions of the generated contents.

A related research direction is the multi-stage story generation. To make a long story more coherent, recent work proposes to generate a skeleton and then generate the full text guided by

---

[3] We find the model performs similarly compared with the GPT2 with no condition during training.

the skeleton. The skeleton could be a sequence of SRL frames (Fan et al., 2019), a sequence of event structure (subject, verb, object, preposition, modifier) (Ammanabrolu et al., 2020), a story premise (Fan et al., 2018), or a story summary (Chen et al., 2019). Users can revise the skeleton to control the generated text, but the approaches assume the existence of the skeleton extractor or labels in the training corpus. Besides, the systems cannot suggest options given the partial text, which is one of the main focuses of our interactive writing assistant.

The skeleton could also be multiple keyphrases. The keyphrases are extracted based on word frequency (Ippolito et al., 2019; Tan et al., 2020; Wu et al., 2020), an off-the-shelf keyword extraction method (Peng et al., 2018; Goldfarb-Tarrant et al., 2019; Yao et al., 2019; Rashkin et al., 2020; Zhang et al., 2020), a sentence compression dataset and reinforcement learning (Xu et al., 2018), or image caption datasets and ConceptNet (Lin et al., 2020). Most of the studies focus on modeling the long-term dependency among the keyphrases and/or forcing the generation to contain the keyphrases. Instead, we focus on allowing users to determine the topical directions of the generation. Compared with conditioning on keyphrases, our interactive writing assistant is especially helpful when users do not know the exact phrases they want to see or when the given keyphrase extractor does not detect the desired topics.

5 Conclusion

We propose an interactive writing assistant that generates topic options given an input prompt and generates the continuation of the prompt given the topics chosen by a user. We decompose the framework into two components and propose a novel model for each component. The automated evaluation and human evaluation indicate that our system generates many topics that are related to but different from the prompt, and generates the sentences that are fluent and relevant to the chosen topics.

Abstract

Abstractive summarization systems generally rely on large collections of document-summary pairs. However, the performance of abstractive systems remains a challenge due to the unavailability of the parallel data for low-resource languages like Bengali. To overcome this problem, we propose a graph-based unsupervised abstractive summarization system in the single-document setting for Bengali text documents, which requires only a Part-Of-Speech (**POS**) tagger and a pre-trained language model trained on Bengali texts. We also provide a human-annotated dataset with document-summary pairs to evaluate our abstractive model and to support the comparison of future abstractive summarization systems of the Bengali Language. We conduct experiments on this dataset and compare our system with several well-established unsupervised extractive summarization systems. Our unsupervised abstractive summarization model outperforms the baselines without being exposed to any human-annotated reference summaries.[1]

1 Introduction

The process of shortening a large text document with the most relevant information of the source is known as automatic text summarization. A good summary should be coherent, non-redundant, and grammatically readable while retaining the original document's most important contents (Nenkova and McKeown, 2012; Nayeem et al., 2018). There are two types of summarizations: extractive and abstractive. Extractive summarization is about ranking important sentences from the original text. The abstractive method generates human-like sentences using natural language generation techniques. Traditionally used abstractive techniques are sentence compression, syntactic reorganization, sentence fusion, and lexical paraphrasing (Lin and Ng, 2019). Compared to extractive, abstractive summary generation is indeed a challenging task.

A cluster of sentences uses multi-sentence compression (**MSC**) to summarize into one single sentence originally called sentence fusion (Barzilay and McKeown, 2005; Nayeem and Chali, 2017b). The success of neural sequence-to-sequence (**seq2seq**) models with attention (Bahdanau et al., 2015; Luong et al., 2015) provides an effective way for text generation which has been extensively applied in the case of abstractive summarization of English language documents (Rush et al., 2015; Chopra et al., 2016; Nallapati et al., 2016; Miao and Blunsom, 2016; Paulus et al., 2018; Nayeem et al., 2019). These models are usually trained with lots of gold summaries, but there is no large-scale human-annotated abstractive summaries available for low-resource language like Bengali. In contrast, the unsupervised approach reduces the human effort and cost for collecting and annotating large amount of paired training data. Therefore, we choose to create an effective Bengali Text Summarizer with an unsupervised approach. The summary of our contributions:

- To the best of our knowledge, our **Ben**gali Text **Summ**arization model (**BenSumm**) is

the very first unsupervised model to generate abstractive summary from Bengali text documents while being simple yet robust.

- We also introduce a highly abstractive dataset with document-summary pairs to evaluate our model, which is written by professional summary writers of National Curriculum and Textbook Board (**NCTB**).[2]
- We design an unsupervised abstractive sentence generation model that performs sentence fusion on Bengali texts. Our model requires only **POS** tagger and a pre-trained language model, which is easily reproducible.

2 Related works

Many researchers have worked on text summarization and introduced different extractive and abstractive methods. Nevertheless, very few attempts have been made for Bengali Text summarization despite Bangla being the 7^{th} most spoken language.[3] Das and Bandyopadhyay (2010) developed Bengali opinion based text summarizer using given topic which can determine the information on sentiments of the original texts. Haque et al. (2017, 2015) worked on extractive Bengali text summarization using pronoun replacement, sentence ranking with term frequency, numerical figures, and overlapping of title words with the document sentences. Unfortunately, the methods are limited to extractive summarization, which ranks some important sentences from the document instead of generating new sentences which is challenging for an extremely low resource language like Bengali. Moreover, there is no human-annotated dataset to compare abstractive summarization methods of this language.

Jing and McKeown (2000) worked on Sentence Compression (**SC**) which has received considerable attention in the NLP community. Potential utility for extractive text summarization made **SC** very popular for single or multi-document summarization (Nenkova and McKeown, 2012). TextRank (Mihalcea and Tarau, 2004) and LexRank (Erkan and Radev, 2004) are graph-based methods for extracting important sentences from a document. Clarke and Lapata (2008); Filippova (2010) showed a first intermediate step towards abstractive summarization, which compresses original sentences for a summary generation. The Word-Graph based approaches were first proposed by (Filippova, 2010), which require only a POS tagger and a list of stopwords. Boudin and Morin (2013) improved Filippova's approach by re-ranking the compression paths according to keyphrases, which resulted in more informative sentences. Nayeem et al. (2018) developed an unsupervised abstractive summarization system that jointly performs sentence fusion and paraphrasing.

3 BenSumm Model

We here describe each of the steps involved in our **Ben**gali Unsupervised Abstractive Text **Summ**arization model (**BenSumm**) for single document setting. Our preprocessing step includes tokenization, removal of stopwords, Part-Of-Speech (**POS**) tagging, and filtering of punctuation marks. We use the **NLTK**[4] and **BNLP**[5] to preprocess each sentence and obtain a more accurate representation of the information.

3.1 Sentence Clustering

The clustering step allows us to group similar sentences from a given document. This step is critical to ensure good coverage of the whole document and avoid redundancy by selecting at most one sentence from each cluster (Nayeem and Chali, 2017a). The Term Frequency-Inverse Document Frequency (**TF-IDF**) measure does not work well (Aggarwal and Zhai, 2012). Therefore, we calculate the cosine similarity between the sentence vectors obtained from **ULMfit** pre-trained language model (Howard and Ruder, 2018). We use hierarchical agglomerative clustering with the ward's method (Murtagh and Legendre, 2014). There will be a minimum of 2 and a maximum of $n-1$ clusters. Here, n denotes the number of sentences in the document. We measure the number of clusters for a given document using the silhouette value. The clusters are highly coherent as it has to contain sentences similar to every other sentence in the same cluster even if the clusters are small. The following formula can measure silhouette Score:

$$\text{Silhouette Score} = \frac{(x-y)}{max(x,y)} \tag{1}$$

where y denotes mean distance to the other instances of intra-cluster and x is the mean distance to the instances of the next closest cluster.

3.2 Word Graph (WG) Construction

Textual graphs to generate abstractive summaries provide effective results (Ganesan et al., 2010). We chose to build an abstractive summarizer with a sentence fusion technique by generating word graphs (Filippova, 2010; Boudin and Morin, 2013) for the Bengali Language. This method is entirely unsupervised and needs only a **POS** tagger, which is highly suitable for the low-resource setting. Given a cluster of related sentences, we construct a word-graph following (Filippova, 2010; Boudin and Morin, 2013). Let, a set of related sentences S = $\{s_1, s_2, ..., s_n\}$, we construct a graph $G = (V, E)$ by iteratively adding sentences to it. The words are represented as vertices along with the parts-of-speech (**POS**) tags. Directed edges are formed by connecting the adjacent words from the sentences. After the first sentence is added to the graph as word nodes (punctuation included), words from the other related sentences are mapped onto a node in the graph with the same **POS** tag. Each sentence of the cluster is connected to a dummy start and end node to mark the beginning and ending sentences. After constructing the word-graph, we can generate M-shortest paths from the dummy start node to the end node in the word graph (see Figure 1).

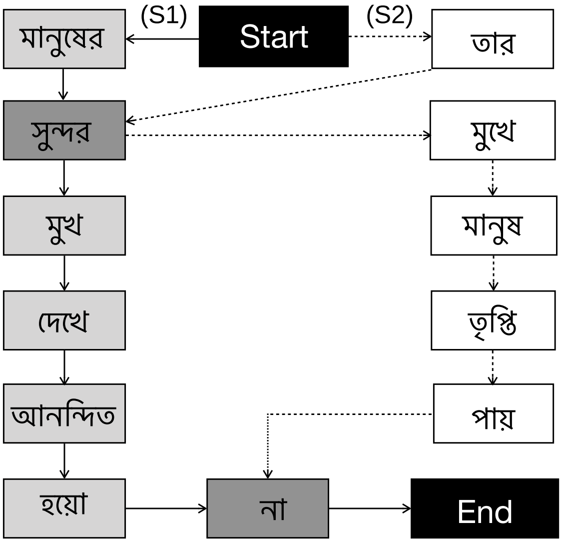

Figure 1: Sample WG of two related sentences.

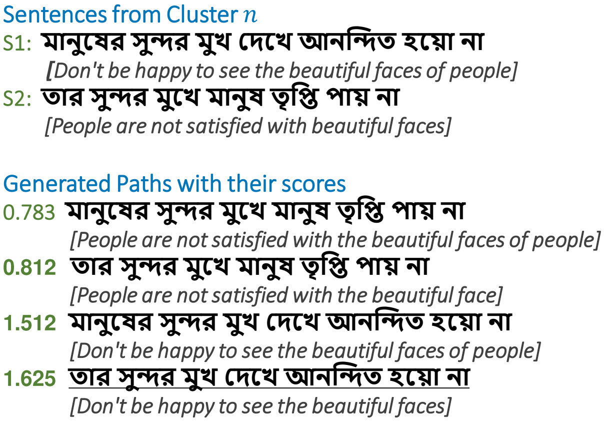
Figure 2 presents two sentences, which is one of the source document clusters, and the possible paths with their weighted values are generated using the word-graph approach. Figure 1 illustrates an example **WG** for these two sentences.



Sentences from Cluster n

S1: মানুষের সুন্দর মুখ দেখে আনন্দিত হয়ো না

[Don't be happy to see the beautiful faces of people]

S2: তার সুন্দর মুখে মানুষ তৃপ্তি পায় না

[People are not satisfied with beautiful faces]

Generated Paths with their scores

0.783 মানুষের সুন্দর মুখে মানুষ তৃপ্তি পায় না

[People are not satisfied with the beautiful faces of people]

0.812 তার সুন্দর মুখে মানুষ তৃপ্তি পায় না

[People are not satisfied with the beautiful face]

1.512 মানুষের সুন্দর মুখ দেখে আনন্দিত হয়ো না

[Don't be happy to see the beautiful faces of people]

1.625 তার সুন্দর মুখ দেখে আনন্দিত হয়ো না

[Don't be happy to see the beautiful faces]

Figure 2: Output of WG given two related sentences. The underlined sentence is the top-ranked sentence to be included in the final summary.

After constructing clusters given a document, a word-graph is created for each cluster to get abstractive fusions from these related sentences. We get multiple weighted sentences (see Figure 2) form the clusters using the ranking strategy (Boudin and Morin, 2013). We take the top-ranked sentence from each cluster to present the summary. We generate the final summary by merging all the top-ranked sentences. The overall process is presented in Figure 3. We also present a detailed illustration of our framework with an example source document in the Appendix.

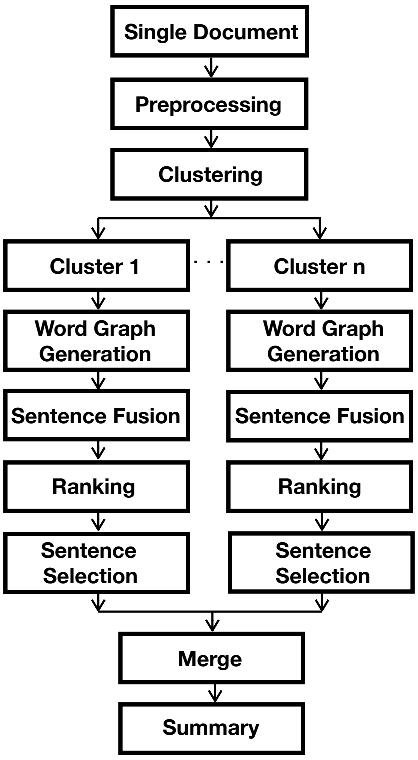


Figure 3: Overview of our **BenSumm** model.

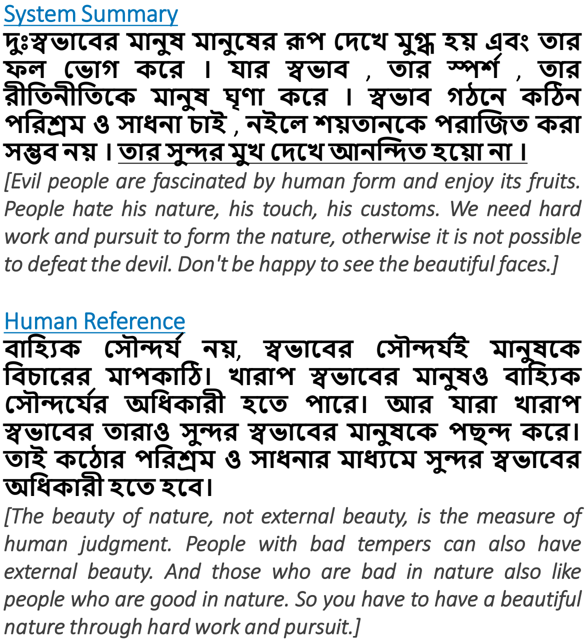

System Summary

দুঃস্বভাবের মানুষ মানুষের রূপ দেখে মুগ্ধ হয় এবং তার ফল ভোগ করে । যার স্বভাব , তার স্পর্শ , তার রীতিনীতিকে মানুষ ঘৃণা করে । স্বভাব গঠনে কঠিন পরিশ্রম ও সাধনা চাই , নইলে শয়তানকে পরাজিত করা সম্ভব নয় । তার সুন্দর মুখ দেখে আনন্দিত হয়ো না ।

[Evil people are fascinated by human form and enjoy its fruits. People hate his nature, his touch, his customs. We need hard work and pursuit to form the nature, otherwise it is not possible to defeat the devil. Don't be happy to see the beautiful faces.]

Human Reference

বাহ্যিক সৌন্দর্য নয়, স্বভাবের সৌন্দর্যই মানুষকে বিচারের মাপকাঠি। খারাপ স্বভাবের মানুষও বাহ্যিক সৌন্দর্যের অধিকারী হতে পারে। আর যারা খারাপ স্বভাবের তারাও সুন্দর স্বভাবের মানুষকে পছন্দ করে। তাই কঠোর পরিশ্রম ও সাধনার মাধ্যমে সুন্দর স্বভাবের অধিকারী হতে হবে।

[The beauty of nature, not external beauty, is the measure of human judgment. People with bad tempers can also have external beauty. And those who are bad in nature also like people who are good in nature. So you have to have a beautiful nature through hard work and pursuit.]

Figure 4: Example output of our **BenSumm** model with English translations.

4 Experiments

This section presents our experimental details for assessing the performance of the proposed **BenSumm** model.

Dataset We conduct experiments on our dataset which consists of *139* samples of human-written abstractive document-summary pairs written by professional summary writers of the National Curriculum and Textbook Board (**NCTB**). The NCTB is responsible for the development of the curriculum and distribution of textbooks. The majority of Bangladeshi schools follow these books.[6] We collected the human written document-summary pairs from the several printed copy of NCTB books. The overall statistics of the datasets are presented in Table 1. From the dataset, we measure the *copy rate* between the source document and the human summaries. It's clearly visible from the table that our dataset is highly abstractive and will serve as a robust benchmark for this task's future works. Moreover, to provide our proposed framework's effectiveness, we also experiment with an extractive dataset **BNLPC**[7] (Haque et al., 2015). We remove the abstractive sentence fusion part to compare with the baselines for the extractive evaluation.

	NCTB [Abstractive]	**BNLPC [Extractive]**
Total #Samples	139	200
Source Document Length	91.33	150.75
Human Reference Length	36.23	67.06
Summary Copy Rate	**27%**	**99%**

Table 1: Statistics of the datasets used for our experiment. Length is expressed as Avg. #tokens.

NCTB [Abstractive]	**R-1**	**R-2**	**R-L**
Random Baseline	9.43	1.45	9.08
GreedyKL	10.01	1.84	9.46
LexRank	10.65	1.78	10.04
TextRank	10.69	1.62	9.98
SumBasic	10.57	1.85	10.09
BenSumm [Abs] (*ours*)	**12.17**	**1.92**	**11.35**
BNLPC [Extractive]	**R-1**	**R-2**	**R-L**
Random Baseline	35.57	28.56	35.04
GreedyKL	48.85	43.80	48.55
LexRank	45.73	39.37	45.17
TextRank	60.81	**56.46**	60.58
SumBasic	35.51	26.58	34.72
BenSumm [Ext] (*ours*)	**61.62**	55.97	**61.09**

Table 2: Results on our **NCTB** Dataset and **BNLPC**.

Automatic Evaluation We evaluate our system (**BenSumm**) using an automatic evaluation metric ROUGE F1 (Lin, 2004) without any limit of words.[8] We extract 3-best sentences from our system and the systems we compare as baselines. We report unigram and bigram overlap (ROUGE-1 and ROUGE-2) to measure informativeness and the longest common subsequence (ROUGE-L) to measure the summaries' fluency. Since ROUGE computes scores based on the lexical overlap at the surface level, there is no difference in implementation for summary evaluation of the Bengali language.

Baseline Systems We compare our system with various well established baseline systems like **LexRank** (Erkan and Radev, 2004), **TextRank** (Mihalcea and Tarau, 2004), **GreedyKL** (Haghighi and Vanderwende, 2009), and **SumBasic** (Nenkova and Vanderwende, 2005). We use an open source implementation[9] of these summarizers and adapted it for Bengali language. It is important to note that these summarizers are completely extractive and

Bengali Text Documents Summarizer

Bengali Text:

মানুষের সুন্দর মুখ দেখে আনন্দিত হয়ো না। স্বভাবে সে সুন্দর নয়, দেখতে সুন্দর হলেও তার স্বভাব, তার স্পর্শ, তার রীতিনীতিকে মানুষ ঘৃণা করে। দুঃস্বভাবের মানুষ মানুষের হৃদয়ে জ্বালা ও বেদনা দেয়। তার সুন্দর মুখে মানুষ তৃপ্তি পায় না। অবোধ লোকেরা মানুষের রূপ দেখে মুগ্ধ হয় এবং তার ফল ভোগ করে। যার স্বভাব মন্দ, সে নিজেও দুষ্ক্রিয়াশীল, মিথ্যাবাদী, দুর্মতিকে ঘৃণা করে। মানুষ নিজে স্বভাবে সুন্দর না হলেও সে স্বভাবের সৌন্দর্যকে ভালোবাসে। স্বভাব গঠনে কঠিন পরিশ্রম ও সাধনা চাই, নইলে শয়তানকে পরাজিত করা সম্ভব নয়।

Extractive Summary:

স্বভাবে সে সুন্দর নয়, দেখতে সুন্দর হলেও তার স্বভাব, তার স্পর্শ, তার রীতিনীতিকে মানুষ ঘৃণা করে। দুঃস্বভাবের মানুষ মানুষের হৃদয়ে জ্বালা ও বেদনা দেয়। অবোধ লোকেরা মানুষের রূপ দেখে মুগ্ধ হয় এবং তার ফল ভোগ করে।

Abstractive Summary:

দুঃস্বভাবের মানুষ মানুষের রূপ দেখে মুগ্ধ হয় এবং তার ফল ভোগ করে । যার স্বভাব , তার স্পর্শ , তার রীতিনীতিকে মানুষ ঘৃণা করে । স্বভাব গঠনে কঠিন পরিশ্রম ও সাধনা চাই , নইলে শয়তানকে পরাজিত করা সম্ভব নয় । তার সুন্দর মুখ দেখে আনন্দিত হয়ো না ।

Figure 5: Interface of our Bengali Document Summarization tool. For an input document D with N sentences, our tool can provide both extractive and abstractive summary for the given document. The translations of both the document and summary are provided in the Appendix (see Figure 6).

designed for English language. On the other hand, our model is unsupervised and abstractive.

Results We report our model's performance compared with the baselines in terms of F1 scores of R-1, R-2, and R-L in Table 2. According to Table 2, our abstractive summarization model outperforms all the extractive baselines in terms of all the ROUGE metrics even though the dataset itself is highly abstractive (reference summary contains almost 73% new words). Moreover, we compare our extractive version of our model **BenSumm** without the sentence fusion component. We get better scores in terms of R1 and RL compared to the baselines. Finally, we present an example of our model output in Figure 4. Moreover, We design a Bengali Document Summarization tool (see Figure 5) capable of providing both extractive and abtractive summary for an input document.[10]

Human Evaluation Though ROUGE (Lin, 2004) has been shown to correlate well with human judgments, it is biased towards surface level lexical similarities, and this makes it inappropriate for the evaluation of abstractive summaries. Therefore, we assign three different evaluators to rate each summary generated from our abstractive system (*BenSumm [Abs]*) considering three different aspects, i.e., Content, Readability, and Overall Quality. They have evaluated each system generated summary with scores ranges from 1 to 5, where 1 represents very poor performance, and 5 represents very good performance. Here, content means how well the summary can convey the original input document's meaning, and readability represents the grammatical correction and the overall summary sentence coherence. We get an average score of **4.41**, **3.95**, and **4.2** in content, readability, and overall quality respectively.

5 Conclusion and Future Work

In this paper, we have developed an unsupervised abstractive text summarization system for Bengali text documents. We have implemented a graph-based model to fuse multiple related sentences, requiring only a **POS** tagger and a pre-trained language model. Experimental results on our proposed dataset demonstrate the superiority of our approach against strong extractive baselines. We design a Bengali Document Summarization tool to provide both extractive and abstractive summary of a given document. One of the limitations of our model is that it cannot generate new words. In the future, we would like to jointly model multi-sentence compression and paraphrasing in our system.

Acknowledgments

We want to thank all the anonymous reviewers for their thoughtful comments and constructive suggestions for future improvements to this work.

From Toxicity in Online Comments to Incivility in American News: Proceed with Caution

Abstract

The ability to quantify incivility online, in news and in congressional debates, is of great interest to political scientists. Computational tools for detecting online incivility for English are now fairly accessible and potentially could be applied more broadly. We test the Jigsaw Perspective API for its ability to detect the degree of incivility on a corpus that we developed, consisting of manual annotations of civility in American news. We demonstrate that toxicity models, as exemplified by Perspective, are inadequate for the analysis of incivility in news. We carry out error analysis that points to the need to develop methods to remove spurious correlations between words often mentioned in the news, especially identity descriptors and incivility. Without such improvements, applying Perspective or similar models on news is likely to lead to wrong conclusions, that are not aligned with the human perception of incivility.

1 Introduction

Surveys of public opinion report that most Americans think that the tone and nature of political debate in this country have become more negative and less respectful and that the heated rhetoric by politicians raises the risk for violence (Center, 2019). These observations motivate the need to study (in)civility in political discourse in all spheres of interaction, including online (Ziegele et al., 2018; Jaidka et al., 2019), in congressional debates (Uslaner, 2000) and as presented in news (Meltzer, 2015; Rowe, 2015). Accurate automated means for coding incivility could facilitate this research, and political scientists have already turned to using off-the-shelf computational tools for studying civility (Frimer and Skitka, 2018; Jaidka et al., 2019; Theocharis et al., 2020).

Computational tools however, have been developed for different purposes, focusing on detecting language in online forums that violate community norms. The goal of these applications is to support human moderators by promptly focusing their attention on likely problematic posts. When studying civility in political discourse, it is primarily of interest to characterize the overall civility of interactions in a given source (i.e., news programs) or domain (i.e., congressional debates), as an average over a period of interest. Applying off-the-shelf tools for toxicity detection is appealingly convenient, but such use has not been validated for any domain, while uses in support of moderation efforts have been validated only for online comments.

We examine the feasibility of quantifying incivility in the news via the Jigsaw Perspective API, which has been trained on over a million online comments rated for toxicity and deployed in several scenarios to support moderator effort online[1]. We collect human judgments of the (in)civility in one month worth of three American news programs. We show that while people perceive significant differences between the three programs, Perspective cannot reliably distinguish between the levels of incivility as manifested in these news sources.

We then turn to diagnose the reasons for Perspective's failure. Incivility is more subtle and nuanced than toxicity, which includes identity slurs, profanity, and threats of violence along other unacceptable incivility. In the range of civil to borderline civil human judgments, Perspective gives noisy predictions that are not indicative of the differences in civility perceived by people. This finding alone suggests that averaging Perspective scores to characterize a source is unlikely to yield meaningful results. To pinpoint some of the sources of the noise in predictions, we characterize individual words as likely triggers of errors in Perspective or sub-error triggers that lead to over-prediction of toxicity.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2620–2630
April 19 - 23, 2021.

We discover notable anomalies, where words quite typical in neutral news reporting are confounded with incivility in the news domain. We also discover that the mention of many identities, such as Black, gay, Muslim, feminist, etc., triggers high incivility predictions. This occurs despite the fact that Perspective has been modified specifically to minimize such associations (Dixon et al., 2018a). Our findings echo results from gender debiasing of word representations, where bias is removed as measured by a fixed definition but remains present when probed differently (Gonen and Goldberg, 2019). This common error—treating the mention of identity as evidence for incivility—is problematic when the goal is to analyze American political discourse, which is very much marked by us-vs-them identity framing of discussions. These findings will serve as a basis for future work in debiasing systems for incivility prediction, while the dataset of incivility in American news will support computational work on this new task.

Our work has implications for researchers of language technology and political science alike. For those developing automated methods for quantifying incivility, we pinpoint two aspects that require improvement in future work: detecting triggers of civility overprediction and devising methods to mitigate the errors in prediction. We propose an approach for a data-driven detection of error triggers; devising mitigation approaches remain an open problem. For those seeking to contrast civility in different sources, we provide compelling evidence that state-of-the-art automated tools are not appropriate for this task. The data and (in)civility ratings would be of use to both groups as test data for future models for civility prediction[2].

2 Related Work

2.1 Datasets for Incivility Detection

Incivility detection is a well-established task, though it is not well-standardized, with the degree and type of incivility varying across datasets.

Hate speech, defined as speech that targets social groups with the intent to cause harm, is arguably the most widely studied form of incivility detection, largely due to the practical need to moderate online discussions. Many Twitter datasets have been collected, of racist and sexist tweets (Waseem and Hovy, 2016), of hateful and offensive tweets (Davidson et al., 2017), and of hateful, abusive, and spam tweets (Founta et al., 2018). Another category of incivility detection that more closely aligns with our work is toxicity prediction. Hua et al. (2018) collected a dataset for toxicity identification in online comments on Wikipedia talk pages. They defined toxicity as comments that are rude, disrespectful, or otherwise likely to make someone leave a discussion. All these datasets are built for social media platforms using either online comments or tweets. We work with American news. To verify if Perspective can reproduce human judgments of civility in this domain, we collect a corpus of news segments annotated for civility.

2.2 Bias in Incivility Detection

Models trained on the datasets described above associate the presence of certain descriptors of people with incivility Hua et al. (2018). This bias can be explained by the distribution of words in incivility datasets and the fact that systems are not capable of using context to disambiguate between civil and uncivil uses of the word, instead associating the word with the dominant usage in the training data.

To mitigate this bias, Jigsaw's Perspective API was updated, and model cards (Mitchell et al., 2019) were released for the system to show how well the system is able to predict toxicity when certain identity words are mentioned in a text. Simple templates such as "I am <IDENTITY>" were used to measure the toxicity associated with identity words. More recently, many more incorrect associations with toxicity were discovered. Prabhakaran et al. (2019) found that Perspective returned a higher toxicity score when certain names are mentioned, and Hutchinson et al. (2020) found that this was also the case for words/phrases representing disability. "I am a blind person" had a significantly higher toxicity score than "I am a tall person". We show that when measured with different templates, the bias that was mitigated in Perspective still manifests. Further, we propose a way to establish a reference set of words and then find words associated with markedly higher toxicity than the reference. This approach reveals a larger set of words which do not lead to errors but trigger uncommonly elevated predictions of toxicity in the lower ranges of the toxicity scale.

Waseem and Hovy (2016) found that the most common words in sexist and racist tweets in their corpus are "not, sexist, #mkr, women, kat" and

---

[2] Available at https://github.com/anushreehede/incivility_in_news

"islam, muslims, muslim, not, mohammed". Any system trained on this dataset would likely learn these correlations with the frequent words as well, and computational methods to prevent this are yet to be developed.

Studies have shown that African American English is more likely to be labeled as toxic by both annotators and systems due to differences in dialect (Sap et al., 2019; Xia et al., 2020; Davidson et al., 2019). Our work does not involve AAE but does reveal how words quite common in news reporting can be erroneously associated with incivility.

3 Data Collection for Incivility in News

We study the following American programs: PBS NewsHour, MSNBC's The Rachel Maddow Show and Hannity from FOX News. For brevity, we use the network to refer to each source: PBS, MSNBC, and FOX, in the following discussions. These sources are roughly representative of the political spectrum in American politics, with NewsHour being Left-Center and MSNBC and FOX with strong left and right bias respectively. These are generally one-hour shows, with about 45 minutes of content when commercial breaks are excluded.

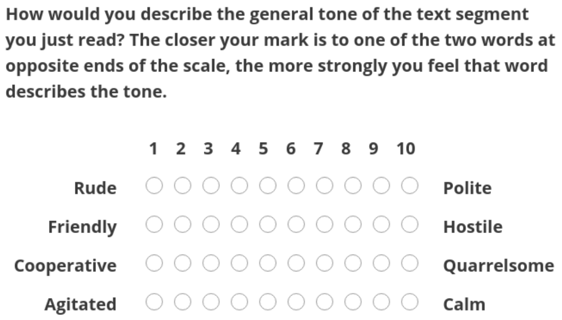
The transcripts, which provide speaker labels and turns, are from February 2019. We take only the days when all three shows aired, and we had transcripts, for a total of 51 transcripts.

We analyze the programs on two levels with the help of paid research assistants paid $15 per hour. All of them are undergraduate students in non-technical majors at the University of Pennsylvania. In Pass I, we ask a single rater to read through a transcript and identify speaker turns that appear particularly uncivil or notably civil. We characterize the programs according to the number of uncivil segments identified in each transcript.[3]

After that, in Pass II, a research assistant chose a larger snippet of about 200 words that includes the selection identified as notably uncivil (and respectively civil), providing more context for the initially selected speaker turns. We also selected several snippets of similar length at random but not overlapping with the civil and uncivil snippets. Each of these snippets, 219 it total, was then rated for perceived civility by two raters, neither of whom participated in the initial selection of content. The raters did not know why a snippet that they were rating was selected. We choose to annotate such snippets, corresponding to about a minute of show content, to ensure sufficient context is available to make meaningful judgments about the overall tone of presentation. Table 1 gives an overview of number of Uncivil, Civil and Random speaker turns around which longer snippets were selected for fine-grained annotation of incivility. The largest number of civil turns was found in PBS and most uncivil turns were identified in FOX.

Show	U	C	R	Overall	Avg Len	Vocab
FOX	81	12	23	116	201.0	3960
MSNBC	13	23	8	44	209.6	1763
PBS	11	31	17	59	216.4	2627
Overall	105	66	48	219	206.9	5962

Table 1: Number of Pass II snippets, separated by show and Pass I class: U(ncivil), C(ivil) and R(andom), along with average length of the snippets in words and the size of the vocabulary (unique words).



How would you describe the general tone of the text segment you just read? The closer your mark is to one of the two words at opposite ends of the scale, the more strongly you feel that word describes the tone.

	1	2	3	4	5	6	7	8	9	10	
Rude	○	○	○	○	○	○	○	○	○	○	Polite
Friendly	○	○	○	○	○	○	○	○	○	○	Hostile
Cooperative	○	○	○	○	○	○	○	○	○	○	Quarrelsome
Agitated	○	○	○	○	○	○	○	○	○	○	Calm

Figure 1: Annotation interface

Snippets were presented for annotation in batches of 15. Each batch had a mix of snippets from each of the programs, displayed in random order. The annotators read each snippet and rated it on a 10 point scale in four dimensions used in prior work to assess civility in news (Mutz and Reeves, 2005): Polite/Rude, Friendly/Hostile, Cooperative/Quarrelsome and Calm/Agitated. The dimensions appeared in random order and alternated which end of the dimension appeared on the left and which on the right, prompting raters to be more thoughtful in their selection and making it difficult to simply select the same value for all. A screenshot of the interface is shown in Figure 1.

The composite civility score is then obtained by first reversing the ratings to account for the alter-

---

[3] For this first analysis of incivility, we pre-selected uncivil segments, to ensure that they are well represented in the data. Incivility is rare, so a random sample of snippets will contain considerably fewer clearly uncivil snippets. We are currently augmenting the dataset with data from later months, with segments for annotation drawn from randomly selected timestamps, giving a more representative sample of the typical content that appears in the show.

nations of the ends for each dimension, such that all ratings result in small ratings for the civil ends of the scale (Polite, Friendly, Cooperative, Calm) and high values for the uncivil ends of the scales. The four scores were averaged for each annotator. Finally, the scores for the two annotators are averaged to obtain a civility score for each snippet, ranging between 1 and 10, where 1 is the most civil and 10 is the most uncivil possible.

4 Annotator Agreement

Here we briefly discuss the annotator agreement on the perceived incivility. We characterize the agreement on the transcript level in terms of the civil and uncivil speaker turns flagged in Pass I and on the text snippet level in terms of correlations and absolute difference in the scores assigned by a pair of raters in Pass II.

Pass I selection of turns was made by one person, but we are still able to glean some insights about the validity of their selection from analyzing the ratings of Pass II snippets. The Pass I selection can be construed as a justification for the score assigned in Pass II, similar to other tasks in which a rationale for a prediction has to be provided (DeYoung et al., 2020). Figure 2 shows the distribution of scores for the 200-word snippets that were selected around the initial 40-50-word speaker turns deemed notably civil, uncivil or that were randomly chosen. The distribution is as expected, with segments including uncivil turns almost uniformly rated as uncivil, with civility score greater than 5. According to our scale, a score of 5 would correspond to borderline civil on all dimensions or highly uncivil on at least one. Only three of the 105 snippets selected around an uncivil turn got scores a bit under 5: the remaining snippets including a rationale for incivility, were rated as uncivil with high consistency by the independent raters in Pass II.

In Pass II, each pair of annotators rated a total of 37 or 36 segments. Correlations between the composite ratings are overall high, ranging from 0.86 to 0.65 per pair. For only one of the six pairs, the correlation is below 0.75. The absolute difference in composite incivility scores by the two independent annotators is about 1 point.

Overall, the consistency between initial selection from the transcript and the independent ratings of civility, as well as the correlation between civility ratings of two raters for the snippets, are very good.

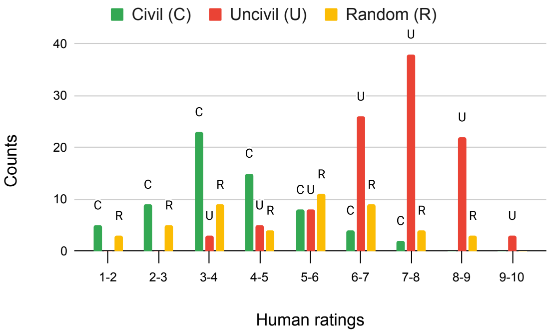


Figure 2: Distribution of snippet civility ratings (obtained in Pass II) by rationale type (obtained in Pass I). The snippets deemed to contain uncivil during Pass I are consistently rated as highly uncivil in Pass II.

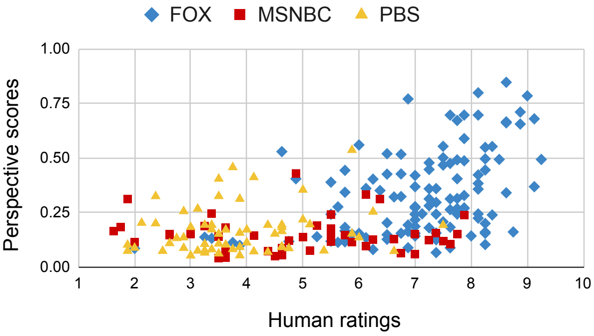

Figure 3: Scatterplot of human and Perspective scores

5 Predicting Incivility in American News

With the corpus of real-valued civility in the news, we can now compare sources according to the perception of people with those provided by Perspective. We perform the analysis on the transcript level and the snippet level. On the transcript level, we use the number of uncivil utterances marked in Pass I as the indicator of incivility. For the snippet level, we use the average composite civility ratings by the raters in Pass II. For automatic analysis, we obtain Perspective scores for each speaker turn as marked in the transcript and count the number of turns predicted as having toxicity 0.5 or greater. For snippets, we obtain Perspective scores directly, combining multiple speaker turns.

Figure 3 gives the scatter plot of civility scores per segment, from raters and Perspective. The plot reveals that Perspective is not sensitive enough to detect any differences in levels of incivility for human rating lower than six. For the higher levels of incivility, Perspective scores also increase and have better differentiation. However, the snippets from MSNBC rated as uncivil by people receive low scores. We verified that these segments are indeed uncivil, but in a sarcastic, indirect way. Portions of the turns can be seen in Table 2.

There is only one snippet with Perspective toxicity score over 0.5 for the civil to borderline civil segments from the news shows; this indicates it has good precision for binary identification of civil content. Perspective's performance in detecting binary incivility (for snippets with ratings greater than 5) is mixed. The recall for incivility is not that good, with some of these snippets receiving low toxicity scores. The trend of increasing Perspective score with increasing human-rated incivility is observed mostly on segments from FOX. The incivility in FOX appears to be more similar to that seen in online forums, with name-calling and labeling of individuals. Some examples can be seen in Table 3. The more subtle, snarky comments from MSNBC are not detected as toxic by Perspective.

However, when characterizing shows by incivility, detecting utterances that may be problematic is not of much interest. The goal is to characterize the show (daily, weekly, monthly) overall. For this, we inspect the average incivility per show on the transcript and segment level (see Table 4). On both granularities, people perceive a statistically significant difference in civility between each pair of shows, with FOX perceived as the most uncivil, followed by MSNBC and PBS as the most civil.

On the transcript level, the presence of incivility in PBS is not statistically significant. The raters chose 0.29 (fewer than one) uncivil utterances from PBS from all shows on the 17 days we study, compared with 4.5 per show for FOX. The 95% confidence interval for the mean for uncivil utterances per show covers zero for PBS, so it is not statistically significant. The lower end of the 95% confidence intervals of the mean transcript-level incivility in FOX and MSNBC is greater than zero, indicating consistent incivility in these programs.

The segment-level analysis of civility ratings reveals the same trend, with a one-point difference between PBS and MSNBC and two points between MSNBC and FOX. All of these differences are statistically significant at the 0.01 level, according to a two-sided Mann-Whitney test.

The automated analyses paint a different picture. On the transcript level, FOX is overall the most uncivil, with about 6 speaker turns per predicted to be toxic, with a Perspective score greater than 0.5. PBS appears to be the next in levels of incivility, with more than one toxic turn per transcript. For both of these shows, incivility is over-predicted, and many of the segments predicted as uncivil are civil according to the human ratings. MSNBC is predicted to have fewer than one toxic turns per transcript, under-detecting incivility. On the segment level, FOX is again assessed as the most uncivil, and PBS again appears to be more uncivil than MSNBC. On the segment level, the differences are statistically significant. Perspective incorrectly characterizes PBS as significantly more uncivil than MSNBC.

The correlation between human and Perspective incivility scores is 0.29 on the transcript and 0.51 on the segment level. Overall for broadcast news, Perspective cannot reproduce the incivility perception of people. In addition to the inability to detect sarcasm/snark, there seems to be a problem with over-prediction of the incivility in PBS and FOX.

In the next section, we seek to establish some of the drivers of over-prediction errors, characterizing individual words as possible triggers of absolute or relative over-prediction of incivility.

6 Incivility Over-prediction

Prior work has drawn attention to the fact that certain words describing people are incorrectly interpreted as triggers of incivility by Perspective, leading to errors in which a perfectly acceptable text segment containing the words would be predicted as toxic (Dixon et al., 2018b; Hutchinson et al., 2020). Their analysis, similar to other work on bias in word representations, starts with a small list of about 50 words to be analyzed in an attempt to find toxicity over-prediction triggers.

In our work, we seek to apply the same reasoning with the same goals, but in a more data-driven manner, without having to commit to a very small list of words for analysis. Given our text domain of interest (news) and the desiderata to characterize sources rather than individual text segments, we also find sub-errors, or words that do not lead to errors in toxicity prediction but have much higher than average toxicity associated with them compared to other words.

Ideally, we would like to test the full vocabulary of a new domain for (sub-)error triggers, but methods for doing so do not exist and may not be practical when the vocabulary is too large. For this reason, we sample words in a way informed by the target application, choosing words that con-

... They say that he is also going to declare the national emergency, but with this presidency, honestly, is that actually going to happen? We don't know. The White House says it's going to happen, but in this presidency, is anything really done and dusted before Fox & Friends says it's done and dusted?	7.50	0.12
... Well, he better take a few moments, I know he doesn't read, but perhaps someone could read Article I Section 7 and 8 of the Constitution. The power of appropriation lies with the Congress, not with the president. If he were trying to do this, he is basically establishing an imperial president, his majesty...	7.75	0.15
proposing fireworks for the Fourth of July. Even in D.C., it's a bold idea from the president today. Presumably this will be followed by an executive order proclaiming that from here on out, we're going to start a whole new calendar year every year on the first day of January. What? Also, he's going to declare that we're going to start a new American pastime, a ball game where one person holds a stick and that person runs around a series of bases to come home if the person with the stick hits the ball well enough and hard enough, a lot of people try to catch it and prevent the batter from rounding the bases and get home. The president will soon announce a name for that and announce that he has invented this game. Also, he's invented rap music and the idea of taking a vacation in the summer if you're a school kid. I mean, I kid you not, the president proposed to reporters from the White House in all seriousness from the White House that he's thinking there should maybe be fireworks and a parade on the Fourth of July in Washington, D.C. It could catch on. It could become a tradition.	7.63	0.10

Table 2: Snippets from MSNBC rated as highly uncivil by humans but with low toxicity score from Perspective. Human rating are between 1-10 and Perspective scores between 0-1.

Snippets from FOX	Human	Perspective
Meanwhile, this garbage deal that I've been telling you about, out of Washington, which allocates a measly additional $1.375 billion for wall construction – well, that has not been signed by the president. As a matter of fact, nobody in the White House has seen any language in the bill, none. So, let's be frank. It's not nearly enough money. Washington lawmakers, the swamp creatures, they have once again let we, the people, the American people down, this is a swamp compromise. Now, let me make predictions. Based on what the president is saying publicly, I love the press love to speculate, how did Hannity get his information? All right. We know this is a president that keeps his promises. And he goes at the speed of Trump. And if you watch every speech, if you actually listen to Donald Trump's words, you know, especially you people in the hate Trump media, you psychos, he telegraphs. He's saying exactly what he's planning to do. You're too stupid to listen.	8.13	0.80
The Democratic party with no plan to make your life better. More safe, more secure, more prosperous for not only you but for your children and you grandchildren. They are fueled too by a rage, hate and obsession with victimhood and identity politics, entitlement, pushing doom and gloom day and night, climate hysteria, indoctrinating your kids into believing the world is ending in 12 years. Just to push the socialist agenda. A party fueled by what can only be described as psychotic, literally unhinged, rage and hatred every second, minute and hour of the day against the duly elected president. They are not even trying to hide it. Just today we learned that shifty Adam Schiff, former MSNBC legal analyst, collusion conspiracy theorist Daniel Goldman to leave his new witch hunt against the President.	9.00	0.78

tribute the most to the average incivility score of one on the news sources compared to another of the sources. We sample a thousand words from each show. Occasionally, the same word is sampled for more than one show, so the final list for detailed analysis consists of 2,671 words.

6.1 Template-Derived Word Toxicity

Then we proceed similarly to prior work, to fill short templates in which only one word differs, and a fixed slot is filled in with each word in turn. We use five templates, chosen in an ad-hoc way similar to prior work. We do not reuse templates from prior work because they are tailored for the analysis of identity words, while we would like any word from the vocabulary to be an acceptable completion of the template. The average toxicity of templates filled in with a given word now provides us with a word-specific incivility score by which we can compare the full set of selected words.

We fill in five short templates with each word in turn, to obtain a comparable incivility score for each word. The first two were chosen to be neutral; the third one contained a word with a possibly negative connotation but used in a neutral sense, the fourth contains negation, and the last one is a question, to account for a wider variety of possible contexts in which the incivility triggers may occur. The five templates we use are:

(i) We wrote WORD on the page.
(ii) They whispered WORD to themselves.
(iii) I erased the word WORD from the page.
(iv) You didn't write WORD.
(v) Did he say WORD?

We use Perspective to predict the toxicity of each template when WORD is substituted with each of the words in our list for analysis. The average and maximum of these toxicities serve as a useful characterization of the words.

The templates were chosen so that the full sentence is not offensive, that is neither of the examples, even when filling it with an offensive word should be interpreted as deliberately rude or uncivil without any additional context. Higher values of predicted incivility would implicate the word substituted in the placeholder as the perceived trigger of incivility. We wish to find words where this association is wrong.

6.2 Offensive Words

At the same time, without reference or knowledge of the template word-scores, we classified the words as offensive or not. Two of the authors classified words independently and then adjudicated the disagreements in a conversation. Ultimately, there were 65 words we judged as offensive out of the full list of 2,671 words.

Separating offensive words from the rest is helpful. Using these words, we can get a sense of the degree to which Perspective incorporates context to make the prediction and then exclude them from further analysis. When templates are filled in with offensive words, the templates present hard cases for prediction. For these cases, context interpretation is necessary to make the correct prediction; word-spotting without incorporating context is likely to lead to an error. The ability to do this is important for our application: in the news, it is acceptable to report on someone else's incivility and their uncivil statements. If this is done with the purpose of expressing disapproval of the incivility, the reporting itself is not uncivil.

Furthermore, the set of offensive words allows us to quantify the degree to which the template scores justify our choice of rules to classify non-offensive words as error and sub-error triggers. We will consider words to be error triggers if at least one template was judged by Perspective to have toxicity greater than 0.5. Sub-error triggers are words for which all five templates had toxicity lower than 0.5, but their average toxicity was markedly higher than that for other words.

The average template toxicity for offensive words is 0.48, compared to 0.11 for the 2,606 non-offensive words in the list we analyzed. Of the 65 offensive words, 54% had at least one template with toxicity greater than 0.5. Perspective clearly is not simply word-spotting to make the prediction. It produces toxicity scores below 0.5 for about half of the offensive words. For the other half, however, it often produces an error.

In addition, 35% of the offensive words met the criteria for sub-error trigger. Overall, 89% of the offensive words meet either the error triggers or sub-error triggers criteria, confirming that these ranges of toxicity are the appropriate ones in which we should focus our attention in search of words that may have an unusually high association with toxicity. Example offensive words that met the sub-error criteria are: bozo, cheater, Crazy, crock, deplorables, F-ing, hoax, insane, mad, etc.

Other words, which we deemed non-offensive, have a template profile similar to that of the vast majority of offensive words. They are ones for which Perspective over-predicts toxicity.

7 Error Trigger Words for Perspective

We consider a word to be an error trigger if at least one of the templates has a toxicity score of 0.5 or greater from Perspective. Below is the full list of error trigger words from the news shows. We informally organize them into categories to facilitate inspection.

Identity African-Americans, anti-Semites, anti-white, anti-women, BlacKkKlansman, feminism, Feminist, gay, Homophobia, Homophobic, homophobic, Islam, Islamic, Jew, LGBT, Muslim, women

Violence and Sex annihilation, assassinated, beheaded, die, kill, killed, killing, murdered, shooting; intercourse, pedophiles, pornography, prostitution, rape, raped, rapist, rapists, sex, sexist, Sexual, sexual, sexually, sodomized

Ambiguity Dick, dirty, garbage, rats

Informal dopest, farting

Other brain, counter-intelligence, blackface, hypocrisy

Many error triggers are identity words describing people. Many of these identities, like gay and Muslim, were known triggers of incorrect toxicity prediction, and Perspective was specially altered to address this problem (Dixon et al., 2018a). Clearly, however, they are still a source of error, and the approaches for bias mitigation have not been fully successful. As we mentioned in the introduction, a system that is unstable in terms of its predictions when identity words appear in a text is not suitable for analysis of political discourse, where identities are mentioned often and where in many cases, it is of interest to quantify the civility with which people talk about different identity groups.

The second large class of error triggers consists of words related to death and sex. In online comments, toxic statements are often threats of sexual

0, 115-pound, abortion, abuse, abused, abusively, abysmal, accosted, adult, Africa, age-old, aliens, America, Americans, anti-semite, Anti-Trump, anti-Trump, Aryan, assaulted, assaulting, attack, baby, bad, barrier, Basically, beaten, belly, Black, black, Blow, blowing, bomber, bottom, bouncer, British, Brooks, brown, bunch, caliphate, capacity, cares, Catholic, Catholics, chicken, chief, child, children, China, Chinese, chock-full, Christian, church, Clinton, conforming, Content, COOPER, country, Covington, cows, crackers, crawling, creatures, cries, crime, crimes, criminal, CROSSTALK, cruelty, crying, DANIELS, dare, daughter, death, decrepit, defy, dehumanizing, Democrat, Democrats, demonize, denigrate, destroy-, died, Dingell, Dinkins, disrespectful, Donald, doomed, drug, drugs, Drunk, ducking, Duke, dumping, eggs, epidemic, European, evil, exist, explode, exploit, extremist-related, face, fake, Fallon, firearm, fithy, folks, Foreign, Former, FRANCIS, fraud, fry, gag, gagged, gang, gender, girls, governor, gun, guy, guy's, guys, handgun, harassed, harboring, hate, hate-, hate-Trump, hatred, head, heads, heartless, Hebrew, Hegel, her, herein, heroin, Hillary, HIV, horrors, hts, human, hush, Hymie, ifs, illness, imperialists, impugning, inaudible, inconclusive, infanticide, infuriating, inhumane, intelligence, interracial, invaders, Iran, Iraqi, ISIS, Islamophobic, Israel, Israelites, jail, Juanita, Kaine, Karine, kid, kids, Klan, Korea, laid, LAUGHTER, lie, lied, lies, life-and-death, life-death, limbs, litig, lying, MADDOW, MAGA-inspired, males, mama, man, men, mental, military, minors, missile, mock, mockery, molested, mouth, muck, N-, n't, NAACP, nation-state, needless, newscasters, Nonproliferation, nose, nuke, Obama, Obama's, obscene, obsessions, obsessive-compulsive, obsolete, organ, outrageous, ovations, Oversight, oxygen, p.m., painful, Pakistan, patriarchal, people, person, police, pope, President, president, president's, pretty, priest, priests, prison, prog, punched, punches, Putin, Putin's, queer, racial, Racism, racism, Rage, ranted, relations, religion, religious, relitigating, remove, REP., Republican, Republicans, RUSH, Russian, Russians, S, Saudi, savagely, self-confessed, self-defining, self-proclaimed, semitic, she, SHOW, sick, slavery, sleet, slurs, smear, socialist, son, Spartacus, stick, stop, stunning, supporters, supremacist, swamp, Syria, tampering, terror, terrorism, terrorists, thrash, threat, throat, tirade, toddler, TRANSCRIPT, trashing, treasonous, Trump, tumor, U.K., U.S, U.S., U.S.-backed, undress, unsuccessful, unvetted, upstate, vandalized, Vatican, Venezuela, Venezuelans, videotaped, videotaping, violated, violence, violent, VIRGINIA, virulent, voters, War, war, weird, welcome, Whitaker, White, white, WITH, woman, worse, worth, xenophobic, Yemen, you, your, yourself

Table 5: Sub-error trigger Words. The list comprises many identity words, words with negative connotations, words describing controversial topics, and words related to violence.

violence and death. Perhaps this is why words broadly related semantically are associated with toxicity. These words, however, can appear in news contexts without any incivility. Reports of violence at home and abroad are a mainstay of news, as well as reports of accusations of sexual misconduct and abuse. A system that is not capable of distinguishing the context of usage is not going to provide reliable quantification of incivility in the news.

Similarly, the ambiguous error triggers are words with more than one meaning, which could be offensive but can be used in civil discussion as well. For these, Perspective has to disambiguate based on the context. All of the templates we used were neutral, so for these, Perspective makes an error. For example, the name 'Dick' is an error trigger. The word indeed has an offensive meaning, but in the news shows we analyze, all mentions are in the sense of a person's name.

A couple of error-triggers are informal, clashing more in register than conveying incivility.

8 Sub-Error Triggers

Sub-error triggers of incivility are words that are not offensive and for which Perspective returns a toxicity score below 0.5 for each of the five templates when the word is plugged in the template. The error triggers we discussed above lead to actual errors by Perspective for its intended use. The sub-error triggers are in the acceptable level of noise for the original purpose of Perspective but may introduce noise when the goal is to quantify the typical overall civility of a source.

To establish a reference point for the expected average template civility of non-offensive words, we sample 742 words that appeared in at least 10 speaker turns (i.e., were fairly common) and appeared in speaker turns in the news shows that received low toxicity predictions from Perspective, below 0.15. These were part of the list we classify as offensive or not. No word in this reference sample was labeled as offensive.

The average template score for the reference sample is 0.09, with a standard deviation of 0.01. We define sub-error triggers to be those whose average template toxicity score is two standard deviations higher than the average in the reference list. There are 325 non-offensive words that meet the criteria for sub-error triggers. They are shown in Table 5 The list is long, which is disconcerting because it is likely that sentences containing multiple of these words will end up triggering errors.

A sizeable percentage of sub-error triggers are related to identities of people—gender, age, religion, country of origin. Oddly, a number of child-describing words appear in the list (baby, child, kid, toddler). There are also several personal names in the list, which indicates spurious correlations learned in Perspective; names by themselves can not be uncivil.

Second person pronouns (you, your) and third-person feminine pronouns (her, she) are sub-error triggers. The second-person pronouns are likely spuriously associated with toxicity due to over-representation in direct toxic comments directed to other participants in the conversation. Similarly, the association of female pronouns with toxicity is likely due to the fact that a large fraction of the indirect toxic comments online are targeted to women.

Regardless of the reasons why these words were associated with incivility by Perspective, the vast majority of them are typical words mentioned in the news and political discussions, explaining to an extent why Perspective is not able to provide a

The other thing that's important, both sides seem to be mad about this. On the conservative side, you have conservative voices who are saying, this deal is **pathetic**, it's an insult to the president. On the Democratic side and on the liberal side, I have activists that are texting me saying, Nancy Pelosi said she wasn't going to give $1 for this wall, and now she is.
I do feel safe at school. And I know that sounds kind of **ridiculous**, since tomorrow makes a year since there was a shooting at my school. But I do feel safe at school. And I feel safe sending my children to school. I know that there are recommendations that have been made to arm teachers, and I think that is the **stupidest** thing that I have ever heard in my life. Me having a gun in my classroom wouldn't have helped me that day.
VIRGINIA ROBERTS, Victim: It ended with sexual abuse and intercourse, and then a pat on the back, you have done a really good job, like, you know, thank you very much, and here's $200. You know, before you know it, I'm being lent out to politicians and to academics and to people that – royalty and people that you just – you would never think, like, how did you get into that position of power in the first place, if you're this **disgusting**, evil, decrepit person on the inside?
In a major incident like this, at first there's, you know, there's sort of a stunned numb thing that happens. And then you kind of go into this honeymoon phase. There's just a high level of gratefulness for all of the help that's coming. And then you get to the phase that we're kind of beginning to dip in now, which is life **sucks** right now, and I don't know how long it's going to **suck**.
It's **insane**. We are throwing away tremendous amounts of food every day. And there are people next door a block away that aren't getting enough food.

Table 6: Segments from PBS that contain offensive words (marked in boldface).

Category	FOX	MSNBC	PBS	Total
Error	197 [.44]	55 [.12]	196 [.44]	448
Sub-error	1537 [.39]	723 [.18]	1708 [.43]	3968
Offensive	277 [.52]	101 [.19]	156 [.29]	534

Table 7: Number [and fraction] of segments containing at least one (sub-)error trigger or offensive word.

meaningful characterization of civility in the news.

Table 7 shows the distribution of error triggers, sub-error triggers, and offensive words in the three programs. Most of the segments containing error and sub-error triggers are in FOX and PBS; this could explain the observation that incivility is much higher in FOX compared to the other two programs when analyzed with Perspective than compared to that from human judgments. This also explains why PBS, judged significantly more civil than MSNBC by people, appears to be somewhat less civil. Not only is Perspective not able to detect some of the incivility in sarcasm present in MSNBC, but also PBS segments include substantially more (sub-)error triggers than MSNBC.

More segments from PBS contain uncivil words, compared to MSNBC. Table 6 shows some representative PBS segments with offensive words. They are often reported incivility, or occur in segments where a guest in the program uses such language. Most of the segments are not overall uncivil.

9 Conclusion

The work we presented was motivated by the desire to apply off-the-shelf methods for toxicity prediction to analyse civility in American news. These methods were developed to detect rude, disrespectful, or unreasonable comment that is likely to make you leave the discussion in an online forum. To validate the use of Perspective to quantify incivility in the news, we create a new corpus of perceived incivility in the news. On this corpus, we compare human ratings and Perspective predictions. We find that Perspective is not appropriate for such an application, providing misleading conclusions for sources that are mostly civil but for which people perceive a significant overall difference, for example, because one uses sarcasm to express incivility. Perspective is able to detect less subtle differences in levels of incivility, but in a large-scale analysis that relies on Perspective exclusively, it will be impossible to know which differences would reflect human perception and which would not.

We find that Perspective's inability to differentiate levels of incivility is partly due to the spurious correlations it has formed between certain non-offensive words and incivility. Many of these words are identity-related. Our work will facilitate future research efforts on debiasing of automated predictions. These methods start off with a list of words that the system has to unlearn as associated with a given outcome. In prior work, the lists of words to debias came from informal experimentation with predictions from Perspective. Our work provides a mechanism to create a data-driven list that requires some but little human intervention. It can discover broader classes of bias than people performing ad-hoc experiments can come up with.

A considerable portion of content marked as uncivil by people is not detected as unusual by Perspective. Sarcasm and high-brow register in the delivery of the uncivil language are at play here and will require the development of new systems.

Computational social scientists are well-advised to not use Perspective for studies of incivility in political discourse because it has clear deficiencies for such application.

Abstract

This paper presents a finite-state computational model of the verbal morphology of Michif. Michif, the official language of the Métis peoples, is a uniquely mixed language with Algonquian and French origins. It is spoken across the Métis homelands in what is now called Canada and the United States, but it is highly endangered with less than 100 speakers. The verbal morphology is remarkably complex, as the already polysynthetic Algonquian patterns are combined with French elements and unique morpho-phonological interactions. The model presented in this paper, LI VERB KAA-OOSHITAHK DI MICHIF handles this complexity by using a series of composed finite-state transducers to model the concatenative morphology and phonological rule alternations that are unique to Michif. Such a rule-based approach is necessary as there is insufficient language data for an approach that uses machine learning. A language model such as LI VERB KAA-OOSHITAHK DI MICHIF furthers the goals of Indigenous computational linguistics in Canada while also supporting the creation of tools for documentation, education, and revitalization that are desired by the Métis community.

1 Introduction

In recent years there has been an increase in computational linguistic analysis of Indigenous languages spoken in what is now called Canada, and in particular Algonquian languages such as East Cree (Arppe et al., 2017a), Plains Cree (Harrigan et al., 2017), and Odawa (Bowers et al., 2017). This paper adds Michif—a mixed language of Cree and French origin—to the list with a description of LI VERB KAA-OOSHITAHK DI MICHIF. LI VERB KAA-OOSHITAHK DI MICHIF, which translates as "The Michif verb maker", is a computational model of the verbal morphology of Michif, implemented in the XFST framework of Beesley and Karttunen (2003).

2 Motivation

During the 19th century, marriage between French fur traders and Cree and Anishinaabe women in the Métis homeland was common, and their descendants became known as the Métis peoples (Bakker, 1997; Rosen and Souter, 2009). Michif (ISO 639-3: crg), an Algonquian language, emerged as a mixed language which combined elements of French with the Indigenous Algonquian languages Cree and Saulteaux—a distinct dialect of Ojibwa (Bakker, 1997; Rosen and Souter, 2009). There are many varieties of the Michif language, however LI VERB KAA-OOSHITAHK DI MICHIF is based on a variety spoken mainly in Manitoba, Southern Saskatchewan, North Dakota, and Montana.

Lack of linguistic documentation and analysis restricts the ability to create formalized teaching tools and technologies and hinders the efforts of language learners and activists in Indigenous communities. The number of speakers has decreased significantly. It is difficult to estimate true numbers of speakers of the "intertwined" language (Bakker, 1997), but Michif language activists estimate approximately 50-100 speakers with only a handful presently robust enough to be involved in revitalization work (Souter, 2020).

LI VERB KAA-OOSHITAHK DI MICHIF aims to create a complete model of the verbal morphology of Michif based on the current language data. The output of such a model has many applications, including a smartphone application for conjugating verbs in Michif.[1] LI VERB KAA-OOSHITAHK DI MICHIF represents a collabora-

---

[1] As of this writing, one such app is in development that incorporates LI VERB KAA-OOSHITAHK DI MICHIF.

tive effort between linguists, computer scientists, and the Michif speech community.

The source code for Li Verb kaa-Ooshitahk di Michif is not publicly available to maintain Métis sovereignty of the language data as requested by the community.

3 Michif linguistic background

The unique mixed origins of Michif are reflected in all linguistic domains. The phonological inventory of Michif is sourced from both French and Cree (with the "Saulteaux" or "Chippewa" dialect of Objibwe being a more minor source language). The pronominals are largely French based and verbal constructions are primarily Algonquian-derived (Sammons, 2019; Prichard and Shwayder, 2014; Rosen, 2007). However, while the morphemes and their concatenations are similar to Algonquian languages such as Plains Cree, the morpho-phonological interactions differ significantly from its sources (Sammons, 2019).

Michif is similar to other Algonquian languages in the degree of polysynthetic complexity, yet there are still distinguishing features that make it unique. Verbs can be highly productive by concatenating morphemes containing many categories of syntactic information; Figure 1 provides an illustration of the basic verbal template. The glosses below show an example of a simple verb form and one of a more complex verb form.

(1) *ayaaw*
ayaa-w
IND.PRS.have.VAI-3SG

'He/she has.'

(2) *ee-ka-kishkeetamiiyit*
ee-ka-kishkeet-amii-yi-t
CONJ-FUT-know.VTI-3>3-OBV1-OBV2

'As/that he/she (OBV) knows it.'

Michif verbs can be broken down into four inflectional classes by transitivity and animacy. Transitive verbs combine with the animacy of the object to create their inflectional classes (Transitive Animate (VTA) & Transitive Inanimate (VTI)), while intransitive verbs combine with the animacy of the subject (Animate Intransitive (VAI) & Inanimate Intransitive (VII)) (Wolvengrey, 2011; Sammons, 2019). Person marking, obviation, and direction affixes vary according to the inflectional class. There are also two minor classes, Animate Intransitive Transitive (VAIt) (Sammons, 2019) and Animate Intransitive Transitive animate/inanimate (VAIta/i) (Antonov, 2019).

All inflectional classes can be further broken down into the independent and conjunct orders. The independent order marks person and number with long distance agreement between prefixes and suffixes, and is used to express the indicative mode. The conjunct order expresses the indicative and subjunctive modes, and is typically marked with the '*ee-*' prefix, meaning 'while/as'.

Preverbs provide inflectional and lexical information before the stem of a verb, but occur *after* the person marking prefix in the independent order, or *after* the conjunct marker in the conjunct order. Grammatical preverbs cover tense or relativization, while lexical preverbs are a closed class that add lexical meaning (Sammons, 2019; Rhodes, 2009). Preverbs are optional, and a verb can be modified by multiple preverbs, as seen in the below example. However, while recursion of preverbs is theoretically possible in Michif, such forms are not used by speakers in practice, so this recursion is not modelled by Li Verb kaa-Ooshitahk di Michif.

'We (EXCL) will want to begin to work'

VTA verbs in Michif are the only class which has direction, where actions are either direct or inverse depending on a hierarchy of actors as in other Algonquian languages such as Plains Cree (Harrigan et al., 2017). In the direct VTA forms, the 'ni-/ki-/∅-' prefix refers to the subject, while the person marking suffix refers to the object. In the inverse VTA forms, the 'ni-/ki-/∅-' prefix refers to the object, while the person marking suffix refers to the subject. This can be observed in the difference between the suffixes in the glossed examples below.

(4) *ki-miyeumin*
ki-miyeum-**in**

(5) *ki-miyeumitin*
ki-miyeum-**itin**
1.IND-PRS.like.VTA-**INV**.1SG>2SG

'I like you (SG)'

Obviation occurs across all inflectional classes in Michif and is triggered by obviative nouns (marked or unmarked) (Sammons, 2019). It only occurs in the 3rd person, and number distinction is not specified, although the verb takes the 3SG suffix[2]. VAI verbs mark obviation in up to two places, relying on long distance dependencies. The '*yi*' morpheme occurs immediately following the stem. The independent order will have an extra '*a*' morpheme following the person marking affix, while the conjunct order will not. This pattern is visible in the examples in the glosses below.

4 Finite-state computational modelling

Li Verb kaa-Ooshitahk di Michif is a morphological model—a series of composed finite-state transducers (FSTs) called a lexical transducer (Beesley and Karttunen, 2003). There are two primary components of a lexical transducer: the Lexicon and the RewriteRules. The Lexicon uses a set of labelled sub-Lexicons which declare the rules for morphological concatenation (Hulden, 2009). This is accomplished by using regular expressions and flag diacritics. Then, the RewriteRules further constrain the output of the FSTs by using regular expressions to apply phonological restrictions. Foma (Hulden, 2009), a finite-state compiler, takes the Lexicon and the RewriteRules to create a composed finite-state transducer—in this case, Li Verb kaa-Ooshitahk di Michif. Using FSTs to model low-resource languages such as Michif is advantageous, as rule-based definitions of verbal paradigms do not rely on access to large, morphologically-tagged corpora which do not exist for Michif.

4.1 Morphological modelling in the Lexicon

The Lexicon allows for the linear concatenation of morphemes in the form of a continuation grammar. Each sub-Lexicon adds two components: morphological tags to the "upper" side, which provide syntactic information, and the surface form morphemes themselves on the "lower" side. Figure 2 illustrates the main sub-Lexicons of the Li Verb kaa-Ooshitahk di Michif.

Long distance dependencies are particularly challenging to model with continuation grammars, as they require knowledge of previous states. *Flag diacritics* enable these long distance dependency checks between states so that phenomena such as obviation can be modelled (Hulden, 2009; Beesley and Karttunen, 2003). Li Verb kaa-Ooshitahk di Michif employs three types of flags: `P`: **P**ositive set; `R`: **R**equire feature/value; and `D`: **D**isallow feature/value. Each feature can be thought of as a set; `P` flags add a value to this

---

[2] This paper only focuses on obviation in VAI verbs. See Sammons (2019) for a description of obviation in all verb classes.

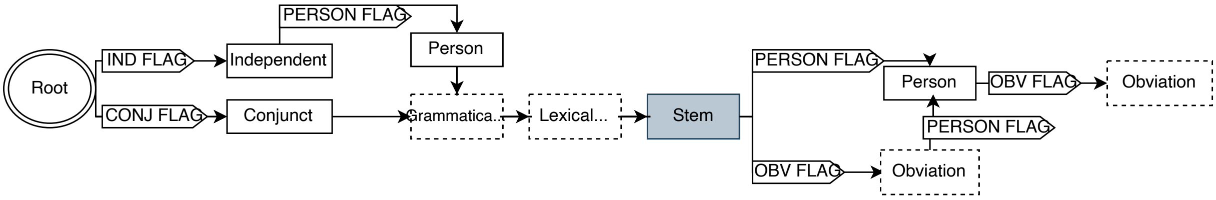

Figure 2: Schematic representation of paths through the LEXICON

feature set, while R flags require a specific value or the entire feature to be set.

As obviation in Michif only occurs with the 3rd person, flag diacritics have to be used to avoid over-application of the obviative concatenation rules. A 'person' feature is used, which distinguishes between 1st and 2nd person forms. When this feature is disallowed, such as with a *@D.person@* flag, only 3rd person forms can pass through. Any forms set to 1st or 2nd person will pass through the null path and continue to the `VAIPersonSuffix` sub-LEXICON, while the 3rd person forms will receive obviative marking before continuing to the `VAIPersonSuffix` sub-LEXICON.

```
LEXICON VAIObviativeMarking
 0                      VAIPersonSuffix;
 @D.person@@P.obv.yi@   VAIYi;

LEXICON VAIYi
 0:yi VAIPersonSuffix;
```

LI VERB KAA-OOSHITAHK DI MICHIF treats obviative as a feature set by a flag. The *@P.obv.yi@* sets the obviative feature, for any forms containing the '*yi*' morpheme. In the example below, the first sub-LEXICON ensures that only obviative forms receive the `[OBV]` tag. The *@D.obv@* flag accepts only those forms which have not previously been set to positive for the obviative feature. The *@R.obv@* flag requires obviative forms, outputting the tag on the "upper" side.

```
LEXICON VAIObviative1
 @D.obv@                EndVerb;
 @R.obv@[OBV]:@R.obv@   VAIObviative2;

LEXICON VAIObviative2
 @R.order.indep@:@R.order.indep@a EndVerb;
 @D.order.indep@a                 EndVerb;
```

The obviative forms then pass to the second sub-LEXICON, where they are sorted by order using flags. The *@R.order.indep@* requires forms belonging to the independent order, which adds the '*-a*' morpheme. All other forms, i.e. those belonging to the conjunct order, pass through the path with the *@D.order.indep@* flag (disallow any independent forms). Reaching *EndVerb* indicates that the transduction is complete. Table 1 shows examples of lexical outputs before the application of the phonological rules.

The modelling of obviation in Michif takes the opposite approach of the Plains Cree FST in Harrigan et al. (2017). In LI VERB KAA-OOSHITAHK DI MICHIF, the direction and person morpheme are treated as a single unit. Each obviative morpheme is then concatenated individually, rather than as part of the person and direction affixes. For example, LI VERB KAA-OOSHITAHK DI MICHIF would generate '*<eeyi<eew<a>*' instead of '*<eeyieewa>*'. As the intended use of this model is in contexts where all verb forms will only be generated once instead of with each query, the speed of generation is not required to be optimized, and more leniency with regards to stylistic choice is possible.

4.2 Phonological restrictions with REWRITERULES

LI VERB KAA-OOSHITAHK DI MICHIF only accounts for morpho-phonological rules which interact with the verbal morphology of Michif. When morphemes are concatenated, phonemes that would otherwise not co-occur become adjacent, creating the need for phonological rules which handle these issues. The REWRITERULES finite-state machine treats each phonological rule as an individual FST which is then composed to form the final FST (Hulden, 2009; Beesley and Karttunen, 2003).

The *'ni-/ki-'* prefixes host a multitude of morpho-phonological interactions unique to Michif.[3] There is significant vowel reduction as the prefixes are unstressed, which results in the eventual deletion of entire morphemes. Accounting for these alternations requires flag diacritics, such as with obviation, but additionally requires REWRITERULES.

---

[3] See Bakker (1991) for a full account of morpho-phonological rules in Michif.

<achimostaaweew[VTA][IND][FUT][3][INV][3PL-OBJ][OBV]	<kii-achimostaaw<ikwak>
<ayamihaaw[VAI][IND][PRS][1SG]	<ni-ayamihaa<n>

Table 1: Sample output of Li Verb kaa-Ooshitahk di Michif Lexicon

Lexicon Output	t-Insertion	ni-Deletion
ni-ayamihaan	ni-t-ayamihaan	d-ayamihaan
ni-ka-maachi-kipahaaw		ga-maachi-kipahaaw

Table 2: Sample derivation of the t-Insertion and ni-Deletion RewriteRules

1. t-Insertion
   [..] -> t || [n i | k i] "-" _ Vowel ;
2. ni-Deletion
   n i "-" t (->) d "-" || _ Vowel ;
   n i "-" k (->) g "-" || _ Vowel ;

Following the *'ni-/ki-'* morphemes, [t] is epenthesized when followed by a vowel (Rosen, 2007). Voiceless consonants are voiced when preceded by the *'ni-'* prefix and followed by a vowel. The *'ni-'* prefix is then deleted following the voicing (Bakker, 1991). The RewriteRules combine these two processes into one regular expression rule to avoid over-application of both the voicing and deletion. Table 2 illustrates the application of these rules.

5 Discussion

The latest version of Li Verb kaa-Ooshitahk di Michif includes 105 verb stems, which generate a total of 155,621 verb forms. Compared to the Plains Cree FST, which has around 13,000 verb stems and effectively infinite verbs forms due to recursion, Li Verb kaa-Ooshitahk di Michif is relatively small. However, it is important to recognize that the difference in size is a direct consequence of the linguistic situation of Michif. There is no Gold Standard morphologically-tagged corpus, such as that which exists for Plains Cree (2017b), against which to compare output forms. As a result, the generated forms are hand-verified by speakers (Souter, 2020), so having such a large model is less feasible.

The primary challenge that was faced when creating Li Verb kaa-Ooshitahk di Michif is the lack of consistent language data. The published paradigms conflict in their analysis of Michif verbal morphology, particularly with regards to phonological elements such as vowel length in person marking suffixes (Sammons, 2019; Bakker, 1997; Rosen, 2007). Initially, much of the FST was based on data scraped together from glosses discussing other phenomena, resulting in paradigm gaps. In the absence of accurate language data, the role of speakers becomes vital to ensuring the model generates accurate outputs, beginning with having complete morphological paradigms.

The imperative, subjunctive, and reflexive modes are not currently part of the model. While paradigms for these forms now exist at least partially, in order to implement them the structure of the current FST would have to be built again from the ground up. At the time of creating the current model these paradigms were not available, and so they were not included in the original architectural design and layout of the FST in Foma.

6 Conclusion

Despite the development of Li Verb kaa-Ooshitahk di Michif, much more work is needed to create a complete account of the verbal morphology of Michif. Computational language modelling is an important foundational step towards creating language learning resources and making the creation of those resources more accessible to Indigenous language communities.

A Few Topical Tweets are Enough for Effective User Stance Detection

Abstract

User stance detection entails ascertaining the position of a user towards a target, such as an entity, topic, or claim. Recent work that employs unsupervised classification has shown that performing stance detection on vocal Twitter users, who have many tweets on a target, can be highly accurate (+98%). However, such methods perform poorly or fail completely for less vocal users, who may have authored only a few tweets about a target. In this paper, we tackle stance detection for such users using two approaches. In the first approach, we improve user-level stance detection by representing tweets using contextualized embeddings, which capture latent meanings of words in context. We show that this approach outperforms two strong baselines and achieves 89.6% accuracy and 91.3% macro F-measure on eight controversial topics. In the second approach, we expand the tweets of a given user using their Twitter timeline tweets, which may not be topically relevant, and then we perform unsupervised classification of the user, which entails clustering a user with other users in the training set. This approach achieves 95.6% accuracy and 93.1% macro F-measure.

1 Introduction

Stance detection entails identifying the position of a user towards a topic, an entity, or a claim (Mohammad et al., 2016b). Effective stance detection, particularly in the realm of social media, can be instrumental in gauging public opinion, identifying intersecting and diverging groups, and understanding issues of interest to different user communities (Magdy et al., 2016a). Much recent works have explored varying stance detection methods including supervised, semi-supervised, and unsupervised user classification (Darwish et al., 2020; Magdy et al., 2016a; Pennacchiotti and Popescu, 2011; Wong et al., 2013), and much of the work has focused on stance detection for Twitter users. The different approaches have advantages and disadvantages. For example, supervised methods are simple to implement, but they require manually annotated training data and their accuracy varies widely based on classification features, classification techniques, and the number of training and test examples (Magdy et al., 2016a). Though semi-supervised and unsupervised methods typically use user interactions and often may yield perfect classification, they are effective in classifying highly vocal users with many topical tweets (Darwish et al., 2020). Most of these methods produce sub-optimal results for users who rarely express their opinion, and for whom we may only have one or two topically related tweets. Though a single tweet might be explicitly clear, often it may lack sufficient context to determine the stance of the user. Figure 1 show two tweets that pertain to the 2018 US midterm elections, where the first expresses a lucid pro-Republican stance and the second could have been authored by a supporter of either the Republican or Democratic party. In this paper, we aim to effectively identify the stance of Twitter users towards specific targets (entities or topics), where the users have mentioned the targets in only a few tweets (less than two tweets on average).

Figure 1: Sample 2018 US midterm election related tweets that either express a very clear stance (a) or not (b)

To do so, we employ two approaches. In the first

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2637–2646
April 19 - 23, 2021.

approach, we classify users based on their tweets that are represented using contextualized embeddings, which capture latent meanings of words in context. Specifically, we use BERT embeddings to represent tweets, and we fine tune the embeddings for every topic. We compare this approach to two strong baselines, namely using Support Vector Machine (SVM) classification and fastText, which is a deep learning based classifier. In the second approach, we expand the tweets of a given user using their Twitter timeline tweets, and then we use the additional tweets, which would typically be not relevant to the topic at hand, to perform unsupervised classification of the user by clustering him/her with the users in the training set. Using such expansion allows us to make use of user homophily, which is manifested in the echo chambers that form on Twitter, where users with similar views tend to retweet similar accounts beyond the topic at hand. To test our approaches, we use a dataset containing tweets on 8 polarized US-centric topics. We also examine the effect of expansion when using SVM, fastText, and contextualized embeddings. For testing, we randomly selected 100 users for each topic that have less than 5 topical tweets, and we manually labeled them for stance. To construct the training set, we used unsupervised stance detection to automatically label the 5,000 most active users per topic, and for every topic we used a balanced set of 500 users per stance as our training set (Darwish et al., 2020). Since the approaches rely on different features and utilize different classification techniques, we indicate which approach works best under different conditions.

The contributions of this paper are as follows:

- We fine-tune contextualized embeddings to generate latent representations of tweets to effectively classify the stance of users based on only one or two tweets. We achieve an accuracy of 89.6% and macro F-measure of 91.3%, which are significantly higher than the scores achieved using two strong baselines.
- We show that using additional timeline tweets for the users that we wish to classify, and then using unsupervised classification, where we cluster the test user with users in our training, leads to an accuracy of 95.6% and macro F1-measure of 92.0%. In doing so, we extend prior work on unsupervised stance detection to effectively classify both users who are vocal on a topic as well as those with perhaps one or two topical tweets.
- We show that expanding user tweets using their timeline tweets can significantly improve some supervised classification setups.
- We conduct error analysis on our best setups to determine the sources of the errors and to guide the choice of classification methods.
- We plan to release the tweet IDs of the test set along with the associate gold labels. Further, we plan to release the code that performs classification based on contextualized embeddings.

2 Related Work

Over the last few years, much research has focused on user stance detection. The goal of stance detection is to ascertain the positions of users towards some target such as a topic, person, or claim (Thomas et al., 2006; Mohammad et al., 2016a; Barberá, 2015; Barberá and Rivero, 2014; Borge-Holthoefer et al., 2015; Cohen and Ruths, 2013; Colleoni et al., 2014; Conover et al., 2011; Fowler et al., 2011; Himelboim et al., 2013; Magdy et al., 2016a,b; Makazhanov et al., 2014; Weber et al., 2013). While stance may easily be detected by humans, machine learning models often fall short, particularly for users who talk about a target sparingly. Several studies have focused on modeling stance by introducing different features ranging from linguistic and structural features (Mohammad et al., 2016a) to network interactions and profile information (Borge-Holthoefer et al., 2015; Magdy et al., 2016a,b; Weber et al., 2013). Much work on stance detection involved using supervised and semi-supervised classification methods. One of the major downsides of both classification methods is the need for a seed list of manually labeled users, which is time consuming and requires topic expertise. Supervised learning is sensitive to the classification features, the size of the training sets, the number of available tweets for users in the test set, and the classification algorithm (Borge-Holthoefer et al., 2015). Some common classification features include: lexical, syntactic, and semantics feature; network features such as retweeted accounts and user mentions; content features such as words and hashtags; and user profile information such as name and location (Aldayel and Magdy, 2019; Magdy et al., 2016a,b; Pennacchiotti and Popescu, 2011). Some commonly used classification algorithms include SVMs and deep learning classification (Zarrella and Marsh, 2016). Popat et al.

(2019) presented a neural network model for stance classification by augmenting BERT representations with a novel consistency constraint to determine stance with respect to both a claim and perspective. We extend their work in two ways, namely: we drop the need to have a claim and perspective, and we couple BERT supervised classification with unsupervised classification to effectively tag vocal and non-vocal users. Semi-supervised methods such as *label propagation* (Barberá, 2015; Borge-Holthoefer et al., 2015; Weber et al., 2013) often rely on two users retweeting identical accounts or tweets to propagate a label of one user to another. Though such typically achieves high precision (often above 95%) (Darwish et al., 2018), it is generally successful in tagging vocal users with strong opinions. Recently, Darwish et al. (2020) have introduced a highly effective unsupervised method for predicting the stance of prolific Twitter users towards controversial topics. By projecting users onto a low-dimensional space and then clustering them allows for clear separation between vocal users with respect to their stance (Darwish et al., 2020). This method confers two main advantages over previous methods, namely: it does not require any initial manual labeling, and classification accuracy is nearly perfect. However, it is successful in labeling vocal users only and fails on users with very few topical tweets. We extend prior work on unsupervised stance detection to effectively classify both prolific and non-prolific users in a holistic way by aggregating both supervised and unsupervised methods. Further, we extend prior deep-learning based supervised classification to use contextual embeddings that capture syntactic and semantic features of words in context.

We are framing the problem as user-based classification, which is common in the computational social science community, as opposed to tweet-based classification, which is common in the NLP community (Mohammad et al., 2016b). This is motivated by two aspects, namely: 1) tweets often don't provide sufficient context for proper annotation; and 2) users have durable stances over time. For example, if someone says "Most important election in history! Vote!", it is nearly impossible to know if the author's position without context.

3 Data Sets

Topics Our dataset includes tweets on eight polarizing topics that are US-centric, which were graciously provided to us by Stefanov et al. (2020). Table 1 lists all the topics including when the tweets were collected and the number of tweets per topic. The topics include both long-standing issues such as gun control and transient issues such as the nomination of Judge Kavanaugh to the US Supreme Court. There is also a non-political issue, namely vaccination. The tweets were also filtered based on user-stated locations to limit the data to US users. The filtering was done using a gazetteer that includes either US (or its variants) and state names (and their abbreviations).

Topic	Date Range	Tweets
Climate change	Feb 25–Mar 4, 2019	1,284,902
Gun control	Feb 25–Mar 3, 2019	1,782,384
Ilhan Omar (remarks on Israeli lobby)	Mar 1–9, 2019	2,556,871
Immigration	Feb 25–Mar 4, 2019	2,341,316
Midterm (elections 2018)	Feb 25–Mar 3, 2019	2,564,784
Kavanaugh (nomination to Supreme Court)	Sept. 28-30 & Oct. 6-9, 2018	2,322,141
Vaccination	Mar 1–9, 2019	301,209

Table 1: Controversial topics used in study.

Training Set Given the tweets for every topic, we performed per topic unsupervised stance detection (Darwish et al., 2020). This approach identifies the most active n users per topic and computes similarity between them based on a common feature, such as which hashtags they use or which accounts that they retweet. Next, the users are projected onto a lower dimensional space in a manner where similar users are brought closer together and dissimilar users are pushed further apart. Then the projected users are clustered. Using the best reported setup of Darwish et al. (2020), we used the 5,000 most active users with at least 10 tweets, computed similarity between them based on which accounts they retweeted, projected users using UMAP (McInnes and Healy, 2018), and clustered them using the mean shift clustering algorithm (Fukunaga and Hostetler, 1975). Stefanov et al. (2019) estimated the accuracy of the unsupervised approach on the 8 topics to be 98%. Next, we took 500 random users from the two largest clusters to construct a balanced training set, and we manually inspected a few users from each cluster to give an overall label to each cluster (ex. pro- or anti- gun control). Further, we crawled the timeline tweets of the users in our training set.

Topic	Skip	Agree	Pro	Anti
Climate	10.6	100	81	18
Gun control	71.0	85	62	37
Ilhan	1.0	95	52	47
Immigration	10.7	90	57	42
Midterm	0.0	90	71	28
Police/Racism	0.0	100	80	20
Kavanaugh	2.0	100	39	60
Vaccine	1.0	100	90	9
Avg.	12.0	95	66.5	32.6

Table 2: Test set information: % skipped tweets, inter-annotator agreement, % pro, and % anti.

Topic	Labeled Users	w/Timelines
Climate change	100	54
Gun control	58	26
Ilhan Omar	100	39
Immigration	100	43
Midterm	100	45

Kavanaugh	100	55
Vaccines	100	57

Table 3: Per topic labeled users in test set along with the number of users for which were able to scrape their timelines

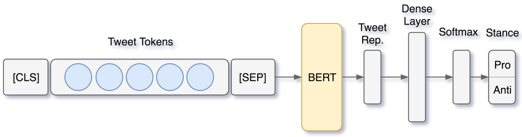

Figure 2: Fine-tuning BERT for stance classification.

Test Set For each topic, we randomly selected 200 users who have less than 5 tweets. The average number of tweets per user ranged across topics between 1.25 and 1.77 tweets. An annotator who is well versed with US politics manually examined the per topic tweets of users to determine their stances. If the tweets of a user were not sufficient to ascertain their stance, the annotator manually searched and examined their tweets on Twitter in an effort to find further clues. If no conclusive evidence of stance were found, the annotator skipped the user. The annotator labeled up to 100 users per topic. We asked another annotator to annotate 20 tweets per topic to ascertain inter-annotator agreement. Table 2 lists the percentage of skipped tweets, inter-annotator agreement, and percentage of pro- and anti-tweets. Next, we scraped the timeline of all the labeled users. Due to the time difference between collecting topical tweets and when we initiated the scraping of users' timelines, some user accounts were deleted, suspended, or made protected. Table 3 lists the number of labeled users and the subset of them for whom we were able to scrape their timelines. Thus, we put users for whom we were not able to collect timeline tweets into Set A, and we put the remaining users in Set B. We report results for both sets separately.

4 Classification Models

Supervised Classification As baselines, we used two different classification methods, namely a Support Vector Machines (SVM) classifier and a deep learning based text classifier. For the SVM classifier, we used the SVM^{Light} implementation with a linear kernel with default parameters (Joachims, 2002)[1]. We employed two feature types, namely: the accounts that users retweeted; and the words in tweets, including retweeted accounts, hashtags, and user mentions and replies. Prior work has shown that using retweeted accounts as features yields better results compared to using the content of tweet (Darwish et al., 2018). When using words in tweets, we tokenized tweets using NLTK (Bird et al., 2009), removed all URLs and emoticons, retained all hashtags and user mentions, and specifically delineated retweeted accounts by adding ’RT_’ before them. We chose to distinguish between retweeted accounts and user mentions because retweeting commonly signifies agreement and user mentions (including replies) may indicate opposition. We concatenated the aforementioned features from all the tweets of a user, and we constructed a feature vector, where the value of each unique feature was set to its frequency across all tweets of a user. For the deep learning based classifier, we used fastText, which is an efficient text classifier that has been shown to be effective for different text classification tasks (Joulin et al., 2016). Since fastText was designed for sentence-level classification, we opted to perform tweet-level classification. During training, we assigned the label of a user to all his/her tweets. During testing, we averaged per class confidence scores across all tweets for a user, and we assigned the label with the highest average confidence to the user. As for features, we used all the words in tweets, and we preprocessed tweets in the manner described earlier for

---

[1] http://svmlight.joachims.org/

SVM. We opted not use retweeted accounts only as the number of retweeted accounts was arbitrary for each user and fastText is not well suited for long input text.

Contextualized Embeddings Over the last several years, pre-trained embedding (Mikolov et al., 2013; Pennington et al., 2014) have helped achieve significant improvements in a wide range of classification tasks in natural language processing. Representing words as vectors in a low-dimensional continuous space and then using them for downstream tasks lowered the need for extensive manual feature engineering. However, these pre-trained vectors are static and fail to handle polysemous words, where different instances of a word have to share the same representation regardless of context. More recently, different deep neural language models have been introduced to create contextualized word representations that can cope with the issue of polysemy and the context-dependent nature of words. Models such as OpenAi GPT (Radford et al., 2018), ELMo (Peters et al., 2018), BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2019), and UMLFIT (Howard and Ruder, 2018), to name a few, have achieved groundbreaking results in many NLP classification and language understanding tasks. For this paper, we use $\text{BERT}_{\text{base-multilingual}}$[2] (referred to hereafter simply as BERT), which we fine-tune for stance detection, as this eliminates the need for heavily engineered task-specific architectures. BERT is pre-trained on Wikipedia text from 104 languages and comes with hundreds of millions of parameters. It contains an encoder with 12 Transformer blocks, hidden size of 768, and 12 self-attention heads. As shown in Fig. 2, We fine-tuned BERT by adding a fully-connected dense layer followed by a softmax output layer, minimizing the binary cross-entropy loss function for the training data. For all experiments, we used HuggingFace[3] transformer implementation with PyTorch[4] as it provides pre-trained weights and vocabulary. As for features, we used all the words in tweets that were preprocessed in the manner described earlier for SVM and fastText. Similar to fastText, we performed tweet-level classification, and we used the average softmax output scores per class across all tweets for a user to assign a label to a test user.

Unsupervised Classification For unsupervised classification, we used the same unsupervised classification method described earlier, which we used to prepare the training set. Specifically, we constructed a feature vector for each test user based on the accounts he/she retweeted, computed its similarity to all users in the training set, projected all the users in the training along with the test user into a lower dimensional space using UMAP, and lastly clustered the users using mean shift. We then labeled the test user using the majority label of the cluster in which the user appeared.

5 Experiments

We split users in our test set on the basis of whether we were able to crawl their timelines or not. Set A includes users for which we were not able to obtain their timeline tweets. Set B includes users for which we were able to collect their timeline tweets. We separated between them, because Set B would allow us to compare between setups that use timeline tweets with those that do not on identical users.

For Set A, we always trained on the training users with their on-topic tweets and the tested on the test users, who typically had less than 2 tweets on average. We used four different classification setups, namely using fastText, SVM with retweeted accounts as features (SVM_{RT}), SVM with all words as features (SVM_{TEXT}), and fine-tuned BERT embeddings with a dense neural layer and softmax output (BERT). We experimented with using the unsupervised method on Set A, but the unsupervised algorithm was not able to assign any test user to a cluster, mostly because the number of tweets and subsequently retweeted users per test user were too few. For Set B, we experimented with the same classifiers using four different conditions, namely: not expanding either training or test sets with users' timeline tweets; expanding the test set only; expanding the training set only; and expanding both the training and test sets.

6 Results and Discussion

For all experiments, we report on per topic accuracy ($\mathcal{A}$) and macro precision ($\mathcal{P}$), recall ($\mathcal{R}$), and F-measure ($\mathcal{F}$) across stances on a topic. Table 4

---

[2] We also experimented with different contextualized embedding, such as RoBERTa (Liu et al., 2019), Albert (Lan et al., 2019), and XLM (Lample and Conneau, 2019) and $\text{BERT}_{\text{base-multilingual}}$ performed the best.

Table 4: Results on Sets A (no expansion). The best results in a row are in bold.

reports the results on Sets A where we were not able to expand the test set using timeline tweets. As the results show, BERT yielded the best results in terms of $\mathcal{A}$, $\mathcal{P}$, $\mathcal{R}$, and $\mathcal{F}$ for most topics, with the highest overall averages across all scores. fastText trailed BERT, and SVM$_{TEXT}$ performed much worse. SVM$_{RT}$ performed better than SVM$_{TEXT}$. This suggests that BERT, which uses contextual embeddings, is effective in performing accurate stance detection, even when classifying users with a very small number of topical tweets. As for the Unsupervised method, using the unsupervised method was not able to assign any test user to a cluster, mostly because the number of tweets per test user were too few. Hence, we omitted the unsupervised method from Table 4. Table 5 shows the results on Set B, where we expanded the test, training, or either or both training and test user tweets using timeline tweets. The results suggest the following:

- For BERT and fastText, which rely on the content of the tweets, we achieved the best results with no expansion or when we only expanded the training set. The inclusion of non-topical tweets in the test set led to worse results overall. We suspect that is happened because of the mismatch between the training and test sets.
- For SVM$_{RT}$ and Unsupervised classification, which rely exclusively on whom users retweeted, the expansion of the test dramatically improved overall $\mathcal{A}$, $\mathcal{P}$, $\mathcal{R}$, and $\mathcal{F}$. The positive improvement for both after timeline expansion suggests that the accounts that a user retweets are a strong signal of stance across multiple topics, and stances on multiple topics are likely correlated. For example, a user who supported the Kavanaugh nomination was likely to vote republican in the midterm elections. For future work, we plan to examine cross topic classification.
- Similar to the results observed for Set A (4), when no expansion is used, BERT led to the best overall results. However, using unsupervised classification led to the best overall results across all setups, with expanding the test set only yielding slightly better results than expanding both the training and test sets. Expanding the test set only is significantly more efficient than expanding both training and test sets.
- Using unsupervised classification failed to all users in the test set for any topic when the test set was not expanded, mostly because the number of tweets per test user and subsequent number of retweeted accounts were too few.
- SVM$_{TEXT}$ yielded the worse results overall, despite the inclusion of all the features in the tweets, such as retweeted accounts, hashtags, words, etc. It seems that the inclusion of more features (compared to SVM$_{RT}$) confused the classifier leading to lower results.
- SVM$_{TEXT}$ and SVM$_{RT}$ led to the lowest results when we only expanded the training set. For both setups, the classifier classified all users as belonging to one of the stances or the other. Hence, $\mathcal{R}$ for one class was 100.0 and 0.0 for the other (with macro $\mathcal{R}$ = 50.0). We suspect that expanding the feature space in the training set confused the SVM classifier. Both setups are unusable.

We computed the standard deviation (SD) of all our measures across topics for every setup. Lower SD coupled with high $\mathcal{A}$ and $\mathcal{F}$ is desirable as they indicate the setup produces consistently high results across topics. Unsupervised classification yielded the lowest SD values and highest overall score. BERT and fastText with no expansion and SVM$_{RT}$ with expanded test set had slightly higher SD. Thus, if we are able to scrape a user's timeline tweets, it is advantageous to use a method that relies on which accounts a user retweets, with unsupervised classification producing the best results. As we will show in the error analysis, the success of

Error Type	No.	Examples
Unexplained	52	*Ilhan*: RIP CONS ... When they see me they take their hat off... I am DJ *Gun Control*: @BreitbartNews @NRA more lies *Climate Change*: $200 million a year could reverse climate change
Vague	48	*Kavanaugh*: following the senate confirmation vote *Midterm*: RT_@ali irresponsible for twitter *Police & Racism*: after 40 yrs of reflection
Quoting other side	24	*Immigration*: this is a real crisis at the border *Kavanaugh*: why did jeff flake demand an investigation and then accept a bogus one
Sarcasm	4	*Immigration*: RT_@infantry0300 someone should let "Ms Hitler was a really great guy until he crossed the border into Poland"

Table 6: BERT error types with examples

unsupervised classification is contingent on users retweeting a sufficient number of times, particularly politically related accounts in our case. When timeline tweets are not available, it is best to use contextualized embeddings.

Error Analysis We analyzed all the errors in Set B that were produced by BERT with no expansion, as it represents the best results when expansion is not possible, and those produced by unsupervised classification with the expansion of the test set only, as this produced the best overall results. Since we used BERT to perform tweet-level classification, we manually inspected all 129 misclassified tweets across all topics. Generally we found four types of errors, namely: unexplainable errors where the tweets clearly expressed stance, but the classifier mislabeled them; vague tweets that have no clear clues; tweets in which the user uses the language of the opposing side; and sarcastic tweets. Table 6 lists the error types with their frequencies and provides example tweets. When we used LIME (Ribeiro et al., 2016) to analyze the output of BERT, we noticed two important phenomena. First, BERT was able to identify stance based on retweeted accounts, and not just the text of the tweet. Second, BERT was able to learn correlations between topic. For example, the tweet "RT ***BernieSanders***: I believe ***health care*** must be a right", BERT based its decision on BernieSanders, the democratic presidential hopeful in 2016 and 2020, and on "health care", where positions on *health care* and *climate change* are often aligned.

For unsupervised classification, we manually examined all 15 users that were missclassified, of whom 7 were from the Kavanaugh topic. Prominent reasons for incorrect classification were: Lack of sufficient retweets for a user, where the percentage of retweets ranged between 1-1.4% of all tweets for three of the misclassified users (2 for *climate change* and 1 for *Kavanaugh*); Geographic mislabeling, where 2 accounts were not US accounts (1 for *Ilhan* and 1 for *Kavanaugh*); Users retweeting mostly apolitical accounts such as music, art, or cars related accounts (1 for *climate change*, 1 for *vaccine*, and 3 for *Kavanaugh*) – retweeting of politically biased accounts and media sources seem to provide strong signals for classification; or User goes against the general opinion of his group as in the clearly republican user who was criticizing the National Rifle Association (NRA) (*gun control*).

Thus, the most common reason for misclassification was the dearth of retweets from politically oriented or topically related accounts.

7 Conclusion

In this paper, we presented two methods for classifying users according to their stance towards a target. The first utilizes contextualized embeddings to represent tweets and then uses deep neural network for classification. This approach led to results that outperform two strong baselines. The second utilizes additional tweets from users' timelines to cluster test users with other users with known labels in an unsupervised manner. The first method yielded the best results when timeline tweets were not available, while the second yielded even better results overall. Given the overall setup described in the paper, where the training data was obtained using unsupervised user classification, we can automatically label the most active users with nearly perfect accuracy, and we can label users with only few topical tweets with high accuracy, often above 95% when we can obtain their timeline tweets. For future work, we plan to explore the effectiveness of cross topic classification, where training and testing are done on different topics. Perhaps, we can build unified models that could be used across multiple topics for a given a population of Twitter users (ex. users who are interested in US politics).

Abstract

Much recent work suggests that incorporating syntax information from dependency trees can improve task-specific transformer models. However, the effect of incorporating dependency tree information into *pre-trained* transformer models (e.g., BERT) remains unclear, especially given recent studies highlighting how these models implicitly encode syntax. In this work, we systematically study the utility of incorporating dependency trees into pre-trained transformers on three representative information extraction tasks: semantic role labeling (SRL), named entity recognition, and relation extraction.

We propose and investigate two distinct strategies for incorporating dependency structure: a *late fusion* approach, which applies a graph neural network on the output of a transformer, and a *joint fusion* approach, which infuses syntax structure into the transformer attention layers. These strategies are representative of prior work, but we introduce additional model design elements that are necessary for obtaining improved performance. Our empirical analysis demonstrates that these syntax-infused transformers obtain state-of-the-art results on SRL and relation extraction tasks. However, our analysis also reveals a critical shortcoming of these models: we find that their performance gains are highly contingent on the availability of human-annotated dependency parses, which raises important questions regarding the viability of syntax-augmented transformers in real-world applications.[1]

1 Introduction

Dependency trees—a form of syntactic representation that encodes an asymmetric syntactic relation between words in a sentence, such as *subject* or *adverbial modifier*—have proven very useful in various NLP tasks. For instance, features defined in terms of the shortest path between entities in a dependency tree were used in relation extraction (RE) (Fundel et al., 2006; Björne et al., 2009), parse structure has improved named entity recognition (NER) (Jie et al., 2017), and joint parsing was shown to benefit semantic role labeling (SRL) (Pradhan et al., 2005) systems. More recently, dependency trees have also led to meaningful performance improvements when incorporated into neural network models for these tasks. Popular encoders to include dependency tree into neural models include graph neural networks (GNNs) for SRL (Marcheggiani and Titov, 2017) and RE (Zhang et al., 2018), and biaffine attention in transformers for SRL (Strubell et al., 2018).

In parallel, there has been a renewed interest in investigating self-supervised learning approaches to pre-training neural models for NLP, with recent successes including ELMo (Peters et al., 2018), GPT (Radford et al., 2018), and BERT (Devlin et al., 2019). Of late, the BERT model based on pre-training of a large transformer model (Vaswani et al., 2017) to encode bidirectional context has emerged as a dominant paradigm, thanks to its improved modeling capacity which has led to state-of-the-art results in many NLP tasks.

BERT's success has also attracted attention to what linguistic information its internal representations capture. For example, Tenney et al. (2019) attribute different linguistic information to different BERT layers; Clark et al. (2019) analyze BERT's attention heads to find syntactic dependencies; Hewitt and Manning (2019) show evidence that BERT's hidden representation embeds syntactic trees. However, it remains unclear if this linguistic information helps BERT in downstream tasks during finetuning or not. Further, it is not evident if external syntactic information can further improve

BERT's performance on downstream tasks.

In this paper, we investigate the extent to which pre-trained transformers can benefit from integrating external dependency tree information. We perform the first systematic investigation of how dependency trees can be incorporated into pre-trained transformer models, focusing on three representative information extraction tasks where dependency trees have been shown to be particularly useful for neural models: semantic role labeling (SRL), named entity recognition (NER), and relation extraction (RE).

We propose two representative approaches to integrate dependency trees into pre-trained transformers (i.e., BERT) using syntax-based graph neural networks (syntax-GNNs). The first approach involves a sequential assembly of a transformer and a syntax-GNN, which we call *Late Fusion*, while the second approach interleaves syntax-GNN embeddings within transformer layers, termed *Joint Fusion*. These approaches are inspired by recent work that combines transformers with external input, but we introduce design elements such as the alignment between dependency tree and BERT wordpieces that lead to obtaining strong performance. Comprehensive experiments using these approaches reveal several important insights:

- Both our syntax-augmented BERT models achieve a new state-of-the-art on the CoNLL-2005 and CoNLL-2012 SRL benchmarks when the gold trees are used, with the best variant outperforming a fine-tuned BERT model by over 3 F_1 points on both datasets. The Late Fusion approach also provides performance improvements on the TACRED relation extraction dataset.
- These performance gains are consistent across different pre-trained transformer approaches of different sizes (i.e. $\text{BERT}_{\text{BASE/LARGE}}$ and $\text{RoBERTa}_{\text{BASE/LARGE}}$).
- The Joint Fusion approach that interleaves GNNs with BERT achieves higher performance improvements on SRL, but it is also less stable and more prone to errors when using noisy dependency tree inputs such as for the RE task, where Late Fusion performs much better, suggesting complementary strengths from both approaches.
- In the SRL task, the performance gains of both approaches are highly contingent on the availability of human-annotated parses for both training and inference, without which the performance gains are either marginal or non-existent. In the NER task, even the gold trees don't show performance improvements.

Although our work does obtain new state-of-the-art results on SRL tasks by introducing dependency tree information from syntax-GNNs into BERT, however, our most important result is somewhat negative and cautionary: the performance gains are only substantial when human-annotated parses are available. Indeed, we find that even high-quality automated parses generated by domain-specific parsers do not suffice, and we are only able to achieve meaningful gains with human-annotated parses. This is a critical finding for future work—especially for SRL—as researchers routinely develop models with human-annotated parses, with the implicit expectation that models will generalize to high-quality automated parses.

Finally, our analysis provides indirect evidence that pre-trained transformers do incorporate sufficient syntactic information to achieve strong performance on downstream tasks. While human-annotated parses can still help greatly, with our proposed models it appears that the knowledge in automatically extracted syntax trees is largely redundant with the implicit syntactic knowledge learned by pre-trained models such as BERT.

2 Models

In this section, we will first briefly review the transformer encoder, then describe the graph neural network (GNN) that learns syntax representations using dependency tree input, which we term the syntax-GNN. Next, we will describe our syntax-augmented BERT models that incorporate such representations learned from the GNN.

2.1 Transformer Encoder

The transformer encoder (Vaswani et al., 2017) consists of three core modules in sequence: embedding layer, multiple encoder layers, and a task-specific output layer. The core elements in these modules are different sets of learnable weight matrices that perform linear transformations. The embedding layer consists of wordpiece embeddings, positional embeddings, and segment embeddings (Devlin et al., 2019). After embedding lookup, these three embeddings are added to obtain token embeddings for an input sentence. The encoder layers then transform the input token embeddings to hidden state representations. The encoder layer con-

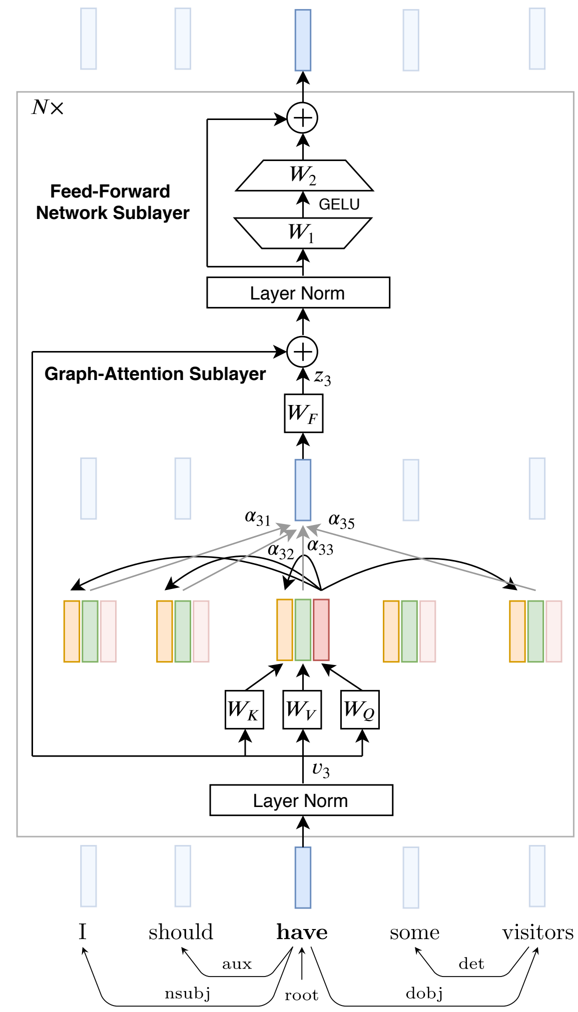

Figure 1: Block diagram illustrating syntax-GNN applied over a sentence's dependency tree. In the example shown, for the word "*have*", the graph-attention sublayer aggregates representations from its three adjacent nodes in the dependency graph.

sists of two sublayers: multi-head dot-product self-attention and feed-forward network, which will be covered in the following section. Finally, the output layer is task-specific and consists of one layer feed-forward network.

2.2 Syntax-GNN: Graph Neural Network over a Dependency Tree

A dependency tree can be considered as a multi-attribute directed graph where the nodes represent words and the edges represent the dependency relation between the head and dependent words. To learn useful syntax representations from the dependency tree structure, we apply graph neural networks (GNNs) (Hamilton et al., 2017; Battaglia et al., 2018) and henceforth call our model *syntax-GNN*. Our syntax-GNN encoder as shown in Figure 1 is a variation of the transformer encoder where the self-attention sublayer is replaced by *graph attention* (Veličković et al., 2018). Self-attention can also be considered as a special case of graph-attention where each word is connected to all the other words in the sentence.

Let $V = \{v_i \in \mathbb{R}^d\}_{i=1:\mathcal{N}^v}$ denote the input node embeddings and $E = \{(e_k, i, j)_{k=1:\mathcal{N}^e}\}$ denote the edges in the dependency tree, where the edge e_k is incident on nodes i and j. Each layer in our syntax-GNN encoder consists of two sublayers: graph attention and feed-forward network.

First, interaction scores (s_{ij}) are computed for all the edges by performing dot-product on the adjacent linearly transformed nodes embeddings

$$s_{ij} = (v_i \boldsymbol{W_Q})(v_j \boldsymbol{W_K})^\top. \qquad (1)$$

The terms $v_i \boldsymbol{W_Q}$ and $v_i \boldsymbol{W_K}$ are also known as *query* and *key* vectors respectively. Next, an attention score (α_{ij}) is computed for each node by applying softmax over the interaction scores from all its connecting edges:

$$\alpha_{ij} = \frac{\exp(s_{ij})}{\sum_{k \in \mathcal{N}_i} \exp(s_{ik})}, \qquad (2)$$

where $\mathcal{N}_i$ refers to the set of nodes connected to i^{th} node. The graph attention output (z_i) is computed by the aggregation of attention scores followed by a linear transformation:

$$z_i = (\sum_{j \in \mathcal{N}_i} \alpha_{ij}(v_j \boldsymbol{W_V}))\boldsymbol{W_F}. \qquad (3)$$

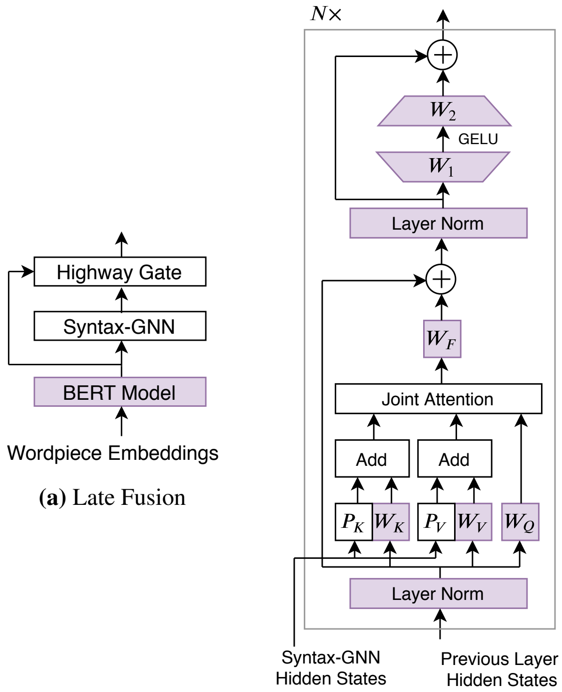
The term $v_j \boldsymbol{W_V}$ is also referred to as *value* vector. Subsequently, the message (z_i) is passed to the second sublayer that consists of two layer fully connected feed-forward network with GELU activation (Hendrycks and Gimpel, 2016).

$$\mathrm{FFN}(z_i) = \mathrm{GELU}(z_i \boldsymbol{W_1} + b_1)\boldsymbol{W_2} + b_2\ . \qquad (4)$$

The FFN sublayer outputs are given as input to the next layer. In the above equations $\boldsymbol{W_K}$, $\boldsymbol{W_V}$, $\boldsymbol{W_Q}$, $\boldsymbol{W_F}$, $\boldsymbol{W_1}$, $\boldsymbol{W_2}$ are trainable weight matrices and b_1, b_2 are bias parameters. Additionally, layer normalization (Ba et al., 2016) is applied to the input and residual connections (He et al., 2016) are added to the output of each sublayer.

2.2.1 Dependency Tree over Wordpieces

As BERT models take as input subword units (also known as wordpieces) instead of linguistic tokens,



(a) Late Fusion

(b) Joint Fusion

Figure 2: Block diagrams illustrating our proposed syntax-augmented BERT models. Weights shown in color are pre-trained while those not colored are either non-parameterized operations or have randomly initialized weights. The inputs to each of these models are wordpiece embeddings while their output goes to task-specific output layers. In subfigure 2b, $N\times$ indicates that there are N layers, with each of them being passed the same set of syntax-GNN hidden states.

this also necessitates to extend the definition of a dependency tree to include wordpieces. For this, we introduce additional edges in the original dependency tree by defining new edges from the first subword (head word) of a token to the remaining subwords (tail words) of the same token.

2.3 Syntax-Augmented BERT

In this section, we propose parameter augmentations over the BERT model to best incorporate syntax information from a syntax-GNN. To this end, we introduce two models— Late Fusion and Joint Fusion. These models represent novel mechanisms—inspired by previous work—through which syntax-GNN features are incorporated at different sublayers of BERT (Figure 2). We refer to these models as Syntax-Augmented BERT (SA-BERT) models. During the finetuning step, the new parameters in each model are randomly initialized while the existing parameters are initialized from pre-trained BERT.

Late Fusion: In this model, we feed the BERT contextual representations to the syntax-GNN encoder *i.e.* syntax-GNN is stacked over BERT (Figure 2a). We also use a Highway Gate (Srivastava et al., 2015) at the output of the syntax-GNN encoder to adaptively select useful representations for the training task. Concretely, if v_i and z_i are the representations from BERT and syntax-GNN respectively, then the output (h_i) after the gating layer is computed as,

$$g_i = \sigma(\boldsymbol{W}_g v_i + b_g) \tag{5}$$

$$h_i = g_i \odot v_i + (1 - g_i) \odot z_i, \tag{6}$$

where σ is the sigmoid function $1/\left(1 + e^{-x}\right)$ and $\boldsymbol{W}_g$ is a learnable parameter. Finally, we map the output representations to linguistic space by adding the hidden states of all the wordpieces that map to the same linguistic token respectively.

Joint Fusion: In this model, syntax representations are incorporated within the self-attention sublayer of BERT. The motivation is to *jointly* attend over both syntax- and BERT representations. First, the syntax-GNN representations are computed from the input token embeddings and its final layer hidden states are passed to BERT. Second, as is shown in Figure 2b, the syntax-GNN hidden states are linearly transformed using weights $\boldsymbol{P}_K$, $\boldsymbol{P}_V$ to obtain additional *syntax-based* key and value vectors. Third, syntax-based key and value vectors are added with the BERT's self-attention sublayer key and value vectors respectively. Fourth, the query vector in self-attention layer now attends over this set of keys and values, thereby augmenting the model's ability to fuse syntax information. Overall, in this model, we introduce two new set of weights per layer $\{\boldsymbol{P}_K, \boldsymbol{P}_V\}$, which are randomly initialized.

3 Experimental Setup

3.1 Tasks and Datasets

For our experiments, we consider information extraction tasks for which dependency trees have been extensively used in the past to improve model performance. Below, we provide a brief description of these tasks and the datasets used and refer the reader to Appendix A.1 for full details.

Semantic Role Labeling (SRL) In this task, the objective is to assign semantic role labels to text spans in a sentence such that they answer the query:

Who did *what* to *whom* and *when*? Specifically, for every target *predicate* (verb) of a sentence, we detect *syntactic constituents* (arguments) and classify them into predefined semantic roles. In our experiments, we study the setting where the predicates are given and the task is to predict the arguments. We use the CoNLL-2005 SRL corpus (Carreras and Màrquez, 2005) and CoNLL-2012 OntoNotes[2] dataset, which contains PropBank-style annotations for predicates and their arguments, and also includes POS tags and constituency parses.

Named Entity Recognition (NER) NER is the task of recognizing entity mentions in text and tagging them to entity categories. We use the OntoNotes 5.0 dataset (Pradhan et al., 2012), which contains 18 named entity types.

Relation Extraction (RE) RE is the task of predicting the relation between the two entity mentions in a sentence. We use the label corrected version of the TACRED dataset (Zhang et al., 2017; Alt et al., 2020), which contains 41 relation types as well as a special *no_relation* class indicating that no relation exists between the two entities.

3.2 Training Details

We select *bert-base-cased* to be our reference pretrained baseline model.[3] It consists of 12 layers, 12 attention heads, and 768 model dimensions. In both the variants, the syntax-GNN component consists of 4 layers, while other configurations are kept the same as *bert-base*. Also, for the Joint Fusion method, syntax-GNN hidden states were shared across different layers. It is worth noting that as our objective is to assess if the use of dependency trees can provide performance gains over pre-trained transformer models, it is important to tune the hyperparameters of these baseline models to obtain strong reference scores. Therefore, for each task, during the finetuning step, we tune the hyperparameters of the default *bert-base* model and use the same hyperparameters to train the SA-BERT models. We refer the reader to Appendix A.2 for additional training details.

4 Results and Analysis

In this section, we present our main empirical analyses and key findings.

4.1 Benchmark Performance

To recap, our two proposed variants of the Syntax-Augmented BERT models in Section 2.3 mainly differ at the position where syntax-GNN outputs are fused with the BERT hidden states. Following this, we first compare the effectiveness of these variants on all the three tasks, comparing against previous state-of-the-art systems such as (Strubell et al., 2018; Jie and Lu, 2019; Zhang et al., 2018), which are outlined in Appendix B due to space limitations. For this part we use gold dependency parses to train the models for SRL and NER, and predicted parses for RE, since gold dependency parses are not available for TACRED.

We present our main results for SRL in Table 1 and Table 2, NER in Table 3, and RE in Table 4. All these results report average performance over five runs with different random seeds. First, we note that for all the tasks, our *bert-base* baseline is quite strong and is directly competitive with other state-of-the-art models.

We observe that both the Late Fusion and Joint Fusion variants of our approach yielded the best results in the SRL tasks. Specifically, on CoNLL-

---

Table 4: Relation extraction results on the revised TACRED test set (Alt et al., 2020), averaged over 5 independent runs. † marks results reported by Alt et al. (2020).

2005 and CoNLL-2012 SRL, Joint Fusion improves over *bert-base* by an absolute 3.5 F_1 points, while Late Fusion improves over *bert-base* by 2.65 F_1 points. On the RE task, the Late Fusion model improves over *bert-base* by approximately 0.3 F_1 points while the Joint Fusion model leads to a drop of 4.5 F_1 points in performance (which we suspect is driven by the longer sentence lengths observed in TACRED). On NER, the SA-BERT models lead to no performance improvements as their scores lies within one standard deviation to that of *bert-base*.

Overall, we find that syntax information is most useful to the pre-trained transformer models in the SRL task, especially when intermixing the intermediate representations of BERT with representations from the syntax-GNN. Moreover, when the fusion is done after the final hidden layer of the pre-trained models, apart from providing good gains on SRL, it also provides small gains on RE task. We further note that, as we trained all our syntax-augmented BERT models using the same hyperparameters as that of *bert-base*, it is possible that separate hyperparameter tuning would further improve their performance.

4.2 Impact of Parsing Quality

In this part, we study to what extent parsing quality can affect the performance results of the syntax-augmented BERT models. Specifically, following existing work, we compare the effect of using parse trees from three different sources: (a) gold syntactic annotations[4]; (b) a dependency parser trained using gold, *in-domain* parses[5]; and (c) available off-the-shelf NLP toolkits.[6] In previous work, it was shown that using in-domain parsers can provide good improvements on SRL (Strubell et al., 2018) and NER tasks (Jie and Lu, 2019), and the performance can be further improved when gold parses were used at test time. Meanwhile, in many practical settings where gold parses are not readily available, the only option is to use parse trees produced by existing NLP toolkits, as was done by Zhang et al. (2018) for RE. In these cases, since the parsers are trained on a different domain of text, it is unclear if the produced trees, when used with the SA-BERT models, can still lead to performance gains. Motivated by these observations, we investigate to what extent *gold*, *in-domain*, and *off-the-shelf* parses can improve performance over strong BERT baselines.

Comparing off-the-shelf and gold parses. We report our findings on the CoNLL-2005 SRL (Table 5), CoNLL-2012 SRL (Table 6), and OntoNotes-5.0 NER (Table 7) tasks. Using gold parses, both the Late Fusion and Joint Fusion models obtain greater than 2.5 F_1 improvement on SRL tasks compared with *bert-base* while we don't observe significant improvements on NER. We further note that as the gold parses are produced by expert human annotators, these results can be considered as the attainable performance ceiling from using parse trees in these models.

We also observe that using off-the-shelf parses from the Stanza toolkit (Qi et al., 2020) provides little to no gains in F_1 scores (see Tables 5 and 7). This is mainly due to the low in-domain accuracy of the predicted parses. For example, on the CoNLL-

---

[4] We use Stanford *head rules* (de Marneffe and Manning, 2008) implemented in Stanford CoreNLP v4.0.0 (Manning et al., 2014) to convert constituency trees to dependency trees in UDv2 format (Nivre et al., 2020).

[5] The difference between settings (a) and (b) is during test time. In (a) gold parses are used for both training and test instances while in (b) gold parses are used for training, while during test time, parses are extracted from a dependency parser which was trained using gold parses.

[6] In this setting, the parsers are trained on general datasets such as the Penn Treebank or the English Web Treebank.

Test Set	P	R	F_1
Stanza Dependency Parses (UAS: 84.20)			
Late Fusion	86.85	88.06	87.45

Joint Fusion	87.09	87.95	87.52
Gold Dependency Parses			
Late Fusion	89.17	91.09	90.12
Joint Fusion	90.59	91.35	**90.97**

Table 5: SRL results with different parses on the CoNLL-2005 WSJ test set averaged over 5 independent runs. † marks results from Strubell et al. (2018).

2005 SRL test set the UAS is 84.2% for the Stanza parser, which is understandable as the parser was trained on the EWT corpus which covers a different domain.

In a more fine-grained error analysis, we also examined the correlation between parse quality and performance on individual examples on CoNLL-2005 (Figures 3a and 3b), finding a mild but significant positive correlation between parse quality and relative model performance when training and testing with Stanza parses (Figure 3a). Interestingly, we found that this correlation between parse quality and validation performance is much stronger when we train a model on gold parses but then evaluate with noisy Stanza parses (Figure 3b). This suggests that the model trained on noisy parses tends to rely less on the noisy dependency tree inputs, while the model trained on gold parses is more sensitive to the external syntactic input. This correlation is further reinforced by our manual error analysis presented in Appendix C (Figures 4 and 5), where we show how the erroneous edges in the Stanza parses can lead to incorrect predictions of the SRL tags.

Do in-domain parses help? Lastly, for the setting of using in-domain parses, we only evaluate on the SRL task, since on the NER task even using gold parses does not yield substantial gain. We train a biaffine parser (Dozat and Manning, 2017) on the gold parses from the CoNLL-2005 training set and obtain parse trees from it at test time. We observe that while the obtained parse trees are fairly accurate (with a UAS of 92.6% on the test set), it leads to marginal or no improvements over *bert-base*. This finding is also similar to the results obtained by Strubell et al. (2018), where their LISA+ELMo model only obtains a relatively small improvement over SA+ELMo. We hypothesize that as the accuracy of the predicted parses further increases, the F_1 scores would be closer to that from using the gold parses. One possible reason for these marginal gains from using the in-domain parses is that as they are still imperfect, the errors in the parse edges is forcing the model to ignore the syntax information.

Test Set	P	R	F_1
Stanza Dependency Parses (UAS: 82.73)

Joint Fusion	88.58	89.31	88.94

Table 7: NER results with different parses on the OntoNotes-5.0 test set averaged over 5 independent runs. † marks results from Jie and Lu (2019).

Overall, we conclude that *parsing quality has a drastic impact on the performance of the Syntax-Augmented BERT models, with substantial gains only observed when gold parses are used.*

5 Generalizing to BERT Variants

Our previous results used the *bert-base* setting, which is a relatively small configuration among pre-trained models. Devlin et al. (2019) also proposed larger model settings (*bert-large*[7], *whole-word-masking*[8]) that outperformed *bert-base* in all the benchmark tasks. More recently, Liu et al. (2019)

proposed RoBERTa, a better-optimized variant of BERT that demonstrated improved results. A research question that naturally arises is: *Is syntactic information equally useful for these more powerful pre-trained transformers, which were pre-trained in a different way than bert-base?* To answer this, we finetune these models—with and without Late Fusion—on the CoNLL-2005 SRL task using gold parses and report their performance in Table 8.[9]

As expected, we observe that both *bert-large* and *bert-wwm* models outperform *bert-base*, likely due to the larger model capacity from increased width and more layers. Our Late Fusion model consistently improves the results over the underlying BERT models by about 2.2 F_1. The RoBERTa models achieve improved results compared with the BERT models. And again, our Late Fusion model further improves the RoBERTa results by about 2 F_1. Thus, it is evident that *the gains from the Late Fusion model generalize to other widely used pre-trained transformer models*.

6 Generalizing to Out-of-Domain Data

In real-world applications, NLP systems are often used in a domain different from training. And it was previously shown that many NLP systems, such as information extraction systems, suffer from substantial performance degradation when applied to out-of-domain data (Huang and Yates, 2010). While it is evident that syntax trees may help models generalize to out-of-domain data (Wang et al., 2017), since the inductive biases introduced by these trees are invariant across domains, it is unclear if this hypothesis holds for more recent pre-trained models. To study this, we run experiments on SRL with the CoNLL-2005 SRL corpus because this is where we have access to both in-domain and out-of-domain test data using the same annotation schema. The training set of this corpus contains WSJ articles from the newswire domain and the test set consists of two splits: WSJ articles (in-domain) and Brown corpus[10] (out-of-domain). For training, we use both BERT and RoBERTa pre-trained models and leverage gold parses in syntax-GNN models.

From the results in Table 9, the utility of syntax-GNN is evident, as we find that the Late Fusion model always improves over its corresponding BERT and RoBERTa baselines by 2-3% relative F_1, with RoBERTa-large based Late Fusion achieving the best F_1 on both WSJ and Brown datasets. We also compare the performance across both domains, with the last column showing the relative drop in the F_1 score between WSJ and Brown datasets. We observe that the performance of all models drops substantially on the Brown set. However, compared with randomly initialized transformer

---

[9] We use the *Late Fusion* model with *gold parses* in this section, as it is computationally more efficient to train than Joint Fusion model.

Table 9: Out-of-domain SRL results on the CoNLL-2005 WSJ and Brown test sets. † marks results reported in Strubell et al. (2018). $\%\Delta$ denotes the relative gain in F_1 over pre-trained models when using Late Fusion model, $\%\nabla$ denotes the relative drop in F_1 when a model trained on WSJ dataset is tested on the Brown dataset.

models, where the results can drop by 13%, both syntax-fused and pre-trained models lead to better generalization as the relative error drop reduces to 6–7%. *We see that using Late Fusion does not lead to a better out-of-domain generalization, when compared to strong pre-trained transformers without using parse trees.* Lastly, we find that among all pre-trained models, RoBERTa-large and its syntax-fused variant Late Fusion achieves the lowest out-of-domain generalization error.

7 Related Work

Our work is based on finetuning large pre-trained transformer models for NLP tasks, and is closely related to existing work on understanding the syntactic information encoded in them, which we have earlier covered in Section 1. Here we instead focus on discussing related work that studies incorporating syntax into neural NLP models.

Relation Extraction Neural network models have shown performance improvements when shortest dependency path between entities was incorporated in sentence encoders: Liu et al. (2015) apply a combination of recursive neural networks and CNNs; Miwa and Bansal (2016) apply tree-LSTMs for joint entity and relation extraction; and Zhang et al. (2018) apply graph convolutional networks (GCN) over LSTM features.

Semantic Role Labeling Recently, several approaches have been proposed to incorporate dependency trees within neural SRL models such as learning the embeddings of dependency path between predicate and argument words (Roth and Lapata, 2016); combining GCN-based dependency tree representations with LSTM-based word representations (Marcheggiani and Titov, 2017); and linguistically-informed self-attention in one transformer attention head (Strubell et al., 2018). Kuncoro et al. (2020) directly inject syntax information into BERT pre-training through knowledge distillation, an approach which improves the performance on several NLP tasks including SRL.

Named Entity Recognition Moreover, syntax has also been found to be useful for NER as it simplifies modeling interactions between multiple entity mentions in a sentence (Finkel and Manning, 2009). To model syntax on OntoNotes-5.0 NER task, Jie and Lu (2019) feed the concatenated child token, head token, and relation embeddings to LSTM and then fuse child and head hidden states.

8 Conclusion

In this work, we explore the utility of incorporating syntax information from dependency trees into pre-trained transformers when applied to information extraction tasks of SRL, NER, and RE. To do so, we compute dependency tree embeddings using a syntax-GNN and propose two models to fuse these embeddings into transformers. Our experiments reveal several important findings: syntax representations are most helpful for SRL task when fused within the pre-trained representations, these performance gains on SRL task are contingent on the quality of the dependency parses. We also notice that these models don't provide any performance improvements on NER. Lastly, for the RE task, syntax representations are most helpful when incorporated on top of pre-trained representations.

A Experimental Setup

A.1 Task-Specific Modeling Details

Semantic Role Labeling (SRL): We model SRL as a sequence tagging task using a linear-chain CRF (Lafferty et al., 2001) as the last layer. During inference, we perform decoding using the Viterbi algorithm (Forney, 1973). To highlight predicate position in the sentence, we use indicator embeddings as input to the model.

Named Entity Recognition (NER): Similar to SRL, we model NER as a sequence tagging task, and use a linear-chain CRF layer over the model's hidden states. Sequence decoding is performed using the Viterbi algorithm.

Relation Extraction (RE): As is common in prior work (Zhang et al., 2018; Miwa and Bansal, 2016), the dependency tree is pruned such that the subtree rooted at the lowest common ancestor of entity mentions is given as input to the syntax-GNN. Following Zhang et al. (2018), we extract sentence representations by applying a max-pooling operation over the hidden states. We also concatenate the entity representations with sentence representation before the final classification layer.

A.2 Additional Training Details

During the finetuning step, the new parameters in each model are randomly initialized while the existing parameters are initialized from pre-trained BERT. For regularisation, we apply dropout (Srivastava et al., 2014) with $p = 0.1$ to attention coefficients and hidden states. For all datasets, we use the canonical training, development, and test splits. We use the Adam optimizer (Kingma and Ba, 2015) for finetuning.

We observed that the initial learning rate of 2e-5 with a linear decay worked well for all the tasks. For the model training to converge, we found that 10 epochs were sufficient for CoNLL-2012 SRL and RE and 20 epochs were sufficient for CoNLL-2005 SRL and NER. We evaluate the test set performance using the best-performing checkpoint on the development set.

For evaluation, following convention we report the micro-averaged precision, recall, and F_1 scores in every task. For variance control in all the experiments, we report the mean of the results obtained from five independent runs with different seeds.

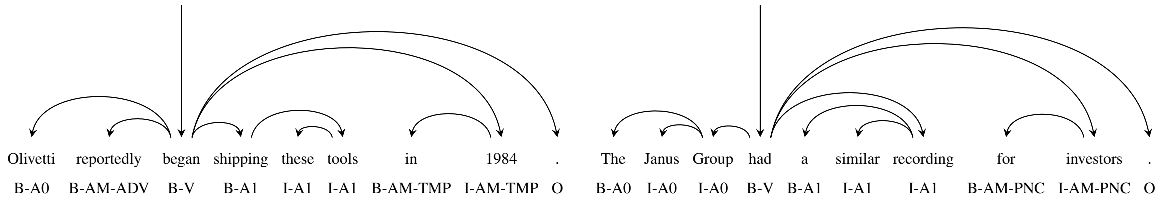
B Additional Baselines

Besides BERT models, we also compare our results to the following previous work, which had obtained good performance gains on incorporating dependency trees with neural models:

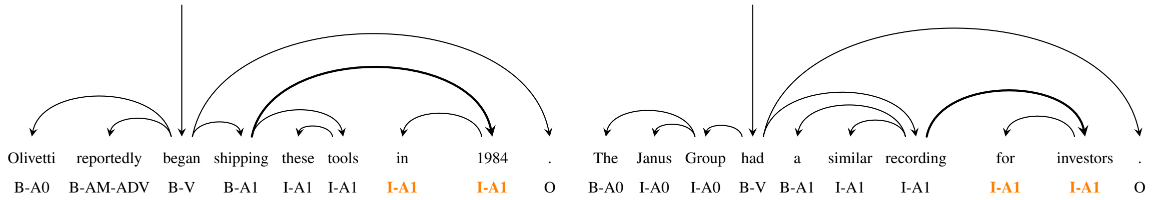
- For SRL, we include results from the SA (self-attention) and LISA (linguistically-informed self-attention) model by Strubell et al. (2018). In LISA, the attention computation in one attention-head of the transformer is biased to enforce dependent words only attend to their head words. The models were trained using both GloVe (Pennington et al., 2014) and ELMo embeddings.
- For NER, we report the results from Jie and Lu (2019), where they concatenate the child token, head token, and relation embeddings as input to an LSTM and then fuse child and head hidden states.
- For RE, we report the results of the GCN model from Zhang et al. (2018) where they apply graph convolutional networks on pruned dependency trees over LSTM states.

C Manual Error Analysis

In this section, we present several examples from our manual error analysis of the predictions from the Late Fusion model when it is trained on CoNLL-2005 SRL WSJ dataset using gold and Stanza parses. Specifically, we show how the incorrect edges present in the parse tree can induce wrong SRL tag predictions. In Figure 4, we observe two examples where the model when trained with gold parses outputs perfect predictions but the when trained with Stanza parses outputs two incorrect SRL tags due to one erroneous edge present in the dependency parse. In Figure 5, we show an example of a longer sentence where due to the presence of four erroneous edges in the Stanza parse, the model makes a series of incorrect predictions of the SRL tags.



(a) Predicted SRL tags using **Gold parses**



(b) Predicted SRL tags using **Stanza parses**

Figure 4: Examples of sentences with their predicted SRL tags when the Late Fusion model is trained using gold parses (4a) and Stanza parses (4b). While the predicted SRL tags using the gold parses are accurate, the erroneous edges in the Stanza parses (highlighted in bold) leads to incorrect SRL tags predictions (highlighted in orange color).

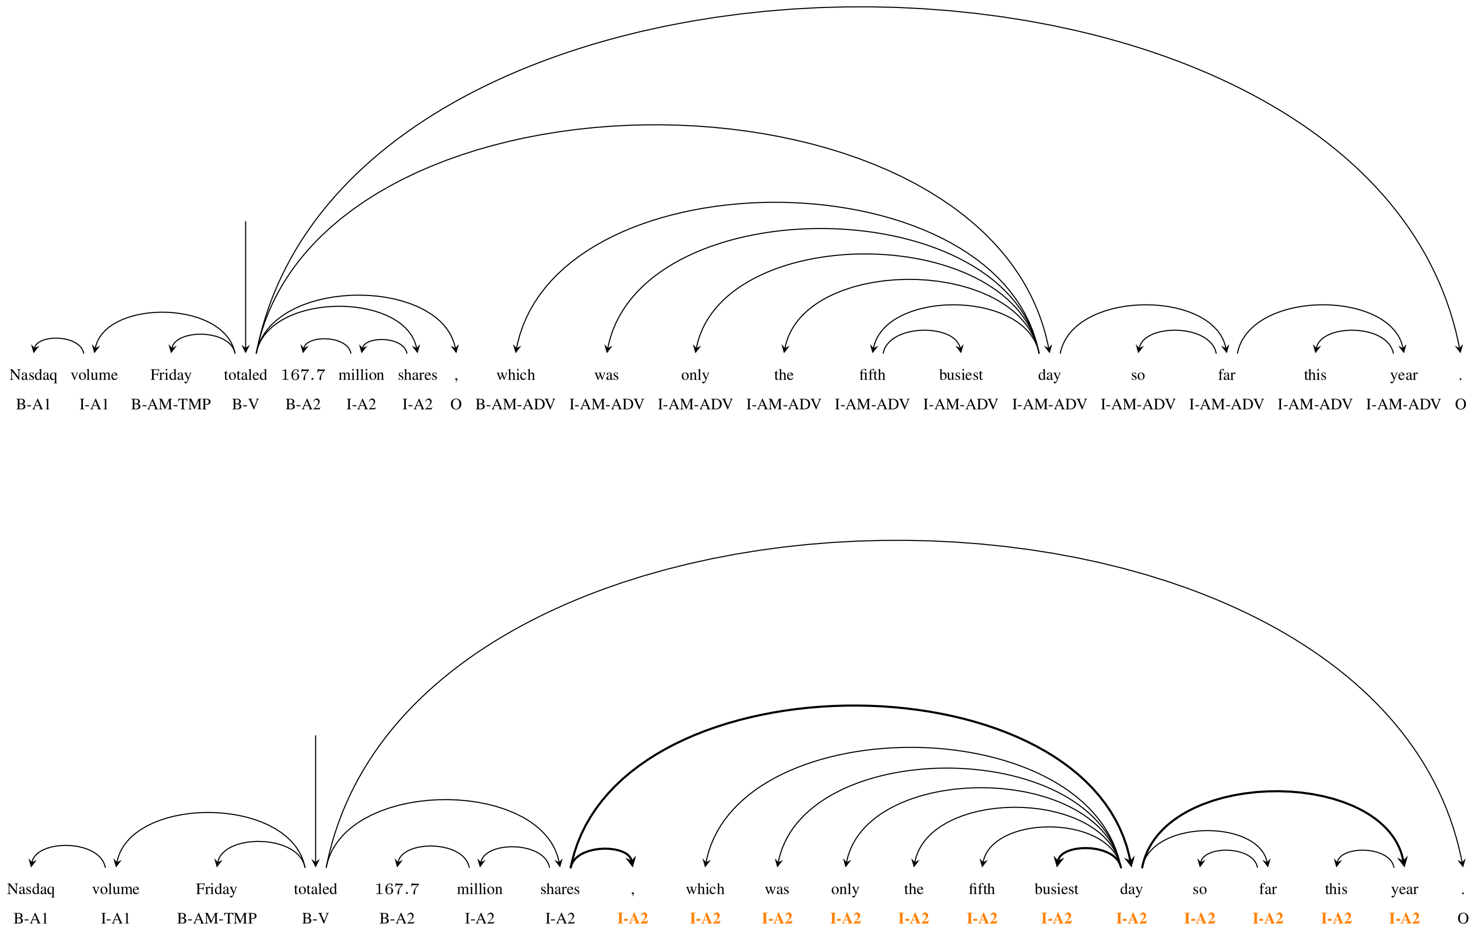


Figure 5: Example of a longer sentence with its predicted SRL tags when the Late Fusion model is trained using gold parses (above figure) and Stanza parses (lower figure). The erroneous edges in the Stanza parses are highlighted in bold. While the predicted SRL tags using the gold parses are accurate, the erroneous edges in the Stanza parses leads to a series of incorrect SRL tag predictions (highlighted in orange color).

Informative and Controllable Opinion Summarization

Abstract

Opinion summarization is the task of automatically generating summaries for a set of reviews about a specific target (e.g., a movie or a product). Since the number of reviews for each target can be prohibitively large, neural network-based methods follow a two-stage approach where an *extractive* step first pre-selects a subset of salient opinions and an *abstractive* step creates the summary while conditioning on the extracted subset. However, the extractive model leads to loss of information which may be useful depending on user needs. In this paper we propose a summarization framework that eliminates the need to rely only on pre-selected content and waste possibly useful information, especially when customizing summaries. The framework enables the use of all input reviews by first *condensing* them into multiple dense vectors which serve as input to an abstractive model. We showcase an effective instantiation of our framework which produces more informative summaries and also allows to take user preferences into account using our zero-shot customization technique. Experimental results demonstrate that our model improves the state of the art on the Rotten Tomatoes dataset and generates customized summaries effectively.

1 Introduction

The proliferation of opinions expressed in online reviews, blogs, and social media has created a pressing need for automated systems which enable customers and companies to make informed decisions without having to absorb large amounts of opinionated text. Opinion summarization is the task of automatically generating summaries for a set of opinions about a specific target (Conrad et al., 2009). Figure 1 shows various reviews about the movie "Coach Carter" and example summaries generated by humans and automatic systems.

"Coach Carter" Reviews
• Samuel L. Jackson plays the real-life coach of a high school basketball team in this solid sports drama ... • Great performance by Samuel Jackson but predictable as a slam dunk ... • ... excellent basketball choreography, Coach Carter is fun, hopeful, occasionally silly and, what can I say, inspiring.
Consensus Summary
Even though it's based on a true story, Coach Carter is pretty formulaic stuff, but it's effective and energetic, thanks to a strong central performance from Samuel L. Jackson.
EXTRACT-ABSTRACT Framework
Coach Carter is a preposterously plotted thriller that borrows heavily from other superior films. *(factually incorrect)*
CONDENSE-ABSTRACT Framework
General: An inspirational flick with a healthy dose of message, but it's too predictable. *Customized (acting)*: An inspirational flick with a healthy dose of humor, Coach Carter is a perceptive sports drama with a standout performance from Samuel L. Jackson. *Customized (plot)*: A feel-good tale with a healthy dose of heart, Coach Carter is a worthy addition to the basketball system that it's difficult to resist.

Figure 1: Three out of 150 reviews for the movie "Coach Carter", and summaries written by the editor, and generated by a model following the EXTRACT-ABSTRACT approach and the proposed CONDENSE-ABSTRACT framework. The latter produces more informative and factual summaries whilst allowing to control aspects of the generated summary (such as the acting or plot of the movie).

The vast majority of previous work (Hu and Liu, 2004) views opinion summarization as the final stage of a three-step process involving: (1) aspect extraction (i.e., finding features pertaining to the target of interest, such as battery life or sound quality); (2) sentiment prediction (i.e., determining the sentiment of the extracted aspects); and (3) summary generation (i.e., presenting the identified opinions to the user). Textual summaries are created following mostly extractive methods which select representative segments (usually sentences) from the source text (Popescu and Etzioni,

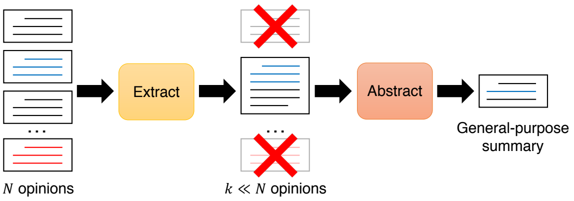
Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2662–2672
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

2005; Blair-Goldensohn et al., 2008; Lerman et al., 2009). Despite being less popular, abstractive approaches seem more appropriate for the task at hand as they attempt to generate summaries which are maximally informative and minimally redundant without simply rearranging passages from the original opinions (Ganesan et al., 2010; Carenini et al., 2013; Gerani et al., 2014).

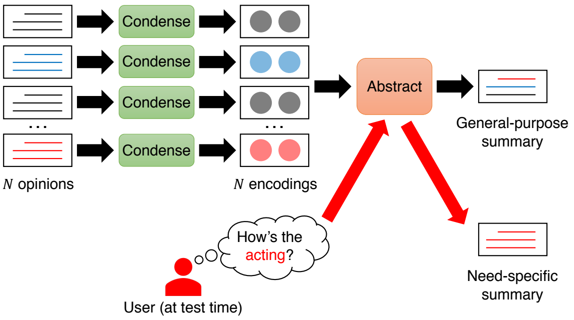
General-purpose summarization approaches have recently shown promising results with end-to-end models which are data-driven and take advantage of the success of sequence-to-sequence neural network architectures. Most approaches (Rush et al., 2015; See et al., 2017) encode documents and then decode the learned representations into an abstractive summary, often by attending to the source input (Bahdanau et al., 2014) and copying words from it (Vinyals et al., 2015). Under this modeling paradigm, it is no longer necessary to identify aspects and their sentiment for the opinion summarization task, as these are learned *indirectly* from training data (i.e., sets of opinions and their corresponding summaries). These models are usually tested on domains where the input is either one document or a small set of documents.

However, the number of input reviews for each target entity tends to be very large (150 for the example in Figure 1). It is therefore practically unfeasible to train a model in an end-to-end fashion, given the memory limitations of modern hardware. As a result, current approaches (Wang and Ling, 2016; Liu et al., 2018; Liu and Lapata, 2019) sacrifice end-to-end elegance in favor of a two-stage framework which we call EXTRACT-ABSTRACT (EA): an *extractive* model first selects a subset of opinions and an *abstractive* model then generates the summary while conditioning on the extracted subset (see Figure 2a). The extractive pass unfortunately has two drawbacks. Firstly, on account of having access to only a small subset of reviews, the summaries can be less informative and inaccurate, as shown in Figure 1. And secondly, user preferences cannot be easily taken into account (e.g., a user may wish to obtain a summary focusing on the acting or plot of a movie as opposed to a general-purpose summary) since more specialized information might have been removed.

In this paper, we propose CONDENSE-ABSTRACT (CA), an alternative two-stage framework which enables the use of *all* input reviews when generating the summary (see Figure 2b). The CONDENSE model first represents the input reviews as encodings, aiming to condense their meaning and distill information relating to sentiment and various aspects of the target being reviewed. The ABSTRACT model then fuses these condensed representations into one aggregate encoding and generates an opinion summary from it. We implement a simple yet effective instantiation of the CA framework, using a vanilla autoencoder as the CONDENSE model, and a decoder with attention and copy mechanisms as the ABSTRACT model. We also introduce a zero-shot customization technique allowing users to control important aspects of the generated summary at test time. Our approach enables controllable generation while leveraging the full spectrum of opinions available for a specific target.



(a) EXTRACT-ABSTRACT (EA) Framework



(b) CONDENSE-ABSTRACT (CA) Framework

Figure 2: Illustration of EA and CA frameworks for opinion summarization. In the CA framework, users can obtain need-specific summaries at test time (e.g., give me a summary focusing on acting).

We perform experiments on a dataset consisting of movie reviews and opinion summaries elicited from the Rotten Tomatoes website (Wang and Ling, 2016; see Figure 1). Our proposed approach outperforms state-of-the-art models by a large margin using automatic metrics and in a judgment elicitation study. We also verify that our zero-shot customization technique can effectively generate need-specific summaries.

2 Related Work

Most opinion summarization models follow extractive methods (see Kim et al., 2011 and Angelidis and Lapata, 2018 for overviews), with the exception of a few systems which are able to generate novel words and phrases not featured in the source text. Ganesan et al. (2010) propose a graph-based framework for generating concise opinion summaries, while Gerani et al. (2014) represent reviews as discourse trees which they aggregate to a global graph to generate a summary. Other work (Carenini et al., 2013; Mukherjee and Joshi, 2013) takes the distribution of opinions and their aspects into account so as to generate more readable summaries. Di Fabbrizio et al. (2014) present a hybrid system which uses extractive techniques to select salient quotes from the input reviews and embeds them into an abstractive summary to provide evidence for positive or negative opinions.

More recent work has seen the effective application of sequence-to-sequence models (Sutskever et al., 2014; Bahdanau et al., 2014) to various abstractive summarization tasks including headline generation (Rush et al., 2015), single- (See et al., 2017; Nallapati et al., 2016), and multi-document summarization (Wang and Ling, 2016; Liu et al., 2018; Liu and Lapata, 2019). Closest to our approach is the work of Wang and Ling (2016) who generate opinion summaries following a two-stage process which first selects/extracts reviews bearing pertinent information, and then generates the summary by conditioning on these reviews. More recent models (Chu and Liu, 2019; Bražinskas et al., 2020; Amplayo and Lapata, 2020) perform opinion summarization in an unsupervised way. However, these are mostly done on toy datasets (Chu and Liu, 2019), typically with a small number of reviews per target entity.

Our proposed framework works better on real-world datasets with a large number of reviews, since it eliminates the need to rely only on pre-selected salient reviews which we argue leads to information loss and subsequently less customizable generation. Instead, our model first *condenses* the source reviews into multiple dense vectors which serve as input to a decoder to generate an abstractive summary. Beyond producing more informative summaries, we demonstrate that our approach also allows to customize them. Recent conditional generation models have focused on controlling various aspects of the output such as politeness (Sennrich et al., 2016), length (Kikuchi et al., 2016), content (Fan et al., 2018), or style (Ficler and Goldberg, 2017). In contrast, our zero-shot customization technique requires neither training examples of documents and corresponding (customized) summaries nor specialized pre-processing to encode which tokens in the input might give rise to customization.

3 CONDENSE-ABSTRACT Framework

We propose an alternative to the EXTRACT-ABSTRACT (EA) approach which enables the use of all input reviews when generating the summary. Figure 2b illustrates our proposed CONDENSE-ABSTRACT (CA) framework. In lieu of an integrated encoder-decoder, we generate summaries using two separate models. The CONDENSE model returns review encodings for N input reviews, while the ABSTRACT model uses these encodings to create an abstractive summary. This two-step approach has two advantages for multi-document summarization. Firstly, CA-based models are more space-efficient, since the set of N reviews is not treated as one large instance but as N separate instances when training the CONDENSE model. And secondly, it is possible to generate maximally informative and customizable summaries targeting specific aspects of the input since the ABSTRACT model operates over the encodings of *all* available reviews.

In the following subsections, we explain how we instantiate a model using the CA framework, which we call CONDASUM, with an LSTM-based[1] vanilla autoencoder (CONDENSE model) and a decoder with attention and copy mechanisms (ABSTRACT model).

3.1 The CONDENSE Model

Let $\mathcal{D}$ denote a cluster of N reviews about a specific target (e.g., a movie or product). For each review $X = \{w_1, w_2, ..., w_M\} \in \mathcal{D}$, the CONDENSE model learns an encoding d, and word-level encodings $h_1, h_2, ..., h_M$. We employ a Bidirectional Long Short Term Memory (BiLSTM) encoder (Hochreiter and Schmidhuber, 1997) as our

---

[1] We use LSTMs as our text encoder instead of other popular alternatives, such as Transformers (Vaswani et al., 2017), since LSTMs work better on autoencoder architectures, as shown in the literature (Liu et al., 2019; Zhang et al., 2020), as well as during our preliminary experiments.

CONDENSE model:

$$\{\overrightarrow{h}_i, \overleftarrow{h}_i\} = \text{BiLSTM}_f(w_i) \tag{1}$$

$$h_i = [\overrightarrow{h}_i; \overleftarrow{h}_i] \quad d = [\overrightarrow{h}_M; \overleftarrow{h}_1] \tag{2}$$

where $\overrightarrow{h}_i$ and $\overleftarrow{h}_i$ are forward and backward hidden states of the BiLSTM at timestep i, and ; denotes concatenation.

Training is performed with a reconstruction objective. We use a separate LSTM as the decoder where the first hidden state z_0 is set to d. Words w'_t are generated using a softmax classifier:

$$z_t = \text{LSTM}_d(w'_{t-1}, z_{t-1}) \tag{3}$$

$$p(w'_t) = \text{softmax}(W z_t + b) \tag{4}$$

The auto-encoder is trained with a maximum likelihood loss:

$$\mathcal{L}_{condense} = -\sum\nolimits_{t=1}^{M} \log p(w_t) \tag{5}$$

Once training has taken place, we use the CONDENSE model to obtain N pairs of review encodings $\{d_i\}$ and word-level encodings $\{h_{i,1}, h_{i,2}, ..., h_{i,M}\}$, $1 \leq i \leq N$ as representations for the reviews in $\mathcal{D}$.

3.2 The ABSTRACT Model

The ABSTRACT model first fuses the multiple encodings obtained from the CONDENSE stage and then generates a summary using a decoder.

Multi-source Fusion We aggregate N pairs of review encodings $\{d_i\}$ and word-level encodings $\{h_{i,1}, h_{i,2}, ..., h_{i,M}\}$, $1 \leq i \leq N$ into a single pair of review encoding d' and word-level encodings $h'_1, h'_2, ..., h'_V$, where V is the number of total unique tokens in the input.

Review encodings are fused using an attentive pooling method which gives more weight to important reviews. Specifically, we learn a set of weight vectors $a_i \in \mathbb{R}^{D_d}$, where D_d is the dimension of d_i, to weight-sum the review encodings:

$$\bar{d} = \sum\nolimits_i d_i / N \tag{6}$$

$$a_i = \text{softmax}(d_i^\top W_p \bar{d}) \tag{7}$$

$$d' = \sum\nolimits_i a_i * d_i \tag{8}$$

where the mean encoding $\bar{d}$ is used as the query vector, and $W_p \in \mathbb{R}^{D_d \times D_d \times D_d}$ is a learned tensor.

We also fuse word-level encodings, since the same words may appear in multiple reviews. To do this, we simply average all encodings of the same word, if multiple tokens of the word exist:

$$h'_j = \sum\nolimits_{(i,k):w_{i,k}=w_j} h_{i,k} / V_{w_j} \tag{9}$$

where V_{w_j} is the number of tokens for word w_j in the input.

Decoder The decoder generates summaries conditioned on the fused review encoding d' and word-level encodings $h'_1, h'_2, ..., h'_V$. We use a simple LSTM decoder enhanced with attention (Bahdanau et al., 2014) and copy mechanisms (Vinyals et al., 2015). We set the first hidden state s_0 to d', and run an LSTM to calculate the current hidden state using the previous hidden state s_{t-1} and word y'_{t-1} at time step t:

$$s_t = \text{LSTM}(y'_{t-1}, s_{t-1}) \tag{10}$$

At each time step t, we use an attention mechanism over word-level encodings to output the attention weight vector a_t and context vector c_t:

$$e_t^i = v^\top \tanh(W_h h'_i + W_s s_t + b_a) \tag{11}$$

$$a_t = \text{softmax}(e_t) \tag{12}$$

$$c_t = \sum\nolimits_i a_t^i * h'_t \tag{13}$$

Finally, we employ a copy mechanism over the input words to output the final word probability $p(y'_t)$ as a weighted sum over the generation probability $p_g(y'_t)$ and the copy probability $p_c(y'_t)$:

$$p_g(y'_t) = \text{softmax}(W_g[s_t; c_t] + b_g) \tag{14}$$

$$\sigma_t = \sigma(v_s^\top s_t + v_c^\top c_t + v_y^\top y'_t) \tag{15}$$

$$p_c(y'_t) = \sum\nolimits_{i:y'_i=y'_t} a_t^i \tag{16}$$

$$p(y'_t) = \sigma_t * p_g(y'_t) + (1 - \sigma_t) * p_c(y'_t) \tag{17}$$

where W, v, and b are learned parameters, and t is the current timestep.

Salience-biased Extracts The model presented so far has no explicit mechanism to encourage salience among reviews. We direct the decoder towards salient reviews by incorporating information from an extractive step. Specifically, we use BERTCENT, a centroid-based (Radev et al., 2000) document extraction method that obtains document representations by resorting to BERT (Devlin et al., 2019).

BERTCENT can be simply described as follows. Firstly, given a review, we obtain its encoding as the average of its token encodings obtained from BERT. We then take the average of the review encodings and treat it as the *centroid* of the input reviews, which approximately represents the information that is considered salient. We select the top k reviews whose encodings are the nearest neigbors to the centroid. The selected reviews are concatenated into a long sequence and encoded using a separate BiLSTM whose output serves as input to an LSTM decoder. This decoder generates a *salience-biased* hidden state r_t. We then update hidden state s_t in Equation (10) as $s_t = [s_t; r_t]$.

Using these extracts, we still take all input reviews into account, while acknowledging that some might be more descriptive than others. This module is a key component to generating *general-purpose* opinion summaries, where a set of aspects is deemed more salient than others (e.g., in general, people care more about the plot rather than the special effects of a movie). However, this extractive module may hurt the customizability of the model (e.g., generating *need-specific* summaries, details explained in Section 3.3), which we show in our experiments in Section 5.

Training We use two objective functions to train the ABSTRACT model. Firstly, we use a maximum likelihood loss to optimize the generation probability distribution $p(y'_t)$ based on gold summaries $Y = \{y_1, y_2, ..., y_L\}$ provided at training time:

$$\mathcal{L}_{generate} = -\sum\nolimits_{t=1}^{L} \log p(y_t) \tag{18}$$

Secondly, we propose a way to introduce supervision and guide the attention pooling weights W_p in Equation (7) when fusing the review encodings. Our motivation is that the resulting fused encoding d' should be roughly equivalent to the encoding of summary y, which can be calculated as $z = \text{CONDENSE}(y)$. Specifically, we use a hinge loss that maximizes the inner product between d' and z and simultaneously minimizes the inner product between d' and n_i, where n_i is the encoding of one of five randomly sampled negative summaries:

$$\mathcal{L}_{fuse} = \sum\nolimits_{i=1}^{5} \max(0, 1 - d'z + d'n_i) \tag{19}$$

The final objective is then the sum of both loss functions:

$$\mathcal{L}_{abstract} = \mathcal{L}_{generate} + \mathcal{L}_{fuse} \tag{20}$$

3.3 Zero-shot Customization

At test time, we can either generate a general-purpose summary or a *need-specific* summary. To generate the former, we run the trained model as is and use beam search to find the sequence of words with the highest cumulative probability. To generate the latter, we employ the following simple technique that revises the query vector $\bar{d}$ in Equation (6).

More concretely, in the movie review domain, users might wish to obtain a summary that focuses on a specific sentiment (positive or negative) or aspect (e.g., acting, plot, etc.) of a movie. In a different domain, users might care about the price of a product, its comfort, and so on. Since these summaries are not available at training time, we undertake such customization without requiring access to need-specific summaries. Instead, at test time, we assume access to background reviews to represent the user need. For example, if we wish to generate a positive summary, our method requires a set of reviews with positive sentiment. This is an easy and practical way to approximately provide the model some background on how sentiment is communicated in a review.

We use these background reviews conveying a user need x (e.g., acting, plot, positive or negative sentiment) in the multi-source fusion module to attend more to input reviews related to x. Let C_x denote the set of background reviews. We obtain a new query vector $\hat{d} = \sum_{c=1}^{|C_x|} d_c / |C_x|$, where d_c is the encoding of the c'th review in C_x, calculated using the CONDENSE model. This simple change allows the model to focus on input reviews with semantics similar to the user's need as conveyed by the background reviews C_x. The new query vector $\hat{d}$ is used instead of $\bar{d}$ to obtain review encoding d' (see Equation (6)).

4 Experimental Setup

Dataset We performed experiments on the Rotten Tomatoes dataset[2] provided in Wang and Ling (2016). It contains 3,731 movies; for each movie we are given a large set of reviews written by professional critics and users and a gold-standard consensus summary written by an editor (see an example in Figure 1). We report the dataset statistics in Table 1. Following previous work (Wang and Ling, 2016), we used a generic label for movie

	Train	Dev	Test
#movies	2,458	536	737
#reviews/movie	100.0	98.0	100.3
#tokens/review	23.6	23.5	23.6
#tokens/summary	23.8	23.6	23.8

Table 1: Dataset statistics of Rotten Tomatoes.

titles during training which we replace with the original titles during inference.

Training Configuration For all experiments, our model used word embeddings with 128 dimensions, pretrained using GloVe (Pennington et al., 2014). We set the dimensions of all hidden vectors to 256 and the batch size to 8. For decoding summaries, we use a length-normalized beam search with beam size of 5. We applied dropout (Srivastava et al., 2014) at a rate of 0.5. The model was trained using the Adam optimizer (Kingma and Ba, 2015) with default parameters and l_2 constraint (Hinton et al., 2012) of 2. We performed early stopping based on model performance on the development set. Our model is implemented in PyTorch[3].

Comparison Systems We compare our approach against two types of methods: one-pass methods and methods that use the EA framework. One-pass methods include (a) LEXRANK (Erkan and Radev, 2004), a PageRank-like summarization algorithm which generates a summary by selecting the n most salient units, until the length of the target summary is reached; (b) OPINOSIS (Ganesan et al., 2010), a graph-based abstractive summarizer that generates concise summaries of highly redundant opinions; (c) SUMMARUNNER (Nallapati et al., 2017), a supervised neural extractive model where each review is classified as to whether it should be part of the summary or not; and (d) BERTCENT, a centroid-based method discussed in Section 3.2 that selects $k = 1$ review nearest to the centroid.

EA-based methods include (g) REGRESS+S2S (Wang and Ling, 2016), an instantiation of the EA framework where a ridge regression model with hand-engineered features implements the EXTRACT model, while an attention-based sequence-to-sequence neural network is the ABSTRACT model; (h) BERTCENT+S2S, our implementation of an EA-based system which uses BERTCENT instead of REGRESS as the EXTRACT model; and (i) BERTCENT+PTGEN, the same model as (h) but enhanced with a copy mechanism (Vinyals et al., 2015). For all extractive steps, we set $k = 5$, which is tuned on the development set.

5 Results

Automatic Evaluation We considered two evaluation metrics which are also reported in Wang and Ling (2016): METEOR (Denkowski and Lavie, 2014), a recall-oriented metric that rewards matching stems, synonyms, and paraphrases, and ROUGE-SU4 (Lin, 2004) which is calculated as the recall of unigrams and skip-bigrams up to four words. We also report F_1-scores for ROUGE-1/2/L (Lin, 2004). Unigram and bigram overlap (ROUGE-1 and ROUGE-2) are a proxy for assessing informativenes while the longest common subsequence (ROUGE-L) measures fluency.

Our results are presented in Table 2. Among one-pass systems, the extractive model BERTCENT performs the best; despite being unsupervised and extractive, it benefits from the ability of large neural language models to learn general-purpose representations. When used in EA-based systems, BERTCENT also improves the system performance, where BERTCENT+PTGEN performs the best. Interestingly, BERTCENT performs better than BERTCENT+PTGEN in terms of METEOR and ROUGE-SU4, while the latter performs better in terms of ROUGE-1/2/L. Our CA-based model CONDASUM outperforms all other models across all metrics, showing that exploiting information about all reviews helps in improving performance.

We present in Table 3 various ablation studies, which assess the contribution of different model components. Results confirm that our multi-source fusion method and the fusion loss improve performance. Morevoer, using BERTCENT for the salient-biased extractive step is better than no extractive step or using SUMMARUNNER, which is a weaker extractive model. Both multi-source fusion and salient-biased extracts help create better general-purpose summaries; the former learns which reviews to focus on while the latter explicitly selects the most important ones.

Human Evaluation In addition to automatic evaluation, we also assessed system output by eliciting human judgments. Participants compared summaries produced from the best extractive baseline (BERTCENT), the best EA system (BERTCENT+PTGEN), and our model CONDA-

BertCent+PtGen	-0.263	-0.358	-0.152*
BertCent	-0.179	-0.112	-0.102*
CondaSum	-0.042	0.021	-0.078
Gold	0.483	0.448	0.331

Table 4: Best-worst scaling scores on informativeness (Inf), correctness (Corr) and grammaticality (Gram). All pairwise systems differences between CondaSum and other system summaries are significant, except the values marked with asterisk (*), based on a one-way ANOVA with posthoc Tukey HSD tests ($p < 0.05$).

Sum, respectively. As an upper bound, we also included Gold standard summaries.

The study was conducted on the Amazon Mechanical Turk platform using Best-Worst Scaling (BWS; Louviere et al., 2015), a less labor-intensive alternative to paired comparisons that has been shown to produce more reliable results than rating scales (Kiritchenko and Mohammad, 2017). Specifically, participants were shown the movie title and basic background information (i.e., synopsis, release year, genre, director, and cast). They were also presented with three system summaries and asked to select the *best* and *worst* among them according to three criteria: *Informativeness* (i.e., does the summary convey opinions about specific aspects of the movie in a concise manner?), *Correctness* (i.e., is the information in the summary factually accurate and corresponding to the information given about the movie?), and *Grammaticality* (i.e., is the summary fluent and grammatical?). Examples of summaries are shown in Figure 1 and more can be found in the Appendix. We randomly selected 50 movies from the test set and compared all possible combinations of summary triples for each movie. We collected three judgments for each comparison. The order of summaries and movies was randomized per participant.

The scores are computed as the percentage of times it was chosen as best minus the percentage of times it was selected as worst. The scores range from -1 (worst) to 1 (best) and are shown in Table 4. Perhaps unsurprisingly, the human-generated gold summaries were considered best, whereas our model CondaSum was ranked second, indicating that humans find its output more informative, correct, and grammatical compared to other systems. BertCent was ranked third followed by BertCent+PtGen. We inspected the summaries produced by the latter system and found they were factually incorrect bearing little correspondence to the movie (examples shown in the Appendix), possibly due to the huge information loss at the extraction stage.

Customizing Summaries We further assessed the ability of CA systems to generate customized summaries at test time. We evaluate CondaSum models with and without the salience-biased extractive step. The latter model biases summary generation towards the k most salient extracted opinions using an additional extractive module which may

Gold

Whether you choose to see it as a statement on consumer culture or simply a special effects-heavy popcorn flick, Gremlins is a minor classic.

CondaSum with extractive step

General: Gremlins is a wholesome, entertaining horror film with an enormous cast of eager stars.

Customized (Positive): Gremlins is a wholesome, entertaining horror film with an enormous cast of eager stars.

Customized (Negative): Gremlins is a wholesome, entertaining horror film with an enormous cast of eager stars.

CondaSum without extractive step

General: Gremlins may appeal to the dark Christmas horror genre.

Customized (Positive): Gremlins is an intelligent, funny Christmas horror film from Joe Dante's novel.

Customized (Negative): Gremlins is an atrociously-acted project whose unoriginal and ineptly-staged horror film from Joe Dante's novel.

Figure 3: Examples of general-purpose and need-specific opinion summaries for the movie "Gremlins", generated by two versions of CondaSum. We also show the consensus summary (Gold). Words/phrases in color highlight aspects pertaining to positive and negative. More examples can be found in the Appendix.

discard information relevant to the user's need. We thus expect this model to be less effective for customization than CondaSum which makes no assumptions regarding which summaries to consider.

In this experiment, we assume users may wish to control the output summaries in four ways focusing on acting- and plot-related aspects of a movie review, as well as its sentiment, which may be positive or negative. Let Cust(x) be the zero-shot customization technique discussed in the Section 3.3, where x is an information need (i.e., acting, plot, positive, or negative). We sampled a set of background reviews C_x ($|C_x|$=1,000) from a corpus of 1 million reviews covering 7,500 movies from the Rotten Tomatoes website, made available in Ficler and Goldberg (2017). The reviews contain sentiment labels provided by their authors and heuristically classified aspect labels. We then ran Cust(x) using both the CondaSum models. We show in Figure 3 customized summaries generated by the models.

To determine which system is better at customization, we again conducted a judgment elicitation study on Amazon Mechanical Turk. Participants read a summary which was created by a general-purpose system or its customized variant. They were then asked to decide if the summary is generic or focuses on a specific aspect (plot or acting) and expresses positive, negative, or neutral sentiment. We selected 50 movies (from the test set) which had mixed reviews and collected judgments from three different participants per summary. The summaries were presented in random order per participant.

	with extracts		without extracts	
Customized	No	Yes	No	Yes
Acting	40.3	40.3	42.0	**78.0**
Plot	73.3	75.0	51.3	**76.7**
Positive	66.0	67.7	65.3	**80.0**
Negative	22.7	22.0	20.7	**40.7**

Table 5: Proportion of summaries which mention a specific aspect/sentiment. **Boldfaced** values show a significant increase ($p < 0.01$; using two-sample bootstrap tests) compared to the non-customized system variant. Aspects are not mutually exclusive (e.g. a summary may talk about both acting and plot), thus the total percentage may exceed 100%.

Table 5 shows what participants thought of summaries produced by non-customized systems (see column No) and systems which had customization switched on (see column Yes). Overall, we observe that CondaSum without the extractive step is able to customize summaries to a great extent. In all cases, crowdworkers perceive a significant increase in the proportion of aspect x when using Cust(x). CondaSum with the extractive step is unable to generate need-specific summaries, showing no discernible difference between generic and customized summaries. This indicates that the use of an extractive module, which is one of the main components of EA-based approaches, limits the flexibility of the abstractive model to customize summaries based on a user need.

6 Conclusions

We introduced the Condense-Abstract (CA) framework for opinion summarization which eliminates the need to rely only on a small subset of extracted reviews and allows the use of all reviews to generate maximally informative summaries. We presented CondaSum, an instantiation of this framework and showed in both automatic and human-based evaluation that it is superior to purely extractive models and abstractive models that include an extractive pre-selection stage. We also showed that when an extractive step is not used, our zero-shot customization technique is able to generate need-specific summaries at test time. In the future, we plan to apply the CA framework to other multi-document summarization tasks.

Coloring the Black Box:
What Synesthesia Tells Us about Character Embeddings

Katharina Kann*

Mauro M. Monsalve-Mercado*
Columbia University
mauro.m.monsalve@columbia.edu

Abstract

In contrast to their word- or sentence-level counterparts, character embeddings are still poorly understood. We aim at closing this gap with an in-depth study of English character embeddings. For this, we use resources from research on grapheme–color synesthesia – a neuropsychological phenomenon where letters are associated with colors –, which give us insight into which characters are similar for synesthetes and how characters are organized in color space. Comparing 10 different character embeddings, we ask: How similar are character embeddings to a synesthete's perception of characters? And how similar are character embeddings extracted from different models? We find that LSTMs agree with humans more than transformers. Comparing across tasks, grapheme-to-phoneme conversion results in the most human-like character embeddings. Finally, ELMo embeddings differ from both humans and other models.

1 Introduction

Neural network models have become crucial tools in natural language processing (NLP) and define the state of the art on a large variety of tasks (Wang et al., 2018). However, they are difficult to understand and are often considered "black boxes".[1] This can make their use difficult to defend in many settings, for instance in a legal context, and constitutes a barrier for model improvement. Therefore, a lot of research has been dedicated to investigating the information encoded by neural networks. Especially word embeddings, contextualized word representations, and language representation models like BERT (Devlin et al., 2019) have been exhaustively studied (Rogers et al., 2020).

Figure 1: Characters as they might be seen by a grapheme–color synesthete. The colors in this example are randomly chosen.

Character embeddings are used for a large set of tasks, either as a supplement to word-level input, e.g., for part-of-speech tagging by Plank et al. (2016), or on their own, e.g., for character-level sequence-to-sequence (seq2seq) tasks by Kann and Schütze (2016). Despite this, they have not yet been explicitly analysed. One reason for this might be that identifying relevant properties to study is more challenging than for their word-level counterparts. However, we argue that, in order to truly shine light into black-box NLP models, it is necessary to understand each and every component of them.

In this paper, we perform a detailed study of English character embeddings. Our **first contribution** is a **character similarity task** (§3) in analogy to the word-based version: *Do embeddings agree with humans on which pairs of characters are similar?* While e.g., *cat* and *tiger* are generally considered more similar than *cat* and *chair*, this is not trivial for characters. For our annotations, we exploit a phenomenon called *synesthesia*. People with synesthesia, *synesthetes*, share perceptual experiences between two or more senses (§2). For grapheme–color synesthetes, each letter is associated with a color, which is consistent over a person's life time (Eagleman et al., 2007), cf. Figure 1. Using a dataset of letters from the English alphabet and the associated colors from 4269 synesthetes (Witthoft et al., 2015), we compute differences in color space (§3.3) as a proxy for character similarity.

As our **second contribution**, we propose a set

---

*Equal contribution.

[1] This fact has led to the establishment of a workshop with the same name: https://blackboxnlp.github.io

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2673–2685
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

of methods to **characterize the structure of character embedding matrices** (§4). The methods we propose are (i) a clustering analysis, (ii) computing the clustering coefficient, (iii) measuring betweenness centrality, and (iv) computing cut-distances.

Our **final contribution** is a detailed **character embedding analysis** (§6). We explore 6 types of embeddings, obtained from 4 different architectures trained on 3 different tasks, as well as 4 embedding matrices from pretrained ELMo models (Peters et al., 2018). Comparing across models trained on the same task, character embeddings from LSTMs, which, similar to humans, process input sequentially, correlate more with human similarity scores than embeddings from transformers. Comparing across tasks, character embeddings from language modeling show a surprisingly low correlation with human judgments. In contrast, the correlation is highest for grapheme-to-phoneme conversion (G2P). This is in line with findings that colors perceived by synesthetes are influenced by the sound of each letter (Asano and Yokosawa, 2013).

2 Synesthesia

Synesthesia is the perceptual phenomenon that two or more sensory or cognitive pathways are co-activated in the brain by stimulating only one of them. For example, for a person with chromesthesia, a common form of synesthesia, hearing a particular sound evokes the visual perception of colors (Cytowic, 2018; Simner, 2012).

By far the most common form of synesthesia is grapheme-color synesthesia, for which subjects report the perception of colors when seeing numerals or letters (cf. Figure 1). The neural basis behind the phenomenon is still a much debated topic, but evidence suggests it might be the result of increased effective connectivity between the brain areas involved (Ramachandran and Hubbard, 2001a). For example, visual area V4a in the ventral pathway, often associated with contextual processing and perception of color, has shown to be part of a complex in the fusiform gyrus exhibiting higher cortical thickness, volume, and surface area in synesthetes (Hubbard et al., 2005). Belonging to this complex and adjacent to the color processing region is the area dedicated to the visual recognition and processing of graphemes, suggesting that a prominence of this type of synesthesia is due to higher region interconnectivity being more probable.

Additional evidence supports the idea that synesthetic associations often involve the extraction of meaning from a stimulus, suggesting that abstract constructions play a major role in the associations formed (Mroczko-Wasowicz and Nikolic, 2014). For cases where language is involved, semantics may in part underlie color representations of words and graphemes in V4.

The study of synesthesia presents a unique opportunity to understand the neural basis of cognitive models of language (Ramachandran and Hubbard, 2001b; Simner, 2007). Here, grapheme–color synesthesia serves as a window to look at how the brain represents individual characters.

3 A Character Similarity Task

3.1 Motivation: Word Similarity

Our first contribution is a character-level analogue of the word similarity task, an intrinsic evaluation method for word embeddings. It consists of judging the similarity of pairs of words, e.g., of *cat* and *tiger*. To obtain a gold standard for this task, human annotators assign similarity scores to a list of word pairs. This is not always trivial: are *cat* and *bird* more or less similar than *cat* and *fish*? However, people tend to agree on general tendencies.

Word embeddings are evaluated on similarity datasets as follows: The similarity – usually cosine similarity – of all pairs of words is computed. The agreement between models and human annotations is then quantified as the correlation between the two vectors of scores. Word embeddings with a higher performance on word similarity tasks are expected to perform better on downstream tasks, since they encode valuable information about words and the relationships between them.

3.2 From Word to Character Similarity

In order to design a *character* similarity task, we require a gold standard. However, we are not likely to get a meaningful answer when asking people if *B* and *J* are more similar than *C* and *Q*.

We solve this problem by looking at how different characters are represented by grapheme–color synesthetes in color space. This tells us how similar characters are perceived to be without having to ask explicitly. We leverage a dataset collected by Witthoft et al. (2015), which consists of letter-to-color mappings collected from 4269 synesthetes and compute pair-wise perceptually uniform distances between characters. Analogously to the word-level version of the task, we then take as our gold standard the average over all annotators. For embeddings, we compute cosine similarities between character vectors.

We differ from the word similarity task in an important detail: we do not evaluate the *quality* of embeddings. Instead, we aim to understand character embeddings by assessing how *similar to the human perception of characters* they are. In particular, we do not necessarily expect embeddings which score higher on our task to perform better on downstream applications.

3.3 Human Perception of Color Differences

To motivate the distance metric we use, we first summarize human perception of color. The visual process of color perception starts in the retina, where three types of light-sensitive receptors are tuned to respond broadly around three distinct frequencies in the visible spectrum. However, color perception is not simply reduced to combinations of these physiological responses. The human brain can perceive the same physical light frequency as a different color depending on a plethora of contextual markers, mostly due to further processing upstream of the retina into high-level visual cortical areas, where associations are formed between environmental cues and the object being visualized.

Important contextual properties of color affecting perception, often discussed in color theory as the Munsell (or HSL) color system, are its hue, saturation, and lightness. Combinations of these properties are interpreted in a *highly non-linear* manner by cortical areas tasked with color perception. Not surprisingly, simple metrics for color comparison, such as the Euclidean distance in RGB space, perform poorly in situations involving a color discrimination task. Constructing perceptually uniform metrics that deal with these perceived non-linearities is an active field of research. One standard metric for perceptual color comparison is the CIEDE2000 color difference (Sharma et al., 2005), which includes several correction factors for a modified Euclidean metric on HSL space. We employ CIEDE2000 in our analysis.

4 Analysis of the Distance Matrix

CIEDE2000 allows us to obtain pair-wise distances between all letters in the alphabet by computing color differences for the associated colors as perceived by synesthetes. The character similarity task then compares *vectors* of pair-wise distances. However, we can gain additional insight from the distance *matrices*, which represent fully connected networks whose nodes are the letters in the alphabet and whose edges are weighted by the pair-wise differences. Thus, we further propose four well-established methods from network theory (Newman, 2018) for the analysis of character embeddings and human difference matrices.

Clustering analysis. To characterize the global structure of the network, we first propose Ward's variance minimization algorithm to identify clusters, i.e., groups of letters that are similar to each other, but far away from other letters. Ward's algorithm is part of a family of hierarchical clustering algorithms whose objective function aims at minimizing the variance within clusters (Ward, 1963). Starting from a forest of clusters (initially single nodes), the algorithm evaluates the Ward distance d between a new cluster u made up of clusters s and t, and a third cluster v not used yet, as

$$d(u, v) = \sqrt{a + b - c}, \tag{1}$$

with

$$a = \frac{|v| + |s|}{T} d(v, s)^2, \tag{2}$$

$$b = \frac{|v| + |t|}{T} d(v, t)^2, \tag{3}$$

$$c = \frac{|v|}{T} d(s, t)^2, \tag{4}$$

where $T := |s| + |t| + |v|$, and $|\cdot|$ is the size of the cluster. If u is a good cluster, then s and t are removed from the forest and the algorithm continues until only one cluster is left. Finally, the *number of clusters*, *their sizes*, and the *Ward distances between clusters* characterize the global structure of the network.

Clustering coefficient. The clustering coefficient provides a way to measure the degree to which nodes in a network cluster together. For a binary network, the local version represents the fraction of the number of pairs of neighbors of a node that are connected, over the total number of pairs of neighbors of said node, and it measures the influence of a node on its immediate neighbors. Several generalizations for weighted networks have been proposed (Saramäki et al., 2007). Here, we use the average of the weights for neighbors in the subgraph of a node u

$$c_u = \frac{1}{deg(u)(deg(u) - 1))} \sum_{vw} (\hat{w}_{uv} \hat{w}_{uw} \hat{w}_{vw})^{1/3},$$

where $\hat{w}_i$ denotes weight w_i normalized by the maximum weight in the network, and *deg* is the degree of the node (the sum of its edges' weights). The average over all nodes is used as a proxy for the overall level of clustering within the network.

Betweenness centrality. Different concepts of centrality attempt to capture the relative importance of particular nodes in the network. One such concept, *betweenness*, measures the extent to which a node lies on the shortest path between pairs of nodes (Brandes, 2008). In a sense, it generalizes the clustering coefficient from a measure of the local influence of a node to immediate neighbors to the whole network. In particular, it accounts for nodes that connect two different clusters while not being a part of either. Betweenness centrality is computed as the fraction of all-pairs shortest paths that pass through a particular node u

$$B(u) = \sum_{s,t} \frac{n(s,t|u)}{n(s,t)},$$

where the sum is over all nodes s and t in the network, and n counts the number of shortest paths between two nodes, optionally taking into account if it passes through u.

Cut-distance. The fourth and last approach we propose to characterize our matrices of character distances is to employ a matrix norm called cut-norm. It is widely used in graph and network theory and has been shown to capture global features such as clustering and sparseness (Frieze and Kannan, 1999). The cut-norm of a matrix $A = (a_{ij})_{i \in M, j \in N}$ is defined as

$$||A||_c := \max \left\{ \frac{\left|\sum_{i \in I} \sum_{j \in J} a_{ij}\right|}{|I||J|} : \begin{matrix} I \subset M \\ J \subset N \end{matrix} \right\},$$

i.e., the maximum over all possibles sub-matrix arrangements is taken as the norm. In practice, we compute it using an efficient implementation[2] that relies on Grothendieck's inequality for an approximation (Alon and Naor, 2004; Wen et al., 2013). In addition, the norm naturally gives rise to a distance metric $d_c(A, B) := ||A - B||_c$ that allows us to compare pairs of distance matrices directly.

5 Models and Tasks

We now describe the tasks and model architectures we employ to train different character embeddings.

5.1 Tasks

Language modeling. The task of language modeling consists of computing a probability distribution over all elements in a predefined vocabulary, given a sequence of past elements. Language models can either be used to assign a probability to an input sequence or to generate text by sampling from the probability distributions. We train language models on the character level, i.e., the vocabulary consists of the English alphabet.

All our language models are trained on wikitext-103.[3] We use the provided training, development, and test splits. The training set consists of roughly 1 million tokens.

Morphological inflection. In languages that exhibit rich inflectional morphology, words inflect: grammatical information like number, case, and tense are incorporated into the word itself. For instance, *wrote* is the inflected form of the English lemma *write*, expressing past tense.

The task of morphological inflection consists of mapping a lemma to an inflected form which is defined by a set of morphological tags. Morphological inflection is typically being cast as a character-level seq2seq task, where the characters of the lemma together with the morphological tags are the input, and the characters of the inflection are the output (Kann and Schütze, 2016):

`PST w a l k` → `w a l k e d`

We train our inflection models on the $10,000$ English training examples provided by Cotterell et al. (2017) and use the corresponding development and test sets with $1,000$ examples each.

Grapheme-to-phoneme conversion. Given a word's spelling, G2P consists of generating an (IPA-like) representation of its pronunciation:

`p r e t t i e r` → `P R IH T IY ER`

It has been shown that similar-sounding letters tend to be associated with similar synesthetic colors (Asano and Yokosawa, 2013). Hence, we assume that the embedding space induced by this task could be similar to human perception of characters.

We train all G2P models on examples extracted from the CMU Pronouncing Dictionary.[4] Our training, development, and test sets consist of 114,399, 5447, and 12,855 examples, respectively.[5]

5.2 Architectures

To isolate the effects of task and model architecture, we train different architectures for each task. All test set performances are shown in Table 1. We train 50 models with different random seeds for seq2seq tasks, and 10 instances for language models. For our analysis, we look at the input embeddings and average pair-wise distances over models for each group. All models have been trained on an NVidia Tesla K80 GPU.

LSTM seq2seq architecture. Our first architecture is a seq2seq model similar to that by Bahdanau et al. (2015). It consists of a bi-directional long short-term memory (LSTM; Hochreiter and Schmidhuber, 1997) encoder and an LSTM decoder, which are connected via an attention mechanism. We apply it on the character level.

We train this architecture on morphological inflection (**Infl$_{\text{LSTM}}$**) and G2P (**G2P$_{\text{LSTM}}$**), using the fairseq sequence modeling toolkit for our implementation.[6] All embeddings and hidden states are 100-dimensional, and both encoder and decoder have 1 hidden layer. For training, we use an Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of 0.001, dropout with a coefficient of 0.3, and a batch size of 20. To account for different training set sizes, we train our model for G2P for 15 and our model for inflection for 100 epochs.

Transformer seq2seq architecture. We further experiment with a transformer seq2seq architecture (Vaswani et al., 2017). Similar to the LSTM seq2seq model, this architecture consists of an encoder and a decoder which are connected by an attention mechanism. However, the encoder and the decoder consist of combinations of feed-forward and attention layers instead of LSTMs.

We apply this architecture to morphological inflection (**Infl$_{\text{T}}$**) and G2P (**G2P$_{\text{T}}$**), and implement the models using the fairseq toolkit. All embeddings have 256 dimensions, and hidden layers are 1024-dimensional. Both encoder and decoder have 4 layers, and use 4 attention heads. We employ an Adam optimizer with an initial learning rate of 0.001 for training, together with dropout with a coefficient of 0.3, and a batch size of 400. We train our models for G2P for 30 epochs and our models for morphological inflection for 100 epochs.

Infl$_{\text{LSTM}}$	**Infl$_{\text{T}}$**	**G2P$_{\text{LSTM}}$**	**G2P$_{\text{T}}$**	**LM$_{\text{LSTM}}$**	**LM$_{\text{T}}$**
0.95	0.94	0.64	0.62	3.37	2.62
50	50	50	50	10	10

Table 1: **Top**: accuracy for inflection and G2P and character-level perplexity for language modeling. **Bottom**: number of model instances. Results are averaged over all runs; models are described in the text.

LSTM language model architecture. We also experiment with an LSTM language model (**LM$_{\text{LSTM}}$**). This architecture consists of a unidirectional LSTM, and it receives the last generated character as input at each time step.

Our implementation is based on the official pytorch LSTM language model example.[7] We use the default hyperparameters except for the following: our embeddings and LSTM hidden states are 512-dimensional, we use 2 hidden layers, and we train for 2 epochs with a batch size of 64.

Transformer language model architecture. Our last architecture is a transformer language model (**LM$_{\text{T}}$**). Like the LSTM language model, it receives previously generated characters as input and computes a probability distribution over the character vocabulary.

Again, we use the fairseq toolkit for our implementation, and employ the default hyperparameters for the transformer language model. We use an Adam optimizer with an initial learning rate of 0.0005 for training, and dropout with a coefficient of 0.1. This model is trained for 3 epochs.

5.3 Pretrained Models

We further analyze the character embeddings of ELMo models (Peters et al., 2018). ELMo models are pretrained networks, aimed at producing contextualized word embeddings for use in downstream NLP tasks. The model architecture consists of a convolutional layer over character embeddings, whose output is then fed into a 2-layer bidirectional LSTM. ELMo models are trained with a bidirectional language modeling objective.

We experiment with 4 English models which are available online:[8] small (**ELMo$_{\text{s}}$**), medium (**ELMo$_{\text{m}}$**), original (**ELMo$_{\text{o}}$**) and original-5.5B (**ELMo$_{\text{l}}$**). Those models differ in the number of their parameters and the amount of text they have been trained on: ELMo$_{\text{s}}$ and ELMo$_{\text{m}}$ have 13.6 million and 28 million parameters, respectively.

Figure 3: Cut-distance between the average human distance matrix and all character embeddings.

Both ELMo$_\mathrm{o}$ and ELMo$_\mathrm{l}$ have 93.6 million parameters. All models except for ELMo$_\mathrm{l}$ have been trained on the 1 Billion Word Benchmark.[9] ELMo$_\mathrm{l}$ has been trained on a combination of Wikipedia and news crawl data, which together result in a dataset of 5.5 billion tokens.

6 Character Embedding Analysis

6.1 Results on the Character Similarity Task

The Pearson correlation of all models with human judgements as well as with each other is shown in Figure 2. G2P$_\mathrm{LSTM}$ shows the highest correlation with 0.30, while LM$_\mathrm{T}$ is not correlated at all, and ELMo$_\mathrm{m}$ obtains the strongest negative correlation with -0.07.

More generally, we see that most models are correlated with each other (between 0.17 and 0.83), with the exception of the ELMos: the predictions of ELMo$_\mathrm{l}$ are the only ones which have a Pearson correlation ≥ 0.1 with those of some other models.

Comparing to human scores, we find the following patterns: embeddings from seq2seq tasks show a higher correlation than embeddings from language models. Even ELMo models, which are trained on large amounts of text, obtain a maximum correlation of 0.08. Thus, we conclude that language modeling does not result in embeddings which perform well on our character similarity task. Embeddings for G2P correlate more strongly with human character perception than embeddings from inflection, when comparing identical architectures. This is noteworthy, since colors perceived by synesthetes are supposed to be influenced by the sound of each letter (Asano and Yokosawa, 2013), similar to the embeddings for G2P. Finally, comparing across architectures, we see that LSTM models correlate stronger with human judgments than transformer models, which is in line with the common understanding that recurrent neural networks might be better models of human cognition.

6.2 Comparing Humans and Machines

Clustering analysis. First, we look at the global structure of all character embeddings (cf. Figure 5). All but the ELMo models exhibit a marked separation between a tight cluster of vowels (`AEIOU`) or extended vowels (+`Y`), which are highly similar, and the rest of the alphabet. In contrast, this distinction is not found for humans, neither for individuals nor the average distance matrix. Despite this, the human average does present a clear global structure (cf. appendix for details). One clear cluster is `BDGJKMNPQRVWXZ`, with the particularly close pairs `MN` and `XZ`, perhaps due to the letters' shape, sound, or proximity in the alphabet. This cluster is far away from the letters in `AES`, which themselves do not form a cluster. Another cluster, on average far form the first, is formed by the letters `CILOUY`.

Apart from the clear separation between vowels and consonants, character embeddings exhibit rich additional structure (cf. Figure 5). For Infl$_\mathrm{LSTM}$, the cluster `BCFHJMPQW` contains the tighter subcluster `BJQW` that is similar to the letters `GKVX`. In contrast, Infl$_\mathrm{T}$ has the two small clusters `HJKQ` and `LNR` far from each other, and a less clear-cut

Cut-Shuffle	0.02	0.02	0.01	0.03	0.02	0.01	0.02	0.02	0.02	0.02	0.02
Cut-Random	0.30	0.22	0.36	0.29	0.36	0.36	0.33	0.13	0.14	0.12	0.06
Cut-Norm	0.38	0.46	0.45	0.48	0.47	0.47	0.43	0.44	0.43	0.44	0.44
Cut-Homo	0.59	0.50	0.51	0.48	0.50	0.50	0.53	0.52	0.53	0.52	0.52
Clu-Coef	0.81	0.72	0.88	0.80	0.87	0.87	0.84	0.62	0.64	0.61	0.55

Figure 4: Comparison measures for models of character embedding. **Top**: Betweenness centrality. **Bottom**: Cut-distances and cluster coefficients for the average human distance matrix and all character embeddings.

structure among the rest of the consonants.

Embeddings from G2P_{LSTM} exhibit a structure clearly connected to the G2P task. The distance network has many small clusters of similar sounding letters, e.g., `UW`, `IJ`, `JY`, `GJ`, `CKQ`, `SXZ`, and `BFPV`. G2P_{LSTM}'s counterpart, G2P_{T}, produces similar groupings, but displays a more homogeneous structure overall.

LM_{LSTM} has the tight cluster `KSXYZ` within the larger `BCDFGKMPSTVWXYZ` cluster, and weaker connections between other letters. LM_{T} has a clearer cluster structure, showing the strongest separation between vowels and consonants, especially from the non-cluster `JKQXZ`, which is also well-separated from other consonants. ELMo models are outliers in that they do not present a clear global structure: only loose clusters can be identified.

Cluster coefficient. Looking at the cluster coefficients (cf. Figure 4, last row) we also see a difference between ELMo embeddings and the other models: all models except for the ELMos have cluster coefficients between 0.72 and 0.88 and, thus, close to the human average of 0.81. In contrast, the cluster coefficients for ELMo embeddings are between 0.64 for ELMo_{s} and 0.55 for ELMo_{l}.

Betweenness centrality. The local values of betweenness centrality (cf. Figure 4) show the rich structure of the similarity matrices for most embeddings. For all but the ELMo models, the majority of letters have either extremely high or low levels of betweenness. In particular vowels tend to occupy prominent places in the network structure. Humans, in contrast, are more similar to ELMo embeddings.

Cut-distance. Looking at cut-distances (cf. Figure 4), we find that the structure of ELMo embeddings is significantly more similar to a random matrix than that of the other embeddings. The cut-distances (cf. Figure 3) between humans and embeddings largely agree with the conclusions from Section 6.1 – G2P_{LSTM} and the ELMo models are respectively the most similar and dissimilar –, even though correlation for node-to-node similarities does not necessarily imply a similar global structure.

7 Related Work

Neural network analysis. A lot of ink has been spilled on what neural network models learn and how. For instance, Zhang and Bowman (2018) investigated different pretraining objectives on their ability to induce syntactic and part-of-speech information. Pruksachatkun et al. (2020) studied model performance on probing tasks to investigate what models learn from intermediate-task training. Belinkov et al. (2017) explored what neural machine translation models learn about morphology.

Other work created test sets to evaluate specific linguistic model abilities. Linzen et al. (2016) made a dataset to investigate the ability of neural networks to detect mismatches in subject–verb agreement in the presence of distractor nouns. Warstadt et al. (2019) created a benchmark called BLiMP to assess the ability of language models to handle specific syntactic phenomena in English. Mueller et al. (2020) introduced a similar suite of test sets in English, French, German, Hebrew and Russian, also focusing on syntactic phenomena. Similarly, Xiang et al. (2021) presented CLiMP, a benchmark for the evaluation of Chinese language models.

Besides that, attention mechanisms (Bahdanau et al., 2015) in neural models have been common subjects of investigation. Jain and Wallace (2019) claimed that ”attention is not explanation”, to be later on challenged by Wiegreffe and Pinter (2019), who argued that ”attention is not not explanation”. However, the relationship between inputs, attention weights, and outputs is still poorly understood.

Furthermore, our work is related to research on which information is learned and how information is encoded by so-called language representation models, e.g., BERT (Devlin et al., 2019) or

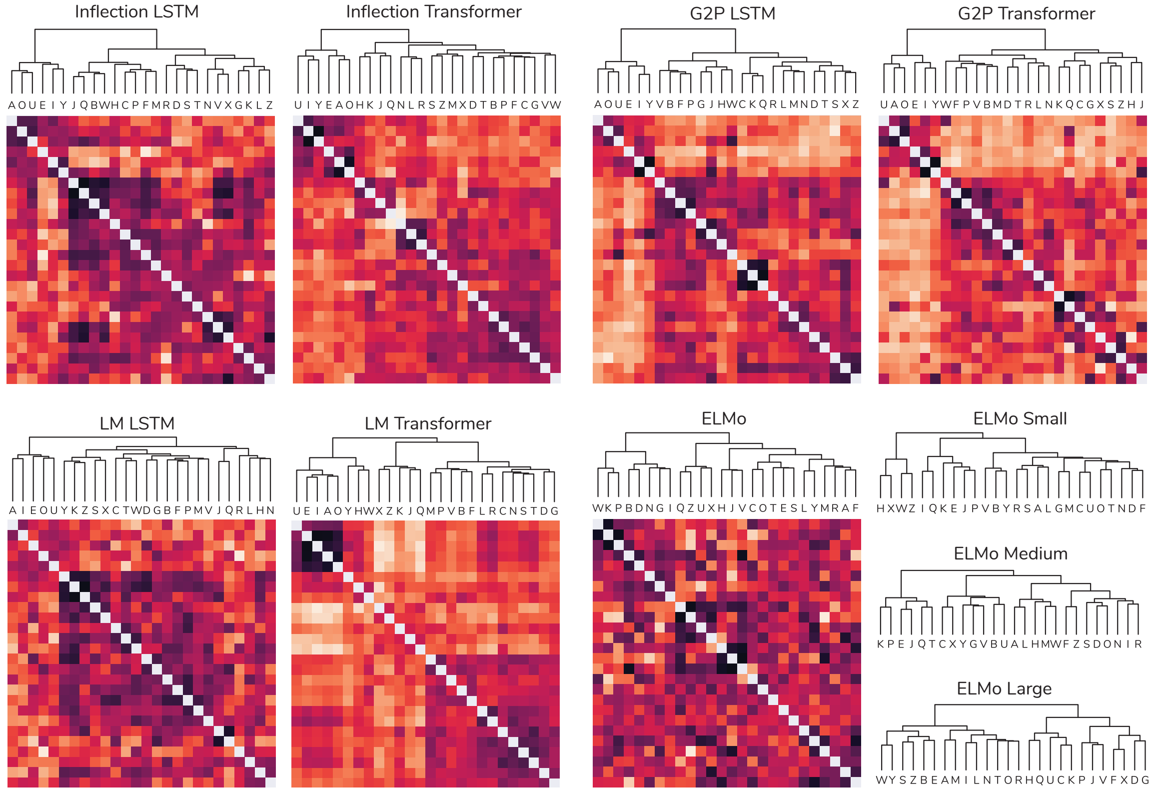

Figure 5: Distance matrices and corresponding dendrograms reveal the cluster structure of character embeddings. Darker colors depict small distances (high similarity) between pairs. Dendrograms summarize the cluster structure, with the height of horizontal lines depicting the Ward distance between the corresponding clusters being joined.

RoBERTa (Liu et al., 2019). Similar to attention in other models, attention in BERT has been investigated exhaustively. Clark et al. (2019) found that it captures substantial syntactic information, and Vig (2019) built a visualization tool for the attention mechanism. Hewitt and Manning (2019) evaluated whether syntax trees could be recovered from BERT or ELMo's word representation space. An overview of over 40 different studies of BERT can be found in Rogers et al. (2020).

Embedding analysis. The research which is closest to our work investigates which information is captured by different types of embeddings, often by training a classifier to predict certain features of interest. For instance, Kann et al. (2019) used a classifier-based approach to examine whether word and sentence embeddings encode information about the frame-selectional properties of verbs. Ettinger et al. (2016) investigated the grammatical information contained in sentence embeddings regarding multiple linguistic phenomena. Qian et al. (2016) mapped a dense embedding to a sparse linguistic property space to explore the contained information. Bjerva and Augenstein (2018) studied language embeddings.

Different word similarity datasets have been used for word embedding evaluation, for instance RG-65 (Rubenstein and Goodenough, 1965), WordSim-353 (Finkelstein et al., 2002), or SimLex-999 (Hill et al., 2015).

In contrast to the work in this paragraph, which was concerned with word or sentence embeddings, we aim at understanding *character* embeddings.

8 Conclusion

In this paper, we performed an in-depth analysis of character embeddings extracted from various character-level models for NLP. We leveraged resources from research on grapheme–color synesthesia – a neuropsychological phenomenon where letters are associated with colors –, to construct a dataset for a character similarity task. We further performed an analysis of networks representing characters as nodes and similarities as edge weights to understand how characters are organized by human synesthetes in comparison to character embeddings. Analysing 10 different character embeddings, we found that LSTMs agreed with humans more than transformer models. Comparing different tasks, G2P resulted in embeddings more similar to human character representions than inflection and, by a wide margin, language modeling. ELMo embeddings differed from humans and other models in that they exhibited no clear structure.

Appendix B: Analysis of Color Differences of Characters as Perceived by Synesthetes

In additional to the most important findings mentioned in the main part of this paper, we further present an in-depth study of the character similarities according to human synesthetes in this section.

Clustering Analysis. For each individual, we compute a character difference matrix using CIEDI2000 (normalized to values between 0 and 1). We then use Ward's hierarchical clustering algorithm to explore hidden structural features. Several examples suggest that individual synesthetes tend to represent certain groups of letters with closely matching colors, since their perceptual color differences tend to form tight clusters (Figure 6A), as opposed to the node-to-node average over the entire population of synesthetes (Figure 6B). To make this finding concrete, we compute several measures aimed to address the degree of clustering of each network.

First, we compute the distances between identified clusters in the distance matrix for each individual (Figure 6C). Pooled over the whole population, the distribution of cluster distances reveal an over-representation of small distances when compared to shuffled data. Over-represented small clustered distances and large jumps to big distances implies the existence of just a handful of tight clusters with small within-cluster distances and larger inter-cluster distances, as suggested by the dendrogram examples in Figure 6A.

Imposing a cut-off cluster distance for the dendrograms, we effectively select the cluster structure of the distance matrix. Although several methods for selecting the cut-off have been studied, they often strongly depend on the nature of the dataset in question. Using three largely different cut-offs we find robustly that each distance matrix encodes only a handful of tight clusters (cf. Figures 6D, E), typically around 3 to 5 clusters with an average size of 6 letters per cluster.

Clustering coefficient. Next, we compute the local clustering coefficient for each node in each distance matrix and observe no strong differences among nodes belonging to the same matrix. For each matrix, we average the cluster coefficient over all nodes and look at their distribution by pooling over all individuals (cf. Figure 6F). This reveals a narrow distribution of low clustering coefficients peaked around 0.4, implying a small average distance of any node to its neighbours. For comparison, we compute the clustering coefficient for a random uniform distance matrix (symmetric with zeroes in its diagonal) whose coefficient places at 0.5 (averaged over 100 iterations), and also for a homogeneous distance matrix (all entries are equal with a zero diagonal) with a coefficient of 1. Moreover, we repeat the analysis for the node-to-node average distance matrix and show a relatively higher coefficient (0.8), implying higher distances on average for any node with respect to its neighbors.

Betweenness centrality. Next, we examine the betweenness centrality of nodes (cf. Figure 6H). We compute this measure on the auxiliary similarity matrix $0.5 - d$, where d is a distance matrix, in order to interpret high betweenness values as the most important nodes. The distribution over all individuals reveals the top-ranking nodes as `CEILOSY`. These are the nodes found to be in most shortest paths between pair of nodes, and possibly lie at the intersection between otherwise separate clusters.

Cut-distance. Finally, cut-distances between the individual distance matrices and a reference matrix offer an additional characterization of their global structure. We compute cut-distances with respect to a zero matrix (the cut-norm), a random and an homogeneous matrix (defined as in the last paragraph), and with respect to shuffled versions of themselves, averaged over 100 iterations (cf. Figure 6G). We find narrow distributions suggesting all individuals share a similar global structure.

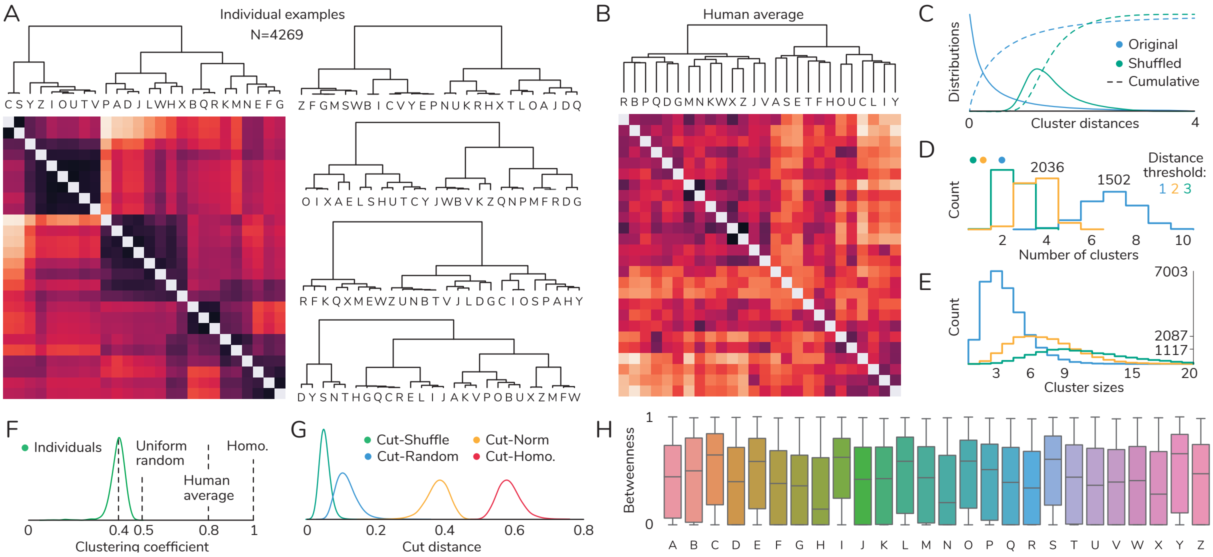

Figure 6: Network analysis of human synesthetes. **(A)** Five randomly chosen examples illustrate the typical distance matrices for individual synesthetes (N=4269). The dendrogram summarizing the clustering structure is presented on top of its corresponding distance matrix for one example (left). The dendrogram is a tree-level representation of the identified clusters, where the height of each horizontal line represents the Ward distance between the selected pair of clusters. **(B)** The clustered distance matrix and corresponding dendrogram of the node-to-node average for all human synesthetes. **(C)** Distribution of all the distances between clusters for each distance matrix pooled over all individuals. Cluster distances correspond to the heights of all horizontal lines in each dendrogram. For comparison, the distribution of cluster distances corresponding to all shuffled distance matrices is presented, together with their cumulative distributions. **(D)** Histograms of the number of clusters in each distance matrix pooled over all individuals for three different cutoff cluster distances. **(E)** Histograms of the size of the clusters found for the procedure in (D). **(F)** Distribution of the average clustering coefficient for each distance matrix pooled over all individuals. For comparison the average clustering coefficient for a random distance matrix, for the human average of (B), and for an homogeneous distance matrix are also marked by dashed lines. **(G)** Distribution of cut-distances between all the human distance matrices and the zero matrix (cut-norm), a random distance matrix (average over 100 iterations), a homogeneous distance matrix, and shuffle versions of themselves (average over 100 iterations). **(H)** Distribution of betweenness centrality for each letter pooled over all individual synesthetes.

How Good (really) are Grammatical Error Correction Systems?

Abstract

Standard evaluations of Grammatical Error Correction (GEC) systems make use of a fixed reference text generated relative to the original text; they show, even when using multiple references, that we have a long way to go. This analysis paper studies the performance of GEC systems relative to *closest-gold* – a gold reference text created relative to the *output* of a system. Surprisingly, we show that the real performance is 20-40 points better than standard evaluations show. Moreover, the performance remains high even when considering any of the top-10 hypotheses produced by a system. Importantly, the type of mistakes corrected by lower-ranked hypotheses differs in interesting ways from the top one, providing an opportunity to focus on a range of errors – local spelling and grammar edits vs. more complex lexical improvements. Our study shows these results in English and Russian, and thus provides a preliminary proposal for a more realistic evaluation of GEC systems.

1 Introduction

Grammatical Error Correction (GEC) systems are typically evaluated using reference-based evaluation measures. This is common in language generation tasks, where the system output is compared against a set of gold references, such as the set of correct translations in Machine Translation or the set of valid corrections for a source sentence in GEC. Importantly, the references are generated relative to the original text and are independent of the system outputs. In GEC, the space of valid outputs for a given source sentence is very large, making it extremely difficult to evaluate. Specifically, *reference-based evaluations (most GEC datasets contain one reference correction) are known to underestimate system performance* (Chodorow et al., 2012; Felice and Briscoe, 2015; Bryant and Ng, 2015). Bryant and Ng (2015) showed that using two references is better than one, and the results improve further with more references; however, they used references that were generated relative to the original text. Choshen and Abend (2018b) further demonstrated that the issue can be only slightly alleviated but not completely solved by increasing the number of references. This is because many errors have a long-tailed distribution on valid corrections. One can expect that as GEC systems mature and manage to address more complex errors, the underestimation of their performance will be further exacerbated.

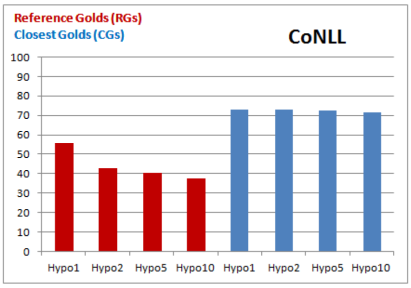

Figure 1: Performance by hypothesis rank (F-score) against Reference Gold (RG) vs. Closest Golds (CGs) generated for each hypothesis. Observe dramatic drop in performance between top hypothesis and the rest in RG evaluation, vs. stability in CG evaluation; and, large gaps between scores even for the top hypotheses in RG vs. CG evaluations.

Choshen and Abend (2018b) discuss another consequence of having a large space of valid corrections, pertaining to training. They show that *GEC systems have a strong tendency to under-correct*, due to using the one-reference-gold approach for tuning (and training) the systems. Essentially, due to the low likelihood of a system's proposed change being matched to gold, GEC systems are discouraged from proposing corrections, and propose far fewer corrections compared to humans. The under-correction phenomenon is more pronounced for errors with a large number

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2686–2698
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

of correction candidates. For example, mistakes on closed-class words, e.g. errors in determiners, where the number of valid corrections is small, suffer from under-correction to a lesser extent than mistakes in word choice. As a result, current systems generally prefer to make small targeted changes on closed-class errors.

We further study the effects of having a large space of valid corrections on GEC system development and automatic evaluation. Given a potentially erroneous sentence, we assume there is a space of gold references corresponding to it. Evaluation is typically done by drawing one gold from this set. We refer to this as *reference gold* (RG). We generate a new gold that is as close as possible to the system output (*hypothesis*), by correcting the hypothesis itself, instead of the original text. We call it *closest gold* (CG). We show by how much performance is really underestimated when a reference gold is used instead of the closest one, and claim that the latter should reflect the true performance of the system. We use a ranked 10-best list of hypotheses for a given source sentence, produced by state-of-the-art GEC systems on two English and two Russian GEC datasets. We generate CGs for hypotheses at different ranks.

Our findings are as follows. First, evaluation against RGs shows a large performance gap between the top hypothesis and the rest. We show that the reason for this is that lower-ranked hypotheses propose more diverse changes, including lexical changes, that have a lower chance to match RGs. In contrast, evaluation against CGs reveals that qualitatively, there is very little degradation in the hypotheses, when considering the top-10 list. While RG evaluation reveals severe drops in F-score and, in particular, precision, we find that relative to CGs quality does not substantially degrade. This is illustrated in Figure 1 for one of the datasets; we show more results in Section 4.1.

Second, contrary to the observation made by Choshen and Abend (2018a) about GEC systems being disinsentivized to propose corrections, we find that it only applies to the top-ranked hypothesis.[1] Moreover, the number of proposed edits increases steadily with the hypothesis rank.

We further evaluate the output by computing the post-editing effort, i.e. the number of edits needed to correct the output hypothesis. We show that post-editing effort is very similar for top hypothesis and lower-ranked hypotheses, reinforcing the claim that lower-ranked hypotheses do not degrade in quality. Finally, we evaluate the types of edits by hypothesis rank and show that lower-ranked hypotheses propose more diverse lexical changes, in contrast to the top hypotheses that mostly attempt local spelling and grammar misuse.

Our analysis should provide insight into better training and evaluation practices for GEC. A better understanding of the under-correction phenomenon and the diversity and quality of the lower-ranked hypotheses can help improve the current training and tuning framework that relies on texts with single RGs and, arguably, hinders the development of GEC systems that can potentially address more complex linguistic phenomena.

Next, we discuss reference-based evaluation. Section 3 presents the definitions and experimental setup. Section 4 presents the evaluation using closest golds. Section 5 analyzes the edits proposed by top and lower-ranked hypotheses.

2 Reference-Based Evaluation

The standard approach to evaluating GEC systems is to use reference-based measures, that is comparing the system output to a reference that has been generated by a human annotator who corrected mistakes in the original source sentence. We refer to these as reference golds (RGs). It is common to instruct annotators to follow the principle of “minimal edits”, that is making the smallest number of edits to render the sentence grammatical and well-formed. We follow a similar principle with our annotators, and the key distinction of our approach is that standard evaluations use golds that are independent of the system outputs, whereas we are creating golds by directly correcting the hypotheses output by the system. We note that there have been other proposals that argue that this principle still does not make the output fluent and propose generating references based on fluency (Sakaguchi et al., 2016). As suggested by Choshen and Abend (2018b), correcting for fluency further increases the space of valid corrections for a sentence, and we do not attempt to do this in this work.

Reference-based evaluations include several measures, such as the MaxMatch scorer M^2 (Dahlmeier and Ng, 2012), GLEU (Napoles et al., 2015), ERRANT (Bryant et al., 2017), and I-measure (Felice and Briscoe, 2015). These met-

---

[1] The proposed corrections are all corrections suggested by a system, some of which could be wrong.

rics have some commonalities, e.g. both MaxMatch and ERRANT measure precision, recall, and F-score. M^2 has been used with different beta parameter values, the default is $beta = 0.5$, weighting precision twice as high as recall, which is more common than assigning equal weights and has been shown to have stronger correlation with human ratings (Grundkiewicz et al., 2015). GLEU focuses on the fluency aspect – it is an extension of the BLEU metric in Machine Translation (Papineni et al., 2002). I-measure emphasizes accuracy and calculates the weighted accuracy of correction and detection. Napoles et al. (2019) proposed GMEG-Metric, that is an ensemble of existing metrics, and showed that its correlation with human judgments is higher on several GEC datasets. The MaxMatch metric has been widely used in evaluating GEC systems in many published works and in several shared tasks (Ng et al., 2013, 2014), and we adopt it in this work. We use the default beta value of 0.5 and refer to the result as F-score.

3 Definitions and Experimental Setup

We start with some definitions and then describe the experimental setup.

3.1 Definitions

Given the original learner sentence (a *source* sentence), a state-of-the-art (neural) GEC system generates a ranked list of outputs, referred to as *hypotheses*. We refer to the top hypothesis as H_1, and, similarly, to other hypotheses by the rank that they occupy. A system is evaluated using reference-based metrics where for each source sentence there is at least one corresponding corrected version that was generated by a human expert. We refer to this corrected version as *Reference Gold* (RG). The set of possible correct versions for a given source sentence is very large – possibly infinite – and any single reference gold is just a single point in that space. Most of the GEC evaluation sets contain one RG for each source sentence, although some (English) datasets contain more (CoNLL-test has 2 and an additional set of 8 generated later, and JFLEG (Napoles et al., 2017) has 4 fluency-based references). System performance is computed by scoring the top-ranked hypothesis H_1 for each sentence against the corresponding RG.

In addition to RGs, we create for each pair of (source, H_i), where H_i is the system hypothesis, another gold, which is generated by an expert by correcting the hypothesis itself. We refer to this gold as closest gold (CG_i) relative to H_i. The annotators who generated CGs were instructed to apply the minimal edit principle – i.e. correct the output to ensure it is grammatical and also preserves the meaning of the original source sentence. We thus assume that CG is as close as possible to the system output.

Given a pair of sentences, edit distance is the minimum number of edits (deletions, replacements, insertions, not necessarily single-tokens) needed, so that the sentences match. A *gold edit* is an edit between a source sentence and an RG or CG. A *proposed edit* is an edit between a source sentence and a hypothesis. A *correct edit* is an edit in the intersection of gold and proposed edits. We define Dist (S,RG) to be the number of edits between source and reference gold, and Dist (H_i,CG_i) to be the number of edits between a hypothesis H_i and CG_i relative to this hypothesis. The last one is interesting for practical purposes, since it is the post-editing effort required to completely correct the text. These are shown below.

- *S* – original text
- H_i – hypothesis at rank i
- *RG* – reference gold
- CG_i – closest gold to hypothesis H_i
- *Gold edit* – an edit between a source sentence and an RG or CG
- *Proposed edit* – an edit between a source sentence and a system hypothesis
- *Correct edit* – a proposed edit that is also a gold edit relative to a system hypothesis and specific reference
- *Dist (S,RG)* – edit distance between source and reference gold
- *Dist (H_i, RG)* – edit distance between hypothesis at rank i and reference gold
- *Dist (H_i, CG_i)* – edit distance between hypothesis at rank i and its closest gold

Table 1 shows a sample source sentence, 2 system hypotheses, the RG, and two CGs, one for each hypothesis. Dist (S,H_1) is 2 and includes 2 proposed edits ("reallistic" → "realistic" and "a" → ∅). Dist (S,RG) is 2 and includes 2 gold edits ("reallistic" → "realistic" and "had" → "gave"). The number of correct edits relative to RG and H_1 is 1 ("reallistic" → "realistic"). Dist (H_{10}, RG) is 4 (4 word replacement edits and one insertion

S	In addition , I think that the settings are very reallistic and the actors had a great performance .
$\mathbf{H_1}$	In addition , I think that the settings are very realistic and the actors had great performance .
$\mathbf{H_{10}}$	In addition , I think that the settings are very realistic and the actors performed very well .
RG	In addition , I think that the settings are very realistic and the actors gave a great performance .
$\mathbf{CG_1}$	In addition , I think that the settings are very realistic and the actors had great performances .
$\mathbf{CG_{10}}$	In addition , I think that the settings are very realistic and the actors performed very well .

Table 1: Example of an original sentence (source); the system output (hypotheses at ranks 1 and 10, H_1 and H_{10}); the reference gold (RG), and two additional golds generated on top of each of the hypotheses (CG_1 and CG_{10}).

edit), while Dist (H_{10}, CG_{10}) is 0. The three golds – two CGs and the RG – illustrate the notion of semantic equivalence (multiple ways of correcting the same source sentence, while preserving its meaning), not reflected in the standard evaluation.

3.2 Experimental Setup

We perform experiments on 2 English and 2 Russian datasets, using diverse NMT GEC model frameworks. The English datasets include the commonly used benchmarks – CoNLL-14 (Ng et al., 2014; Dahlmeier et al., 2013), and the BEA corpus (Bryant et al., 2019). The Russian datasets include the RULEC-GEC corpus (Rozovskaya and Roth, 2019) (henceforth RULEC) and another dataset of Russian learner writing that has been recently collected from the online language learning platform Lang-8 (Mizumoto et al., 2011) and annotated by native speakers.[2] We refer to this dataset as Lang8. CoNLL-14 contains two primary RGs against which the systems are standardly evaluated, while the other datasets include one RG for each sentence. We report results using one RG for each dataset for uniformity, and note that the results for the second CoNLL RG are very similar. These datasets were selected with the goal of evaluating on diverse data both in terms of genre and target language.

For the English datasets, we apply a state-of-the-art BERT-Fuse NMT system that incorporates BERT into an encoder-decoder Transformer model by (Kaneko et al., 2020). We obtained a ranked hypothesis list from the authors.

For RULEC, we use the outputs of a state-of-the-art Transformer model that uses pre-training on synthetic data and is fine-tuned on RULEC development data (Naplava and Straka, 2019). For the Lang8 corpus, we use a different state-of-the-art architecture, a Convolutional Neural Network model proposed in Chollampatt and Ng (2018b) for English. We re-implement it for Russian. The model is trained on RULEC training data and synthetic data, and uses language model re-ranking. This model is also tuned on RULEC development data. Our evaluation shows that the models are competitive: the Transformer model performs better by 4 points on the RULEC corpus than the CNN model, while the CNN model outperforms the Transformer on Lang8 by 2 points. However, we stress that our goal is not to compare these models, as we selected several model architectures and datasets to provide a more comprehensive analysis and evaluation that spans across diverse models and datasets.

Generating Closest Golds We consider the top-10 ranked hypothesis list for each dataset and study four hypotheses at the ranks 1, 2 5, and 10, to evaluate the quality of the hypotheses at various ranks and to determine how much quality degrades from the top hypothesis downwards. For each of the 4 hypotheses H_i, $i \in \{1, 2, 5, 10\}$, a closest gold CG_i relative to this hypothesis is generated by post-editing the hypothesis for grammatical errors and other misuse.

Annotation 100 source sentences from each dataset were selected uniformly at random and 4 hypotheses at different ranks were annotated for each sentence. The English outputs were annotated by two annotators – one native English speaker and a fluent non-native speaker. Each annotator corrected all hypotheses for one of the datasets. This was done to ensure consistency across different hypotheses. The Russian outputs were corrected by one native Russian speaker. All of the annotators have a Master's degree and previous annotation experience. The annotators followed the standard annotation protocol in grammar correction, in that they were instructed to follow the minimal-edits principle in correcting the sentences, while also ensuring the output is well-formed and adequate (i.e. the meaning of the original source sentence is preserved), for which they also consulted the source sentence.

---

[2] This is a recently collected dataset that will be made available for research.

4 Evaluating True System Performance

We start by evaluating each hypothesis output H_i for each dataset against reference gold RG and its corresponding closest gold CG_i. We show that evaluation relative to RG is always pessimistic and, given a hypothesis generated by a GEC system, there is always a much better gold.

4.1 Reference Gold vs. Closest Gold

Table 2 shows the results of evaluating each system hypothesis against reference golds and closest golds for two datasets – BEA (English) and RULEC (Russian). Results for all datasets are in Appendix (Table 7). The CG result is significantly higher than the performance relative to RG in all cases. For the top hypothesis, the F-scores increase by 19 points on BEA and 17 points on RULEC. Improvements are greater for lower-ranked hypotheses. The improvements for BEA are 34, 36, and 37, for ranks 2, 5 and 10, respectively, and for RULEC – 34, 28, and 31.

The most substantial changes occur in precision: between 23 and 41 points on BEA, and 24 and 40 for RULEC (similar changes for the other datasets). It should be emphasized that precision improvements relative to RG are greater for lower-ranked hypotheses. This is interesting and suggests that while lower-ranked hypotheses propose significantly more changes than the top-ranked one (see column "Proposed edits"), a lot of those edits are valid corrections, even though they are not recognized in RGs: observe that despite the fact that more edits are being proposed with lower hypotheses rank, the number of correct edits (shown in the table) relative to RG goes down. For instance, 84 out of 125 proposed edits are correct in BEA H_1, while only 75 out of 200 proposed are valid in H_5. This is consistent across the datasets and indicates that *changes proposed in lower-ranked hypotheses are less likely to be included in the RGs.*

Recall is also improved in CGs relative to RGs, although not as dramatically. Recall increases by 10-25 points on CoNLL, 12-34 points for BEA, 7-22 points for RULEC, and 2-12 points for Lang8.

The results in the table strongly indicate that the n-best list does not produce hypotheses of degrading quality. On the contrary, the precision of the proposed corrections remains impressively high (in most cases, well above 50 and often into 70 or 80), which is not reflected in the reference-based evaluation scoring against a reference gold. We further illustrate the finding in Figure 2, where for each dataset, we show F-scores of the 4 hypotheses against RGs, and scores against their corresponding CGs. The first observation is that performances in the first group are much lower than in the second group for each corpus. But it is also clear that the first group shows strong degradation relative to the top-ranked hypothesis in the RG evaluation – performance goes down as you go from H_1 to H_{10}, while in the second group the performance remains almost the same across the four hypotheses.

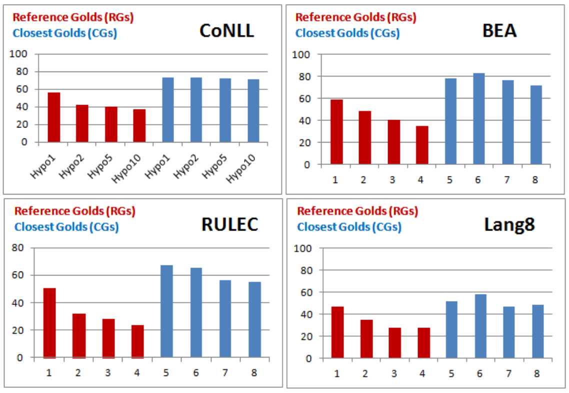

Figure 2: Performance by hypothesis rank (F-score) against Reference Gold (RG) vs. Closest Golds (CGs) generated specially for each hypothesis. Observe dramatic drop in performance between top hypothesis and the rest in RG evaluation, vs. stability in CG evaluation; and large gaps between scores even for the top hypotheses in RG vs. CG evaluations.

Further, as shown in Table 2, the number of correct edits is significantly higher when evaluated against CGs. For instance, the number of correct edits increases from 75 to 163 for BEA H_5, and from 48 to 105 for RULEC H_2. Additionally, the number of gold edits in CGs is much higher than in RGs, and is also greater for lower-ranked hypotheses. For instance, there are 202 golds edits in BEA RG, 217 edits in BEA CG_1 and 282 edits in BEA CG_{10}. This is consistent across the datasets and suggests that *the edits proposed by the models are not necessarily the minimal edits that most of the GEC annotations adopt*. This may be why most of the proposed edits in the lower-ranked hypotheses are not found in the RGs. Table 8 in Appendix also evaluates each hypothesis against CGs relative to the other hypotheses, showing that evaluation against CG always produces superior results.

Dataset	Hypo	Gold type	P	R	F-score	Edits		
						Correct	Proposed	Gold
BEA	H_1	RG	65.9	40.1	58.4	84	125	202
		CG_1	88.4	52.5	**77.8**	114	125	217
	H_2	RG	50.0	43.1	48.4	87	180	202
		CG_2	87.8	66.4	**82.5**	158	180	238
	H_5	RG	41.2	37.1	40.3	75	200	202
		CG_5	81.5	61.0	**76.4**	163	200	267
	H_{10}	RG	34.8	35.1	34.9	71	220	202
		CG_{10}	75.0	59.6	**71.3**	168	220	282
RULEC	H_1	RG	63.6	27.7	50.5	56	90	202
		CG_1	87.5	34.7	**67.1**	77	90	222

	H_5	RG	29.2	24.3	28.0	49	174	202
		CG-H_5	61.6	41.6	**56.2**	109	174	262
	H_{10}	RG	24.0	21.3	23.4	43	194	202
		CG_{10}	59.1	43.0	**55.0**	110	194	256

Table 2: Performance by hypothesis rank against reference gold (RG) and Closest Golds (CGs) generated specially for each hypothesis. For each hypothesis, number of correct, proposed, and gold edits relative to each reference (RG or CG) are also shown. Results for all the datasets are in Appendix (Table 7).

4.2 Quality Estimation with Edit Rate

We have shown above that the quality of the hypotheses does not degrade with rank, and in some cases hypotheses at lower ranks even result in higher F-score than the top-ranked hypothesis, when scored against CG, while the evaluation against RGs is strongly biased against lower-ranked hypotheses. We now wish to evaluate hypotheses quality using the edit rate, i.e. the number of edits needed to fix the output hypothesis so that it matches its corresponding CG. This quality estimation approach that considers the number of edits required to “fix” the hypothesis is used in Machine Translation (Snover et al., 2006), where the quality of a system output is measured as the minimum number of edits needed to transform the system output so that it matches a reference. To this end, a “targeted” reference is created for a translated sentence, by editing the hypothesis until it is both fluent and has the same meaning as the (original) reference(s). The reason for this is that estimating quality against gold “non-targeted” reference ignores notions of semantic equivalence (see also Table 1), thereby underestimating output quality. Thus, a targeted reference provides a more accurate measure of translation quality. Chollampatt and Ng (2018a) proposed a quality estimation model for GEC that builds on this idea of measuring output quality as the number of edits required to fix the hypothesis. However, they make the strong assumption that, unlike in MT, in GEC targeted references need not be created, as RGs can be substituted for CGs, because both human annotators and automatic GEC systems are trained to make minimal changes. As we showed in the previous section, this is not the case and *using RGs severely underestimates system performance, and, as a consequence, post-editing effort.*

We now use CGs to estimate hypotheses quality in terms of post-editing effort in Table 3. We show the number of proposed edits, the number of correct edits relative to CG, and the number of gold edits in the corresponding CG. (The number of proposed, gold, and correct edits also appears in Tables 2 and 7 but is shown here in Table 3 for convenience). The post-editing effort is shown in the last column, estimated as the number of edits required to make the hypothesis output fluent and grammatical, i.e. the edit distance between a hypothesis and its corresponding CG. The number of edits was computed automatically using the ERRANT tool (Bryant et al., 2017) that, given a pair of sentences (source, hypothesis), will produce a set of edits needed to transform the source into the target. The post-editing effort is not necessarily the smallest for the top hypothesis. In fact, on BEA, the smallest value is obtained for H_2 (55 edits), while H_1 and H_{10} are similar (86 and 87). On the other datasets, there is no significant difference for the English datasets across the 4 different hypotheses, while on the Russian datasets there is slight degradation for hypotheses 5 and 10, while H_1 and H_2 are close. This supports our finding above that lower-ranked hypotheses are of high quality. As a side note, our post-edit estimation assumes that there are no errors that have

Dataset	**Hypo**	**Edits**			
		Prop.	**Corr.**	**Gold**	**Post-Edit**
CoNLL	H_1	156	132	300	**130**
	H_2	203	160	349	159
	H_5	239	184	343	138
	H_{10}	266	196	349	142
BEA	H_1	125	114	217	86
	H_2	180	158	238	**55**
	H_5	200	163	267	73
	H_{10}	220	168	282	87
RULEC	H_1	90	88	222	**119**
	H_2	144	105	242	131
	H_5	174	109	262	173
	H_{10}	194	110	256	186
Lang8	H_1	98	65	252	**168**
	H_2	186	117	287	174
	H_5	214	105	298	215
	H_{10}	225	109	312	225

Table 3: Number of edits by hypothesis rank. We show the number of proposed edits, the number of correct edits relative to CG, the number of gold edits in CG, and the post-editing effort required to make the hypothesis fluent and grammatical, estimated as the number of edits between the hypothesis and its CG.

more impact than others. In Section 5, we actually show that the top-ranked hypotheses mostly contain changes on "simpler errors", and, arguably, the lower-ranked hypotheses might even involve less post-editing effort given the more complex errors they manage to fix.

4.3 Do GEC Systems Undercorrect?

We first compare the number of edits in each hypothesis to the number of edits in the original gold (Table 4). The top-ranked hypothesis makes only a fraction of edits compared to RGs. Generally, RGs contain 2.5-3 more edits than the top-1 hypothesis. This is consistent with the analysis in Choshen and Abend (2018b) that shows that GEC systems are disincentivized to make corrections due to the low-coverage bias. What is notable, however, is that the number of edits substantially increases with the hypothesis rank. In particular, *the second-ranked hypothesis contains on average twice as many edits as the first one*, and the number of edits continues to increase. Hypotheses 5 and 10 contain a similar number of edits compared to the number of edits in RG. The under-correction issue is further studied in the next section.

Hypo	**Number of edits proposed**			
	RULEC (2,646)	Lang8 (2,260)	BEA (2,103)	CoNLL (2,665)
H_1	90	98	125	156
H_2	144	186	180	203
H_5	174	214	200	239
H_{10}	194	225	220	266
RG	202	232	202	289

Table 4: Number of proposed edits by hypothesis rank. For each corpus, total number of tokens is shown. The majority of edits are single-token replacements, deletions or insertions. The last row shows the number of gold edits in the *reference gold* for each dataset.

5 Edit Analysis by Hypothesis Rank

We now analyze and compare the edits in the top-ranked hypothesis and in H_{10}, in order to understand better how the edits differ with hypothesis rank. For the English datasets, we apply ERRANT (Bryant et al., 2017) to extract edits using pairs of parallel sentences (source, hypothesis). ERRANT then uses English-language specific rules based on part-of-speech and linguistic knowledge to assign each edit its linguistic type, such as preposition, noun number, etc. We further group the edits into one of the following two categories: *spelling/grammar changes* and *lexical changes*. The first category includes punctuation, spelling, orthography, and grammatical corrections that typically require local context and small changes and are also limited in the number of candidate corrections. These include determiner errors, verb agreement and form, noun number and punctuation, and morphological changes. Lexical changes comprise the categories denoted by ERRANT as "Other", "Verb", "Noun", "Pronoun", "Adverb", which include mostly lexical errors, e.g. changing "get" to "earn", verb tense errors that require wider context and thus are trickier to correct. The number of edits by type is shown in Table 5. Lexical changes are marked with a (*).

In the lower part of the table, we show the distribution of edits between the two categories: in CoNLL, spell/grammar changes account for 51.2% of all changes in the RG and for 74.3% in the top-ranked hypothesis. Lexical changes make up 48.8% in RG, while only 25.7% in the top-ranked hypothesis, although this number increases to 36.2% in the H_{10}. In BEA, 49.5% of RG edits are lexical, while in the top-ranked hypothesis

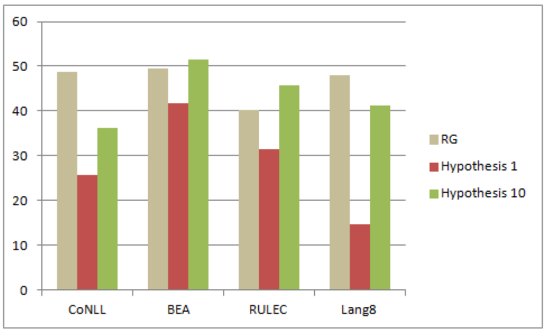

Figure 3: Percentage of lexical edits with respect to total number of changes in reference gold, H_1, and H_{10}.

these account for 41.7% and that number goes up to 51.5% for the H_{10}.

Looking at the number of edits in each category, it can be observed, that the under-correction phenomenon (for the top-ranked hypothesis) is particularly pronounced for lexical errors. In the spell-grammar category, the number of proposed edits is very close to (or even exceeds) the number of edits of this type in RG in both datasets (the only exception is perhaps the punctuation errors). For example, 33 determiner errors are present in CoNLL RG, while there are 25 in H_1. In contrast, 37 errors of category "Other" are in RG for CoNLL but only 8 changes of this type are in the top-ranked hypothesis. In fact, in both CoNLL and BEA, in the top-ranked hypotheses, the majority of the changes are minimal/local changes (74.3% in the CoNLL dataset and 58.3% in the BEA dataset).

We perform a similar analysis for the Russian datasets, where the edits are classified manually by our annotator (due to lack of automatic tool). We find similar behavior (see Appendix A). However, in the most challenging categories (lexical and "Other"), which both comprise word changes, the situation is more severe: the top-ranked hypothesis proposes 0 changes. Overall, the under-correction phenomenon for lexical errors is more pronounced for the Russian language.

Overall, the under-correction phenomenon is especially pronounced for top hypotheses in the lexical error category. The percentage of lexical edits with respect to the total number of edits in the RG and CGs is much higher than in the top hypotheses. Thus, under-correction is mostly a problem for lexical errors, but is partially rectified in the lower-ranked hypotheses, illustrated in Figure 3 that shows the percentage of lexical edits in RG, H_1, and H_{10} for each dataset.

Edit type	**CoNLL**			**BEA**

6 Discussion

We study the current evaluation and training schema in GEC, using 4 datasets in 2 languages and several state-of-the-art model architectures. We make several observations. First, we show that the quality of the systems is significantly better than we think, when we evaluate relative to the closest gold vs. reference gold. And the reason is there are many golds and we show that there is always a gold that is close to the prediction, and we should take this result as the actual performance of the model.[3] Moreover, as we showed, using the CGs provides additional knowledge about the type of errors various hypotheses generate, further guiding the community towards developing additional insights that can be used also in targeting specific models for specific users (based on their abilities, for example). Our second observation is that the top hypothesis is not actually better than the lower-ranked hypotheses in the 10-best list, even though the current evaluations are strongly biased towards the top hypothesis. Third, because

---

[3] In fact, given that sentence-level ensembles computed via multiple references were shown to perform much better than a single hypothesis (Bryant and Ng, 2015), already indicates the existence of better golds, since a sentence-based combination of reference gold is a gold by itself. We claim, though, that even this underestimates the true performance, as shown in our evaluation relative to the CGs.

of the way we train, lower-ranked hypotheses relative to the reference gold are as good or sometimes qualitatively better than the top hypothesis because of the diversity of the type of mistakes that they attempt to correct.

Recommendations based on the paper findings We view this paper as an analysis paper that we hope can contribute to a better understanding of the current issues in the GEC field. We hope that the proposed analysis can give an opportunity to researchers to think about directions for addressing these issues. That said, we believe that our results may serve as a preliminary proposal for developing better ways for evaluating for GEC systems, and would like to outline several recommendations based on our findings. We believe the findings should be useful for thinking about how to modify the training and tuning paradigm in GEC.

Regarding training and tuning, the current schema of using learner texts with single RGs hinders development of GEC systems that, as we show, can potentially address more complex linguistic phenomena and language misuse. For training and tuning, perhaps, it would make sense to generate multiple references by creating additional references that contain paraphrases of the original gold reference. In terms of evaluation, the findings might inspire researchers to think of better ways to evaluate GEC system outputs. For example, instead of computing exact match, we could include paraphrases so as not to penalize hypotheses that propose more liberal sentence-rewrites. A different approach might be to choose lower-ranked hypotheses, since they are as good, and they have some other useful properties, such as the language phenomena they are able to correct that the top hypothesis cannot.

A Edit Analysis for the Russian Datasets

For the Russian corpora, since there is no automated tool that classifies edits by type, we manually classify the edits in the hypotheses and RGs. We first extract all proposed edits using the ERRANT tool (The errant tool both extracts edits given a pair of sentences, and classifies these by type). The edit-extraction component is language-independent, whereas the type-classification is English-based). These edits are then manually classified into one of the grammar categories relevant for Russian. We use the error classification schema in Rozovskaya and Roth (2019) but combine certain types, e.g. we group together noun and adjective case errors, verb tense/aspect errors, and noun and adjective number errors. Unlike English, Russian does not have determiner errors. We similarly group the error type into two categories, spelling/grammar and lexical. However, we assign the noun/adjective number errors and morphology errors to the second group (lexical), as we expect these to display more variability due to the number of of different endings for adjective/noun number because of declensions and gender, and the large number of morphological variants compared to English. The statistics are shown in Table 6.

First, observe that the distribution in the gold references of lexical and spelling/grammar changes in the lower part of the table is similar to the English datasets. 40% or more of all gold edits are lexical. In the top-ranked hypothesis, only 31.5% and 14.6% of edits in RULEC and Lang8, respectively are of this type. This is similar to the results for the English datasets in Table 5, however in the most challenging categories (lexical and "other"), which both comprise word changes, the situation is more severe: the top-ranked hypothesis proposes 0 changes. Overall, the undercorrection phenomenon is more pronounced for the Russian language.

Edit type	**RULEC**			**Lang8**

Abstract

Spotting a lie is challenging but has an enormous potential impact on security as well as private and public safety. Several NLP methods have been proposed to classify texts as truthful or deceptive. In most cases, however, the target texts' preceding context is not considered. This is a severe limitation, as any communication takes place in context, not in a vacuum, and context can help to detect deception. We study a corpus of Italian dialogues containing deceptive statements and implement deep neural models that incorporate various linguistic contexts. We establish a new state-of-the-art identifying deception and find that not all context is equally useful to the task. Only the texts closest to the target, if from the same speaker (rather than questions by an interlocutor), boost performance. We also find that the semantic information in language models such as BERT contributes to the performance. However, BERT alone does not capture the implicit knowledge of deception cues: its contribution is conditional on the concurrent use of attention to learn cues from BERT's representations.

1 Introduction

"The sky is bright green" is easily identified as false statement under normal circumstances. However, following "Look at this surreal painting," the assessment changes. Spotting falsehoods and deception is useful in many personal, economic, legal, and political situations – but it is also extremely complicated. However, the reliability of communication is the basis of the social contract, with implications on personal, economic, legal, and political levels. There has been a growing interest in automatic deception detection from academia and industry in recent years (see section 9).

One of the main research lines tries to increase the collection of deception cues in terms of number and variety. For example, several successful studies show how to exploit multi-modal signals, jointly analyzing verbal, video, and audio data (Pérez-Rosas et al., 2015). For the same reason, several early studies tried to identify deception cues through manual feature annotation, like irony or ambiguity (Fitzpatrick and Bachenko, 2012). While these approaches offer a broad and interpretable description of the phenomenon, their main limitation lies in data collection and preprocessing difficulty.

Surprisingly, so far, little attention has been paid to expanding the targets' linguistic context, which is the easiest source of additional cues and data. Even in dialogues, which by definition are exchanges between different speakers/writers, the main focus is typically on the target text. None consider the preceding statements, be they issued by the same speaker of an interlocutor.

We hypothesize that linguistic context can be useful for text classification. Based on a data set of dialogues in Italian Courts, we train models that incorporate knowledge both from the target sentence and different configurations of the previous ones. We use Hierarchical Transformers and neural models based on BERT for text-pair representations and compare with the previous state-of-the-art methods and other non-contextual neural models, including BERT for single text representation.

We distinguish different kinds of context, depending on the window size and the speaker's identity (same one as of the target sentence or different). We find that context carries useful information for deception detection, but only if it is narrow and produced by the same author of the target text.

We also find that BERT's semantic knowledge helps the classification, but only when it is combined with neural architectures suitable to discover stylistic patterns beyond the texts' content that are potentially associated with deception.

To our knowledge, this is the first study that tests

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2699–2708
April 19 - 23, 2021.

these methods on data collected from real, high-stakes conditions for the subjects and not from a laboratory or game environment.

Contributions The contributions of this paper are as follows:

- We evaluate ways to incorporate contextual information for detecting deception on real-life data.
- We significantly outperform the previous state-of-the-art results.
- We show that language models are useful for the task, but they need the support of methods dedicated to detect deception's stylometric features.

2 Dataset

We use the DECOUR dataset (Fornaciari and Poesio, 2012), which includes courtroom data transcripts of 35 hearings for criminal proceedings held in Italian courts. This provides a unique source of real deception data. The corpus is in Italian. It consists of dialogues between an **interviewee** and some **interviewers** (such as the judge, the prosecutor, the lawyer). Each dialogue contains a sequence of utterances of the different speakers. These utterances are called *turns*. By definition, adjacent turns come from different speakers. Each turn contains one or more *utterances*. Each utterance by the interviewee is labeled as *True*, *False* or *Uncertain*. The utterances of the other speakers are not labeled. Table 1 shows some corpus and labels' statistics.

Role	Turns	Utterances	tokens
Interviewee	2094	3015	42K
Interviewers	2373	3124	87K
	4467	6139	129K

Labels:	True	Uncertain	False	Tot.
Number:	1202	868	945	3015

Table 1: DECOUR's statistics

The authors anonymized the data and released them here.

3 Experimental conditions

Fornaciari and Poesio (2013) use binary classification (*false* utterances versus the *true* and *uncertain* ones, aggregated together into one class of *non-false* utterances, see section 2, Table 1). To avoid overfitting training and testing on utterances from the same hearing, they use leave-one-out cross-validation, where each fold constitutes one hearing. In these settings, in each fold one hearing is used as test set, one as development, and the others as training set. For the sake of comparison, we followed the same approach. We ran five epochs of training for each fold, selecting the model with the best F-score in the development set.

We also identify seven kinds of different contexts that should help the classification task, together with the target utterance. They are as follows:

1 previous utterance - 1prev. We consider the first utterance preceding the target, regardless of the speaker who issued the statement.

2 previous utterances - 2prev. Same as above, but here we collect the first two sentences before the target.

3 previous utterances - 3prev. In this case, we collect the three previous utterances, again regardless of the speaker.

Speaker's previous utterance - s-utt. In this condition, we consider the utterance preceding the target only if the speaker is the same interviewee. If another speaker issues the previous utterance, it is not collected, and the target utterance remains without context.

Speaker's previous utterances - s-utts. Similarly to the previous condition, we only collect the interviewee's utterances, but if the target utterance is preceded by more than one utterance (within the same turn), they are all collected. In other words, we collect all the turn's utterances until the target one.

Speaker's previous utterances + turn - s-utturn. In these conditions, we consider all the possible speaker's utterances and the previous turn, which belongs to another speaker. If there are no previous speaker's utterances, we only collect the previous turn. This would make the instance equal to those created according to the last condition.

Previous turn - turn. We collect the whole previous turn, regardless of the possible previous speaker's utterances. This is the only condition where, by definition, the context is not produced by the interviewee him/herself.

4 Metrics and baselines

We evaluate the model on four metrics: accuracy, precision, recall and, F-measure. While accuracy is a standard metric, its informative power is limited when the data set is imbalanced, and the class of interest is the minority class, like in this case. In fact, the majority class's performance conceals the real performance on the minority one. Even so, it can be a problematic baseline to beat, as the simple heuristic of always predicting the majority class can result in high accuracy. In DECOUR, non-false utterances are the majority class with 68.66% of the instances. Therefore, this is the accuracy we would obtain always predicting the majority class. We use this majority-class prediction as a baseline. For the models' overall evaluation, we rely on the F-measure, which reflects the real proficiency of the models balancing the correct predictions in the two classes.

Besides the majority class prediction, which reaches an F-measure of 40.71, we also compare our models with the previous state-of-the-art. We use the highest performance in F-measure from Fornaciari and Poesio (2013). In that experiment, they jointly used Bag-Of-Words - BOW features and the lexical features provided by the LIWC (Pennebaker et al., 2001) and applied an SVM classifier (Drucker et al., 1997). The accuracy of that model is 70.18% and the F-measure 62.98 (table 2).

5 Methods

We perform the classification with several neural models. For all the models that do not rely on the BERT contextual embeddings (Devlin et al., 2018), we used the pre-trained Fast Text embeddings (Joulin et al., 2016) as initialization weights, and we fine-tuned them during the training process. We did not fine-tune the contextual BERT embeddings for reasons of computational load. However, the high number of the models' parameters required a low learning rate, which we manually adjusted to $1.e-4$, and a small batch size, which was 8. The drop-out probability was 0.1.

5.1 Neural baselines

We add two neural baselines: a Multi-Layer Perceptron (MLP) and a Convolutional Neural Network (CNN).

The MLP did not beat the SVM's performance. The CNN's F-measure was better than that of the SVM, but not significantly. Also, the CNN proved to be less effective than the attention-based models that did not exploit contextual information (table 2). Therefore we did not feed the MLP and the CNN with contextual information and kept them as additional neural baselines. However, to obtain their best performance possible, we carried out a comprehensive hyper-parameters search. For the MLP, we found the best results with trainable FastText embeddings followed by two hidden layers. For the CNN, we used 3 Convolutional-MaxPooling layers with 32, 64, and 128 channels, respectively, and windows' sizes of 2, 4, and 6.

5.2 Transformers-based models

Based on the success of the Transformer architecture in NLP (Vaswani et al., 2017), we used them to create two kinds of models, hierarchical and non-hierarchical. We adopted a non-hierarchical structure to analyze the target sentence alone, and we implemented Hierarchical Transformers to encode the target sentence and the contextual information jointly.

In the Hierarchical model, the input is not a single utterance but a series of utterances. We pad the maximum number of sentences to 5. This limit allows us to collect the whole text from about the 98% of the turns in DECOUR. However, as we will see in sections 6 and 8, considering a broader context would not have been useful.

Not considering the batch, the Hierarchical Transformers take as input a 3D tensor of Documents by Words by Embeddings. Each Words by Embeddings matrix is passed to a multi-layer, multi-head Transformer that provides a representation of each utterance, returning as output a tensor of the same shape of the input. A following fully-connected layer reduces the embeddings' dimension. The documents' representations are then concatenated into a 2D tensor and passed to another multi-layer, multi-head Transformer, which provides the overall document representation. Another fully connected layer is used to reduce the tensor's last dimension, which is then reshaped to a row vector. This vector is fed into the last fully connected layer that provides the prediction. Figure 1 shows such an architecture

With the Hierarchical Transformer, we run the experiments for the seven contexts described in section 3. Again, we tuned our hyper-parameters. In the hierarchical models, we used six layers and six heads Transformers for the encoders both at utterance and at documents level. For the non-hierarchical model, two layers and two heads were

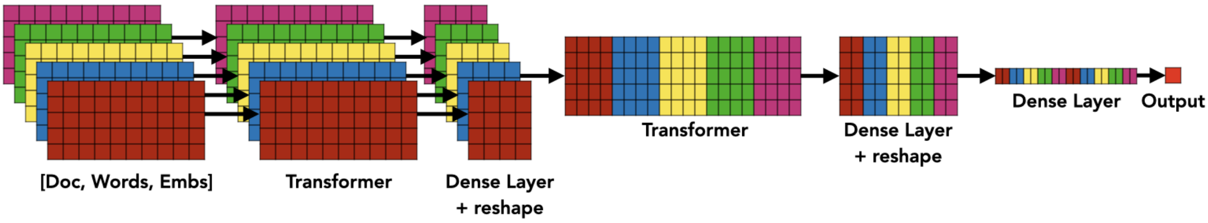

Figure 1: Hierarchical Transformers structure.

sufficient to obtain the best development set results.

5.3 BERT-based models

Finally, we perform the classification using BERT base (Devlin et al., 2018) for Italian.[1] We set up three kinds of models:

BERT + dense layer This is the simplest network, and we use it for predictions on the target utterance alone. We feed the BERT mean pooled output into a fully connected layer that performs the prediction.

BERT + Transformers This is a more expressive network, where the BERT output is passed to a multi-layer, multi-head Transformer. The Transformer's representation is then passed to a fully connected layer that outputs the prediction. We adopted Transformers with six layers and six heads, like the Hierarchical Transformers models. Similarly to the BERT + Dense model, we only feed this network with the target sentence.

text-pair BERT + Transformers The last network is structurally equal to the previous one, but in this case, we use BERT in its text-pair modality. Wet set the target sentence's size to 100 words and for the contexts to 400. The context is the concatenation of the selected texts, padded or truncated at the head. We would lose only the part of the text farthest from the target sentence in case of truncation. However, the corpus mostly contains brief statements: padding to 100 and 400 guarantees a minimum data loss. With this model, we test the seven contexts described above.

6 Results

The results are drawn in table 2.

The first group of experiments contains the baselines from the literature and simple neural networks. The second and the third group show the Transformers-based and the BERT-based models, respectively. We report Accuracy, Precision, Recall, and the F-measure. As a benchmark for the significance test, we use the literature baseline from Fornaciari and Poesio (2013) The asterisks represent the significance levels, computed via bootstrap sampling for $p \leq .05$ and $p \leq .01$. Following Søgaard et al. (2014), who recommend avoiding too small sample sizes, we set our sample at 50% of the corpus.

6.1 Overview

The results show that the SVM's performance is a strong baseline. Only a few models beat its accuracy, and none significantly. The same holds for precision. The recall is the metric where most neural models outperform SVM (significantly in five cases), even though the price they pay is a lower precision of the predictions. As a result, only four models of the 16 Transformer- and BERT-based ones show an F-Measure significantly better than SVM, corresponding to a significant improvement in the recall and better accuracy, albeit not significant. Also, a couple of deep neural models perform poorly. We will discuss them in the next sections.

6.2 Non-contextualized models

Two of the best models consider only the target sentence: the non-hierarchical Transformer and the one using BERT for single text, followed by the Transformers architecture. Despite our effort in the hyper-parameters exploration, including the use of a very low learning rate and regularization methods such as drop-out, we could not prevent that model from strong, early overfitting at a low level of performance. It seems that a single fully connected layer is unable to manage the complexity of this task, as we will discuss in section 8.

---

Table 2: Baselines, Hierarchical Transformers and text-pair BERT + Transformers models' performance in the different conditions (see section 3). In bold the significant results against SVM, with $^{**} : p \leq 0.01; \quad ^{*} : p \leq 0.05$

6.3 Contextualized models

The contextualized models show similar trends within the Transformer- and the BERT- based models. They are more evident and result in higher performance in the BERT models but are visible in the Hierarchical Transformers as well.

None of the Hierarchical Transformers shows an F-measure better than that of the non-hierarchical Transformer model, and they are better than the SVM baseline, but not significantly. We also see that the performance slowly degrades when the context is expanded from one to three utterances, regardless of the speaker of those utterances (green histogram in table 2). The same consideration holds for the subject's previous utterance, all their previous utterances, these utterances plus the previous turn, or the previous turn alone. In this last case, the fall of performance is remarkable. The model struggles to recognize the false utterances, and the recall is around 50%.

The BERT-based models confirm the loss of performance with context from 1 to 3 utterances, regardless of the speaker. In this case, the F-measure slope in the three conditions is even more pronounced than in the case of the Hierarchical Transformers.

The best results come from the two models, which rely on the contexts where only the interviewee's utterances are considered. These models are significantly better than SVM in terms of F-measure, and they have the highest performance even in terms of precision and accuracy. The best model is even significantly better than the one that uses convolutions, both for F1 and for recall, with $p < .05$.

In the conditions where another speaker's previous turn is included in the models, the performance worsens, similarly to the Hierarchical Transformers models tested in the same conditions.

7 The language of deception

We adopt two methods to depict the deceptive language: 1) we compute the Information Gain (IG) of word n-grams (Forman, 2003), and 2) we apply the Sampling and Occlusion (SOC) algorithm (Jin et al., 2019).

Information Gain measures the entropy of (sequences of) terms between the different classes. The more imbalanced the presence of such terms for one label class at the other's expense, the higher the IG value. Table 3 shows the tri-grams with the highest IG values, divided according to the class of which they are indicative, i.e., where they are more frequently found. While we computed the IG score from uni-grams to $penta$-grams, we show only tri-grams that, for illustration, represent the best trade-off between meaningful and frequent chunks of text.

These n-grams show that deceptive statements abound with negations: mostly of not remembering, but also not knowing and not having done. In contrast, truthful statements tend to be more assertive and focused on concrete details of time and circumstances. The IG signal's strength also suggests that sincere expressions are much more varied than deceptive ones, which are repeated more often and seem to be particularly stereotyped.

Even though the patterns detected by the neural models are not necessarily interpretable in terms of human common sense, we also use SOC to highlight the words that the models find to be the most influential for their output.

SOC gives a *post-hoc* explanation of the weight of specific words in a sentence for the classification task by considering the prediction difference after replacing each word with a MASK token (Jin et al., 2019). Since the outcomes depend on the context words, but Jin et al. (2019) are interested in the single words' relevance, they do not use the whole context but sample words from it. In this way, they reduce the context's weight, emphasizing that of the word itself.

Figure 2 shows two examples of correctly classified sentences, one deceptive and one truthful. The model interprets the red words as indicative of deception, the blue ones of truthfulness. They are coherent with the intuition provided by the IG. However, they cannot be interpreted as representative of our most complex models' inner functioning, as SOC relies on a standard BERT-based classifier.

8 Discussion

Our results show that the Transformers-based models, in the hierarchical and non-hierarchical form, obtain good results in the classification task. Even the non-hierarchical model is significantly better than the previous state-of-the-art.

However, the BERT-based models are those that show the best and the worst results. The worst ones come from the BERT for single-text and a simple dense output layer. On the other hand, when the fully connected layer is substituted by multi-layer, multi-head Transformers, while the BERT output is the same, the performance improves substantially (non-contextual models, red histograms in table 2).

We also ran experiments with text-pair BERT + Dense layer. We do not report the details since they do not add to the results: performance is low, while text-pair BERT with Transformers gives the best outcomes (blue histograms).

These results suggest that:

1. BERT does not embody the knowledge necessary for detecting deception. The input representations of a single fully connected layer are not expressive enough to cope with the task's complexity. This makes sense: BERT is not trained on texts and on a task (to predict the masked words) to train it to recognize deception. The cues of deception are essentially stylometric (section 7) and need a dedicated neural architecture to learn them. This is just the case of the Transformers that we associate with BERT. Thanks to their positional embeddings, they can identify the texts' relevant parts, which the task requires. This aspect also explains the SVM's performance based on n-grams and CNNs. Its convolutional layers essentially explore patterns in the n-gram embeddings.

2. When it is combined with architectures that detect deception cues, such as the Transformers, BERT's knowledge becomes an added value that allows the models to reach the best performance. Therefore, the key to success is to combine the power of transfer learning models that bring a robust semantic knowledge base and attention mechanisms to explore sequences, detecting patterns more complex than those identified by simple, fully connected layers.

3. On the other hand, when the contextual knowledge in BERT embeddings is missing, we see an over-estimation of the stylometric features coming from the context. For example, in the Hierarchical Transformers case, the models rely only on the texts' information, which prevents the hierarchical models from outperforming the non-hierarchical ones. Therefore,

we speculate that BERT's contextual knowledge works as a regularizer, which provides the Transformer with previously weighted inputs, according to the sentences' meaning.

Our results concerning BERT's usefulness with context are different from those obtained by Peskov et al. (2020), who work on Diplomacy board-game deception data. Their study associated BERT to LSTM-based contextual models, and they did not find a BERT contribution in their model's performance. They tried to fine-tune it, and they hypothesized that the lack of performance improvement was motivated by the "relatively small size" of the training data. This hypothesis could be correct, but our outcome allows us to formulate another hypothesis. Their data set concerns an online game, where the range of topics in the dialogues is presumably restricted and specific. This limitation would not allow BERT's broad knowledge to give a concrete contribution. In contrast, the data set we use comes from real life. The number of possible topics in Court is the widest. Under such conditions, it is reasonable that BERT's semantic information can play a much more relevant role: this gives a different intuition about the kind of use-cases where BERT can be useful.

Regarding the use of contexts to improve deception detection, it turns out that they can be useful, but they need to be carefully handled. In fact, not any context helps. It is not advisable to generically "collect something" before the target text. To select the previous sentence(s), regardless of the speaker, means to incorporate noise that is more harmful than helpful for the task.

Our best models are those that only consider the utterances of the speaker him/herself. Moreover, even in that case, the context's contribution improves according to its proximity to the target sentence. The overall performance model that only uses the speaker's first previous utterance is slightly better than that of the models considers all of them. This evidence is made even stronger by the observation that, in most cases, there is no previous speaker's utterance, as he/she responds with a single utterance to a statement or question of an interlocutor. To be precise, only 921 utterances of 3015 are preceded by another utterance by the same subject. So in more than two-thirds of the cases, the target utterance has no context from the same speaker and has to be considered standing alone, similarly to non-contextualized models. In other words, meaningful context is often absent but can contribute remarkably to reach better performance, which suggests that context is crucial for the task.

In other words, the fact that the additional information, even if present in less than one-third of the cases, is enough to outperform the other models and to reach the best results suggests that this is the way to obtain the best help from the context when present.

The loss of performance when the contexts include the previous turn is also coherent with the results with the contexts based on a given number of previous utterances: incorporating the statements/questions of the other persons does not help detect deception. If any, the right cues for detecting deception are in the target sentence itself or just nearby.

Also, the contextual information's usefulness is conditioned by using the right models. BERT and the trainable Transformers need to be used together. The attention mechanism that follows BERT is the trainable part of the network and detects the stylometric patterns of deception. However, we speculate that the BERT's contextual word representations act as a regularizer, which reduces the probability that the information from outside the target sentence, carried by non-contextual embeddings, is overestimated.

9 Related work

The first computational linguistics study on deception detection was Newman et al. (2003). They asked subjects to write truthful and deceptive essays and evaluated them using the Linguistic Enquiry and Word Count (LIWC), a lexicon that assigns texts several linguistic and psychological scores. LIWC is a popular tool in deception detection, also used in Fornaciari and Poesio (2013), which we compare to.

There are two main research lines: one relies on artificially produced data, often using crowdsourcing services, and the other focuses on data sets from real-life situations. The common bottleneck for data set creation is the availability of ground truth, i.e., knowing the truth behind a subject's statements. For this reason, many studies rely on data collected in laboratory conditions (Ott et al., 2011). While these studies allow us to gain intuitions about the deceptive language features, there are no real or relevant consequences for the liars. Their validity concerning high-stakes conditions is therefore unclear. Artificially created texts are likely not interchangeable with those from natural conditions (Fornaciari et al., 2020).

The notion of deception itself is used in a broad sense and includes studies that focus on a different kind of deception. A popular area, for example, concerns the detection of fake news (Oshikawa et al., 2018; Girgis et al., 2018) The field is expanding to include models that does not detect deceit strictly speaking, but trolls in social media (Addawood et al., 2019).

Pérez-Rosas et al. (2015) is more similar to our study. They collected videos from public court trials and built a multi-modal model that relies on verbal (unigrams and bigrams) and non-verbal features (Decision Trees (DT) and Random Forest (RF)). Krishnamurthy et al. (2018) used the same data set, but with neural models to represent video, audio, and textual features. In particular, they extracted verbal features relying on pre-trained word embeddings and Convolutional Neural Networks. They reached an accuracy of 96.14%. These studies are particularly interesting for the type of data set and the multi-modal approach. However, neither take the linguistic context of the statements into consideration.

Levitan et al. (2018) used the data set of Levitan et al. (2015), where 170 pairs of subjects play a "lying game". This study addresses deception in dialogues. I.e., the texts are structured as a sequence of turns, each containing one or more statements of a single participant. For the analysis, the authors selected several easily interpretable linguistic features, allowing the authors to draw a description of the deceptive language and feed a Random Forest classifier. This considers both single and multiple turns, finding that the last ones allowed to reach the best performance in their data set (F1-score of 72.33%). However, this is a laboratory experiment that is not a high-stakes scenario for the participants: this limits the possibilities of comparison with our study.

From a methodological point of view, our study is similar to that by Peskov et al. (2020). They collect data from an online negotiation game, where the participants' success depends on their ability to lie. They use state-of-the-art neural models, which also consider contextual information. However, subjects are not in a high-stakes condition in their study, so their findings are not directly comparable to our use case.

10 Conclusion

In this paper, we explore the performance of language models in detecting lies using a unique data set that contains sentences that come from real hearings created by Fornaciari and Poesio (2013) and anonymized for a research setting. We show that context is key to creating models that can detect deception and that BERT with some added attention layers can effectively beat different baselines.

However, there is no evidence that the deception cues derive from dialogic interaction, as the most useful contributions come from the speaker him/herself. To examine in depth this aspect is a line for future research.

11 Ethical statement and limitations

Applying predictive models in a legal and law enforcement context can be problematic, especially of the historical training data is biased towards certain groups (Angwin et al., 2016).

Therefore, we do not propose general-purpose models for deception detection. They only refer to the context of hearings in court, and they can be applied, at best, to similarly ruled events, for example texts coming from police interrogations. However, as statistical models, they do incorporate linguistic biases that are possibly present in the training data (Shah et al., 2020). This should be considered for a fair and respectful interpretation of the results.

It is also important to point out that the model predictions have no absolute certainty but are intrinsically probabilistic. As such, they are only meant to *support* investigations and to inform a judge's decisions. They cannot be a substitute for expert evaluations or for a due legal process.

Abstract

We present a novel approach to efficiently learn a simultaneous translation model with coupled programmer-interpreter policies. First, we present an algorithmic oracle to produce oracle READ/WRITE actions for training bilingual sentence-pairs using the notion of word alignments. This oracle actions are designed to capture enough information from the partial input before writing the output. Next, we perform a coupled scheduled sampling to effectively mitigate the exposure bias when learning both policies jointly with imitation learning. Experiments on six language-pairs show our method outperforms strong baselines in terms of translation quality while keeping the translation delay low.

1 Introduction

Simultaneous machine translation (SIMT) is a setting where the translator needs to incrementally generate the translation while the source utterance is being received. This is a challenging translation scenario as the SIMT model needs to trade off delaying translation output and the quality of the generated translation.

Recent research on SIMT relies on a strategy to decide when to read a word from the input or write a word to the output (Satija and Pineau, 2016; Gu et al., 2017). This is based on a sequential decision making formulation of SIMT, where the decision making about the next READ/WRITE action is made by an *agent*, interacting with the neural machine translation (NMT) *environment*. Current approaches are sub-optimal as they either fix the agent's policy to focus learning the NMT model (Ma et al., 2019; Dalvi et al., 2018) or learn adaptive agent policies while the NMT model is fixed (Gu et al., 2017; Alinejad et al., 2018). We argue that the interpreter should also learn to generate correct translation from incomplete input information. This is challenging as we need to optimize both programmer's and interpreter's policies to balance the tradeoff between quality and delay in the reward.

Previous research has considered the use of imitation learning (IL) to train the agent's policy (Zheng et al., 2019a,b), which is generally superior to reinforcement Learning (RL) in terms of the stability and sample complexity. However, the bottleneck of IL in SIMT is the *un*availability of the *oracle* sequence of actions. Designing *algorithmic* oracles to compute sequence of READ/WRITE actions with low translation latency and high translation quality is under-explored.

We present an IL approach to efficiently learn effective coupled programmer-interpreter policies in SIMT, based on the following contributions. First, we present a simple, fast, and effective algorithmic oracle to produce oracle actions from the training bilingual sentence-pairs based on statistical word alignments (Brown et al., 1993). Next, we design a framework that uses scheduled sampling on both programmer and interpreter. This is different from the typical IL scenarios, where there is only one policy to learn. As the two policies *collaborate*, their learning needs to be robust not only to their own incorrect predictions, but also to incorrect predictions of the other policy to mitigate this coupled *exposure bias*.

Experiments on six language pairs (translating to English from Arabic, Czech, German, Romanian, Hungarian, and Bulgarian) show the policies trained using our approach compares favorably with strong policies from the previous work. We attribute the effectiveness of the learned coupled policies to (i) the scheduled sampling, which handles the coupled exposure bias, resulting in up to 5-8 BLEU score improvements, and (ii) the quality of oracle actions generated by our algorithmic oracle, which balances translation quality and delay.

Algorithm 1 Generation in NPI-SiMT

```
$i, j \leftarrow 0$
while a stopping condition is not met do
    $t \leftarrow i + j$
    $\boldsymbol{s}_{t+1} \leftarrow \boldsymbol{f}_{\text{prog}}(\boldsymbol{s}_t, [a_t, \boldsymbol{g}_j, \boldsymbol{h}_i])$
    $P_{\text{prog}} \leftarrow \text{softmax}(\text{dense}_{\text{prog}}(\boldsymbol{s}_{t+1}))$
    $a_{t+1} \sim P_{\text{prog}}$
    if $a_{t+1} = \text{READ}$ then
        $i \leftarrow i + 1$
        $\boldsymbol{h}_i \leftarrow \boldsymbol{f}_{\text{enc}}(\boldsymbol{h}_{i-1}, x_i)$
    else
        $j \leftarrow j + 1$
        $\boldsymbol{g}_j \leftarrow \boldsymbol{f}_{\text{intp}}(\boldsymbol{g}_{j-1}, y_{j-1}, \boldsymbol{h}_{\leq i})$
        $P_{\text{intp}} \leftarrow \text{softmax}(\text{dense}_{\text{intp}}(\boldsymbol{g}_j))$
        $y_j \sim P_{\text{intp}}$
    end if
end while
```

2 NPI Approach to SiMT

We describe generation in our neural programmer-interpreter (NPI) approach to simultaneous machine translation (SiMT) in Algorithm 1. At each time step t, the *programmer* needs to decide whether to READ the next source word or to WRITE the next target word in the translation. The *interpreter* then immediately *executes* the action generated by the programmer. Both programmer and interpreter are modeled using Markov Decision Process (MDP) where prediction at particular timestep depends on the history of previous predictions. The indices i_t and j_t are the number of READ and WRITE actions in the program up to time step t.

The Programmer needs to *sequentially* decide about the next *action*, given the previous actions $\boldsymbol{a}_{<t}$ and the prefix of the source utterance read so far $\boldsymbol{x}_{\leq i_t}$ as well as the prefix of the target translation generated so far $\boldsymbol{y}_{\leq j_t}$. That is, our programmer is modeled as $P_{\text{prog}}(a|\boldsymbol{a}_{<t}, \boldsymbol{x}_{\leq i_t}, \boldsymbol{y}_{\leq j_t})$.

The Interpreter needs to execute the action generated by the programmer. At time step t, if the generated action a_t is READ, we reveal the next input token. Otherwise, if WRITE, then we generate the next target word according to $P_{\text{intp}}(y|\boldsymbol{a}_{\leq t}, \boldsymbol{x}_{\leq i_t}, \boldsymbol{y}_{\leq j_t})$.[1]

The Probabilistic Model. The probability of simultaneously generating the translation $\boldsymbol{y}$ and the sequence of actions $\boldsymbol{a}$ for a source utterance $\boldsymbol{x}$ is,

$$P_{\text{SiMT}}(\boldsymbol{y}, \boldsymbol{a}|\boldsymbol{x}) = \prod_{t=1}^{|\boldsymbol{x}|+|\boldsymbol{y}|} P_{\text{prog}}(a|\boldsymbol{a}_{<t}, \boldsymbol{x}_{\leq i_t}, \boldsymbol{y}_{\leq j_t}) \times \prod_{t:a_t=\text{WRITE}} P_{\text{intp}}(y|\boldsymbol{a}_{\leq t}, \boldsymbol{x}_{\leq i_t}, \boldsymbol{y}_{\leq j_t}).$$

Training the Model. In SiMT, we are interested in not only producing a high quality translation, but also reducing the delay between the times of receiving the source words and generating their translations. Training of the model based on this hybrid training objective can be done by reinforcement learning (RL) or imitation learning (IL). The RL approach has been attempted by (Satija and Pineau, 2016; Gu et al., 2017; Alinejad et al., 2018) for training the programmer; however, it is unstable due to sparsity of the reward function and these works also assumed a fixed interpreter. We thus take the IL approach for a sample efficient, effective, and stable learning of policies in NPI-SiMT.

3 Deep Coupled Imitation Learning

Our goal is to learn a pair of policies for the programmer and interpreter using IL. §3.1 describes the method of learning of both policies where their learning inter-dependency needs to be taken into account. §3.2 describes our novel *oracle* program actions for each sentence pair in the training set, i.e., the program $\boldsymbol{a}$ which has been responsible for generating the translation $\boldsymbol{y}$ for a source utterance $\boldsymbol{x}$ with as low delay as possible. Our overall training algorithm is depicted in Algorithm 2. $\hat{\boldsymbol{X}} = [\hat{\boldsymbol{x}}_1, ..., \hat{\boldsymbol{x}}_{|\boldsymbol{x}|}]$ is the encoding of the input sequence and $\hat{\boldsymbol{Y}} = [\hat{\boldsymbol{y}}_1, ..., \hat{\boldsymbol{y}}_{|\boldsymbol{y}|}]$ is a list of interpreter hidden states for all predictions. During training, these values are calculated before calculating the loss of the programmer.

3.1 Learning Robust Coupled Policies

Assuming we have the oracle actions, we can learn the policies for both the programmer and interpreter using behavioural cloning in IL (Torabi et al., 2019). That is, the model parameters are learned by maximising the likelihood of the oracle actions for both the programmer and interpreter,

$$\theta^*_{\text{prog}}, \theta^*_{\text{intp}} := \arg\max_{\theta_{\text{prog}}, \theta_{\text{intp}}} \sum_{(\boldsymbol{x},\boldsymbol{y},\boldsymbol{a})} \sum_{t=1}^{|\boldsymbol{x}|+|\boldsymbol{y}|} \log P_{\text{prog}}(a|\boldsymbol{a}_{<t}, \boldsymbol{x}_{\leq i_t}, \boldsymbol{y}_{\leq j_t}; \theta_{\text{prog}}) + \sum_{t:a_t=\text{WRITE}} \log P_{\text{intp}}(y|\boldsymbol{x}_{\leq i_t}, \boldsymbol{y}_{\leq j_t}; \theta_{\text{intp}}).$$

---

[1] The counter i and j are also incremented according to the respective actions at time t.

This is akin to have the expectation, in the original training objective of NPI, under a point-mass distribution over the oracle actions.

IL with behavioural cloning does not lead to robust policies for unseen examples in the test time due to exposure bias (Bengio et al., 2015). That is, the agent is only exposed to situations resulting from the *correct* actions in the training time, leading to its inability to mitigate from propagation of errors faced due to incorrect actions in the test time. Scheduled sampling (Bengio et al., 2015; Ross et al., 2011) addresses this issue by exposing the agent to incorrect decisions in training time through perturbation of the oracle decisions, which we extend to learning policy *pairs*. Crucially, the programmer-interpreter policies need to be robust to incorrect decisions encountered not only in their own trajectories, but also to one anothers' trajectories.

Learning the Programmer. To train our programmer on a training example $(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{a})$ with scheduled sampling, we first create the perturbation $(\boldsymbol{a}', \boldsymbol{y}')$ of the ground truth program and interpreter decisions. The perturbed program $\boldsymbol{a}'$ and translation $\boldsymbol{y}'$ are only used as the input to the recurrent architectures of the programmer and interpreter's decoder. They are created by replacing some of the ground truth element by randomly selecting an action from the predictive distribution of each model. We then maximise the following training objective,

$$\theta^*_{\text{prog}} := \arg\max_{\theta_{\text{prog}}} \sum_{(\boldsymbol{x},\boldsymbol{y}',\boldsymbol{a},\boldsymbol{a}',\boldsymbol{a}'')} \sum_{t=1}^{|\boldsymbol{x}|+|\boldsymbol{y}'|} \log P_{\text{prog}}(a|\boldsymbol{a}'_{<t}, \boldsymbol{x}_{\le i_t}, \boldsymbol{y}'_{\le j_t}; \theta_{\text{prog}}). \quad (1)$$

Based on the generative process described in Algorithm 1, the programmer conditions the generation of actions in each time step on the current states of the NMT's encoder and decoder. Hence, while training the programmer, the valid READ/WRITE actions need to be communicated to the interpreter and be executed in order to provide NMT's encoder/decoder states to the programmer to condition upon. Crucially, the communicated program needs to be valid.

Valid Program A ground truth program $\boldsymbol{a}$ is a valid sequence of READ/WRITE actions if $|\text{READ} \in \boldsymbol{a}| = |\boldsymbol{x}|$ and $|\text{WRITE} \in \boldsymbol{a}| = |\boldsymbol{y}|$. This valid program ensures the NPI model to safely consume a pair of parallel sentence. We generate a valid perturbation $\boldsymbol{a}''$ by only permuting the READ/WRITE actions of the program $\boldsymbol{a}$ (Figure 1).

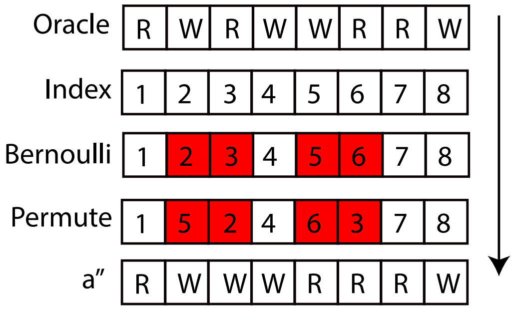

Figure 1: Creating valid perturbation from oracle program. We use a combination of Bernoulli sample and permutation function.

Algorithm 2 Training NPI-SiMT

```
Require: $\mathcal{D}$: Sentence pairs with oracle actions,
    $\beta_1, \beta_2, \beta_3$ : scheduled sampling probabilities
    for $\boldsymbol{y}', \boldsymbol{a}', \boldsymbol{a}''$.
while a stopping condition is not met do
    randomly pick $(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{a}) \in \mathcal{D}$
    $\boldsymbol{y}' \leftarrow$ perturbSeq$(\boldsymbol{y}, \beta_1, \theta_{\text{intp}})$
    $\boldsymbol{a}' \leftarrow$ perturbSeq$(\boldsymbol{a}, \beta_2, \theta_{\text{prog}})$
    $\boldsymbol{a}'' \leftarrow$ perturbProgValid$(\boldsymbol{a}, \beta_3)$
    $\hat{\boldsymbol{y}}, \hat{\boldsymbol{X}}, \hat{\boldsymbol{Y}} \leftarrow$ forward_intp$(\theta_{\text{intp}}, \boldsymbol{x}, \boldsymbol{y}', \boldsymbol{a}'')$
    $\hat{\boldsymbol{a}} \leftarrow$ forward_prog$(\theta_{\text{prog}}, \boldsymbol{a}', \hat{\boldsymbol{X}}, \hat{\boldsymbol{Y}})$
    $\theta_{\text{intp}} \leftarrow \theta_{\text{intp}} - \alpha_1 \nabla \delta(\hat{\boldsymbol{y}}, \boldsymbol{y})$
    $\theta_{\text{prog}} \leftarrow \theta_{\text{prog}} - \alpha_2 \nabla \delta(\hat{\boldsymbol{a}}, \boldsymbol{a})$
end while
```

We further extend the definition of a valid program with respect to the domain knowledge of translation so that: (i) no WRITE at the beginning, and (ii) no READ at the end of the program.

Learning the Interpreter. The interpreter needs to be robust to the incorrect actions in the previously generated words in the translations as well as the READ/WRITE actions generated by the programmer. This is done by communicating $\boldsymbol{a}''$ to the intepreter during training. Thus, the training objective for the interpreter is,

$$\theta^*_{\text{intp}} := \arg\max_{\theta_{\text{intp}}} \sum_{(\boldsymbol{x},\boldsymbol{y},\boldsymbol{y}',\boldsymbol{a}'')} \sum_{t:a''_t=\text{WRITE}} \log P_{\text{intp}}(y|\boldsymbol{x}_{\le i_t}, \boldsymbol{y}'_{\le j_t}; \theta_{\text{intp}}). \quad (2)$$

3.2 Oracle Program Actions

Our proposed oracle should measure the appropriate amount of inputs needed for translating a particular target word $\boldsymbol{y}_{j_t}$. This is done by determining the *key* word or phrases δ_j which contain important information of $\boldsymbol{y}_{j_t}$, and therefore guiding the programmer to read until δ_j before writing $\boldsymbol{y}_{j_t}$. Algorithm 3 outlines our oracle generation

Algorithm 3 Oracle Generation

```
Require: $\boldsymbol{a}$: Symmetrized alignment of $\boldsymbol{x}$ and $\boldsymbol{y}$
    in forms of $\boldsymbol{a}_{i,j}$, which means that $\boldsymbol{x}_i$ is aligned
    to $\boldsymbol{y}_j$. Index starts with 0.
$\delta_{\text{READ}} := -1$
for $j \in$ range$(0, |\boldsymbol{y}|)$ do
    $\delta_j \leftarrow \max[\{i \in a_{i,j}\}]$
    for $(\delta_j - \delta_{\text{READ}})$ times do
        emit READ
    end for

    emit WRITE
end for
```

procedure. No READ operation is emitted if the $\delta_j \leq \delta_{\text{READ}}$ or $\{i \in a_{i,j}\} = \emptyset$.

δ_j can be heuristically determined by using word alignment (Brown et al., 1993; Koehn et al., 2003), which captures strong relationship between tokens. In the case of many to one alignment of source to target, we choose the furthest source word. In the case of no alignment, nothing is done as it means the target word can be induced merely from the decoder without needing to read additional inputs. This oracle can generally generate a valid program. Caution is needed to ensure that no WRITE at the beginning and no READ at the end of the generated oracle. This can be done by aligning the first words of the parallel sentence. Similarly we also need to align the last words of the parallel sentence. [2]

4 Experiments

Our experiments aim to measure the effectiveness of our proposed method versus a strong wait-k baseline, over a range of languages of varying difficulty, syntactic complexity, and lexical complexity.

4.1 Settings

Datasets. Our main experiment will be performed in higher quality corpus which is designed for spoken dialogue and carefully edited dataset. Additionally, we perform a single large scale experiment using crawled corpus such as WMT to show that our method also scales to a large dataset.

We evaluate our proposed method on 6 language pairs, in all cases translating into English, with the source languages chosen to cover a wide range of language families and syntax. We use German (DE), Czech (CS) and Arabic (AR) from the IWSLT 2016 translation dataset (Cettolo et al., 2012). We use the provided training and development sets as-is, and concatenate all provided test sets to create our test set. We also evaluate Hungarian (HR), Bulgarian (BG), and Romanian (RO) from the SETIMES corpus (Tyers and Alperen, 2010). As this corpus is not partitioned, we use the majority of the data for training, holding out 2000 random sentence pairs for development and another 2000 sentence pairs for testing. Together these languages are representative of Germanic, West Slavic, Arabic, Uralic, East Slavic, and Italic language families, respectively.

We use sentencepiece (Kudo and Richardson, 2018) to build and tokenize our training data with 16k vocabulary size. Then we generate our oracle program actions based on the segmented tokens. We use fast_align (Dyer et al., 2013) to generate symmetrized alignments between tokens. Unless otherwise specified, we use the default settings of the mentioned toolkit.

Evaluation. We evaluate the SIMT systems based on its translation quality and delay. Translation quality can be measured by case sensitive BLEU (Papineni et al., 2002).[3] We adopt three delay measurements by previous studies. First, average proportion (AP) (Gu et al., 2017) is a fraction of read source words per emited target words. Second, average lagging (AL) (Ma et al., 2019) is an average number of lagged source words until all inputs are read. Finally the differentiable-AL (DAL) (Arivazhagan et al., 2019) is a refinement of AL which also accumulates the cost of writing output tokens after inputs are fully read.

Baseline. We compare against the wait-k baseline (Ma et al., 2019) where the programmer's policy begins with k numbers of READ, and is followed by switching WRITE and READ, until the source sentence is exhausted or end of sentence (EOS) symbol is written. If the source sentence is exhausted, the programmer will only emit WRITE actions. This baseline was shown to be superior compared to the reinforcement learning approach (Zheng et al., 2019a), and k can be tuned for the desired delay. Arivazhagan et al. (2019)'s approach is superior than the wait-k baseline. However there

Table 1: Full results on IWSLT and SETIMES datasets. Boldface indicates better translation quality versus wait-k are about the same delay (relevant systems indicated using underline within same column). Oracle-at-test is the system where the correct program is given during testing, serving as an upper bound on translation quality at a given delay.

is currently no open source code available and their end-to-end approach is not using an oracle policy. As our goal is not to beat the state-of-the-art, we leave this comparison as a future work.

NPI-SIMT. Both the programmer and interpreter are modelled using a unidirectional recurrent neural network (RNN) with a long short term memory cell (LSTM). In particular, we follow the architecture of Luong et al. (2015) with the multilayer perceptron attention of Bahdanau et al. (2015). Both the programmer and interpreter employ 20% dropout to the network output and 10% dropout to the embedding vector, and use a single layered LSTM with 512 hidden units. For the large scale experiment, we are using the transformer architecture (described in §4.5).

Training. We use `Adam` optimizer (Kingma and Ba, 2015) to train this framework. We track the learning rate of programmer and interpreter separately. We start with 0.001 learning rate, and start halving it whenever perplexity increase on development set. We use a fixed perturbation probability of 5%, 15%, and 15% for $\boldsymbol{y}'$, $\boldsymbol{a}'$, and $\boldsymbol{a}''$ respectively. Early stopping is executed at the fourth learning rate decay.

Testing. We use a beam search algorithm with a beam size of 5 and length normalization algorithm that divides hypothesis score by its length during search (Murray and Chiang, 2018).

4.2 Empirical Results

Scheduled Sampling. Our first experiment tests the effect of scheduled sampling (SS) in learning coupled policies in our NPI-SIMT method. For this purpose, we train four versions of our models where apply SS to both the programmer and the interpreter, only programmer, only interpreter, or neither. Table 1 shows the results, comparing against policies trained using the baseline wait-k method where $k \in \{1, 2, \ldots, 7, \infty\}$. The NPI-SIMT system that is trained using our proposed oracle (NPI SIMT) is able to learn from the low delay oracle as their natural delays (DAL, AL, AP) are generally as low as the delay of the oracle during training. However, it is clearly difficult to perfectly predict the oracle during test-time, and these programmer prediction errors resulted in mistakes in interpreter decisions.

Next, we consider the effect of perturbation and scheduled sampling on the proposed method. Table 1 shows that applying valid perturbation (a'') is more important than doing normal scheduled sampling (a'). This perturbation is directly correlated with the training of the interpreter, as such the noisy program make the interpreter resilient to the exposure bias. Applying both scheduled sampling further increased our proposed method accuracy. The schedule sampling on programmer ($+a', a''$) during training ameliorate this; as it increased up to 10 points of BLEU score in case of Romanian and Hungarian, 8 points in case of Bulgarian and, 5 points for German, Czech and Arabic. Additionally applying scheduled sampling on the interpreter ($+y'$) further improves translation accuracy while slightly decreasing the delay, both effects being consistent across all language pairs.

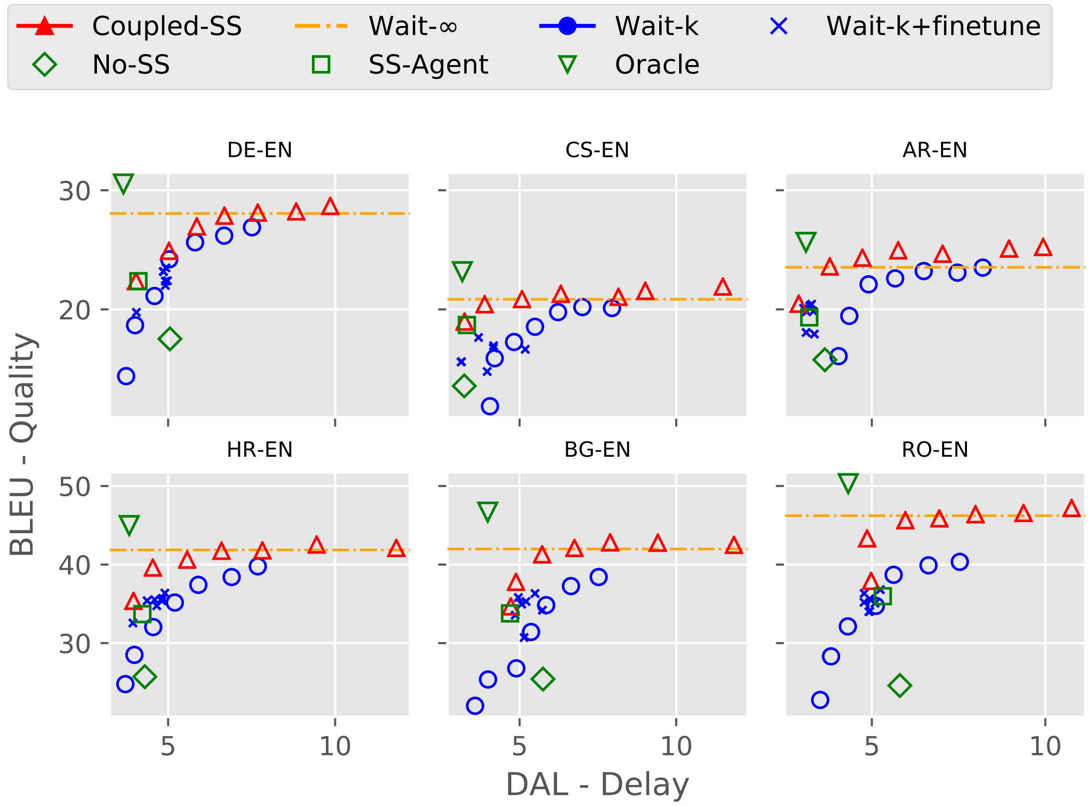

Figure 2: BLEU score versus delay using added delay and finetuning. Our proposed method coupled scheduled-sampling (Coupled-SS) method performs better than the wait-k baseline in all settings. The leftmost △ is the result of our proposed method without added delay, while △s to the right include delay (see description in text). The ◇ and □ are an ablation study considering not doing SS, and doing SS only on the agent, respectively. The × report finetuning various pretrained wait-k models with oracle+SS.

Oracle Policy vs Wait-k Policy. Figure 2 compares the policies trained by our algorithmic oracle vs those trained using the wait-k policy starting from $k = 1$. In each of these six plots, the policy trained using the oracle actions corresponds to the leftmost triangle point on the figure. Observe that the policy trained using the oracle actions compares favorably with those trained using the wait-k method in terms of translation quality (higher is better) and translation delay (lower is better).

Next we investigate the effect of increasing the delay of the oracle policy in a controlled manner onto the translation quality of the trained systems. As such, we increase the delay of the oracle policy by moving the last READ action in the oracle program to the beginning of the program, and thus increasing the delay of the oracle artificially. For additional delay, we repeat this process. We expect that the delayed oracle programs lead to trained policies with better translation quality at increased delay. The triangles in Figure 2 correspond to policies trained using the versions of the oracle program, where we added delays $\{0-5\}$. Observe that policies trained with the delayed versions of the oracle program consistently outperform the wait-k policies, across all languages.

The quality of the oracle is shown as the green triangle in Figure 2. This system is provided the oracle program at test time, unlike the other systems that allow errors to propagate from the interpreter into subsequent decisions of the programmer. Note both the low delay of the oracle, and also the fact that the BLEU score outperforms offline translation (wait-∞). This seemingly surprising finding can be explained by the oracle providing key information to the interpreter in the form of word and phrase segmentation of the inputs.

Achieving oracle level quality with a learned programmer is particularly difficult, which can be attributed to exposure bias. However, our coupled SS method manages to bridge much of the gap between the learned program and the oracle program.

Table 2: The comparison of our wait-k, our coupled-SS (Co-SS) and the oracle trajectory. A column shows a sequence of consecutive READ and WRITE. Here our proposed method is able to imitate the oracle well, by patiently waiting for sufficient input to produce a good translation. Red texts indicate place of translation error.

Finetuning Wait-k. Next we consider warm-starting training using the wait-k model, and finetuning with the oracle program and SS training method. This method of training is cheaper when a wait-k system is available, as training converges in few iterations. In this setting, we allow retraining of the interpreter, as fixing the interpreter yielded poor BLEU scores. The $\times$ points in Figure 2 show the results of this experiment, where each point was warm-started with a different wait-k system. As it can be seen, all of these runs achieve similar results, but with inferior delay and quality to our proposed method (leftmost $\triangle$). One explanation to this result is that the interpreter already converged to the wait-k policy and retraining it results in an inferior model compared to training it jointly from scratch.[4]

4.3 Qualitative Analysis

Gu et al. (2017) address the difficulty of translating sentences in subject-object-verb order when translating from German to English. We show a typical example in Table 2 where the wait-k systems are forced to make difficult decisions with insufficient evidence, in this case of predicting negation of a verb which appears latter in the input. We compare systems with $AL \approx 2$ and $DAL \approx 4$ which is achieved by the wait-2, our coupled-SS system, and the oracle system. Consider first the wait-2 system. From the state shown at bottom right corner of the smaller red box, the system next generates a poor choice of verb ("look"), which was done without access to the verb in the German input. Instead the rightmost context word was "Zusammensetzung" ("composition"), which gives little information about the verb. One way around this problem is to use a specialized classifier which predicts the final verb (Grissom II et al., 2014). However, this is often onerous or impossible. In this example, the model must also predict the negation "nicht" which appears immediately before the final verb. In a real interpretation scenario, the only way to ensure we output a correct translation is to wait for the matrix verb and negation token.

In this example the oracle trajectory breaks down the input sentence into coherent chunks, and this leads to excellent translation of each segment, and with low delay. This is because the word alignment oracle includes crossing alignment inside a phrase, thus producing sequence of READ and WRITE that do not break phrase translations. We posit that this oracle provides the minimal context needed for SIMT to translate on the fly, with sufficient context to generate each output token.

Here our proposed system closely imitates the oracle trajectory. Our proposed method is more conservative in waiting for the input, waiting until the final verb to make precise prediction. This can be explained by the uncertainty over breaking the phrases by the programmer, and thus is incurs additional delay for the sake of better translation quality. Such behaviour that is observed in the output of human interpreters, who will often wait when they are unsure what the main speaker is talking about.

4.4 Oracle Behaviour towards Alignment

Section 4.3 has partly shown our oracle behavior in translating from a final-verb language into English. Here we discuss the oracle's action when translating into a final verb language (English-Dutch). In English, the past participle is usually found right after the auxiliary verb. In this case, our oracle actions are conservative when waiting for inputs on the target side.

The example is shown in Figure 3 in which "have worked" does not produce a crossing alignment. First, the generated oracle will READ "have" and WRITE "heb". Then it will examine the next word, "jaren", and determine whether it needs to

---

[4] Note that we also try to finetune the wait-k system without scheduled sampling but it yields far worse performance than the one with scheduled sampling. This finding is similar with the main experiment.

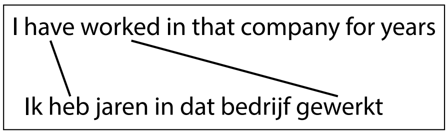

Figure 3: Translation example from English to Dutch. In this case “have worked” produce a non crossing alignment with “heb ... gewerkt” in Dutch.

READ more up until the word it is aligned. When it decided to WRITE “gewerkt”; the word “worked” would have been scanned in the past; so it should WRITE without an additional READ.

Next, it is also inevitable that our produced alignments are noisy and do not align all words correctly. It is currently not clear how much this will hurt the performance of the systems in terms of quality and delay due to alignment errors. In the worst case, our oracle will misguide the interpreter to guess target words without appropriate context (lowering quality, lowering delay) or wait for too many words (increasing quality, increasing delay). Both scenarios resulting from this noisy alignment are not catastrophic as it still depends on the interpreter’s ability to guess translation outputs without appropriate input context.

4.5 Transformer and Large Scale Experiments

To show that the proposed method also extends to the transformer and larger parallel data, we conduct two experiments. The first experiment is changing the LSTM architecture with the transformer architecture similar to Ma et al. (2019). The second experiment uses 4.5 millions DE to EN parallel sentences from WMT 2015.

The interpreter is a standard 6 layers encoder-decoder NMT transformer similar to Vaswani et al. (2017). The programmer consists of single 6 layers encoder transformer with a binary classifier. For both networks, we allow attention to attend only to the previous timesteps. Then we use the program to mask out unseen inputs at each timestep in the interpreter. Unless otherwise specified, we use the default settings of training transformer as in Vaswani et al. (2017). We employ 30% dropout to all transformers and 10% to the embeddings, 16k vocabulary size, an average batch size of 4k, 8k steps learning rate warmup, 50 tokens maximum per sentence during training, for a total of 200k steps. We use a single pass of parallel scheduled sampling (Duckworth et al., 2019) for the transformer to generate $\boldsymbol{a}'$ and $\boldsymbol{y}'$ and set the $\boldsymbol{y}', \boldsymbol{a}', \boldsymbol{a}''$ perturbation rate to be 10%, 15%, and 25%. Training is completed within 20 hours on a single V100 GPU.[5]

Table 3: Results using transformer on IWSLT and WMT corpora.

Table 3 presents the Transformer results on IWSLT and WMT. First we see that our transformer results are competitive or better than the LSTM on IWSLT dataset (compare with Table 1). These results are similar to the Ma et al. (2019) when comparing LSTM and transformer based architectures in the SIMT settings. Second, we see that our coupled scheduled sampling approach is also able to increase BLEU by up to 1.5 points compared to vanilla NPI-SIMT approach while also keeping the delay low (3.27 AL). The higher AL of the SIMT model in WMT compared to IWSLT is likely due to the higher AL of the oracle (2.75 vs. 1.79), which we attribute to the nature of the dataset. Arguably, this crawled corpus is less suitable for SIMT in general, because it contains considerably longer parallel sentences; moreover, the text is less reflective of a real simultaneous interpretation setting as it was built by only matching offline and post-edited texts. We are able to see similar improvements using coupled scheduled sampling over vanilla NPI-SIMT approach, showing the scalability of our approach.

5 Related Work

Satija and Pineau (2016); Gu et al. (2017) and Alinejad et al. (2018) formulate simultane-

---

[5] Because of the limitation of our computational resources, we are unable to use multiple GPUs for larger batch size. Using smaller batch size is known to reduce the overall performance of the transformer.

ous NMT as sequential decision making problem where an agent interacts with the environment (i.e. the underlying NMT model) through READ/WRITE actions. They pre-train the NMT system, while the agent's policy is trained using deep-RL.

Arivazhagan et al. (2020) highlights the poor performance of finetuned offline translation model when translating prefixes of input, which is the case of SIMT. Their approach uses retranslation strategy where every READ is performed, a new translation is generated from scratch, allowing revising translation on the fly and mitigating error propagation on the decoder that was attributed to the insufficient evidence when generating past output words. Their approach uses a stability metric which takes number of suffixes revisions made to produce latest translation. This approach involves wait-k inference, which limits number of words that can be emitted by the interpreter during one writing and thus limiting number of suffix revisions at the next writing. This wait-k inference is a heuristic that can be replaced by learning from the oracle.

Ma et al. (2019); Dalvi et al. (2018) introduced the fixed wait-k policy, which allows the integrated training of the NMT model wrt the fixed policy, as opposed to the adaptive policy of Gu et al. (2017); Arivazhagan et al. (2019) jointly trains an adaptive policy and re-trains the underlying NMT system. Arivazhagan et al. (2019); Zheng et al. (2019b) produces oracle READ/WRITE actions using a pre-trained NMT model, which is then used to train an adaptive agent based on supervised learning, i.e. behavioural cloning in imitation learning. Compared to our oracle which is produced merely from word alignment, their method requires a full decoding of training corpus, which is computationally expensive. These works are different from ours in that: (i) they do not use word alignment to produce the oracle actions, and (ii) they do not use of scheduled sampling.

6 Conclusion

This paper proposes a simple and effective way to train a simultaneous translation system to produce low delay translations. Our central contribution is to determine a sufficient, if not minimum, amount of inputs to translate each target token. This is achieved using word-alignment to create an oracle, which is then used as part of a training algorithm based on imitation learning to learn coupled policies, for a "programmer" which decides when to wait for more input producing translation tokens, and an "interpreter" which generates the translation. We show the importance of scheduled sampling during learning, which is crucial to combat exposure bias. Overall we show improvements in BLEU score over naively trained systems with modest translation delays.

Future work is needed to better understand the effect of various alignment models and symmetrization methods on the generated oracle. Beyond this, other opportunities include applying the model to the real speech input and applying more sophisticated imitation learning techniques that involves the generated trajectories of both "interpreter" and "programmer".

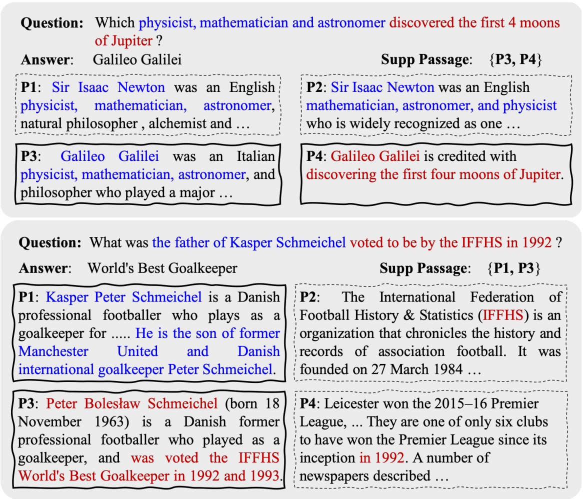
Abstract

This paper proposes a new problem of complementary evidence identification for open-domain question answering (QA). The problem aims to efficiently find a small set of passages that covers full evidence from multiple aspects as to answer a complex question. To this end, we proposes a method that learns vector representations of passages and models the sufficiency and diversity within the selected set, in addition to the relevance between the question and passages. Our experiments demonstrate that our method considers the dependence within the supporting evidence and significantly improves the accuracy of complementary evidence selection in QA domain.

1 Introduction

In recent years, significant progress has been made in the field of open-domain question answering (Chen et al., 2017; Wang et al., 2017, 2018; Clark and Gardner, 2018; Min et al., 2018; Asai et al., 2019). Very recently, some works turn to deal with a more challenging task of asking complex questions (Welbl et al., 2018; Clark et al., 2018; Yang et al., 2018) from the open-domain text corpus. In the open-domain scenario, one critical challenge raised by complex questions is that each question may require multiple pieces of evidence to get the right answer, while the evidence usually scatters in different passages. Examples in Figure 1 shows two types of questions that require evidence from multiple passages.

To deal with the challenging multi-evidence questions, an open-domain QA system should be able to (1) efficiently retrieve a small number of passages that cover the full evidence; and (2) accurately extract the answer by jointly considering the candidate evidence passages. While there have been several prior works in the latter direction (Wang et al., 2017; Clark and Gardner, 2018; Lin et al., 2018), the solutions to the first problem still rely on traditional or neural information retrieval (IR) approaches, which solely measure the relevance between the question and each individual paragraph, and will highly possibly put the wrong evidence to the top.[1] For example in Figure 1 (top), **P1** and **P2** are two candidate evidence passages that are closely related to the question but only cover the same unilateral fact required by the question, therefore leading us to the wrong answer *Newton*.



Question: Which physicist, mathematician and astronomer discovered the first 4 moons of Jupiter ?
Answer: Galileo Galilei
Supp Passage: {**P3, P4**}

P3: Peter Bolesław Schmeichel (born 18 November 1963) is a Danish former professional footballer who played as a goalkeeper, and was voted the IFFHS World's Best Goalkeeper in 1992 and 1993.

P4: Leicester won the 2015–16 Premier League, ... They are one of only six clubs to have won the Premier League since its inception in 1992. A number of newspapers described …

Figure 1: Examples of complex questions involving two facts of a person. Different facts are color-coded. **P#** are all relevant passages, while only the ones with solid-line boxes are the true supporting passages.

This paper formulates a new problem of **complementary evidence identification** for answering complex questions. The key idea is to consider the problem as measuring the properties of the selected passages, more than the individual relevance. Specifically, we hope the selected passages can serve as a set of spanning bases that supports the

---

[1] (Min et al., 2019) pointed out the shortcut problem in multi-hop QA. However, as some works (Wang et al., 2019) show that even a better designed multi-hop model can still benefit from full evidence in such situation.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2720–2726
April 19 - 23, 2021.

question. The selected passage set thus should satisfy the properties of (1)*relevancy*, i.e., they should be closely related to the question; (2) *diversity*, i.e., they should cover diverse information given the coverage property is satisfied; (3) *compactness*, i.e., the number of passages to satisfy the above properties should be minimal. With these three defined properties, we hope to both improve the selective accuracy and encourage the interpretability of the evidence identification. Note that complementary evidence identification in QA is different from Search Result Diversification (SRD) in IR on their requirement of compactness. The size of the selected set is constrained in QA tasks by the capability of downstream reasoning models and practically needs to be a small value, whereas it is not the case in SRD.

To achieve the above goals, a straightforward approach is to train a model that evaluates each subset of the candidate passages, e.g., by concatenating passages in any subsets. However, this approach is highly inefficient since it requires to encode $O(K^L)$ passage subsets, where K is the total number of candidates and L is the maximum size of subsets. Thus, a practical complementary evidence identification method needs to be computationally efficient. This is especially critical when we use heavy models like ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018), where passage encoding is time and memory consuming.

To this end, we propose an efficient method to select a set of spanning passages that is sufficient and diverse. The core idea is to represent questions and passages in a vector space and define the measures of our criterion in the vector space. For example, in the vector space, sufficiency can be defined as a similarity between the question vector and the sum of selected passage vectors, measured by a cosine function with a higher score indicating a closer similarity; and diversity can be defined as ℓ_1 distance between each pair of passages. By properly training the passage encoder with a loss function derived by the above terms, we expect the resulted vector space satisfies the property that the complementary evidence passages lead to large scores. In addition, our method only encodes each passage in the candidate set once, which is more efficient than the naive solution mentioned above. To evaluate the proposed method, we use the multi-hop QA dataset HotpotQA (the full wiki setting) since the ground-truth of evidence passages are provided. Experiments show that our method significantly improves the accuracy of complementary evidence selection.

2 Proposed Method

2.1 Task Definition

Given a question q and a mixture set of paragraphs $\mathcal{P} = \mathcal{P}^+ \cup \mathcal{P}^-$ with some paragraphs $p \in \mathcal{P}^+$ relevant to q and some $p \in \mathcal{P}^-$ irrelevant. Our goal is to select a small subset of paragraphs $\mathcal{P}_{sel} \subset \mathcal{P}$, such that every $p \in \mathcal{P}_{sel}$ satisfies $p \in \mathcal{P}^+$ (relevancy), and all $p \in \mathcal{P}_{sel}$ can jointly cover all the information asked by q (complementary). The off-the-shelf models select relevant paragraphs independently, thus usually cannot deal with the complementary property. The inner dependency among the selected $\mathcal{P}_{sel}$ needs to be considered, which will be modeled in the remaining of the section.

2.2 Model and Training

Vector Space Modeling We apply BERT model to estimate the likelihood of a paragraph p being the supporting evidence to the question q, denoted as $P(p|q)$. Let q and p_i denote the input texts of a question and a passage. We feed q and the concatenation of q and p_i into the BERT model, and use the hidden states of the last layer to represent q and p_i in vector space, denoted as $\boldsymbol{q}$ and $\boldsymbol{p_i}$ respectively. A fully connected layer $f(\cdot)$ followed by sigmoid activation is added to the end of the BERT model, and outputs a scalar $P(p_i|q)$ to estimate how relevant the paragraph p_i is to the question. Note that in our implementation $\boldsymbol{p}_i$ is based on both q and p_i, but we omit the condition on q for simplicity.

Complementary Conditions Previous works extract evidence paragraphs according to $P(p|q)$, which is estimated on each passage separately without considering the dependency among selected paragraphs. To extract complementary evidence, we propose that the selected passages $\mathcal{P}_{sel}$ should satisfy the following conditions that intuitively encourage each selected passage to be a basis to support the question:

- **Relevancy:** $\mathcal{P}_{sel}$ should have a high probability of $\sum_{p_i \in \mathcal{P}_{sel}} P(p_i|q)$;
- **Diversity:** $\mathcal{P}_{sel}$ should cover passages as diverse as possible, which can be measured by the average distance between any pairs in $\mathcal{P}_{sel}$, e.g., maximizing $\sum_{i,j \in \{i,j|p_i,p_j \in \mathcal{P}_{sel}, i \neq j\}} \ell_1(\boldsymbol{p}_i, \boldsymbol{p}_j)$. Here

$\ell_1(\cdot,\cdot)$ denotes L_1 distance;

- **Compactness:** $\mathcal{P}_{sel}$ should optimize the aforementioned conditions while the size being minimal. In this work we constrain the compactness by fixing $|\mathcal{P}_{sel}|$ and meanwhile maximizing $cos(\sum_{i\in\{i|p_i\in\mathcal{P}_{sel}\}}\boldsymbol{p}_i,\boldsymbol{q})$. We use $\cos(\cdot,\cdot)$ to encourage the collection of evidence covers what needed by the question.

Training with Complementary Regularization We propose a new supervised training objective to learn the BERT encoder for QA that optimizes the previous conditions. Note that in this work we assume a set of labeled training examples are available, i.e., the ground truth annotations contain complementary supporting paragraphs. Recently there was a growing in such datasets (Yang et al., 2018; Yao et al., 2019), due to the increasing interest in model explainability. Also, such supervision signals can also be obtained with distant supervision.

For each training instance $(q,\mathcal{P})$, we define

$$\{\boldsymbol{p}_i\}^+ = \{\boldsymbol{p}_i\},\quad \forall i\in\{i|p_i\in\mathcal{P}^+\} \tag{1}$$

$$\{\boldsymbol{p}_i\}^- = \{\boldsymbol{p}_i\},\quad \forall i\in\{i|p_i\in\mathcal{P}^-\} \tag{2}$$

$$\{\boldsymbol{p}_i\} = \{\boldsymbol{p}_i\}^+\cup\{\boldsymbol{p}_i\}^- \tag{3}$$

Denoting $y_{p_i} = 1$ if $p_i\in\mathcal{P}^+$ and $y_{p_i}=0$ if $p_i\in\mathcal{P}^-$, we have the following training objective function:

$$\begin{aligned}\mathcal{L}(\{\boldsymbol{p}_i\};\boldsymbol{q};y) &= \mathcal{L}_{sup}(\{\boldsymbol{p}_i\};\boldsymbol{q};y)\\ &\quad+\alpha\mathcal{L}_d(\{\boldsymbol{p}_i\}^+)+\beta\mathcal{L}_c(\{\boldsymbol{p}_i\};\boldsymbol{q};y)\end{aligned} \tag{4}$$

where

$$\mathcal{L}_{sup}(\{\boldsymbol{p}_i\};\boldsymbol{q};y) = -\sum_i y_{p_i}\log(f(\boldsymbol{p}_i)), \tag{5}$$

$$\mathcal{L}_d(\{\boldsymbol{p}_i\}^+) = \sum_{\boldsymbol{p_i},\boldsymbol{p_j},i\neq j}(1-\ell_1(\boldsymbol{p_i},\boldsymbol{p_j})). \tag{6}$$

$$\mathcal{L}_c(\{\boldsymbol{p}_i\};\boldsymbol{q};y) = \begin{cases}1-\cos(\boldsymbol{q},\sum_i\boldsymbol{p}_i),\\ \quad\text{if }\ \Pi_{p_i}y_{p_i}=1\\ \max(0,\cos(\boldsymbol{q},\sum_i\boldsymbol{p}_i)-\gamma),\\ \quad\text{if }\ \Pi_{p_i}y_{p_i}=0\end{cases} \tag{7}$$

where α and β are the hyperparameter weights and $\ell_1(\cdot,\cdot)$ denotes L1 loss between two input vectors. Eq 5 is the cross-entropy loss corresponding to relevance condition; Eq 6 regularizes the diversity condition; Eq 7 is the cosine-embedding loss[2] for the compactness condition and $\gamma > 0$ is the margin to encourage data samples with better question coverage.

2.3 Inference via Beam Search

Score Function During inference, we use the following score function to find the best paragraph combination:

$$\begin{aligned}g(\mathcal{P}_{sel};q;\{\boldsymbol{p}_i\}) &= \sum_{p_i}P(p_i|q)+\alpha\cos(\sum_{\boldsymbol{p_i}}\boldsymbol{p}_i,\boldsymbol{q})\\ &\quad+\beta\sum_{\boldsymbol{p_i},\boldsymbol{p_j},i\neq j}\ell_1(\boldsymbol{p}_i,\boldsymbol{p}_j)\end{aligned} \tag{8}$$

where α and β are hyperparameters similar to Eq 4. Note that our approach requires to encode each passage in $\mathcal{P}$ only once for each question, resulting in an $O(K)$ time complexity of encoding ($K = |\mathcal{P}|$); and the subset selection is performed in the vector space, which is much more efficient than selecting subsets before encoding.

Beam Search In a real-world application, there is usually a large candidate set of $\mathcal{P}$, e.g., retrieved passages for q via a traditional IR system. Our algorithm requires $O(K)$ time encoding, and $O(K^L)$ time scoring in vector space when ranking all the combinations in L candidates. Thus when K becomes large, it is still inefficient even when $L = 2$. We resort to beam search to deal with scenarios with large Ks. The details can be found in Appendix A.

3 Experiments

3.1 Settings

Datasets Considering the prerequisite of sentence-level evidence annotations, we evaluate our approach on two datasets, a synthetic dataset **MNLI-12** and a real application **HotpotQA-50**. Data sampling is detailed in Appendix B.

- **MNLI-12** is constructed based on the textual entailment dataset MNLI (Williams et al., 2018), in order to verify the ability of our method in finding complementary evidence. In original MNLI, each premise sentence corresponds to three hypotheses sentences: entailment, neutral and contradiction. To generate complementary pairs for each premise sentence, we split each hypothesis sentence into two segments. The goal is to find the segment combination that entails premise sentence, and our dataset, by definition, ensures that only the combination of two segments from the entailment hypothesis can entail the premise, not any of its subset or other combinations. The original train/dev/test splits from MNLI are used.

---

[2] Refer to CosineEmbeddingLoss in PyTorch.

• **HotpotQA-50** is based on the open-domain setting of the multi-hop QA benchmark HotpotQA (Yang et al., 2018). The original task requires to find evidence passages from abstract paragraphs of all Wikipedia pages to support a multi-hop question. For each q, we collect 50 relevant passages based on bigram BM25 (Godbole et al., 2019). Two positive evidence passages to each question are provided by human annotators as the ground truth. Note that there is no guarantee that $\mathcal{P}_{50}$ covers both evidence passages here. We use the original development set from HotpotQA as our test set and randomly split a subset from the original training set as our development set.

3.2 Settings

Baseline We compare with the BERT passage ranker (Nie et al., 2019) that is commonly used on open-domain QA including HotpotQA. The baseline uses the same BERT architecture as our approach described in Section 2.2, but is trained with only the relevancy loss (Eq 5) and therefore only consider the relevancy when selecting evidence.

We also compare the DRN model from (Harel et al., 2019) which is designed for the SRD task. Their ensemble system first finds the most relevant evidence to the given question, and then select the second diverse evidence using their score function. The major differences from our method are that (1) they train two separate models for evidence selection; (2) they do not consider the compactness among the evidences. It is worth mentioning that we replace their LSTM encoder with BERT encoder for fair comparison.

Metric During the evaluation we make each method output its top 2 ranked results[3] (i.e. the top 1 ranked pair from our method) as the prediction. The final performance is evaluated by exact match (EM), i.e., whether both true evidence passages are covered, and the F1 score on the test sets.

3.3 Results

In the experiments, we have $M = 3$, $N = 4$ for MNLI-12 and $M = 4$, $N = 5$ for HotpotQA-50 with our method. The values are selected according to development performance. We follow the settings and hyperparameters used in (Harel et al., 2019) for the DRN model. Table 1 shows the performance. The upper-bound measures how many pieces of true evidences enclosed by the complete set of candidate passages where our proposed ranker selects from. For HotpotQA dataset, we use a bi-gram BM25 ranker to collect top 50 relevant passages and build the basis for the experiments[4], which inevitably leads some of the true evidences to be filtered out and makes its upper-bound less than 100%. For the artificial MNLI-12 dataset, all the true evidences are guaranteed to be included.

System	**HotpotQA-50**		**MNLI-12**	
	EM	**F1**	**EM**	**F1**
Baseline Ranker	16.67	41.29	41.61	67.57
DRN + BERT	1.03	35.37	6.20	46.07
Our Method	**20.15**	**49.10**	**53.81**	**73.18**
Upper-Bound	35.49	61.08	100.00	100.00

Table 1: Model Evaluation (%). The upper-bound indicates the amount of true evidences contained by all candidate passages. The baseline ranker is a BERT ranker trained only with relevancy loss.

Table 1 shows that our method achieves significant improvements on both datasets. On HotpotQA-50, all systems have low EM scores, because of the relatively low recall of the BM25 retrieval. Only 35.49% of the samples in the test set contain both ground-truth evidence passages. On MNLI-12, the EM score is around 50%. This is mainly because the segments are usually much shorter than a paragraph, with an average length of 7 words. Therefore it is more challenging in matching the q with the p_is. Specifically, both our method and the BERT baseline surpass the DRN model on all datasets and metrics, which results from our question-conditioned passage encoding approach. Our defined vector space proves beneficial to model the complementation among the evidence with respect to a given question. The ablation study of our loss function further illustrates that the diversity and the compactness terms efficiently bring additional 20%/30% increase in EM score on two datasets and consequently raise the F1 score by about 8/6 absolute points.

Figure 2 gives examples about how our model improves over the baseline. Our method can successfully select complementary passages while the baselines only select passages that look similar to the question. A more interesting example is given at the bottom where the top-50 only covers one supporting passage. The BERT baseline selects two

---

[3] There is only one positive pair of evidences for each question.

[4] This is the standard setting that starts with BM25 retrieval to make the inference time efficient enough without loss of generality.

incorrect passages that cover identical part of facts required by the question and similarly the DRN baseline select a relevant evidence and an irrelevant evidence, while our method scores lower the second passage that does not bring new information, and reaches a supporting selection. A similar situation contributes to the majority of improvement on one-supporting-evidence data sample in HotpotQA-50.

Inference Speed Our beam search with score function brings slight overheads to the running time. On HotpotQA-50, it takes 1,990 milliseconds (ms) on average to obtain the embeddings of all passages for one data sample whereas our vector-based complementary selection only adds an extra 2 ms which can be negligible compared to the encoding time.

3.4 Future Work

The latest dense retrieval methods (Lee et al., 2019; Karpukhin et al., 2020; Guu et al., 2020) show promising results on efficient inference on the full set of Wikipedia articles, which allows to skip the initial standard BM25 retrieval and avoid the significant loss during the pre-processing step. Our proposed approach is able to directly cooperate with these methods as we all work in the vector space. Therefore, the extension to dense retrieval can be naturally the next step of our work.

4 Conclusion

In the paper, we propose a new problem of complementary evidence identification and define the criterion of complementary evidence in vector space. We further design an algorithm and a loss function to support efficient training and inference for complementary evidence selection. Compared to the baseline, our approach improves more than 20% and remains to scale well to the computationally complex cases.

A Complementary Evidence Selection via Beam Search

For efficient inference when $L = 2$, we start to select the top-N ($N \ll K$) most relevant passages. Then we score the combinations between each passage pair in the top-N set and another top-M set. This reduces the complexity from $O(K^2)$ to $O(MN)$. M is a hyperparameter corresponding to the beam size. In a more general setting with $L \geq 2$, we have an algorithm with the complexity of $O((L-1)MN)$ instead of $O(K^L)$, which is shown in algorithm 1.

Algorithm 1: Complementary Evidence Selection via Beam Search

```
Data: Vector representation of question ($\boldsymbol{q}$), vector representation of all the $N$ passages $\{p_n\}$ ($\{\boldsymbol{p_n}\}$); the maximum
      number of passage to select ($L$); the beam size ($M$); a vector of weights for all regularization terms $\boldsymbol{\lambda}$.
Result: The top ranked complementary passages.
/* Predict the probability $P(\boldsymbol{p_i})$ of being a supporting passage for each passage
   $\boldsymbol{p_i}$ given $\boldsymbol{q}$                                                          */
for $i \in [1, N]$ do
    $P(\boldsymbol{p_i}) \leftarrow f(\boldsymbol{q}, \boldsymbol{p_i})$;
end
Rank the passages by $P(\boldsymbol{p_i})$;
$\boldsymbol{P_{span}}$ = []
Pick $M$ passages with top $P(\boldsymbol{p_i})$ into $\boldsymbol{P_{span}}$;
for $depth \in [2, L]$ do
    $\boldsymbol{P'_{span}}$ = [] ;
    for $j \in [1, M]$ do
        /* $\boldsymbol{P_j}$ is a selected subset, $s_j$ is the corresponding score          */
        Pop the $j$-th tuple $(\boldsymbol{P_j}, s_j)$ from $\boldsymbol{P_{span}}$;
        for $n \in [1, N]$ do
            if The set $\boldsymbol{P_j} \cup \{\boldsymbol{p_n}\}$ is covered by $\boldsymbol{P'_{span}}$ then
                continue
            end
            /* $\boldsymbol{r}_n$ is the regulation increases by adding $\boldsymbol{p_n}$ to $\boldsymbol{P_j}$          */
            Put $(\boldsymbol{P_j} \cup \{\boldsymbol{p_n}\}, s_j + P(\boldsymbol{p}_n) + \boldsymbol{\lambda r}_n)$ into $\boldsymbol{P'_{span}}$;
            if More than $M$ tuples added based on $\boldsymbol{P_j}$ then
                break
            end
        end
    end
    Rank $\boldsymbol{P'_{span}}$ according to the scores;
    $\boldsymbol{P_{span}} \leftarrow \boldsymbol{P'_{span}}[1:M]$
end
Return $\boldsymbol{P_{span}}[0]$
```

B Data Sampling

MNLI-12 In original MNLI, each premise sentence P corresponds to one entailment E_P, one neutral N_P and one contradiction C_P. We take the premise P as q, and split each of its corresponding hypotheses into two segments with a random cutting point near the middle of the sentence, resulting in a total of 6 segments $\{E_P^1, E_P^2, N_P^1, N_P^2, C_P^1, C_P^2\}$. Mixing them with the 6 segments corresponding to another premise X, we can finally have $\mathcal{P}^+ = \{E_P^1, E_P^2\}$ and $\mathcal{P}^- = \{N_P^1, N_P^2, C_P^1, C_P^2, E_X^1, E_X^2, N_X^1, N_X^2, C_X^1, C_X^2\}$. Consequently, we sample one positive and eight negative pairs respectively from $\mathcal{P}^+$ and $\mathcal{P}^-$. A pair like $\{E_P^1, C_X^2\}$ is considered as negative. To ensure the segments are literally meaningful, each segment is guaranteed to be longer than 5 words.

HotpotQA In HotpotQA, the true supporting paragraphs of each question q are given. Therefore, we can easily form $\mathcal{P}^+$ and $\mathcal{P}^-$ and sample positive and negative pairs of paragraphs respectively from $\mathcal{P}^+$ and $\mathcal{P}^-$. A special pair that contains one true supporting paragraph and one non-supporting paragraph is considered as a negative pair.

Entity-level Factual Consistency of Abstractive Text Summarization

Abstract

A key challenge for abstractive summarization is ensuring factual consistency of the generated summary with respect to the original document. For example, state-of-the-art models trained on existing datasets exhibit entity hallucination, generating names of entities that are not present in the source document. We propose a set of new metrics to quantify the entity-level factual consistency of generated summaries and we show that the entity hallucination problem can be alleviated by simply filtering the training data. In addition, we propose a summary-worthy entity classification task to the training process as well as a joint entity and summary generation approach, which yield further improvements in entity level metrics.

1 Introduction

Many recent advances in deep neural networks have led to significant improvement in the quality of abstractive summarization (Radford et al., 2019; Gehrmann et al., 2019; Lewis et al., 2019). Despite this progress, there are still many limitations facing neural text summarization (Kryscinski et al., 2019), the most serious of which is their tendency to generate summaries that are not factually consistent with the input document; a factually consistent summary only contains statements that can be derived from the source document. Recent studies show that about 30% of the summaries generated by neural network sequence-to-sequence models suffer from fact fabrication (Cao et al., 2018). Unfortunately, the widely used ROUGE score is inadequate to quantify factual consistency (Kryscinski et al., 2019).

Factual inconsistency can occur at either the entity or the relation level. At the entity level, a model generated summary may contain named-entities that never appeared in the source document. We call this the entity *hallucination* problem. For example, consider the following model generated summary:

> *People in Italy and the Netherlands are more likely to consume fewer cups of coffee than those in the* <u>UK</u>*, a study suggests.*

"UK" never appeared in the input source document (taken from the test set of the XSUM dataset (Narayan et al., 2018)). In fact, the source document mentioned a study involving people in Italy and Netherlands; "UK" was a result of model hallucination. Another type of inconsistency occurs when the entities indeed exist in the source document but the relations between them are not in the source document. This type of inconsistency is much harder to identify. Open Information Extraction (OpenIE) and dependency parsing tools have been used (Cao et al., 2018) to identify the underlying relations in a summary, but are not yet accurate enough for practical use. Ultimately, these researchers relied on manually classifying generated summaries into *faithful*, *fake*, or *unclear*.

In this paper, we propose a set of simple metrics to quantify factual consistency at the entity-level. We analyze the factual quality of summaries produced by the state-of-the-art BART model (Lewis et al., 2019) on three news datasets. We then propose several techniques including data filtering, multi-task learning and joint sequence generation to improve performance on these metrics. We leave the relation level consistency to future work.

2 Related work

Large transformer-based neural architectures combined with pre-training have set new records across many natural language processing tasks (Vaswani et al., 2017; Devlin et al., 2019;

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2727–2733
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

Radford et al., 2019). In particular, the BART model (Lewis et al., 2019) has shown superior performance in many text generation tasks including abstractive summarization. In contrast to encoder-only pre-training such as in BERT (Devlin et al., 2019) or decoder-only pre-training such as in GPT-2 (Radford et al., 2019), BART is an encoder-decoder transformer-based neural translation model jointly pre-trained to reconstruct corrupted input sequences of text.

Several authors have pointed out the problem of factual inconsistency in abstractive summarization models (Kryscinski et al., 2019; Kryściński et al., 2019; Cao et al., 2018; Welleck et al., 2019). The authors in (Kryściński et al., 2019) proposed to train a neural network model to classify if a summary is factually consistent with a given source document, similar to a natural language inference task. In the dialogue generation setting, authors in (Li et al., 2019) proposed using unlikelihood to surpress logically inconsistent responses. Our work is complementary to such existing approaches as we focus on simple entity-level metrics to quantify and improve factual consistency. Our goal of improving entity-level metrics of summaries is also related to controllable abstractive summarization (Fan et al., 2018), where a list of named-entities that a user wants to see in the summary can be passed as input to influence the generated summary. In contrast, our goal is to *predict* which entities are summary-worthy while generating the summary that contains them. In this view we are trying to solve a more challenging problem.

3 Entity-level factual consistency metrics

We propose three new metrics that rely on off-the-shelf tools to perform Named-Entity Recognition (NER). [1] We use $\mathcal{N}(t)$ and $\mathcal{N}(h)$ to denote the number of named-entities in the target (gold summary) and hypothesis (generated summary), respectively. We use $\mathcal{N}(h \cap s)$ to denote the number of entities found in the generated summary that can find a match in the source document. If a named-entity in the summary consists of multiple words, we consider it a match as long as any n-gram of the named-entity can be found in the source document. This is meant to capture the situation where the named-entity can be shortened; for example, "Obama " is a match for "Barack Obama" and "Harvard" is a match for "Harvard University". When the match is at the unigram level, we make sure that it is not a stop word such as "the". We also make the match case-insensitive to accommodate casing variances.

Precision-source: We propose precision-source ($\mathbf{prec}_s$) to quantify the degree of hallucination with respect to the source: $\mathbf{prec}_s = \mathcal{N}(h \cap s)/\mathcal{N}(h)$. It is simply the percentage of named-entities in the summary that can be found in the source. Low $\mathbf{prec}_s$ means hallucination is severe.

We first evaluate the $\mathbf{prec}_s$ score on the ground truth summaries of the 3 datasets: Newsroom (Grusky et al., 2018), CNN/DailyMail (Nallapati et al., 2016) and XSUM (Narayan et al., 2018). Table 1 shows that among the three datasets, the ground truth summaries in XSUM have the lowest $\mathbf{prec}_s$ score. This is because the ground truth summaries in the XSUM dataset often use the first sentence of the article as the summary; the source document is constructed to be the rest of the article and may not repeat the named-entities that appeared in the summary. We hypothesize that the hallucination problem is largely caused by the training data itself. Thus, we propose to perform entity-based data filtering to construct a "clean" version of these datasets as described next.

	Newsroom			CNNDM			XSUM		
	train	val	test	train	val	test	train	val	test
avg. $\mathcal{N}(t)$	2.08	2.10	2.09	4.36	5.09	4.87	2.08	2.06	2.08
avg. $\mathcal{N}(t \cap s)$	1.88	1.90	1.90	4.21	4.92	4.70	1.64	1.64	1.64
$\mathbf{prec}_s$ (%)	90.6	90.6	90.5	96.5	96.7	96.6	79.0	79.5	79.3

Table 1: Average number of named-entities and the $\mathbf{prec}_s$ scores (%) in the ground truth summary.

Entity-based data filtering: For each dataset, we apply Spacy NER on the gold summary to identify all the named-entities. [2] If any of the entities cannot find a match in the source document, we discard the sentence that contains the entity from the ground truth summary. If the ground truth summary consists of only one sentence and it needs to be discarded, we remove the document-summary pair from the dataset. This way, we ensure that our filtered dataset does not contain hallucination of entities ($\mathbf{prec}_s = 1$) in the ground truth summary. The dataset size before and after the filtering is shown in Table 2. About a third of examples are filtered out for XSUM. Again, this is because of

---

[1] We use Spacy (Honnibal and Montani, 2017).

[2] We ignore certain types of entities such as date, time, numerals because they tend to have large variations in representation and are difficult to determine a match in the source document. The appendix contains more details.

the way XSUM dataset is constructed as mentioned in the previous paragraph. As we shall see in Table 3, entity-based data filtering reduces hallucination of the trained model and the effect is especially significant in the XSUM dataset.

Precision-target and recall-target: Although the precision-source ($\mathbf{prec}_s$) metric quantifies the degree of entity hallucination with respect to the source document, it does not capture the entity-level accuracy of the generated summary with respect to the ground truth summary. To get a complete picture of the entity-level accuracy of the generated summary, we propose the precision-target ($\mathbf{prec}_t$) score: $\mathbf{prec}_t = \mathcal{N}(h \cap t)/\mathcal{N}(h)$, where $\mathcal{N}(h \cap t)$ is the number of named-entities in the generated summary that can find a match in the ground truth summary; and the recall-target ($\mathbf{recall}_t$) score: $\mathbf{recall}_t = \mathcal{N}(h \cap t)/\mathcal{N}(t)$, where $\mathcal{N}(t)$ is the number of named-entities in the ground truth summary. We compute the F1 score as $F1_t = 2 \cdot \mathbf{prec}_t \cdot \mathbf{recall}_t / (\mathbf{prec}_t + \mathbf{recall}_t)$.

4 Multi-task learning:

In addition to entity-based data filtering, we also explore another method to further improve the summarization quality. In particular, we incorporate an additional task of classifying summary-worthy named-entities in the source document. A summary-worthy named-entity in the source document is one that appears in the ground truth summary and thus, is a salient entity, worthy of inclusion in the generated summary. Intuitively, if we can identify these summary-worthy named-entities using the encoder representation, we may potentially increase the entity-level precision and recall metrics as well as the overall quality of the summary. We achieve this by adding a classification head to the encoder of BART. To prepare for the classification label, we first identify the named-entities in the ground truth summary and find the matching tokens in the source document. We then assign the (B)eginning-(I)nside-(O)utside labels to each token of the source document to denote if the token is beginning, inside or outside of a summary-worthy named-entity, respectively. During training, we simply add the classification loss for each token at the encoder to the original sequence-to-sequence loss.

More precisely, let $\{(x^i, y^i)\}_{i=1}^N$ be a dataset of N examples where $x^i = x_1^i, \ldots, x_{ts(i)}^i$ are the tokens of the ith source document and $y^i = y_1^i, \ldots, y_{tt(i)}^i$ are the tokens of the target (ground truth summary). The standard sequence-to-sequence training minimizes the maximum log likelihood estimation (MLE) loss:

$$\mathcal{L}_{\text{MLE}}^i(\theta, x^i, y^i) = -\sum_{t=1}^{tt(i)} \log p_\theta(y_t^i | x^i, y_{<t}^i).$$

With summary-worthy entity classification, each example has an additional sequence of BIO labels $z^i = z_1^i, \ldots, z_{ts(i)}^i, z_t^i \in \{0, 1, 2\}$. By adding an additional fully connected layer on top of the BART encoder, we obtain the classification loss

$$\mathcal{L}_{\text{BIO}}^i(\theta(\text{enc}), x^i, z^i) = -\sum_{t=1}^{ts(i)} \log p_{\theta(\text{enc})}(z_t^i | x^i).$$

Finally, we can minimize the joint loss $\mathcal{L}_{\text{Multitask}}^i = \mathcal{L}_{\text{MLE}}^i + \alpha \mathcal{L}_{\text{BIO}}^i$, where α is a hyper parameter. We choose α between 0.1 to 0.5 via the validation sets.

5 Joint Entity and Summary Generation:

We also explore another generative approach to promote entity-level precision and recall metrics. In particular, instead of just generating the summary, we train the BART model to generate the sequence of summary-worthy named-entities, followed by a special token, and then the summary. We call this approach JAENS (Join sAlient ENtity and Summary generation). Similar to the multi-task learning approach discussed earlier, JAENS encourages the model to jointly learn to identify the summary-worthy named-entities while learning to generate summaries. Since the decoder generates the salient named-entities first, the summaries that JAENS generate can further attend to these salient named-entities through decoder self-attention.

6 Experiment results

We use the pre-trained BART-large model in the Fairseq library (Ott et al., 2019) to fine-tune on the 3 summarization datasets.[3] The appendix contains additional details of experimental setup.

In Table 3, we show the effect of the entity-based data filtering. For each dataset, we train two separate models: using the training data before and after entity-based data filtering as shown in Table 2. We evaluate both models on the "clean" test set after entity-based data

	JAENS	43.4±0.7	21.0±0.3	35.5 ±0.4	**99.0**±0.1	**99.0**±0.1	77.6±0.9	77.1±0.6	79.5±0.6	80.0±0.5	78.5±0.2	78.5±0.1

Table 3: Comparison of models trained using original data, with entity-based data filtering, with an additional classification task and with JAENS. Scores are all in percentages, averaged over 5 runs and shown with standard deviations. We bold the numbers that are significantly better in the sense that the means are separated by at least the standard deviations. We report both the micro and macro averages of our proposed entity-level scores. In all datasets, data filtering leads to higher $\mathbf{prec}_s$ scores, indicating that entity hallucination can be alleviated by this simple technique. In addition, data filtering generally improves other entity level metrics: $\mathbf{prec}_t$, $\mathbf{recall}_t$ and $F1_t$. Adding the classification task (multi-task) or JAENS to data filtering further improves the performance on $\mathbf{prec}_t$ and $\mathbf{recall}_t$ and therefore the overall entity-level $F1_t$.

filtering. We choose this filtered version of the original test set because we only want to measure entity-level consistency against the correct set of entities; using the unfiltered dataset means we could count a hallucinated entity as correct. We observe improvements of $\mathbf{prec}_s$ across all three datasets trained using the filtered subset of data. For example in XSUM, the $\mathbf{prec}_s$ is increased from 93.6% to 98.2%, indicating a significant reduction in entity hallucination. In addition, the entity-based data filtering generally improves other entity-level metrics as well. Even with less training data, the entity-based data filtering is able to maintain the ROUGE scores quite well. For XSUM, about 34% of the training data is filtered out (c.f. Table 2), which explains the more noticable impact on the ROUGE scores. The results in Table 3 suggest that entity-level data filtering is a simple yet effective approach to achieve higher entity-level factual consistency as well as general summarization quality. In Table 4 we provide qualitative examples where the model trained on the original data produces hallucination and the entity-level data filtering removes such hallucination.

Table 3 shows that adding the classification task (multi-task) futher increases the $\mathbf{prec}_t$ and $\mathbf{recall}_t$ metric and therefore the overall entity-level $F1_t$ on top of the improvements from data filtering. Similar gains can be observed with JAENS, which out-performs the multi-task approach on CNNDM and Newsroom datasets. The result confirms our intuition that the summaries in JAENS can benefit from attending to the generated salient entities in terms of the entity level metrics. However, the additional complexity during decoding may have hurt the ROUGE scores.

For the interested readers, we also evaluated the PEGASUS (Zhang et al., 2020) models for the ROUGE and entity level metrics on these three datasets in the appendix.

Accuracy of entity level metrics: As our entity level metrics are based on automatic NER tools and heuristics matching rules, errors in both steps can lead to inaccuracy in the metrics. By manually checking 10 random ground truth summaries together with the source documents in the validation split of XSUM dataset, we found that all of the named entities are correctly identified by the NER tool and the matchings are correct. Therefore, we believe that even our current NER tool and matching rule already produce high

The right column contains the ground truth summaries. The hallucinated named-entities are underscored. Proposed data filtering overcomes hallucination in these examples.

accuracy in practice.

7 Conclusion

In this paper we study the entity-level factual consistency of the state-of-the-art summarization model. We propose precision-source score $\mathbf{prec}_s$ to quantify the degree of entity hallucination. We also propose additional metrics $\mathbf{prec}_t$ and $\mathbf{recall}_t$ to measure entity level accuracy of the generated summary with respect to the ground truth summary. We found that the ground truth summaries of the XSUM dataset contain a high level of entity hallucination. We propose a simple entity-level data filtering technique to remove such hallucination in the training data. Experiments show that such data filtering leads to significant improvement in $\mathbf{prec}_s$. ($\mathbf{prec}_s$ increases from below 94% to above 98% in XSUM for example.) We futher proposed a multi-task learning and a joint sequence generation approach to further improve the entity-level metrics. Overall, combining our proposed approaches significantly reduces entity hallucination and leads to higher entity level metrics with minimal degradation of the ROUGE scores.

A Supplementary material for Entity-level Factual Consistency of Abstractive Text Summarization

A.1 Details of NER filtering

We only consider named-entities of the following types: ’PERSON’ (People, including fictional.), ’FAC’ (Buildings, airports, highways, bridges, etc.), ’GPE’ (Countries, cities, states.), ’ORG’ (Companies, agencies, institutions, etc.), ’NORP’ (Nationalities or religious or political groups.), ’LOC’ (Non-GPE locations, mountain ranges, bodies of water.), ’EVENT’ (Named hurricanes, battles, wars, sports events, etc.). We ignore other types of entities such as date, time, numerals because they tend to have large variations in representation and are difficult to determine a match in the source document.

A.2 Details of experimental setup

We use the pre-trained BART-large model in the Fairseq library (Ott et al., 2019) to fine-tune on the 3 summarization datasets.

In all experiments, we validate the ROUGE scores of the generated summaries on the validation split and early-stop on the epoch with the highest validation score. We use the standard learning rate of 3e-5 for finetuning with linear decay schedule and 500 warmup steps. For Newsroom, we use 4 p3.16xlarge EC2 instances on AWS with a total of 32 Tesla V100 GPUs for finetuning and the effective batch size is 32; for XSUM, we use 1 p3.16xlarge instance with a total of 8 Tesla V100 GPUs and update frequency of 4, giving an effective batch size of 32; for CNNDM, we use 1 p3.16xlarge instance with a total of 8 Tesla V100 GPUs, giving an effective batch size of 8.

We chose the α parameter for multi-task learning between 0.1 and 0.5 with step of 0.05 based on ROUGE scores on the validation set. We found the best values are 0.3, 0.3 and 0.15 for Newsroom, CNNDM and XSUM, respectively. We observe that the ROUGE and entity level metrics on validation and test sets are very close, with the former slightly higher.

During decoding, we use beam size of 1 for Newsroom, 4 for CNNDM and 6 for XSUM (to be consistent with the setting in (Lewis et al., 2019)). We did use trigrams blocking in beam search as we did not see much need for this additional step.

A.3 Evaluation of PEGASUS (Zhang et al., 2020)

In this section we simply evaluate the PEGASUS checkpoints provided by Huggingface (Wolf et al., 2020) on the NER filtered test sets. The checkpoints are downloaded from `https://huggingface.co/google/pegasus-newsroom`, `https://huggingface.co/google/pegasus-cnn_dailymail` and `https://huggingface.co/google/pegasus-xsum`, respectively. The results are summarized in Table 5. Note that PEGASUS performances similarly on CNNDM and XSUM but worse on Newsroom compared to BART-large.

	Rouge1	Rouge2	RougeL	macro $\mathbf{prec}_s$	micro $\mathbf{prec}_s$	macro $\mathbf{prec}_t$	micro $\mathbf{prec}_t$	macro $\mathbf{recall}_t$	micro $\mathbf{recall}_t$	macro $F1_t$	micro $F1_t$
Newsroom	40.6	28.4	37.4	94.6	94.7	53.4	55.5	68.5	67.8	60.0	61.1
CNNDM	42.5	20.7	39.6	99.1	99.0	65.9	66.7	74.7	75.7	70.0	70.9
XSUM	45.3	23.7	37.9	93.9	93.1	76.6	75.8	80.3	80.1	78.4	77.9

On Hallucination and Predictive Uncertainty in Conditional Language Generation

Yijun Xiao, William Yang Wang
University of California, Santa Barbara
{yijunxiao,william}@cs.ucsb.edu

Abstract

Despite improvements in performances on different natural language generation tasks, deep neural models are prone to hallucinating facts that are incorrect or nonexistent. Different hypotheses are proposed and examined separately for different tasks, but no systematic explanations are available across these tasks. In this study, we draw connections between hallucinations and predictive uncertainty in conditional language generation. We investigate their relationship in both image captioning and data-to-text generation and propose a simple extension to beam search to reduce hallucination. Our analysis shows that higher predictive uncertainty corresponds to a higher chance of hallucination. Epistemic uncertainty is more indicative of hallucination than aleatoric or total uncertainties. It helps to achieve better results of trading performance in standard metric for less hallucination with the proposed beam search variant.

1 Introduction

Modern deep neural network models have brought drastic improvements of generation quality measured by standard metrics on different natural language generation (NLG) tasks. However, along with these improvements, researchers find that neural models are more prone to a phenomenon called hallucination, where models generate description tokens that are not supported by the source inputs. This phenomenon seriously damages the applicability of neural language generation models in practice where information accuracy is vital.

Hallucination has been observed in various conditional NLG tasks such as image captioning (Rohrbach et al., 2018), data-to-text generation (Wiseman et al., 2017; Nie et al., 2019; Parikh et al., 2020), abstractive summarization (Cao et al., 2018; Durmus et al., 2020), and neural machine translation (NMT) (Müller et al., 2019). These studies tackle hallucinations within a specific task and give possible explanations of why hallucinations occur. For example, Rohrbach et al. (2018) attributes object hallucination in image captioning to visual misclassification and over-reliance on language priors; Nie et al. (2019) believes hallucination in neural surface realization comes from the misalignment between meaning representations and their corresponding references in the dataset; Müller et al. (2019) claims that hallucinations in NMT are mainly due to domain shift.

We believe that there is a common theme across all the hallucination explanations in conditional NLG tasks: predictive uncertainty. In language generation, predictive uncertainty quantifies the entropy of the token probability distributions a model predicts. There are multiple sources of uncertainty. Two major ones frequently studied are aleatoric and epistemic uncertainties, where the former comes from the data or measurements, and the latter is concerned with the model. With recent progress in Bayesian neural networks (BNNs) (Hinton and Van Camp, 1993; Neal, 1995) and uncertainty quantification (Blundell et al., 2015; Gal and Ghahramani, 2016; Lakshminarayanan et al., 2017), we are able to quantify both parts of predictive uncertainty in neural NLG.

This study draws connections between hallucination and predictive uncertainty and empirically investigates their relationship in image captioning and data-to-text generation tasks. We propose an uncertainty-aware beam search algorithm to reduce the chance of hallucination by penalizing parts or the entirety of the predictive uncertainty during model decoding. We find that the choice of uncertainty matters, and penalizing epistemic uncertainty yields better results compared to penalizing aleatoric or total uncertainty. Our contributions are:

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2734–2744
April 19 - 23, 2021.

- We draw connections between hallucination and predictive uncertainty across various conditional natural language generation tasks and empirically investigate their relationship.
- We propose an uncertainty-aware beam search approach for hallucination reduction to demonstrate that lowering uncertainty can lead to less hallucination.
- We show that uncertainty decomposition helps to achieve better trade-offs between hallucination and performance.

2 Hallucination and Predictive Uncertainty

2.1 Hallucination Probability

In general, hallucination refers to the phenomenon where the model generates false information not supported by the input. For example, in the context of image captioning, hallucination can be defined as generating captions that contain descriptions not present in the given image. Let (x, y) be the pair of variables at interest where x is some structured data containing facts and y is a natural language sentence based on the facts. The task is to learn the conditional distribution of $p(y|x)$ in order to generate sentence y given any new input x. Most neural approaches break the probability into a sequence of single token predictions:

$$p(y|x) = p(y_1|x) \prod_{i=2}^{k} p(y_i|x, y_1, \cdots, y_{i-1}) \quad (1)$$

where $\{y_1, \cdots, y_k\}$ is the collection of tokens in sentence y. We denote $c_i = \{x, y_1, \cdots, y_{i-1}\}$ as the context of the i-th prediction in the following sections for simplicity.

Apparently, hallucination is context-dependent which means we need to look at a certain context c_i and determine whether the next token prediction y_i is hallucinated or not. Let $\mathcal{V}_h^{(c_i)}$ denote the set of tokens that are considered false information given the current context c_i and $\mathcal{V}$ the whole vocabulary. Consider a random sampling decoder where a token is generated based on the predicted categorical distribution. i.e. $\text{Cat}(|\mathcal{V}|, p(y_i|c_i))$. The probability of hallucination at the current step is simply:

$$P(y_i \in \mathcal{V}_h^{(c_i)}) = \sum_{v \in \mathcal{V}_h^{(c_i)}} p(y_i = v|c_i) \quad (2)$$

Practically, it is hard to automatically determine the context-dependent set $\mathcal{V}_h^{(c_i)}$. Task-specific heuristics are often used to determine which tokens are hallucinated. In specific restrictive applications, the context-dependent set can be relaxed to a context-independent one to reduce the complexity of determining hallucination.

2.2 Relationship with Predictive Uncertainty

We use entropy to measure the predictive uncertainty in this work. The total uncertainty of predicting token y_i is:

$$\begin{aligned} & H(y_i|c_i) \\ &= -\sum_{v \in \mathcal{V}} p(y_i = v|c_i) \log p(y_i = v|c_i) \\ &= -\sum_{v \in \mathcal{V} \setminus \mathcal{V}_h^{(c_i)}} p(y_i = v|c_i) \log p(y_i = v|c_i) \\ &\quad - \sum_{v \in \mathcal{V}_h^{(c_i)}} p(y_i = v|c_i) \log p(y_i = v|c_i) \end{aligned} \quad (3)$$

From Equation 3, we can see that there are two sources of uncertainty for the token predictions: one from the uncertainty of choosing suitable tokens to describe the input; another from some unsuitable tokens attaining considerable probability mass either by being confusing in the current context or due to an insufficiently trained system.

The second source of uncertainty is directly related to hallucination probability. Although no monotonic relationship can be derived, a near-zero hallucination probability requires a near-zero value of the second source of uncertainty. This observation prompts us to investigate the relationship between hallucination and predictive uncertainty in practice. Intuitively, the higher the predictive uncertainty is, the more probable some of the probability mass gets assigned to unsuitable tokens.

2.3 Uncertainty Decomposition

There are often two types of uncertainties frequently mentioned in uncertainty quantification literature: epistemic and aleatoric uncertainty (Der Kiureghian and Ditlevsen, 2009; Kendall and Gal, 2017; Depeweg et al., 2018). Epistemic uncertainty reflects the uncertainty on model weights, and aleatoric uncertainty concerns inherent uncertainty in the data or measurement. We are interested in whether the relationship with hallucination is the same for both types of uncertainties.

$$\begin{array}{l|ccc|} & \text{Token 1} & \text{Token 2} & \text{Token 3} \\ \text{Prediction 1} & 0.33 & 0.33 & 0.33 \\ \text{Prediction 2} & 0.33 & 0.33 & 0.33 \\ \text{Prediction 3} & 0.33 & 0.33 & 0.33 \end{array}$$

(a)

$$\begin{array}{l|ccc|} & \text{Token 1} & \text{Token 2} & \text{Token 3} \\ \text{Prediction 1} & 0.98 & 0.01 & 0.01 \\ \text{Prediction 2} & 0.01 & 0.98 & 0.01 \\ \text{Prediction 3} & 0.01 & 0.01 & 0.98 \end{array}$$

(b)

Figure 1: Examples of predictions with (a) high aleatoric but low epistemic uncertainty; and (b) high epistemic but low aleatoric uncertainty.

Bayesian deep learning approaches (Blundell et al., 2015; Gal and Ghahramani, 2016; Lakshminarayanan et al., 2017) are widely studied for uncertainty quantification with neural networks. Following the notations in Section 2.2, the predictive distribution of $p(y_i|c_i)$ can be written as:

$$p(y_i|c_i) = \int_w p(y_i|c_i, w)q(w)dw \tag{4}$$

where w parameterizes the neural network that makes predictions and $q(w)$ denotes the approximate posterior distribution of the weights w given the training data. Notice that if we fix the weights w, $H(y_i|c_i, w)$ represents the entropy that is unrelated to the uncertainty of the model weights. Therefore the aleatoric part of the predictive uncertainty can be calculated with $\mathbb{E}_{q(w)}[H(y_i|c_i, w)]$. The epistemic part of the uncertainty is the difference between the total and the aleatoric uncertainty as shown below:

$$u_{al}(y_i|c_i) = \mathbb{E}_{q(w)}[H(y_i|c_i, w)] \tag{5}$$

$$u_{ep}(y_i|c_i) = H(y_i|c_i) - \mathbb{E}_{q(w)}[H(y_i|c_i, w)] \tag{6}$$

In this study, the aleatoric and epistemic parts of predictive uncertainty are estimated using deep ensembles (Lakshminarayanan et al., 2017). More concretely, denote the model predictions as $\{p_m(y_i|c_i)\}_{m=1}^M$ and the aggregated prediction as $p(y_i|c_i) = \frac{1}{M}\sum_{m=1}^M p_m(y_i = v|c_i)$, aleatoric and epistemic uncertainties are calculated as:

$$u_{al}(y_i|c_i) = \frac{1}{M}\sum_{m=1}^{M} H_m(y_i|c_i) \tag{7}$$

$$u_{ep}(y_i|c_i) = H(y_i|c_i) - u_{al}(y_i|c_i) \tag{8}$$

where $H_m(y_i|c_i)$ and $H(y_i|c_i)$ are the entropy of $p_m(y_i|c_i)$ and $p(y_i|c_i)$ respectively.

Intuitively, in the case of deep ensembles, aleatoric uncertainty measures the average spread of all model predictions, while epistemic uncertainty measures the agreement among all model predictions. Examples with three possible tokens are illustrated in Figure 1.

3 Case Study: Image Captioning

In this section, we analyze image captioning models trained on MSCOCO (Chen et al., 2015) data set.

3.1 Hallucination Probability at Different Uncertainty Levels

The first question we want to investigate is whether hallucination probabilities change at different predictive uncertainty levels. Some experimental settings are listed below.

Model architecture We consider four different image captioning models: **FC** model (Rennie et al., 2017) where image features are used to initialize the RNN decoder; **Att2In** model from (Rennie et al., 2017) applies attention on image features and feeds it into the decoder LSTM (Hochreiter and Schmidhuber, 1997) cell gate; **BUTD** model from (Anderson et al., 2018) uses bottom-up attention which operates at the level of objects and other salient image regions; **Transformer** model where transformers (Vaswani et al., 2017) are used in the encoder-decoder structure for generation. All models are implemented in the open source framework by Luo et al. (2018)[1].

Training We consider the same data split from (Karpathy and Fei-Fei, 2015). All models are trained with batch size 50 for 30 epochs with Adam optimizer (Kingma and Ba, 2014). Evaluations are done on the Karpathy test set.

Hallucination and uncertainty evaluation As in (Rohrbach et al., 2018), synonyms for all possible MSCOCO objects are used to determine

BUTD	0.00	2.94	1.92	12.77	17.24	25.53
Transformer	2.99	5.48	6.58	8.82	12.00	43.75

Table 1: Action hallucination percentages at different levels of predictive uncertainty. Action predictions with higher uncertainty are more prone to hallucination.

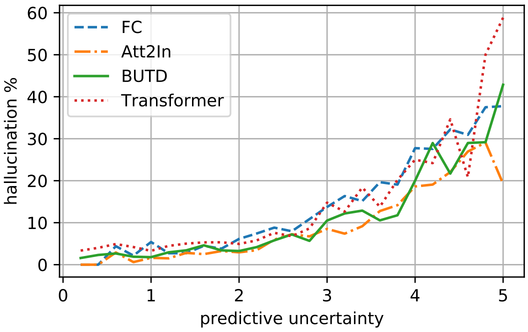

Figure 2: Object hallucination chance at different predictive uncertainty levels. Higher predictive uncertainty corresponds to a higher level of hallucination percentage across all models.

whether an object generated by the captioning model is hallucinated. Hallucination probabilities are calculated by binning all object token prediction entropy and counting the percentage of hallucinated objects in each bin.

3.2 Results and Discussions

Figure 2 shows the object hallucination percentages at different predictive uncertainty levels. At higher uncertainty levels, the generated objects are more likely to be hallucinated. The results are consistent across four different models. The transformer model seems to have a higher hallucination chance at high uncertainty levels than the other three models. However, this does not indicate Transformer models hallucinate more. In fact, the transformer model has an overall lowest hallucination percentage among all four models.

Beyond object hallucination Aside from object hallucination, we also analyze verbs generated by the models to see whether a similar relationship holds for other types of token generations. The same models and training procedures are adopted. We extract all present continuous tense verbs from the generated captions using spaCy part-of-speech tagger[2] and manually label whether they are suitable to describe the corresponding images. There are approximately 3500 generated captions containing verbs, and 400 are annotated for each model. We refer to unsuitable verbs generated in the captions as action hallucinations.

Model	Correlation coefficient	
	epistemic	aleatoric
FC	0.313	0.299
BUTD	0.334	0.228
Att2In	0.360	0.268
Transformer	0.269	0.131

Table 2: Pearson correlation coefficients between hallucination and epistemic/aleatoric uncertainty in image captioning task. Epistemic uncertainty is more indicative of hallucination across four models.

Action predictions are binned according to their uncertainty values, and the results are shown in Table 1. We can observe that action tokens with higher predictive uncertainty are also more likely to be hallucinated. Noticeably, the transformer model also has a higher action hallucination rate at high uncertainty levels.

Examples of predictions with high and low uncertainty Figure 3 shows some example images and their captions generated from a BUTD model on the test set. The token predictions of interests and the corresponding uncertainty values are highlighted in bold and italic, respectively. We observe that highly uncertain predictions often correspond to unusual textures, features resembling the predicted tokens, or blurred images. For example, Figure 3(b) shows a motorcycle covered in vines; Figure 3(d) shows candles in the background which resemble cakes; Figure 3(f) is blurred.

Epistemic and aleatoric uncertainties As we could decompose the total uncertainty into two parts, we are interested in which part is more indicative of hallucination. Table 2 shows the Pear-

son correlation coefficients between hallucination (binary) and epistemic/aleatoric uncertainty for all four models. We can see that both parts of uncertainty are weakly correlated with hallucination, while epistemic uncertainty is more indicative of hallucination across all four models compared to aleatoric uncertainty.

4 Case Study: Data-to-text Generation

Data-to-text generation (Kukich, 1983; McKeown, 1992) is a task to generate textual content conditioned on input content in the form of structured data such as tables. Neural models are prone to hallucination in data-to-text generation tasks compared to traditional template-based systems, and methods are proposed to improve faithfulness (Wiseman et al., 2017; Nie et al., 2019; Tian et al., 2019). In this section, we discuss the relationship between predictive uncertainty and hallucination in data-to-text generation with ToTTo dataset (Parikh et al., 2020).

4.1 Generation Quality and Average Uncertainty

We conduct token-level analysis in Section 3. Now we take a different route and analyze sentence-level quality with different average predictive uncertainty values. Experiment settings are described below.

Dataset ToTTo dataset consists of tables from English Wikipedia articles with their corresponding metadata, such as page title and section title. Candidate description texts are modified by annotators to pair with each table. Relevant table cells supporting the description texts are highlighted by the annotators as well. There are 120,761 table-text pairs in training, 7,700 in validation, and 7,700 in test. We use the baseline standard linearization approach to represent the highlighted portions of the tables along with their corresponding metadata (referred to as subtable with metadata in (Parikh et al., 2020)).

Model architecture and training We use a standard sequence-to-sequence model with attention (Bahdanau et al., 2015; Luo et al., 2018) for analysis. LSTM with 512 hidden size is used for both the encoder and the decoder. Adam optimizer with learning rate 1e-3 is used for the optimization. The model is trained with cross-entropy loss for 20 epochs. The checkpoint with the best validation loss is chosen for the evaluation. The implementation is done using fairseq (Ott et al., 2019)[3].

Evaluation We evaluate the average predictive uncertainty for all generated sentences in the validation set and select the top, bottom, and middle 5% for comparison. BLEU score (Papineni et al., 2002) is used as an automatic metric to evaluate the similarity to the references; further manual annotations are done to evaluate the *fluency*, *faithfulness* (precision), and *coverage with respect to reference*

---

Unc. Level	Avg Unc.	BLEU	Fluency (%)	Faithfulness (%)	Less/Neutral/More Coverage w.r.t. Ref
High	1.83 - 3.74	10.2	46.0	41.3	79.4 / 15.9 / 04.7
Medium	0.83 - 0.89	31.5	87.3	78.9	35.2 / 47.9 / 16.9
Low	0.04 - 0.27	72.8	100.0	99.0	22.2 / 70.1 / 07.7

Table 3: Evaluation results for candidates with high, medium, and low average predictive uncertainty values for ToTTo validation set. Unc. denotes uncertainty. Higher uncertainty candidates have lower quality and higher chance of being hallucinated/unfaithful w.r.t. the input tables.

(recall) of the generated sentences. Particularly, faithfulness reflects how likely the generated sentences hallucinate facts that are not supported by the tables. More details of the human evaluation metrics are described in (Parikh et al., 2020). The goal is to measure how different the generation qualities are for candidates with varying average predictive uncertainties.

4.2 Results and Discussions

Table 3 summarizes the evaluation results for candidates with varying uncertainty values. It is obvious that candidates with higher average predictive uncertainty values are less fluent and more likely to contain hallucinations. Another interesting observation from Table 3 is that the generated sentences with medium average uncertainty are more likely (16.9%) to cover more table facts than the references compared to the ones with high (4.7%) and low (7.7%) average uncertainty. One possible explanation is that some table facts that are not always included in the references, when generated, have higher predictive uncertainty values than the facts that are almost always included in the references. Therefore, generated sentences with low uncertainty tend to include less but more confident facts considered by the model.

5 Reducing Hallucination

5.1 Uncertainty-Aware Beam Search

Because of the positive correlation between hallucination probability and predictive uncertainty, it is straightforward to incorporate uncertainty into the caption generation process to reduce hallucination. Beam search is the most used approximate decoding method in language generation. It keeps track of the top-B scored candidates at each generation step and considers all single token extensions of the current candidates.

More formally, denote the set of B candidates in the beam at time step $t-1$ as $\mathcal{Y}_{t-1} = \{\mathbf{y}_{t-1}^{(b)}\}_{b=1}^{B}$. All possible single token extensions of the candidates in $\mathcal{Y}_{t-1}$ form a set $\mathcal{C}_t = \{\mathbf{y} \mid \mathbf{y}_{t-1} \in \mathcal{Y}_{t-1} \wedge y_t \in \mathcal{V}\}$. Beam at step t is then formed as:

$$\mathcal{Y}_t = \underset{\mathbf{y}_1 \cdots \mathbf{y}_B \in \mathcal{C}_t}{\arg\max} \sum_{b=1}^{B} \log p(\mathbf{y}_b|\mathbf{x}) \quad s.t. \quad \mathbf{y}_i \neq \mathbf{y}_j \quad \forall i \neq j \tag{9}$$

Uncertainty-aware beam search (UABS) adds a weighted penalty term in the beam search objective to balance between log probability and predictive uncertainty of the selected candidates. Let $u(\mathbf{y}|\mathbf{x})$ be the function to measure the aggregated predictive uncertainty of candidate $\mathbf{y}$ given input $\mathbf{x}$, uncertainty-aware beam search updates the beam at step t according to the following equation:

$$\mathcal{Y}_t = \underset{\mathbf{y}_1 \cdots \mathbf{y}_B \in \mathcal{C}_t}{\arg\max} \sum_{b=1}^{B} \log p(\mathbf{y}_b|\mathbf{x}) - \lambda u(\mathbf{y}_b|\mathbf{x}) \quad s.t. \quad \mathbf{y}_i \neq \mathbf{y}_j \quad \forall i \neq j \tag{10}$$

where $\lambda \geq 0$ is the weight controlling the degree to which we want to penalize decoding uncertainty. Larger λ leads to candidates with smaller predictive uncertainty. In practice, this can be done by subtracting the weighted uncertainty term from the aggregated log probability scores at each decoding step before choosing top-B candidates.

An important decision in using uncertainty-aware beam search is the choice of uncertainty term $u(\mathbf{y}|\mathbf{x})$. We could use either the aleatoric or epistemic part of the predictive uncertainty or both. We compare these choices and discuss the results in the next section.

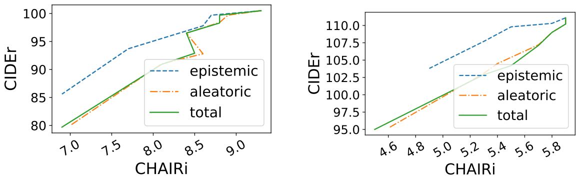
5.2 Image Captioning Results

With larger weights on the uncertainty penalty term, log probabilities of the decoded sentences drop. Therefore, we expect to see a trade-off between the quality of generated captions and the chance of hallucination.

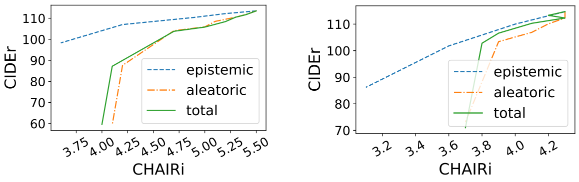
We empirically examine the trade-offs on the image captioning models with different uncertainty

Image	**UABS results with weight λ**		
	0	20	80
	a vase filled with flowers sitting on top of a table	a vase filled with lots of white flowers	there is a vase that has flowers in it
	a wooden cutting board topped with lots of food	a wooden cutting board topped with lots of food	a cutting board that has a bunch on it

Table 4: Two examples of epistemic UABS results with varying penalty weights on the image captioning data set. In the first example the model successfully avoids hallucination of a table with $\lambda = 20$ while in the second example it is unable to change the generated caption until larger penalty weight is set.



(a) FC (b) Att2In



(c) BUTD (d) Transformer

Figure 4: CIDEr plotted against CHAIRi scores of captions generated with UABS with different uncertainty penalty weights. Lower CHAIRi score indicates less hallucination. Upper-left is better. Penalizing epistemic uncertainty in UABS achieves the best results.

choices for the penalty term. We use a five-model ensemble for each of the four model architectures to estimate aleatoric and epistemic uncertainties. Due to the different magnitudes of aleatoric and epistemic uncertainties, we choose penalty weight λ from $[0.1, 0.2, 0.4, 0.8, 1.0, 2.0, 4.0]$ for aleatoric and total uncertainty and $[10, 20, 40, 80]$ for epistemic uncertainty.

Figure 4 shows the trade-offs between CIDEr (Vedantam et al., 2015) and CHAIRi (Rohrbach et al., 2018) scores of captions generated with uncertainty-aware beam search with different uncertainty choices and penalty weights. A smaller value of CHAIRi indicates the model is less likely to generate hallucinated objects, and a higher CIDEr indicates better caption quality. Therefore

	λ	**avg. len.**	**# obj.**	**hal. %**	**gen. %**
ref.		10.44	6114	0	-
base	0	9.31	7328	5.5	0

	80	9.12	6493	3.6	4.6
aleat.	0.1	9.32	7250	5.4	0
	0.4	9.32	7051	5.1	0
	1.0	9.33	6800	4.7	1.0
	4.0	9.43	4349	4.1	28.4

Table 5: Average sentence length and total number of objects detected in the captions generated by BUTD model with varying uncertainty penalty weight λ. Penalizing epistemic uncertainty leads to slightly shorter lengths. Number of objects mentioned by the captions decreases with increasing λ. **gen. %** denotes percentage of generic responses. It is moderate with epistemic penalized results but can be very high if aleatoric uncertainty is heavily penalized.

an approach that is to the upper left of another is better. As the penalty weight increases, we observe a decrease in both the CHAIRi and the CIDEr scores across all models.

Table 4 shows two examples of different generated captions using epistemic UABS with varying penalty weights. In the first example, we can see that a medium penalty weight of 20 not only helps avoid the hallucination of a table but also adds correct information about the color of the flowers. In the second example, a medium penalty weight is unable to change the generated caption.

Regarding the choice of uncertainty, it is notable that when penalizing epistemic uncertainty, the generated captions achieve higher CIDEr scores than penalizing aleatoric or total uncertainty. We

λ	BLEU	Fluency (%)	Faithfulness (%)	Less/Neutral/More Coverage w.r.t. Ref
0	40.1	92	79	34 / 60 / 6
10	33.6	83	84	41 / 51 / 8
20	27.4	73	80	52 / 42 / 6

Table 6: Evaluation results for candidates decoded with different penalty weights for UABS on ToTTo validation set. Epistemic uncertainty is used for uncertainty penalization. Faithfulness first increases, then decreases to the same level as regular beam search results as we increase the penalty weight λ.

Table 7: Two examples of UABS results with varying penalty weights on the ToTTo validation set. Blue tokens are correct table facts that are dropped by candidates generated with larger penalty weights; red tokens are incorrect/hallucinated facts that are dropped with larger penalty weights. In general, UABS with larger weights tend to produce sentences with less information that the model is more confident with.

hypothesize that epistemic uncertainty indicates the uncertainty of model weights. By penalizing epistemic uncertainty, we encourage the model to take the prediction path where it is well-calibrated. On the other hand, penalizing aleatoric uncertainty encourages the model to make low entropy predictions in all contexts regardless of the actual data distributions.

Table 5 shows the average sentence length, the number of objects, the percentage of hallucinations, and the percentage of generic responses in the captions generated by the BUTD model with different uncertainty choices and penalty weights on the test set. We can see that when penalizing epistemic uncertainty, UABS results in slightly shorter caption candidates. Both the number of objects and hallucination percentage decrease as we increase the weight λ. Interestingly, when penalizing aleatoric uncertainty, sentence length stays approximately the same despite lower CIDEr scores, as shown in Figure 4. Further investigation shows that this is partly due to an increasing number of generic captions such as "*there is no image here to provide a caption for*". Penalizing epistemic uncertainty is much less likely to result in such generic captions. We can see that when increasing λ from 1.0 to 4.0 with aleatoric UABS, the percentage of generic responses jumps drastically from 1.0% to 28.4%. In comparison, epistemic UABS keeps the generic response rates low while achieving lower hallucination rates.

5.3 Data-to-text Results

We also evaluate the effect of UABS on the ToTTo dataset. We choose to penalize epistemic uncertainty due to its better performances than aleatoric uncertainty, as shown in the previous section. A five-model deep ensemble is used to quantify the epistemic uncertainty and generate results with UABS. We compare the BLEU score and three human evaluation metrics among results generated with different uncertainty penalty weights. 100 generation results are randomly selected and evaluated for each penalty weight choice. The results are shown in Table 6. We can see that a relatively small penalty weight leads to a reduced hallucination chance (hence more faithful) with a cost on the BLEU score and fluency.

To qualitatively examine the sentences generated with different λ values, we show example results on the ToTTo validation set in Table 7. We can see that with larger penalty weights, the UABS results drop certain statements that the model deems less confident regardless of the correctness. This results in shorter but more confident predictions for UABS results with a larger uncertainty penalty.

6 Related Work

Hallucination There are many pieces of anecdotal evidence of hallucination presented in various NLG tasks. Most recently, researchers started investigating the phenomenon systematically. Rohrbach et al. (2018) analyzes object hallucination focusing on the objects that appeared in the MSCOCO segmentation challenge. They propose the CHAIR metric to quantify the severity of object hallucination. They find that the models tend to make predictions consistent with a language model trained on the captions instead of a model trained to predict objects in an image. Therefore hallucination is caused by an over-reliance on the language priors. Nie et al. (2019) believes that the origin of the hallucination problem in neural surface realization comes from the data side. More specifically, datasets used for NLG systems often include instances with information misalignment between the input structure and the output text. They propose integrating a language understanding module for iterative data refinement to better align meaning representations and output text. Müller et al. (2019) examines hallucination in neural machine translation and observes that the phenomenon is most common in out-of-domain settings. They empirically compare several strategies to improve domain robustness in NMT and find that a combination of reconstruction and a noisy channel model for reranking is most effective.

These observations are consistent with our findings. For example, domain shift and data misalignment are known to lead to a higher level of epistemic uncertainty (Kendall and Gal, 2017) which makes hallucination a more severe problem.

Uncertainty quantification Uncertainty quantification has attracted more attention recently due to the progress in Bayesian deep learning. Bayes by backprop (Blundell et al., 2015), Monte Carlo dropout (Gal and Ghahramani, 2016), and deep ensembles (Lakshminarayanan et al., 2017) are examples of popular Bayesian approaches to evaluate uncertainty with deep neural models. Kendall and Gal (2017) investigates the benefits of modeling epistemic and aleatoric uncertainty in vision tasks such as semantic segmentation and depth regression. They show that it is important to model aleatoric uncertainty with large datasets and real-time applications and epistemic uncertainty with small datasets and safety-critical applications. Other applications of uncertainty quantification have been explored in the context of time series predictions (Zhu and Laptev, 2017), natural language processing tasks (Xiao and Wang, 2019), etc. More broadly, prediction entropy has been analyzed in different neural language generation tasks (Ott et al., 2018; Xu et al., 2020). Depeweg et al. (2018) shows how to extract and decompose uncertainty in Bayesian neural networks with latent variables for decision-making purposes. They show that active learning and risk-sensitive reinforcement learning both benefit from uncertainty decomposition.

7 Discussion and Conclusions

We investigate the relationship between hallucination and predictive uncertainty in image captioning and data-to-text generation tasks and show that predictions with higher uncertainty are more prone to hallucination. In particular, epistemic uncertainty is more indicative of hallucination than aleatoric uncertainty. We propose uncertainty-aware beam search to incorporate uncertainty into the decoding process to reduce hallucination. We show that uncertainty decomposition helps the proposed beam search variant to achieve a better performance-hallucination trade-off. Specifically, penalizing epistemic uncertainty yields better results compared to penalizing aleatoric or total uncertainty.

In this work, we analyze uncertainty from the token level. This might be restrictive because uncertainty corresponds to the current prediction context instead of the predicted token. The relationship between hallucination and uncertainty, therefore, can be much more complicated than a linear one. It is still possible to produce hallucinated information with a very confident model. The proposed UABS reduces hallucination by limiting the total uncertainty of the generated text. As a result, it might lead to shorter generations and lower generation quality. Devising more sophisticated uncertainty-aware training and decoding methods with less adverse effects on the generation quality is a future direction to explore.

Abstract

Most of the previous work on Event Detection (ED) has only considered the datasets with a small number of event types (i.e., up to 38 types). In this work, we present the first study on fine-grained ED (FED) where the evaluation dataset involves much more fine-grained event types (i.e., 449 types). We propose a novel method to transform the Semcor dataset for Word Sense Disambiguation into a large and high-quality dataset for FED. Extensive evaluation of the current ED methods is conducted to demonstrate the challenges of the generated datasets for FED, calling for more research effort in this area.

1 Introduction

Understanding events in text is an important aspect of Natural Language Processing (NLP). Toward this end, Event Detection (ED), a task of Information Extraction (IE), aims to identify event triggers in sentences and classify them into some predefined types of interest. Event triggers represent the most important words (usually single verbs or nominalizations) in the sentences that evoke the events. The current state-of-the-art methods for ED feature the deep learning models where many new network architectures are introduced in the last couple of years (Nguyen and Grishman, 2015; Chen et al., 2015; Liu et al., 2017, 2019a; Lai et al., 2020b).

Among others, the rapid development of the deep learning models for ED can be partly attributed to the availability of the large datasets to evaluate the models (e.g., the ACE 2005 and TAC KBP 2015 datasets (Walker et al., 2006; Mitamura et al., 2015)). Unfortunately, a major issue in these existing datasets for ED is that they tend to only focus on a limited set of event types. For example, the popular ACE 2005 dataset is only annotated for 33 event subtypes (e.g., *Attack, Start-Position, Elect*) while the number of events in the TAC KBP dataset (Mitamura et al., 2015) is 38. On the one hand, the limited numbers of types are unable to cover a wide range of possible events in practice (Araki and Mitamura, 2018). On the other hand, the small label sets often amount to the coarse-grained event types in the existing datasets that cannot capture the slightly different nuances (i.e., fine-grained distinction) of the events. For instance, both the words "*quit*" and "*fired*" in the two sentences "*He decided to* **quit** *the job.*" and "*He was* **fired** *due to a policy violation.*" (respectively) would be considered as the trigger words of the same event type of *End-Position* in the ACE 2005 dataset. However, the nuances in these two events are quite different (i.e., in term of the willingness of the job termination) and the ability to characterize such subtle distinction would be useful for the downstream applications (Choi et al., 2018).

In order to address these problems, we propose to explore the problem of Fine-grained Event Detection (FED) that seeks to solve ED with much larger and finer-grained sets of event types (motivated by the fine-grained entity typing task (Ling and Weld, 2012; Choi et al., 2018)). To our knowledge, this is the first work to explicitly study FED in the literature. A major challenge in this research direction is the creation of the evaluation datasets to enable effective model development and analysis. In particular, it is non-trivial to design a large set of fine-grained event types to be applied to annotate the datasets. In addition, with such a large number of fine-grained event types (i.e., 449 in this work), the traditional labeling procedure with human involvement might be too expensive and error-prone when it comes to the generation of large datasets for FED. To this end, we introduce a novel method to address these challenges and produce a large dataset for FED based on WordNet and Word Sense

April 19 - 23, 2021.

Disambiguation (WSD) datasets. Our method involves two major steps where we first leverage the synset typology in WordNet to formulate the fine-grained event types and then convert the annotated datasets for WSD to establish the datasets for our FED problem. This novel data generation procedure minimizes the human effort and allows us to create a large and high-quality dataset with 449 fine-grained event types for FED. Finally, we extensively evaluate the state-of-the-art ED models on the proposed FED dataset. The experiments show that the performance of the current ED models is not yet satisfactory for FED and further research is needed to advance the performance in this area. We will publicly release the proposed dataset to promote the future research on FED.

2 Data Generation Procedure

The goal of this section is to generate a large dataset for ED with many fine-grained event types to evaluate the FED models. Our proposed procedure to achieve this goal involves two major steps. First, we identify the eventive synsets/senses in WordNet 3.0 (Miller, 1995) and group them into classes with similar eventive meanings. These classes would serve as the fine-grained event types in the resulting FED dataset. As the result, we obtain a mapping from the set of WordNet synsets to the set of the fine-grained event types for our problem (some WordNet synsets might not be mapped to any event type in our case). Afterward, we leverage the Semcor dataset for WSD (Miller et al., 1994) and map the synsets annotated for the words in this dataset into the event types in our setting. This conversion process produces a dataset whose words are assigned with the fine-grained event types in our FED problem. As the Semcor dataset is manually annotated, the resulting FED dataset would be large and have high quality if the synset-event type mapping is constructed well.

In particular, for eventive synset/sense identification, we first start with nouns. Following (Araki and Mitamura, 2018), we assume that any synset for a noun subsumed by one of the three following synsets via the WordNet hyponyms would be considered as eventive: $state_n^2$ (i.e., the way something is with respect to its main attributes), $process_n^6$ (i.e., a sustained phenomenon or one marked by gradual changes through a series of states), and $event_n^1$ (i.e., something that happens at a given place and time). In this way, we find 13,166 eventive synsets over 82,115 synsets for nouns. We call these three general synsets as the eventive root synsets in the following. Starting from these root synsets, we traverse the synset graph in WordNet by following the hyponym links. The graph traversal procedure will generate three different trees whose nodes are the eventive synsets and roots correspond to the three selected synsets. For convenience, we call the synsets in WordNet that can be reached by one of the three synsets above after n hyponym links as the synsets at the n-th level[1] (so the root synsets are at the zero level). In order to form the fine-grained event types for FED, we select the WordNet synsets at the 4^{th} level as the core meanings (called the core synsets) for the event types in our dataset (there are 2,637 core eventive synsets found in this way). We empirically choose the synsets at the 4^{th} level to balance two factors. On the one hand, the synsets at the shallower levels lead to too general event types that cannot achieve the expected fine-grained property. On the other hand, going deeper for the core event meanings reduces the numbers of examples per event type in the final FED dataset converted from Semcor.

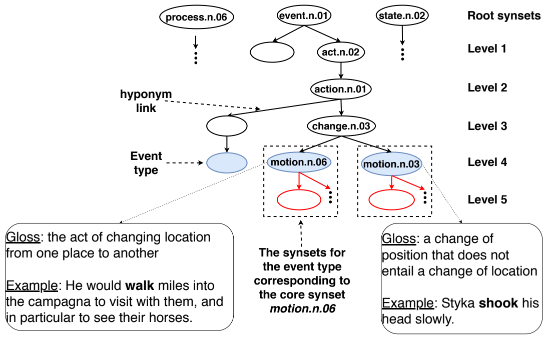

Figure 1: The synsets at different levels and the examples for some event types and their core synsets.

Given a core synset A, we identify the other synsets with similar meaning to A and combine them to represent a fine-grained event type (called E) in our dataset (i.e., the event type E will involve several semantically similar synsets in WordNet). In this work, we include two following classes of synsets in the event type E for A:

- The synsets for nouns that can be reached from A with the hyponym links: Intuitively, the synsets subsumed by A would exhibit the general eventive

---

[1] It is possible that some eventive synsets in WordNet might reside at more than one level as they can be reached from the three root nodes with multiple paths. We resolve this conflict by putting these synsets on the closet level to the roots.

meanings of A with some certain distinctions.

- The synsets of the derivationally related forms of the lemmas/senses l in A and their synset descendants (via the hyponym links): In WordNet, the derivationally related forms of a lemma l in the synset A involve the lemmas from different syntactic categories (e.g., verbs and adjectives) that have the same root form as l and are semantically related to l and A (e.g., destruction → destroy) (Miller, 1995). Due to such semantic similarity, we expect that the synsets of the derivationally related forms of the lemmas in A and their descendants also express the same eventive meaning as A, thereby enriching the synsets for E with the syntactic categories beyond nouns.

Up to this point, we obtain a set of 2,637 event types, each represented by a core synset and a set of related synsets. We combine all the other synsets (i.e., the ones that do not appear in any of the 2637 types) to create a single event type called *Other* as in the traditional ED task. With these grouping information, we can now create a mapping from the synsets/senses in WordNet to the 2638 established event types for our dataset (called the *M-WordNet-Event* mapping). Based on this mapping, we transform each example in the WSD Semcor dataset, which involves a sentence and a word of interest, into an example in the new dataset for FED (called FedSemcor) where the synset/sense label for the word in the original example of Semcor is mapped into the corresponding event type in FedSemcor. As the final processing step, we remove from FedSemcor any event types that have less than 10 examples to ensure that the event types are adequately represented in our dataset. This step significantly reduces the number of event types in FedSemcor, leaving us 449 event types (not including *Other*) with 34,666 examples. These are called the positive examples where we have 77.2 examples per event type in average. As a result, the synsets for the removed event types are also included in the synset set for the *Other* type in the mapping. The number of examples with the *Other* type in the final FedSemcor dataset (called the negative examples) is 98,309. Figure 1 illustrates the synset levels and some examples for the event types.

Implementation Details: In the actual implementation of the data generation procedure for FedSemcor, given a core synset A, we do not include all the descendants of A and the synsets of the derivationally related forms of A's lemmas into the synset set for the correspdoning event type E for A. Instead, we only include the descendants that are at at most 2 hyponym links away from A and the synsets of the derivationally related forms of A's lemmas in E. This is based on our empirical investigation of the data where the descendants with more than 2 links away tend to have semantic drifts from A, potentially introducing noise into the event type E. For example with the core synset $motion_n^6$ (i.e., *the act of changing location from one place to another*) at the 4^{th} level, the descendants at the 5^{th}, 6^{th} and 7^{th} levels include: level 5: $approach_n^2$ (i.e., *the act of drawing spatially closer to something*), level 6: $access_n^6$ (i.e., *the act of approaching or entering*), and level 7: $back\_door_n^6$ (i.e., *a secret or underhand means of access (to a place or a position)*). As we can see, while the synsets at the 5^{th} and 6^{th} levels are related to the original core synset, the synset at the 7^{th} level already involves some semantic departure from the one at the 4^{th} level that should be avoided to improve the precision.

	ACE	**TAC KBP**	**FedSemcor**
# event types	33	38	449
# positive examples	4,907	11,975	34,666
# negative examples	104,217	126,934	98,309

Table 1: Statistics for the FedSemcor, ACE 2005 and TAC KBP 2015 datasets. Negative examples refer to the non-trigger words while positive examples are annotated trigger words for the event types of interest.

Dataset Statistics: Table 1 reports some statistics for FedSemcor and some prior popular datasets for ED (i.e., ACE 2005 (Walker et al., 2006) and TAC KBP 2015 (Mitamura et al., 2015)) to facilitate the comparison. As we can see from the table, FedSemcor has more positive examples, but less negative examples than ACE 2005 and TAC KBP 2015, making FedSemcor a more balanced dataset than the other two. In addition, we show the distribution of 50 event types with the highest numbers of examples in FedSemcor in Figure 2. Finally, Figure 3 illustrates the distribution of the sentence lengths for the examples in FedSemcor.

Evaluation of FedSemCor: As we rely on the manual annotation in Semcor for the synsets for the words, the main bottleneck in the data generation procedure is the mapping from the WordNet synsets to the 450 event types in FedSemCor (including *Other*). In order to evaluate the quality of this mapping, we sample 500 synsets from WordNet that are different from the core synsets of the 449 positive event types. Two experienced NLP re-

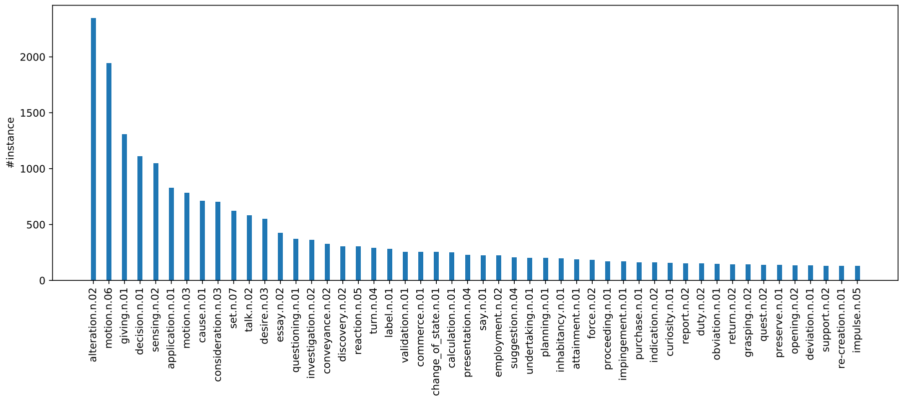

Figure 2: The distribution of the 50 event types with the highest numbers of examples/instances in FedSemcor.

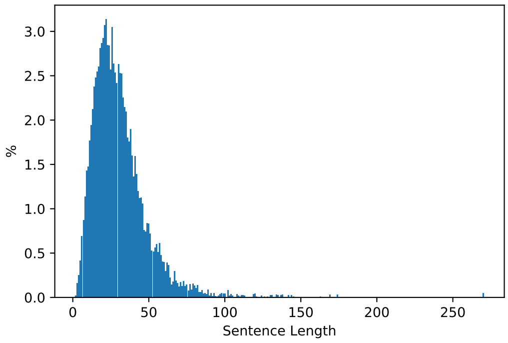

Figure 3: The distribution of the sentence lengths for the examples in FedSemcor.

searchers then independently examine each of these 500 sampled synsets to determine the appropriate event type for it (among the 450 types). In doing so, they examined the glossaries of the synsets as well as the examples provided by WordNet. The two annotators achieved 79.8% agreement for which the synsets with conflicts are resolved by a third NLP researcher. Afterward, we apply the synset-event type mapping obtained in the data generation procedure to annotate the 500 sampled synsets for the event types. The event types provided by the mapping are then compared with those from the annotators, leading to 83.6%, 78.6% and 81.0% as the precision, recall, and F1 scores respectively.

3 Evaluation

Models and Data: In order to understand the complexity of the FedSemcor dataset for FED, this section evaluates the performance of the state-of-the-art models for the traditional ED problem on this dataset. In particular, we first split FedSemcor into the training, development and test data using the 6:2:2 ratio over the entire dataset. Table 2 presents the statistics about these data portions. Note that similar to some prior ED work (Nguyen and Grishman, 2015; Chen et al., 2015), our FED problem is formulated as a word classification problem where given a word in an input sentence, the models need to predict the event type for the word.

Dataset	Training		Development		Test	
	#Pos	#Neg	#Pos	#Neg	#Pos	#Neg
FedSemcor	20,799	58,985	5,546	21,038	8,321	18,286

Table 2: The size of the dataset portions.

Afterward, we consider the following representative models for ED: **CNN** (Nguyen and Grishman, 2015), **DMCNN** (Chen et al., 2015), **SupAtt** (Liu et al., 2017) (i.e., supervised attention), **GCN** (Nguyen and Grishman, 2018), and **MOGANED** (Yan et al., 2019) (i.e., a Multi-Order Graph Convolution model). MOGANED is the state-of-the-art model with uncontextualized word embeddings in traditional ED (i.e., on ACE 2005). For these models, we use both the traditional word embeddings `word2vec` and the recent contextualized word embeddings BERT (i.e., the uncased base model) (Devlin et al., 2019) as the pre-trained word embeddings. For BERT, we further evaluate the ED models in (Wang et al., 2019) (called **DMBERT**) and (Yang et al., 2019) (called **BERT-ED**) that have the best-reported performance on ACE 2005 for ED.

For the experiments in this work, we re-tune the hyper-parameters of the models on the development set of FedSemcor. In particular, depending on which components each model has, we use the following bounds to search for the hyperparameters: $[100, 200, 300, 400, 500]$ for the dimensionality of the hidden vectors in the layers of all the feed-forward, BiLSTM, and GCN networks, $[1, 2, 3]$ for the numbers of layers for BiLSTM and GCN, $[16, 32, 64]$ for the mini-batch size, $[1e\text{-}5, 1e\text{-}4, 1e\text{-}3, 1e\text{-}2, 1e\text{-}1]$ for the learning rate of the Adam optimizer, and $[10, 20, 30, 40, 50]$ for the dimensions of the feature embeddings, i.e., position embeddings in CNN (Nguyen and Grishman, 2015; Chen et al., 2015).

Finally, in order to demonstrate the benefit of the conversion of Semcor (i.e., a WSD dataset) into FedSemcor for FED, we consider a WSD-based baseline for FED where the state-of-the-art WSD model in (Hadiwinoto et al., 2019) is trained on the training data of FedSemcor. As this is a WSD model, instead of using the mapped event types as the labels for the examples (i.e., the 450 types) in the training data, we employ the original word senses of the words as the labels to train this WSD model. Afterward, we apply the trained WSD model on the test data of FedSemcor, producing a word sense for each example. In the last step, the mapping *M-WordNet-Event* is utilized to convert the predicted word senses for the test set examples into the event types for FedSemcor that would be evaluated to obtain the FED performance for this baseline (called **WSD-based**). Note that this WSD model also uses the BERT embeddings.

Results: Table 3 shows the performance of the models on the test set of FedSemcor. From the table, we see that GCN has the best performance among the models with `word2vec` while BERT-ED outperforms all the BERT-based models. However, the best performance on FedSemcor (i.e., 65.0% F1 score with BERT-ED) is still far behind the typical performance (i.e., up to 80.7% in (Yang et al., 2019)) of the models on the traditional ED datasets (i.e., ACE 2005). This suggests the more challenging nature of FedSemcor and FED over traditional ED, presenting a challenge for the future research in this area. Importantly, the performance of the ED models (i.e., with the BERT embeddings) is significantly better than the WSD-based baseline (i.e., up to 9% performance gap with BERT-ED), clearly testifying to the advantages of the conversion from Semcor into FedSemcor for FED.

4 Related Work

ED has been studied extensively in the last decade, featuring feature-based models (Ahn, 2006; Ji and Grishman, 2008; Li et al., 2013, 2015), deep learning models (Chen et al., 2015; Nguyen et al., 2016b,a; Nguyen and Grishman, 2016; Chen et al., 2017; Liu et al., 2018; Yan et al., 2019; Ngo et al., 2020; Lai et al., 2020b), and few/zero-shot learning models (Huang et al., 2018; Lai and Nguyen, 2019; Lai et al., 2020a). The rapid development of such models has been facilitated by the availability of the ED datasets in different domains, including the general domain with the popular ACE and TAC KBP datasets (Walker et al., 2006; Mitamura et al., 2015, 2016), the biomedical domain (Kim et al., 2009, 2011), literature (Sims et al., 2019), cybersecurity (Satyapanich et al., 2020; Man Duc Trong et al., 2020), and the open domain (Araki and Mitamura, 2018; Liu et al., 2019b). However, these datasets only involve a small number of event types and none of them has considered ED with many fine-grained event types as we do.

Model	`word2vec`			BERT		
	P	R	F1	P	R	F1
WSD-based	-	-	-	47.2	68.7	56.0

Table 3: The performance on the FedSemcor test set.

Our FED task is also related to fine-grained entity typing that aims to classify entity mentions into a fine-grained set of types (Karn et al., 2017; Shimaoka et al., 2016; Lin and Ji, 2019). The techniques to generate datasets for fine-grained entity typing include distant supervision (Ling and Weld, 2012; Abhishek et al., 2017) and manual annotation (Murty et al., 2018; Choi et al., 2018). Notably, (Del Corro et al., 2015) also uses WordNet to establish the fine-grained entity types, applying different entity mention extractors over external corpus. Our work is different as we focus on fine-grained event types using the manually annotated corpus Semcor to generate data.

5 Conclusion

We study a new task of FED, featuring 449 fine-grained event types in the dataset for ED. A novel method to generate the evaluation dataset for FED is introduced, leveraging manually annotated WSD datasets (i.e., Semcor) and the eventive synsets in WordNet. We evaluate the state-of-the-art ED models on the new dataset to show the opportunities for the future research on FED.

Abstract

Pretrained language models like BERT have achieved good results on NLP tasks, but are impractical on resource-limited devices due to memory footprint. A large fraction of this footprint comes from the input embeddings with large input vocabulary and embedding dimensions. Existing knowledge distillation methods used for model compression cannot be directly applied to train student models with reduced vocabulary sizes. To this end, we propose a distillation method to align the teacher and student embeddings via mixed-vocabulary training. Our method compresses BERT$_{\text{LARGE}}$ to a task-agnostic model with smaller vocabulary and hidden dimensions, which is an order of magnitude smaller than other distilled BERT models and offers a better size-accuracy trade-off on language understanding benchmarks as well as a practical dialogue task.

1 Introduction

Recently, pre-trained context-aware language models like ELMo (Peters et al., 2018), GPT (Radford et al., 2019), BERT (Devlin et al., 2018) and XLNet (Yang et al., 2019) have outperformed traditional word embedding models like Word2Vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014), and achieved strong results on a number of language understanding tasks. However, these models are typically too huge to host on mobile/edge devices, especially for real-time inference. Recent work has explored, inter alia, knowledge distillation (Ba and Caruana, 2014; Hinton et al., 2015) to train small-footprint student models by implicit transfer of knowledge from a teacher model.

Most distillation methods, however, need the student and teacher output spaces to be aligned. This complicates task-agnostic distillation of BERT to smaller-vocabulary student BERT models since the input vocabulary is also the output space for the masked language modeling (MLM) task used in BERT. This in turn limits these distillation methods' ability to compress the input embedding matrix, that makes up a major proportion of model parameters e.g. the ∼30K input WordPiece embeddings of the BERT$_{\text{BASE}}$ model make up over 21% of the model size. This proportion is even higher for most distilled BERT models, owing to these distilled models typically having fewer layers than their teacher BERT counterparts.

We present a task and model-agnostic distillation approach for training small, reduced-vocabulary BERT models running into a few megabytes. In our setup, the teacher and student models have incompatible vocabularies and tokenizations for the same sequence. We therefore align the student and teacher WordPiece embeddings by training the teacher on the MLM task with a mix of teacher-tokenized and student-tokenized words in a sequence, and then using these student embeddings to train smaller student models. Using our method, we train compact 6 and 12-layer reduced-vocabulary student models which achieve competitive performance in addition to high compression for benchmark datasets as well as a real-world application in language understanding for dialogue.

2 Related Work

Work in NLP model compression falls broadly into four classes: matrix approximation, weight quantization, pruning/sharing, and knowledge distillation.

The former two seek to map model parameters to low-rank approximations (Tulloch and Jia, 2017) and lower-precision integers/floats (Chen et al., 2015; Zhou et al., 2018; Shen et al., 2019) respectively. In contrast, pruning aims to remove/share redundant model weights (Li et al., 2016; Lan et al., 2019). More recently, dropout (Srivastava et al., 2014) has been used to cut inference latency by

(Right) Stage II involving student model with smaller vocabulary (5K) and hidden dims (e.g., 256) and embeddings initialized from stage I.

early exit (Fan et al., 2019; Xin et al., 2020).

Knowledge distillation focuses on implicit transfer of knowledge as soft teacher predictions (Tang et al., 2019), attention distributions (Zagoruyko and Komodakis, 2016) and intermediate outputs (Romero et al., 2014). Approaches close to our work rely on similar methods (Sanh et al., 2019; Sun et al., 2019), while others involve combinations of layer-wise transfer (Sun et al., 2020), task-specific distillation (Jiao et al., 2019), architecture search (Chen et al., 2020) and layer dropout (Xu et al., 2020); many of these are specific to the transformer layer (Vaswani et al., 2017).

Another highly relevant line of work focuses on reducing the size of the embedding matrix, either via factorization (Shu and Nakayama, 2018; Lan et al., 2019) or vocabulary selection/pruning (Provilkov et al., 2019; Chen et al., 2019b).

3 Proposed Approach

Here, we discuss our rationale behind reducing the student vocabulary size and its challenges, followed by our *mixed-vocabulary* distillation approach.

3.1 Student Vocabulary

WordPiece (WP) tokens (Wu et al., 2016) are subword units obtained by applying greedy segmentation to a training corpus. Given such a corpus and a number of desired tokens D, a WordPiece vocabulary is generated by selecting D subword tokens such that the resulting corpus is minimal in the number of WordPiece when segmented according to the chosen WordPiece model. The greedy algorithm for this optimization problem is described in more detail in Sennrich et al. (2016). Most published BERT models use a vocabulary of 30522 WordPieces, obtained by running the above algorithm on the Wikipedia and BooksCorpus (Zhu et al., 2015) corpora with a desired vocabulary size D of 30000.

For our student model, we chose a target vocabulary size D of 5000 WordPiece tokens. Using the same WordPiece vocabulary generation algorithm and corpus as above, we obtain a 4928-WordPiece vocabulary for the student model. This student vocabulary includes all ASCII characters as separate tokens, ensuring no out-of-vocabulary words upon tokenization with this vocabulary. Additionally, the 30K teacher BERT vocabulary includes 93.9% of the WP tokens in this 5K student vocabulary but does not subsume it. We explore other strategies to obtain a small student vocabulary in Section 6.

For task-agnostic student models, we reuse BERT's masked language modeling (MLM) task: words in context are randomly masked and predicted given the context via softmax over the model's WP vocabulary. Thus, the output spaces for our teacher (30K) and student (5K) models are unaligned. This, coupled with both vocabularies tokenizing the same words differently, means existing distillation methods do not apply to our setting.

3.2 Mixed-vocabulary training

We propose a two-stage approach for implicit transfer of knowledge to the student via the student embeddings, as described below.

Stage I (Student Embedding Initialization): We first train the student embeddings with the teacher model initialized from $\text{BERT}_{\text{LARGE}}$. For a given input sequence, we mix the vocabularies by randomly selecting (with probability p_{SV}, a hyperparameter) words from the sequence to segment using the student vocabulary, with the other words segmented using the teacher vocabulary. As in Figure 1 on the left, for input [‘*I*’, ‘*like*’, ‘*machine*’, ‘*learning*’], the words *‘like’* and *‘learning’* are segmented using the student vocabulary (in blue), with the others using the teacher vocabulary (in green). Similar to Lample and Conneau (2019), this step seeks to align the student and teacher embeddings for the same tokens: the model learns to predict student tokens using context which is segmented using the teacher vocabulary, and vice versa.

Note that since the student embeddings are set to a lower dimension than the teacher embeddings, as they are meant to be used in the smaller student model, we project the student embeddings up to the teacher embedding dimension using a trainable affine layer before these are input to the teacher BERT. We choose to keep the two embedding matrices separate despite the high token overlap: this is partly to keep our approach robust to lower vocabulary overlap settings, and partly due to empirical considerations described in Section 6.

Let θ_s/eb_s and θ_t/eb_t denote the transformer layer and embedding weights for the student and teacher models respectively. The loss defined in Equation 1 is the MLM cross entropy summed over masked positions M_t in the teacher input. y_i and c_i denote the predicted and true tokens at position i respectively and can belong to either vocabulary. $v_i{\in}\{s,t\}$ denotes the vocabulary used to segment this token. Separate softmax layers P_{v_i} are used for token prediction, one for each vocabulary, depending on the segmenting vocabulary v_i for token i. All teacher parameters (θ_t, eb_t) and student embeddings (eb_s) are updated in this step.

$$L_{s_1} = -\textstyle\sum_{i \in M_t} (\log P_{v_i}(y_i{=}c_i | \theta_t, eb_s, eb_t)) \quad (1)$$

Stage II (Student Model Layers): With student embeddings initialized in stage I, we now train the student model normally i.e., using only the student vocabulary and discarding the teacher model. Equation 2 shows the student MLM loss where M_s is the set of positions masked in the student input. All student model parameters (θ_s, eb_s) are updated.

$$L_{s_2} = -\textstyle\sum_{i \in M_s} \log P_s(y_i{=}c_i | \theta_s, eb_s) \quad (2)$$

4 Experiments

For evaluation, we finetune the student model just as one would finetune the original BERT model i.e., without using the teacher model or any task-specific distillation. We describe our experiments below, with dataset details left to the appendix.

4.1 Evaluation Tasks and Datasets

We fine-tune and evaluate the distilled student models on two classes of language understanding tasks:

GLUE benchmark (Wang et al., 2019)**:** We pick three classification tasks from GLUE:

- MRPC: Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005), a 2-way sentence pair classification task with 3.7K train instances.
- MNLI: Multi-Genre Natural Language Inference (Williams et al., 2018), a 3-way sentence pair classification task with 393K training instances.
- SST-2: Stanford Sentiment Treebank (Socher et al., 2013), a 2-way sentence classification task with 67K training instances.

Spoken Language Understanding: Since we are also keen on edge device applications, we also evaluate on spoken language understanding, a practical task in dialogue systems. We use the SNIPS dataset (Coucke et al., 2018) of ∼14K virtual assistant queries, each comprising one of 7 intents and values for one or more of the 39 pre-defined slots. The intent detection and slot filling subtasks are modeled respectively as 7-way sentence classification and sequence tagging with IOB slot labels.

4.2 Models and Baselines

For GLUE, we train student models with 6 and 12 layers, 4 attention heads, and embedding/hidden dimensions fixed to 256, each using a compact 5K-WP vocabulary. We also evaluate baselines without knowledge distillation (*NoKD*), parameterized identically to the distilled student models (incl. the 5K vocabulary), trained on the MLM teacher objective from scratch. We also compare our models on GLUE with the following approaches:

- *DistilBERT* (Sanh et al., 2019) distill $\text{BERT}_{\text{BASE}}$ to 4/6 layers by aligning teacher predictions,
- *Patient KD - PKD* (Sun et al., 2019) align hidden states to distill $\text{BERT}_{\text{BASE}}$ to 3/6 layers,
- *BERT-of-Theseus* (Xu et al., 2020) use a layer dropout method to distill $\text{BERT}_{\text{BASE}}$ to 6 layers,
- *TinyBERT* (Jiao et al., 2019) apply task specific distillation to $\text{BERT}_{\text{BASE}}$ and align teacher outputs, hidden states as well as embeddings, and
- *MobileBERT* (Sun et al., 2020) combine layer-wise transfer, architecture search and bottleneck

Model	#Params	MRPC (F1/Acc)	MNLI-m/mm (Acc)	SST-2 (Acc)	Average (F1/Acc)
$\text{BERT}_{\text{BASE}}$ (Devlin et al., 2018)	109M	88.9/-	84.6/83.4	93.5	89.0
$\text{BERT}_{\text{LARGE}}$ (Devlin et al., 2018)	340M	89.3/-	86.7/85.9	94.9	90.3

Table 1: Test set accuracy of distilled models, teacher model and baselines on the GLUE test sets. MNLI-m and MNLI-mm refer to the genre-matched and mismatched test sets. All models other than *NoKD* and our distilled models use a 30K-WordPiece vocabulary. The average uses F1 score for MRPC, accuracy for MNLI-m/SST-2.

structures for an optimized student model.

For SNIPS, we shift our focus to smaller, low-latency models for on-device use cases. Here, we train student models with 6 layers and embedding/hidden dimensions $\in \{96, 192, 256\}$. The smaller models here may not be competitive on GLUE but are adequate for practical tasks such as spoken LU. We compare with two strong baselines:

- $\text{BERT}_{\text{BASE}}$ (Chen et al., 2019a) with intent and IOB slot tags predicted using the `[CLS]` and the first WP tokens of each word respectively, and
- StackProp (Qin et al., 2019), which uses a series of smaller recurrent and self-attentive encoders.

4.3 Training Details

Distillation: For all our models, we train the teacher model with mixed-vocabulary inputs (stage I) for 500K steps, followed by 300K steps of training just the student model (stage II). We utilize the same corpora as the teacher model i.e. BooksCorpus (Zhu et al., 2015) and English Wikipedia.

For both stages, up to 20 input tokens were masked for MLM. In stage I, up to 10 of these masked tokens were tokenized using the teacher vocabulary, the rest using the student vocabulary.

We optimize the loss using LAMB (You et al., 2019) with a max learning rate of .00125, linear warmup for the first 10% of steps, batch size of 2048 and sequence length of 128. Distillation was done on Cloud TPUs in a 8x8 pod configuration. p_{SV}, the probability of segmenting a Stage I input word using the student vocabulary, is set to 0.5.

Finetuning: For all downstream task evaluations on GLUE, we finetune for 10 epochs using LAMB with a learning rate of 0.0001 and batch size of 64. For all experiments on SNIPS, we use ADAM with a learning rate of 0.0001 and a batch size of 64.

5 Results

GLUE: Table 1 shows results on downstream GLUE tasks and model sizes for our proposed models, $\text{BERT}_{\text{BASE/LARGE}}$, and baselines. Our models consistently improve upon the identically parameterized *NoKD* baselines, indicating mixed-vocabulary training is better than training from scratch and avoids a large teacher-student performance gap. Compared with PKD/DistilBERT, our 6-layer model outperforms PKD_3 while being >7x smaller and our 12-layer model is comparable to PKD_6 and DistilBERT_4 while being ~5-6x smaller.

Interestingly, our models do particularly well on the MRPC task: the 6-layer distilled model performs almost as well as PKD_6 while being over 10x smaller. This may be due to our smaller models being data-efficient on the smaller MRPC dataset.

TinyBERT and Bert-of-Theseus are trained in task-specific fashion i.e., a teacher model already finetuned on the downstream task is used for distillation. TinyBERT's non-task-specific model results are reported on GLUE dev sets: these results are, therefore, not directly comparable with ours. Even so, our 12-layer model performs credibly

Model	#Params	Latency	Intent Acc	Slot F1
BERT$_{\text{BASE}}$ (Chen et al., 2019a)	109M	340ms	98.6	97.0
StackProp (Qin et al., 2019)	2.6M	>70ms	98.0	94.2
Mixed-vocab distilled, L-6, H-96	1.2M	6ms	98.9	92.8
Mixed-vocab distilled, L-6, H-192	3.6M	14ms	98.8	94.6
Mixed-vocab distilled, L-6, H-256	6.2M	20ms	98.7	95.0

Table 2: Results on the SNIPS dataset. Latency is measured with 4 CPU threads on a Pixel 4 mobile device.

compared with the two, presenting a competitive size-accuracy tradeoff, particularly when compared to the 6x larger BERT-of-Theseus.

MobileBERT performs strongly for the size while being task-agnostic. Our 12-layer model, in comparison, retains ∼98% of its performance with 57% fewer parameters and may thus be better-suited for use on highly resource-limited devices.

TinyBERT sees major gains from task-specific data augmentation and distillation, and MobileBERT from student architecture search and bottleneck layers. Notably, our technique targets the student vocabulary without conflicting with any of the above methods and can, in fact, be combined with these methods for even smaller models.

SNIPS: Table 2 shows results on the SNIPS intent and slot tasks for our models and two state-of-the-art baselines. Our smallest 6-layer model retains over 95% of the BERT$_{\text{BASE}}$ model's slot filling F1 score (Sang and Buchholz, 2000) while being 30x smaller (< 10 MB w/o quantization) and 57x faster on a mobile device, yet task-agnostic. Our other larger distilled models also demonstrate strong performance (0.2-0.5% slot F1 higher than the respective *NoKD* baselines) with small model sizes and latencies low enough for real-time inference. This indicates that small multi-task BERT models (Tsai et al., 2019) present better trade-offs for on-device usage for size, accuracy and latency versus recurrent encoder-based models such as StackProp.

6 Discussion

Impact of vocabulary size: We trained a model from scratch identical to BERT$_{\text{BASE}}$ except with our 5K-WP student vocabulary. On the SST-2 and MNLI-m dev sets, this model obtained 90.9% and 83.7% accuracy respectively - only 1.8% and 0.7% lower respectively compared to BERT$_{\text{BASE}}$.

Since embeddings account for a larger fraction of model parameters with fewer layers, we trained another model identical to our 6×256 model, but with a 30K-WP vocabulary and teacher label distillation. This model showed small gains (0.1% / 0.5% accuracy on SST-2 / MNLI-m dev) over our analogous distilled model, but with 30% more parameters solely due to the larger vocabulary.

This suggests that a small WordPiece vocabulary may be almost as effective for sequence classification/tagging tasks, especially for smaller BERT models and up to moderately long inputs. Curiously, increasing the student vocabulary size to 7K or 10K did not lead to an increase in performance on GLUE. We surmise that this may be due to underfitting owing to the embeddings accounting for a larger proportion of the model parameters.

Alternative vocabulary pruning: Probing other strategies for a small-vocabulary model, we used the above 6×256 30K-WP vanilla distilled model to obtain a smaller model by pruning the vocabulary to contain the intersection of the 30K and 5K vocabularies (total 4629 WPs). This model is 1.2% smaller than our 4928-WP distilled model, but drops 0.8% / 0.7% on SST-2/MNLI-m dev sets.

Furthermore, to exploit the high overlap in vocabularies, we tried running our distillation pipeline but with the embeddings for student tokens (after projecting up to the teacher dimension) also present in the teacher vocabulary tied to the teacher embeddings for those tokens. This model, however, dropped 0.7% / 0.5% on SST-2/MNLI-m compared to our analogous 6×256 distilled model.

We also tried pretraining BERT$_{\text{LARGE}}$ from scratch with the 5K vocabulary and doing vanilla distillation for a 6×256 student: this model dropped 1.2% / 0.7% for SST-2/MNLI-m over our similar distilled model, indicating the efficacy of mixed-vocabulary training over vanilla distillation.

7 Conclusion

We propose a novel approach to knowledge distillation for BERT, focusing on using a significantly smaller vocabulary for the student BERT models. Our *mixed-vocabulary training* method encourages implicit alignment of the teacher and student WordPiece embeddings. Our highly-compressed 6 and 12-layer distilled student models are optimized for on-device use cases and demonstrate competitive performance on both benchmark datasets and practical tasks. Our technique is unique in targeting the student vocabulary size, enabling easy combination with most BERT distillation methods.

Abstract

Adversarial learning can learn fairer and less biased models of language than standard methods. However, current adversarial techniques only partially mitigate model bias, added to which their training procedures are often unstable. In this paper, we propose a novel approach to adversarial learning based on the use of multiple *diverse* discriminators, whereby discriminators are encouraged to learn orthogonal hidden representations from one another. Experimental results show that our method substantially improves over standard adversarial removal methods, in terms of reducing bias and the stability of training.

1 Introduction

While NLP models have achieved great successes, results can depend on spurious correlations with protected attributes of the authors of a given text, such as gender, age, or race. Including protected attributes in models can lead to problems such as leakage of personally-identifying information of the author (Li et al., 2018a), and unfair models, i.e., models which do not perform equally well for different sub-classes of user. This kind of unfairness has been shown to exist in many different tasks, including part-of-speech tagging (Hovy and Søgaard, 2015) and sentiment analysis (Kiritchenko and Mohammad, 2018).

One approach to diminishing the influence of protected attributes is to use adversarial methods, where an encoder attempts to prevent a discriminator from identifying the protected attributes in a given task (Li et al., 2018a). Specifically, an adversarial network is made up of an attacker and encoder, where the attacker detects protected information in the representation of the encoder, and the optimization of the encoder incorporates two parts: (1) minimizing the main loss, and (2) maximizing the attacker loss (i.e., preventing protected attributes from being detected by the attacker). Preventing protected attributes from being detected tends to result in fairer models, as protected attributes will more likely be independent rather than confounding variables. Although this method leads to demonstrably less biased models, there are still limitations, most notably that significant protected information still remains in the model's encodings and prediction outputs (Wang et al., 2019; Elazar and Goldberg, 2018).

Many different approaches have been proposed to strengthen the attacker, including: increasing the discriminator hidden dimensionality; assigning different weights to the adversarial component during training; using an ensemble of adversaries with different initializations; and reinitializing the adversarial weights every t epochs (Elazar and Goldberg, 2018). Of these, the ensemble method has been shown to perform best, but independently-trained attackers can generally still detect private information after adversarial removal.

In this paper, we adopt adversarial debiasing approaches and present a novel way of strengthening the adversarial component via orthogonality constraints (Salzmann et al., 2010). Over a sentiment analysis dataset with racial labels of the document authors, we show our method to result in both more accurate and fairer models, with privacy leakage close to the lower-bound.[1]

2 Methodology

Formally, given an input x_i annotated with main task label y_i and protected attribute label g_i, a main task model M is trained to predict $\hat{y}_i = M(x_i)$, and an adversary, aka "discriminator", A is trained to predict $\hat{g}_i = A(h_{M,i})$ from M's last hidden layer representation $h_{M,i}$. In this paper, we treat

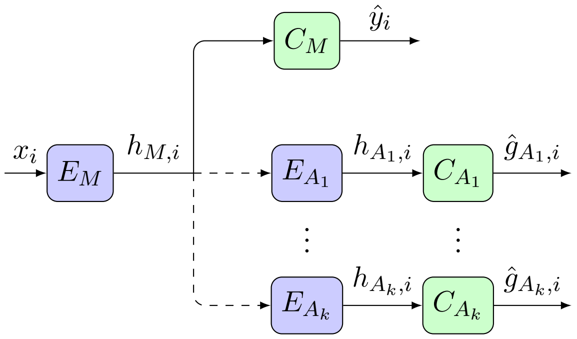

Figure 1: Ensemble adversarial method. Dashed lines denote gradient reversal in adversarial learning. The k sub-discriminators A_i are independently initialized. Given a single input x_i, the main task encoder computes a hidden representation $h_{M,i}$, which is used as the input to the main model output layer and sub-discriminators. From the k-th sub-discriminator, the estimated protected attribute label is $\hat{g}_{A_k,i} = C_{A_k}(E_{A_k}(h_{M,i}))$.

a neural network classifier as a combination of two connected parts: (1) an encoder E, and (2) a linear classifier C. For example, in the main task model M, the encoder E_M is used to compute the hidden representation $h_{M,i}$ from an input x_i, i.e., $h_{M,i} = E_M(x_i)$, and the decoder is used to make a prediction, $\hat{y}_i = C_M(h_{M,i})$. Similarly, for a discriminator, $\hat{g}_i = A(h_{M,i}) = C_A(E_A(h_{M,i}))$.

2.1 Adversarial Learning

Following the setup of Li et al. (2018a) and Elazar and Goldberg (2018) the optimisation objective for our standard adversarial training is:

$$\min_M \max_A \mathcal{X}(y, \hat{y}_M) - \lambda_{\text{adv}} \mathcal{X}(g, \hat{g}_A),$$

where $\mathcal{X}$ is cross entropy loss, and λ_{adv} is the trade-off hyperparameter. Solving this minimax optimization problem encourages the main task model hidden representation h_M to be informative to C_M and uninformative to A. Following Ganin and Lempitsky (2015), the above can be trained using stochastic gradient optimization with a gradient reversal layer for $\mathcal{X}(g, \hat{g}_A)$.

2.2 Differentiated Adversarial Ensemble

Inspired by the ensemble adversarial method (Elazar and Goldberg, 2018) and domain separation networks (Bousmalis et al., 2016), we present *differentiated adversarial ensemble*, a novel means of strengthening the adversarial component. Figure 1 shows a typical ensemble architecture where k sub-discriminators are included in the adversarial component, leading to an averaged adversarial regularisation term:

$$-\frac{\lambda_{\text{adv}}}{k} \sum_{j \in \{1,\ldots,k\}} \mathcal{X}(g, \hat{g}_{A_j}).$$

One problem associated with this ensemble architecture is that it cannot ensure that different sub-discriminators focus on different aspects of the representation. Indeed, experiments have shown that sub-discriminator ensembles can weaken the adversarial component (Elazar and Goldberg, 2018). To address this problem, we further introduce a difference loss (Bousmalis et al., 2016) to encourage the adversarial encoders to encode different aspects of the private information. As can be seen in Figure 1, $h_{A_k,i}$ denotes the output from the k-th sub-discriminator encoder given a hidden representation $h_{M,i}$, i.e., $h_{A_k,i} = E_{A_k}(h_{M,i})$.

The difference loss encourages orthogonality between the encoding representations of each pair of sub-discriminators:

$$\mathcal{L}_{\text{diff}} = \lambda_{\text{diff}} \sum_{i,j \in \{1,\ldots,k\}} \left\| {h_{A_i}}^{\intercal} h_{A_j} \right\|_F^2 \mathbb{1}(i \neq j),$$

where $\|\cdot\|_F^2$ is the squared Frobenius norm.

Intuitively, sub-discriminator encoders must learn different ways of identifying protected information given the same input embeddings, resulting in less biased models than the standard ensemble-based adversarial method. According to Bousmalis et al. (2016), the difference loss has the additional advantage of also being minimized when hidden representations shrink to zero. Therefore, instead of minimizing the difference loss by learning rotated hidden representations (i.e., the same model), this method biases adversaries to have representations that are a) orthogonal, and b) low magnitude; the degree to which is given by weight decay of the optimization function.

2.3 INLP

We include Iterative Null-space Projection ("INLP": Ravfogel et al. (2020)) as a baseline method for mitigating bias in trained models, in addition to standard and ensemble adversarial methods. In INLP, a linear discriminator (A_{linear}) of the protected attribute is iteratively trained from pre-computed fixed hidden representations (i.e., h_M) to project them onto the linear discriminator's

Model	Accuracy↑	TPR Gap↓	TNR Gap↓	Leakage@$\mathbf{h}$↓	Leakage@$\hat{y}$↓

Table 1: Evaluation results ± standard deviation (%) on the test set, averaged over 10 runs with different random seeds. **Bold** = best performance. "↑" and "↓" indicate that higher and lower performance, resp., is better for the given metric. Leakage measures the accuracy of predicting the protected attribute, over the final hidden representation $\mathbf{h}$ or model output $\hat{y}$. Since the Fixed Encoder is not designed for binary sentiment classification, we merge the original 64 labels into two categories based on the results of hierarchical clustering.

null-space, $h_M^* = P_{N(A_{\text{linear}})} h_M$, where $P_{N(A_{\text{linear}})}$ is the null-space projection matrix of A_{linear}. In doing so, it becomes difficult for the protected attribute to be linearly identified from the projected hidden representations (h_M^*), and any linear main-task classifier (C_M^*) trained on h_M^* can thus be expected to make fairer predictions.

3 Experiments

Fixed Encoder Following Elazar and Goldberg (2018) and Ravfogel et al. (2020), we use the DeepMoji model (Felbo et al., 2017) as a fixed-parameter encoder (i.e. it is not updated during training). The DeepMoji model is trained over 1246 million tweets containing one of 64 common emojis. We merge the 64 emoji labels output by DeepMoji into two super-classes based on hierarchical clustering: 'happy' and 'sad'.

Models The encoder E_M consists of a fixed pretrained encoder (DeepMoji) and two trainable fully connected layers ("Standard" in Table 1). Every linear classifier (C) is implemented as a dense layer.

For protected attribute prediction, a discriminator (A) is a 3-layer MLP where the first 2 layers are collectively denoted as E_A, and the output layer is denoted as C_A.

TPR-GAP and TNR-GAP In classification problems, a common way of measuring bias is TPR-GAP and TNR-GAP, which evaluate the gap in the True Positive Rate (TPR) and True Negative Rate (TNR), respectively, across different protected attributes (De-Arteaga et al., 2019). This measurement is related to the criterion that the prediction $\hat{y}$ is conditionally independent of the protected attribute g given the main task label y (i.e., $\hat{y} \perp g | y$). Assuming a binary protected attribute, this conditional independence requires $\mathbb{P}\{\hat{y}|y, g = 0\} = \mathbb{P}\{\hat{y}|y, g = 1\}$, which implies an objective that minimizes the difference (GAP) between the two sides of the equation.

Linear Leakage We also measure the leakage of protected attributes. A model is said to leak information if the protected attribute can be predicted at a higher accuracy than chance, in our case, from the hidden representations the fixed encoder generates. We empirically quantify leakage with a linear support vector classifier at two different levels:

- Leakage@$\mathbf{h}$: the accuracy of recovering the protected attribute from the output of the final hidden layer after the activation function (h_M).
- Leakage@$\hat{y}$: the accuracy of recovering the protected attribute from the output $\hat{y}$ (i.e., the logits) of the main model.

Data We experiment with the dataset of Blodgett et al. (2016), which contains tweets that are either African American English (AAE)-like or Standard American English (SAE)-like (following Elazar and Goldberg (2018) and Ravfogel et al. (2020)). Each tweet is annotated with a binary "race" label (on the basis of AAE or SAE) and a binary sentiment score, which is determined by the (redacted) emoji within it.

In total, the dataset contains 200k instances, perfectly balanced across the four race–sentiment combinations. To create bias in the dataset, we follow previous work in skewing the training data to generate race–sentiment combinations (AAE–

happy, SAE–happy, AAE–sad, and SAE–sad) of 40%, 10%, 10%, and 40%, respectively. Note that we keep the test data unbiased.

Training Details All models are trained and evaluated on the same training/test split. The Adam optimizer (Kingma and Ba, 2015) is used with learning rates of 3×10^{-5} for the main model and 3×10^{-6} for the sub-discriminators. The mini-batch size is set to 1024. Sentence representations (2304d) are extracted from the DeepMoji encoder. The hidden size of each dense layer is 300 in the main model, and 256 in the sub-discriminators. We train M for 60 epochs and each A for 100 epochs, keeping the checkpoint model that performs best on the dev set. Similar to Elazar and Goldberg (2018), hyperparameters (λ_{adv} and λ_{diff}) are tuned separately rather than jointly. λ_{adv} is tuned to 0.8 based on the standard (single-discriminator) adversarial learning method, and this setting is used for all other adversarial methods. When tuning λ_{adv}, we considered both overall performance and bias gap (both over the dev data). Since adversarial training can increase overall performance while decreasing the bias gap (see Figure 2), we select the adversarial model that achieves the best task performance. For adversarial ensemble and differentiated models, we tune the hyperparameters (number of sub attackers and λ_{diff}) to achieve a similar bias level while getting the best overall performance. To compare with a baseline ensemble method with a similar number of parameters, we also report results for an adversarial ensemble model with 3 sub-discriminators. The scalar hyperparameter of the difference loss (λ_{diff}) is tuned through grid search from 10^{-4} to 10^{4}, and set to $10^{3.7}$. For the INLP experiments, fixed sentence representations are extracted from the same data split. Following Ravfogel et al. (2020), in the INLP experiments, both the discriminator and the classifier are implemented in scikit-learn as linear SVM classifiers (Pedregosa et al., 2011). We report Leakage@$\hat{y}$ for INLP based on the predicted confidence scores, which could be interpreted as logits, of the linear SVM classifiers.

Results and Analysis Table 1 shows the results over the test set. Training on a biased dataset without any fairness restrictions leads to a biased model, as seen in the Gap and Leakage results for the Standard model. Consistent with the findings of Ravfogel et al. (2020), INLP can only reduce bias at the expense of overall performance. On the other hand, the Single Discriminator and Adv(ersarial) Ensemble baselines both enhance accuracy and reduce bias, consistent with the findings of Li et al. (2018a).

Compared to the Adv Ensemble baseline, incorporating the difference loss in our method has two main benefits: training is more stable (results have smaller standard deviation), and there is less bias (the TPR and TNR Gap are smaller). Without the orthogonality factor, $\mathcal{L}_{\text{diff}}$, the sub-discriminators tend to learn similar representations, and the ensemble degenerates to a standard adversarial model. Simply relying on random initialization to ensure sub-discriminator diversity, as is done in the Adv Ensemble method, is insufficient. The orthogonality regularization in our method leads to more stable and overall better results in terms of both accuracy and TPR/TNR Gap.

As shown in Table 1, even the Fixed Encoder model leaks protected information, as a result of implicit biases during pre-training. INLP achieves significant improvement in terms of reducing linear hidden representation leakage. The reason is that Leakage@$\mathbf{h}$ is directly correlated with the objective of INLP, in minimizing the linear predictability of the protected attribute from the $\mathbf{h}$. Adversarial methods do little to mitigate Leakage@$\mathbf{h}$, but substantially decrease Leakage@$\hat{y}$ in the model output. However, both types of leakage are well above the ideal value of 50%, and therefore none of these methods can be considered as providing meaningful privacy, in part because of the fixed encoder. This finding implies that when applying adversarial learning, the pretrained model needs to be fine-tuned with the adversarial loss to have any chance of generating a truly unbiased hidden representation. Despite this, adversarial training does reduce the TPR and TNR Gap, and improves overall accuracy, which illustrates the utility of the method for both bias mitigation and as a form of regularisation.

Overall, our proposed method empirically outperforms the baseline models in terms of debiasing, with a better performance–fairness trade-off.

Robustness to λ_{adv} We first evaluate the influence of the trade-off hyperparameter λ_{adv} in adversarial learning. As can be seen from Figure 2, λ_{adv} controls the performance–fairness trade-off. Increasing λ_{adv} from 10^{-2} to around 10^{-0}, TPR Gap and TNR Gap consistently decrease, while the accuracy of each group rises. To balance up accu-

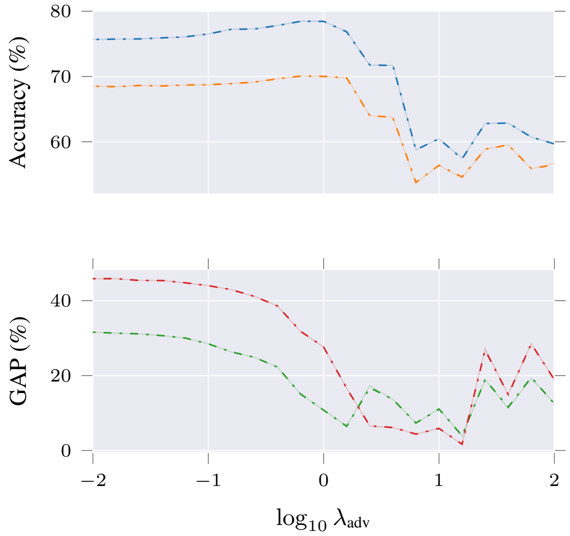

Figure 2: λ_{adv} sensitivity analysis, averaged over 10 runs for a single discriminator adversarial model. Main task accuracy of group *SAE* (blue) and *AAE* (orange), *TPR-GAP* (green), and *TNR-GAP* (red) are reported.

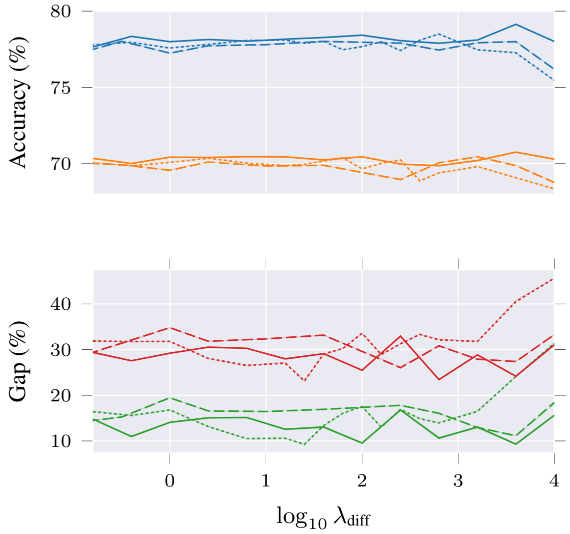

Figure 3: λ_{diff} sensitivity analysis for differentiated adversarial models with 3 (“——”), 5 (“- - - -”), and 8 (“········”) sub-discriminators, in terms of the main task accuracy of group *SAE* (blue) and *AAE* (orange), and *TPR-GAP* (green) and *TNR-GAP* (red).

racy and fairness, we set λ_{adv} to $10^{-0.1}$. We also observe that an overly large λ_{adv} can lead to a more biased model (starting from about $10^{1.2}$).

Robustness to λ_{diff} Figure 3 presents the results of our model with different λ_{diff} values, for $N \in \{3, 5, 8\}$ sub-discriminators.

First, note that when λ_{diff} is small (i.e., the left side of Figure 3), our Differentiated Adv Ensemble model generalizes to the standard Adv Ensemble model. For differing numbers of sub-discriminators, performance is similar, i.e., increasing the number of sub-discriminators beyond 3 does not improve results substantially, but does come with a computational cost. This implies that an Adv Ensemble model learns approximately the same thing as larger ensembles (but more efficiently), where the sub-discriminators can only be explicitly differentiated by their weight initializations (with different random seeds), noting that all sub-discriminators are otherwise identical in architecture, input, and optimizer.

Increasing the weight of the difference loss through λ_{diff} has a positive influence on results, but an overly large value makes the sub-discriminators underfit, and both reduces accuracy and increases TPR/TNR Gap. We observe a negative correlation between N and λ_{diff}, the main reason being that $\mathcal{L}_{\text{diff}}$ is not averaged over N and as a result, a large N and λ_{diff} force the sub-discriminators to pay too much attention to orthogonality, impeding their ability to bleach out the protected attributes.

Overall, we empirically show that λ_{diff} only needs to be tuned for Adv Ensemble, since the results for different Differentiated Adv models for a given setting achieve similar results. I.e., λ_{diff} can safely be tuned separately with all other hyperparameters fixed.

4 Conclusion and Future Work

We have proposed an approach to enhance sub-discriminators in adversarial ensembles by introducing a difference loss. Over a tweet sentiment classification task, we showed that our method substantially improves over standard adversarial methods, including ensemble-based methods.

In future work, we intend to perform experimentation over other tasks. Theoretically, our approach is general-purpose, and can be used not only for adversarial debiasing but also any other application where adversarial training is used, such as domain adaptation (Li et al., 2018b).

Abstract

GQA (Hudson and Manning, 2019) is a dataset for real-world visual reasoning and compositional question answering. We found that many answers predicted by the best vision-language models on the GQA dataset do not match the ground-truth answer but still are semantically meaningful and correct in the given context. In fact, this is the case with most existing visual question answering (VQA) datasets where they assume only one ground-truth answer for each question. We propose Alternative Answer Sets (AAS) of ground-truth answers to address this limitation, which is created automatically using off-the-shelf NLP tools. We introduce a semantic metric based on AAS and modify top VQA solvers to support multiple plausible answers for a question. We implement this approach on the GQA dataset and show the performance improvements.

1 Introduction

One important style of visual question answering (VQA) task involves open-ended responses such as free-form answers or fill-in-the-blanks. The possibility of multiple correct answers and multi-word responses makes the evaluation of open-ended tasks harder, which has forced VQA datasets to restrict answers to be a single word or a short phrase. Despite enforcing these constraints, from our analysis of the GQA dataset (Hudson and Manning, 2019), we noticed that a significant portion of the visual questions have issues. For example, a question *“Who is holding the bat?”* has only one ground truth answer *“batter”* while other reasonable answers like *“batsman”*, *“hitter”* are not credited. We identified six different types of issues with the dataset and illustrated them in Table 1.

A large-scale human-study conducted by (Gurari and Grauman, 2017) on VQA (Antol et al., 2015) and VizWiz (Gurari et al., 2019) found that almost 50% questions in these datasets have multiple possible answers. datasets had similar observations. The above evidence suggests that it is unfair to penalize models if their predicted answer is correct in a given context but does not match the ground truth answer.

With this motivation, we leverage existing knowledge bases and word embeddings to generate Alternative Answer Sets (AAS) instead of considering visual questions to have fixed responses. Since initially obtained AAS are generated from multiple sources and observed to be noisy, we use textual entailment to verify semantic viability of plausible answers to make alternative answer sets more robust. We justify the correctness and quality of the generated AAS by human evaluation. We introduce a semantic metric based on AAS and train two vision-language models LXMERT (Tan and Bansal, 2019) and ViLBERT (Lu et al., 2019) on two datasets. The experimental results show that the AAS metric evaluates models’ performances more reasonably than the old metric. Lastly, we incorporate AAS in the training phase and show that it further improves on the proposed metric. Figure 2 gives an overview of our work.

2 Related Works

We discuss related works from two aspects, dataset creation and evaluation.

Dataset Creation-Level Large-scale VQA datasets are often curated through crowd-sourcing, where open-ended ground-truths are determined by majority voting or annotator agreement. The subjectivity in crowd-sourced datasets is well-studied in human-computer interaction literature- (Gurari and Grauman, 2016, 2017; Yang et al., 2018) etc. Ray et al. (2018) suggested creating a semantically-grounded set of questions

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2766–2771
April 19 - 23, 2021.

Issue Type	Definition	%
[1] Synonym and Hypernym	Synonym or hypernym of the ground-truth can also be considered as a correct answer for a given question-image pair.	9.1
[2] Singular/Plural	Singular or plural of the ground-truth can also be considered as a correct answer for a given question-image pair.	1.0
[3] Ambiguous Objects	Question refers to an object but the image contains multiple such objects that can lead to different possible answers.	5.8
[4] Multiple Correct Answers	If a given image-question pair is not precise, annotators might have different opinion which leads to multiple correct answers	7.0
[5] Missing Object(s)	Object referred in the question is not clearly visible in image.	4.3
[6] Wrong Label	The ground-truth answer to a question-image pair is incorrect.	6.7

Table 1: Six types of issues observed in the GQA dataset, their definition and their distribution observed in manual review of 600 samples from testdev balanced split. For example of each issue type, refer Figure 1.

for consistent answer predictions. (Bhattacharya et al., 2019) analyzed VQA and VizWiz datasets to present 9-class taxonomy of visual questions that suffer from subjectivity and ambiguity. Our analysis on GQA partially overlaps with this study. GQA dataset only provides one ground truth for each question; thus, we propose AAS to extend answers by phrases with close semantic meaning as the ground-truth answer.

Evaluation-Level For open-ended VQA tasks, the standard accuracy metric can be too stringent as it requires a predicted answer to exactly match the ground-truth answer. To deal with different interpretations of words and multiple correct answers, (Malinowski and Fritz, 2014) defined a WUPS scoring from lexical databases with Wu-Palmer similarity (Wu and Palmer, 1994). (Abdelkarim et al., 2020) proposed a soft matching metric based on wordNet (Miller, 1998) and word2vec (Mikolov et al., 2013). Different from them, we incorporate more advanced NLP resources tools to generate answer sets and rely on textural entailment to validate semantics for robustness. We propose a new metric to evaluate a system's response.

3 Analysis of GQA Dataset

GQA is a dataset for real-world visual reasoning and compositional question answering. Instead of human annotation, answers to the questions in GQA are generated from the scene graphs of images. We found that automatic creation leads to flaws in the dataset; thus, we manually analyze 600 questions from the testdev balanced split of GQA dataset, and identify six issues shown in Table 1. Figure 1 shows examples of each type of issue.

These issues are caused by (not limited to) three reasons. First, the dataset assumes only one ground truth so that other answers with semantic closed meaning are ignored. We propose AAS to address this issue to some extent and describe AAS in the next section. Second, some questions referring to multiple objects cause ambiguous meaning. We leverage scene graphs to address this issue and found 2.92% and 2.94% ambiguous questions in balanced training split and balanced validation split, respectively. These ambiguous questions can be removed from the dataset. Third, there are incorrect scene graph detections so that some questions and/or labels do not match with the given images. We plan to address these issues in our future work.

4 Alternative Answer Set

To credit answers with semantically close meaning as the ground-truth, we propose a workflow that can be visualized from Figure 2. Each item in VQA dataset consists of <I, Q, GT>, where I is an image, Q is a question, and GT is a ground-truth answer. We define an Alternative Answer Set (AAS) as a collection of phrases $\{A_1, A_2, A_3,.., A_n\}$ such that A_i replaced with GT is still a valid answer to the given Image-Question pair. We construct AAS for each unique ground-truth automatically from two knowledge bases: Wordnet (Miller, 1998) and ConcpetNet (Liu and Singh, 2004), two word embeddings: BERT (Devlin et al., 2018) and counter-fitting (Mrkšić et al., 2016). We assign a semantic score to each alternative answer by textural entailment and introduce the AAS metric.

[1] Synonym and Hypernym

Question: Who is holding the bat?
Ground-truth: batter
Explanation: 'batsman' is a synonym of 'batter'
SU-AAS: batter, batsman, hitter, ballplayer, player

[2] Singular/Plural

Question: Who is wearing the dress?
Ground-truth: women
Explanation: singular form 'woman' is also correct (there is only one woman in the picture)
SU-AAS: women, female, woman, people, adult female

[3] Ambiguous Objects

Question: Does the person in front of the cabinets have brunette color?
Ground-truth: Yes
Explanation: there are two people in front of the cabinet and it is not clear which person is being referred to
SU-AAS: yes

[4] Multiple Correct Answers

Question: Which place is it?
Ground-truth: road
Explanation: some person might answer 'road' and some might answer 'street'
SU-AAS: road, street, roadway, paved

[5] Missing Object(s)

Question: Does the marker look narrow?
Ground-truth: Yes
Explanation: the 'marker' is missing from the image
SU-AAS: yes

[6] Wrong Label

Question: Do the door and the logo have the same color?
Ground-truth: Yes
Explanation: the correct answer is 'no' as the door is white and logo is green.
SU-AAS: yes

Figure 1: Examples from GQA dataset for each issue type and SU-AAS i.e. AAS of ground-truth based on semantic union approach. SU-AAS can resolve Synonym and Hypernym, Singular/Plural, and Multiple Correct Answers for a given problem.

4.1 Semantic Union AAS

We take a union of four methods to find all alternative answers. For example, "stuffed animal" is semantic similar to "teddy bear", which appears in the AAS based on BERT but not in WordNet. However, the union might include phrases that we want to distinguish from the label like "man" is in the AAS of "woman" when using the BERT-based approach. For this reason, we employ the textural entailment technique to compute a semantic score of each alternative answer. For each label, we first obtain 50 sentences containing the ground-truth label from GQA dataset. We take each sentence as a premise, replace the label in this sentence with a phrase in its AAS as a hypothesis to generate an entailment score between 0-1. Specifically, we use publicly available RoBERTa (Liu et al., 2019) model trained on SNLI (Stanford Natural Language Inference) (Bowman et al., 2015) dataset for entailment computation. The semantic score of the alternative answer is the average of 50 entailment scores. If the semantic score is lower than the threshold of 0.5, then this alternative answer is thrown out. We choose 0.5 since it is the middle of 0 and 1.

Lastly, we sort the AAS by semantic score and keep the top K in the semantic union AAS, annotated by SU-AAS. We experiment with different values of K from 2 to 10, and decide K to be 6, a trade-off between accuracy and robustness. Note that the performance of textual entailment model is a contributing factor in obtaining quality AAS. Therefore, we recommend using the state-of-the-art entailment model when our proposed method is applied on other VQA datasets.

4.2 Evaluation Metric Based on AAS

We propose AAS metric and semantic score: given a question Q_i, an image I_i, the alternative answer set of GT_i denoted by $\mathrm{S}_{\mathrm{GT}_i}$, the prediction of model P_i is correct if and only if it is found in $\mathrm{S}_{\mathrm{GT}_i}$, and the score of P_i is $\mathrm{S}_{\mathrm{GT}_i}(\mathrm{P}_i)$, where $\mathrm{S}_{\mathrm{GT}_i}(\mathrm{P}_i)$ is the semantic score of P_i. Mathematically,

$$\mathrm{Acc}(\mathrm{Q}_i, \mathrm{I}_i, \mathrm{S}_{\mathrm{GT}_i}, \mathrm{P}_i) = \begin{cases} S_{\mathrm{GT}_i}(\mathrm{P}_i) & \text{if } \mathrm{P}_i \in \mathrm{S}_{\mathrm{GT}_i} \\ 0 & \text{else} \end{cases}$$

5 Experiments

In this section, we first show that the performance of vision-language models on two datasets is improved based on the AAS metric. Then, we describe our experiment to incorporate AAS with one model on GQA dataset. Last, we verify the correctness of AAS by human evaluation.

5.1 Baseline Methods

We select two top Vision-and-Language models, ViLBERT (Lu et al., 2019) and LXMERT (Tan

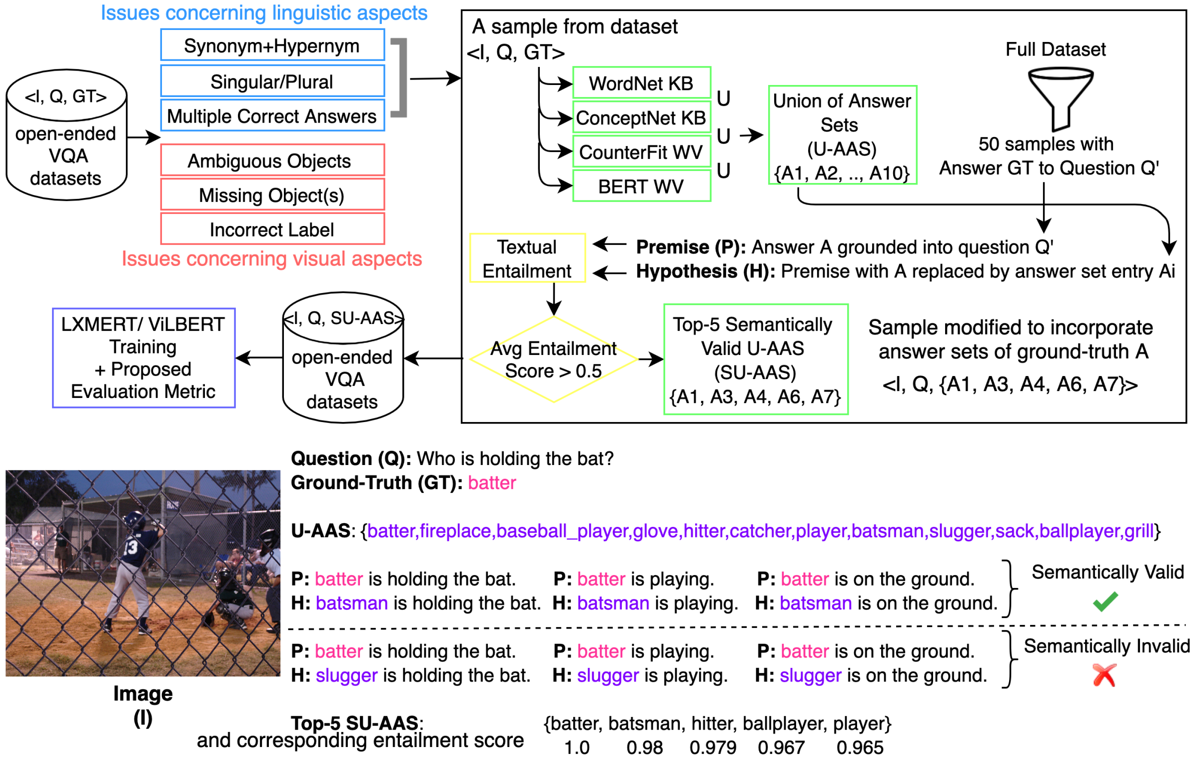

Figure 2: (top) The workflow for generating Alternative Answer Set (AAS) for VQA datasets (bottom) An example from GQA dataset showing semantically valid AAS for the answer 'batter' generated using above workflow

and Bansal, 2019) and evaluate their performances based on the AAS metric. From Table 2, we see that for the GQA dataset, LXMERT and ViLBERT have 4.49%, 4.26% improvements on union AAS metric separately. For VQA2.0 dataset, LXMERT and ViLBERT have 0.82%, 0.53% improvements on union AAS metric separately. It is expected that the improvement on VQA2.0 dataset is less than GQA since the former dataset already provides multiple correct answers. Figure 3 shows the impacts of the value K of Union AAS on the scores. From the figure, we see that when K increases from 2 to 6, the score gets increased significantly, and slightly when k increases from 6 to 9, but not increases more after K is 9. Since values 7 and 8 do not significantly improve the score, and the value 9 introduces noise, we take the top 6 as the SU-AAS.

5.2 Training with AAS

We incorporate SU-AAS of ground truth in training phase, so the model learns that more than one answer for a given example can be correct. We train LXMERT on GQA dataset with this objective.

Table 3 shows the results of LXMERT trained with AAS compared with the baseline. Not surprisingly, the performance evaluated on the original method drops because the model has a higher chance to predict answers in AAS, which are different from the ground truth, and thus the performance evaluated on SU-AAS metric increases.

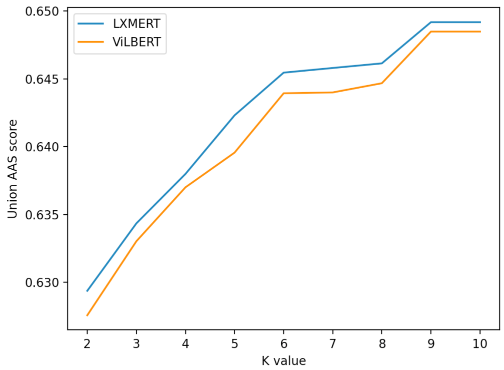

Figure 3: Union AAS score of different value of K

Dataset	Exact Matching Accuracy		SU-AAS Accuracy	
	LXMERT	LXMERT$_{AAS}$	LXMERT	LXMERT$_{AAS}$
GQA(testdev)	**60.06**	59.02	64.55	**65.22**

Table 3: Incorporate AAS in the training phase of LXMERT (LMXERT$_{AAS}$) on GQA dataset.

5.3 Evaluation of AAS

To validate the correctness of AAS, we measure the correlation between human judgment and AAS.

Dataset	Model	Original Metric	WordNet	BERT	CounterFit	ConceptNet	Union
GQA	LXMERT	60.06	61.79	62.69	62.75	63.58	**64.55**
(testdev)	ViLBERT	60.13	61.90	62.69	62.74	63.67	**64.39**
VQA	LXMERT	69.98	70.21	70.54	70.33	70.52	**70.80**
(valid)	ViLBERT	77.65	77.82	78.10	77.93	78.06	**78.28**

Table 2: The evaluation of two models on GQA and VQA with original metric and AAS based metrics.

Specifically, for each label of GQA, we take the SU-AAS and ask three annotators to justify if alternative answers in AAS can replace the label. If the majority of annotators agree upon, we keep the answer in the AAS, remove otherwise. In this way, we collect the human-annotated AAS. We compare the human-annotated AAS with each automatically generated AAS. We take the intersection over union (IoU) score to evaluate the correlation between automatic approach and human annotation: a higher IoU score means stronger alignment.

Method	WordNet	BERT	CounterFit	ConceptNet	Union
IoU%	48.25	56.18	58.95	58.39	80.5

Table 4: The IoU scores between human annotations and AAS based on five approaches.

6 Discussion and Conclusion

To evaluate a model from a semantic point of view, we define an alternative answer set (AAS). We develop a workflow to automatically create robust AAS for ground truth answers in the dataset using Textual Entailment. Additionally, we did human verification to assess the quality of automatically generated AAS. The high agreement score indicates that entailment model is doing a careful job of filtering relevant answers. From experiments on two models and two VQA datasets, we show the effectiveness of AAS-based evaluation using our proposed metric.

AAS can be applied to other tasks, for example, machine translation. BLEU(Papineni et al., 2002) score used to evaluate machine translation models incorporates an average of n-gram precision but does not consider the synonymy. Therefore, METEOR (Banerjee and Lavie, 2005) was proposed to overcome this problem. However, METEOR only relies on the synset of WordNet to get the synonyms. Our proposed AAS has the advantage of both knowledge base and word embeddings, which would help better evaluate translation tasks.

Acknowledgments

Better Neural Machine Translation by Extracting Linguistic Information from BERT

Hassan S. Shavarani **Anoop Sarkar**
School of Computing Science

Abstract

Adding linguistic information (syntax or semantics) to neural machine translation (NMT) has mostly focused on using point estimates from pre-trained models. Directly using the capacity of massive pre-trained contextual word embedding models such as BERT (Devlin et al., 2019) has been marginally useful in NMT because effective fine-tuning is difficult to obtain for NMT without making training brittle and unreliable. We augment NMT by extracting dense fine-tuned vector-based linguistic information from BERT instead of using point estimates. Experimental results show that our method of incorporating linguistic information helps NMT to generalize better in a variety of training contexts and is no more difficult to train than conventional Transformer-based NMT.

1 Introduction

Probing studies into large contextual word embeddings such as BERT (Devlin et al., 2019) have shown that these deep multi-layer models essentially reconstruct the traditional NLP pipeline capturing syntax and semantics (Jawahar et al., 2019); information such as part-of-speech tags, constituents, dependencies, semantic roles, coreference resolution information (Tenney et al., 2019a,b) and subject-verb agreement information can be reconstructed from BERT embeddings (Goldberg, 2019). In this work, we wish to extract the relevant pieces of linguistic information related to various levels of syntax from BERT in the form of dense vectors and then use these vectors as linguistic "experts" that neural machine translation (NMT) models can consult during translation.

But can syntax help improving NMT? Linzen et al. (2016); Kuncoro et al. (2018); Sundararaman et al. (2019) have reported that learning grammatical structure of sentences can lead to higher levels of performance in NLP models. In particular, Sennrich and Haddow (2016) show that augmenting NMT models with explicit linguistic annotations improves translation quality.

BERT embeddings have been previously considered for improving NMT models. Clinchant et al. (2019) replace the encoder token embedding layer in a Transformer NMT model with BERT contextual embeddings. They also experiment with initializing all the encoder layers of the translation model with BERT parameters, in which case they report results on both freezing and fine-tuning the encoder parameters during training. In their experiments BERT embeddings can help with noisy inputs to the NMT model, but otherwise do not help improving NMT performance.

Imamura and Sumita (2019) suggest that replacing the encoder layer with BERT embeddings and fine-tuning BERT while training the decoder leads to a *catastrophic forgetting* phenomenon where useful information in BERT is lost due to the magnitude and number of updates necessary for training the translation decoder and fine-tuning BERT. They present a two-step optimization regime in which the first step freezes the BERT parameters and trains only the decoder while the next step fine-tunes the encoder (BERT) and the decoder at the same time. Yang et al. (2020) also try to address the *catastrophic forgetting* phenomenon by thinking of BERT as a teacher for the encoder of the neural translation model (student network) (Hinton et al., 2015). They propose a dynamic switching gate implemented as a linear combination of the encoded embeddings from BERT and the encoder of NMT. However these papers do not really focus on the linguistic information in BERT, but rather try to combine pre-trained BERT and NMT encoder representations.

Sundararaman et al. (2019) identify *part-of-speech*, *case*, and *sub-word position* as essential lin-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2772–2783
April 19 - 23, 2021.

guistic information to improve the quality of both BERT and the neural translation model. They extract each linguistic feature using the Viterbi output of separate models, embed the extracted linguistic information (similar to trained word embeddings) and append these vectors to the token embeddings. However, their model uses point estimates of the syntactic models and they do not use the linguistic information in BERT embeddings.

Weng et al. (2019) use multiple multi-layer perceptron (MLP) modules to combine the information from different layers of BERT into the translation model. To make the most out of the fused information, they also alter the translation model training objective to contain auxiliary knowledge distillation (Hinton et al., 2015) parts concerned with the information coming from the pre-trained language model. Zhu et al. (2020) also inject BERT into all layers of the translation model rather than only input embeddings. Their model uses an attention module to dynamically control how each layer interacts with the representations. In both of these works, the training of the Transformer for NMT becomes quite brittle and is prone to diverge to local optima.

In this paper, we propose using pre-trained BERT as a source of linguistic information rather than a source of frozen pre-trained contextual embedding. We identify components of the BERT embeddings that correspond to different types of linguistic information such as part-of-speech, etc. and fine-tune dense vector embeddings for these linguistic aspects of the input and use them within an NMT model. Our approach does not radically complicate the Transformer NMT model training process both in terms of time and hardware requirements and also in terms of training difficulty (avoids bad local optima).

Our contributions are as follows: (1) A method of linguistic information extraction from BERT which needs supervision while training but works without supervision afterwards. (2) An easily trainable procedure for integrating the extracted information into the translation model. (3) Evaluation of the proposed model on small, medium and large translation datasets.

The source code and trained aspect extractors are available at https://github.com/sfu-natlang/SFUTranslate and our experiments can be replicated using scripts under `resources/exp-scripts/aspect_exps`.

2 NMT and BERT

Machine translation is the problem of transforming an input utterance sequence X in source language l_f into another utterance sequence Y (possibly with varying length) in target language l_e. Machine translation models search among all possible sequences in target language to find the most probable sequence based on the probability distribution of Equation 1.

$$P(y|X, y \in l_e) = \prod_{i=0}^{|max\ len|} p(y_i|X, y_0, ..., y_{i-1}) \tag{1}$$

Neural machine translation (NMT) tries to model the probability distribution $p(y|X)$ using neural networks by taking advantage of deep learning techniques. Transformers (Vaswani et al., 2017) are one type of encoder-decoder neural networks used for translation tasks. In Transformers, the input (in one-hot format) is passed through N layers of encoder and N layers of decoder. In each layer, the layer input passes through multiple attention heads (h heads; each considered a specialist in a different sentence-level linguistic attribute) and then gets transformed to the input for the next layer using a two layer feed-forward perceptron module with input size of d_{model} and hidden layer size of d_{ff}. The final probability distribution $p(y|X)$ is generated using an affine transformation applied to the output of the last feed-forward module in the N^{th} decoder layer. Please see (Vaswani et al., 2017) for further details.

BERT (Devlin et al., 2019) adopts the encoder part of the transformer model and requires training it on large amounts of text data using a *masked language model* objective over sub-words $p(y_i|X, y_0, ..., y_{i-1}, y_{i+1}, ..., y_{max\ len})$ instead of guessing the next sub-word $p(y_i|X, y_0, ..., y_{i-1})$. This bidirectional context turns BERT into a provider of strong contextual sub-word embeddings in many languages. These massively overparameterized neural networks have revolutionized many different NLP tasks. Effective application of BERT in NMT has been studied in a number of contemporary research projects; Language Modeling, Named Entity Recognition, Question Answering, Natural Language Inference, Text Classification (Devlin et al., 2019), and Question Generation (Chan and Fan, 2019). We approach this problem from the novel perspective of extracting linguistic information encoded in BERT and applying such information in NMT.

3 Linguistic Aspect Extraction from BERT

Since BERT contextual embeddings contain a variety of information (linguistic and non-linguistic), extraction of relevant information plays an important role in further improvement of the downstream tasks. In the rest of this section, we define *aspect vectors* as single-purpose dense vectors of extracted linguistic information from BERT, discuss how aspect vectors can be extracted, and explain how to integrate aspect vectors into NMT.

3.1 Aspect Vectors

To start the information extraction process, we initially need to choose a limited (desired) set of linguistic attributes to look for in BERT embeddings. This attribute set can contain a number of linguistic aspects (e.g. part-of-speech). Each linguistic aspect itself will be defined over a possible aspect tag set (e.g. the set of $\{NOUN, ADJ, ...\}$ in part-of-speech). In this paper, we show a linguistic attribute set with $\mathbb{A}$, show a generic aspect with a and point to its relative tag set with t_a.

Given the definition of a linguistic aspect and inspired by the information bottleneck idea (Tishby and Zaslavsky, 2015), we define an *aspect vector* as a single-purpose dense vector extracted from BERT and containing information about a certain linguistic aspect of a particular (sub-word) token in the input sequence. Aspect vectors can be interpreted as feature values equivalent to a specific key (aspect).

3.2 Aspect Vector Extraction

For each embedding vector $\mathbf{E}$ and linguistic aspect a, we define M_a as an aspect-extraction function where $\mathbf{e}_a = M_a(\mathbf{E})$ is a single-purpose dense vector containing maximum aspect information and minimum irrelevant other information.

We ensure the aspect encoding power of $\mathbf{e}_a$ by retrieving its equivalent tag in t_a using a classifier. The aspect prediction loss for a linguistic attribute set $\mathbb{A}$ of size n can be calculated as the average cross entropy loss ($\mathcal{L}_{CE}$) between the classifier prediction and the expected aspect tags for each aspect (Equation 2).

$$\mathcal{L}_a = \frac{1}{n}\sum_{i=0}^{|n|}\mathcal{L}_{CE}^{i} \qquad (2)$$

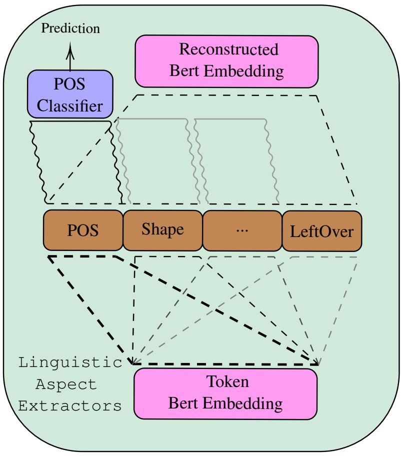

Figure 1: Schematic Aspect Extraction from BERT

We also ensure information integrity[1] of $\mathbf{e}_a$ by concatenating all the aspects (in addition to a "*left-over*" aspect equivalent to all the other non-interesting information) and reconstructing the original embedding vector $\mathbf{E}$ from them[2] in reconstruction vector $\mathbf{R}$. The reconstruction loss ($\mathcal{L}_r$) for the extracted aspect vectors can be calculated as the euclidean distance of the reconstruction vector $\mathbf{R}$ and the original embedding vector $\mathbf{E}$ (Equation 3).

$$\mathcal{L}_r = ||\mathbf{R} - \mathbf{E}||^2 \qquad (3)$$

In addition, since our aspect extractor is similar in architecture to a multi-head attention module (with a difference in the fact that we know what exactly each head will be responsible for), to prevent learning redundant representations (Michel et al., 2019), we add the average euclidean similarity ($\mathcal{L}_s$) of each pair of aspect vectors to the training loss function (Equation 4).

$$\mathcal{L}_s = 1 - \left(\frac{1}{n(n-1)}\sum_{i=0}^{|n|}\sum_{j\neq i=0}^{|n|} ||e_i - e_j||^2\right) \qquad (4)$$

The aspect extractor will be trained over the accumulation of the three mentioned loss components (Equation 5). Figure 1 demonstrates different parts of the aspect extractor and their connections.

$$\mathcal{L}_{fe} = \mathcal{L}_a + \mathcal{L}_r + \mathcal{L}_s \qquad (5)$$

---

[1] We don't expect M_a to change the information inside $\mathbf{E}$ but rather to extract the relevant information.

[2] This idea is analogous to stack-propagation (Zhang and Weiss, 2016) in which propagating the information loss for two tasks helps improving the quality of the encoded representations.

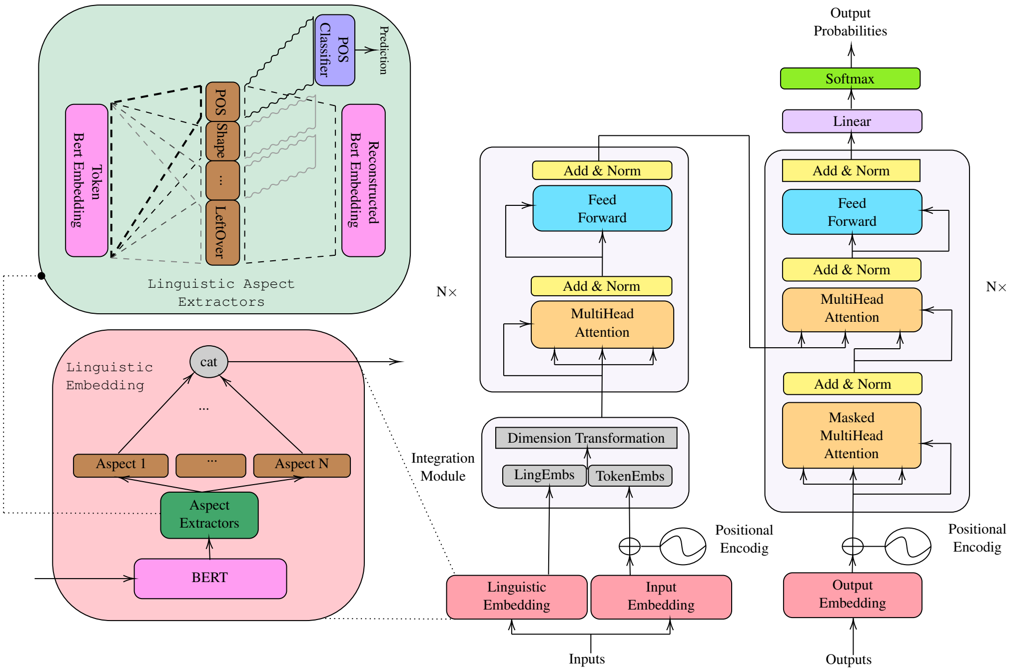

Figure 2: Integration of Extracted Aspect Vectors into NMT. The right hand side part of this figure is taken from Vaswani et al. (2017).

As another important point, a pre-trained BERT model has multiple encoder layers as well as an embedding layer. Choosing the proper layer which contains all of our desired aspects is not simply possible since different layers specialize in different linguistic aspects (Jawahar et al., 2019; Tenney et al., 2019a).

Therefore, as Peters et al. (2018) suggest, we define BERT embedding vector **E** as a weighted sum of all BERT layers (of size ℓ) using Equation 6 where α weights are learnable parameters and will be trained along with the other aspect extractor parameters.

$$\mathbf{E} = \sum_{j=0}^{\ell} \alpha_j \mathbf{E}_j^{BERT} \tag{6}$$

3.3 Integrating Aspect Vectors into NMT

Once the aspect vectors are created, we throw away the classifiers and the reconstruction layers and place the encoder part of our trained aspect extractor (the mapping from BERT contextual embeddings to aspect vectors) in an input integration module designed to augment the neural translation model input with aspect vectors[3].

The integration module (constructed using a two layer perceptron network) receives the concatenated aspect vectors (we call this concatenated vector a linguistic embedding[4]) and the token embedding (inherited from the Transformer model), and maps the linguistic embedding into a vector of the same size as the token embedding. Then, it projects the concatenation of both embeddings to a vector with the same size as the token embedding of the original Transformer model[5]. Figure 2 demonstrates this process.

4 Experiments

In this section, we initially examine our designed aspect extractor and report its classification accuracy scores. Next, we integrate the extracted aspect vectors into the neural machine translation framework as explained in Section 3.3 and study the effects of integrated vectors on the performance of the models.

4.1 Data

We choose three German (which has explicit and nuanced linguistic features) to English datasets in different data sizes to examine our proposed framework.

---

[3] We use the same sub-word model in pre-trained BERT to provide sub-word tokens to our NMT model.

[4] This embedding vector can be similar to what a factor token contains in Factored-NMT (García-Martínez et al., 2016) with a difference that it is generated in the space of linguistic aspects and does not need an embedding layer.

[5] This step is necessary to prevent any change in other parts of the model which would make comparison of the results unfair due to effects on the number of parameters and the learning capability of the model.

We use Multi30k (M30k)[6] as our small dataset. This dataset contains a multilingual set of image descriptions in German, English and French. Due to this reason, we also consider experimenting on German to French as our second small dataset. The M30k data contains 29K training sentences, 1014 validation sentences (val) and 1000 test sentences ($test$2016).

We take IWSLT (Cettolo et al., 2012)[7] as our medium sized dataset. The sentences in this dataset are quite different from M30k since they are composed from the transcriptions of TED talks as well as dialogues and lectures[8]. The IWSLT data contains 208K training sentences, 888 validation sentences (dev2010) and multiple test sets (tst2010 to tst2015 with 1568, 1433, 1700, 993, 1305, and 1080 sentences, respectively).

For the large data size, we consider WMT[9], a large (4.5M training sentences) set of parallel sentences from the proceedings of the European Parliament as well as web crawled news articles. We remove 0.05% of the training data (2290 sentences; lines with numbers divisible by 2000) and use it as the validation set (we call it wmt_val) and take $newstest$ data from 2014 to 2019 as our test sets (with 3003, 2169, 2999, 3004, 2998 and 1997 sentences, respectively).

We remove train data sentences longer than 100 words and uncase and normalize both side sentences using `MosesPunctNormalizer`[10] before tokenization. The reference side of the test data remains untouched in all the steps of our experiments.

4.2 Linguistic Aspect Vector Extraction

In this section, we study our linguistic aspect extractor training procedure and analyze the quality of the extracted aspect vectors.

We choose our linguistic attribute set ($\mathbb{A}$) as Sundararaman et al. (2019) suggest, however, we replace '*case*' with '*word-shape*'[11] since we believe the complete shape of the word is much more informative specially in sub-word settings. In addition, we consider a two-level hierarchy in part-of-speech tags to benefit from both higher accuracy in exploring the syntactic search space and lower model confusion in cases where the fine-grained tags are not helpful. Therefore, we consider coarse-grained and fine-grained *part-of-speech* (CPOS and FPOS), *word-shape* (WSH), and *sub-word position*[12] (SWP) to form our experimental linguistic attribute set ($\mathbb{A}$). Other linguistic attributes such as dependency parses or sentiment could be considered as aspects in our model but we leave that for future work.

We use the spaCy German tagger[13] model to acquire our intended linguistic aspect labels. Since spaCy is trained on word-level while BERT is trained on sub-word level, we had to align the sequences using a monotonic alignment algorithm (see Appendix A.1.1). The fine-grained part-of-speech tagger in spaCy[14] is pre-trained on TIGER Corpus[15] (Smith et al., 2003) and inherits its 55 fine-grained tags from TIGER treebank. The coarse-grained spaCy part-of-speech tagger has been trained by defining a direct mapping from 55 tags of the TIGER treebank to the 16 tags in the Universal Dependencies v2 POS tag set[16].

We use a 12-layer[17] German pre-trained BERT model for encoding the source sentences in aspect extractors. We use an uncased model as our translation model performs on lowercased data and the results are recased using the moses recaser so that the results are cased BLEU scores comparable to other systems[18]. We pass the BERT-encoded source sentences through a single perceptron middle layer of size 1000. We divide the output of this layer to

[18] We recommend using a cased BERT model for translation systems that handle casing differently.

	Sub-word Level					Word Level			
	CPOS	FPOS	WSH	SWP	`#tokens`	CPOS	FPOS	WSH	`#tokens`
M30k	96.88	96.18	99.79	99.93	16096	97.95	97.34	99.74	12823
IWSLT	92.69	90.48	99.73	97.14	22687	94.84	93.07	99.69	19039
WMT	92.64	91.60	97.74	98.94	70139	94.86	94.01	97.38	55135

Table 1: F-1 scores acquired after training the aspect extractor on German side of parallel data and passing the validation sets of each data set through trained aspect extractors. The `#tokens` column shows the number of tokens in the validation set.

Aspect Extractor Training Data	FPOS	SWP
M30k	79.39	90.63
IWSLT	77.80	88.34
WMT	82.13	91.42
TIGER	84.64	92.64

Table 2: F-1 scores of fine-grained part-of-speech prediction of TIGER corpus test data (BERT encoded) fed to each of the trained aspect classifiers. The scores are calculated over a total of 7516 sub-word tokens in 358 test sentences of TIGER. Extractors trained on M30k, IWSLT, and WMT have not been provided with any part of TIGER before evaluation.

'*number of aspects + 1*' splits to form our desired aspect vectors (of size 200). Please see Appendix A.1.1 for more implementation details.

We train three different aspect extractors, one for each dataset and feed in the source sentences of the dataset to our model in batches of size 32 for 3 epochs[19]. Table 1 shows F-1 scores of classifying the validation set data using different aspect vectors after training the aspect extractors on the train set sentences. Please note that for calculating the word-level scores, in cases of disagreement between different sub-word tokens, the sub-word prediction of the first sub-word token has been counted as the prediction for the word label.

We also validate our trained (on M30k, IWSLT, and WMT) aspect extractors against the manual annotations of TIGER treebank with which the spaCy fine-grained part-of-speech tagger has been trained. We train an extra aspect extractor using the train set of TIGER corpus and test all four trained aspect extractors against TIGER data test set[20]. This experiment evaluates the absolute power of our simple feed-forward aspect extractors in performing the aspect classification task. Please note that our goal in this experiment is not to achieve the state-of-the-art fine-grained part-of-speech tagging results as our aspect extractors receive their input from BERT and do not directly access the tagged input sentences. Table 2 contains the results of comparison between predictions of different aspect extractor classifiers and TIGER gold labels.

4.3 Uniqueness of Information in Linguistic Aspect Vectors

Considering the high F-scores for each aspect category in each dataset (Table 1), we can conclude that our aspect extractor maximizes the relevant information extraction from BERT embeddings. The loss in Equation 4 maximizes the distance between aspect vectors. To test whether this leads to a diverse set of aspect vectors, each specialized to their own linguistic attributes, we consider each aspect category a, after training the aspect extractors. We take each of the other extracted aspect vectors a' (except the "*left-over*" vector) and use each of them to train a new classifier[21] that predicts the right class for category a based on aspect vector a'. This will test the correlation between the information in aspect vectors a' and the tags in category a. If the classification scores for this counterfactual test are high then our model has failed in fine-tuning each aspect vector to predict a particular linguistic aspect. We compare the classification scores to a trivial baseline: predict the most frequent class always. Table 3 shows the results of this counterfactual test on the aspect extractor trained on TIGER data. We can see that the average F-1 scores are very low when we use counterfactual aspect vectors to predict a linguistic aspect on which it was not fine-tuned (e.g. use aspect vector trained on part-

---

[19] Since the number of WMT sentences are much bigger, we stop training WMT aspect extractors when there is no improvement in aspect classification result (rounded to have 3 decimal places) of any label for at least 40 batches.

[20] We use `german_tiger_test_gs.conll` in the version of TIGER released in *2006 CoNLL Shared Task - Ten Languages*. Both train and test data are accessible through https://catalog.ldc.upenn.edu/LDC2015T11.

[21] We thank the anonymous reviewers for their valuable feedback on this procedure.

TIGER test	Sub-word Level			
	CPOS	FPOS	WSH	SWP
most frequent class	NOUN	NN	xxxx	single
percentage in total	27.12	27.07	39.07	59.92
average classification F-1	1.89	0.23	12.20	42.97
`#tokens`	$7516 \times 3 = 22548$			

Table 3: Classification scores of each aspect classifier when fed with other extracted aspect vectors. We expect the F-1 scores to be low so we can conclude that our aspect extractor truly excludes irrelevant information from each aspect.

of-speech to predict word shape). This shows that our training method fine-tunes each aspect vector to its linguistic task.

To validate the loss in Equation 3, we calculate the average euclidean distance of the aspect extractor reconstructed vectors and the original BERT embedding vectors[22] for M30k German to English dataset. We unit normalize each of the vectors for a score in $[0, 1]$. The average euclidean distance value of 0.1863 tells us that the reconstruction component of the aspect extractor is capable of reconstructing vectors that are close to the original embedding vectors.

4.4 Linguistic Aspect Integrated Machine Translation

After confirming the adequacy and uniqueness of linguistic information in aspect vectors, we integrate the encoder part of aspect extractors into the translation model and perform translation experiments on M30k, IWSLT, and WMT datasets. In our experiments, we compare our model to three baselines : (1) the vanilla transformer model (Vaswani et al., 2017) which does not use any external source of information, (2) the syntax-infused transformer model (Sundararaman et al., 2019) which explicitly embeds linguistic aspect labels and concatenates their embedding to the token embedding, (3) the transformer model with bert-freeze input setting (Clinchant et al., 2019) which replaces the input embedding layer of the encoder module in transformer with a fully pre-trained BERT model. Appendix A.1.2 provides the configurations and sufficient details for replication of our experiments in this section.

During each training trial, we perform 9 validation set evaluation steps (one after visiting each 10% of the data). In each step, the validation set is translated with the current state of the model (at the time of evaluation) and the generated sentences are detokenized and compared to the validation set reference data to produce sentence-level BLEU (Lin and Och, 2004) scores. The best scoring model throughout training is selected as the model with which the test set(s) are translated.

For M30k and IWSLT data sets, we train two separate models, one using the aspect vectors trained on the source side of its own training data (in-domain) and the other using the aspect vectors trained on the source side of WMT data (out-of-domain). We use cased BLEU (evaluated with the standard `mteval-v14.pl` script) and METEOR (Denkowski and Lavie, 2014) to compare different models. Tables 4 and 7 show the results of evaluating the models trained with different mentioned settings.

The evaluation results show that taking advantage of aspect vectors improves the accuracy of translating German to both English and French in M30k as well as German to English in IWSLT and WMT. Also, in majority of the cases WMT-trained aspect vectors have pushed the model to produce more accurate results since they contain more generalized information. Based on these results, we conjecture that aspect vectors trained on large out-of-domain data can be helpful in low-resource settings but we leave the examination of this idea for future work.

Aside from performance, our model is approximately 5 times faster than syntax-infused translation model (Sundararaman et al., 2019) while demanding less number of trainable parameters. Although it is not as fast as bert-freeze model (Clinchant et al., 2019) in large settings (because of the size of computations required for calculating the linguistic embedding), it is comparable in speed to bert-freeze in medium and small scale settings. Appendix A.2 contains some additional insights regarding how aspect vectors can help translation systems trained on different dataset sizes.

Tables 5 and 6 demonstrate some examples of cases where aspect vectors has been useful in improving the translation quality.

---

Table 4: Evaluated cased BLEU score (calculated using `mteval-v14.pl` script) results on M30k, IWSLT, and WMT datasets. `#param` represents the number of trainable parameters (size of BERT model parameters [110.5M] has not been added to the model size for the aspect augmented and bert-freeze models since BERT is not trained in these settings). `runtime` is the total time the training script has ran and includes time taken for reading the data and training the model from scratch (iterating over the instances for all the epochs).
All the baseline results are achieved using our re-implementation of the mentioned papers.
[*] We have used a single GeForce GTX 1080 GPU for M30k experiments and a single Titan RTX GPU for IWSLT and WMT experiments.
[†] Each experiment was repeated three times, and we report the average in this table.

5 Conclusion and Future Work

In this paper, we proposed a simple method of extracting linguistic information from BERT contextual embeddings and integrating them into neural machine translation framework. We showed that the linguistic aspect vectors provide the translation models with out-of-domain knowledge which not only improves the translation quality but also helps the model to better deal with out-of-vocabulary words. In the future, we would like to reconsider the integration module as a multi-head attention module, except that it will attend to different linguistic aspects of the current sub-word or sub-word tokens of a single word. Increasing the number of linguistic aspects (especially the use of syntactic dependencies and morphology) and studying the effects of the aspect vector size on the quality of generated translations are other directions of future research. We would also like to examine the effectiveness of aspect vectors trained on large out-of-domain data in low-resource settings and explore the effects of using linguistic aspect vectors in tasks other than machine translation.

A Appendices

A.1 Implementation Details

In this section, we provide implementation details that could not be placed in the main write-up due to space limitations, but we believe are quite helpful for replication of our work. We divide this section into two parts, one focused on linguistic aspect vector extraction (Section 4.2) and the other on linguistic aspect integrated machine translation (Section 4.4).

A.1.1 Linguistic Aspect Vector Extraction Implementation Details

The pre-trained spaCy tagger that we used in our experiments is trained on the word-level while the pre-trained BERT operates on sub-word level[23]. The two sequences need to be aligned, so we can assign aspect attributes to BERT sub-word tokens. Inspired by Gale and Church (1993), we align the two sequences using a heuristic divide-and-conquer monotonic alignment technique which finds the parts of the two sequences that are certainly equal and aligns the parts in between using recursive calls to itself[24].

Next, we explain how we implement the aspect extractors. We implement our aspect extractors using PyTorch framework and initialize them using Xavier initialization (Glorot and Bengio, 2010). We perform backpropagation using SGD (initial learning rate of 0.05, momentum value of 0.9, gradient clip norm of 5.0). To cope with inequality in the frequency of the different tags in each aspect tag set (t_a, see §3.1), we practice weighted

---

[23] The alignment is non-trivial e.g. “`hadn't`” is tokenized to “`hadn`” and “`'t`” by spaCy and to “`had`” and “`n't`” by BERT, causing many-to-many alignments.

*The maximum number of sub-word tokens per batch.

backpropagation with weights proportional to the inverse frequency of each tag. We decay learning rate with a factor of 0.9 when the loss value stops improving.

A.1.2 Linguistic Aspect Integrated Machine Translation Implementation Details

We implement our baseline transformer model using the guidelines suggested by Rush (2018) in our translation toolkit SFUTranslate and extend it for implementing the aspect-augmented model as well as the syntax-infused transformer and transformer with bert-freeze input setting. Table 8 provides the configuration settings for each of the models used in our experiments.

We use the pre-trained WordPiece[25] (Schuster and Nakajima, 2012) tokenizer packaged and shipped with BERT (containing 31,102 sub-word tokens for German language) to tokenize the source side data, and tokenize the target side data with MosesTokenizer[26] followed by the same WordPiece tokenizer model, trained on target data, to split the target tokens into sub-tokens. We set the target side WordPiece vocabulary size to 30,000 sub-words for English and French. Our models share the vocabulary and embedding modules of both source and target (Press and Wolf, 2017) since both source and target are trained in sub-word space. The shared vocabulary sizes of M30k (German to English), M30k (German to French), IWSLT, and WMT are 16645, 16074, 40807, 47940, respectively.

We generate target sentences using beam search with beam size 4 and length normalization factor (Wu et al., 2016) of 0.6. We merge the WordPiece tokens in the generated sentences (a post-processing step to create words) and use MosesDetokenizer[27] to detokenize the generated outputs. We use Moses recaser[28] to produce cased translation outputs. We use `mteval-v14.pl` script for cased BLEU evaluation.

For all models, we set positional encoding max length to 4096, dropout to 0.1, loss prediction smoothing to 0.1, and initialize the models using Xavier initialization (Glorot and Bengio, 2010). We train all models using `NoamOpt` optimizer (Rush, 2018) and perform the gradient accumulation trick (Ott et al., 2018) with one update per a number of batches (Table 8; `grad accumulation`) to simulate larger batch sizes on a single GPU.

A.2 Additional Analysis of Linguistic Aspect Integrated Machine Translation Results

In this section, we analyze the results of our aspect integrated translation experiments. We provide our analysis in two parts, one for small and medium sized datasets and the other for large ones.

For smaller datasets (containing a few hundred thousand sentence pairs or less), the broader perspective of BERT knowledge is helpful in limiting the search space for the model. So using our technique, the translation model receives more information regarding the general use cases of (locally) rare words. Linguistic aspect vectors also help the model better understand less familiar (in comparison to what is frequent in its limited size training data) syntactic structures in input sentences. This is why we believe aspect vectors can be helpful in low-resource settings.

Improving models with large amounts of data (with several million sentence pairs) is a challenging task. The best practice in training neural translation models is to initialize the embedding module with small random values and let the model search through the parameter space to find the optimal parameter settings. Extracted aspect vectors, as an external source of monolingual knowledge on the source side, are a more reasonable starting point for large models than random initialization. Integrating aspect vectors thus helps these models find a better path towards the optimal point(s) and increases the chances of the model ending up in a more desirable point in search space.

Abstract

Linguistically informed analyses of language models (LMs) contribute to the understanding and improvement of these models. Here, we introduce the corpus of Chinese linguistic minimal pairs (CLiMP), which can be used to investigate what knowledge Chinese LMs acquire. CLiMP consists of sets of 1,000 minimal pairs (MPs) for 16 syntactic contrasts in Mandarin, covering 9 major Mandarin linguistic phenomena. The MPs are semi-automatically generated, and human agreement with the labels in CLiMP is 95.8%. We evaluate 11 different LMs on CLiMP, covering n-grams, LSTMs, and Chinese BERT. We find that classifier–noun agreement and verb complement selection are the phenomena that models generally perform best at. However, models struggle the most with the *bǎ* construction, binding, and filler-gap dependencies. Overall, Chinese BERT achieves an 81.8% average accuracy, while the performances of LSTMs and 5-grams are only moderately above chance level.

1 Introduction

Language models (LMs) are crucial parts of natural language processing (NLP) systems for a large variety of tasks, including summarization, machine translation, and dialog generation. More recently, they have become popular in the form of pretrained models,[1] which are then fine-tuned on downstream tasks and often obtain state-of-the-art performance (Peters et al., 2018; Devlin et al., 2019; Conneau et al., 2020). However, which linguistic phenomena language models can or cannot learn is still poorly understood for many languages.

Resources for the syntactic evaluation of LMs, such as BLiMP (Warstadt et al., 2020) have focused mainly on English, and non-English resources currently only cover a small set of phenomena (Mueller et al., 2020; Gulordava et al., 2018; Ravfogel et al., 2018). In order to spur the analysis and subsequent improvement of LMs in Chinese, we introduce the corpus of Chinese linguistic minimal pairs (CLiMP), which can be used to evaluate LMs' knowledge of Chinese grammar.

CLiMP consists of 16 individual datasets that are semi-automatically generated from grammar templates. Each set—or *paradigm*—contains 1,000 minimal pairs (MPs). Together, they cover 9 core linguistic phenomena in Chinese. Human agreement on this corpus is 95.8%, confirming that CLiMP represents robust contrasts in Chinese grammar. High performance on CLiMP thus implies high correlation with human acceptability judgments across these phenomena.

We use CLiMP to study Chinese BERT (Devlin et al., 2019),[2] 6 LSTM (Hochreiter and Schmidhuber, 1997) LMs, and 4 5-gram LMs. We evaluate for each MP whether the LM assigns a higher probability to the grammatical or the ungrammatical sentence. Our results show that Chinese BERT is closest to human performance, achieving an 81.8% accuracy on average over all phenomena, while the performances of LSTMs and 5-grams, regardless of the training data size, are only moderately above chance level. Classifier–noun agreement and verb complement selection are the phenomena that models generally perform best at, suggesting that Chinese LMs are better at acquiring knowledge of local selectional restrictions. The *bǎ* construction, binding, and filler-gap dependencies are the phenomena models have the most difficulties with. This indicates that they struggle to learn hierarchical syntax and to identify long-distance dependencies.

---

[1] Throughout this paper, we adopt a broad definition of LMs, which includes language representation models which have been trained on a masked language modeling objective.

2 Related Work

2.1 Language Models

LMs assign probabilities to sequences of words (Jurafsky and Martin, 2009). Recently, they have become commonly used as pretrained models, which can be fine-tuned for downstream NLP tasks (Peters et al., 2018; Devlin et al., 2019; Conneau et al., 2020). Strictly speaking, LMs compute the probabilities of words based only on past context. BERT (Devlin et al., 2019), however, is trained using a masked language modeling objective: it predicts words based on past and future tokens. Wang and Cho (2019) show that BERT is a Markov random field language model that can assign sentences a pseudo-log-likelihood score, which is computed by summing the conditional log probabilities of all tokens in the sentence, as well as generate text. Shin et al. (2019) and Salazar et al. (2020) apply pseudo-log-likelihood scores to sentence ranking and LM evaluation.

2.2 Evaluation of Linguistic Knowledge

Numerous methods exist for probing syntactic knowledge of neural network models in English (Hewitt and Manning, 2019; Tenney et al., 2019), and a growing body of work evaluates the syntactic knowledge of neural models by testing whether they can judge the grammatical acceptability of sentences. One common version of this task uses MPs to evaluate LMs' linguistic knowledge (Linzen et al., 2016; Marvin and Linzen, 2018; Warstadt et al., 2020; Wilcox et al., 2018).

A MP is a pair of sentences that only differ in acceptability due to a single edit, as in (1) and (2). Native speakers can be asked to choose which sentence in each pair sounds more grammatical. Semi-automatically generating MPs can yield a larger set of controlled sentences, providing sufficient data for model evaluation (Linzen et al., 2016; Marvin and Linzen, 2018; Ettinger et al., 2018).

(1) 王鑫 把 自行车 扔 了。
Wángxīn bǎ zìxíngchē rēng le
SUBJ. BA. OBJ. V. PST.

(2) 王鑫 被 自行车 扔 了。
Wángxīn bèi zìxíngchē rēng le
SUBJ. PASS. OBJ. V. PST.
"Xin Wang was thrown away by a bike."

It is possible to model acceptability in a totally unsupervised way using LMs. The model assigns a probability to each sentence in a MP, and the one with the higher score is predicted as correct, and the model's predictions can be evaluated against human judgments (Marvin and Linzen, 2018; Warstadt et al., 2020). Supervised approaches are also possible (Warstadt et al., 2019), but can be less informative on LMs' linguistic knowledge acquisition due to the bias introduced by training on acceptability judgment labels.

Some prior work evaluates the linguistic knowledge of different non-English models (Ravfogel et al., 2018; Gulordava et al., 2018; Mueller et al., 2020). However, these efforts focus mainly on subject-verb agreement, which is absent in Chinese, and the knowledge of Chinese LMs has not yet been explicitly studied.

Finally, the linguistic abilities of English BERT have been investigated in a a lot of prior work, e.g., Clark et al. (2019); Vig (2019); Hewitt and Manning (2019). We refer the reader to Rogers et al. (2021) for an overview.

3 CLiMP

Our main contribution is CLiMP, a corpus of Chinese MPs designed to evaluate Chinese LMs. CLiMP consists of 1,000 MPs for each of 16 grammatical contrasts, covering 9 major Chinese linguistic phenomena. Example MPs for each phenomenon are shown in Table 1.

3.1 Data Generation

We generate data from grammar templates for every paradigm we incorporate. Our templates set lexical, syntactic, and semantic constraints for each paradigm, aiming at building robust contrasts and keeping the sentence length the same within each MP. We then build an annotated vocabulary, and generate sentences by sampling words from it. (1) and (2) show an MP together with the template[3] used to create it.

3.2 Vocabulary

We translate Warstadt et al.'s (2020) English vocabulary, containing 3,000 English words with morphological, syntactical, and semantic annotations. We add words and features specific to Chinese linguistic phenomena to our vocabulary, including classifiers, verb complements, action verbs, and

---

[3] The template example is only for demonstrative purposes. More information is encoded for the actual data generation.

coverbs. Our final vocabulary contains 3,456 words and 84 features.

We show the frequency of words in CLiMP's vocabulary in the Chinese Internet Corpus[4] in Figure 1. 1,055 of the words in CLiMP are within the 5,000 most frequent words in the Chinese Internet Corpus.

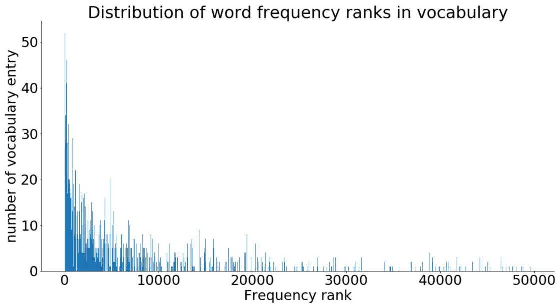

Figure 1: Comparison of word frequencies in CLiMP and the Chinese Internet Corpus.

3.3 Linguistic Phenomena

CLiMP covers 9 major linguistic phenomena in Mandarin Chinese, cf. Table 1. They are picked from a comprehensive Chinese grammar book by Po-Ching and Rimmington (2015). Following Po-Ching and Rimmington's discussion, we now explain the phenomena not present in English. The ***bǎ* construction** is an SOV construction involving the particle *bǎ*, which precedes the object and moves the object to a position before the main verb. It is only grammatical with a subset of transitive verbs. **Coverbs** are verb-like items that precede the main verb in a serial verb construction. They almost invariably have to be used in conjunction with other verbs in a sentence. They share some properties with prepositions, but are not syntactically interchangeable with them. **Classifiers** obligatorily appear with nouns when those are modified by numerals or adjectives. Mandarin has dozens of classifiers, and nouns select the classifier they combine with. **Verb complements** follow a verb, often expressing a result or manner of an event. Not all verbs can be used with all complements, making certain combinations ungrammatical. **NP head finality** is present in Mandarin noun phrases. The relative clause precedes noun phrases.

3.4 Data Validation

To verify whether the MPs in our dataset show clear contrasts, we conduct two rounds of human validation with 22 annotators. They are all native speakers of Chinese, 14 females and 8 males, whose ages range from 20 to 48. All of them have at least a high school degree.

In our first human validation, each human annotator is assigned a subset (100 MPs) of a paradigm. We let them perform the same forced-choice task as our models: decide for each MP which sentence seems more acceptable. We discard one paradigm, the coverb-direction paradigm, after this validation, because its human validation accuracy is below 85%. The average human agreement for the remaining paradigms is 95.8%.

In the second human validation, we sample 15 MPs from each of the remaining paradigm, resulting in a dataset consisting of 240 MPs. 16 annotators complete the same forced-choice task on this dataset. We count a MP as valid if more than half of the annotators agree with its label. The human agreement on this dataset is 97.1%, showing that our data creation results in valid examples.

3.5 Comparison with BLiMP

BLiMP consists of 67 datasets, each containing 1,000 MPs and organized by phenomenon into 12 categories. CLiMP only contains 16 datasets due to the less inflectional nature of Mandarin Chinese. 3 phenomena are covered by both corpora: anaphor agreement, binding, and filler-gap. The human agreement for these three phenomena in BLiMP is 97.5%, 87.3%, and 86.9%, respectively. The corresponding accuracies in CLiMP are 94.5%, 99%, and 100%, respectively. The overall human agreement for BLiMP is 88.6%, which is 7.2% lower than for CLiMP.

4 Models and Methods

We use accuracy for evaluation. A MP in CLiMP is classified correctly if a LM assigns a higher probability to the grammatical sentence than to the ungrammatical one. We evaluate statistical and neural LMs, including masked LMs. Corpora which contain 0.4M, 2M, and 21.5M sentences are used for further exploration. We also investigate the effect of different tokenizations.[5]

Chinese BERT BERT (Devlin et al., 2019) is a transformer-based neural model (Vaswani et al., 2017). Here, we evaluate Chinese BERT.[6] This

Table 1: Nine Chinese linguistic phenomena covered by CLiMP with acceptable and unacceptable sentence examples. Minimal differences are underlined. The second line of each example shows a gloss, the third line is an English translation. N represents how many paradigms (each with 1,000 examples) are within each phenomena.

model has 12 layers, 768 hidden units, 12 attention heads, and 110M parameters. The training dataset contains 25M sentences. We assign probabilities to sentences with this model by masking the words in a sentence one by one, computing the probability of each masked word, and, finally, multiplying the probabilities of all words (Wang and Cho, 2019; Salazar et al., 2020).[7]

LSTM LMs We further evaluate 6 LSTM (Hochreiter and Schmidhuber, 1997) LMs. These model have 2 layers, 200 hidden units, and 2 attention heads. We train them using Pytorch's word language model code[8] on 3 differently-sized Chinese Wikipedia corpora: 0.4M, 2M, and 21.5M sentences. We further compare word-level and character-level models (cf. Table 2). For evaluation, we employ code adapted by Warstadt et al. (2020) from Gulordava et al. (2018).[9]

***n*-gram LMs** Finally, we experiment with 4 different 5-gram LMs, which have been trained on 0.4M and 2M sentences from Chinese Wikipedia. For each corpus size, we train one word-based and one character-based LM. Those models are implemented using KenLM.[10]

5 Results

All results are shown in Table 2.

Phenomenon-specific Results Our LMs perform best on classifier–noun agreement and verb complement selection: Chinese BERT's accuracy is only 6.8% and, respectively, 3% lower than that of humans on these two phenomena. LSTMs and 5-grams remain around 30% behind humans, but still perform better on these phenomena than on others in CLiMP. This indicates that Chinese LMs acquire local selection knowledge better than the linguistic knowledge needed to master other phenomena.

Our LMs stuggle most with the *bǎ* construction, binding, and filler-gap dependencies. All models perform close to chance level for binding, suggesting that they lack the hierarchical knowledge necessary to correctly resolve the structural relationship between a reflexive and its binder. Similarly, most models perform near chance on filler-gap dependencies. This suggests that they do not robustly represent long-distance dependencies.[11]

Table 2: Percentage accuracy of all humans and models on CLiMP. Random guessing yields an accuracy of 50%. Bold numbers indicate the phenomenon each model is best at. Numbers in model names (21.5, 2, 0.4) refer to the number of sentences in the training corpus.

On the head-final construction, Chinese BERT performs surprisingly poorly as compared to the other models: only 53.1% accuracy as compared to an average accuracy of 81% by the LSTMs. The coverb construction, in contrast, is easy for Chinese BERT: it achieves 87.9% accuracy, while the highest accuracy among all other models is 47%.

Model-specific Results Comparing across models, Chinese BERT achieves by far the highest overall accuracy with 81.8%. Our different LSTMs all perform worse, but obtain surprisingly similar scores: from 60.4% to 66.0%. The performances of our *5*-grams range from 55.9% to 65.7%. Keeping tokenization and corpus size constant, three out of four *5*-grams are outperformed by LSTMs. Thus, we overall find that neural models have advantages as compared to statistical models.

Comparing among the LSTMs, we find similarly to Hu et al. (2020) that the corpus size does not have much influence on the overall performance, with the caveat that these models perform close to chance. In contrast, a larger corpus size does result in a better performance in *5*-grams. We also compare the effect of different tokenizations: Character-based *5*-grams demonstrate better performance than word-based ones. For LSTMs, however, using characters only results in a better performance for our smallest corpus size (0.4M).

Compared to English LMs (Warstadt et al., 2020), the human–model gap is much bigger for Chinese models. While neither models nor datasets are directly comparable between our and previous work, this still suggests that more analyses and developments are needed for non-English models.

6 Conclusion

We introduced CLiMP, a suite of diagnostic test sets aimed at evaluating which syntactic phenomena Chinese LMs learn, and used it to evaluate 11 different models. All LMs appeared to have learned local selectional restrictions, but struggled with argument structure alternations, hierarchical structure, and long-distance dependencies. Chinese BERT performed best on CLiMP overall. However, it obtained a 14% lower accuracy than humans, suggesting there is still much room for improvement. We hope that CLiMP will serve as a linguistically informed resource for benchmarking and analyzing future progress on Chinese LMs. CLiMP is available at `https://nala-cub.github.io/resources`.

Measuring and Improving Faithfulness of Attention in Neural Machine Translation

Abstract

While the attention heatmaps produced by neural machine translation (NMT) models seem insightful, there is little evidence that they reflect a model's true internal reasoning. We provide a measure of faithfulness for NMT based on a variety of stress tests where attention weights which are crucial for prediction are perturbed and the model should alter its predictions if the learned weights are a faithful explanation of the predictions. We show that our proposed faithfulness measure for NMT models can be improved using a novel differentiable objective that rewards faithful behaviour by the model through probability divergence. Our experimental results on multiple language pairs show that our objective function is effective in increasing faithfulness and can lead to a useful analysis of NMT model behaviour and more trustworthy attention heatmaps. Our proposed objective improves faithfulness without reducing the translation quality and has a useful regularization effect on the NMT model and even improve translation quality in some cases.

1 Introduction

How trustworthy are our neural models? This question has led to a wide variety of contemporary NLP research focusing on (a) different axes of interpretability including *plausibility* (or interchangeably *human-interpretability*) (Herman, 2017; Lage et al., 2019) and *faithfulness* (Lipton, 2018; Jacovi and Goldberg, 2020b), (b) interpretation of the neural model components (Belinkov et al., 2017; Dalvi et al., 2017; Vig and Belinkov, 2019), (c) explaining the decisions made by neural models to humans (using explanations, highlights, rationales, etc.) (Ribeiro et al., 2016; Li et al., 2016; Ding et al., 2017; Ghaeini et al., 2018; Bastings et al., 2019; Jain et al., 2020), and (d) evaluating different explanation methods from different perspectives (Samek et al., 2016; Mohseni and Ragan, 2018; Poerner et al., 2018; Jain and Wallace, 2019; Serrano and Smith, 2019; Wiegreffe and Pinter, 2019; Li et al., 2020).

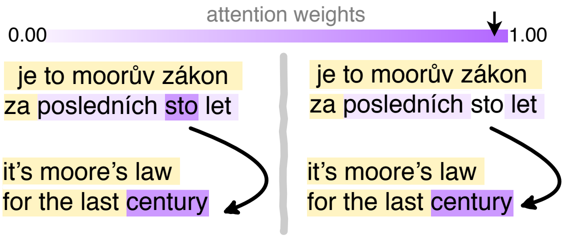

Figure 1: An example of *unfaithful* attention weights produced during a Cs-En translation. Note in the left attention heatmap, the attention is on the word sto while the decoder generates century. However, in the right heatmap, sto is not attended to at all but century is still produced as the output. This shows unfaithful behavior.

All of these approaches make NLP neural models more trustworthy. In this work, we focus on faithfulness which intuitively provides the extent to which an explanation accurately represents the true reasoning behind a prediction. It is particularly important for NLP practitioners who wish to debug their neural models and improve them. Faults of a neural model cannot be identified if the neural model does not provide a faithful and trustworthy description of what it is doing.

However, the formal definition of faithfulness and the proper approach to its evaluation are still contended in the literature. Jacovi and Goldberg (2020b) emphasize distinguishing faithfulness from human-interpretability in interpretability research by providing several clarifications about the terminology used by researchers. They describe the following conditions on the evaluation of how well a research project tackles the notion of faithfulness:

- Be explicit: provide a measurable evaluation of faithfulness.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2791–2802
April 19 - 23, 2021.

- Human judgements are not relevant because we are interested in model internals.
- Do not match against gold labels (e.g. AER) because faithfulness of both correct and incorrect decisions made by the model are equally important.
- No model is "inherently" faithful. We need to measure faithfulness not as a binary aspect of a model (it is faithful or not) but rather as a gray-scale measure.
- A more faithful system is a necessary but not sufficient condition for model interpretation by humans, c.f. Jacovi and Goldberg (2020a).

Aligned with these criteria, we study faithfulness of NLP neural models, specifically NMT models. We provide a faithfulness measure that is computed based on a variety of stress tests where attention weights that are crucial for prediction are perturbed. We expect from a faithful model to change its prediction under such tests (Figure 1). We quantify faithfulness based on how often the model outputs changed. The proposed metric is defined based on discrete changes in the output. It is not differentiable and cannot be simply included in the loss function of NMT to be optimized. We propose a novel differentiable objective based on probability divergence and study its effect on the discrete faithfulness measure. Our findings show that our objective is effective in increasing faithfulness and can lead to a useful analysis of NMT model behaviour and more trustworthy attention heatmaps. We assert that faithfulness is a good property to have in a model whether or not it will be useful for downstream interpretation. A model that is faithful can be trusted better as a component in a larger end-to-end neural model.

Contributions We seek to improve faithfulness of NMT models. To this end, we make the following contributions in this work:

- We propose a measure for quantifying faithfulness in NMT.
- We introduce a novel learning objective based on probability divergence that rewards faithful behavior and which can be included in the training objective for NMT.
- We provide empirical evidence that we can improve faithfulness in an NMT model. Our approach results in more a more faithful NMT model while producing better BLEU scores.[1]

We chose to study the impact of faithfulness in NMT because it is under-studied in terms of interpretability. Most previous work has focused on document or sentence-based classification tasks where attention models are not as directly useful as in NMT models. Attention is also more challenging in terms of faithfulness in the context of NMT models due to the substantial impact of the decoder component. While Transformers (Vaswani et al., 2017) generally produce better NMT models, they rely on multiple heads for attention. Defining an *overall* faithfulness measure in this case is challenging as different heads possibly have different faithfulness. Before addressing this more complicated problem, we first focus on the simpler single-head attention models. However, we expect larger and overparameterized models to get worse in terms of faithfulness because the language model in the decoder gets stronger in guessing the next word which, as we shall discuss in more detail later, tends to make attention less faithful.

2 Faithfulness in NMT Models

Intuitively, a faithful explanation should reflect the true internal reasoning of the model. Although there is no formal definition for faithfulness, a common approach in the community is to design stress tests to perturb the model parameters chosen in such a way that the model's decision should change if the model is faithful (Jacovi and Goldberg, 2020b). A common stress test is the *erasure* test in which the most-relevant part of the input is removed (Arras et al., 2017). In the context of NMT, at decoding time step t the attention component assigns attention weights α_t, attending to the source word at position $m_t = \text{argmax}_i \, \alpha_t[i]$ (or the k-best attended-to words in the source). These weights are often implicitly or explicitly regarded as an interpretation for the model's prediction at the time step t (Tu et al., 2016; Mi et al., 2016; Liu et al., 2016; Wang et al., 2016; Lee et al., 2017; Ding et al., 2017; Ghaeini et al., 2018). The erasure stress test for evaluating faithfulness offered by α_t is done by setting $\alpha_t[m_t]$ to zero and observing whether or not the output changes. It is worth noting that erasure is only one of the possible stress tests for evaluating faithfulness. Passing

---

[1] Our code is available at `https://github.com/sfu-natlang/attention_regularization`

more stress tests implies a more faithful model as it is properly reacting to more adversaries by changing its decision. In this paper we consider three intuitive stress test cases:

ZeroOutMax: (Arras et al., 2017): Here we remove attention from the most important token according to the attention weights by setting $\alpha_t[m_t] = 0$.

Uniform: (Moradi et al., 2019): In this stress test all attention weights are set to be equal, $\alpha_t = \frac{1}{m}\vec{1}$, where m is the length of the source sentence. This is to confuse the model about which part of the input is the most important one.

RandomPermute: (Jain and Wallace, 2019): In this stress test we randomly permute attention weights several times until a change in the model output is observed. We ensure that m_t, the most important token according to attention, is always changed. We set $\alpha'_t = \texttt{random\_permute}(\alpha_t)$ such that $\text{argmax}_i\, \alpha'_t[i] \neq m_t$

Many prior studies of attention (Jain and Wallace, 2019; Wiegreffe and Pinter, 2019) have used a binary measure: either attention is faithful or it is not. These studies typically are about whether attention has the potential to be useful in terms of accuracy and faithful in terms of model behaviour. In many cases, especially in the case of NMT models, attention is clearly useful and by and large it must be faithful. The question is can we measure the faithfulness and improve faithfulness. It is more natural to have a gray-scale notion of faithfulness for evaluation (Jacovi and Goldberg, 2020b). Following this reasoning, we define $F(M)$ as faithfulness of attention heatmaps in model M as the following equation:

$$F(M) = \frac{\text{\# tokens passing stress tests}}{\text{\# tokens}} \tag{1}$$

$F(M)$ is a number between 0 to 1 measuring the percentage of output tokens during inference which passed the stress tests, i.e., they changed in the presence of adversarial attention. This metric can also be regarded as a measure of trust we can assign to the attention heatmap to fully reflect the internal reasoning of the NMT model.

3 Approach

The conventional objective function in a sequence-to-sequence task is a cross-entropy loss $\mathcal{F}_{acc}$:

$$\mathcal{F}_{acc}(\theta) = -\frac{1}{|S|} \sum_{(X,Y)\in S} \log p(Y|X;\theta) \tag{2}$$

where S is the training data and X and Y are source sentence and the correct translation respectively. This training objective does not explicitly model the interpretability aspects (e.g. faithfulness) of the network and it remains unoptimized during training.

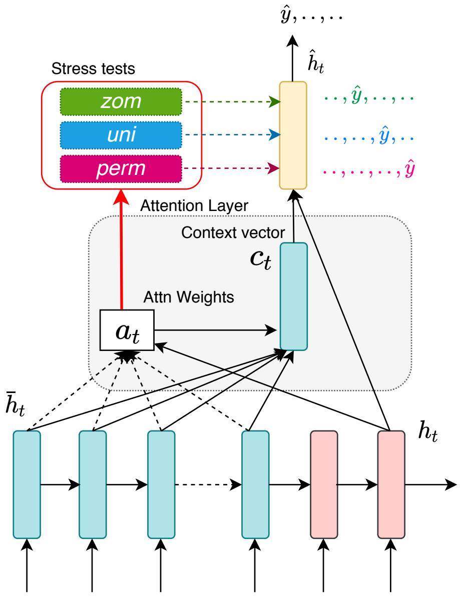

Figure 2: Using *ZeroOutMax, Uniform,* and *RandomPermute* stress tests, we generate adversaries to the attention weights. When adversarial attention weights are used, in a faithful model we expect the probability of the original output ($\hat{y}$) to drop significantly. We use this criterion to define a faithfulness objective function.

Faithfulness Objective In an effort to develop a model that is *right for right reason*, Ross et al. (2017) change the loss function of their classifier to model both *right answers* and *right reasons* instead of only the former. They achieve this by introducing a regularizing term that tends to shrink irrelevant gradients. In a similar spirit, we change our objective to account for the NMT model's faithfulness as well as the cross-entropy score against the reference translations:

$$\mathcal{F} = \mathcal{F}_{acc} + \lambda_{faith}\mathcal{F}_{faith} \tag{3}$$

$\mathcal{F}_{faith}$ is an additional component that rewards the model for having more faithful attention. The parameter λ_{faith} regulates the trade-off between faithfulness and accuracy objectives. Our proposed metric for faithfulness is calculated based on discrete changes in the output under adversarial attention. It is not differentiable and cannot be simply used as $\mathcal{F}_{faith}$ to be optimized. Thus, we propose a novel differentiable objective which mimics a faithful behavior hoping it improves the discrete faithfulness metric.

While here we intend to improve faithfulness using adversarial attention weights, it is important to note that making the *model* more *robust* is *not* our main goal. Robustness of a model is its resilience against adversarial input or small perturbations such as typos. Whether or not our approach results in a more robust model is a separate research question that we have not focused on.

3.1 Divergence-based Faithfulness Objective

Consider a predictive model g_θ in which an intermediate calculation is later employed to justify predictions:

$$\hat{y} = \arg\max_y p(y|x) = \arg\max_y g_\theta(x, IC(x), y) \tag{4}$$

where $IC(x)$ is the intermediate calculation on the input. A concrete example for $IC(x)$ would be the context vector calculated by the attention mechanism.

Hypothesis If there exists an intermediate calculation $IC'(x)$ that conveys a contradictory post-hoc attention compared to $IC(x)$, then $IC(x)$ cannot be regarded as faithful for predicting $\hat{y}$. If $IC(x)$ is faithful, we expect the model to *diverge* from predicting $\hat{y}$ when $IC'(x)$ is employed instead.

Based on our hypothesis, we propose a divergence-based objective which mimics behavior of a faithful explanation under stress test:

$$\mathcal{F}_{faith} = \log p(\hat{y}|x, IC'(x)) \tag{5}$$

This objective is a negative loss that should be minimized. The minimum of this objective is achieved when the probability of the original prediction approaches zero under the stress test which is the ideal. Thus, it promotes reduction in output probability under an adversarial intermediate calculation (Figure 2). It is worth noting that this objective can be potentially employed in models where outputs are modeled as soft probabilities and thus is not limited to NMT. To put model under various stress tests we manipulate the context vector during training time by changing the attention weights and feed it to the decoder to calculate the probability. More precisely:

$$\begin{aligned}\mathcal{F}_{faith} = \lambda_{zom} \log p(\hat{y}|x, IC'_{zom}(x)) \\ + \lambda_{uni} \log p(\hat{y}|x, IC'_{uni}(x)) \\ + \lambda_{perm} \log p(\hat{y}|x, IC'_{perm}(x))\end{aligned} \tag{6}$$

where IC'_{zom}, IC'_{uni} and IC'_{perm} are *ZeroOutMax*, *Uniform* and *RandomPermute* methods (see Sec. 2) to manipulate attention weights, respectively. $\lambda_{\{method\}}$ parameters regulate the contribution of each objective. We use the term $\mathcal{F}_{all}$ when all $\lambda_{\{method\}}$s in Eq. (6) are non-zero. Moreover, we use the term $\mathcal{F}_{\{method\}}$ when $\lambda_{\{method\}}$ is set to 1 and other regularization weights are zero.

3.2 On Attention Sparsity

Do the models trained with the faithfulness objective have sparser attention weights? Sharper attention in a model M might correlate with an intensified contribution of the most-attended source hidden state on the prediction resulting in higher faithfulness.

To measure sparseness of the attention, we take an average over the normalized entropy of attention distribution for each output token during inference on test data. We use normalized entropy which is in range [0,1] to account for the fact that the range of the entropy for each output token depends on the length of the corresponding source sentence.

$$AvgEnt = \frac{1}{\sum_{i=1}^{|S|} \left|\hat{Y}_i\right|} . \sum_{i=1}^{|S|} \sum_{j=1}^{\left|\hat{Y}_i\right|} NormEnt(\alpha_{ij}) \tag{7}$$

$$NormEnt(P) = -\sum_i \frac{P_i \log P_i}{\log N} \tag{8}$$

Here α_{ij} is the attention distribution for the output token j in the generated translation of source sentence i, and P is a discrete probability distribution. In Eq. (8) low entropy indicates a sharper distribution.

Attention Entropy Regularization Alongside investigating sparsity of the models trained by the faithfulness objective, we also train a model in which sparsity in attention is directly optimized. We used attention entropy regularization (Zhang et al., 2018):

$$\mathcal{F}_{ent} = \mathcal{F}_{acc} + \lambda_{ent} \sum_{i=1}^{|S|} \sum_{j=1}^{\left|\hat{Y}_i\right|} Ent(\alpha_{ij}) \tag{9}$$

where entropy of attention weights is added to the cross-entropy loss (2) as a regularization term.

4 Experimental Setup

4.1 Datasets

We use the Czech-English (Cs-En) dataset from IWSLT2016[2] and the German-English (De-En) dataset from IWSLT2014[3]. For the Czech-English dataset we use dev2010, tst2010, tst2011, tst2012, and tst2013 as the test data. For the German-English dataset we use dev2010, tst2010, tst2011, dev2012, and tst2012 as the test data. We used Moses (Koehn et al., 2007) to tokenize the dataset.

4.2 Architecture and Hyperparameters

We use OpenNMT (Klein et al., 2017) as our translation framework. We employ a 2 layer LSTM-based encoder-decoder (Sutskever et al., 2014; Cho et al., 2014) model with global attention (Luong et al., 2015). Dimension of the hidden states and the word embeddings for both source and target languages are set to 500. Vocabulary size for both the source and target language is set to 50000. We remove sentences with more than 50 tokens from the training data. We use Adam (Kingma and Ba, 2014) for training our models and we set the learning rate to 0.001. Models are trained until convergence. Our models have around 82M parameters. We optimize the hyperparameters of our models using the validation set. The baseline model is trained using Eqn. (2) and we call it $\mathcal{F}_{baseline}$. λ_{ent} in Eq. (9) is set to 0.04. We refer to the objective as $\mathcal{F}_{all}$ when λ_{zom}, λ_{uni}, and λ_{perm} are set to 0.5, 0.375, and 0.125 respectively. λ_{faith} is set to 1.

4.3 Training Difficulties

Our first attempts at using the modified objective function in Eq. (3) trained poorly. We observed that it was difficult for the model to learn the faithfulness constraint without having already learned to assign a reasonable probability to correct translations. To address this problem, we first train the NMT model using the standard unmodified objective function and then fine-tune this trained model by switching the objective function to Eq. (3).

One caveat is that the value of faithfulness loss can be arbitrarily large and interfere with the learning because cross-entropy error converge to infinity as the probability approaches to zero. However, we found that as long as the original output token received a small probability, there was no need for further reduction in it. Empirically, we clip losses more than 2.5 to 2.5 for each output token.

5 Results and Discussion

5.1 Impact on Faithfulness

To measure the effectiveness of the proposed objectives, we choose the best model in terms of provided faithfulness but within the 0.5 BLEU score of the maximum achieved BLEU score in the validation set. The reason is that we prefer a model that is both accurate and with faithful attention-based explanations. Table 1 shows the performance of the different faithfulness objective functions when generating content words and function words across different attention manipulation methods in the Czech-English (Cs-En) and German-English (De-En) datasets.

Results indicate that the proposed divergence-based objective has been effective in increasing the faithfulness metric. $\mathcal{F}_{all}$ is the most effective objective for increasing faithfulness when all stress tests are included in Eq. (1). When using $\mathcal{F}_{all}$, faithfulness of attention-based explanations for content words is increased 78% to 89%, while that of the function words is from 33% to 82%(see *All* column in Table 1). The same reductions are from 76% to 89% for content works and from 32% to 86% for function words in De-En dataset. These results establish the effectiveness of our proposed objectives to increase the faithfulness metric.

It is worth noting that increase in faithfulness of attention-based explanations for function words is much more than that of content words. This can be attributed to the fact the function words are mostly generated using the target-side information in the decoder (Tu et al., 2017; Moradi et al., 2019) and manipulating attention does not have much effect on generating them. However, our proposed faithfulness objective ($\mathcal{F}_{faith}$) seems to tighten the dependence of the decoder on the attention component. This results in much more increase in faithfulness for function words compared to such content words.[4] We also plot faithfulness over different

---

[3] https://sites.google.com/site/iwsltevaluation2014/

[4] If this dependence is not desired, it is possible not to penalize function words in the faithfulness objective. However, relying on attention for generating function words can be helpful, not necessarily for interpretability but for dealing with long-range dependencies (Vaswani et al., 2017) and, as a result, better translations.

	Objective	Content Words				Function Words			
		ZOM	*Uniform*	*RandPerm*	*All*	*ZOM*	*Uniform*	*RandPerm*	*All*

5.2 Effect of Training With Single Adversary on Passing Other Stress Tests

An interesting observation in Table 1 is that training with an adversary has positive effects on the model for passing stress tests from other types of adversaries. As an example, in Table 1 the column *Uniform* is the faithfulness metric when only Uniform test is employed in Eq. (1). When using this metric, we can observe that training a model with $\mathcal{F}_{perm}$ increased faithfulness from 90% to 95% for content words and from 48% to 97% for function words. We can see such effect for the German-English dataset as well. This observation indicates that training with each adversary can be beneficial for making model tolerant against other types of stress tests. It seems that training with each adversary strengthens the dependence of the decoder on the attention component which can be beneficial for passing other stress tests.

5.3 POS-tag Analysis

In addition to categorizing tokens into function and content words, we also analyze the effect of our proposed objective within different universal part-of-speech (POS) tags (Petrov et al., 2012) in Table 2. Our proposed objective has increased faithfulness in each POS tag and in our both datasets. Tokens with less lexical meaning are the ones affected the most as explained in Sec. 5.1. As expected, punctuations (PUNC) and particles (PRT) tags have benefited the most from increase in the faithfulness. Interestingly numbers (NUM tag) have the lowest increase in faithfulness. One reason might be that they already had a high initial faithfulness and this has made further increase less likely.

	De-En		**Cs-En**	
Tag	Baseline	Ours	Baseline	Ours
PUNC	0.19	**0.70**	0.28	**0.66**
PRON	0.42	**0.78**	0.35	**0.75**
VERB	0.47	**0.80**	0.50	**0.81**
ADP	0.30	**0.75**	0.40	**0.65**
DET	0.35	**0.74**	0.38	**0.70**
PRT	0.13	**0.63**	0.17	**0.50**
ADV	0.66	**0.80**	0.63	**0.79**
NOUN	0.63	**0.87**	0.64	**0.85**
ADJ	0.68	**0.87**	0.69	**0.85**
NUM	0.84	**0.86**	0.79	**0.86**
X	0.67	**0.78**	0.55	**0.80**

Table 2: Faithfulness metric within different part-of-speech (POS) tags.

5.4 Regularization Effect

The model checkpoints used in Tables 1 were selected based on maximum increase in faithfulness without sacrificing accuracy. To investigate if the proposed objective can have a general positive side effect in terms of accuracy, we train three independent models using the $\mathcal{F}_{baseline}$ and $\mathcal{F}_{all}$ objectives.

To make it fair for the baseline, we also add additional steps of training for the baseline model as well to isolate the benefit of adding the faithfulness objective. Table 3 contains the average BLEU score of the trained models. It indicates that the model trained with $\mathcal{F}_{all}$, has +0.7 and +0.4 increase in BLEU score compared to the baseline for the Czech-English and German-English language pairs respectively.

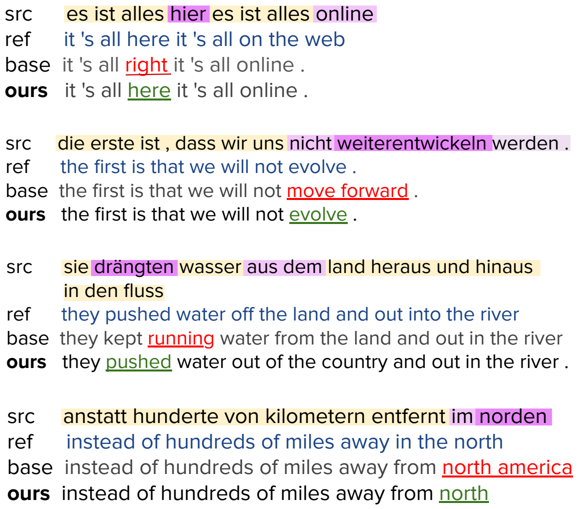
	Objective	BLEU%
Cs-En	$\mathcal{F}_{baseline}$	19.68
	$\mathcal{F}_{all}$	**20.4**
De-En	$\mathcal{F}_{baseline}$	24.85
	$\mathcal{F}_{all}$	**25.21**

Table 3: BLEU score of the baseline and the model trained with $\mathcal{F}_{all}$. Pairwise bootstrap resampling (Koehn, 2004) resulted in a p-value < 0.01 which indicates the statistical significance of the observed difference.

Improved BLEU scores for the faithful model can be due to two reasons: 1) the faithfulness objective can be seen as a regularization term which prevents the model from relying too much on the target-side context and the implicit language model in the decoder, which results in increased contribution of attention on the decoder and reducing some bias in the model. 2) penalizing the model for the lack of connection between justification and prediction forces the model to learn better translations by forcing it to justify each output in a *right answer for the right reason* paradigm. Figure 4 shows some examples of how our proposed model can produce better translations.

5.5 Do the New Models Have Sparser Attention?

Table 4 shows the average entropy and average normalized entropy for the baseline, the proposed model ($\mathcal{F}_{all}$), and the model trained with attention entropy regularization respectively. Evidently, the proposed model has not increased sparsity. On the other hand attention entropy regularization has been very effective in making attention weights sparser. But Table 1 indicates that attention entropy regularization has not been effective in increasing faithfulness. This suggests that sharper attention weights only affect the context vector and do not contribute to increased dependence of the decoder on attention.



src es ist alles hier es ist alles online
ref it 's all here it 's all on the web
base it 's all right it 's all online .

ours instead of hundreds of miles away from north

Figure 4: These examples show some cases where the more faithful model trained using our faithfulness objective produces better translations compared to the baseline model. In each of these cases, perturbing the attention weights has no effect on the baseline model output. The faithful model is able to focus on the source side when needed in order to produce a more accurate translation.

6 Related Work

Attention and Different Axes of Interpretability While several studies have focused on understanding the semantic notions captured by attention (Ghader and Monz, 2017; Vig and Belinkov, 2019; Clark et al., 2019), evaluating attention as an interpretability approach has garnered a lot of interest. From the faithfulness perspective, (Jain and Wallace, 2019; Serrano and Smith, 2019) show that for instances in a data set there can be adversarial attention heatmaps that do not change the output of the text classifier. In other words, adversarial attention leads to no decision flip in each instance. They use this to claim that attention heatmaps are not to be trusted, or unfaithful. Wiegreffe and Pinter (2019) argue against per-instance modifications at test time for two reasons: 1) in classification tasks attention may not be useful so perturbing attention is misleading. This is not true for NMT since attention is very useful in NMT. 2) they train an adversarial attention model (e.g. uniform attention) chosen to produce attention weights distant from the original attention weights while at the same time trying to minimize classification error. They show that such adversarial attention models are not as accurate as models with attention. In our work we acknowledge that attention is useful and faithful to some extent and we aim to improve faithfulness of NMT models.

While most of these works provide evidence that attention weights are not always faithful, Moradi et al. (2019) confirm similar observations on the unfaithful nature of attention in the context of NMT models. Li et al. (2020) is one of the few papers examining attention models in NMT. However, they are focused on the task of identifying relevant source words to explain the output translations selected by the NMT model. They look for optimal proxy models that agree with the NMT model such that the relevant source words picked as an explanation by a proxy model exhibits similar behaviour to the target model. They use the notion of *fidelity* over proxy models and evaluate several alternative proxy models using empirical risk minimization. Attention weights are evaluated alongside other proxy models for this task. In contrast, our work is about improving the faithfulness of NMT models and we focus on the internal state of the NMT model rather than proxy models. They use human references, e.g. AER, for evaluating fidelity. As discussed earlier, evaluation of faithfulness cannot involved human judgements or reference data. It is possible that our faithful NMT models are also better at fidelity, but that is an open question.

While prior works have mostly failed to explicitly distinguish faithfulness from plausibility in their arguments, Jacovi and Goldberg (2020a,b) focus on formalizing faithfulness and addressing evaluation of faithfulness separately from plausibility respectively. Subramanian et al. (2020) have investigated the concept of faithfulness in neural modular networks (NMN) which are employed for modeling compositionality. They question the faithfulness of the structure of the network modules describing the true abstract reasoning of the model. Similar to us, they attempt to quantify faithfulness and improve upon it. However their contributions like training with an auxilary atomic-task supervision for improved faithfulness are specific to the context of NMNs. Pruthi et al. (2020) demonstrate that it is possible to train a model that produces a deceptive attention mask, questioning the use of attention weights as explanation from the fairness and accountability perspective. Alvarez-Melis and Jaakkola (2018) investigate the interpretability methods from the robustness perspective. They attempt to quantify robustness and show that current interpretability methods cannot be considered as robust.

Sparsity For Improved Interpretability This line of work suggests making attention sparser so that the most contributing input word is more distinguishable over other input words. Martins and Astudillo (2016); Malaviya et al. (2018) propose sparse but differential alternatives to *softmax* function for calculating attention weights, while Zhang et al. (2018) propose sparsity regularization terms such as entropy regularization to promote sparsity in the attention.

Regularizing Explanations Ross et al. (2017) augment the loss function of their classification model with an explanation objective to constrain input gradient explanations. Rieger et al. (2019) follow a similar spirit but they use *contextual decomposition* (Murdoch et al., 2018) to extract explanations offered by the model. Aligning attention (as explanation) with prior knowledge has also been extensively studied. This prior knowledge can include alignment data (Mi et al., 2016; Liu et al., 2016), human rationales (Zhong et al., 2019), or even structural biases (Cohn et al., 2016).

Inherently Interpretable Neural Models Contrary to post-hoc explanation methods for interpreting a neural model, Stahlberg et al. (2018) show that the NMT model can be made self-explanatory by training it to produce the discrete decisions made by the model (from which the translations can be extracted later). In another work, (Lei et al., 2016; Bastings et al., 2019) propose models in which first a rationale is selected from the input and then is further used for prediction.

7 Conclusion

We proposed a method for quantifying faithfulness of NMT models. To optimize faithfulness we have defined a novel objective function that rewards faithful behavior through probability divergence. We also show that the additional constraint in the training objective for NMT does not harm translation quality and in some cases we see some better translations presumably due to the regularization effect of our faithfulness objective.

Future Work We aim to investigate and improve faithfulness of attention-based explanations in more sophisticated attention models such as Transformers (Vaswani et al., 2017). We can generalize our approach by designing explanatory modules in NMT through functionality separation (alignment, reordering, etc.) instead of relying only on attention. We also plan to investigate if faithful models can also be more useful for copy models and other applications of attention heatmaps in NMT.

Progressively Pretrained Dense Corpus Index for Open-Domain Question Answering

Wenhan Xiong*, **Hong Wang***, **William Yang Wang**
University of California, Santa Barbara
`{xwhan, hongwang600, william}@cs.ucsb.edu`

Abstract

Commonly used information retrieval methods such as TF-IDF in open-domain question answering (QA) systems are insufficient to capture deep semantic matching that goes beyond lexical overlaps. Some recent studies consider the retrieval process as maximum inner product search (MIPS) using dense question and paragraph representations, achieving promising results on several information-seeking QA datasets. However, the pretraining of the dense vector representations is highly resource-demanding, *e.g.*, requires a very large batch size and lots of training steps. In this work, we propose a sample-efficient method to pretrain the paragraph encoder. First, instead of using heuristically created pseudo question-paragraph pairs for pretraining, we use an existing pretrained sequence-to-sequence model to build a strong question generator that creates high-quality pretraining data. Second, we propose a simple progressive pretraining algorithm to ensure the existence of effective negative samples in each batch. Across three open-domain QA datasets, our method consistently outperforms a strong dense retrieval baseline that uses 6 times more computation for training. On two of the datasets, our method achieves more than 4-point absolute improvement in terms of answer exact match.

1 Introduction

With the promise of making the vast amount of information buried in text easily accessible via user-friendly natural language queries, the area of open-domain QA has attracted lots of attention in recent years. Existing open-domain QA systems are typically made of two essential components (Chen et al., 2017). A *retrieval module* first retrieves a compact set of paragraphs from the whole corpus (such as Wikipedia) that includes millions of documents. Then a *reading module* is deployed to extract an answer span from the retrieved paragraphs.

Over the past few years, much of the progress in open-domain QA has been focusing on improving the reading module of the system, which only needs to process a small number of retrieved paragraphs. Specifically, improvements include stronger reading comprehension models (Wang et al., 2018b; Yang et al., 2019; Xiong et al., 2020; Min et al., 2019a) and paragraph reranking models (Wang et al., 2018a; Lin et al., 2018) that assign more accurate relevance scores to the retrieved paragraphs. However, the performance is still bounded by the retrieval modules, which simply rely on traditional IR methods such as TF-IDF or BM25 (Robertson and Zaragoza, 2009). These methods retrieve text solely based on n-gram lexical overlap and can fail on cases when deep semantic matching is required and when there are no common lexicons between the question and the target paragraph.

While neural models have proven effective at learning deep semantic matching between text pairs (Bowman et al., 2015; Parikh et al., 2016; Chen et al., 2018; Devlin et al., 2019), they usually require computing question-dependent paragraph encodings (*i.e.*, the same paragraph will have different representations when considering different questions), which is formidable considering space constraints and retrieval efficiency in practice. More recent studies (Lee et al., 2019; Chang et al., 2020; Guu et al., 2020) show that such a dilemma can be resolved with large-scale matching-oriented pretraining. These approaches use separate encoders for questions and paragraphs and simply model the matching between the question and paragraph using inner products of the output vectors. Thus, these systems only need to encode all paragraphs in a question-agnostic fashion, and the resulted dense corpus index could be fixed and reused

April 19 - 23, 2021.

for all possible questions. While achieving significant improvements over the BM25 baseline across a set of information-seeking QA datasets, existing pretraining strategies are highly sample-inefficient and typically require a large batch size (up to thousands), such that diverse and effective negative question-paragraph pairs could be included in each batch. When using a small batch size in our experiments, the model ceases to improve after certain updates. Given that a 12G GPU can only store around 10 samples with the BERT-base architecture at training time, the wider usage of these methods to corpora with different domains (*e.g.*, non-encyclopedic web documents or scientific publications) is hindered given modest GPU hardware.

In this work, we propose a simple and sample-efficient method for pretraining dense corpus representations. We achieve stronger open-domain QA performance compared to an existing method (Lee et al., 2019) that requires 6 times more computation at training time. Besides, our method uses a much smaller batch size and can be implemented with only a small number of GPUs, *i.e.*, we use at most 4 TITAN RTX GPUs for all our experiments. In a nutshell, the proposed method first uses a pretrained sequence-to-sequence model to generate high-quality pretraining data instead of relying on heuristics to create pseudo question-paragraph pairs; for the training algorithm, we use clustering techniques to get effective negative samples for each pair and progressively update the clusters. Our method's efficacy is further validated through ablation studies, where we replicate existing methods that use the same amount of resources. For the downstream QA experiments, we carefully investigate different finetuning objectives and show the different configurations of the retrieval and span prediction losses have nontrivial effects on the final performance. We hope this analysis could save the efforts on trying out various finetuning strategies of future research that focus on improving the retrieval component of open-domain QA systems.

The main contributions of this work include:

- We show the possibility of pretraining an effective dense corpus index for open-domain QA with modest computation resources.

- Our data generation strategy demonstrates that pretrained language models are not only useful as plug-and-play contextual feature extractors: they could also be used as high-quality data generators for other pretraining tasks.

- We propose a clustering-based progressive training paradigm that improves the sample-efficiency of dense retrieval pretraining and can be easily incorporated into existing methods.

2 Framework

We begin by introducing the network architectures used in our retrieval and reading comprehension models. Next, we present how to generate high-quality question-paragraph pairs for pretraining and how we progressively train the retrieval model with effective negative instances. Finally, we show how to finetune the whole system for QA.

2.1 Model Architectures

Notations We introduce the following notations which will be used through our paper. The goal of open-domain QA is to find the answer derivation (p, s) from a large text corpus $\mathcal{C}$ given a question q, where p is an evidence paragraph and s is a text span within p. The start and end token of s are denoted as $\mathrm{START}(s)$ and $\mathrm{END}(s)$ respectively. We refer the retrieval module as $\mathrm{P}_\theta(p|q)$, with learnable parameters θ. Similarly, we refer the reading comprehension module as $\mathrm{P}_\phi(s|p,q)$, which can be decomposed as $\mathrm{P}_\phi(\mathrm{START}(s)|p,q) \times \mathrm{P}_\phi(\mathrm{END}(s)|p,q)$. We use D^k to represent the top-k paragraphs from the retrieval module; a subset of $D^* \in D^k$ represents the paragraphs in D^k that cover the correct answer; for each paragraph $p \in D^*$, we define S_p^* as all the spans in p that match the answer string.

The Retrieval Module We uses two isomorphic encoders to encode the questions and paragraphs, and the inner product of the output vectors is used as the matching score. The encoders are based on the BERT-base architecture. We add linear layers $\mathbf{W}_q \in \mathbb{R}^{768\times 128}$ and $\mathbf{W}_p \in \mathbb{R}^{768\times 128}$ above the final representations of the [CLS] token to derive the question and paragraph representations:

$$\begin{aligned} h_q &= \mathbf{W}_q \mathrm{BERT}_Q(q)([\mathrm{CLS}]) \\ h_p &= \mathbf{W}_p \mathrm{BERT}_P(p)([\mathrm{CLS}]), \end{aligned}$$

The matching score is modeled as $h_q^\top h_p$. Thus, the probability of selecting p given q is calculated as:

$$\mathrm{P}_\theta(p|q) = \frac{e^{h_q^\top h_p}}{\sum_{p' \in \mathcal{C}} e^{h_q^\top h_{p'}}}.$$

In practice, we only consider the top-k retrieved paragraphs $\mathcal{C}$ for normalization.

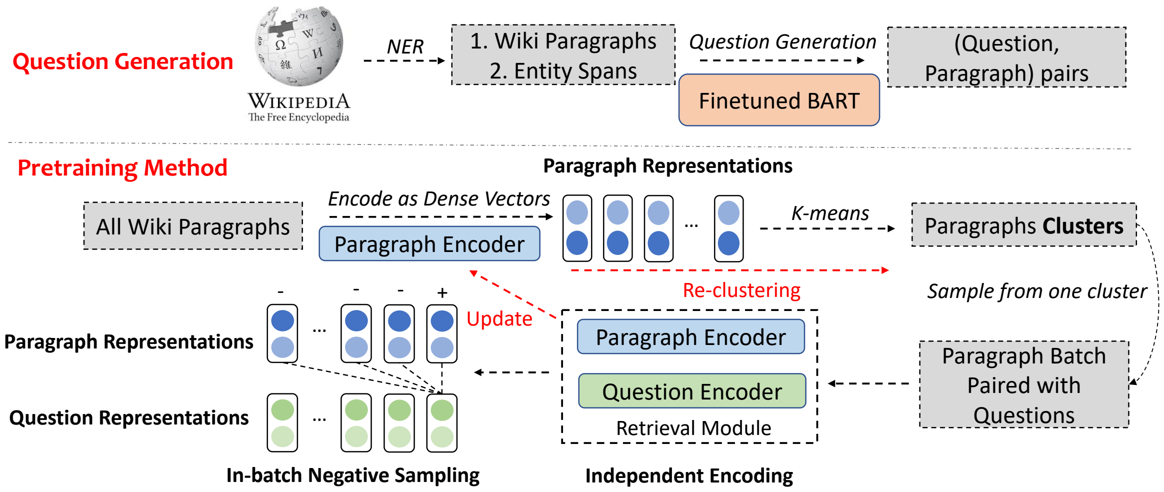

Figure 1: An overview of the progressive pretraining approach.

The Reading Module The architecture of our reading comprehension model is identical to the one in the original BERT paper (Devlin et al., 2019). We use two independent linear layers to predict the start and end position of the answer span. At training time, when calculating the span probabilities, we apply the shared-normalization technique proposed by Clark and Gardner (2018), which normalizes the probability across all the top-k retrieved paragraphs. This encourages the model to produce globally comparable answer scores. We denote this probability as $\mathrm{P}_{\phi}^{sn}(s|p,q)$ in contrast to the original formulation $\mathrm{P}_{\phi}(s|p,q)$ that normalizes the probability within each paragraph.

2.2 The Pretrainining Method

We now describe how to pretrain the retrieval module using a better data generation strategy and a progressive training paradigm. Figure 1 depicts the whole pretraining process.

Pretraining Data Generation Previous dense retrieval approaches usually rely on simple heuristics to generate synthetic matching pairs for pretraining, which do not necessarily reflect the underlying matching pattern between questions and paragraphs. To minimize the gap between pretraining and the end task, we learn to generate high-quality questions from the paragraphs using a state-of-the-art pretrained seq2seq model, *i.e.*, BART (Lewis et al., 2019). More specifically, we finetune BART on the original NaturalQuestions dataset (Kwiatkowski et al., 2019) such that it learns to generate questions given the groundtruth answer string and the groundtruth paragraph (labeled as *long answer* in NaturalQuestions). We concatenate the paragraph and the answer string with a separating token as the input to the BART model. We find this simple input scheme is effective enough to generate high-quality questions, achieving a 55.6 ROGUE-L score on the dev set. Samples of the generated questions could be found in the appendix. Afterward, we use spaCy[1] to recognize potential answer spans (named entities or dates) in all paragraphs in the corpus and use the finetuned BART model to generate the questions conditioned on the paragraph and each of the potential answers.

It is worth noting that the groundtruth answer paragraph supervision at this step could be eventually dropped and we could just use weakly supervised paragraphs to train the question generator; thus, our system becomes fully weak-supervised. As the pretraining process takes a long training time and lots of resources, we are unable to repeat the whole pretraining process with the weakly-supervised question generator. However, additional question generation experiments suggest that while using weakly-supervised paragraphs, the question generator still generates high-quality questions, achieving a ROUGE-L score of 49.6.[2]

In-batch Negative Sampling To save computation and improve the sample efficiency of pretraining, we choose to use in-batch negative sampling (Logeswaran and Lee, 2018) instead of gathering negative paragraphs for each question to pre-

---

[1] `https://spacy.io`

[2] For reference, a state-of-the-art QG model (Ma et al., 2020) trained with strong supervision achieves 49.9 ROUGE-L on a similar QA dataset also collected from real-user queries.

train the retrieval module. Specifically, for each pair (q, p) within a batch B, the paragraphs paired with other questions are considered negative paragraphs for q. Thus, the pretraining objective for each generated question is to minimize the negative log-likelihood of selecting the correct p among all paragraphs in the batch:

$$\mathcal{L}_{pre} = -\log \mathrm{P}_\theta(p|q). \tag{1}$$

A graphic illustration of this strategy is shown in Figure 1. As the batch size is usually very small compared to the number of all the paragraphs in the corpus, the pretraining task is much easier compared to the final retrieval task at inference time. In the whole corpus, there are usually lots of similar paragraphs and these paragraphs could act as strong distractors for each other in terms of both paragraph ranking and answer extraction. The desired retrieval model should be able to learn fine-grained matching instead of just learning to distinguish obviously different paragraphs. However, since existing dense retrieval methods typically use uniform batch sampling, there could be many easy negative samples in each batch, and they can only provide weak learning signals. Thus, a large batch size is usually adopted to include sufficient effective negative samples. Unfortunately, this is generally not applicable without hundreds of GPUs.

The Progressive Training Paradigm To provide effective negative samples, we propose a progressive training algorithm, as shown in the lower part of Figure 1. The key idea is to leverage the retrieval model itself to find groups of similar paragraphs. At a certain training step, we use the paragraph encoder at that moment to encode the whole corpus and cluster all (q, p) pairs into many groups based on the similarity of their paragraph encodings. These groups are supposed to include similar paragraphs and potentially related questions. Then, we continue our pretraining by sampling each batch from one of the clusters. By doing this, we can provide challenging and effective negative paragraphs for each question, even with small batch size. Every time we recluster the whole corpus, the model will be encouraged to learn finer-grained matching between questions and paragraphs. Algorithm 1 provides a formal description of the entire process. Note that our training algorithm shares spirits with Curriculum Learning (Bengio et al., 2009) and Self-Paced Learning (Kumar et al., 2010; Jiang et al., 2015), in which the models are trained with harder instances as the training progresses. Instead of utilizing a predefined or dynamically generated order of all the instances according to their easiness, our algorithm makes use of a dynamic grouping of all the training instances and is specifically designed for the efficient in-batch negative sampling paradigm.

Algorithm 1 The Clustering-based Progressive Pretraining

```
Input:
a) all $(q, p)$ pairs from the question generation model;
b) the retrieval module $\mathrm{BERT}_Q$ and $\mathrm{BERT}_P$;
while not finished do
    Encode the whole corpus with $\mathrm{BERT}_P$;
    Clustering all paragraphs into $C$ clusters using the dense encodings;
    for updates = $1{:}K$ do
        Random sample a paragraph cluster;
        Sample $B$ paragraphs from the cluster;
        Fetch the corresponding questions;
        Calculate gradients wrt $\mathcal{L}_{pre}$;
        if updates % $U$ == 0 then
            Update $\mathrm{BERT}_Q$ and $\mathrm{BERT}_P$;
        end if
    end for
end while
```

2.3 QA Finetuning

Once pretrained, we use the paragraph encoder to encode the corpus into a large set of dense vectors. Following previous practice, we only finetune the question encoder and the reading module so that we can reuse the same dense index for different datasets. For every training question, we obtain the question representation h_q from the question encoder and retrieve the top-k paragraphs D^k on the fly using an existing maximum inner product search package. To train the reading module, we apply the shared-normalization trick and optimize the marginal probability of all matched answer spans in the top-k paragraphs:

$$\mathcal{L}_{reader} = -\log \sum_{p \in D^*} \sum_{s \in S_p^*} \mathrm{P}_\phi^{sn}(s|p, q). \tag{2}$$

In additional to the reader loss, we also incorporate the "early" loss used by Lee et al. (2019), which updates the question encoder using the top-5000 dense paragraph vectors. If we define D^*_{5000} as those paragraphs in the top-5000 that contain the correct answer, then the "early" loss is defined as:

$$\mathcal{L}_{early} = -\log \sum_{p \in D^*_{5000}} \mathrm{P}_\theta(p|q). \tag{3}$$

Thus our total finetuning loss is $\mathcal{L}_{early} + \mathcal{L}_{reader}$. Note this is different from the joint formulation

Method	**Dataset** NaturalQuestions-Open	 WebQuestions	 CuratedTREC
DrQA (Chen et al., 2017)	-	20.7	25.7
R^3 (Wang et al., 2018a)	-	17.1	28.4

WKLM (Xiong et al., 2020)	-	34.6	-
GraphRetriever (Min et al., 2019b)	34.5	36.4	-
ORQA (Lee et al., 2019)	33.3	36.4	30.1
ProQA(Ours)	**37.4**	**37.1**	**34.6**

Table 1: Open-domain QA results in terms of exact answer match (EM). The first part of the table shows results from methods that use the traditional IR component. Note that these methods retrieve more paragraphs (typically dozens) than dense retrieval methods listed in the second part of the table, which only finds answers from the top-5.

used by Lee et al. (2019) and Guu et al. (2020), which consider the paragraphs as latent variables when calculating $\mathrm{P}(s|q)$. We find the joint objective does not bring additional improvements, especially after we use shared normalization. More variants of the finetuning objectives will be discussed in §3.5. At inference time, we use a linear combination of the retrieval score and the answer span score to rank the answer candidates from the top-5 retrieved paragraphs. The linear combination weight is selected based on the validation performance on each tested dataset.

3 Experiments

3.1 Datasets

We center our studies on QA datasets that reflect real-world information-seeking scenarios. We consider **1) NaturalQuestions-Open** (Kwiatkowski et al., 2019; Lee et al., 2019), which includes around 10K real-user queries (79,168/8,757/3,610 for train/dev/test) from Google Search; **2) WebQuestions** (Berant et al., 2013), which is originally designed for knowledge base QA and includes 5,810 questions (3,417/361/2,032 for train/dev/test) generated by Google Suggest API; **3) CuratedTREC** (Baudis and Sedivý, 2015), which includes 2,180 real-user queries (1,353/133/694 for train/dev/test) from MSNSearch and AskJeeves logs. Compared to other datasets such as SQuAD (Rajpurkar et al., 2016) and TriviaQA (Joshi et al., 2017), questions in these datasets are created without the presence of ground-truth answers and the answer paragraphs, thus are less likely to have lexical overlap with the paragraph.

3.2 Essential Implementation Details

For pretraining, we use a batch size of 80 and accumulate the gradients every 8 batches. We use the Adam optimizer (Kingma and Ba, 2015) with learning rate 1e-5 and conduct 90K parameter updates. Following previous work (Lee et al., 2019), we use the 12-20-2018 snapshot of English Wikipedia as our open-domain QA corpus. When splitting the documents into chunks, we try to reuse the original paragraph boundaries and create a new chunk every time the length of the current one exceeds 256 tokens. Overall, we created 12,494,770 text chunks, which is on-par with the number (13M) reported in previous work. These chunks are also referred to as paragraphs in our work. For progressive training, we recluster all the chunks with k-means around every 20k updates using the paragraph encodings.

While finetuning the modules for QA, we fix the paragraph encoder in the retrieval module. For each question, we use the top-5 retrieved paragraphs for training and skip the question if the top-5 paragraphs fail to cover the answer. The MIPS-based retrieval is implemented with FAISS (Johnson et al., 2019). On NaturalQuestions-Open, we finetune for 4 epochs. To save the finetuning time on this large dataset, we only use a subset (2,000 out of 8,757) of the original development set for model selection. For WebQuestions and CuratedTREC (both of them are much smaller), we finetune for 10 epochs. The optimizer settings are consistent with the pretraining. Hyperparameters and further details can be found in the appendix.

3.3 QA Performance

Following existing studies, we use the exact match (EM) as the evaluation metric, which indicates the percentage of the evaluation samples for which the

Method	EM	model size	batch size	# updates
ORQA	33.3	330M	4096	100K
T5	36.6	11318M	-	-
REALM	**40.4**	330M	512	200K
ProQA	37.4	330M	80*8	90K

Table 2: Resource comparison with SOTA models. EM scores are measured on NaturalQuestions-Open. *batch size* and *updates* all refer to the dense index pretraining. Note that REALM uses ORQA to initialize its parameters and we only report the numbers after ORQA initialization. “80*8” indicates that we use a batch size of 80 and accumulate the gradients every 8 batches.

predicted span matches the groundtruth answers. In Table 1, we first show that our progressive method (denoted as **ProQA**) is superior to all of the open-domain QA systems (the upper part of the table) that use conventional IR methods, even though we only use the top-5 paragraphs to predict the answer while these methods use dozens of retrieved paragraphs. For the dense retrieval methods, we compare with ORQA (Lee et al., 2019), which is most relevant to our study but simply uses pseudo question-paragraph pairs for pretraining and also requires a larger batch size (4,096). We achieve much stronger performance than ORQA with much fewer updates and a limited number of GPUs. To the best of our knowledge, this is the first work showing that an effective dense corpus index can be obtained without using highly expensive computational resources. The reduced requirement of computation also makes our method easier to replicate for corpora in different domains.

In Table 2, we compare our method other more recently published QA systems in terms of both performance and computation cost. It is worth noting that although we need to use a BART model to generate training questions for Wikipedia documents, the inference cost of the question generator is still much lower than the training cost of our system and is not significant for comparing the overall computation cost: with the same GPU hardware, generating all the questions takes less than 1/6 of the training time. When using the *batch size* × *# of updates* to approximate the training FLOPs, we see that our system is at least 6 times more efficient than ORQA. Compared to the recent proposed T5 (Roberts et al., 2020) approach, which converts the QA problem into a sequence-to-sequence (decode answers after encoding questions) problem and relies on the large model capacity to answer questions without retrieving documents, our system achieves better performance and is also much faster at inference time, due to the much smaller model size. The state-of-the-art REALM model (Guu et al., 2020) uses a more complicated pretraining approach that requires asynchronously refreshing the corpus index at train time. As it relies on ORQA initialization and further pretraining updates, it is even more computational expensive at training time. Also, as our method directly improves the ORQA pretraining, our method could easily stack with the REALM pretraining approach.

Method	R@5	R@10	R@20
ProQA (90k)	**52.0**	**61.0**	**68.8**
ORQA* (90k)	20.4	29.0	37.2
ProQA (no clustering, 90k)	42.9	52.6	60.8
ProQA (no clustering; 70k)	43.8	53.5	61.3
ProQA (no clustering; 50k)	38.8	48.2	56.7

Table 3: Ablation studies on different pretraining strategies. The retrieval modules (Recall@k) are tested on WebQuestions. *Our reimplementation.

Concurrent to our work, Karpukhin et al. (2020) show that it is possible to use the groundtruth answer paragraphs in the original NaturalQuestions dataset to train a stronger dense retriever. However, they use a larger index dimension (768) while encoding paragraphs and also retrieve more paragraphs (20∼100) for answer extraction. As a larger index dimension naturally leads to better retrieval results (Luan et al., 2020) (despite sacrificing search efficiency) and using more paragraphs increases the recall of matched answer spans[3], this concurrent result is not directly comparable to ours, and we leave the combination effect of efficient pretraining and strong supervision (*i.e.*, using human-labeled paragraphs) to future work.

3.4 Ablation Studies

To validate the sample efficiency of our method, we replicate the inverse-cloze pretraining approach from ORQA using the same amount of resource as we used while training our model, *i.e.*, the same batch size and updates (90k). We also study the effect of the progressive training paradigm by pretraining the model with the same generated data but without the clustering-based sampling. We test the retrieval performance on the WebQuestions test

---

[3] While using more paragraphs, we achieve 40.6 EM (compared to 41.5 EM in (Karpukhin et al., 2020)) even with a much smaller index dimension. Also, we did not use the gold paragraphs (strong supervision) to train our reading module.

set before any finetuning. We use Recall@k as the evaluation metric, which measures how often the answer paragraphs appear in the top-k retrieval. The results are shown in Table 3. We can see that for the non-clustering version of our method, the improvements are diminishing as we reach certain training steps, while the progressive training algorithm brings around 8% improvements on different retrieval metrics. This suggests the importance of introducing more challenging negative examples in the batch when the batch size is limited. Comparing the no-clustering version of our method against ORQA, we see that using our data generation strategy results in much better retrieval performance (more than 22% improvements on all metrics).

3.5 Analysis on Finetuning Objectives

Noting that different finetuning configurations have been used in existing studies , we conduct additional experiments to investigate the efficacy of different finetuning objectives and provide insights for future research that intends to focus on improving the model itself. Specifically, we study the effects of using a joint objective (Lee et al., 2019; Guu et al., 2020) and adding an additional reranking objective that is commonly used in sparse-retrieval QA systems (Min et al., 2019a; Xiong et al., 2020).

The joint objective treats the retrieved paragraphs as latent variables and optimizes the marginal probability of the matched answer spans in all paragraphs:

$$\mathcal{L}_{joint} = -\log \sum_{p \in D^\star} \mathrm{P}_\theta(p|q) \sum_{s \in S_p^*} \mathrm{P}_\phi(s|p,q). \tag{4}$$

The reranking objective is usually implemented through a paragraph reranking module that uses a question-dependent paragraph encoder, *e.g.*, a BERT encoder that takes the concatenation of the question and paragraph as input. This kind of reranker has been shown to be beneficial to conventional IR methods since it can usually provide more accurate paragraph scores than the TF-IDF or BM25 based retriever while ranking the answer candidates. To implement this reranking module, we simply add another reranking scoring layer to our BERT-based span prediction module $\mathrm{P}_\phi(s|p,q)$, which encodes the paragraphs in a question-dependent fashion. At inference time, we use the paragraph scores predicted by this reranking component instead of the pretrained retrieval model to guide our final answer selection.

id	**Objective Settings** *joint*	 *rerank*	 *shared-norm*	EM
1	-	-	✓	38.5
2	✓	-	✓	38.3
3	-	✓	✓	38.2
4	✓	-	-	36.2
5	-	-	-	35.1

Table 4: Analysis on different finetuning objectives on NaturalQuestions-Open. EM scores are measured on the 2,000 validation samples we used for model selection.

Table 4 shows the results of different objective settings. Comparing the results of (4) and (5), we can see that the joint objective can bring some improvements when shared-normalization is not applied. However, it does not yield improvements when shared-normalization is applied, according to the results of (1) and (2). By comparing (1) and (3), we see that with the strong pretrained retrieval model, adding an extra reranking module that uses question-dependent paragraph encodings is no longer beneficial. This is partially because our pretrained retrieval model gets further improved during finetuning, in contrast to a fixed TF-IDF based retriever. Finally, from (1) and (5), we see that the shared normalization brings much larger improvements than the other factors. This aligns with the findings from an existing work (Wang et al., 2019) that only tested on SQuAD questions.

4 Error Analysis

To investigate the fundamental differences of the dense and sparse retrieval methods in open-domain QA, we conduct an error analysis using both the proposed method and a baseline system that uses TF-IDF and BM25 for retrieval. This baseline uses a similar retrieval pipeline as Min et al. (2019a) and is trained with the finetuning objective defined in Eq. 2. This sparse retrieval baseline achieves 29.7 EM on the official dev set of NaturalQuestions-Open while our method achieves 36.7 EM[4]. Figure 2 shows the Venn diagram of the error sets from both systems. Our key findings are summarized in the following paragraphs.

The difference retrieval paradigms could complement each other. First, according to the error set differences (shown by the white regions in Figure 2), a considerable portion of the error cases (9.1% of the devt set) of our dense-retrieval system

---

[4] Note that this number is different from the number in Table 4 as we did not use the whole dev set for model selection.

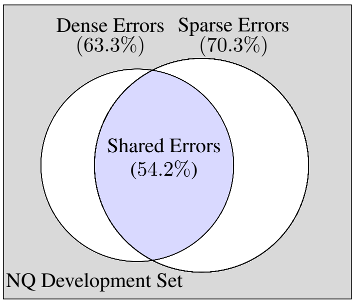

Figure 2: The error sets (from the official dev set of NaturalQuesitons-Open) of our dense retrieval method and a baseline system using sparse retrieval methods like TF-IDF. We use circles to represent the error sets of both systems. The percentages show the relative size of each set in terms of the whole dev set.

does not occur in the sparse-retrieval system and vice versa. This suggests the necessity of incorporating different retrieval paradigm when building real-world applications. In fact, the hybrid approach has already been adopted by a phrase-level retrieval method (Seo et al., 2019) and concurrent studies (Luan et al., 2020; Karpukhin et al., 2020).

Both systems are underestimated. As shown in Figure 2, 54.2% of the questions cannot be correctly answered by either system. However, our manual inspection on 50 of the shared error cases suggests that around 30% of these errors are due to annotation issues (14%) or the ambiguous nature of real-user queries (16%). One obvious annotation issue is the incompleteness of the answer labels. Example questions include *"When did Brazil lose to in 2014 World Cup?"*, to which both *"Germany"* and *"Netherlands"* are correct answers. This issue occurs because the annotators of NaturalQuestions only have a local view of the knowledge source as they are only asked to label the answer span using one document. In terms of the ambiguous questions, many of them are due to constraints unspecified by the question words, such as *"What is the population of New York City?"* (the time constraint is implicit) or *"When did Justice League come out in Canada?"* (needs entity disambiguation). This kind of questions result from the information-seeking nature of the open-domain QA task where the users usually use the minimal number of words for searching and they are not aware of the potential ambiguous factors. To solve this kind of questions, an interactive QA system might be necessary. In the appendix, we show more ambiguous questions in which other kinds of constraints are missing.

5 Related Work

The task of answering questions without specifying specific domains has been intensively studied since the earlier TREC QA competitions (Voorhees, 1999). Studies in the early stage (Kwok et al., 2001; Brill et al., 2002; Ferrucci et al., 2010; Baudiš, 2015) mostly rely on highly sophisticated pipelines and heterogeneous resources. Built on the recent advances in machine reading comprehension, Chen et al. (2017) show that open-domain QA can be simply formulated as a reading comprehension problem with the help of a standard IR component that provides candidate paragraphs for answer extraction. This two-stage formulation is simple yet effective to achieve competitive performance while using Wikipedia as the only knowledge resource.

Following this formulation, a couple of recent studies have proposed to improve the system using stronger reading comprehension models (Yang et al., 2019; Wang et al., 2018b), more effective learning objectives (Clark and Gardner, 2018; Min et al., 2019a; Wang et al., 2019) or paragraph reranking models (Wang et al., 2018a; Lin et al., 2018; Lee et al., 2018). However, the retrieval components in these systems are still based on traditional inverted index methods, which are efficient but might fail when the target paragraph does not have enough lexicon overlap with the question.

In contrast to the sparse term-based features used in TF-IDF or BM25, dense paragraph vectors learned by deep neural networks (Zhang et al., 2017; Conneau et al., 2017) can capture much richer semantics beyond the n-gram term features. To build effective paragraph encoders tailed for the paragraph retrieval in open-domain QA, more recent studies (Lee et al., 2019; Chang et al., 2020; Guu et al., 2020) propose to pretrain Transformer encoders (Vaswani et al., 2017) with objectives that simulate the semantic matching between questions and paragraphs. For instance, Lee et al. (2019) uses the inverse cloze pretraining task to train a bi-encoder model to match a sentence and the paragraph in which the sentence belongs to. These approaches demonstrate promising performance but require a lot of resources for pretraining. The focus of this paper is to reduce the computational requirements of building an effective corpus index.

6 Conclusion

We propose an efficient method for pretraining the dense corpus index which can replace the traditional IR methods in open-domain QA systems. The proposed approach is powered by a better data generation strategy and a simple yet effective data sampling protocol for pretraining. With careful finetuning, we achieve stronger QA performance than ORQA that uses much more computational resources. We hope our method could encourage more energy-efficient pretraining methods in this direction such that the dense retrieval paradigm could be more widely used in different domains.

A Appendix

A.1 Further Implementation Details

The pretraining process takes 4 TITAN RTX GPUs, each with a 24G memory. We use the NVIDIA Apex package for mixed-precision training. 90K parameter updates take around 7 days to finish. For QA experiments, We use the **IndexIVFFlat** index for efficient search. We assign all the vectors to 100 Voronoi cells and only search from the closest 20 cells. The random seed is set as 3 for all QA datasets. We use a batch size of 8 (8 questions, each of them are paired with 5 paragraphs) for NaturalQuestions-Open and 1 for the other datasets. We limit the maximum answer length to 10 subword tokens. For NaturalQuestions-Open, we evaluate the model every 1000 updates and save the best checkpoint based on validation EM. For WebQuesitons and CuratedTREC, we evaluate the model after every epoch. As neither of these two small datasets has an official dev set, we use a small split to find the best hyperparameters and then retrain the model with all the training questions. To accelerate training, especially for the early loss function which requires annotate the top5000 retrieved paragraphs, we pre-annotate the top10000 paragraphs retrieved by the untuned retrieval module and build an answer paragraph set for each question. At finetuning time, we direct check whether a particular paragraph is in the precomputed paragraph set, instead of doing string matching for each of the 5000 paragraphs. Our BERT implementations are based on huggingface Transformers[5].

A.2 Qualitative Examples

Here we include more examples that complement the results and analysis of the paper. Table 5 shows the generated questions from the finetuned BART model and Table 6 complements the error analysis.

Abstract

Real-world knowledge graphs are often characterized by low-frequency relations—a challenge that has prompted an increasing interest in few-shot link prediction methods. These methods perform link prediction for a set of new relations, unseen during training, given only a few example facts of each relation at test time. In this work, we perform a systematic study on a spectrum of models derived by generalizing the current state of the art for few-shot link prediction, with the goal of probing the limits of learning in this few-shot setting. We find that a simple *zero-shot* baseline—which ignores any relation-specific information—achieves surprisingly strong performance. Moreover, experiments on carefully crafted synthetic datasets show that having only a few examples of a relation fundamentally limits models from using fine-grained structural information and only allows for exploiting the coarse-grained positional information of entities. Together, our findings challenge the implicit assumptions and inductive biases of prior work and highlight new directions for research in this area.

1 Introduction

A knowledge graph (KG) is a multi-relational graph that offers a structured way to organize facts about the world. Encoder-decoder approaches are commonly used to predict new facts from existing ones where entities and relations are embedded in a low-dimensional vector space via an encoder, to then score the likelihood of observing a new fact via a decoder (Nickel et al., 2015; Bordes et al., 2013; Trouillon et al., 2017; Dettmers et al., 2018).

It is well known that the performance of these methods can significantly drop when predicting for relations that are only observed in a few example facts. However, link prediction for these low-frequency relations is very important, as not only are these relations abundant in most knowledge graphs, they are also key for knowledge graph completion tasks where new relations may appear after model training.

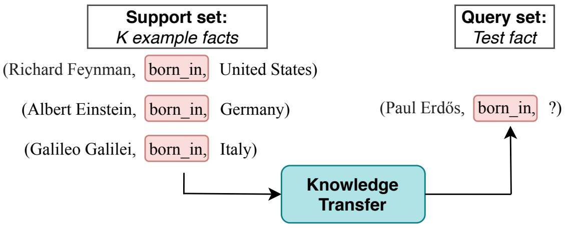

Figure 1: The few-shot link prediction task

To study this low-frequency regime, Xiong et al. (2018) created the Nell-One and Wiki-One benchmarks where the task is to predict new facts for a set of new relations at test time, where each relation is only observed a *few* times (as specified by some small fixed number K). Previous approaches have shown promising results using metric-based (Xiong et al., 2018) and gradient based meta-learning techniques (Chen et al., 2019). However, we argue that these models are limited by the current task formulation to only exploit coarse-grained positional signals (i.e., nodes belonging to the same community) that are abundant in these benchmarks, rather than leveraging structural signals (e.g. transitivity, symmetry).

Present work. In this work, we take a critical take on current approaches for few-shot link prediction over knowledge graphs. We posit that current meta-learning based approaches benefit largely due to the positional signals in entities, rather than utilising information about the low frequency relations. We corroborate these insights by conducting a systematic study on a spectrum of models with decreasing complexity. Interestingly, we find that a much simpler zero-shot variant of the state of the art —devoid of any meta-learning scheme— yields surprisingly competitive results, while not consuming any example facts about a relation. Motivated by these observations, we design a set of null models tailored to different learning signals a model might utilize to drive effective link predic-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2816–2822

tion. Empirically, we validate that these existing meta-learning models are ill-equipped to infer logical patterns about the few-shot relations. These findings bring forth the shortcomings of the current task formulation and raises new questions in both task and model design while highlighting new directions of research in few-shot link prediction.

2 Few-shot link prediction

2.1 Problem definition

The goal of few-shot link prediction is to predict missing links for a new relation by only observing K example triples of that relation (Figure 1). Following literature in few-shot classification (Ravi and Larochelle, 2016; Vinyals et al., 2016; Snell et al., 2017), we organize our dataset as a set of tasks, where a task corresponds to predicting links for a new relation. The set of tasks for training and testing are disjoint, with the added constraint that entities in the test tasks are a subset of the entities in the train tasks. Let $\mathcal{V}$ denote the set of entities in the knowledge graph. For each new relation r_i, we then construct a support set $\mathcal{S}_i = \{(h_k, r_i, t_k)\}_{k=1}^K$ containing K example entity pairs, $h_k, t_k \in \mathcal{V}$, connected by relation r_i, and a query set $\mathcal{Q}_i = \{(h_j, r_i, ?)\}_{j=1}^J$ containing J query triples over entities in $\mathcal{V}$. As shown in Figure 1, the goal is then to learn how to extract knowledge from the support set such that we can predict the missing tail entities in the query set.

2.2 Overview of the framework

The foundation of our analyses focuses on a generalization of the current state-of-the-art gradient-based meta-learning approach (Chen et al., 2019). This approach follows the encoder-decoder paradigm of embedding-based knowledge graph completion methods (Hamilton et al., 2017), where the entities and relations are embedded in a low-dimensional vector space and the embeddings are used to predict the likelihood of a given triple.

Encoder functions. The key idea in few-shot learning is to transfer knowledge from support set to query set by learning a function $\texttt{RelLearner} : \mathcal{S}_i \mapsto \mathbb{R}^d$. This maps a support set $\mathcal{S}_i$, which characterizes the relation r_i, to a low dimensional embedding via an encoder function $\texttt{E} : \mathcal{V} \mapsto \mathbb{R}^d$

$$\mathbf{r}_i = \texttt{RelLearner}(\{(\texttt{E}(h_k), \texttt{E}(t_k)\}_{k=1}^K). \quad (1)$$

The `RelLearner` function can vary from a simple MLP (Hastie et al., 2009) to more complicated recurrent architectures (Rumelhart et al., 1985; Jordan, 1997; Hochreiter and Schmidhuber, 1997). Further, the entity encoder `E` can vary from TransE-style embeddings (Bordes et al., 2013; Sun et al., 2019) to a graph neural network (Schlichtkrull et al., 2018) that explicitly leverages the neighborhood information around entities.

Decoder and loss function. A decoder function ingests the embeddings of the entities $\mathbf{h}, \mathbf{t}$ and of the relation $\mathbf{r}$ to score the likelihood of a given triple (h, r, t). Using a simple TransE decoder (Bordes et al., 2013), it is then optimized to score positive triples higher than negative triples using a contrastive loss $\mathcal{L}$ (Dyer, 2014). In the few-shot setting we compute the support set loss $\mathcal{L}(\mathcal{S}_i)$, and the final query set loss $\mathcal{L}(\mathcal{Q}_i)$, which are used to update the model parameters (Chen et al., 2019).

Meta-gradient update. Instead of directly using the relation embedding $\mathbf{r}_i$ from Equation (1) to compute the final query loss $\mathcal{L}(\mathcal{Q}_i)$, we first make an update on the relation embedding using the gradient of the support set loss $\mathcal{L}(\mathcal{S}_i)$

$$\mathbf{r}'_i = \mathbf{r}_i - \eta \nabla_{\mathbf{r}_i} \mathcal{L}(\mathcal{S}) \quad (2)$$

where η denotes the learning rate. This update encourages $\mathbf{r_i}$ to be such that it effectively predicts the support set triples via minimizing $\mathcal{L}(\mathcal{S}_i)$.

2.3 Baselines

Our objective is to probe how much models leverage the support set to perform the query task. To this end, we perform a systematic study of different model variants, where each falls into the general framework described in Section 2.2.

MetaR follows Chen et al. (2019), where the `RelLearner` is defined as a 2-layer MLP (Hastie et al., 2009) over the support set entity embeddings. The encoder `E` simply maps each entity to a fixed learnable vector as in Bordes et al. (2013).

SharedEmbed skips Equation (1), and instead sets $\mathbf{r_i} = \mathbf{r_g}$, where $\mathbf{r_g}$ is a single learnable embedding shared across all relations. We propose this modification to measure the effect of representing all relations by the same embedding $\mathbf{r_g}$, where the only information from the support set comes via the gradient update in Equation (2).

ZeroShot further removes the meta-gradient update in Equation (2) and lets $\mathbf{r'_i} = \mathbf{r_g}$. This effectively reduces the model to perform zero-shot link prediction on the relation's query set without any relation-specific information from the support set.

		MRR		Hits@10		Hits@5		Hits@1	
		1-shot	5-shot	1-shot	5-shot	1-shot	5-shot	1-shot	5-shot

Table 1: Average metrics on Nell-One and Wiki-One few-shot link prediction tasks. * For Wiki-One we used pre-trained embeddings, similar to Chen et al. (2019).

R-GCN uses the same `RelLearner` as in MetaR, with the exception that support set entity embeddings are learned via a multi-relational graph neural network, R-GCN (Schlichtkrull et al., 2018), instead of a TransE-style embeddings. R-GCN learns entity representation via aggregating the 2-hop neighbors of a given entity. With this model we probe the extent to which injecting structural bias into entity representations can influence performance in link prediction.

3 Null Models

In order to probe and understand the performance of different models, we introduce two *null models*, which are used to generate synthetic data that satisfy certain properties. Motivated by recent literature on position versus structure-aware methods in relational learning (You et al., 2019; Srinivasan and Ribeiro, 2020), we test the models' ability to learn from two key sources of information: *structural information* and *positional information*. In the context of knowledge graphs, *structural information* corresponds to the fine-grained relational semantics. These are the logical patterns that are extracted by state-of-the-art rule induction systems, such as RuleN (Meilicke et al., 2018).

On the other hand, *positional information* corresponds to the coarse-grained community structure of the nodes in the graph. In other words, two nodes are said to be positionally 'close' in the graph, i.e., if they belong to the same community (Newman, 2018).

3.1 Structural Null Models

The first type of null models contains synthetic relations that satisfy simple logical properties. For the sake of exposition, we focus on two simple logical patterns: symmetry and transitivity. For the purposes of all synthetic data generation, we only consider the largest connected component of respective datasets, denoted $\mathcal{G}^L$.

Synthetic symmetric relations. To generate $2N$ edges connected by a symmetric relation r^*_{s}, we repeat the following steps N times.:

1. Uniformly sample a pair of unique entities–h_i, t_i–from all the entities in $\mathcal{G}^L$.
2. Add two edges–$((h_i, r^*_{\mathrm{s}}, t_i)), ((t_i, r^*_{\mathrm{s}}, r_i))$ to the set of synthetic symmetric edges.

Synthetic transitive relations. To sample $3N$ edges connected by a transitive relation r^*_{t}, we generate 3 edges at a time. In particular, we repeat the following steps N times:

1. Uniformly sample 3 unique entities–e_1, e_2, and e_3–from all the entities in $\mathcal{G}^L$.
2. Add three edges–$(e_1, r^*_{\mathrm{t}}, e_2)$, $(e_2, r^*_{\mathrm{t}}, e_3)$, $(e_1, r^*_{\mathrm{t}}, e_3)$–to our collection.

3.2 Positional Null Models

The second type of null models focuses on generating synthetic relations that depend on the underlying community structure in the graph. We call these relations *positional* because they depend on the relative global position of the entities, rather than on local structural properties.

We first cluster the largest connected component $\mathcal{G}^L$ into K communities using a standard algorithm originally proposed by Blondel et al. (2008). Let $\{C_i\}_{i=1}^K$ denote the set of communities generated, where each community is a set of entities from $\mathcal{G}^L$. To generate N synthetic edges for a positional relation r_p, we repeat the following steps N times:

1. Uniformly sample a community index i from the set $\{1, , K\}$.
2. Uniformly sample two unique entities h, t from community C_i; add (h, r^*_{p}, t) to the set.

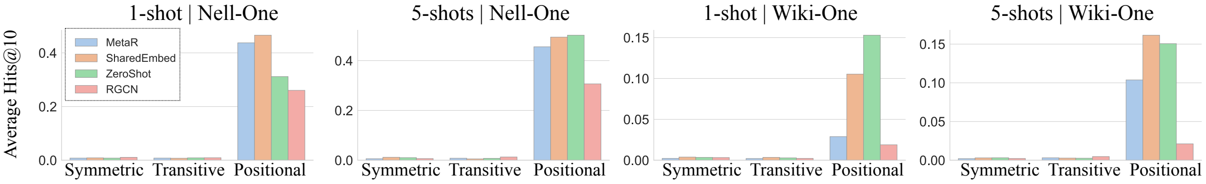

Figure 2: Average Hits@10 on synthetically generated relations using our proposed null models.

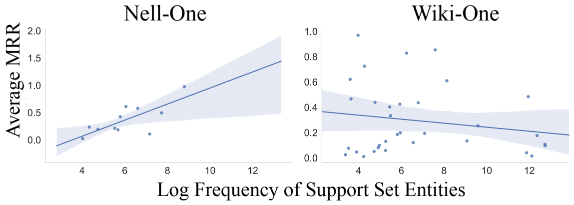

Figure 3: Pearson's R between MRR and the log frequency of support set entities in training graph. We observe strong correlation for Nell-One, but not for Wiki-One. For more details on this, see Appendix C.

4 Experiments

We followed the same experimental setup as in Chen et al. (2019), as described in Appendix A. We conducted our experiments on the Nell-One and Wiki-One datasets[1]. For more details on these benchmarks, we refer the reader to Table 1 in Xiong et al. (2018). Similar to earlier work, we report MRR, Hits@1, Hits@5 and Hits@10 on our test relations, using a type-constrained candidate set.

4.1 Results and Analysis

Experiments on Real Data. As shown in Table 1, for Nell-One, we find that SharedEmbed model yields competitive performance to MetaR, with Hits@10 of 45.4% and 49.5%, as compared to MetaR's Hits@10 of 46.4% and 50.0% for 1 and 5-shot, respectively. The same observation holds for Wiki-One, where SharedEmbed yields 39.9% and 41.5% Hits@10, compared to MetaR's Hits@10 of 44.8% and 40.8%, for 1 and 5-shot, respectively.

It is surprising how competitive SharedEmbed is, given that the only relation-specific information the model gets to observe comes via the meta-gradient update in Equation (2). In fact, we find that even in absence of this gradient signal, i.e., without *any* relation-specific information, ZeroShot performs relatively good, with Hits@10 of 34.2% and 36.5% on Nell-One, and 36.1% and 36.7% on Wiki-One.

The nontrivial performance of these simple models suggests that such models may exploit some easily accessible positional signals around entities, without the need to learn meaningful representations for relations. In fact, Figure 3 shows a high correlation between performance and the degrees of entities in the support set for Nell-One. We reconcile this observation by noting that as models observe more signals about entities, they start relying less on the support set, and thus on the relation representations. Furthermore, contrary to our expectation, even when we equip models with structural biases, as done via an R-GCN, they do not yield better results.

Null Model Experiments. We probed the above trained models on the synthetically generated test tasks following the procedure discussed in Section 3. As shown in Figure 2, we find a consistent trend for these models to yield higher performance on tasks that rely on positional signals, as compared to tasks that require logical inference.

Indeed, in the current task formulation, where we are given a support set of K randomly sampled examples, it is unlikely that logically consistent patterns will be captured in the K-shot examples. For example, seeing conclusive evidence of transitivity when only given a small random sample of tuples is highly unlikely. In fact, as we show in Appendix B, one provably cannot learn certain logical patterns for some values of K in the K-shot setting.

5 Conclusion

We conducted a systematic study of various models to probe their limits in performing few-shot link prediction. Our experiments on both synthetic and real data show that the current task formulation encourages models to mainly rely on positional information around entities, rather than leveraging logical signals about relations. In fact, we empirically show that having only K examples of a relation fundamentally limits the types of logical patterns that can be learned. We argue that a future direction in few-shot link prediction should allow for a more careful construction of the support set, to scaffold the use of logical patterns in few-shot learning.

A Hyperparameters

As discussed, we followed the experimental setup described in Chen et al. (2019). We used the Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.001, using 1 to 3 ratio of positive to negative samples. During training, we used 3 queries per task on each dataset.

We adapted the batch size to be 1024, and the number of queries to test on to be 3, based on their open-sourced codebase. These hyperparameters yielded the best performing models. Similarly, we also used the same train/validation/test relation splits of 51:5:11 and 133:16:34 for Nell-One and Wiki-One respectively.

For our R-GCN model, we considered a range of [5, 10, 20] as the number of neighbors to sample for each message passing step, and [2, 4] as the number of basis. Furthermore, we used 2 layers in the R-GCN. Finally, we used 50 and 20 as the R-GCN hidden layer dimension for Nell-One and Wiki-One, respectively. These hyperparameters were partly followed from Schlichtkrull et al. (2018), and were decided upon consideration for our available compute infrastructure.

Our models were trained on a single Nvidia 1080Ti GPU, and each model training took between 13-18 hours depending on the model and dataset settings.

B Logical inference in the few-shot domain

Figure 4 shows five example support sets to demonstrate that inferring logical properties such as symmetry and transitivity requires a minimum number of carefully designed K-shot examples.

C Entity Frequency Analysis

Figure 5 shows the 100 highest-degree entities out of all 4,838,244 entities in the Wiki-One knowledge graph. We find that the median degree of entities is 1, and the highest degree is 227,390, which connects to 4.69% of the total graph. We suspect that these high-degree entities, so-called hub nodes, may add noise to the embeddings of support set entities. This could in turn affect performance and explain why we do not observe a strong correlation between the degrees of support set entities and performance in Wiki-One.

K-shot	Example support sets of varying K-shots.	Query triple	Answer

Abstract

At the heart of text based neural models lay word representations, which are powerful but occupy a lot of memory making it challenging to deploy to devices with memory constraints such as mobile phones, watches and IoT. To surmount these challenges, we introduce ProFormer – a projection based transformer architecture that is faster and lighter making it suitable to deploy to memory constraint devices and preserve user privacy. We use LSH projection layer to dynamically generate word representations on-the-fly without embedding lookup tables leading to significant memory footprint reduction from $\mathcal{O}(V.d)$ to $\mathcal{O}(T)$, where V is the vocabulary size, d is the embedding dimension size and T is the dimension of the LSH projection representation. We also propose a *local projection attention (LPA)* layer, which uses self-attention to transform the input sequence of N LSH word projections into a sequence of N/K representations reducing the computations quadratically by $\mathcal{O}(K^2)$.

We evaluate ProFormer on multiple text classification tasks and observed improvements over prior state-of-the-art on-device approaches for short text classification and comparable performance for long text classification tasks. ProFormer is also competitive with other popular but highly resource-intensive approaches like BERT and even outperforms small-sized BERT variants with significant resource savings – reduces the embedding memory footprint from 92.16 MB to 1.7 KB and requires 16× less computation overhead, which is very impressive making it the fastest and smallest on-device model.

1 Introduction

Transformers (Vaswani et al., 2017) based architectures like BERT (Devlin et al., 2018), XL-net (Yang et al., 2019), GPT-2 (Radford et al., 2019), MT-DNN (Liu et al., 2019a), RoBERTA (Liu et al., 2019b) reached state-of-the-art performance on tasks like machine translation (Arivazhagan et al., 2019), language modelling (Radford et al., 2019), text classification benchmarks like GLUE (Wang et al., 2018). However, these models require huge amount of memory and need high computational requirements making it hard to deploy to small memory constraint devices such as mobile phones, watches and IoT. Recently, there have been interests in making BERT lighter and faster (Sanh et al., 2019; McCarley, 2019). In parallel, recent on-device works like SGNN (Ravi and Kozareva, 2018), SGNN++ (Ravi and Kozareva, 2019) and (Sankar et al., 2019) produce lightweight models with extremely low memory footprint. They employ a modified form of LSH projection to dynamically generate a fixed binary projection representation, $\mathbb{P}(x) \in [0, 1]^T$ for the input text x using word or character n-grams and skip-grams features, and a 2-layer MLP + softmax layer for classification. As shown in (Ravi and Kozareva, 2018) these models are suitable for short sentence lengths as they compute T bit LSH projection vector to represent the entire sentence. However, (Kozareva and Ravi, 2019) showed that such models cannot handle long text due to significant information loss in the projection operation.

On another side, recurrent architectures represent long sentences well, but the sequential nature of the computations increases latency requirements and makes it difficult to launch on-device. Recently, self-attention based architectures like BERT (Devlin et al., 2018) have demonstrated remarkable success in capturing long term dependencies in the input text via purely attention mechanisms. BERT's model architecture is a multi-layer bidirectional Transformer encoder based on the original implementation in (Vaswani et al., 2017). The

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2823–2828
April 19 - 23, 2021.

self-attention scores can be computed in parallel as they do not have recurrent mechanisms. But usually these architectures are very deep and the amount of computation is quadratic in the order of $\mathcal{O}(L \cdot N^2)$, where L is the number of layers (Transformer blocks) and N is the input sentence length. Straightforward solutions like reducing the number of layers is insufficient to launch transformers on-device due to the large memory and quadratic computation requirements.

In this paper, we introduce a projection-based neural architecture ProFormer that is designed to (a) be efficient and learn compact neural representations (b) handle out of vocabulary words and misspellings (c) drastically reduce embedding memory footprint from hundreds of megabytes to few kilobytes and (d) reduce the computation overhead *quadratically* by introducing a local attention layer which reduces the intermediate sequence length by a constant factor, K. We achieve this by bringing the best of both worlds by combining LSH projection based representations (for low memory footprint) and self-attention based architectures (to model dependencies in long sentences). To tackle computation overheard in the transformer based models, we reduce the number of self-attention layers and additionally introduce an intermediate local projection attention (LPA) to quadratically reduce the number of self-attention operations. The main contributions of our paper are:

- We propose novel on-device neural network called ProFormer which combines LSH projection based text representations, with transformer architecture and locally projected self-attention mechanism that captures long range sentence dependencies while yielding low memory footprint and low computation overhead.
- ProFormer reduces the computation overhead $\mathcal{O}(L \cdot N^2)$ and latency in multiple ways: by reducing the number of layers L from twelve to two and introducing new local projection attention layer that decreases number of self-attention operations by a quadratic factor.
- ProFormer is light weigh compact on-device model, while BERT on-device still needs huge embedding table (92.16 MB for $V = 30k$, $d = 768$) with number of computation flops in the order of $\mathcal{O}(L \cdot N^2)$, where L is the number of layers, N is the number of words in the input sentence.
- We conduct empirical evaluations and comparisons against state-of-the-art on-device and prior deep learning approaches for short and long text classification. Our model ProFormer reached state-of-art performance for short text and comparable performance for long texts, while maintaining small memory footprint and computation requirements.

2 ProFormer: LSH Projection based Transformers

In this section, we show the overall architecture of ProFormer in Figure 1. ProFormer consists of multiple parts: (1) word-level Locality Sensitive Hashing (LSH) projection layer, (2) local projection attention (LPA) layer, (3) transformer layer (Devlin et al., 2018) and (4) a max-pooling + classifier layer. Next, we describe each layer in detail.

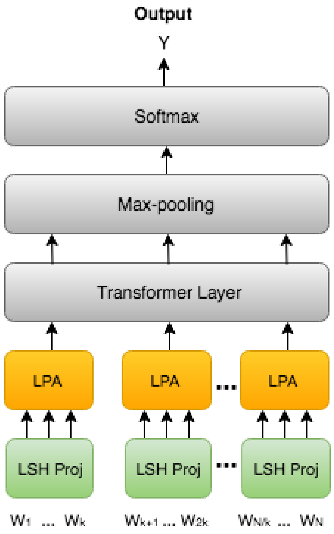

Figure 1: ProFormer: Our **Pro**jection Trans**former** Network Architecture

2.1 LSH Projection Layer

It is a common practice to represent each word in the input sentence, $\mathbf{x} = [w_1, w_2, \cdots, w_N]$ as an embedding vector based on its one-hot representation. Instead, we adopt LSH projection layer from (Ravi, 2017, 2019) which dynamically generates a T bit representation, $\mathbb{P}(w_i) \in [0, 1]^T$ for the input word, w_i based on its morphological features like n-grams, skip-grams from the current and context words, parts-of-speech tags, etc.

Since the LSH projection based approach does not rely on embedding lookup tables to compute word representation, we obtain significant memory savings of the order, $O(V \cdot d)$, where V is the vocabulary size and d is the embedding dimension. For instance, the embedding look-up table occupies 92.16 MB ($V = 30k$, $d = 768$ (Devlin et al., 2018)), while the LSH projection layer requires only $\approx$ 1.7 KB ($T = 420$) as shown in Table 1.

Models	**Embedding memory**	**Computations**
BERT	$\mathcal{O}(V.d)$	$\mathcal{O}(N^2)$
ProFormer (our model)	$\mathcal{O}(T)$	$\mathcal{O}(N^2/K^2)$

Table 1: Memory and computations overhead comparison between BERT (Devlin et al., 2018) and ProFormer (our model). N is the number of words in the input. For $V = 30k$, $d = 768$, $T = 420$, BERT's embedding table occupies 92.16 MB while ProFormer requires only **1.7** KB. For $K = 4$, we reduce the BERT computation overhead by **16** times.

2.2 Local Projection Attention (LPA) Layer

The LPA layer shown in Figure 2 consists of a single layer multi-headed self-attention layer similar to the Transformer architecture in (Vaswani et al., 2017) followed by a max-pooling layer yielding a compressed representation of K input words, $[w_1, w_2, \cdots w_K]$.

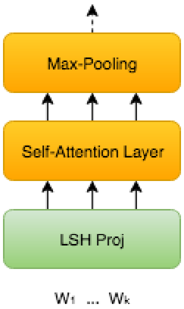

Figure 2: Local Projection Attention (LPA) layer.

The LPA layer transforms the N word-level projections, $\mathbb{P}(w_i)$ to a sequence of N/K representations as in Equation 1.

$$[\mathbb{P}(w_1), \cdots \mathbb{P}(w_N)]_N \longrightarrow [\mathcal{LPA}(\mathbb{P}(w_{1:K})), \cdots \mathcal{LPA}(\mathbb{P}(w_{N/K:N}))]_{N/K} \quad (1)$$

where $\mathcal{LPA}$ consists of the self-attention and max-pooling operation, K is a *Group factor*[1]. We equally divide the N word-level LSH projection representations into N/K groups of size K. The LPA layer compresses each group of K word representations into $\mathcal{LPA}(\mathbb{P}(w_{1:K})) \in \mathbb{R}^d$ yielding N/K representations in total. The LPA layer reduces the self-attention computation overhead in the subsequent transformer layer (Vaswani et al., 2017) by $\mathcal{O}(K^2)$.

2.3 Transformer Layer

This layer consists of 2-layer bidirectional Transformer encoder based on the original implementation described in (Vaswani et al., 2017). This layer transforms the N/K input representations from the LPA layer described in the previous sub-section into N/K output representations. In this layer, we reduce both the computation overhead and memory footprint by reducing the number of layers from L to 2 reducing the computation overhead by $\mathcal{O}(L/2)$ (6 times in the case of 12-layer *BERT-base* model).

2.4 Max-Pooling and Classification Layer

We summarize the N/K representations from the transformer layer to get a single d dimensional vector by max-pooling across the N/K time-steps, followed by a softmax layer to predict the output class Y.

3 Datasets & Experimental Setup

In this section, we describe our datasets and experimental setup. We use text classification datasets from state-of-the-art on-device evaluations such as: MRDA (Shriberg et al., 2004) and ATIS (Tür et al., 2010), AG News (Zhang et al., 2015a) and Yahoo! Answers (Zhang et al., 2015a). Table 2 shows the characteristics of each dataset.

Tasks	# Classes	Avg-len	Train	Test
MRDA (Dialog act)	6	8	78k	15k
ATIS (Intent prediction)	21	11	$4.4k$	$0.89k$
AG (News Categorization)	4	38	120k	7.6k
Y!A (Yahoo! Answers Categorization)	10	108	1400k	60k

Table 2: Classification Dataset Characteristics

We train ProFormer on multiple classification tasks individually and report *Accuracy* on corresponding test sets. We fix the projection size, $T = 420$, n-gram size=5, skip-gram size=1 for the LSH projection operation, $\mathbb{P}$. For the LPA layer, We experiment with two values for $K = 1, 4$, where $K = 1$ corresponds to the null operation in the LPA layer which just passes the word LSH projection representation to the Transformer layer. For the transformer layer, we fix the number of layers, $L = 2$ and set all layer sizes, $d = 768$ (including the intermediate size for the dense layer).[2]

---

[1] We choose K such that N is divisible by K.

[2] The rest of the parameters are same as the one used in

We compare our model with previous state of the art neural architectures, including on-device approaches. We also fine-tune the pretrained 12-layer *BERT-base* model (Devlin et al., 2018) on all classification tasks and compare to our model. *BERT-base* consists 12-layers of transformer blocks (Vaswani et al., 2017) and is pretrained in an unsupervised manner on a large corpus (BooksCorpus (Zhu et al., 2015) and English WikiPedia) using masked-language model objective. We fine-tune the pretrained *BERT-base* (Devlin et al., 2018) to each of the classification tasks. For training, we use Adam with learning rate of 1e-4, β_1=0.9, β_2=0.999, $L2$ weight decay of 0.01, learning rate warmup over the first $10,000$ steps, and linear decay of the learning rate. We use dropout probability of 0.1 on all layers and training batch size of 256. For further comparison, we also trained much smaller BERT baselines with 2-layers of transformer blocks and smaller input embedding sizes.

4 Results

Tables 3 and 4 show the results on the ATIS & MRDA short text classification and AG & Y!A long text classification tasks. We compare our approach, ProFormer against prior state-of-the-art on-device works, fine-tuned *BERT-base*, smaller 2-layer *BERT* variants and other non-on-device neural approaches.

Overall, our model ProFormer improved upon non-on-device neural models while keeping very small memory footprint and high accuracy. This is very impressive since ProFormer can be directly deployed to memory constraint devices like phones, watches and IoT while still maintaining high accuracy. ProFormer also improved upon prior on-device state-of-the-art neural approaches like SGNN (Ravi and Kozareva, 2018) and SGNN++ (Ravi and Kozareva, 2019) reaching over 35% improvement on long text classification. Similarly it improved over on-device ProSeqo (Kozareva and Ravi, 2019) models for all datasets and reached comparable performance on MRDA. In addition to the quality improvements, ProFormer also keeps smaller memory footprint than ProSeqo, SGNN and SGNN++.

In addition to the non-on-device and on-device neural comparisons, we also compare against *BERT-base* and other smaller variants. Our experiments show that ProFormer outperforms the small *BERT* baselines on all tasks. Moreover, although the 12-layer fine-tuned *BERT-base* (Devlin et al., 2018) model converged to the state-of-the-art in almost all of the tasks, ProFormer converges to $\approx 97.2\%$ *BERT-base*'s performance on an average while occupying only 13% of *BERT-base's* memory. ProFormer has 14.4 million parameters, while BERT-base has 110 million. For fair comparison, we also test ProFormer with $K = 4$, which only occupies 38.4% the memory footprint of 2-layer BERT-base model and reduces the computation overhead by 16 times. The embedding look up table occupies nearly 23 million parameters out of 38 million parameters in the 2-layer BERT model. We notice that K=4 model performs slightly worse than K=1 indicating information loss in the LPA layer. Overall, our experiments demonstrate that ProFormer reaches better performances that prior non-on-device and on-device neural approaches, and comparable performance to BERT-base models while preserving smaller memory footprint.

Models	MRDA	ATIS
ProFormer (K=1) (our model)	**89.3**	**98.2**
ProFormer (K=4) (our model)	86.7	97.0

5 Conclusion

We proposed a novel on-device neural network ProFormer, which combines LSH projection based

---

$bert\_config.json$ in *BERT-base* model (Devlin et al., 2018) text representations, with trans-former architecture and locally projected self-attention mechanism that captures long range sentence dependencies. Overall, ProFormer yields low memory footprint and reduces computations quadratically. In series of experimental evaluations on short and long text classifications we show that ProFormer improved upon prior neural models and on-device work like SGNN (Ravi and Kozareva, 2018), SGNN++ (Ravi and Kozareva, 2019) and ProSeqo (Kozareva and Ravi, 2019). ProFormer reached comparable performance to our BERT-base implementation, however it produced magnitudes more compact models than BERT-base. This is very impressive showing both effectiveness and compactness of our neural model.

Abstract

We consider the problem of multi-label classification, where the labels lie in a hierarchy. However, unlike most existing works in hierarchical multi-label classification, we do not assume that the label-hierarchy is known. Encouraged by the recent success of hyperbolic embeddings in capturing hierarchical relations, we propose to jointly learn the classifier parameters as well as the label embeddings. Such a joint learning is expected to provide a twofold advantage: i) the classifier generalises better as it leverages the prior knowledge of existence of a hierarchy over the labels, and ii) in addition to the label co-occurrence information, the label-embedding may benefit from the manifold structure of the input datapoints, leading to embeddings that are more faithful to the label hierarchy. We propose a novel formulation for the joint learning and empirically evaluate its efficacy. The results show that the joint learning improves over the baseline that employs label co-occurrence based pre-trained hyperbolic embeddings. Moreover, the proposed classifiers achieve state-of-the-art generalization on standard benchmarks. We also present evaluation of the hyperbolic embeddings obtained by joint learning and show that they represent the hierarchy more accurately than the other alternatives. The source code of the paper is available here.

1 Introduction

The problem of multi-label text classification is well known and extensively studied in literature (McCallum, 1999; Yang et al., 2009; Liu et al., 2017). The fundamental assumption is that a document is associated with multiple labels from a fixed vocabulary of labels. Often, these labels are organised in a hierarchical structure. For ex. consider a sample headline from the NYT (NewYork Times) corpus "Voice Recognition Is Improving, but Don't Stop the Elocution Lessons" for which labels are "Top/News/Technology". Here, labels are arranged in a hierarchy, hereafter referred as label hierarchy. We undertake the task of labelling documents with classes that are hierarchically organised; this problem is popularly known as *hierarchical multi-label text classification* (HMC). HMC methods have found several applications in online advertising systems (Agrawal et al., 2013), bio-informatics (Peng et al., 2016; Triguero and Vens, 2016), text classification (Rousu et al., 2006; Mao et al., 2019).

The main challenge in HMC is in modelling classification of the document into a large, imbalanced and structured output space. In HMC, the label taxonomy is a partially ordered set $(L, \prec)$ where L is a finite set of all class labels. Relation $\prec$ refers to *is-a* relationship between labels, which is asymmetric, anti-reflexive and transitive (Silla and Freitas, 2011).

Hierarchical structures can provide important insights for learning and classification tasks. However, explicit knowledge of hierarchy is not available in several domains, for instance, extreme classification datasets (Bhatia et al., 2016). In this paper, we consider the problem of structured prediction from unstructured text, in which label hierarchy is not known *apriori*. We infer hierarchies from classification judgements on the outputs that are readily available. We focus on discovering relationships between the labels in a hyperbolic space, which has natural capacity to encode hierarchical structures.

In our approach, HIDDEN (**H**yperbol**I**c label embe**DD**ings for hi**E**rarchical multi-label classificatio**N**), the labels are represented in a hyperbolic space to help respect their latent hierarchical organisation. We use this intuition to learn label embeddings for HMC without explicit supervision

on the label hierarchy.

Apart from employing hyperbolic embeddings, another key aspect of our methodology is that the parameters of the classifier as well as of the label embedding are learnt jointly. We next explain the advantage in doing so. In the absence of any partial information regarding the hierarchy, label embeddings are typically learnt using the weak supervision available in label co-occurrences (Nickel and Kiela, 2017, 2018). This weak form of supervision can be complemented if the label embedding learning is also aware of the manifold structure of the input (documents). For *e.g.*, similar documents may have similar labels, *etc.* Such a strengthening is possible only if learning happens in a joint fashion. Moreover, the generalization of the classifier also improves because of the improved embeddings (and vice-versa). Our contributions can be summarised as follows:

1. We present an approach HIDDEN, that models the implicit hierarchical organisation of labels for improved classification. It leverages properties of hyperbolic geometry to help learn embeddings for the hierarchically organised labels.
2. We present a novel formulation for jointly learning the parameters of the classifier as well as the label embedding, which can be trained solely using the supervision from the training data, and without using any explicit information regarding the label hierarchy.
3. We evaluate HIDDEN on real-world as well as synthetic datasets and show:
   (a) significant improvement over classical multi-label classification methods as well as baselines that employ hyperbolic label embeddings learnt in isolation solely based on label co-occurrence information
   (b) HIDDEN sometimes generalizes even better than state-of-the-art hierarchical multi-label classifiers that have complete access to the true label hierarchy
   (c) label embeddings learnt using the joint optimisation approach correlate better with the ground truth than other alternatives.

2 Related Work

Several conventional classification methods are capable of handling classification in multi-label settings. However, relatively fewer of these are designed to incorporate the possibly hierarchical organisation of the class labels. These include both traditional methods (Gopal and Yang, 2013; Lewis et al., 2004) as well as deep learning methods (Johnson and Zhang, 2015; Peng et al., 2018) across varied domains such as news articles, web content, *etc.* Some approaches (Bairi et al., 2015, 2016) have also attempted to identify a subset of class labels from the classification hierarchy that effectively *represents* most instances from the training dataset.

Traditional or flat classification approaches typically perform prediction assuming that all the classes are independent of each other, ignoring the class hierarchy. Whereas 'local' classification approaches (Koller and Sahami, 1997; Cesa-Bianchi et al., 2006) train a set of classifiers at each level of the hierarchy. However, it has also been argued (Cerri et al., 2011) that it is impractical to train separate classifiers at each level. On the other hand, 'global' approaches (Silla Jr and Freitas, 2009; Wang et al., 2001) train a single classifier that factors in the complete class hierarchy, while often also explicitly factoring in the label-label correlation (Kulkarni et al., 2018). Unlike the local approach, 'global' approaches do not suffer from the error propagation problem, although they are prone to under-fit by not considering local information in the hierarchy.

Some recent papers have proposed a mix of local and global approaches for HMC. Wehrmann et al. (2018) propose an objective that leverages both local and global information while introducing global hierarchical violation penalty. Mao et al. (2019) employ a reinforcement learning framework to learn a label assignment policy. They model HMC as a *markov decision process*, wherein, the agent takes an action of label assignment on the tree hierarchy and receives scalar rewards as feedback for the actions. Chen et al. (2019) embed both document and label hierarchy in the same hyperbolic space and use interactions between these embeddings for HMC. Our approach differs from these in two important ways: (i) we embed only labels into the hyperbolic space and (ii) label hierarchy is not known *apriori* - all we assume is that there is some hidden hierarchy.

Recently, the use of hyperbolic geometry has been found to be promising in machine learning and network sciences to model data with latent hierarchies. Krioukov et al. (2010) showed that properties of complex networks, namely *heterogeneous degree distribution* and *strong clustering*, naturally manifest in hyperbolic geometry. They showed that if a network has some heterogeneous degree distribution and metric structure, the network can be mapped effectively to the hyperbolic space (since euclidean distance has limitations in approximating the distance between nodes in a tree). Gromov (1987) have shown that any finite tree structure can be embedded into a finite hyperbolic space while preserving the distance between nodes. Nickel and Kiela (2017) learnt hierarchical representations of symbolic data by embedding them into an n-dimensional Poincaré ball by leveraging the distance property of hyperbolic spaces. Instead of relying on the true hierarchy to learn embeddings, Nickel and Kiela (2018) inferred hierarchies from real-valued similarity scores using the Lorentz model of hyperbolic geometry. We used a similar formulation in our model HIDDEN to build our HMC model by leveraging the co-occurrence count of labels for each document, but additionally (and more importantly), in a joint manner, learn the parameters of the classifier.

3 Hyperbolic Geometry & the Poincaré Model

In this section, we give an overview of hyperbolic geometry and the Poincaré model for embedding in hyperbolic spaces (Nickel and Kiela, 2017). A hyperbolic space is a non-Euclidean Riemannian manifold of constant negative curvature. Though there are several fundamental differences between the Euclidean and the hyperbolic geometry, the most interesting characteristic of hyperbolic spaces is their ability to naturally represent hierarchical relations (Krioukov et al., 2010). In the Poincaré ball model, which is one of the standard models for hyperbolic geometry, the Euclidean distances between equidistant points, according to the inherent manifold metric d, fall exponentially as one moves from origin towards the surface of the ball. This interesting property is the key for enabling learning of continuous embeddings of hierarchies. For example, one can imagine root node of hierarchy at origin and leaf nodes near the ball's surface. Then, this model can easily accommodate exponentially growing number of equidistant siblings at deeper levels of the hierarchy. Whereas, such an accommodation is not possible using Euclidean geometry. Below we provide some details of this model.

Let $\mathcal{B}^n = \{x \in \mathbb{R}^n | \; \|x\| < 1\}$ be the *open* n-dimensional unit ball, where $\|.\|$ is the Euclidean 2 norm. The Poincaré ball model is a Riemannian Manifold $(\mathcal{B}^n, g_x)$, the open unit ball equipped with the Riemannian metric tensor $g_x = \left(\frac{2}{1-\|x\|^2}\right)^2 g^E$, where $x \in \mathcal{B}^d$ and g^E is the Euclidean metric tensor. The geodesic distance between two points $u, v \in \mathcal{B}^d$ is given as

$$d(u,v) = arcosh\left(1 + 2\frac{\|u-v\|^2}{(1-\|u\|^2)(1-\|v\|^2)}\right) \tag{1}$$

Given any $x \in \mathbb{R}^n$, one can show that $\frac{x}{1+\sqrt{1+\|x\|_2^2}}$ always lies in the Poincare ball (refer Appendix for detailed explanation).

4 Problem Formulation and Approach

In this section, we present present details of our model, training, as well as inference.

4.1 Problem Formulation

Here we consider an interesting special case of multi-label classification. The training data is of the form: $\mathcal{D} = \{(D_1, y_1), (D_2, y_2), \ldots, (D_m, y_m)\}$, where $D_i \in \mathbb{R}^n$ is the input representation of the i^{th} document, $y_i \in \{0,1\}^L$ represents the set of active/annotated labels for it ($y_i^l = 1 \iff D_i$ is labelled with l), and L is the total number of labels. Importantly, the labels are assumed to be nodes of an unknown, yet fixed, hierarchy. Using this prior knowledge and the training data, the goal is to learn a classifier that generalises well for labelling new documents.

Classical text classification methods ignore the informative prior knowledge that the set of labels form a hierarchy. Most of the hierarchical multi-class classification models assume that the hierarchy over the labels is completely known, which might not be a pragmatic assumption, since constructing hierarchies is an expensive process, especially when the number of labels is large (Bhatia et al., 2016). In contrast, here we assume no explicit information regarding the hierarchy other than it's existence, and the implicit information encoded in the training data. Also, in our set-up, we do not restrict the labels to be the leaves nodes in the hierarchy. As motivated earlier, here we propose to learn a classifier that jointly learns the classifier parameters as well as the label embeddings.

4.2 Our Model: HIDDEN

Our proposed model HIDDEN has two key components: one for representing the documents that may lead to well-generalizing classifiers and the other for embedding the labels in a hyperbolic space. Recall that hyperbolic spaces have shown to be well-suited for data satisfying hierarchical relations.

Document Model $\mathcal{F}_w$ accepts as input a document, D, and outputs a n-dimensional representation of it, $\mathcal{F}_w(D) \in \mathbb{R}^n$. Here, w is the set of parameters to be learnt. In this work, we use TextCNN (Kim, 2014) as the document model. But our approach remains valid irrespective of the chosen document model.

Label Embedding Model $\mathcal{G}_\Theta$ accepts as input a label l and outputs a finite dimensional representation, $\mathcal{G}_\Theta(l)$. Here, Θ is the set of parameters to be learnt. In this work, following Nickel and Kiela (2018), we employ the simple look-up based model defined by $\mathcal{G}_\Theta(l) \equiv \Theta * y^l = \Theta_l$, where $\Theta \in \mathbb{R}^{n \times L}$ and Θ_l is the l^{th} column of Θ. These Euclidean embeddings Θ_l are then projected onto the Poincare manifold using the transformation $\Pi(x) = \frac{x}{1+\sqrt{1+\|x\|_2^2}}$. In summary, the hyperbolic embedding of label, l, is given by $\Pi(\Theta_l)$.

We next assume that there exists some optimal set of parameters w^*, Θ^* such that the labels annotated/active for a document, D, are exactly those whose label representations are highly aligned with that of D's representation. Here, alignment between the representations is intended to model the natural intuition of appropriateness between label and document. Following the principle of large-margin separation, in this paper we employ the **alignment model** defined below:

$$\hat{y}_D^l\left(w, \Theta\right) \equiv \sigma\left(\mathcal{F}_w\left(D\right)^\top \Theta_l\right) \tag{2}$$

where $\hat{y}_D^l\left(w, \Theta\right)$ denotes the alignment between the document, D, and the l^{th} label as per the model with parameters (w, Θ), and σ is the Sigmoid activation function.

Inference: Given the learnt parameters $(\hat{w}, \hat{\Theta})$, the labels with $\hat{y}_D^l(\hat{w}, \hat{\Theta}) > 0.5$ are predicted to be the active ones for D. We next detail the proposed joint objective for learning the parameters.

4.3 Joint Objective

The proposed objective consists of two terms: the first is an empirical multi-label loss term over the training data, and the second is a loss for ensuring that the hyperbolic label embeddings respect the pairwise label co-occurrence or any other such (pairwise) partial information regarding the underlying label hierarchy.

First Term is simply a binary cross entropy loss to promote high alignment scores for each annotated label and vice-versa:

$$\mathcal{L}_1\left(w, \Theta\right) = \sum_{i=1}^{m}\sum_{l=1}^{L}\Big[y_i^l \log\left(\hat{y}_i^l\left(w, \Theta\right)\right) + \left(1 - y_i^l\right)\log\left(1 - \hat{y}_i^l\left(w, \Theta\right)\right)\Big] \tag{3}$$

where $\hat{y}_i^l$ is a short-hand for $\hat{y}_{D_i}^l$.

Second Term induces lesser geodesic distance in the hyperbolic space between the label embeddings that have higher co-occurrences than those between label pairs that have less co-occurrence (Nickel and Kiela, 2018):

$$\mathcal{L}_2(\Theta) = \sum_{\substack{l,l' \in L,\\ l' \neq l}} \log\left(\frac{e^{-d(\Pi(\Theta_l),\Pi(\Theta_{l'}))}}{\sum_{z \in \mathcal{N}(l,l')} e^{-d(\Pi(\Theta_l),\Pi(\Theta_{l'}))}}\right) \tag{4}$$

where d is the metric in the hyperbolic space given by Eq.1, $\Pi(\Theta_l)$ is hyperbolic embedding of l^{th} label, and $\mathcal{N}\left(l, l'\right)$ is the set of all labels that less frequently co-occur with l than l' co-occurs with l.

The overall objective function is a weighted sum of the two components described above

$$\mathcal{L}\left(w, \Theta\right) = \mathcal{L}_1\left(w, \Theta\right) + \lambda \mathcal{L}_2\left(\Theta\right) \tag{5}$$

We refer to the model corresponding to the parameters $(w_{\text{jnt}}, \Theta_{\text{jnt}})$ that minimizes this joint objective in Eq.5 as **HIDDEN$_{\text{jnt}}$**:

$$(w_{\text{jnt}}, \Theta_{\text{jnt}}) \in \arg\min_{w,\Theta} \mathcal{L}(w, \Theta) \tag{6}$$

Both components of our loss interact with each other to minimize the distance between document and label embeddings in the hyperbolic space. The advantage of the joint learning is well illustrated when HIDDEN$_{\text{jnt}}$ is compared with the following baseline, henceforth referred to as **HIDDEN$_{\text{cas}}$**:

(1) $\mathcal{L}_2$ is minimized to obtain label embeddings $\hat{\Theta}_{\text{cas}} \in \arg\min_\Theta \mathcal{L}_2\left(\Theta\right)$.

(2) These are then used in $\mathcal{L}_1$ to obtain document parameters: $\hat{w}_{\text{cas}} \in \arg\min_w \mathcal{L}_1(w, \hat{\Theta}_{\text{cas}})$.

We also empirically compare with the following multi-class classification baseline, henceforth referred to as **HIDDEN$_{\text{flt}}$**:

(1) Θ_{flat} is fixed to the identity matrix.

(2) These are then used in $\mathcal{L}_1$ to obtain document parameters: $\hat{w}_{\text{flat}} \in \arg\min_w \mathcal{L}_1(w, \hat{\Theta}_{\text{flat}})$.

To evaluate the benefit of using hyperbolic spaces for embedding labels, we also compare with a variant of HIDDEN$_{\text{jnt}}$ called **HIDDEN$_{\text{euc}}$** for which $\mathcal{L}_2$ is modified to be

$$\mathcal{L}_{2\text{Euc}}(\Theta) = \sum_{\substack{l,l' \in L, \\ l' \neq l}} \log \left(\frac{e^{-\|\Theta_l - \Theta_{l'}\|_2}}{\sum_{z \in \mathcal{N}(l,l')} e^{-\|\Theta_l - \Theta_{l'}\|_2}} \right) \tag{7}$$

to obtain the parameters $(w_{\text{euc}}, \Theta_{\text{euc}})$ as $(w_{\text{euc}}, \Theta_{\text{euc}}) \in \arg\min_{w,\Theta} \mathcal{L}_1(w, \Theta) + \lambda \mathcal{L}_{2\text{Euc}}(\Theta)$

Note that none of the variants of HIDDEN assume any explicit information regarding the underlying hierarchy. However, the former three exploit the prior knowledge that there exists a label hierarchy; whereas the latter, which is the classical multi-label classification network, completely ignores this useful information. Moreover, since the proposed model HIDDEN$_{\text{jnt}}$ performs joint learning, it is expected that HIDDEN$_{\text{jnt}}$ not only achieves better generalization, but also leads to better label embeddings, when compared to HIDDEN$_{\text{cas}}$. The simulation results in section 5 confirm the same.

4.4 Training Details

In all our experiments, the initial word embedding layer of TextCNN in the document model is initialized using 300 dimensional GloVe embeddings (Pennington et al., 2014). Following Nickel and Kiela (2017), we randomly initialize Θ from the uniform distribution $\mathcal{U}(-0.001, 0.001)$. Both the document and label representations are are of length $n = 300$. We randomly choose 10% of training set as the validation set and report test set results on the best validation epoch. During training, dropout is applied to the outputs of document model as well the label model with probabilities 0.1 and 0.6 respectively. We found $\lambda = 0.1$ to yield the best validation performance. The number of training epochs are set to 30 for all experiments. Both models are optimized using stochastic gradient descent using Adam optimizer (Kingma and Ba, 2014) with learning rate as 0.001 for TextCNN.

We run all our experiments on Nvidia RTX 2080 Ti GPUs 12 GB RAM over Intel Xeon Gold 5120 CPU having 56 cores and 256 GB RAM. It takes around 1, 2 and 5 hours to train the model on RCV1, NYT and Yelp datasets respectively.

5 Experiments

In this section, we compare our approach against the baseline models and other state-of-the-art HMC approaches. First we describe the evaluation metrics and illustrating results in a synthetic setting.

5.1 Evaluation Measures

Classifier Evaluation Measures: We use standard measures for evaluating any HMC, *viz.*, **Macro-F1** and **Micro-F1**. Let TP, TN, FN, FP denote the true positive, true negative, false negative and false positive labels respectively. Precision is $\frac{TP}{TP+FP}$ and recall is $\frac{TP}{TP+FN}$. F1-score is the harmonic mean of precision and recall. **Macro-F1** assigns equal weightage to each class and is computed as the averaged F1 score over all classes. **Micro-F1** is the F1-score computed over all instances.

Label Embedding Evaluation Measures: For a given application, let us say $\mathcal{H}_*$ is provided to us as the ground truth hierarchy of labels/nodes, which was assumed to be unknown in our problem formulation in Section 4.1. Recall that none of the variants of HIDDEN has access to $\mathcal{H}_*$. How consistent with respect to $\mathcal{H}_*$ are the label embeddings learnt by these models? We attempt to assess this consistency by adopting standard measures such as Spearman's rank correlation coefficient (Zar, 2005) and Normalized Discounted cumulative gain (NDCG) (Järvelin and Kekäläinen, 2002).

Recall from Section 4.3, that the hyperbolic embedding for label l is $\Pi(\Theta_l)$ and likewise for l', it is $\Pi(\Theta_{l'})$. The model parameters Θ might be learnt using any variant of HIDDEN. Given a query label, l, the geodesic distance $d(\Pi(\Theta_l), \Pi(\Theta_{l'}))$ is used to rank all other labels $l' \neq l$; smaller the distance, larger the rank. Any two labels $l' \neq l''$ that are at the same geodesic distance from l, will be assigned the same rank $r = r''$. Next, we define a graded relevance score for labels with respect to the ground truth hierarchy, $\mathcal{H}_*$. For any given query label $l \in \mathcal{H}_*$, we also assign a graded relevance $rel' \in \mathbb{N}$ to every other label $l' \neq l$ based on the distance (number of hops $hops(l, l')$) of l' from l in the hierarchy $\mathcal{H}_\mathcal{D}$; smaller the distance, larger the graded relevance (we considered $rel' \propto \frac{1}{hops(l,l')}$, for example).

Discounted Cumulative Gain (DCG) (Järvelin and Kekäläinen, 2002) is a standard measure of the quality of ranking of an approach with respect to the graded relevance provided in the ground truth. DCG@k measures items (*eg:* labels l') k hops away

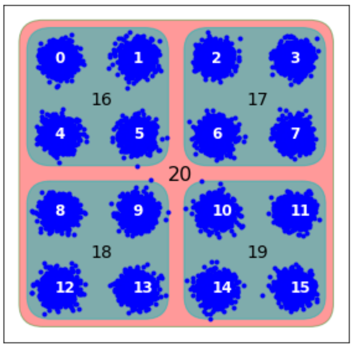

Figure 1: Gaussian used for the synthetic experiment

Prob	0.00		0.20		0.40	
	Micro F1	Macro F1	Micro F1	Macro F1	Micro F1	Macro F1
HIDDEN$_{\text{flt}}$	96.8	89.1	93.2	87.8	90.4	87.7
HIDDEN$_{\text{cas}}$	98.0	93.4	94.4	88.9	91.9	91.0
HIDDEN$_{\text{jnt}}$	98.1	94.0	94.8	91.6	92.3	91.7

Table 1: Comparison of methods on the Synthetic **SETTING 1** with respect to increasing probability with which a label is randomly dropped. Synthetic data used here has 12000 training and 8000 test samples.

from the query l. The gain is accumulated from the top of the ranked list upto some pre-specified position k in the list, with the gain of each result discounted at lower ranks: $DCG_k = \sum_{i=1}^{k} \frac{rel_i}{log_2(i+1)}$. Here, rel_i is the graded relevance at position i. This result is itself averaged over all query labels $l \in \mathcal{H}_*$.

Spearman's rank correlation coefficient denoted by r is a non-parametric metric to measure statistical dependence between ranking of two variables. For each query label (l), we first measure rank correlation between the predicted rank r_p of a label l' and its own rank r_h as per ground truth hierarchy h. The correlation coefficient between r_{l_p} and r_{l_h} is computed as $r_l = \frac{cov(r_p, r_h)}{\sigma_{r_p}\ \sigma_{r_h}}$. Here, cov is the covariance and σ, the standard deviation. The final score, r is the averaged score across all labels l' in the set.

5.2 Validation via Synthetic Experiments

To observe the behaviour of the proposed approach HIDDEN with respect to the evaluation measures in a controlled environment, we present one such synthetic setup. The goal in this section is to illustrate the advantage of joint learning of parameters over isolated learning. Consider 2D data generated from 16 neatly separated Gaussians laid out on a grid as illustrated in Figure 1. Each of the 16 gaussians corresponds to a single label $l_1, l_2 ... l_{16}$. We consider a second layer of 4 labels $l_{17} ... l_{20}$, obtained by grouping the gaussians into 4; each quadrant in the larger square would correspond to a single label. Finally, we have a third layer consisting of a single label l_{21} - *viz.*, the entire large square. This simple hierarchy is hidden from our variants of HIDDEN as well as from the flat model. The synthesized data is split randomly into train-test in the ratio 60:40. For each of the jointly optimised model HIDDEN$_{\text{jnt}}$, the cascaded model HIDDEN$_{\text{cas}}$ as well as the flat model, we observe (i) the performance of the classification models $\mathcal{F}_w(D)$ measured in terms of **Micro-F1** and **Macro-F1** as well as (ii) the consistency of the label embedding models $\mathcal{G}_\Theta(l)$ with respect to the hidden 3-level hierarchy over the 21 labels. We record observations in two settings:

SETTING 1 in which *for each training instance, one of the annotated labels are dropped, uniformly at random:* In Table 1 we note the performances of the different approaches with increasing rate at which labels are dropped. The jointly optimised model HIDDEN$_{\text{jnt}}$ accounts for the classification task through loss component $\mathcal{L}_1$ as also the somewhat redundant label co-occurrence through the loss component $\mathcal{L}_2$.

As expected, we observe that the performance of HIDDEN$_{\text{jnt}}$ is more robust to this form of label noise than the HIDDEN$_{\text{cas}}$ and HIDDEN$_{\text{flt}}$models. This is because HIDDEN$_{\text{flt}}$ entirely relies on the training data and ignores the prior knowledge of existence of a label hierarchy. HIDDEN$_{\text{cas}}$ is also less robust as it over-relies on the label co-occurrence by minimising $\mathcal{L}_2$ (which, in isolation will be sensitive to label noise), before venturing into the classification task by minimising $\mathcal{L}_1$.

SETTING 2 in which the size of the *training set is decreased without corrupting labels:* We observe the performances of the different approaches with decreasing size of the training set and note that the performance of the jointly optimised model HIDDEN$_{\text{jnt}}$ falls back on the label correlation signals through the loss component $\mathcal{L}_2$ and is therefore more robust to decreasing size of the data set than the flat classifier. We observed similar results for other synthetic settings. Owing to space constraints, the plots and other ranking results are provided in the supplementary material.

5.3 Real-world Text Datasets

We used three datasets, namely, RCV1, Yelp and NYT in our experiments:

(1) **RCV1** (Lewis et al., 2004) - RCV1 is a

newswire dataset of the articles collected between 1996-1997 from Reuters

(2) **NYT** (Sandhaus, 2008) - This corpus contains articles from New York Times published between January 1st, 1987 and June 19th, 2007

(3) **Yelp** [1] - Yelp is a review dataset of restaurants and each review is labelled with hierarchical categories of restaurants. Following the experimental design in Mao et al. (2019), we use the set of reviews for a business to predict the categories to which the business belongs.

Some statistics pertaining to these datasets are presented in Table 2.

Dataset	Hierarchy	|L|	Avg(|L|)	Max(|L|)	Train	Val	Test
RCV1	Tree	104	3.24	17	20833	2314	781265
NYT	Tree	120	6.58	24	86461	9606	9903
Yelp	DAG	539	4.07	32	98460	10939	46884

Table 2: Statistics of the datasets used in the experiments. $|L|$ denotes the number of labels, Avg($|L|$) is the average number of labels per instance and Max($|L|$) is the maximum number of labels for an instance.

5.4 Comparison of models that do not use the true hierarchy

We compare performance of the different models that do not use the true hierarchy. These include our flat baseline HIDDEN$_{\text{flt}}$, the cascaded model HIDDEN$_{\text{cas}}$ as well as our joint model HIDDEN$_{\text{jnt}}$. We compare them against the baseline TextCNN-flat model reported in Mao et al. (2019). The results are presented in Table 3 for $\lambda = 0.1$.

Overall, our baseline (HIDDEN$_{\text{flt}}$) performs better than the previous baseline with the exception of Macro-F1 on NYT. We observe improvement of the joint model HIDDEN$_{\text{jnt}}$ over the flat (HIDDEN$_{\text{flt}}$) and cascaded (HIDDEN$_{\text{cas}}$) models on RCV1 and NYT (for each of which, the labels form a tree) in Table 3. However, on the Yelp dataset, the cascaded model (HIDDEN$_{\text{cas}}$) performs somewhat worse (-2 Micro-F1 and -3.3 Macro-F1) than our baseline model (HIDDEN$_{\text{flt}}$), hinting at the possibility that label co-occurrence information might not be helpful toward the classification task. This could be partly also because the labels in Yelp are structured in the form of a DAG. Constant curvature property of hyperbolic spaces makes them unsuitable for learning DAG structures (Li et al., 2018). However, the Macro-F1 performance of HIDDEN$_{\text{jnt}}$ is far better than that of the cascaded model HIDDEN$_{\text{cas}}$. This illustrates that our joint model is able to better recover from less reliable (or less useful) label co-occurrence information, just as was illustrated in the Table 1 for the synthetic setting.

Dataset	Method	Micro-F1	Macro-F1
RCV1	TextCNN-Flat*	76.6	43.0
	HIDDEN$_{\text{flt}}$	77.9	44.5
	HIDDEN$_{\text{cas}}$	78.0	45.5
	HIDDEN$_{\text{jnt}}$	**79.3**	**47.3**
NYTimes	TextCNN-Flat*	69.5	39.5
	HIDDEN$_{\text{flt}}$	76.4	37.1
	HIDDEN$_{\text{cas}}$	74.6	33.2
	HIDDEN$_{\text{jnt}}$	**77.0**	**43.6**
Yelp	TextCNN-Flat*	**62.8**	27.3
	HIDDEN$_{\text{flt}}$	62.5	**37.9**
	HIDDEN$_{\text{cas}}$	60.5	33.9
	HIDDEN$_{\text{jnt}}$	60.8	35.6

Table 3: Performance comparison on all three datasets with TextCNN as the base classification model. Recall that HIDDEN$_{\text{flt}}$ is our own multi-class classification baseline. We observe that the numbers reported by Mao et al. (2019) (indicated by *) for the TextCNN based flat baseline model are consistently outperformed by the proposed HIDDEN models.

5.5 Comparison of Hyperbolic space and Euclidean space

To assess the utility of the hyperbolic space for embedding hierarchical labels, we compare HIDDEN$_{\text{jnt}}$ and HIDDEN$_{\text{euc}}$. Table 4 presents this comparison on the three datasets. HIDDEN$_{\text{euc}}$ performs worse than HIDDEN$_{\text{jnt}}$ which uses the hyperbolic space for embedding labels (except Micro-F1 for Yelp due to reasons stated before). This is expected since embedding trees is much more effective in the hyperbolic space compared to Euclidean space since in the hyperbolic space, volume grows exponentially with distance from the origin while in Euclidean space, this growth is polynomial. The number of nodes in a tree also increases exponentially with distance from the root, making Hyperbolic spaces useful for embedding hierarchies.

5.6 Comparison with model that explicitly uses the true hierarchy

We compare performance of our joint approach HIDDEN$_{\text{jnt}}$ against a state-of-the-art hierarchical multi-label classifier, HiLAP (Mao et al., 2019). However, unlike our proposed models (variants of HIDDEN), HiLAP has access to the true hierarchy

---

[1] `https://www.yelp.com/dataset/challenge`

Dataset	Method	Micro-F1	Macro-F1
RCV1	HIDDEN$_{\text{euc}}$	78.4	47.6
	HIDDEN$_{\text{jnt}}$	**79.3**	**47.3**
NYTimes	HIDDEN$_{\text{euc}}$	76.4	40.4
	HIDDEN$_{\text{jnt}}$	**77.0**	**43.6**
Yelp	HIDDEN$_{\text{euc}}$	**61.1**	34.2
	HIDDEN$_{\text{jnt}}$	60.8	**35.6**

Table 4: Performance comparison for HIDDEN$_{\text{jnt}}$ with HIDDEN$_{\text{euc}}$. HIDDEN$_{\text{jnt}}$ consistently has better Macro-F1 better than HIDDEN$_{\text{euc}}$ and generally better Micro-F1 too. This illustrates the utility of Hyperbolic spaces for embeddding label hierarchies.

both training and inference. Thus, HiLAP serves as some form of skyline for the HIDDEN suite of approaches proposed in this paper. HiLAP learns label assignment policy using the reinforcement learning framework.

In Table 5, we compare the performance of HIDDEN$_{\text{jnt}}$ against HiLAP model as reported in Mao et al. (2019). Interestingly, on RCV1, we obtain better Micro-F1 score (+0.7) for the joint model HIDDEN$_{\text{jnt}}$ over the HiLAP method. On NYT, our Micro-F1 score is far better (+7.1) than HiLAP; our Macro-F1 score is also marginally better (+0.4) than their Macro-F1 scores. These results are interesting because HIDDEN$_{\text{jnt}}$ seems to obtain better generalisation through joint learning of the document classifier and label embeddings in a hyperbolic space, even without access to the true hierarchy. However, on Yelp, HiLAP seems to benefit over HIDDEN$_{\text{jnt}}$ by explicitly using the true hierarchy.

Dataset	HIDDEN$_{\text{jnt}}$		HiLAP	
	Micro	Macro	Micro	Macro
RCV1	**79.3**	47.3	78.6	**50.5**
NYTimes	**77.0**	**43.6**	69.9	43.2
Yelp	60.8	35.6	**65.5**	**37.3**

Table 5: Performance comparison of HIDDEN$_{\text{jnt}}$ with HiLAP with respect to Macro-F1 and Micro-F1. It it interesting to note here that though HIDDEN$_{\text{jnt}}$ does not know the true hierarchy, it performs better than HiLAP (which uses the true hierarchy) in some cases. (HiLAP numbers are those reported by Mao et al. (2019))

5.7 Evaluating performance of embeddings

We compare embeddings learned using different approaches with the ground truth hierarchy to evaluate the effectiveness of the embeddings. Figure 2 shows the plot of NDCG scores for different values of k on the RCV1 and NYTimes dataset across HIDDEN$_{\text{cas}}$ and HIDDEN$_{\text{jnt}}$ (for two different values of λ). In Table 6, we compare the Spearman rank correlation. The superior performance of HIDDEN$_{\text{jnt}}$strongly suggests that the embeddings learnt using the joint model are more representative of the true hierarchical organisation of the labels than those obtained using the flat and cascaded variants. This also goes to show that even the first term in our objective has positive contribution towards the learning of hyperbolic embeddings and indeed joint learning is beneficial.

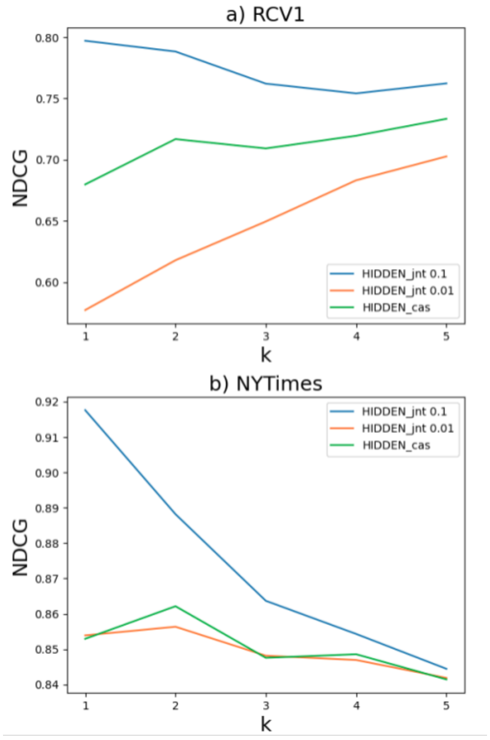

Figure 2: Plot of NDCG versus k for assessing the quality of the learnt label embeddings with respect to the actual hierarchy on RCV1 and NYT datasets. The better performance of HIDDEN$_{\text{jnt}}$ indicates the label embeddings Θ_{jnt} are most representative of the true hierarchy.

6 Conclusion

We propose a novel approach to hierarchical multi-label classification based on joint learning of document classifier and label embeddings in hyperbolic space. The proposed framework HIDDEN allows us to discover label hierarchical relationship by leveraging properties of hyperbolic geometry. Even though label-hierarchy is assumed to be unavailable, our method achieves comparable results

	HIDDEN$_{\text{flt}}$	HIDDEN$_{\text{jnt}}$	HIDDEN$_{\text{cas}}$
RCV1	21.2	**53.9**	44.1
NYTimes	11.4	**39.5**	36.1
Yelp	16.3	**31.9**	28.8

Table 6: Spearman rank correlation test for the generated embeddings for all the datasets. Each method is compared against the ground truth hierarchy. Highest values for HIDDEN$_{\text{jnt}}$ indicates the label embeddings Θ_{jnt} are most representative of the true hierarchy.

with state-of-the-art *hierarchy aware* methods. We performed extensive experiments on three datasets and demonstrate effectiveness of the learned embeddings.

Appendix

1 Explanation for $\Pi(x)$

The Lorentz model is defined as the Riemannian Manifold, $\mathcal{L}^n = (\mathcal{H}^n, g_l)$, where $\mathcal{H}^n = \{\mathbf{x} \in \mathbb{R}^{n+1} : \langle \mathbf{x}, \mathbf{x} \rangle_{\mathcal{L}} = -1, \mathbf{x}_0 > 0\}$, and $g_l = diag([-1\ 1\ \dots\ 1])$. Here, $\langle \mathbf{x}, \mathbf{y} \rangle_{\mathcal{L}}$, known as the Minkowski inner-product, is given by

$$\langle \mathbf{x}, \mathbf{y} \rangle_{\mathcal{L}} = -x_0 y_0 + x_1 y_1 + \ldots + x_n y_n$$

The Poincaré model and the Lorentz model are equivalent in isometry. Therefore points in Lorentz manifold can be mapped into Poincaré ball as, $p : \mathcal{H}^n \to \mathcal{P}^n$

$$p(x_0, x_1, \ldots, x_n) = \frac{(x_1, \ldots, x_n)}{x_0 + 1}$$

A point $\mathbf{x}$ in the Euclidean space $\mathbb{R}^n$ can be projected onto the Lorentz manifold $\mathcal{H}^n$ using the transformation $\Omega(\mathbf{x}) = \left[\sqrt{1 + \|\mathbf{x}\|^2}, \mathbf{x}\right]$. This transformation ensures that the Minkowski inner-product, $\langle \Omega(\mathbf{x}), \Omega(\mathbf{x}) \rangle_{\mathcal{L}}$, is equal to -1, and that the first component, $\Omega(\mathbf{x})_0 \equiv \sqrt{1 + \|\mathbf{x}\|^2}$ is positive, as required for membership in the Lorentz manifold.

Now using the isometry between Poincaré and Lorentz models (Nickel and Kiela, 2018), we have $\Pi : \mathbb{R}^n \to \mathcal{P}^n$ as

$$\Pi(\mathbf{x}) = p\left(\Omega(\mathbf{x})\right) = \frac{\mathbf{x}}{1 + \sqrt{1 + \|\mathbf{x}\|^2}}$$

2 Dataset Details

We describe the details of the datasets used in our experiments.

For RCV1 dataset (Lewis et al., 2004), we use the original training/test split and use 10% of the training set as the validation set. We introduce an extra *Root* label in addition to the 103 labels present in the dataset. Each document in the dataset is labelled with this label.

The details for the other datasets used are same as in Mao et al. (2019) and we refer the readers to the same.

3 Remarks on Synthetic Experiments

In **SETTING 1**, with increasing probability of a label being randomly dropped, we observe in Figure 3 that the performance of all the models decreases which is expected. However, it is interesting to note that HIDDEN$_{\text{jnt}}$ is more robust to the noisy labels and always performs better than HIDDEN$_{\text{flt}}$ since it has an additional source of information about the labels via label co-occurrences. This information is also implicitly available to HIDDEN$_{\text{flt}}$ but from our experiments, we observe that providing this information explicitly improves performance. We also observe that performance of HIDDEN$_{\text{cas}}$ fluctuates quite a bit which is probably due to the fact that it overly relies on label co-occurrence and commits to a set of label embedding before trying to solve the classification task.

In **SETTING 2**, with increasing number of points in the training set, we observed in Figure 4 that with very small datasets, HIDDEN$_{\text{cas}}$ performs slightly better than HIDDEN$_{\text{jnt}}$ but with increasing dataset sizes, HIDDEN$_{\text{jnt}}$ performs better. Since there is no label noise in this setting, the label co-occurances are expected to be quite meaningful and with small dataset sizes, jointly learning both the document embedding model $\mathcal{F}_w$ and the label embeddings Θ jointly (HIDDEN$_{\text{jnt}}$) is more difficult compared learning Θ first and then $\mathcal{F}_w$ (HIDDEN$_{\text{cas}}$).

HIDDEN$_{\text{jnt}}$ and HIDDEN$_{\text{cas}}$ perform better than HIDDEN$_{\text{flt}}$ since the former can fall back of the label correlation signal via $\mathcal{L}_2$ which is available in a much more easily usable format than to HIDDEN$_{\text{flt}}$. As discussed above, having the label co-occurrences available explicitly to the models help achieve better performance.

We observe similar results in other synthetic settings.

4 Hierarchy of the Synthetic data

As described in the paper, the synthetic data is generated from 16 Bivariate Gaussian distributions with their means placed evenly in a 4×4 grid. These Gaussians are then grouped at various levels to get an hierarchy with 3 level as shown in Figure 5.

5 Contrasting label hierarchies across datasets

Recall, how in Table 3 of the paper, we observe improvement of the joint model HIDDEN$_{\text{jnt}}$ over the flat (HIDDEN$_{\text{flt}}$) and cascaded (HIDDEN$_{\text{cas}}$) models on RCV1 and NYTimes datasets. Note that the labels of RCV1 as well as of NYTimes form trees. However, on the Yelp dataset, the cascaded model (HIDDEN$_{\text{cas}}$) performs somewhat worse (-2 on micro and -3.3 on macro) than our baseline

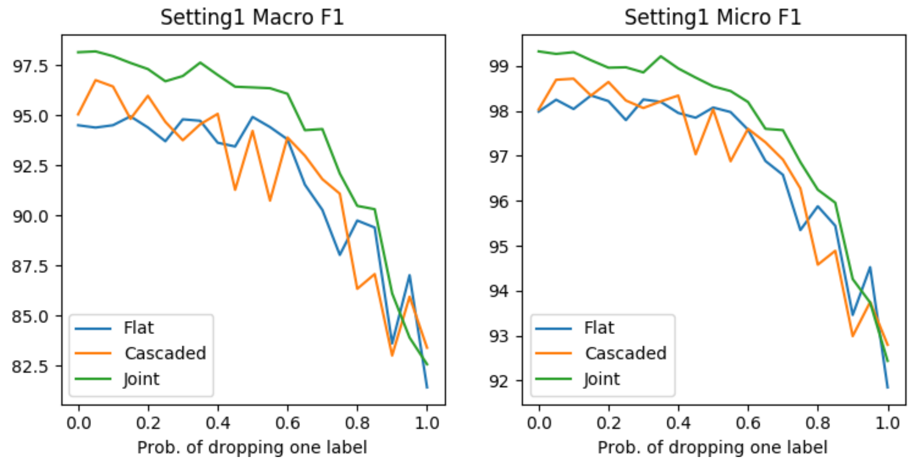

Figure 3: Micro and Macro F1 scores with increasing probability of randomly dropping one label for all three model. Scores are averaged over 10 runs

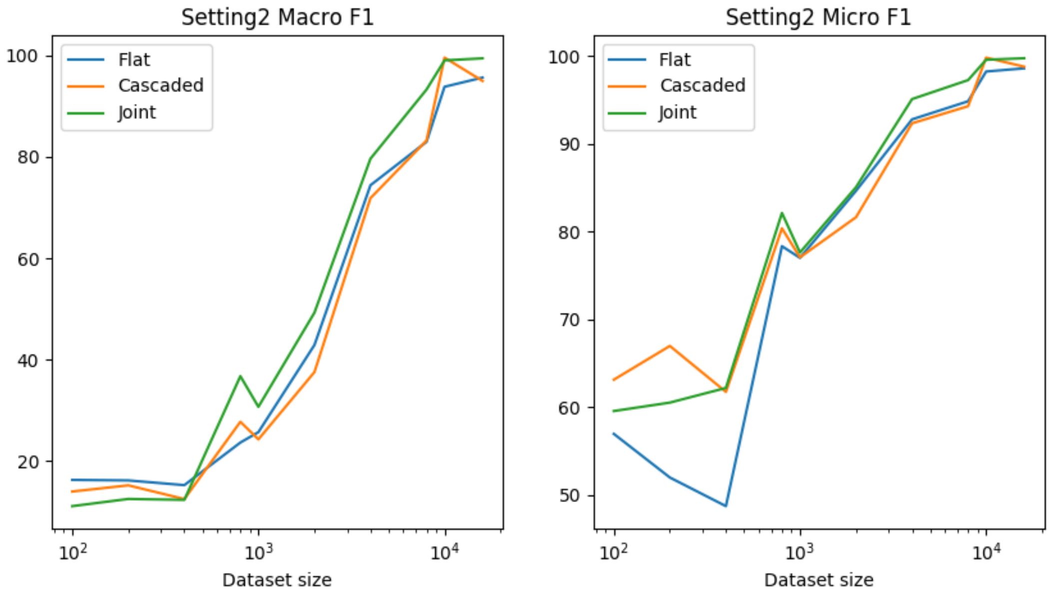

Figure 4: F1 scores with increasing dataset sizes (number of points in train set) for all three model

model (HIDDEN$_{\text{flt}}$), hinting at the possibility that label co-occurrence information might not be helpful toward the classification task. This could be partly also because the labels in Yelp are structured in the form of a DAG with 12 labels in the labels set having more than one parent.

Dataset	RCV1	NYT	Yelp
Hyperbolicity	0	1	1

Table 7: Hyperbolicity (Gromov, 1987) of the label hierarchies for the datasets used

5.1 δ-hyperbolicity

To further investigate why our method fails to perform well on Yelp dataset, we compute hyperbolicity (Gromov, 1987) for each of the label hierarchies. The hyperbolicity δ of a graph G is a measure of how tree-like the graph is. Lower the δ, the more tree-like is the graph. Hyperbolicity δ is 0 for trees.

As shown in Table 7, RCV1 has 0 hyperbolicity as expected, since the label hierarchy is a tree. We would have expected NYT to also have a hyperbolicity of 0 but the label `Others` appears at different levels of the hierarchy making it a DAG. However, this is the only deviation from being a tree and thus our method is able to perform well on NYT. For Yelp, the hyperbolicity is 1 and there are multiple labels with more than one parent and thus it is less tree-like than the NYT hierarchy. It

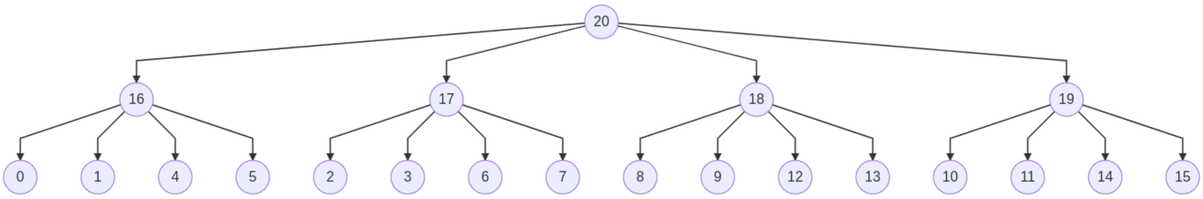

Figure 5: Hidden Hierarchy in the Synthetic experiments

is due to this DAG-ness that our method does not perform as well on Yelp as the other datasets. Note that this a limitation of hyperbolic spaces and using other geometric spaces which are conducive to embeddings DAGs, our method is expected to perform well even when the implicity label hierarchy is a DAG. In summary, hyperbolic spaces are good for embedding low δ-hyperbolicity graphs and thus our methods performance better with graphs having low hyperbolicity.

Segmenting Subtitles for Correcting ASR Segmentation Errors

Abstract

Typical ASR systems segment the input audio into *utterances* using purely acoustic information, which may not resemble the sentence-like units that are expected by conventional machine translation (MT) systems for Spoken Language Translation. In this work, we propose a model for correcting the acoustic segmentation of ASR models for low-resource languages to improve performance on downstream tasks. We propose the use of subtitles as a proxy dataset for correcting ASR acoustic segmentation, creating synthetic acoustic utterances by modeling common error modes. We train a neural tagging model for correcting ASR acoustic segmentation and show that it improves downstream performance on MT and audio-document cross-language information retrieval (CLIR).

1 Introduction

Typical ASR systems segment the input audio into *utterances* using purely acoustic information, i.e., pauses in speaking or other dips in the audio signal, which may not resemble the sentence-like units that are expected by conventional MT systems for spoken language translation (SLT) (Cho et al., 2017). Longer utterances may span multiple sentences, while shorter utterances may be sentence fragments containing only a few words (see Figure 1 for examples). Both can be problematic for downstream MT systems. In this work, we propose a model for correcting the acoustic segmentation of an ASR model to improve performance on downstream tasks, focusing on the challenges inherent to SLT pipelines for low-resource languages.

While prior work has trained intermediate components to segment ASR output into sentence-like units (Matusov et al., 2007; Rao et al., 2007), these have primarily focused on highly resourced language pairs such as Arabic and Chinese. When the source language is low-resource, suitable training data may be very limited for ASR and MT, and even nonexistent for segmentation. Since typical low-resource language ASR datasets crawled from the web do not have hand-annotated segments, we propose deriving proxy segmentation datasets from film and television subtitles. Subtitles typically contain segment boundary information like sentence-final punctuation, and while they are not exact transcriptions, they are closer to transcribed speech than many other large text corpora.

Our proposed model takes as input a sequence of tokens and segmentation boundaries produced by the acoustic segmentation of the ASR system and returns a corrected segmentation. While subtitles are often similar to speech transcripts, they lack an existing acoustic segmentation for our model to correct. To account for this, we generate synthetic acoustic segmentation by explicitly modeling two common error modes of ASR acoustic segmentation: under- and over-segmentation.

We evaluate the downstream MT performance in a larger SLT pipeline, and show improvements in translation quality when using our segmentation model to correct the acoustic segmentation provided by ASR. We also extrinsically evaluate our improved SLT pipeline as part of a document-level cross-lingual information retrieval (CLIR) task, where we show that improvements in ASR segmentation also lead to improved relevance of search results. We report results for nine translation settings: Bulgarian (BG) to English, Lithuanian (LT) to English, and Farsi (FA) to English, and when using either phrase-based, statistical MT (SMT) or one of two neural MT (NMT) models. We finally perform an ablation study to examine the effects of our synthetic acoustic boundaries and our over- and under-segmentation noise.

This paper makes the following contributions. *(i)* We propose the use of subtitles as a proxy dataset for correcting ASR acoustic segmentation and *(ii)* a method for adding synthetic acoustic utterance segmentations to a subtitle dataset, as well as *(iii)* a

simple neural tagging model for correcting ASR acoustic segmentation before use in an MT pipeline. *(iv)* Finally, we show downstream performance increases on MT and document-level CLIR tasks, especially for more syntactically complex segments.

2 Related Work

Segmentation in SLT has been studied quite extensively in high-resource settings. Early work used kernel-based SVM models to predict sentence boundaries using language model probabilities along with prosodic features such as pause duration (Matusov et al., 2007; Rao et al., 2007) and part-of-speech features derived from a fixed window size (Rangarajan Sridhar et al., 2013). Other work has modeled the problem using hidden markov models (Shriberg et al., 2000; Gotoh and Renals, 2000; Christensen et al., 2001; Kim and Woodland, 2001) and conditional random fields (Liu et al., 2005; Lu and Ng, 2010).

More recent segmentation work uses neural architectures, such as LSTM (Sperber et al., 2018) and Transformer models (Pham et al., 2019). These models benefit from the large training data available for high-resource languages. For example, the TED corpus (Cettolo et al., 2012) for SLT from English to German includes about 340 hours of well-transcribed data. To our knowledge, such datasets do not exist for the languages we are interested in. Wan et al. (2020) develop a segmentation model in our setting using subtitles; however, they do not take into account explicit modeling of segmentation errors and show only minimal and intermittent improvements in downstream tasks.

Recent work has increasingly focused on end-to-end models of SLT in a high-resource setting, since these systems reduce error propagation and latency when compared to cascaded approaches (Weiss et al., 2017; Cross Vila et al., 2018; Sperber et al., 2019; Gaido et al., 2020; Bahar et al., 2020; Lakumarapu et al., 2020). In spite of these advantages, end-to-end systems have only very recently achieved competitive results due to the limited amount of parallel data for speech translation as compared to the data that is available to train ASR systems and translation systems separately (Gaido et al., 2020; Ansari et al., 2020).

3 Problem Definition

We treat the ASR acoustic segmentation problem as a sequence tagging problem (Stolcke and Shriberg, 1996). Unlike a typical tagging problem, which aims to tag a single input sequence, our input is a pair of aligned sequences of n items, $\mathbf{x} = [x_1, \ldots, x_n]$ and $\boldsymbol{\gamma} = [\gamma_1, \ldots, \gamma_n]$ where $\mathbf{x}$ and $\boldsymbol{\gamma}$ are the ASR tokens and acoustic segmentation respectively. The tokens x_i belong to a finite vocabulary $\mathcal{V}$, while the acoustic segmentation boundary tags are binary, i.e., $\gamma_i \in \{0, 1\}$, where $\gamma_i = 1$ indicates that the ASR acoustic segmentation placed a boundary between tokens x_i and x_{i+1}. The goal is to predict a corrected segment boundary tag sequence $\mathbf{y} = [y_1, \ldots, y_n] \in \{0, 1\}^n$ from $\mathbf{x}$ and $\boldsymbol{\gamma}$.

We do this by learning a probabilistic mapping from token/segmentation sequences to corrected segmentation $p(\cdot|\mathbf{x}, \boldsymbol{\gamma}; \theta) : \{0, 1\}^n \rightarrow (0, 1)$ where p is a neural tagging model with parameters θ. While $\boldsymbol{\gamma}$ are produced solely from acoustic cues, p can take advantage of both the acoustic information (via $\boldsymbol{\gamma}$) as well as syntactic/semantic cues implicit in $\mathbf{x}$.

Synthetic Acoustic Segmentation (γ):

YEAH ■ THE HOLIDAY MARKET ■ IS TOO ■ BUSY YES ■

Figure 2: Example of synthetic acoustic segmentation (γ) creation. For each training datapoint, we have as model input the tokens $\mathbf{x}$ and the corresponding model output sentence boundary labels $\mathbf{y}$. To generate the synthetic acoustic segmentation (γ), we apply under-segmentation ($\breve{\gamma}$) and over-segmentation ($\hat{\gamma}$) noise to $\mathbf{y}$. Dashes indicate the tokens where the particular noise is not applicable. Bold indicates the changed labels due to the noise. We generate the additional input γ by combining both $\breve{\gamma}$ and $\hat{\gamma}$.

4 Generating Training Data from Subtitles

One of our primary contributions is a method for converting subtitle data into suitable training data for an ASR segmentation correction model. The subtitle data contains speech-like utterances of dialogue between characters in film and television shows. For the purposes of this paper, we do not use information about speaker identity, only the text and information about segmentation. We obtain the ground truth output label segmentation $\mathbf{y}$ by segmenting the subtitle text on sentence final punctuation.[1] We remove the punctuation but keep the implied label sequence to obtain the input token sequence $\mathbf{x}$ and ground truth output label segmentation $\mathbf{y}$. However, we do not have acoustic segmentation available for $\mathbf{x}, \mathbf{y}$ pairs derived from subtitle data, which we will need as additional input if our model is to learn to correct acoustic segmentation provided by an ASR component. We thus create a synthetic acoustic segmentation sequence γ as input by adding two types of noise to $\mathbf{y}$. Specifically, we imitate two common ASR system errors, under-segmentation noise and over-segmentation, so that at test time the model can correct those errors.

Under-segmentation Noise In the ASR model, under-segmentation occurs when pauses between words are brief, and the resulting ASR output is an utterance that could ideally be split into multiple sentence-like segments. We simulate this by adding *under-segmentation noise* which converts ground truth segmentation boundaries $y_i = 1$, to $y_i = 0$ with probability $\breve{\alpha}$ and leaves $y_i = 0$ unchanged.

Over-segmentation Noise Over-segmentation occurs in an ASR model when a speaker takes a longer pause in the middle of what could be interpreted as a contiguous sentence-like utterance. *Over-segmentation noise* is simulated by inserting random segment boundaries within an utterance. That is, with probability $\hat{\alpha}$ we convert a non-boundary tag $y_i = 0$ to $y_i = 1$, while leaving all $y_i = 1$ unchanged.

Synthetic Segmentation Input Generation We can then sample a synthetic acoustic segmentation sequence γ from the following distribution,

$$\gamma_i \sim \begin{cases} \text{Bernoulli}(\breve{\alpha}) & \text{if } y_i = 1 \\ \text{Bernoulli}(\hat{\alpha}) & \text{otherwise} \end{cases}$$

for $i \in \{1, \ldots, n\}$. This can be thought of as dropout applied to the correct label sequence $\mathbf{y}$. See Figure 2 for an example. Our proposed segmentation correction model will learn to denoise the input segmentation sequence γ and produce the corrected sequence $\mathbf{y}$.

5 Model

We employ a Long Short-Term Memory (LSTM)-based model architecture for this task (Hochreiter and Schmidhuber, 1997). Given an input sequence of ASR tokens $\mathbf{x} = [x_1, \ldots, x_n]$ along with corresponding ASR segmentation sequence

---

[1] Set of sentence final punctuation: { **( ) : - ! ? .** }.

$\boldsymbol{\gamma} = [\gamma_1, \ldots, \gamma_n]$, we first get an embedding representation $\mathbf{e}_i \in \mathbb{R}^{316}$ for each token as follows:

$$\mathbf{e}_i = G(x_i) \oplus F(\gamma_i)$$

where $G \in \mathbb{R}^{|\mathcal{V}| \times 300}$ and $F \in \mathbb{R}^{2 \times 16}$ are embedding lookup tables, and $\oplus$ is the concatenation operator. We initialized G with FastText embeddings pre-trained on Common Crawl data (Mikolov et al., 2018). F is randomly initialized.

We pass the embedding sequence through a two-layer bi-directional LSTM, with 512 hidden units each, to get the contextual representation $\mathbf{h}_i \in \mathbb{R}^{1024}$ for each token as follows:

$$\mathbf{h}_i = \overrightarrow{\mathrm{LSTM}}(\mathbf{e}_i) \oplus \overleftarrow{\mathrm{LSTM}}(\mathbf{e}_i)$$

where $\overrightarrow{\mathrm{LSTM}}$ and $\overleftarrow{\mathrm{LSTM}}$ are the forward direction and backward direction LSTMs respectively.

Each output state $\mathbf{h}_i$ is then passed through a linear projection layer with a logistic sigmoid to compute the probability of a segment boundary $p(y_i = 1 | \mathbf{h}_i; \theta)$. The log-likelihood of a corrected segmentation boundary sequence is $\log p(\mathbf{y}|\mathbf{x}, \boldsymbol{\gamma}; \theta) = \sum_{i=1}^{n} \log p(y_i|\mathbf{h}_i; \theta)$. We fit the parameters, θ, by approximately minimizing the negative log-likelihood on the training set $\mathcal{D}$, $\mathcal{L}(\theta) = -\frac{1}{|\mathcal{D}|} \sum_{(\mathbf{x}, \boldsymbol{\gamma}, \mathbf{y}) \in \mathcal{D}} \log p(\mathbf{y}|\boldsymbol{\gamma}, \mathbf{x}; \theta)$, using mini-batch stochastic gradient descent.

6 Datasets

6.1 Subtitles Dataset

We obtain monolingual subtitle data from the OpenSubtitles 2018 corpus (Lison and Tiedemann, 2016). OpenSubtitles contains monolingual subtitles for 62 languages drawn from movies and television. The number of subtitle documents varies considerably from language to language. LT has only 1,976 documents, while BG and FA have 107,923 and 12,185 respectively. We randomly down-sample from the larger collection to 2,000 documents to ensure our segmentation correction models are all trained with similar amounts of data.

Treating the subtitles for a complete television episode or movie as the source of a single training instance $(\mathbf{x}, \boldsymbol{\gamma}, \mathbf{y})$ introduces some complications because they are usually quite long relative to typical SLT system input. To better match our evaluation conditions, we arbitrarily split each document into M instances, where the length l in tokens for each instance m is sampled from $L \sim U(1, 100)$, i.e. uniformly from 1 to 100 tokens. This range was determined to to approximate the length distribution of our evaluation datasets.

See Table 1 for statistics on the number of training instances created as well as the average number of sentence segments per instance. Note that even though the number of subtitle documents is close to equal, the documents can vary considerably in length. As result, the BG dataset has more than twice the training instances of FA or LT. In some cases, an instance may contain only a few words that do not constitute a sentence, and such instances would have no segment boundaries; this helps prevent the model from learning pathological solutions such as always inserting a segment boundary at the end of the sequence.

Since we do not evaluate the segmentation directly on OpenSubtitles, we split the available data into training and development partitions, with 90% of the instances in the training set.

6.2 Speech Retrieval Dataset

For extrinsic evaluation of ASR segments, we use the speech retrieval dataset from the MATERIAL[2] program. The goal of MATERIAL is to develop systems that can retrieve text and speech documents in low-resource languages that are relevant to a given query in English. To bootstrap speech retrieval systems in low-resource languages, MATERIAL collects BG, FA, and LT speech training data for ASR systems, as well as additional separate collections of BG, FA, and LT speech documents along with their relevance judgments for a set of English language queries. Since the retrieval of speech documents requires a cascade of ASR, MT, and CLIR systems, the MATERIAL data allows us to measure the impact of ASR segmentation on both the translation quality, as well as the downstream retrieval system. The data partitions in MATERIAL are numerous and to avoid confusion, we briefly describe them here.

The *BUILD* partition contains a small amount of ASR training and development data for BG, FA, and LT, i.e. audio files paired with reference transcripts. We use the BUILD data for fine-tuning our subtitle trained model. We apply the same synthetic acoustic segmentation generation procedure to this collection as we do to the subtitle data when using it for fine-tuning. See Table 1 for dataset statistics.

The *Test (Small)* partition contains audio docu-

LT	300	496	1,000	3,297

Table 2: Number of queries (Q) and documents (D) in the speech retrieval test collections.

ments and a set of English language queries and relevance judgements for those queries. At test time, we use the acoustic segmentation provided by the ASR system as the input γ instead of generating acoustic label sequences. Additionally, roughly half of the audio documents in this collection include ground-truth transcriptions and translations to English, which allows us to evaluate MT.

The *Test (Large)* partition is similar to the Test (Small) partition, but much bigger in size. There are no transcripts or translations, so it can be used only to evaluate CLIR. The Test (Large) partition is available only for LT.

We use the translated portion of Test (Small) as a test set for MT and both Test (Small) and Test (Large) as extrinsic test sets for CLIR. The statistics of the MATERIAL partitions can be found in Table 2.[3]

The speech retrieval datasets come from three domains: news broadcast, topical broadcast such as podcasts, and conversational speech from multiple low-resource languages. Some speech documents have two speakers, with each speaker on a separate channel, i.e., completely isolated from the other speaker. When performing segmentation we treat each channel independently, creating a separate (re-segmented) ASR output for each channel. To create the document transcript for MT, we merge the two output sequences by sorting the token segments based on their wall-clock start time.

7 Experiments

7.1 Segmentation Model Training

For all datasets, we tokenize all data with Moses (Koehn et al., 2007). To improve performance on out of vocabulary words, we use Byte-Pair-Encoding (Sennrich et al., 2016) with 32,000 merge operations to create subwords for each language.

We then train the segmentation model on the subtitle dataset. When creating γ sequences on the subtitles data, we set under- and over-segmentation noise to $\breve{\alpha} = 0.25$ and $\hat{\alpha} = 0.25$ respectively.[4] We use the Adam optimizer (Kingma and Ba, 2015) with learning rate of 0.001. We use early stopping on the validation loss of the OpenSubtitles validation set to select the best stopping epoch for the segmentation model.

We further fine-tune this model on the BUILD partition to expose the model to some in-domain training data. The data is similarly prepared as OpenSubtitles. We use early stopping on the development loss of this partition.

7.2 ASR-Segmentation-MT-CLIR Pipeline

We evaluate our segmentation correction model in the context of a CLIR pipeline for retrieving audio documents in BG, FA, or LT that are relevant to English queries. We refer to the three languages BG, FA, and LT as *source languages*. This pipeline uses ASR to convert source language audio documents to source language text transcripts, and MT to translate the source language transcripts into English transcripts. Then a monolingual English IR component is used to return source language documents that are relevant to the issued English queries. We insert our segmentation correction model into

---

[3] The official MATERIAL collections are named ANALYSIS+DEV and EVAL, but we refer to them as Test (Small) and Test (Large) to avoid confusion.

[4] Values for $\breve{\alpha}$ and $\hat{\alpha}$ were determined by grid-search over $\{0.25, 0.5, 0.75\}$ that minimized loss on the BUILD Valid data.

this pipeline between the ASR and MT components, i.e. *(i)* ASR to *(ii)* Segmentation Correction, to *(iii)* MT to *(iv)* IR. For clarity we reiterate, the segmentation model takes as input a source language transcript and returns the source language transcript with corrected segmentation.

To implement the ASR, MT, and IR components, we use implementations developed by MATERIAL program participants (Oard et al., 2019).

7.2.1 ASR System

We use the ASR systems developed jointly by the University of Cambridge and the University of Edinburgh (Ragni and Gales, 2018; Carmantini et al., 2019). The ASR system uses a neural network based acoustic model, trained in a semi-supervised manner on web-scraped audio data, to overcome the small amount of training data in the BUILD data. Separate models are trained for narrow-band audio (i.e., conversational speech) and wide-band audio (i.e. news and topical broadcast).

7.2.2 Segmentation Correction

At test time, given a speech document, the ASR system produces a series of acoustically derived utterances, i.e. $\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(m)}$, from this input. In our setting, the corresponding acoustic label sequence $\boldsymbol{\gamma}^{(i)}$ for each utterance would be zero everywhere except the final position, i.e. $\boldsymbol{\gamma}^{(i)} = [0, 0, \ldots, 0, 1]$. If we were to process each utterance, $(\mathbf{x}^{(i)}, \boldsymbol{\gamma}^{(i)})$, individually, the model may not have enough context to correct under-segmentation at the ends of the utterance. For example, when correcting the final token position, which by definition will precede a long audio pause, the model will only see the left-hand side of the context. To avoid this, we run our segmentation correction model on consecutive pairs of ASR output utterances, i.e. $\left(\mathbf{x}^{(i)} \oplus \mathbf{x}^{(i+1)}, \boldsymbol{\gamma}^{(i)} \oplus \boldsymbol{\gamma}^{(i+1)}\right)$. Under this formulation each ASR output utterance is corrected twice (except for the first and last utterances which are only corrected once), therefore we have two predictions $\hat{y}_j^{(i,L)}$ and $\hat{y}_j^{(i,R)}$ for the j-th segment boundary. We resolve these with the logical-OR operation to obtain the final segmentation correction, i.e. $\hat{y}_j^{(i)} = \hat{y}_j^{(i,L)} \vee \hat{y}_j^{(i,R)}$.

Based on the segmentation corrections produced by our model, we re-segment the ASR output tokens and hand the resulting segments off to the MT component where they are individually translated.

7.2.3 MT Systems

We evaluate with three different MT systems. We use the neural MT model developed by the University of Edinburgh (EDI-NMT) and the neural and phrase-based statistical MT systems from the University of Maryland (UMD-NMT and UMD-SMT, respectively). The EDI-NMT and UMD-NMT systems are Transformer-based models (Vaswani et al., 2017) trained using the Marian Toolkit (Junczys-Dowmunt et al., 2018) and Sockeye (Hieber et al., 2018), respectively. UMD-NMT trains a single model for both directions of a language pair (Niu et al., 2018), while EDI-NMT has a separate model for each direction. UMD-SMT is trained using the Moses SMT Toolkit (Koehn et al., 2003), where the weights were optimized using MERT (Och, 2003).

7.2.4 IR System

For the IR system, we use the bag-of-words language model implemented in Indri (Strohman et al., 2005). Documents and queries are both tokenized and normalized on the character level to avoid potential mismatch in the vocabulary. The queries are relatively short, typically consisting of only a few words, and they define two types of relevancy – the conceptual queries require the relevant documents to be topically relevant to the query, while the simple queries require the relevant document to contain the translation of the query. However, no specific processing is used for these two relevance types in our experiments.

7.3 MT Evaluation

Our first extrinsic evaluation measures the BLEU (Papineni et al., 2002) score of the MT output on the Test (Small) sets after running our segmentation correction model, where we have ground truth reference English translations. We refer to our model trained only on the BUILD data as *Seg*, and our subtitle-trained model as *Seg + Sub*. As our baseline, we compare the same pipeline using the segmentation produced by the acoustic model of the ASR system, denoted *Acous*.

Since each segmentation model produces segments with different boundaries, we are unable to use BLEU directly to compare to the reference sentences. Therefore, we concatenate all segments of a document and treat them as one segment, which we refer to as “document-level” BLEU score. We use SacreBLEU[5] (Post, 2018) with the lowercase

---

[5] `https://github.com/mjpost/sacrebleu`

option due to the different casing for the reference English translation and MT output.

We also provide BLEU scores for the MT output using the reference transcriptions (Ref) to show the maximum score the system can achieve when there is no ASR or segmentation error. This represents the theoretical upper bound for our pipeline with a perfect ASR system.

Segmentation errors (i.e., the acoustic model incorrectly segmented an utterance) and word errors (i.e., the ASR system produces an incorrect word) can both affect the downstream MT performance. To isolate the segmentation errors from word errors, we align the ASR output tokens to the reference transcriptions by timecode in order to obtain a reference system that has no segmentation errors, but does have transcription errors. This represents a more realistic ceiling for our model because while we can correct segmentation, we cannot correct word errors. We refer to this system in the results section as Align.

7.4 Document-Level CLIR Evaluation

Our second extrinsic evaluation is done on the MATERIAL CLIR task. We are given English queries and asked to retrieve audio documents in either BG, FA, or LT. In our setup, we only search over the English translations of the segmented transcripts produced by our pipeline, i.e., we do not translate the English query into the other languages or search the audio signal directly. We evaluate the performance of CLIR using the Maximum Query Weighted Value (MQWV) from the ground-truth query-relevance judgements for documents in the Test (Small & Large) collections. MQWV, which is a variant of the official MATERIAL program metric called Actual Query Weighted Value (NIST, 2017, AQWV), is a recall-oriented rank metric that measures how well we order the retrieval collection with respect to query relevance.

AQWV is calculated as the average of $1-(P_m+\beta*P_{fa})$ for each query, where P_m is the probability of misses, P_{fa} is the probability of false alarms, and β is a hyperparameter. The maximum possible value is 1 and the minimum value is given by $-\beta$. In our experiments β it is set to 40. AQWV thus not only depends on the ranking of the documents but also on β.

Additionally, AQWV is sensitive to the threshold used by the IR system to determine document relevance. To avoid the tuning of thresholds, we report MQWV which is calculated for the optimal threshold; in our experiments this threshold is estimated over the ranks of the documents. Thus, MQWV doesn't depend on the ability to estimate the threshold and only depends on the quality of the document ranking for a given query.

Lang.	Model	EDI NMT	UMD NMT	UMD SMT
BG	Acous.	20.48	20.39	**21.24**
	Seg	22.38*	23.35*	21.23
	Seg + Sub	**24.73***	**25.92***	21.23
	Align	24.98	27.81	21.29
	Ref	43.75	35.40	29.50
FA	Acous.	5.35	6.26	**4.54**
	Seg	5.32	6.22	3.28
	Seg + Sub	**6.47***	**6.83***	4.50
	Align	7.67	7.02	4.59
	Ref	17.08	11.24	7.76
LT	Acous.	15.20	**8.38**	14.76
	Seg	15.18	8.34	14.76
	Seg + Sub	**15.22**	8.33	14.76
	Align	15.60	8.71	14.84
	Ref	20.40	11.94	21.30

Table 3: Document-level BLEU scores on ANALYSIS set. * represents statistical significance when compared to Acous. at the 0.05 level. We show the result of translations using the original acoustic segmentation (Acous.), our model trained only on the BUILD dataset (Seg), and our full model (Seg + Sub). For reference, we provide the scores of translation on ASR tokens aligned to the reference transcription segmentation (Align), and the reference transcription (Ref).

8 Results

8.1 MT

Table 3 shows the results of the MT evaluation. The best non-reference system for each language and MT system is in bold. We compute statistical significance against the acoustic (*Acous.*) segmentation baseline using Welch's T Test (Welch, 1947). Our subtitle-based segmentation model (*Seg + Sub*) consistently improves BLEU scores of NMT models for BG and FA, while not making significant differences in SMT. This echoes prior work (Khayrallah and Koehn, 2018; Rosales Núñez et al., 2019) suggesting SMT models are more robust to noisy inputs than neural models.

Lang.	Model	EDI NMT	UMD NMT	UMD SMT
BG	Acous.	0.173	0.134	0.164
	Seg + Sub	**0.177**	**0.180**	0.164
FA	Acous.	0.040	0.039	0.046
	Seg + Sub	**0.071**	**0.042**	**0.145**
LT	Acous.	0.128	**0.067**	0.157
	Seg + Sub	**0.136**	0.060	**0.172**

Table 4: MQWV scores on Test (Small) set.

In 6 out of 9 cases, we see that adding the subtitles data improves over using only the BUILD data. Of the remaining cases, the scores remain similar (i.e., it doesn't hurt the model). Training on the BUILD data alone improves BG NMT models, but for SMT and the other languages, it either makes no difference or is worse than the acoustic model.

Comparing Seg + Sub with Align in all languages, we see that there is only a small gap between the two. This suggests that our model is nearing the ceiling on what correcting segmentation can do to improve downstream MT. Furthermore, on LT where our model offers only small or no improvement, we see that the original acoustic segmentation is almost performing as well as Align. This suggests that there is relatively little room for improving LT MT by correcting sentence boundaries alone.

8.2 Document-Level CLIR

MQWV on the Test (Small) and Test (Large) partitions are shown in Table 4 and Table 5 respectively. On the Test (Small) partition, we see that our segmentation model improves the CLIR performance over the acoustic segmentation in 7 out of 9 cases. On the Test (Large) partition, we see that our segmentation model improves downstream retrieval performance consistently across all three MT systems. We note that while we measure the downstream retrieval performance separately for each MT system, a real-world CLIR system could perform IR over the union of multiple MT systems, which could yield even further improvements in retrieval performance (Zhang et al., 2020).

8.3 Complexity Analysis

Lang.	Model	EDI NMT	UMD NTM	UMD SMT
LT	Acous.	0.292	0.175	0.328
	Seg + Sub	**0.293**	**0.179**	**0.399**

Table 5: MQWV scores on the Test (Large) set.

ARI Quartile	Model	EDI NMT	UMD NMT
Q1	Acous.	17.78	**24.70**
	Seg + Sub	**17.92**	11.62
Q2	Acous.	20.76	22.09
	Seg + Sub	**26.89**	**31.24**
Q3	Acous.	22.87	20.38
	Seg + Sub	**29.96**	**33.22**
Q4	Acous.	23.41	21.00
	Seg + Sub	**29.87**	**35.24**

Table 6: Bulgarian BLEU scores on Test (Small) (transcribed portion) when separated into quartiles by sentence complexity (as measured by ARI).

We hypothesize that the effects of improved segmentation should be more pronounced for more complex utterances with more opportunities to misplace boundaries. Therefore, we calculate a measure of sentence complexity, the Automated Readability Index (ARI) (Senter and Smith, 1967), for all documents in Test (Small)[6] and examine the performance of our *Sub* model on MT. We separate the documents into quartiles based on their calculated ARI, where a higher ARI (and thus a higher quartile) indicates a more complex document, and present the average document-level BLEU score for each quartile in Table 6. In the interest of space, we present results for Bulgarian and for NMT, and defer other languages and SMT to Appendix A. We see that the most dramatic gains in BLEU occur for documents in the third and fourth quartiles, which matches our intuition. In other words, our segmentation model most improves the translation quality of more syntactically complex segments.

9 Ablation Study

We perform an ablation study on two components in our proposed model, *(i)* the use of acoustic segmentation boundary labels γ as input and *(ii)* training with a combination of over- and under-segmentation noise. We use the same training and

---

[6] Only the transcribed portion with reference translations. For each MT system, we compute ARI on the document translation using the reference transcription.

Model	EDI NMT	UMD NMT	UMD SMT
Acous.	20.48	20.39	21.24
Lex.	23.96	24.97	**21.58**
Lex. + Under	24.27	25.84	21.48
Lex. + Over	24.69	25.88	21.23
Full	**24.73**	**25.92**	21.23

Table 7: Document-level BLEU score for the models in ablation studies. We provide the acoustic model (Acous.) and our proposed model (Full).

evaluation process and only modify the affected component. We perform our ablation on the BG MT task, since it had a wider range of improvements than the other languages.

Use of Acoustic Segmentation Boundaries. We train a segmentation model using only ASR output tokens $\mathbf{x}$ as input without the the ASR segmentation sequence γ. For this model, we modify the embedding representation $\mathbf{e}_i$ so that we do not use F:

$$\mathbf{e}_i = G(x_i)$$

This model, which we refer to as *Lex.*, must exclusively use the lexical information of the ASR token sequence $\mathbf{x}$ to make predictions.

Over-segmentation and Under-segmentation. The two segmentation problems of the system may have different impact on the MT system. To see their individual effects, we train two models where the synthetic acoustic segmentation boundary sequence γ is created using only under-segmentation or over-segmentation noise. We refer to those models as *Lex. + Under* and *Lex. + Over* respectively.

Results Table 7 shows the effects of the model ablations on MT system BLEU score. On both NMT systems, we see that there is a roughly 1 point improvement on BLEU when including the ASR segmentation boundaries as input. For both NMT models we also find that over-segmentation noise helps slightly more than adding under-segmentation noise, but that these additions are complementary, i.e. the full model does best overall. For SMT, we surprisingly find that model without acoustic segmentation boundary input does best. The overall difference between the acoustic (*Acous.*) baseline and any of the segmentation correction models is small compared to the gains had on NMT. This again suggests that SMT is more robust to changes in segmentation.

10 Conclusion

We propose an ASR segmentation correction model for improving SLT pipelines. Our model makes use of subtitles data as well as a simple model of acoustic segmentation error to train an improved ASR segmentation model. We demonstrate downstream improvements on MT and CLIR tasks. In future work, we would like to find a better segmentation error model that works well in conjunction with SMT systems in addition to NMT systems.

Crisscrossed Captions: Extended Intramodal and Intermodal Semantic Similarity Judgments for MS-COCO

Zarana Parekh, Jason Baldridge, Daniel Cer, Austin Waters, and Yinfei Yang
Google Research
`{zarana, jasonbaldridge, cer, austinwaters, yinfeiy}@google.com`

Abstract

By supporting multi-modal retrieval training and evaluation, image captioning datasets have spurred remarkable progress on representation learning. Unfortunately, datasets have limited cross-modal associations: images are not paired with other images, captions are only paired with other captions of the same image, there are no negative associations and there are missing positive cross-modal associations. This undermines research into how inter-modality learning impacts intra-modality tasks. We address this gap with *Crisscrossed Captions* (CxC), an extension of the MS-COCO dataset with human semantic similarity judgments for **267,095** intra- and inter-modality pairs. We report baseline results on CxC for strong existing unimodal and multimodal models. We also evaluate a multitask dual encoder trained on both image-caption and caption-caption pairs that crucially demonstrates CxC's value for measuring the influence of intra- and inter-modality learning.

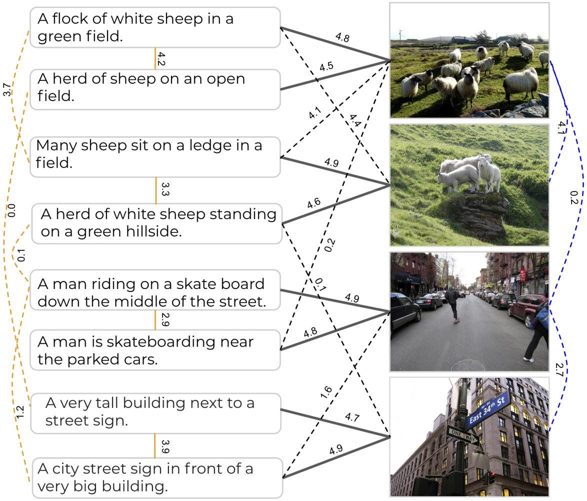

Figure 1: Crisscrossed Captions extends the MS-COCO evaluation sets by adding semantic similarity ratings for existing image-caption pairs and co-captions (solid lines), and it increases annotation density by adding further ratings for new image-caption, caption-caption and image-image pairs (dashed lines).

1 Introduction

Phrases such as *blue*, *chair*, and *garden path* have strong visual components, yet computational word representations are usually created with text-only corpora. Encouragingly, some recent work that derives representations using visual contexts shows improvements for both word similarity ranking and image-text retrieval (Kiros et al., 2018), and query-based training of image models demonstrates language's power to improve image representations (Juan et al., 2020). Learning representations for both vision and language jointly should be even more effective—indeed, much progress has been made on such cross-modal learning using image captioning data (Karpathy and Li, 2015; Harwath and Glass, 2017; Faghri et al., 2018; Li et al., 2019). However, it is not yet clear whether learning representations in multimodal contexts improves performance *within* as well as across modalities as there are no datasets ideally suited for this at present.

Image captioning datasets such as Flickr8k (Rashtchian et al., 2010), Flickr30k (Young et al., 2014), Multi30k (Elliott et al., 2016), Microsoft Common Objects in COntext (MS-COCO) (Lin et al., 2014), and Conceptual Captions (Sharma et al., 2018) only capture relationships between images and textual captions created for them. They miss many valid relationships between unassociated images and captions, from captions to other captions, and from images to other images. We address this gap with Crisscrossed Captions (CxC, exemplified in Figure 1), a dataset with graded, denser annotations for relationships between and among captions and images in the MS-COCO evaluation splits of (Karpathy and Li, 2015) (with 25k English captions and 5k images each).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2855–2870
April 19 - 23, 2021.

CxC extends MS-COCO's existing image-caption pairs with continuous (0-5) semantic similarity ratings for those pairs and new pairs. The rating criteria extend those used for Semantic Textual Similarity (Agirre et al., 2012). Intramodal pairs are selected for annotation via an indirect sampling scheme biased to gain a broad distribution of similarities. In all, CxC contains *human* ratings for **267,095** pairs (derived from 1,335,475 independent judgments), a massive extension in scale and detail to the 50k original binary pairings.

MS-COCO *incompletely* supports three retrieval tasks: image-text, text-image and text-text. CxC enhances all of these with new positive pairs, and it also supports a *new* image-image retrieval task. With its graded similarity judgements, CxC also supports correlation measures comparing model and human rankings. Retrieval metrics focus on positive pairs, but CxC's correlation scores additionally account for low-scoring items (non matches). Supporting these evaluations on a common set of images and captions makes them more valuable for understanding inter-modal learning—compared to disjoint sets of caption-image, caption-caption, and image-image associations. Also, multimodal representations such as CLIP (Radford et al.) are useful for downstream tasks such as Visual Question Answering (Goyal et al., 2017), Vision and Language Navigation (Majumdar et al., 2020), Referring Expressions (Yu et al., 2018) and Visual Commonsense Reasoning (Zellers et al., 2019), and we hope the additional relationships and evaluations provided by CxC will help develop even better representations for tasks that span these modalities.

To establish baselines for CxC, we provide results for existing unimodal models for text (Bag-of-Words, USE (Cer et al., 2018)) and images (InceptionV3 (Szegedy et al., 2016), ResNet-152 (He et al., 2016), SimCLRv2 (Chen et al., 2020b) as well as for two cross-modal retrieval models VSE++ (Faghri et al., 2018) and VSRN (Li et al., 2019).

We furthermore demonstrate CxC's utility by evaluating a dual encoder that combines a bidirectional loss for image-text retrieval with a loss for text-text retrieval. The text encoder is composed of transformer layers over pre-trained BERT word representations and the image encoder is a pre-trained EfficientNet (B4) (Tan and Le, 2019a). This model delivers the strongest overall performance across all four retrieval tasks and correlation with human scores for text-text, image-image and image-text similarity. Compared to the same dual encoder trained only with image-text pairs, this model realizes small gains for image-text tasks and large gains for text-text task but with some degradation for image-image tasks. This indicates that the model trades capacity to encode images for better text encoding—an insight that would not be easily assessed without CxC's image-image annotations.

Our main contributions are the following:

- We describe a method for sampling items to get a broad distribution of similarities.
- We annotate the semantic similarity of 267,095 pairs. These enhance existing retrieval tasks and support a new image-image retrieval task. They also support correlation measures; these assess models' judgments of both positive *and* negative associations.
- We establish baseline scores for existing models and a multitask dual encoder on all tasks and demonstrate that CxC allows model performance to be assessed more holistically.
- With its new positive pairs, CxC improves the recall@k measures common in image-text and text-image retrieval. This shows a 1-3% increase in recall@k over several models.
- We release CxC's annotations at `https://github.com/google-research-datasets/Crisscrossed-Captions`, along with code to merge CxC with existing MS-COCO data.

2 Dataset Collection

Existing resources already support learning joint representations of images and text. However, we need better evaluation resources, so we extend the MS-COCO evaluation splits with graded similarity associations within and across modalities. MS-COCO has five captions for each image, split by (Karpathy and Li, 2015) into 410k training, 25k development, and 25k test captions (82k/5k/5k for images). An ideal extension would rate every pair, but this is infeasible[1] and most pairs are dissimilar anyway. To obtain new pairs with high expected similarity, we introduce a biased sampling scheme.

The data is collected in two phases. First, we define an indirect sampling scheme that uses model-based similarities from the co-modality items to

---

[1] A split with 5k images and 25k captions has ≈12.5M image-image, ≈312M caption-caption and ≈125M image-caption pairs, so annotating all items in the validation and test splits with 5 replications would require ≈4.5B judgments.

Caption 1: A tennis player swinging a racket at a ball.

Caption 2: A man playing tennis with a crowd watching.

Caption 3: A living room with some black furniture and a colorful rug.

Caption 4: A dog laying on a leather sofa in a living room.

Figure 2: **Top:** Captions of the same image are often not paraphrases. **Bottom:** Such *co-captions* often focus on different aspects and can diverge substantially.

select *intra*modality pairs. We use these items and their human ratings to select *inter*modality pairs for annotation. We also annotate all existing intermodal pairs and a large sample of co-captions (captions associated with the same image). See the appendix for details about the annotation interface and instructions, composition of the dataset and illustrative examples.

Intramodality Two images of a man and a dog can be described differently, while two similar sentences about a man and a dog can describe dissimilar images. In Figure 2, caption 1 gives a visual description while caption 2 gives a broader event description. Divergences also occur when caption creators perceive a scene differently: caption 3 describes the room and caption 4 focuses on the dog and sofa. This semantic gap between images and their captions creates an opportunity to sample *intra*modal pairs with varying similarities. Our key idea is to use model-based similarities of images for biased sampling of caption pairs, and vice versa, and use existing image-caption pairs as pivots between modalities. This selects image pairs that are different in appearance but similar in what they depict based on their descriptions, and vice versa.

Denote the known images and captions as V ($v_1 ... v_n$) and C ($c_1 ... c_n$) (the latter representing *co-caption* groups of five captions each). Each item is encoded with an off-the-shelf unimodal model. Cosine similarity between items defines two symmetric matrices: S^C (pairwise caption similarities) and S^V (pairwise image similarities). The diagonals are set to zero to not sample identical items.

We encode images with Graph-RISE (486) and construct S^I, the image-based similarity for pairs of co-caption groups. We encode captions with Universal Sentence Encoder (USE) (Cer et al., 2018) and average bag of words (BoW) based on GloVe embeddings (Pennington et al., 2014). Co-caption representations are averaged to create a single representation. From these, we construct S^C, the caption-based similarity for images pairs. USE and BoW embeddings produce two S^C matrices, but we gloss over this detail below.

We use S^C to select *image* pairs and S^I for *caption* pairs. Because of the cross-modal semantic gap, diversity and size of the underlying data, these pairs exhibit a wide range of similarity. Selecting the five most similar items (according to model-based S^V and S^C) thus produces good representation of varying amounts of similarity as judged by people. Because S^V covers co-caption groups, one caption is randomly chosen from each group to produce a caption pair for rating.

Caption-caption and image-image candidates are referred to as $C2C$ and $I2I$, respectively. $I2I$ pairs are selected with the above *other-modality* method. For $C2C$ pairs, we sample half the pairs using the other-modality method and half from within co-captions. The latter introduces (mostly) positive associations between caption pairs describing the same image. This gives a balanced set of caption pairs describing same and different images.

Pairs in $C2C$ and $I2I$ are scored by in-house raters using a continuous scale between 0 and 5. We adopt the widely used Semantic Textual Similarity (STS) (Cer et al., 2017) for text pairs and extend it to images to define Semantic Image Similarity (SIS). To recognize that this is a graded (rather than discrete) judgment, we encouraged raters to select scores like *1.3* and obtain the final score for a pair as the average of five individual ratings.

Intermodality We select caption-image candidates $C2I$ based on human ratings for $I2I$ and $C2C$ pairs. We mainly seek new positive matches like those identified by annotators in Ilharco et al. (2019). For each $I2I$ pair (i_j, i_k), a $C2I$ pair (c_k, i_j) is generated, where c_k is a MS-COCO caption for i_k. We generate pairs from $C2C$ similarly. Half of the $C2I$ pairs are selected based on $C2C$ ranks and the other half by $I2I$ ranks (skipping pairs already selected from $C2C$). Finally, all MS-COCO pairs (25k in validation and 25k in test) are selected to obtain caption-image similarity ratings for the known items.

Caption 1	**Caption 2**	**STS**	**BoW**	**USE**
A man standing on a tennis court holding a racquet.	A man standing on a tennis court holding a tennis racquet.	5.0	0.98	0.99
A man riding a skateboard off the side of a ramp.	A man riding up the side of a skateboard ramp.	4.2	0.99	0.94
A yellow tray topped with a cup of coffee and a donut.	A white plate topped with donuts sitting on a stove top.	3.1	0.94	0.39
A bird sitting on top of a park bench.	An empty park bench sitting in front of trees.	2.2	0.90	0.69
An old car sitting on top of a lush green field.	A couple of motorcycles parked next to each other.	1.3	0.85	0.21
A man sanding next to an orange frisbee.	A couple of swans swimming in a pond next to two people.	0.2	0.84	0.11

Table 1: A comparison of CxC STS annotation scores and cosine similarity scores using GloVe BoW embeddings and Universal Sentence Encoder (USE) for five example MS-COCO caption pairs.

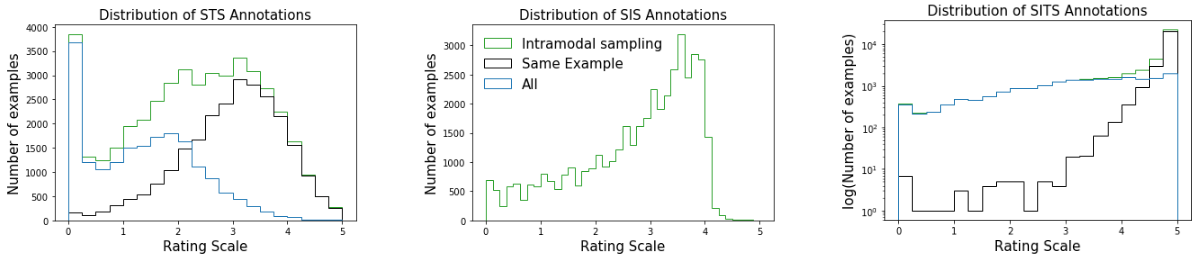

Figure 3: Distribution of ratings for the CxC validation set. *Intramodal Sampling* refers to examples selected using *other-modality* selection, *Same Example* refers to original MS-COCO pairs, and *All* covers all examples for a task.

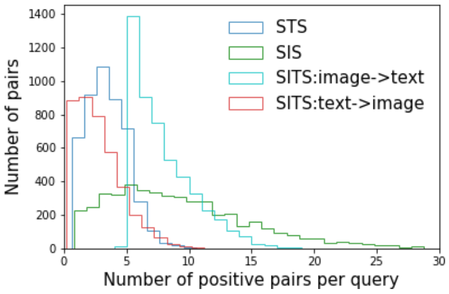

Figure 4: Distribution of counts of positive pairs (score ≥ 3) of annotations for each task (validation split).

We extend STS to define Semantic Image-Text Similarity (SITS). Raters provide a continuous score from 0 to 5 using an interface similar to that for STS and SIS. Each $C2I$ pair receives five ratings; the average is used as the final SITS score.

3 Crisscrossed Captions Dataset

Using our selection and annotation methodology, we obtained ratings for 267,095 caption-caption, image-image, and caption-image pairs (1,335,475 total judgments). Figure 3 shows rating distributions for each task (validation split). It also shows the distributions of ratings for STS and SIS pairs included from other-modality selection and from original MS-COCO pairs. The test set distributions are similar. Figure 4 gives the distribution of counts of positive examples in each task (validation split), where a score ≥ 3 (for STS, SITS) and a score ≥ 2.5 (for SIS) is considered positive. These positive examples are used for intermodal and intramodal retrieval evaluation.

STS. The majority of caption pairs selected using image similarity are negative (ratings in [0, 3)), which is expected given the divergences noted in Figure 2. Nevertheless, the approach produces 20,587 positive pairs. Table 1 shows pairs with their STS annotation scores and cosine similarity with BoW and USE embeddings. There is broad agreement, but the annotated similarity is not fully captured by either BoW or USE. USE provides a broader range, but scores the third pair lower than the fourth. BoW scores are bunched within a high similarity band[2] that aligns well with these five examples. Overall, there is a weak positive correlation between BoW and STS scores, as shown in Figure 5, which plots average BoW cosine similarity versus STS for 1000 randomly sampled pairs.

Figure 6 shows a pair of captions (and corresponding images) selected by the other-modality strategy with higher STS compared to their respective co-captions. For co-caption pairs, STS scores are more positive but many are still negative (Figure 3, left). Thus, combining both approaches leads to a more representative distribution overall. The large number of negative pairs from co-captions underscores the problem with assuming captions of the same image are paraphrases.

SIS. All image pairs $I2I$ are selected using the other-modality strategy. This plus the stringent cri-

---

[2] BoW scores fall mostly in the range .8 to 1.0 over all possible pairs; STS scores fall mostly in 1 (.2) to 4 (.8).

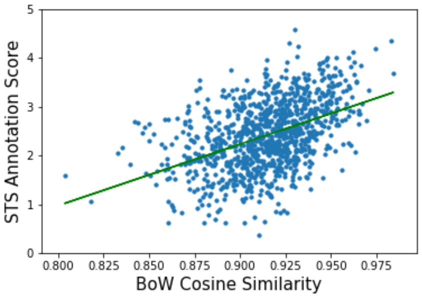

Figure 5: Plot BoW cosine similarity and STS scores for a sample of caption pairs, with the line of best fit.

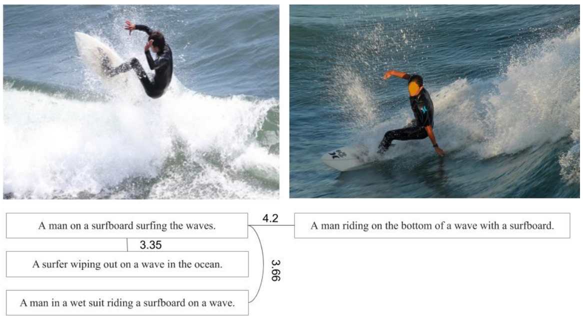

A man on a surfboard surfing the waves.

A man riding on the bottom of a wave with a surfboard.

A surfer wiping out on a wave in the ocean.

A man in a wet suit riding a surfboard on a wave.

Figure 6: An example of *other-modality* caption pairs (horizontal pair) with higher STS compared to their respective co-captions (vertical pairs). Each caption is placed under its corresponding image.

teria for SIS rating of 5 means very few examples are rated above 4. Nevertheless, there are many pairs with SIS ≥ 3, indicating there are many images depicting similar scenes and events.

SITS. As shown in Figure 4, there are many more pairs with 4-5 SITS ratings, compared to STS and SIS. This is by design, as the $C2I$ pairs are selected based on decreasing STS/SIS scores. This captures more positive intermodality associations and augments the existing validation and test splits. Since these pairs are missing from the existing data, they are among the examples that inappropriately penalize a model that identifies them correctly in image-caption retrieval. The SITS ratings collected for known pairs also support new correlation based evaluations, as discussed in the next section.

4 Evaluation Tasks and Metrics

CxC supports intermodal retrieval like MS-COCO but with denser annotations between image-caption pairs. It also enables intramodal retrieval and semantic similarity correlation evaluations, which were not possible before.

Karpathy and Li (2015) first used MS-COCO for image-to-caption and caption-to-image retrieval. We extend the existing associations with positive CxC pairs, and also add new caption-to-caption and image-to-image retrieval tasks using positive STS and SIS pairs (a total of four retrieval tasks). To the best of our best knowledge, CxC is the first dataset to support image-to-image retrieval over captioned images. Following Karpathy and Li (2015), we evaluate using Recall@K (R@K), computed as the fraction of times a correct item was found among the top K results, and median rank (med. r) of the closest ground truth result in the list.

Semantic similarity tasks such as Semantic Textual Similarity (Cer et al., 2017) and Visual Semantic Textual Similarity(vSTS) (de Lacalle et al., 2020) require a model to produce a continuous similarity score given two inputs. Typically, the models are evaluated based on the Pearson's r of their scores with the human judgments over a set of input pairs. This is valid when training data is available to calibrate model scores to the human ratings. With CxC, we do not have such training data, so we instead use Spearman's r to assess whether a model *ranks* pairs similarly to human raters.

It would be tempting to simply measure Spearman's r over all pairs, but this would be flawed because CxC's dense annotation means that the scores between many pairs are themselves correlated. To mitigate this, we use a sampled bootstrap correlation instead. For each correlation estimate, we sample half of the queries (to increase diversity across samples) and for each selected query, we choose one of the items for which CxC supplies a paired rating. We compute Spearman's r between the CxC scores and the model scores for the selected pairs. The final correlation is the average over 1000 of these bootstrap samples.

vSTS (de Lacalle et al., 2020) contains 2677 pairs of MS-COCO captions and corresponding images. As noted above, vSTS is related dataset for multimodal semantic similarity. We considered mixing CxC and vSTS; however, this was infeasible because CxC uses the widely adopted Karpathy splits, while items in vSTS's training, dev and test splits are spread among the Karpathy splits. We could not just make a separate cut of CxC because vSTS pairs can cross splits, e.g. an image-caption item in Karpathy training and another in Karpathy test. Given the small size of vSTS, we focused our efforts on CxC evaluations.

5 Evaluated Models

In order to establish baselines for CxC, we benchmark pretrained models for images and text. Note that these are off-the-shelf models that have not been trained on MS-COCO. We also evaluate cross-modal retrieval models that are trained on MS-COCO. Here, we focus on models that support efficient retrieval (e.g. dual encoders). We expect models with extensive cross-modal interactions, such as ViLBERT (Lu et al., 2019) and LXMERT (Tan and Bansal, 2019), will show strong performance on CxC tasks, either as standalone models that (inefficiently) score all possible item pairs or as rerankers for outputs of retrieval models.

To the best of our knowledge, there is no prior work that explores joint learning or evaluation on intra- and inter-modality retrieval tasks. Ngiam et al. (2011) and Collell Talleda and Moens (2016) show evidence that inter-modality learning helps improve intra-modality performance, but do not explore multitask learning. Lu et al. (2020) explore multitask learning but only focus on intermodal representation learning for intermodal downstream tasks. To illustrate how CxC allows us to measure how intermodal representation learning can improve both intra- and inter-modal performance, we train a dual encoder model on bidirectional image-text and text-text in-batch retrieval losses.

5.1 Pretrained Model Baselines

Text-only Models First, we use a bag-of-words (*BoW*) approach using averaged GloVe embeddings (Pennington et al., 2014) for each token in a caption as the caption representation. Second, the Universal Sentence Encoder (*USE*) (Cer et al., 2018) is a sentence level representation model that has shown strong performance on the related STS benchmark. We use the multilingual transformer version from TensorFlow Hub (Yang et al., 2020).[3]

Image-only Models *InceptionV3*, *ResNet-152*, and *SimCLRv2* are deep convolutional models (Szegedy et al., 2016; He et al., 2016; Chen et al., 2020a,b) trained on the ImageNet dataset. We extract 2048-dimensional image-level representations on a central crop containing 87.5% of the original image area. We access them via TensorFlow Hub.[4]

Intermodal Models *VSE++* (Faghri et al., 2018) is a dual encoder (see Sec. 5.2) trained to learn a joint space of aligned images and captions. The state-of-the-art VSRN model (Li et al., 2019) is another dual encoder that uses additional training annotations to predict and use bounding boxes for more fine-grained and coherent image analysis, while using only a simple text encoder trained from scratch.[5]

5.2 Dual Encoder Baselines

We also consider several neural baseline models, all of which are *dual encoders* (Gillick et al., 2018; Yang et al., 2019) that encode both inputs separately. Dual encoder models have been proven as an effective approach to learn strong semantic representations (Cer et al., 2018; Chen et al., 2020a,b). They are often trained using an *in-batch sampled softmax* loss, as this has been observed to converge quickly and perform well on retrieval tasks (Gillick et al., 2018; Yang et al., 2019). We employ the bidirectional in-batch sampled softmax loss (eq. 1):

$$\begin{aligned}\mathcal{L} = &-\frac{1}{K}\sum_{i=1}^{K}\left(S(l_i,r_i) - \log\sum_{j=1\, j\neq i}^{K} e^{S(l_i,r_j)}\right)\\ &-\frac{1}{K}\sum_{i=1}^{K}\left(S(r_i,l_i) - \log\sum_{j=1\, j\neq i}^{K} e^{S(r_i,l_j)}\right)\end{aligned} \qquad (1)$$

where $S(x, y)$ is the dot product of embeddings of examples x and y. This loss encourages the score of a correct pair $S(l_i,\, r_i)$ to be higher than scores of non-matching input pairs from the batch $S(l_i,\, r_j)$. Unlike full cross-attention models, this architecture enables large-scale retrieval through approximate nearest neighbor search.

We train dual encoders for caption-image and caption-caption tasks, as well as a multitask model that combines both tasks. We use EfficientNet-B4 (Tan and Le, 2019b) (pre-trained on ImageNet) as our image encoder; it yields a 1792-dimensional representation. The text encoder employs a frozen[6] BERT-Base model (Devlin et al., 2019) followed by three transformer layers. The additional transformer layers have 8 attention heads, hidden dimension of 3072, and–like BERT-base–output 768-dimensional token-level features. We use the fea-

tures at the 0^{th} token position of the final layer as the caption representation. BERT parameters are initialized from the public BERT checkpoint.[7] The additional, trainable transformer layers are randomly initialized.

We construct three dual encoder models from these base encoders. (1) A *Text-Text* model (DE_{T2T}) uses a shared text encoder for both sides. (2) An *Image-Text* model (DE_{I2T}) uses the aforementioned text and image encoders, and includes a layer above the text encoder to project its 768 dimensions to 1792 (to match the image encoder output). (3) A *Multitask* model ($\text{DE}_{\text{T2T+I2T}}$) is trained on a combination of tasks (Chidambaram et al., 2019). It shares DE_{I2T}'s architecture and is trained in the same way; however, its loss is a weighted sum of image-text ($i2t$, $t2i$) and text-text ($t2t$) losses:

$$\mathcal{L} = \mathcal{L}_{i2t} + \mathcal{L}_{t2i} + c * \mathcal{L}_{t2t} \tag{2}$$

Here c is a scalar controlling the weights of losses from each task. This model has one text encoder, shared between all retrieval tasks. For hyperparameter tuning and training setup, see the appendix.

6 Results

Intermodal Retrieval Table 2 summarizes intermodal retrieval performance on both the original MS-COCO annotations and CxC. We report performance of two versions of VSRN (Li et al., 2019)–one using the checkpoint on the author's Github (VSRN-github, which allows us to perform CxC evaluations) and the other from the original paper (VSRN-paper, which has higher MS-COCO scores). Comparing each model on MS-COCO and CxC, the new positive items added by CxC show improved retrieval performance as they identify missing positives that are incorrectly penalized when using only original pairs (as noted in Ilharco et al. (2019) for Flickr8k). Multitask training in $\text{DE}_{\text{T2T+I2T}}$ provides a boost over using only intermodal pairs for training (i.e. DE_{I2T}). It performs similarly with VSRN-paper—it seems likely that VSRN's greater investment on the image analysis (with representations based on extracted object bounding boxes) is matched by $\text{DE}_{\text{T2T+I2T}}$'s greater investment in the text encoder.

Figure 7 shows three examples of images retrieved for caption queries. The CxC annotations capture missing examples in the first two cases, and the last two show there are still more positive pairs that remain unassociated in CxC. Figure 8 shows the same for captions retrieved from image queries, again showing that many examples are captured in CxC that are missing in MS-COCO.

Intramodal Retrieval Tables 3 and 4 give intramodal retrieval results enabled by CxC's STS

and SIS ratings respectively. $\text{USE}_{\text{mling-large}}$ is a strong baseline for Text→Text, but all the cross-modal models beat $\text{USE}_{\text{mling-large}}$ by a wide margin, likely due to learning on in-domain captions. InceptionV3 and ResNet-152 prove surprisingly weak for Image→Image, but SimCLRv2 proves to be a strong unimodal baseline for this task. The cross-modal models nevertheless beat SimCLRv2 by a wide margin, even though none were trained on image-image retrieval directly. In terms of joint intra- and inter-modal learning, the multitask $\text{DE}_{\text{T2T+I2T}}$ model provides strong, balanced performance: it is close to DE_{T2T} for Text→Text and DE_{I2T} for Image→Image and far outperforms the latter for Text→Text. The strong performance is especially notable considering that both DE_{I2T} and $\text{DE}_{\text{T2T+I2T}}$ have the same model capacity.

Semantic Similarity Table 5 shows Spearman's R bootstrapped correlation for all models with respect to CxC's STS, SIS and SITS scores. Overall, VSE++, VSRN-github and $\text{DE}_{\text{T2T+I2T}}$ perform better than unimodal baselines, but interesting further patterns emerge. Despite being much worse for retrieval, VSE++ actually beats VSRN-github on STS and SIS; however, its low SITS score indicates it fails to bridge the two modalities as well. The correlation scores also show that DE_{I2T} is too focused on images: it has the highest SIS (81.3), but has worse STS (50.9) than even BoW (55.1). Adding the text-text loss to DE_{I2T} training, i.e. $\text{DE}_{\text{T2T+I2T}}$, produces much more balanced overall performance. On SIS, SimCLRv2 is stronger than all cross-modal models, except DE_{I2T}. SITS scores appear to rank all models similarly to retrieval (Table 2).

The fact that $\text{DE}_{\text{T2T+I2T}}$ is better than both DE_{T2T} and unimodal baselines for STS and Text→Text retrieval is encouraging, and it demonstrates the value of having a single set of annotations covering the relatedness of a common set of images and captions. We expect that a multitask model which also uses image-image training pairs could demonstrate gains across all tasks—measurements made possible by the CxC annotations (especially the new image-image associations).

7 Conclusion

The CxC dataset provides a much more complete set of relationships between and among images and captions than the raw MS-COCO image-caption pairs. We demonstrate that a dual encoder that learns from both image-caption pairs and caption-

caption pairs ($\mathrm{DE}_{\mathrm{T2T+I2T}}$) exhibits strong, balanced performance across four retrieval tasks and three correlation measures. There is much remaining headroom for future models for all these tasks.

CxC's annotations themselves validate the strong semantic alignment between images and their original captions—these have an average similarity of 4.85. However, we also find that co-captions (captions for the same image) have an average score of just 3.0. This calls into question the use of such pairs in training and evaluating paraphrase generation models (Gupta et al., 2018) and reinforces the need for images as context for human evaluation in paraphrasing (Wang et al., 2019).

Acknowledgments

We thank Julia Hockenmaier for her inputs on CxC's formulation, the Google Data Compute Team, especially Ashwin Kakarla and Mohd Majeed for their tooling and annotation support, Yuan Zhang, Eugene Ie for their comments on the initial versions of the paper and Daphne Luong for executive support for the data collection.

CxC Annotations - Collection and Analysis

We present additional details of the human annotation process. To annotate the CxC dataset, in house annotators were employed: 170 (74 men, 96 women) for STS, 61 (28 men, 33 women) for SIS and 113 (46 men, 67 women) for SITS. All were aged between 20-35 years. The annotators were paid hourly wages that are competitive for their locale. They have standard rights as contractors. They were fluent English speakers.

We define separate annotation interfaces for each of Semantic Textual Similarity (STS), Semantic Image Similarity (SIS) and Semantic Image Text Similarity (SITS) tasks. We define a similarity scale ranging from 0 to 5 for all three tasks, following Cer et al. (2017).

We conducted a few pilot annotation rounds with the annotators to evaluate the effectiveness of the annotation instructions and the annotation interface. We learned that allowing the annotators to rate on a continuous 0-5 scale instead of a discrete one like STS resulted in higher correlation between the individual ratings. As a result, we decided to use the continuous ratings in the task but still keep the similarity definition for each discrete value in the annotation instructions. The final annotation interfaces are illustrated in Figures 4 for STS, 5 for SIS and 6 for SITS. Task-specific high-level instructions are displayed at the top in an expandable text box followed by a pair of examples. At the bottom there is a sliding bar with 0-5 score instructions along the scale. Since the SITS instructions are longer, they are shown when the annotator hovers over the corresponding score to improve readability for this task.

Each annotator is required to evaluate the displayed example based on the instructions and score them. The sliding scale makes it intuitive for the annotators to rate an example 2.87 if they feel the semantic similarity of the pair lies between score descriptions of 2 and 3, leaning towards 3. Finally, the annotator response is recorded when they click the submit button at the bottom of the page. The absolute score is deliberately not displayed so as not to distract the workers towards trying to get a clean integer value like 3.0 instead of 2.94 or 2.97.

The annotators were able to get a better grasp of the task through the pilot annotations and got quicker at scoring the pairs. They took an average of 37, 17 and 17 seconds per example for STS, SIS and SITS tasks respectively for the final round of annotations. Table 2 describes the instructions shared with the annotation workers for each task. The side-by-side comparison shows how each rating on the SIS and SITS scales compares to the STS benchmark. Figure 1 shows a set of SIS and SITS examples for the 0-5 rating scale shared along with the instructions. Table 1 contains the breakdown of the number of annotations per task per split.

Split \ Task	STS	SIS	SITS	Total (per split)
Validation	44,009	42,767	44,722	131,498
Test	44,045	46,719	44,833	135,597
Total (per task)	88,054	89,486	89,555	267,095

Table 1: Number of annotations per task and split.

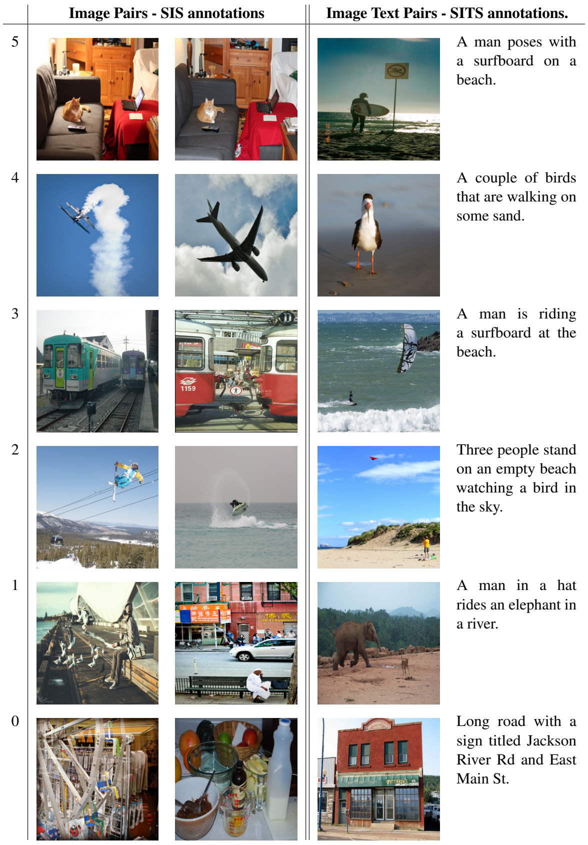

Figure 1: Examples for each annotation score (0-5) of SIS (left) and SITS (right) tasks.

Figure 2 shows a distribution of the standard deviation of raw annotations for each item per task. For STS, there is larger overall deviation compared to the other two tasks–it seems that pairs of short captions leave more ambiguity and are open for broader interpretation than when at least one image is involved. Note also that SITS is expected to have lower deviation because of the sampling based on STS and SIS annotations.

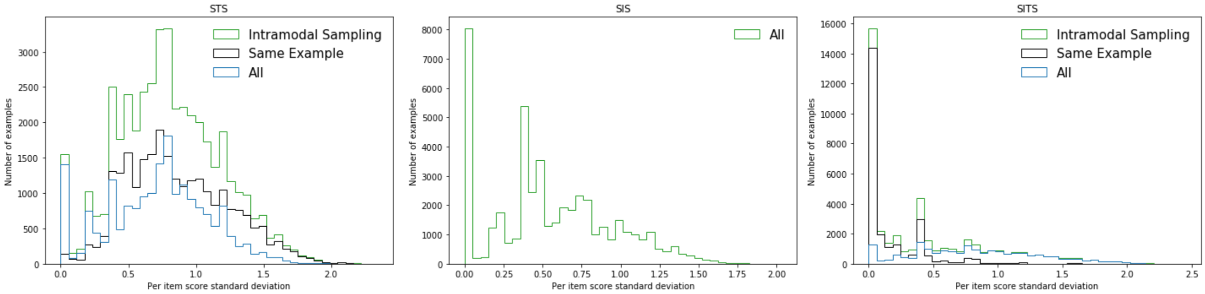

Figure 2: Standard deviation per item in CxC. *Intramodal Sampling* refers to examples selected using *other-modality* selection, *Same Example* refers to original MS-COCO pairs, and *All* covers all examples for a task.

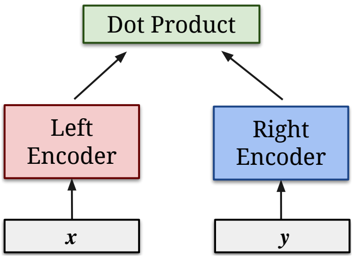

Figure 3: Dual Encoder with inputs x and y, encoded by the left and right encoders, respectively. Similarity is computed as the dot product of the encodings.

Training Setup

Figure 3 shows the basic architecture of the dual encoder models from Section 5.2, which establish strong baselines on all the retrieval and correlation tasks. The image encoder and text encoder are both pre-trained in all experiments. Following Ilharco et al. (2019), we pretrain our dual encoders on the Conceptual Captions dataset (Sharma et al., 2018) with image-to-caption and caption-to-image losses. Conceptual Captions contains 3.3 million pairs of images and captions—far larger than MS-COCO. Pre-training uses the Adam optimizer ($\beta_1 = 0.9, \beta_2 = 0.999$) and a learning rate that starts at 1e-4 and decays by 0.1% every 1000 steps. We stop pre-training after $\approx$30k steps and select the checkpoint that maximizes R@10 on a held-out set. We then fine-tune this checkpoint on MS-COCO using the same hyper parameters, except for a smaller learning rate of 5e-6.

Our models are trained on 32-core slices of Cloud TPU V3 pods, with a per-replica batch size of $K = 64$ during both pre-training and fine-tuning. Because in-batch sampled softmax loss is known to perform best when computed over a large number of negative samples (Gillick et al., 2018), our training setup pools image and caption encodings from all replicas before computing the loss. That is, each replica computes l and r for its local mini-batch and broadcasts them to all others to be used as negative samples. Training with N cores thus allows the loss to be computed over the global batch of $N \cdot K$ examples and $(N \cdot K)^2$ pairs (in our case 2048 examples and 2048^2 example pairs).

Ablation Experiments

Our model architecture and training setup differ from prior work in key ways. In particular, best known results for VSE++ and VSRN are from models that were trained with much smaller batch sizes, did not undergo Conceptual Captions pre-training, and had different image encoder architectures. To evaluate the effect of these factors, we trained variants of our DE_{I2T} model (here, the *baseline* training recipe) with the following one-off ablations:

- The *small batch size* ablation reduces the training batch size to 128 examples, to match that of VSE++ and VSRN in (Faghri et al., 2018) and (Li et al., 2019), respectively.
- *No pretraining* skips dual encoder pretraining on Conceptual Captions.
- *ResNet-152* uses the same recipe as *baseline*, but replaces the EfficientNet-B4 image encoder with ResNet-152, which was used in VSE++. Notably, EfficientNet-B4 has fewer parameters than ResNet-152, but achieves higher classification accuracy on ImageNet.

Table 3 summarizes the performance of the ablated models. Reducing the batch size causes a small but consistent reduction in recalls across all tasks. Removing Conceptual Captions pretraining leads to larger regressions on all tasks – except on Text-Text retrieval, where results are curiously better than the baseline. Likewise, models using ResNet-152 image encoders perform worst overall,

Score	Semantic Textual Similarity (STS)	Semantic Image Similarity (SIS)	Semantic Image-Text Similarity (SITS)
5	**The texts are completely equivalent** as they mean the same thing.	**The scenes are near duplicates**, possibly being viewed from a different perspective.	**The image and sentence are perfectly matched.** The sentence is an almost perfect description for the image.
4	**The texts are mostly equivalent** but some unimportant details differ.	**The two scenes are mostly equivalent**, but some unimportant details differ such as involving different but the same or highly similar types of participants, actions, objects and background.	**The image and sentence are mostly matched**, but some unimportant details differ such as involving different but the same or highly similar types of participants, actions, objects and background. The text can partially describe the image.
3	**The texts are roughly equivalent** but some important information differs or is missing.	**The two scenes are roughly equivalent**, but some important details are different or missing such as involving a notable difference in the types of participants, actions, objects or background.	**The image and sentence are roughly matched**, but some important details are different or missing such as involving a notable difference in the types of participants, actions, objects or background. The image cannot be described using the text.
2	**The texts are not equivalent** but share some details.	**The two scenes are not equivalent**, but share some details in terms of the types of participants, actions, objects or background.	**The image and sentence are not matched**, but share some details in one or more of the types of participants, actions, objects or background.
1	**The texts are not equivalent** but are on the same topic.	**The two scenes are not equivalent**, but are loosely thematically related.	**The image and sentence are not matched**, but are loosely thematically related.
0	**The texts are on different topics.**	**The two scenes are completely dissimilar.**	**The image and sentence are completely unmatched.**

Table 2: Intramodality annotation criteria for Semantic Image Similarity (SIS) and Intermodality annotation criteria for Semantic Image-Text Similarity (SITS) with comparison to equivalent Semantic Textual Similarity (STS) annotations (Agirre et al., 2012).

but also perform (slightly) better than the baseline on Text-Text retrieval.

Overall, we conclude that pretraining and choice of image encoder architecture have large effects on model performance; large-batch training is beneficial, but has a smaller impact. Finally, the asymmetric shifts in task performance suggest models make implicit trade-offs based on the relative difficulty of each task – here, apparently, a function of encoder strength and quantity of training data. Understanding these dynamics, and building models that perform well across all tasks, requires future study. Crisscrossed Captions enables such work by giving a more complete picture of model quality on both intra- and inter-modal tasks.

Annotations	Model	Image → Text R@1	Image → Text R@10	Text → Image R@1	Text → Image R@10	Text → Text R@1	Text → Text R@10	Image → Image R@1	Image → Image R@10

Instruction

For this task, you will compare two sentence length snippets of English text and rate how similar they are in meaning to each other

− Detailed Instructions (click to show/hide)

Task Instructions

Two snippets of text can mean the same thing even if they use very different words and phrases. Conversely, two texts that are superficially very similar in their word choice, phrasing and overall composition can have very different meanings.

For this task, you will compare two phrase or sentence length segments of text and select whether or not they have same underlying meaning or message in terms of what they refer to,say or ask about the world.

For example, do both snippets refer to the exact same person, action, event, idea or thing? Or are they similar but different according to either large or small details?

Tips

- *Assign ratings according to the underlying meaning of the two snippets rather than their superficial similarities or differences.*
- *Be careful of wording differences that have an important impact on what is being said or described.*
- *Ignore grammatical errors and awkward wordings as long as they do not obscure what is being conveyed.*
- *Use the full range of scores and do not be concerned about selecting precise values such as (2.0) or (3.5).*
- *Be fast! Do not spend time obsessing over one numerical value versus another (e.g. a (1) vs a (2)) -- in such cases, pick a value somewhere between them and closer to the value you think represents their similarity.*

Instruction

For this task, you will compare two sentence length snippets of English text and rate how similar they are in meaning to each other

+ Detailed Instructions (click to show/hide)

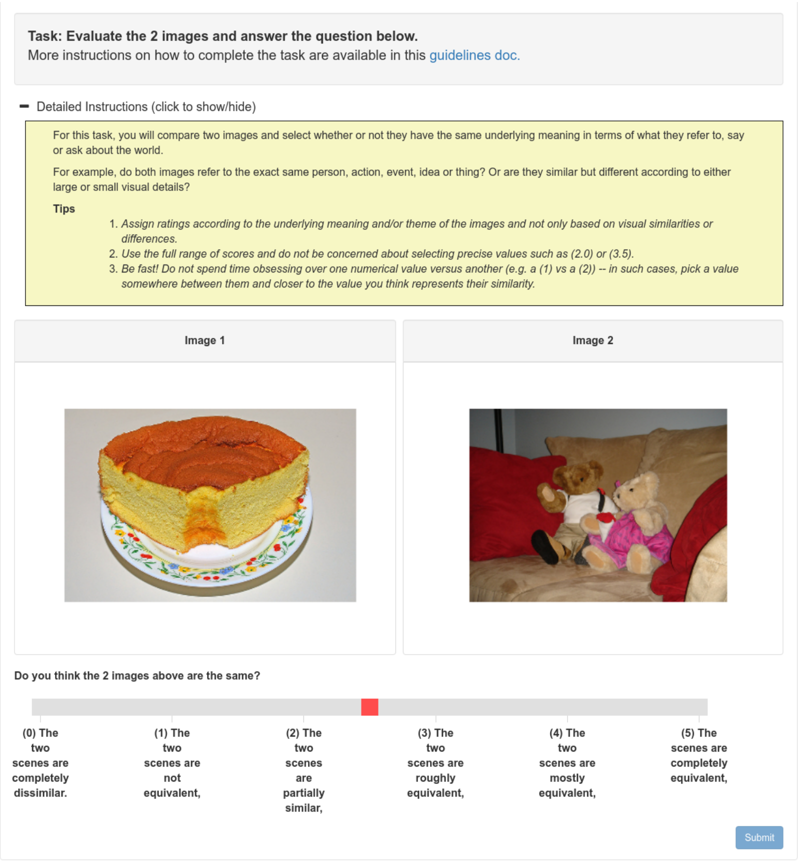
Task

Are the following two snippets of text equivalent in meaning?

sentence 1: A dog riding on a skateboard next to a person.

sentence 2: a man riding a skateboard with his dog.

Figure 4: STS Annotation Interface



Task: Evaluate the 2 images and answer the question below.
More instructions on how to complete the task are available in this guidelines doc.

Detailed Instructions (click to show/hide)

For this task, you will compare two images and select whether or not they have the same underlying meaning in terms of what they refer to, say or ask about the world.

For example, do both images refer to the exact same person, action, event, idea or thing? Or are they similar but different according to either large or small visual details?

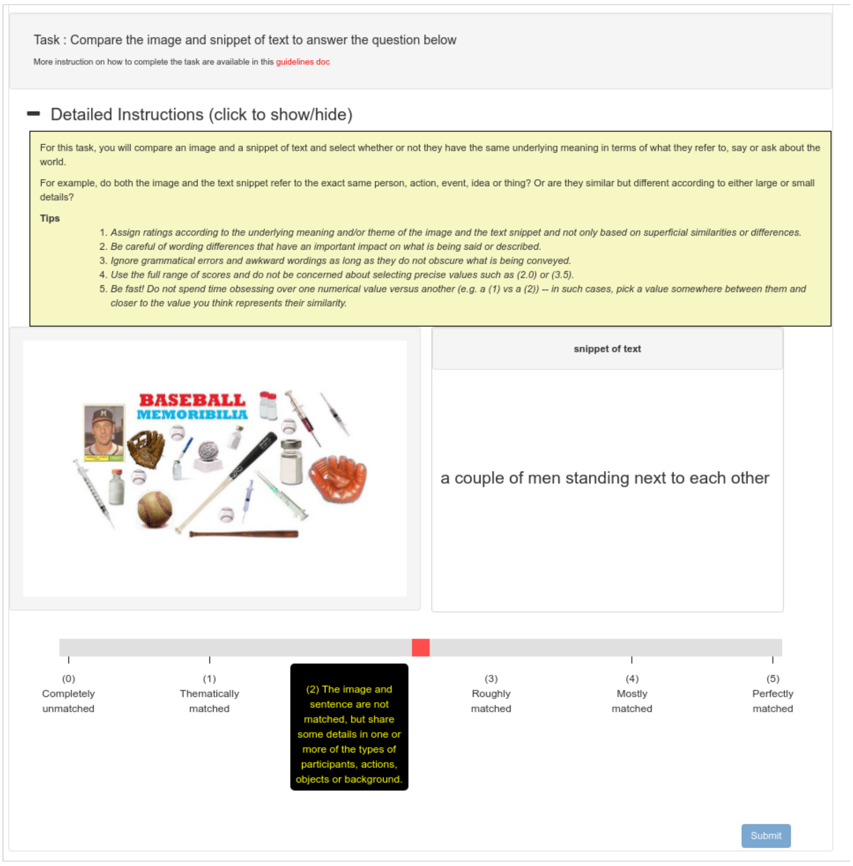
Tips

1. *Assign ratings according to the underlying meaning and/or theme of the images and not only based on visual similarities or differences.*
2. *Use the full range of scores and do not be concerned about selecting precise values such as (2.0) or (3.5).*
3. *Be fast! Do not spend time obsessing over one numerical value versus another (e.g. a (1) vs a (2)) -- in such cases, pick a value somewhere between them and closer to the value you think represents their similarity.*

Do you think the 2 images above are the same?

(0) The two scenes are completely dissimilar.
(1) The two scenes are not equivalent,
(2) The two scenes are partially similar,
(3) The two scenes are roughly equivalent,
(4) The two scenes are mostly equivalent,
(5) The scenes are completely equivalent,

Figure 5: SIS Annotation Interface



Task : Compare the image and snippet of text to answer the question below

More instruction on how to complete the task are available in this guidelines doc

Detailed Instructions (click to show/hide)

For this task, you will compare an image and a snippet of text and select whether or not they have the same underlying meaning in terms of what they refer to, say or ask about the world.

For example, do both the image and the text snippet refer to the exact same person, action, event, idea or thing? Or are they similar but different according to either large or small details?

Tips

1. *Assign ratings according to the underlying meaning and/or theme of the image and the text snippet and not only based on superficial similarities or differences.*
2. *Be careful of wording differences that have an important impact on what is being said or described.*
3. *Ignore grammatical errors and awkward wordings as long as they do not obscure what is being conveyed.*
4. *Use the full range of scores and do not be concerned about selecting precise values such as (2.0) or (3.5).*
5. *Be fast! Do not spend time obsessing over one numerical value versus another (e.g. a (1) vs a (2)) -- in such cases, pick a value somewhere between them and closer to the value you think represents their similarity.*

a couple of men standing next to each other

(0) Completely unmatched
(1) Thematically matched
(2) The image and sentence are not matched, but share some details in one or more of the types of participants, actions, objects or background.
(3) Roughly matched
(4) Mostly matched
(5) Perfectly matched

Abstract

Recently, there has been a strong interest in developing natural language applications that live on personal devices such as mobile phones, watches and IoT with the objective to preserve user privacy and have low memory. Advances in Locality-Sensitive Hashing (LSH)-based projection networks have demonstrated state-of-the-art performance in various classification tasks without explicit word (or word-piece) embedding lookup tables by computing on-the-fly text representations.

In this paper, we show that the projection based neural classifiers are inherently robust to misspellings and perturbations of the input text. We empirically demonstrate that the LSH projection based classifiers are more robust to common misspellings compared to BiLSTMs (with both word-piece & word-only tokenization) and fine-tuned BERT based methods. When subject to misspelling attacks, LSH projection based classifiers had a small average accuracy drop of 2.94% across multiple classifications tasks, while the fine-tuned BERT model accuracy had a significant drop of 11.44%.

1 Introduction

At the core of Natural Language Processing (NLP) neural models are pre-trained word embeddings like Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014a) and ELMo (Peters et al., 2018). They help initialize the neural models, lead to faster convergence and have improved performance for numerous application such as Question Answering (Liu et al., 2018), Summarization (Cheng and Lapata, 2016), Sentiment Analysis (Yu et al., 2017). While word embeddings are powerful in unlimited constraints such as computation power and compute resources, it becomes challenging to deploy them to on-device due to their huge size.

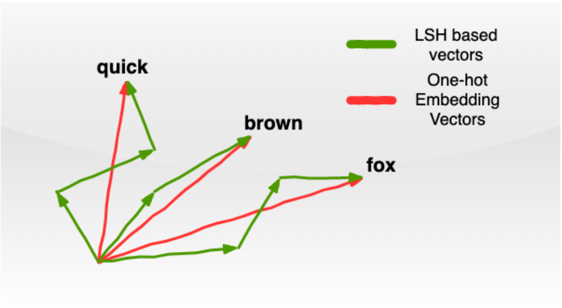

Figure 1: One-hot word embedding look-up vectors vs linear combination of LSH projection based vectors (Ravi, 2017) representing the same word.

This led to interesting research by (Ravi and Kozareva, 2018; Sankar et al., 2019), who showed that word embeddings can be replaced with lightweight binary Locality-Sensitive Hashing (LSH) based projections learned on-the-fly. The projection approach surmounts the need to store any embedding matrices, since the projections are dynamically computed. This further enables user *privacy* by performing inference directly on device without sending user data (e.g., personal information) to the server. The embedding memory size is reduced from $O(V)$ to $O(K)$, where V is the token vocabulary size and $K << V$, is the binary LSH projection size. The projection representations can operate on either word or character level, and can be used to represent a sentence or a word depending on the NLP application. For instance, recently the Projection Sequence Networks (ProSeqo) (Kozareva and Ravi, 2019) used BiLSTMs over word-level projection representations to represent long sentences and achieved close to state-of-the-art results in both short and long text classification tasks with varying amounts of supervision and vocabulary sizes.

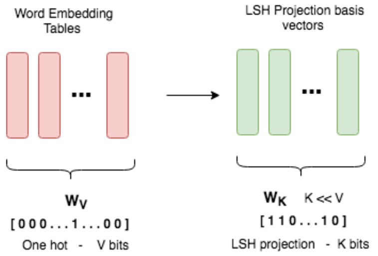

Figure 2: Memory for V look-up vectors for each token vs storing $K(<< V)$ vectors and linearly combining them for token representation. We consider $K = 1120$ following (Ravi and Kozareva, 2018) in this paper.

Despite being successful, there are no existing systematic research efforts focusing on evaluating the capabilities of the LSH based projection for text representations. To that end, we empirically analyze the effectiveness and robustness of the LSH projection approach for text representation by conducting two types of studies in this paper.

1. *Classification with perturbed inputs*, where we show that Projection based networks 1) Projection Sequence Networks (ProSeqo) (Kozareva and Ravi, 2019) and 2) Self-Governing Neural Networks (SGNN) models (Ravi and Kozareva, 2019) evaluated with perturbed LSH projections are robust to misspellings and transformation attacks, while we observe significant drop in performance for BiLSTMs and fine-tuned BERT classifiers.

2. *Perturbation Analysis*, where we test the robustness of the projection approach by directly analyzing the changes in representations when the input words are subject to the char misspellings. The purpose of this study is to examine if the words or sentences with misspelling are nearby in the projection space instead of frequently colliding with the projection representations of other valid words.

Overall, our studies showcase the robustness of LSH projection representations and resistance to misspellings. Due to their effectiveness, we believe that in the future, text representations using LSH projections can go beyond memory constrained settings and even be exploited in large scale models like Transformers (Vaswani et al., 2017).

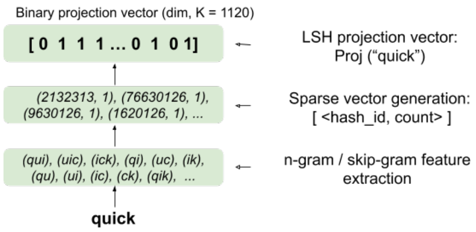

Figure 3: Binary Locality-Sensitive Hashing (LSH) projection representation for text.

2 Binary LSH projections for text representations

The dependency on vocabulary size V, is one of the primary reasons for the huge memory footprint of embedding matrices. It is common to represent a token, x by one-hot representation, $\mathbb{Y}(x) \in [0,1]^V$ and a distributed representation of the token is obtained by multiplying the one-hot representation with the embedding matrix, $W_V \in \mathbb{R}^{d \times V}$ as in

$$U_V(x) = W_V * \mathbb{Y}(x)^\top \in \mathbb{R}^d$$

One way to remove the dependency on the vocabulary size is to learn a smaller matrix, $W_K \in \mathbb{R}^{d \times K}$ ($K << V$), as shown in Figure 2. For instance, 300-dimensional Glove embeddings, W_V (Pennington et al., 2014b) with 400k vocabulary size occupies $>$ 1 GB while the W_K occupies only $\approx$ 1.2 MB for $K = 1000$ yielding a $1000\times$ reduction in size. Instead of learning a unique vector for each token in the vocabulary, we can think of the columns of this W_K matrix as a set of basis vectors and each token can be represented as a linear combination of basis vectors in W_K as in Figure 1. We select the basis vectors from W_K for each token with a fixed K-bit binary vector instead of a V-bit one-hot vector.

The LSH *Projection function*, $\mathbb{P}$ (Figure 3)(Ravi, 2017, 2019) used in SGNN (Ravi and Kozareva, 2018) and ProSeqo (Kozareva and Ravi, 2019) does exactly this as it dynamically generates a fixed binary projection representation, $\mathbb{P}(x) \in [0,1]^K$ for any token, x by extracting morphological input features like char (or token) n-gram & skip-gram features, parts of speech tags etc. from x and a modified Locality-Sensitive Hashing (LSH) based transformation, $\mathbb{L}$ as in

$$x \xrightarrow{\mathbb{F}} [f_1, \cdots, f_n] \xrightarrow{\mathbb{L}} \mathbb{P}(x) \in [0,1]^K$$

where $\mathbb{F}$ extracts n-grams (or skip-grams), $[f_1, \cdots, f_n]$ from the input text. Here, $[f_1, \cdots, f_n]$

could refer to either character level or token level n-grams(or skip-grams) features. Given the LSH projection representation, $\mathbb{P}(x)$, the distributed representation of the token, x is represented as in

$$U_W(x) = W_K * \mathbb{P}(x)^\top \in \mathbb{R}^d$$

. It is worth noting that projection operation, $\mathbb{P}$ can also be used map an entire sentence directly to the $[0,1]^K$ space.

As for the projection based classifiers, the ProSeqo model (Kozareva and Ravi, 2019) runs a BiLSTM over word-level binary LSH projection representations to predict the correct classes, while the SGNN model (Ravi and Kozareva, 2018) computes a binary LSH projection representation for the entire input text, followed by a 2-layer MLP and a softmax layer on top of it for class prediction. SGNN was designed for short text, while ProSeqo is also suitable for long text classification tasks.

There have been a number of research efforts (Sakaguchi et al., 2016; Edizel et al., 2019; Pruthi et al., 2019) to improve the robustness of neural classifiers to misspelling attacks and other text transformations. Recently, Pruthi et al. (2019) observe that fine-tuned BERT and BiLSTM based models are very brittle (for e.g., accuracy drops from 90.3% to 45.8% in the SST (Socher et al., 2013) classification task) to adversarial misspelling attacks. Contrary to intuition, they observe that word-piece and character-level models are more susceptible to spelling attacks compared to the word-level models.

The LSH projection operation, $\mathbb{P}$, is a function of n-grams (and skip-grams) of the input text x and usually the fraction of n-grams affected by spelling attacks tend to be minimal resulting in insignificant changes to the projection representation, $\mathbb{P}(x)$. Therefore, we hypothesize that the projection based models like ProSeqo, SGNN, etc. are *inherently* robust to commonly occurring spelling attacks. In the following sections, we investigate the robustness of projection based classifiers by subjecting them to common misspellings, followed by an analysis of changes in the binary LSH projections of input text under such transformations.

3 Effect of Misspellings on Text Classification

We study the robustness of two types of projection based models – ProSeqo and SGNN. On the other hand, we fine-tune the pretrained BERT-base model (with word-piece tokenization) (Devlin et al., 2018) and train two-layer BiLSTMs (with both word-only and word-piece tokenization) for comparable accuracies with respect to the projection based models for a fair comparison. By word-only tokenization, we mean that models encode input words using a lookup table for each word. In our setup, we test the robustness of the neural classifiers by subjecting the corresponding test sets to common misspellings and omissions. We consider the following perturbation operations: randomly dropping, inserting, and swapping internal characters within words of the input sentences (Gao et al., 2018; Pruthi et al., 2019) [1]. We decide to perturb each word in a sentence with a fixed probability, $P_{perturb}$. Following (Ravi and Kozareva, 2018), we fix the projection dimension to $K = 1120$.

3.1 Datasets

For evaluation purposes, we use the following text classification datasets for dialog act classification MRDA (Shriberg et al., 2004) and SWDA (Godfrey et al., 1992; Jurafsky et al., 1997), for intent prediction ATIS (Tür et al., 2010) and long text classification Amazon Reviews (Zhang et al., 2015) and Yahoo! Answers (Zhang et al., 2015). Table 1 shows the characteristics of each dataset.

Tasks	**# Classes**	**Avg-len**	**Train**	**Test**
ATIS (Dialog act)	21	11	$4.4k$	$0.89k$
MRDA (Dialog act)	6	8	78k	15k
SWDA (Intent Prediction)	42	7	193k	5k
YAHOO (Answers Categorization)	10	108	1400k	60k
AMAZON (Review Prediction)	5	92	3000k	650k

Table 1: Classification Dataset Characteristics

Accuracy drop (%) ± std-deviation (over 5 runs)				
Datasets → **Models ↓**	**MRDA**	**ATIS**	**YAHOO**	**AMAZON**
BERT-base	$8.25_{\pm 3.4}$	$15.57_{\pm 1.2}$	$9.06_{\pm 5.4}$	$12.88_{\pm 3.8}$
BiLSTM-wp	$8.91_{\pm 3.9}$	$20.11_{\pm 3.1}$	$11.32_{\pm 4.5}$	$9.46_{\pm 1.3}$
BiLSTM-w	$15.14_{\pm 4.3}$	$16.23_{\pm 2.6}$	$9.32_{\pm 2.3}$	$8.88_{\pm 2.4}$
SGNN	$\mathbf{1.91}_{\pm \mathbf{0.5}}$	$\mathbf{2.80}_{\pm \mathbf{0.3}}$	-	-
ProSeqo	$2.11_{\pm 0.4}$	$2.84_{\pm 0.6}$	$\mathbf{3.11}_{\pm \mathbf{0.3}}$	$\mathbf{3.91}_{\pm \mathbf{0.5}}$

Table 2: Each entry in the table denotes the average drop in accuracy(%) when classifiers are subject to test inputs with misspellings, $P_{perturb} = 0.2$. ATIS and MRDA are smaller datasets, while Yahoo! Answers and Amazon reviews are larger. BERT-base refers to the BERT-base (Devlin et al., 2018) word-piece model fine-tuned to individual tasks and it converged to state-of-the-art for all tasks.

Table 3: Comparison of projection based models vs BiLSTMs subject to various types and amounts of perturbations. BiLSTM-wp and BiLSTM-w refer to models with word-piece and word-only tokenization respectively.

3.2 Experiments and Results

Table 2 reports the average classifier accuracy drops when all the models are subject to all types of perturbations (*swap*, *drop*, & *add*) on multiple classification tasks (two short text and two long text). We see that the accuracy drop for the projection based models is significantly lower across all datasets. It is also worth noting that the standard deviations across the 5 runs are also minimal for the projection based models further showcasing the stability of projection representations.

In another experiment shown in Table 3, we subject different models to varying types and amounts of perturbations. Similarly, we see that the accuracy drop for the projection based models is the smallest across all datasets and amounts of perturbation. Compared to the word-only models, we observe that the word-piece models are also comparably susceptible to character perturbations which agrees with the findings in (Pruthi et al., 2019).

4 Perturbation Analysis

Apart from the classification experiments, we also directly analyze the changes in the binary LSH projection representations by subjecting input text to different types and amount of perturbations. To that end, we take a large corpus ***enwik9***[2] (vocabulary size of $500k$ and $129M$ words) to analyze the average Hamming distance between LSH projections of the words in the corpus. Next, we compute the average changes in the projection representations by subjecting them to the character perturbations from Section 3. Table 4 shows the results. We make the following observations from our experiments:

LSH Proj.Dim (K)	**Character Perturbations**	
	5%	10%
840	10.08	24.33
980	15.48	31.24
1120	18.83	33.65
1260	19.71	39.01

Table 4: Avg. changes in word projections (bits) for different Char Perturbation % in *enwik9* corpus.

1. Average Hamming distance between LSH projections of words is $\approx K/2$, where K is the projection dimension which implies that the words are more or less uniformly spread out from each other indicating that there are no bias issues in the $[0, 1]^K$ representation space.
2. Assuming $P_{perturb} = 0.2$, we observe that LSH projection changes only by $\approx 11\%$ w.r.t the average Hamming distance between the words in the corpus when subject to misspellings. For instance, if the average Hamming distance between LSH projections of words is 100 bits, misspellings change the projections by only 11 bits on average. Intuitively, this suggests that neural layers on top of the LSH projection tend to rarely confuse a misspelled word for another valid word.

Also from Table 4, we found that the changes in the LSH-projection, $\Delta_{\mathbb{P}(x)}$ due to perturbations is directly proportional to LSH projection dimension, K and perturbation probability, $P_{perturb}$ as in, $\Delta_{\mathbb{P}(x)} \propto K \cdot P_{perturb}$.

5 Conclusion

In this work, we perform a detailed study analyzing the robustness of recent LSH-based projection

neural networks for memory-efficient text representations. Based on multiple text classification tasks and perturbation studies, we find projection-based neural models to be robust to text transformations compared to BERT or BiLSTMs with embedding lookup tables for words and word-pieces.

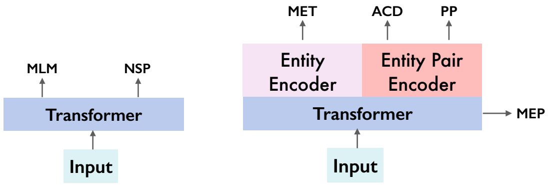
Abstract

Current state-of-the-art systems for joint entity relation extraction (Luan et al., 2019; Wadden et al., 2019) usually adopt the multi-task learning framework. However, annotations for these additional tasks such as coreference resolution and event extraction are always equally hard (or even harder) to obtain. In this work, we propose a pre-training method EnPaR to improve the joint extraction performance. EnPaR requires only the additional entity annotations that are much easier to collect. Unlike most existing works that only consider incorporating entity information into the sentence encoder, we further utilize the entity pair information. Specifically, we devise four novel objectives, *i.e.*, masked entity typing, masked entity prediction, adversarial context discrimination, and permutation prediction, to pre-train an entity encoder and an entity pair encoder. Comprehensive experiments show that the proposed pre-training method achieves significant improvement over BERT on ACE05, SciERC, and NYT, and outperforms current state-of-the-art on ACE05.

1 Introduction

Joint extraction of entities and relations is a fundamental task in information extraction, it aims to extract entities and relations with a unified model. Current approaches (Luan et al., 2019; Wadden et al., 2019) usually adopt the multi-task learning framework that optimizes many objectives simultaneously, including entity recognition, relation extraction, coreference resolution, and event extraction. However, as large-scale manually labeled data required by these methods is unavailable in many domains, their applicability is severely restricted. Therefore, we expect to catch or even surpass the multi-task based joint models with less annotation cost. Compared with the annotations of coreference resolution and event extraction, entity annotations can be easily obtained through automatic NER annotation tools (e.g., spaCy [1]). In this paper, we focus on improving the model's performance with just extra entity annotations.



(a) BERT (b) EnPaR

Figure 1: The network architectures and objectives of BERT and EnPaR. Our work introduce an entity encoder and an entity pair encoder. MLM = masked language model, NSP = next sentence prediction, MET = masked entity typing, MEP = masked entity prediction, ACD = adversarial context discrimination, PP = permutation prediction.

Although pre-trained models, like BERT, have shown impressive performance in many downstream tasks, they have mainly two limitations when applied in the joint entity relation extraction task. One is that currently pre-trained objectives are insufficient for this task. Specifically, these commonly used universal pre-trained model (e.g., BERT) do not consider the entity-related knowledge that is crucial for better extracting entities and relations. The other is that these models only provide pre-trained representations for tokens and sentences, but not entities and entity pairs. To obtain the representations for entities and entity pairs, additional parameters that are not pre-trained are introduced in the fine-tuning stage, which may futher impair the joint extraction performance.

To address the first limitation, recent several works try to incorporate entity-related information

into pre-training objectives. Zhang et al. (2019) fuses heterogeneous information from both texts and knowledge graphs and proposes a denoising entity auto-encoder objective based on BERT. Sun et al. (2019c) presents two knowledge masking strategies in the pre-training stage (entity-level masking and phrase-level masking). Both of them utilize extra entity annotations (*i.e.*, entities in knowledge graphs and automatic entity annotations, respectively). In this paper, we follow this line of works and build a large-scale entity annotated corpus using the spaCy NER tool.

For the second limitation, we propose ENPAR, a pre-training method customized for entity relation extraction. ENPAR consists of an underlying sentence encoder, an entity encoder, and an entity pair encoder. Compared with BERT (Figure 1(a)), the proposed entity encoder and entity pair encoder directly provide representations of entities and entity pairs. To train the three encoders, we devise four novel pre-training tasks: *masked entity typing*, *masked entity prediction*, *adversarial context discrimination* and *permutation prediction* (Figure 1(b)). In the first two tasks, we randomly mask some entity words and then predict the masked tokens and the entity type. These two tasks are natural extensions of the masked language model. To learn a better entity pair encoder, we draw inspirations from the denoising auto-encoder (Zhang et al., 2019) and propose the last two tasks. Specifically, when the entity pair or its context in a sentence are perturbed, we hope that the entity pair encoder is capable of tracking such changes. We employ the parameter-sharing method for these four tasks and train these objectives jointly.

To sum up, our main contributions are as follows [2]:

- We introduce an entity encoder and an entity pair encoder to incorporate not only the entity information but also the entity pair information, which were ignored in current universal pre-trained models.

- We propose four novel pre-training tasks that help to learn the proposed encoders. These tasks only require additional entity annotations (with commonly used entity types), which can be automatically generated by public annotation tools, such as spaCy NER.

- We conduct comprehensive experiments and demonstrate that the proposed method achieves significant improvement on ACE05 and NYT dataset and is comparable with the state-of-the-art on the SciERC dataset.

2 Approach

Given an input sentence $s = x_1, \ldots, x_{|s|}$ and a set of entities $\mathcal{E}$ (automatically annotated) in s, ENPAR is to encode each entity $e \in \mathcal{E}$ and each entity pair (e_1, e_2) into a contextual representation vector. As shown in Figure 2, ENPAR is composed of a shared Transformer (Vaswani et al., 2017), an entity-level CNN followed by an MLP (multi-layer perceptron), a context-level CNN followed by an MLP, and the last MLP. In the pre-training stage, we optimize ENPAR with four objectives, namely, masked entity typing, masked entity prediction, adversarial context discrimination and permutation prediction. These pre-training objectives can integrate rich entity-related information into the proposed network. After pre-training, we can easily fine-tune the pre-trained network for entity relation extraction task.

2.1 Pre-training Network Architecture

In this section, we will introduce the overall ENPAR architecture in three parts: the sentence encoder, the entity encoder, and the entity pair encoder.

Sentence Encoder As previous pre-training models (UNILM, BERT, and XLM), we also apply the multi-layer Transformer (Vaswani et al., 2017) as the basic sentence encoder for obtaining the contextual representations $\mathbf{h}_i$ for each token in the sentence s. The output of multi-layer Transformer is computed via:

$$\{\mathbf{h}_1, \ldots, \mathbf{h}_{|s|}\} = \texttt{Transformer}(\{\mathbf{x}_1, \ldots, \mathbf{x}_{|s|}\})$$

The word representation $\mathbf{x}_i$ of x_i follow that of BERT (Devlin et al., 2018), which is a sum of the corresponding token, segment and position embeddings.

Entity Encoder For each entity $e \in \mathcal{E}$ in the sentence s, the corresponding contextual entity representation $\mathbf{h}_e$ can be obtained by employing a CNN (a single convolution layer with a max-pooling layer) followed by an MLP on vectors $\{\mathbf{h}_i | x_i \in e\}$, as shown in Figure 2(a).

---

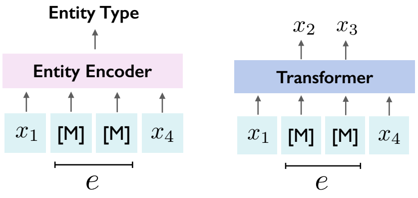
(a) Entity Encoder (b) Entity Pair Encoder

Figure 2: Entity encoder and entity pair encoder based on a shared sentence encoder. Both share the entity-level CNN with MLP, and entity pair encoder contains a context-level CNN with MLP.



(a) MET (b) MEP

Figure 3: Two objectives to learn enhanced representation of single entities.

Entity Pair Encoder For each entity pair (e_1, e_2) in the sentence s, to obtain the corresponding contextual entity pair representation $\mathbf{h}_{e_1,e_2}$, we extract two types of features. The first is the features regarding words in e_1, e_2, and the second is the features regarding contexts of the entity pair (e_1, e_2). For features on words in e_1, e_2, we use the output of entity encoder, namely, $\mathbf{h}_{e_1}$ and $\mathbf{h}_{e_2}$. For context features of the entity pair (e_1, e_2), we extract three feature vectors by looking at left context words, middle context words and right context words of the entity pair (e_1, e_2). Similar to entity encoder, we compute three feature vectors by employing another CNN followed by an MLP. Finally, we concatenate the five feature vectors into a single vector. To get the resulting entity pair representation $\mathbf{h}_{e_1,e_2}$, the single vector was fed into another MLP, as shown in Figure 2(b).

2.2 Pre-training Objectives

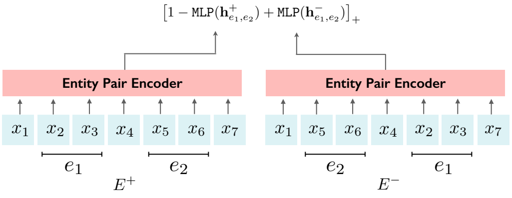
We design four pre-training objectives to guide EnPaR to absorb more entity-related knowledge, which is particularly important for entity relation extraction task. The four objectives can be divided into two groups: the first two objectives are to enhance the representations of single entities, and the latter two objectives are to enhance the representations of entity pairs. These objectives are trained jointly (simply sum the objective functions). Our pre-training objectives are based on a dataset with entity annotation, which can be obtained through the public annotation tool. For instance, `PER`("Obama"), `ORG`("Labour Party") were annotated by spaCy NER, and `PER`, `ORG` are entity types (there are 18 entity types).

Masked Entity Typing (MET) In this task, we simply mask some entity words at random, and then predict the corresponding entity type[3]. For instance, given a masked word sequence "x_1, `[M]`, `[M]`, x_4", to predict the masked entity type (e.g., `PER`), we first use the entity encoder to extract the contextual masked entity representation, and then predict the entity type. The objective is to minimize the cross-entropy loss computed using the predicted entity type and the original entity type, as shown in Figure 3(a).

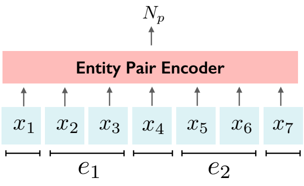
Masked Entity Prediction (MEP) This task is similar to the masked LM in BERT and is identical to the entity-level masking in (Sun et al., 2019c). Specifically, we randomly choose some entity words in the sentence, and replace them with special word `[M]`. Then we feed their corre-

---

[3] It is worth noting that the entity types annotated by spaCy NER may be different from the entity types of downstream datasets.



(a) ACD



(b) PP

Figure 4: Two objectives to learn enhanced representation of entitie pairs.

sponding output vectors computed by the sentence encoder into a softmax classifier to predict the masked entity word. The model is learned to recover the masked entity words, as shown in Figure 3(b). In short, both mask entity typing and mask entity prediction encourage the model to learn the information of single entities.

Adversarial Context Discrimination (ACD) Given an input sentence s with an entity pair (e_1, e_2), we regard it as a positive sample $E^+ = (s, e_1, e_2)$. According to E^+, we can generate a negative sample $E^- = (s', e_1, e_2)$ that has a main property: the context words and the order of context words w.r.t. the entity pair (e_1, e_2) in E^- are minimally different from those in the original sample E^+. If the entity pair encoder can characterize the context words well, it should be able to recognize small context differences of the entity pair between E^+ and E^-. We refer to this objective as adversarial context discrimination. The hinge loss function was imposed into the positive sample and corresponding negative samples to achieve the goal. Specifically, as shown in Figure 4(a), we can obtain a score using the entity pair encoder with an MLP for each sample, then the hinge loss function is computed via:

$$\left[1 - \texttt{MLP}(\mathbf{h}^+_{e_1,e_2}) + \texttt{MLP}(\mathbf{h}^-_{e_1,e_2})\right]_+ .$$

where $[u]_+ = \max(u, 0)$ is the hinge loss and $\texttt{MLP}$ outputs a scalar value. $\mathbf{h}^+_{e_1,e_2}$ and $\mathbf{h}^-_{e_1,e_2}$ are the output of entity pair encoder for positive sample E^+ and negative sample E^-.

Here we introduce our strategies of generating a negative sample $E^- = (s', e_1, e_2)$ according to a positive sample $E^+ = (s, e_1, e_2)$. In fact, there are many negative samples. For the sake of simplicity and clarity, we only adopt following simple rules to generate five negative samples.

Permutation	Class
(left context, e_1, middle context, e_2, right context)	001
(left context, e_1, middle context, right context, e_2)	002
(left context, e_1, e_2, middle context, right context)	003
⋮	⋮
(right context, e_2, middle context, e_1, left context)	120

Figure 5: Permutation samples.

- Swap entity e_1 and entity e_2 in the original sample E^+;
- Shift the entity e_1 few positions (n_s) to the left or right.
- Shift the entity e_2 few positions (n_s) to the left or right.

Permutation Prediction (PP) Given an input sentence s with an entity pair (e_1, e_2), the sentence s was split into five parts, namely, left context, e_1, middle context, e_2 and right context. If we shuffle the five parts, does the entity pair encoder have the ability to recognize it? Inspired by this question, we propose an enhanced objective, named permutation prediction, to help to learn a better entity pair encoder. Formally, let $\mathcal{P}$ be the set of all possible permutation of the fives parts, as shown in Figure 5. Obviously, the number of all possible permutations is 5! ($|\mathcal{P}| = 120$). For each permutation $p \in \mathcal{P}$, we first assign it a unique permutation class $N_p (1 \leq N_p \leq 120)$, and then use the entity pair encoder to extract the contextual entity pair representation for predicting the permutation class, as shown in Figure 4(b). The objective is to optimize the cross-entropy loss computed using the predicted permutation class and the gold permutation class. It is costly to consider all permutations. So we sample n_p permutations in practice (we always include the correct permutation).

2.3 Pre-training Setup

In the pre-training stage, we directly optimize the sum of the above four objective functions. Same as UniLM (Dong et al., 2019), we use gelu as activation function. And the sentence encoder is initialized with $\text{BERT}_{\text{BASE}}$ weights. We use the

English Wikipedia [4] as pre-training corpus, which has been processed in similarly as (Devlin et al., 2018). The spaCy NER [5] was used to annotate entities. After preprocessing the corpus, there are nearly 820M words and 95M entities in the annotated input. We discard the sentences having less than 3 entities for effectiveness, and only pre-train our model for one epoch. The vocabulary size is 28996, The maximum length of the input sequence is 256. For each entity, we replace the entity words with `[M]` with probability 15%, randomly replace other entity with probability 5% and keep the original entity words for the rest. Adam (Kingma and Ba, 2014) with $\beta_1 = 0.9, \beta_2 = 0.999$ is used for optimization. The batch size is 512. The learning rate is 5e-5, with linear warmup rate over the first 10% steps and linear decay. The dropout rate is 0.1. The weight decay is 0.01. It takes about 20 hours for 10, 000 steps using 1 Nvidia Telsa V100 16GB GPU.

2.4 Fine-tuning for Entity Relation Extraction

In the fine-tuning stage, we adopt the same definition of entity relation extraction task as (Sun et al., 2019a). The joint entity relation extraction task can be decomposed into three objectives: entity span detection, entity typing, and relation typing. Firstly, we treat the entity span detection as a sequence labeling task. We regard the first sub-word's output of the sentence encoder as the token-level representation. Then we take the token-level representation as the input to the softmax classifier and compute the cross-entropy loss with respect to gold entity span labels. Secondly, for each detected entity span, the entity classifier uses the corresponding output of the entity encoder to predict entity type. For each detected entity span pair, the relation classifier uses the corresponding output of the entity pair encoder to predict relation type. Both the entity classifier and the relation classifier are randomly initialized softmax layer. Also, we adopt the cross-entropy loss for these two tasks. Besides, all three objectives are optimized simultaneously.

We only tune the hyperparameters on the ACE2005 development set based on the joint performance of entity and relation, then apply the same hyperparameters on the SciERC and NYT datasets. Scheduled sampling strategy (Miwa and Bansal, 2016) and discriminative fine-tuning strategy (Howard and Ruder, 2018) are emploied in fine-tuning. We kepp the same dropout rate as pre-training (*i.e.*, 0.1). The learning rate is 2.5e-5 with weight decay 0.01. We apply a linear warmup scheduler over the first 20% steps and then linear decay. We train our model with a maximum of 200 epochs with early stop strategy in a single Nvidia GeForce GTX 1080 Ti GPU.

3 Experiments

We conduct experiments on three benchmark entity relation extraction datasets: ACE05, SciERC, and NYT. For space limitation, we will mainly discuss the results on ACE05 and report basic results on the remaining two datasets.

ACE05 The ACE05 dataset [6] that is a standard corpus for entity relation extraction task annotates entity and relation labels for a collection of documents. ACE05 contains 7 entity types and 6 relation types. We use the same data split and preprocessing of ACE05 dataset (351 training, 80 validating and 80 testing) as (Miwa and Bansal, 2016) and (Sun et al., 2018).

SciERC The SciERC dataset [7] annotates entity, coreference and relation labels for 500 scientific abstracts from 12 AI conference/workshop proceedings. We only use the annotations of entities and relations. SciERC contains 6 scientific term (entity) types and 7 relation types. We use the same data split and preprocessing of SciERC dataset (350 training, 50 validating and 100 testing) as (Luan et al., 2019).

NYT The NYT dataset[8] is a large-scale corpus which automatically annotates a collection of New York Times news articles. NYT contains 3 types of entities and 12 types of relations. The training set is automatically annotated by distant supervision. While the validation and testing data are manually labeled by (Jia et al., 2019). We choose the latest version of NYT released by (Jia et al., 2019).

Evaluation. As previous works (Miwa and Bansal, 2016; Sun et al., 2019a), we evaluate the

Model	**Entity**	**Relation**	**Relation** (exactly)
Sun, 2019a	84.2	–	59.1
Li, 2019$^{\diamond}$	84.8	–	60.2
Luan, 2019$^{\star,\circ}$	88.4	63.2	–
Wadden, 2019 $^{\diamond,\circ}$	**88.6**	63.4	–
EnPaR $^{\diamond}$	86.9	**66.1**	**63.5**

Table 1: Results on the ACE05 test data. $\diamond$ means that the model uses BERT. $\star$ means that the model uses ELMo as token embeddings. $\circ$ stands for training the model with multi-task learning. EnPaR is the proposed model fine-tuned on ACE05 dataset.

performances using F1 score. Specifically, an output entity is correct if its type label and head region match with a gold entity, then an output relation is correct if both its type and its two argument entities are all correct (i.e. exactly match). While some previous works (Luan et al., 2019; Wadden et al., 2019; Sanh et al., 2019) do not consider entity type in relation evaluation. Thus, we also report this result for comparison.

3.1 Results on ACE05

First, we compare the proposed pre-training method with previous works in Table 1. In general, the relation performance of EnPaR significantly exceeds all existing models in two relation evaluation criteria. Specifically, in exactly matching mode, our method achieves 4.4 points improvement compared with the LSTM-based GCN joint model(Sun et al., 2019a) and increases by 3.3 points compared with the BERT-based QA model(Li et al., 2019). Even compared to the multi-task learning models based on BERT (Wadden et al., 2019), our method still achieves 2.7 points improvement on relation performance. Although the entity performance of our method inferior to the multi-task learning models (Luan et al., 2019; Wadden et al., 2019), we believe that those additional supervision signals such as coreference and event information in the fine-tuning step may cause the gap. Besides, they even consider all spans and cross-sentence context, which are empirically beneficial to entity performance. However, even with the slightly inferior entity encoder and lack of additional multi-task training data, our pre-trained entity pair encoder still achieves significantly superior relation performance, which fully demonstrates the powerfulness of the proposed pre-training method.

Model	**Entity**	**Relation**	**Relation** (exactly)
BERT	87.2	65.1	62.2
EnPaR	86.9	**66.1**	**63.5**
- MET	87.1	65.3	62.5
- MEP	**87.4**	65.6	62.7
- ACD	87.2	65.7	62.9
- PP	87.1	64.2	61.6
- CNN	87.1	66.0	62.9

Table 2: Results on the ACE05 test data in different settings. BERT is our model without pre-training, which is initialized by BERT$_{\text{BASE}}$ and fine-tuned on ACE05 dataset. "- *" is EnPaR without * task, where $* \in$ {MET, MEP, ACD, PP} ; "- CNN" means that only loading parameters of the sentence encoder from EnPaR, and the other parameters (i.e., the entity encoder and the entity pair encoder) are randomly initialized.

100%	86.9	65.2	61.7
75%	86.8	65.3	62.5
50%	87.1	64.6	61.5
25%	86.9	**66.1**	63.5
15%	87.3	65.9	**63.6**
5%	**87.4**	65.9	63.4

Table 3: Results on the ACE05 test data by varying the size of pre-training data.

Next, we evaluate the proposed pre-training method with different settings. We have following four detailed observations regarding the results in Table 2.

- EnPaR (line 2) achieves superior relation performance (1.0 point and 1.3 points improvement) and comparable entity performance compared with BERT (line 1). This result demonstrates that the proposed pre-training objectives inject more entity-related information into the pre-trained model and enhance the relation extraction performance.

- Overall, the entity performances of all models fluctuate quite slightly (0.5 points). Interestingly, "- MEP" (line 4) achieves the best entity performance though its relation performance is not the best. The stable entity performance reflects that the token-level information is likely enough for entity recognition. Besides, the final training objectives may bias entity objectives or entity pair objectives, which leads to more improvement in relation performance than entity performance. Thus, we pay more attention relation perfromance in this paper.

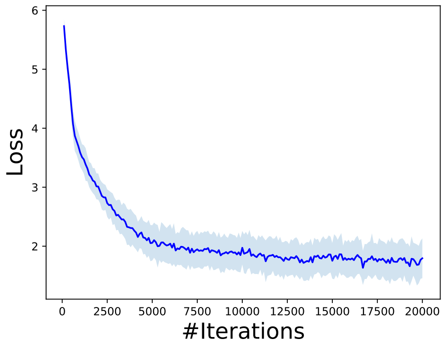

Figure 6: Pre-training loss with respect to the number of pre-training iterations.

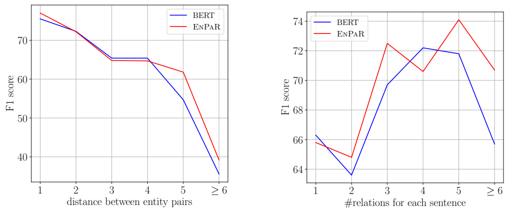
- When any pre-training objective is removed, the relation performance will decrease with varying degrees. Particularly, "- PP" (line 6) drops the most (both 1.9 points decline in two relation evaluation criteria). This phenomenon just indicates the importance of the "PP" objective for the entity pair encoder and relation extraction.

- We also try only to use the pre-trained weights of the Transformer (sentence encoder), while the other parameters are randomly initialized in the fine-tuning step (line 7). The relation performance of the "- CNN" slightly declines compared with EnPaR, but it still outperforms BERT. This result reflects that the sentence encoder has absorbed the entity-related knowledge and can achieve more encouraging performance with the entity encoder and the entity pair encoder.

Thirdly, we present the influences of pre-training data size (Table 3). In experiments, we found the loss of the pre-trained model tends to be stable after iterating 5k steps (about 25% of all data), as shown in Figure 6. Table 3 demonstrates that the performance of the pre-trained model was quite competitive using 25% of pre-training data [9], and more pre-training data does not further improve performance. There is a similar conclusion on text classification (Sun et al., 2019b), which performs within-task further pre-training. This observation shows that the proposed pre-training method does not require expensive training costs.

Finally, we examine the relation performance with respect to different distances between entity pairs (Figure 7(a)) and different the number of relations for each sentence (Figure 7(b)), and also give some concrete examples to verify it (Table 4) [10]. Comparing with BERT, EnPaR is good at handling long-distance relation dependencies and interactions between multiple relations in a sentence. For S1, BERT does not detect the long distance relation `PHYS` between "[barbara starr]" and "[pentagon]" while EnPaR can handle it. For S2, EnPaR identifies a relation `PHYS` between "[charles]" and "[london]", but BERT fails even the relation `PHYS` between "[vladimir putin]" and "[london]" was detected. It shows BERT does not fully exploit the multiple relations in a sentence. We attribute these results to the powerful representations learned by the proposed pre-training objectives.



(a)

(b)

Figure 7: (a) F1 score with respect to the distance between the entity pairs. (b) F1 score with respect to the number of relation for each sentence.

3.2 Results on SciERC and NYT

SciERC The upper part of Table 5 shows the results of SciERC. Compared with BERT, EnPaR achieves 0.5 points improvement on entity performance and 2.2 points (exactly match) improvement on relation performance. This result reflects the effectiveness of the proposed pre-training objectives for entity relation extraction. Compared with the previous state-of-the-art model (Wadden et al., 2019), which is a multi-task learning model based on BERT, EnPaR achieves superior entity performance and comparable relation performance without additional multi-task training data. It worth noting that, the entities in the SciERC dataset are different from our pre-training data. Therefore, the entity encoder and the entity pair encoder can encode contexts of entities rather than only encoding information respect to specific entities. This property is desired as it means that we could utilize any entity annotator.

---

[9] In all experiments, we choose the number of pre-training data, n_p and n_s according to the performance on the development set during the fine-tuning step.

EnPar $^{\diamond}$	**94.8**	**54.4**	**52.6**

Table 5: Results on the SciERC test data (upper part) and the NYT test data (bottom part).

NYT For entity relation extraction task, there are no previous works on this dataset. We list the BERT and EnPar results in the same way as the previous two datasets. For the bottom part of the Table 5, we observe that EnPar significantly outperforms BERT on entity performance and relation performance. This again verifies the effectiveness of our proposed pre-training method.

4 Related Work

Joint entity relation extraction is an important task that has been extensively studied. One simple method to achieve joint learning is through parameters sharing, which usually share some input embeddings or sentence encoders (Miwa and Bansal, 2016; Katiyar and Cardie, 2017). To further explore the interactions between the outputs of the entity model and the relation model, many joint decoding algorithms were introduced into this joint task (Yang and Cardie, 2013; Li and Ji, 2014; Katiyar and Cardie, 2016; Zheng et al., 2017; Ren et al., 2017; Wang et al., 2018; Sun et al., 2018; Fu et al., 2019). Besides, (Li et al., 2019) tackle this task under the framework of multi-turn QA. And (Sun et al., 2019a) conduct joint type inference via GCN on a bipartite graph composed of entities and relations. Recently, transfer learning (Sun and Wu, 2019), multi-task learning (Sanh et al., 2019; Wadden et al., 2019; Luan et al., 2019) were also applied in this task. In this work, we investigate the pre-trained model for entity relation extraction. For simplicity, we restrict the joint model of parameters sharing, which can be easily extended to jont decoding methods.

Pre-trained models (Yang et al., 2019; Dong et al., 2019; Joshi et al., 2020) have made many amazing breakthroughs on various NLP downstream tasks. Pre-training paradigm first pretrain networks with some pre-training objectives on large-scale unlabeled text corpora, and then fine-tune the pre-trained networks on downstream tasks. These pre-training objectives determine the knowledge absorbed by the pre-trained models. For example, BERT (Devlin et al., 2018) adopts masked language model and next sentence prediction to learn deep contextual representations and the relation between two sentences respectively. XLNet (Yang et al., 2019) uses permutation language model to learn bidirectional representations with autoregressive model. UniLM (Dong et al., 2019) fuses three types of language model: unidirectional, bidirectional and seq2seq prediction. However, these models and objectives all ignore the entity-related information, which is crucial for entity relation extraction task. Recently, there are several public works that explore how to properly integrate entity inforamtion into pre-trained models. Specifically, (Zhang et al., 2019) achieve enhanced language representation by injecting informative entities in KGs into pre-training models. And (Sun et al., 2019c) propose two higher-level masking strategies: entity-level masking and phrase-level masking. In this work, we not only integrate entity information, but also extend to entity pair information and learn more powerful representations for entities and entity pairs.

5 Conclusion

We propose EnPar, a pre-training method customized for entity relation extraction only with additional entity annotations. Instead of only pre-training sentence encoder in universal pre-trained models, we also pre-train an entity encoder and an entity pair encoder. Then the proposed four objectives can incorporate entity and entity-pair knowledge into the pre-trained encoders to enhance the encoders' representations. Experiments on three datasets demonstrate that ENPAR achieves comparable or even superior performances compared with multi-task based joint models.

A More Evaluations

Table 6 and Table 7 show the performances of “BERT” and our “EnPaR” on each entity type and relation type, respectively. For entity performance, “EnPaR” is almost the same as “BERT”. However, for relation performance, we can find “EnPaR” is superior to “BERT” on all relation types except “PER-SOC” relation. The major reason is “EnPaR” significantly improves recall while keeping or sacrificing little precision.

Figure 8 and Figure 9 demonstrate the relation performances (exactly match) of “BERT” and “EnPaR” in different situations. Specifically, Figure 8 shows the results with respect to the number of entities for each sentence, while Figure 9 shows the results with respect to the sentence length for each sentence. In Figure 8, our “EnPaR” significantly outperforms “BERT” when the number of entities in a sentence is more than 2. Similarly, when the sentence length is more than 10, our “EnPaR” is also superior to “BERT” as shown in Figure 9. Both results show the powerful ability of “EnPaR” to identify relations in complicate sentences and long sentences. Moreover, it also proves that the proposed pre-training objectives indeed prompt the model to learn entity related information, which contributes to improving the relation extraction performance.

Entity Type	Model	P	R	F

Abstract

Traditional data augmentation aims to increase the coverage of the input distribution by generating augmented examples that strongly resemble original samples in an online fashion where augmented examples dominate training.

In this paper, we propose an alternative perspective—a *multi-task view* (MTV) of data augmentation—in which the primary task trains on original examples and the auxiliary task trains on augmented examples. In MTV data augmentation, both original and augmented samples are weighted substantively during training, relaxing the constraint that augmented examples must resemble original data and thereby allowing us to apply stronger levels of augmentation.

In empirical experiments using four common data augmentation techniques on three benchmark text classification datasets, we find that the MTV leads to higher and more robust performance improvements than traditional augmentation.

1 Introduction

Most data augmentation techniques aim to generate augmented examples for training that are similar to original data. In computer vision, operations such as flipping, cropping, and color jittering are both widely used and highly effective—it is self-evident that augmented examples closely resemble original data, and so we generate augmented data in an online fashion during each minibatch such that no original, unmodified examples are seen during training (Krizhevsky et al., 2012; Zagoruyko and Komodakis, 2016; Huang et al., 2017).

In language, on the other hand, even slight modifications can cause significant semantic changes, and so it is not always clear whether augmented examples resemble original data. Despite this uncertainty, many augmentation techniques in NLP still generate examples stochastically and ignore original data (Zhang et al., 2015; Sennrich et al., 2016a; Xie et al., 2017; Li et al., 2017; Kobayashi, 2018; Wang et al., 2018). When it is unclear whether augmented examples resemble original data—as is often the case—is it wise to neglect the original training data?

Traditional Data Augmentation

- **Intuition:** Increase coverage of input distribution by using augmented examples for training.
- **Guideline:** Augmented examples should be similar to original data.
- **Training:** Dominated by augmented examples that are generated stochastically.

Multi-Task View (MTV) of Data Augmentation

- **Intuition**: Auxiliary task of classifying augmented examples acts as regularization for the primary task of classifying original examples.
- **Guideline**: It might be a good idea for augmented samples to resemble original data, but they can be anything that boosts performance.
- **Training**: Both original and augmented data receive substantive weighting during training.

Table 1: Summary of traditional data augmentation versus MTV data augmentation.

Our paper questions this practice by proposing to include original data during training. Specifically, we make two contributions:

1. We propose a *multi-task view of data augmentation* (MTV data augmentation), which trains on both original and augmented examples and therefore allows us to relax the constraint that augmented examples must resemble original data. The MTV facilitates augmentation using a higher strength parameter.

2. We show empirically that four common data augmentation techniques provide higher and more robust performance gains using the MTV compared with traditional augmentation.

April 19 - 23, 2021.

2 Traditional Data Augmentation[1]

Situation. During regular training, the canonical maximum likelihood objective minimizes the cost of the original training set J_O:

$$J_\mathrm{O}(\theta) = \mathbb{E}_{x,y \sim \hat{\mathbf{p}}(X,Y)} \left[-\log \mathbf{p}_\theta(y|x) \right],$$

where $\hat{\mathbf{p}}(X,Y)$ is the empirical distribution of training pairs x, y and $\mathbf{p}_\theta(y|x)$ is the parameterized model that we aim to learn (e.g., a neural network). As $\hat{\mathbf{p}}(X,Y)$ is typically the observed data, it will likely have some mismatch with the true data distribution $\mathbf{p}(X,Y)$. When the mismatch is dramatic—for instance, when $\hat{\mathbf{p}}(X,Y)$ does not sufficiently cover the training space—model performance will likely suffer.

Remedy. In practice, we often use data augmentation to mitigate the inadequacy of $\hat{\mathbf{p}}(X,Y)$ by providing additional training data. We generate an augmented distribution $\mathbf{q}(\hat{X},\hat{Y})$ and now minimize the cost of this augmented training set J_aug:

$$J_\mathrm{aug}(\theta) = \mathbb{E}_{x,y \sim \mathbf{q}(\hat{X},\hat{Y})} \left[-\log \mathbf{p}_\theta(y|x) \right].$$

As we now optimize solely on $\mathbf{q}(\hat{X},\hat{Y})$, our goal is to find $(\hat{x},\hat{y})$ pairs that are likely to fall in the true distribution $\mathbf{p}$. Assuming the smoothness of $\mathbf{p}$, similar (x,y) pairs will have similar probabilities, and therefore if an augmented example is more similar to an observed example, it is more likely to be sampled under the true distribution. In other words, good augmented examples resemble the observed data, and we aim to find them. Conversely, if an augmented example diverges too far from any observed data, it is likely invalid and thus harmful for training; we don't want to train on these examples.

The majority of prior work follows this framework of augmented examples resembling real data. As popular techniques, semantic noising substitutes tokens with synonyms (Wang and Yang, 2015; Zhang et al., 2015; Li et al., 2017); Pervasive Dropout randomly removes words from the input sequence (Sennrich et al., 2016a); and SwitchOut (for machine translation) replaces some words in both source and target sentences with other words from their corresponding vocabularies (Wang et al., 2018).

Moreover, most of these techniques perform augmentation on every training example in an online fashion, implicitly assuming that augmented examples so closely resemble original data that directly training on original examples is not even worth considering. As we shall see in the next section, adding in these original examples during training might actually be a worthwhile idea.

3 MTV Data Augmentation

Multi-task optimization jointly trains on a primary task and one or more auxiliary tasks—the intuition is that requiring an algorithm to also learn an auxiliary task can act as better regularization than penalizing all complexity uniformly. Prior work has found that multi-task models work particularly well when the tasks are similar, but can also improve performance even on unrelated tasks (Paredes et al., 2012; Hajiramezanali et al., 2018).

We propose a multi-task view of data augmentation that has a primary task that optimizes regular training on original examples and an auxiliary task that optimizes training on augmented data. This MTV jointly optimizes the primary and auxiliary task(s) using a weighted cost function so that both original and augmented data receive substantial weight during training:

$$J(\theta) = \gamma_\mathrm{O} \cdot J_\mathrm{O}(\theta) + \gamma_\mathrm{aug} \cdot J_\mathrm{aug}(\theta),$$

where γ_O is the weight of **o**riginal data and γ_aug is the weight of **aug**mented data, and $\gamma_\mathrm{O} + \gamma_\mathrm{aug} = 1$. In this context, observe that vanilla training uses $\gamma_\mathrm{O} = 1$ and $\gamma_\mathrm{aug} = 0$, and traditional data augmentation uses $\gamma_\mathrm{O} = 0$ and $\gamma_\mathrm{aug} = 1$.

The MTV gives us an important freedom that is not offered by the traditional data augmentation framework. Since traditional data augmentation only trains on augmented examples, performance suffers detrimentally when augmented data differs too much from the true distribution—therefore, most studies aim to generate augmented examples that resemble original data. MTV data augmentation, however, jointly trains on both original and augmented data, thereby allowing us to relax the constraint that original and augmented examples come from the same distribution. In fact, accepting that the original and augmented distributions might differ or could even be unrelated—as work in multi-task learning has done (Paredes et al., 2012; Hajiramezanali et al., 2018; Rai and Daumé, 2010)—liberates us to apply stronger levels of data augmentation, which, as we will demonstrate in the next section, leads to higher and more robust performance.

---

[1] We closely follow the intuition and notation of Wang et al. (2018)

4 Experiments

This section compares multi-task view augmentation to traditional augmentation for various datasets and augmentation techniques.

4.1 Experimental Setup

Datasets. We conduct experiments on three text classification tasks often used as benchmarks (Kim, 2014): (1) Stanford Sentiment Treebank (**SST2**) (Socher et al., 2013) of movie reviews classified as positive/negative, (2) subjectivity/objectivity dataset (**SUBJ**) (Pang and Lee, 2004), where sentences are classified as either subjective or objective, and (3) question type dataset (**TREC**) (Li and Roth, 2002), in which questions ask for either a description, entity, abbreviation, human, location, or number.

Models and Experimental Procedures. For text classification, we use BERT (Devlin et al., 2019) (`bert-base-uncased` from HuggingFace) to extract features by averaging the last hidden states of the input tokens. To reduce the number of model hyperparameters and save computation time, we classify these features using a linear SVM trained for 1000 epochs.[2] Since training data size depends on the amount of augmented data, we adjust the number of training epochs so that all models receive the same number of updates. All experiments are run for five random seeds. Our baseline models without data augmentation achieved 84.5%, 93.1%, and 83.9% accuracy respectively on the SST2, SUBJ, and TREC tasks.

Augmentation Techniques. In this paper, we experiment with four simple and common data augmentation techniques studied in Wei and Zou (2019): **(1) Token Substitution** (Zhang et al., 2015) replaces words with WordNet (Miller, 1995) synonyms; **(2) Pervasive Dropout** (Sennrich et al., 2016a) applies word-level dropout; **(3) Token Injection** (Wei and Zou, 2019) insert a synonym of a random token in the sequence into a random position in that sequence; **(4) Positional Shuffling** (Wei and Zou, 2019) randomly chooses two tokens and swaps their positions. For all four techniques, a parameter α indicates *augmentation strength* by dictating how many perturbations are performed. For a given α, we perform $n = \alpha\, l$ perturbations, where l is the sequence length.

Aug. Technique	MTV	Best α	Avg. Boost	(Δ_{MTV})
Token Substitution	✗	0.05	1.3%	-
	✓	0.3	2.1%	(+0.8%)
Pervasive Dropout	✗	0.1	1.8%	-
	✓	0.4	2.5%	(+0.7%)
Token Injection	✗	0.05	0.7%	-
	✓	0.5	2.2%	(+1.5%)
Positional Shuffling	✗	0.05	1.4%	-
	✓	0.4	2.5%	(+1.1%)

Table 2: Average performance boost on three text classification tasks for four augmentation techniques using the best-performing augmentation strength from $\alpha \in \{0.05, 0.1, 0.2, 0.3, 0.4, 0.5\}$. Traditional data augmentation works best at low α, whereas MTV data augmentation provides the strongest performance for high α. Δ_{MTV} indicates additional boost from using the MTV compared with traditional augmentation.

4.2 Stronger augmentation for more gains

Table 2 summarizes results for data augmentation in the MTV using $\gamma_{\text{O}} = \gamma_{\text{aug}} = 0.5$ compared with traditional augmentation for the best-performing augmentation strength from $\alpha \in \{0.05, 0.1, 0.2, 0.3, 0.4, 0.5\}$. In the traditional framework, pervasive dropout had the strongest performance boost of 1.8% using $\alpha = 0.1$. The MTV, however, allowed for stronger augmentation (i.e., $\alpha \geq 0.3$) that resulted in all four techniques to achieving boosts of more than 2.0%.

Perhaps strikingly, token injection and positional shuffling, which are less intuitive and not as commonly used as token substitution and pervasive dropout, achieve the strongest gains ($> 1.0\%$) from using the MTV. One potential reason for this is that, compared with token substitution and pervasive dropout, token injection and positional shuffling are non-destructive in that they do not remove any of the original words, and so the nature of examples augmented at high α could be more conducive for the MTV.

4.3 More-robust gains at high α

When using data augmentation with high α, high levels of noising are employed and augmented data are therefore more likely to diverge from their original examples. Figure 1 takes a closer look at how performance is affected by varying α. Whereas traditional augmentation often negatively affected performance at high α, the multi-task view, which jointly optimizes the original distribution, had robust performance gains at high augmentation strengths.

---

[2] This setup is not state-of-the-art but allows for experiments to be performed on CPU.

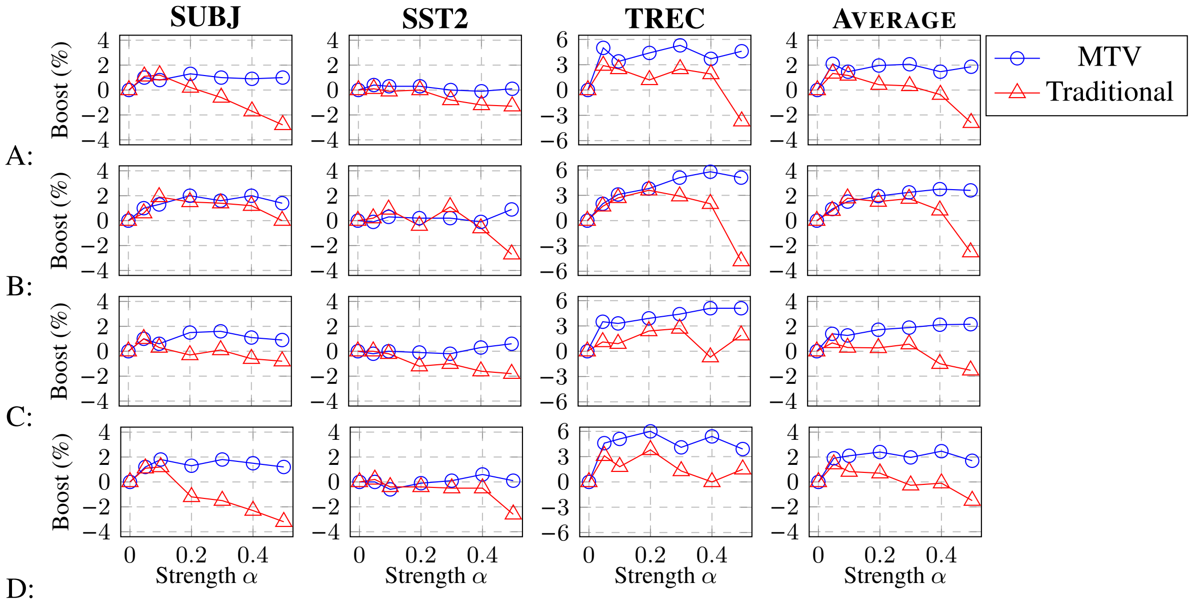

Figure 1: Performance boosts on three tasks using the traditional and multi-task view (MTV) frameworks for four data augmentation techniques: Token Substitution (Zhang et al., 2015) (A), Pervasive Dropout (Sennrich et al., 2016a) (B), Token Injection (Wei and Zou, 2019) (C), Positional Shuffling (Wei and Zou, 2019) (D). In the traditional framework, improvements are largest when augmentation strength α is small, with performance deteriorating for large α. The MTV, on the other hand, jointly optimizes for both original and augmented data, leveraging higher α to provide higher and more robust performance gains.

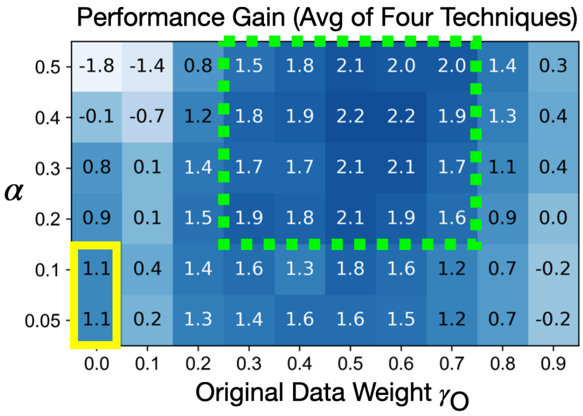

α \ γ_O	0.0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9
0.5	-1.8	-1.4	0.8	1.5	1.8	2.1	2.0	2.0	1.4	0.3
0.4	-0.1	-0.7	1.2	1.8	1.9	2.2	2.2	1.9	1.3	0.4
0.3	0.8	0.1	1.4	1.7	1.7	2.1	2.1	1.7	1.1	0.4
0.2	0.9	0.1	1.5	1.9	1.8	2.1	1.9	1.6	0.9	0.0
0.1	1.1	0.4	1.4	1.6	1.3	1.8	1.6	1.2	0.7	-0.2
0.05	1.1	0.2	1.3	1.4	1.6	1.6	1.5	1.2	0.7	-0.2

Figure 2: Performance boost (%) with varying augmentation strengths α and weights of original data γ_O during training. Traditional data augmentation (yellow solid box in lower left) uses modest augmentation strength ($\alpha = 0.05, 1$) with no original examples for training ($\gamma_O = 0$). The MTV data augmentation approach (green dashed box) suggests substantive weighting of original examples (e.g., $\gamma_O = 0.5$) which allows for much stronger augmentation (e.g., $\alpha \geq 0.3$).

4.4 Choosing γ_O and γ_{aug} weighting

As our experiments so far have used the MTV with balanced weighting of original and augmented data ($\gamma_O = \gamma_{\text{aug}} = 0.5$), in this section we explore different weightings of γ_O and γ_{aug}. Figure 2 shows these results averaged over all three datasets and all four augmentation techniques. Traditional data augmentation, which uses modest augmentation strength (e.g., $\alpha \in \{0.05, 0.1\}$) and does not train on original data ($\gamma_O = 0.0$), achieves reasonable performance gains. As expected, when stronger augmentations were applied (e.g., $\alpha \geq 0.4$), training with only augmented data hurts performance. When training on both augmented and original data, however, performance improved with stronger augmentation and remained robust for varying augmentation strengths $0.2 \leq \alpha \leq 0.5$ and original data weights $0.3 \leq \gamma_O \leq 0.7$.

5 Further Related Work

Prior work on data augmentation, to our knowledge, generally follows the traditional data augmentation framework. In addition to the methods mentioned in §2, Xie et al. (2017) replaced words with samples from the unigram frequency distribution; Yu et al. (2018) translated English sentences to French and back to English (backtranslation); and Kobayashi (2018) replaced words with other words based on a language model. All these methods could potentially be formulated in the MTV.

Some prior work has also drawn connections between seeing data augmentation as multiple tasks. Similar to how we optimize augmented data as a separate task, Meyerson and Miikkulainen (2018) created fake tasks by using multiple distinct decoders to train a shared structure to solve the same problem in different ways. In machine translation, Sennrich et al. (2016b) used monolingual training examples as parallel examples with an empty source side, noting that their setup could be seen as multi-task learning with the tasks as translation with known sources and language modeling with unknown sources. Compared with these papers that create multiple tasks in very specialized scenarios, the multi-task view that we have presented here can be used for any type of text data augmentation.

To be clear, our study is not the first to mix original and augmented data in training. For instance, Wang and Yang (2015) use a ratio of 1:5 original to augmented examples, but this weight of original data is much smaller than the $0.3 \leq \gamma_O \leq 0.7$ that we advocate for. Sennrich et al. (2016b) also include original data when training with back-translation augmentation, but the given ratios of original and augmented data they use appear to dictated by the speed of their back-translation models rather than an intentionally-motivated design choice. We see our work as the first to explicitly formulate the MTV, advocate for a joint optimization function, and comprehensively explore its implications on common text augmentation techniques.

As a limitation, our study has focused on label-preserving augmentation techniques, and our line of reasoning may not apply when augmentation techniques intentionally change the label. Moreover, we have only studied text classification with simple models using task-agnostic augmentation techniques. Future work in this direction could experiment with larger-scale models or study task-specific augmentation.

6 Conclusions

We have proposed a multi-task view that gives both original and augmented examples substantial weight during training, contrasting prior work that performs stochastic data augmentation and ignores original training data. For four common augmentation techniques, we found experimentally that this alternative view allows for stronger levels of augmentation, which in turn leads to better and more robust performance than traditional augmentation. We hope our paper inspires future work using text data augmentation to think more explicitly about how much augmented examples resemble original data and consider substantive weighting of original data when using data augmentation to improve model performance.

To close, we leave the enthusiastic reader with one last thought. Most existing text data augmentation techniques have obediently followed the paradigm from computer vision of generating augmented examples that are similar to the original data. Who's to say that's how data augmentation ought to work in NLP? In this paper, we've shown how to search for relative freedom from this constraint, simply by taking a different view of the underlying assumptions. Now, a bigger question arises on the horizon—what new text augmentation techniques are unlocked when augmented data are not forced to resemble the original?

Representations for Question Answering from Documents with Tables and Text

Vicky Zayats[†][*] **Kristina Toutanova**[†] **Mari Ostendorf**[§]

Abstract

Tables in Web documents are pervasive and can be directly used to answer many of the queries searched on the Web, motivating their integration in question answering. Very often information presented in tables is succinct and hard to interpret with standard language representations. On the other hand, tables often appear within textual context, such as an article describing the table. Using the information from an article as additional context can potentially enrich table representations. In this work we aim to improve question answering from tables by refining table representations based on information from surrounding text. We also present an effective method to combine text and table-based predictions for question answering from full documents, obtaining significant improvements on the Natural Questions dataset.

1 Introduction

Tables are a common type of information representation used across the Internet. With billions of search queries a day,[1] question answering on tables is an important task that translates into a large number of search queries every second about information present in tables. In general, research on Question Answering (QA) can be categorized in terms of the resources that are used in answering the question: text documents (often referred as *unstructured* text in the literature), tables, or a structured knowledge base (KB). In our work we are interested in the combination of text-based and structured resources for question answering, particularly articles that contain both tables and text. This is a natural next step for question answering on tables, in that most tables are embedded in documents that discuss them, creating the challenge of determining whether the answer is in the text or the table (if anywhere). In addition, very often information presented in tables is compact and abbreviated. The associated text can potentially provide rich context that can be used to enhance the representation of the table for more robust question answering.

The main focus of this paper is to investigate how to improve question answering on documents that contain both text and tables. While recently there has been a lot of interest in reading comprehension for both text and tables, little research has been done in combining the two sources of information. The only prior study we are aware of is by Chen et al. (2020) who introduced a new dataset for multi-hop QA over tabular and textual data. In their work, the authors heavily rely on the assumption that the questions would be unanswerable if either text or table information is missing. Here we investigate a more realistic scenario of naturally occurring questions, where the answer can be found in either text, tables, both, or none. We evaluate our approach on the Natural Questions corpus (Kwiatkowski et al., 2019) which consists of real anonymized queries issued to the Google search engine and corresponding Wikipedia articles, simulating a real use case of such a system.

Prior work on the Natural Questions dataset has treated text and tables uniformly, linearizing tables and representing them and text segments using the same contextual token representations (for example, starting from pre-trained transformers (Vaswani et al., 2017) like BERT (Devlin et al., 2019)). However, representations developed for text are sub-optimal for tables, since they do not account for the special relationships between table cells, defined by the row and column structure. In this work, we extend the BERT architecture to account for inter-cell relationships in tables. This approach is motivated by Graph Neural Networks with a transformer (Shaw et al., 2018) and is

closely related to the one in Müeller et al. (2019). In our work, we pretrain parameters for the new relationships using a large table corpus extracted from Wikipedia (Bhagavatula et al., 2013).

In addition, we present a novel approach that refines table representations by attending to related representations of text in the surrounding article. This allows information to propagate from the text to table elements, improving the ability of the model to interpret tables and find answers in them.

Overall, the main contributions of our work are three-fold. First, to the best of our knowledge, this is the first work that investigates how to effectively combine text-based and table-based approaches in a setting where it is unknown which, if any, of these modalities contains an answer to a question. Second, we introduce a novel mechanism to enrich table representations based on text surrounding the table, which improves the performance of a model for question answering from tables. Finally, this is the first model that uses the Natural Questions corpus for question answering on tables, improving the baseline in Alberti et al. (2019) that does not distinguish between tables and text.

2 Related Work

Most work on QA with tables prior to BERT involves first converting the table to a Knowledge Graph (KG) where cell entries are entities with row/column relations, then using entity linking to identify spans in the question that match an entity in the knowledge graph, and finally parsing the question to generate a SQL query using some variant of a sequence-to-sequence model (Krishnamurthy et al., 2017). Due to the advances in contextualized word embeddings, more recent work proposed a modification of the BERT transformer architecture to be used for representing tables. Hwang et al. (2019) proposed the usage of additional `[SEP]` tokens between headers of the table to make a BERT model more suitable for the tables. Recently, Yin et al. (2020) introduced a pretraining procedure for joint representation of tabular data paired with an utterance, where the approach is to linearize the structure of tables to be compatible with a BERT model. Our approach for table encoding is most similar to that of Müeller et al. (2019), where the authors generalized the BERT architecture similarly to Shaw et al. (2018) with new types of relations to encode table-specific relationships. The main differences between our table representation and Müeller et al. (2019) is that in our representation we use 5 types of relations, cell-column, cell-row, in-cell, cross-column and cross-row (more details in Section 3.1), while in their work the authors use cell-column and cell-row relations only for the table representation, but in addition use question-cell relations for marking matches between tokens in the question and corresponding cell values. Finally, the two most recent works on table representation learning, TaPaS (Herzig et al., 2020) and GraPPa (Yu et al., 2020), also use pretraining on the Wikitables dataset (Bhagavatula et al., 2013) that we use in our work. Therefore, our table representations based on transformers and our pretraining method are comparable to those in recent and concurrent work.

Leveraging tables is a hard problem. However, most studies on table-based QA omit an important additional information source: the text in the article discussing the table. Prior attempts at integrating a KB and text use early fusion of document text and KG information (Sun et al., 2018), where they integrate text and a KG sub-graph in a single graph, from which an entity is selected to answer the question. Structured KGs are often easier to interpret than tables, which have a wide variety of possible schemas. InfoTabS (Gupta et al., 2020) introduced a dataset for the natural language inference task based on premises that are tables, where the authors explore multiple table representations, including a key-value approach and linearized representations with table rows corresponding to ”sentences.” Hypothesis representations are calculated separately. Recently, TaBERT (Yin et al., 2020) introduced a joint table-utterance representation approach, where a table row is concatenated with a short text utterance, such as the query in question answering, and passed as an input to a BERT-based model. Such an approach relies on the initial table representation to select the table rows most relevant to the query. In contrast, we enrich the table representation using an attention mechanism with the representations of the most relevant parts of the context of the article in which the table appears.

The Natural Questions is a large corpus that contains real user queries along with their corresponding Wikipedia articles, which may or may not contain an answer anywhere in the article. Alberti et al. (2019) provided a BERT-based baseline that treats both table and text segments like text: a sequence of tokens with word and position embeddings. Recently, Liu et al. (2020) improved this baseline by using dynamic dual-attention over paragraphs and cascade answer predictor. In another direction, Ravula et al. (2020) used an extended transformer architecture that models extra-long documents with limited propagation of information among different segments. All three approaches did not distinguish between text and table input, treating tables as text while not taking into account table structure. To the best of our knowledge, this is the first work that focuses on table-based QA for the real user queries in the Natural Questions corpus, and shows that table-based and overall QA performance can be improved by building on state-of-the-art pre-trained representations of table structure, additionally enriched via attention to related article text.

3 Methods

This section describes two methods that improve table representations for QA from tables: an extension of the BERT architecture for table encoding to better capture the relationships between table elements, and a mechanism that incorporates related unstructured text of an article as context to further improve the table representation. We then describe an approach for question answering from both text and tables that combines predictions from text QA and table QA models using a late fusion approach.

3.1 Table Encoding

Our table encoding is a generalization of the transformer architecture (Vaswani et al., 2017), with the self-attention sub-layer extended to incorporate relations between structural components in tables, similar to the one introduced by Müeller et al. (2019). This approach is motivated by Graph Neural Networks (GNNs) with a transformer (Shaw et al., 2018, 2019) where the authors generalize the transformer by introducing multiple types of relations between inputs.

3.1.1 GNNs with a Transformer

In the original transformer, the multi-head self-attention for head h is calculated using query (Q), key (K) and value (V) projections as follows:

$$Att(Q, K, V) = softmax(\frac{(W_h^Q Q)^T (W_h^K K)}{\sqrt{d_k}}) W_h^V V$$

where W_h^Q, W_h^K and W_h^V are learned parameters, and d_k is the query/key dimension. By calculating the dot product between query and key projections, a transformer captures the interaction between each pair of inputs x_i and x_j (e.g. wordpieces in BERT) at positions i and j for $0 \leq i, j \leq N$. This interaction can be generalized to account for relation type t between x_i and x_j by biasing the key projection using r_{ij}^t:

$$s_{ij}^h = \frac{(W_h^Q x_i)^T (W_h^K x_j + r_{ij}^{t,h})}{\sqrt{d_k}}$$

and then scaling using softmax across all inputs $0 \leq j \leq N$. Thus, the standard transformer can be considered as a special case with $r_{ij} = 0$. Similarly, the value projection can also be updated with the corresponding relation type represented using the bias term ρ_{ij}^t, with the overall attention head h calculated as follows:

$$\alpha_{ij}^h = softmax(\frac{s_{ij}^h}{\sum_j s_{ij}^h})$$
$$w_i^h = \sum_j \alpha_{ij}^h (W_h^V x_j + \rho_{ij}^{t,h})$$

The parameters $r^{t,h}$ and $\rho^{t,h}$ are head- and layer-specific.

3.1.2 Table Encoding using GNN

Table structure can be encoded using the model described above to account for special relations in the table. Here, we use the following relation types:

- token cell - token column header relation
- token cell - token row header relation
- in-cell token relations
- cross-column header relations
- cross-row header relations

For each of these table-specific types of relations we learn different type-specific biases r^t and ρ^t for each layer and head, while for the rest of the relations we use the original BERT configuration with zero bias. Figure 1 shows an example of a table with the table relations used in this work.

Our table encoding is similar to the one independently proposed by Müeller et al. (2019) with the main difference of having relations on a token level rather than cell level. Also, in their approach, the authors use only cell-column and cell-row relation, while in our work we also use cross-column header, cross-row header and in-cell relations. The above mentioned paper includes additional relations based on n-gram matches with the question, and special processing of numerical values.

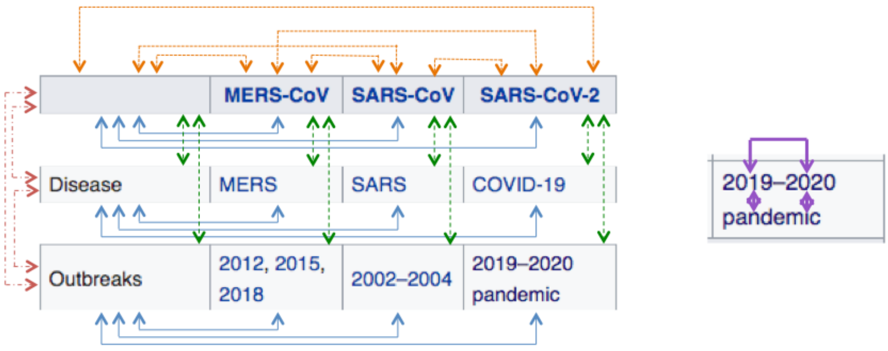

Figure 1: Example of a table encoding with relations: (*green, dashed*) token cell - token column header relations; (*blue, solid*) token cell - token row header relations; (*violet, bold*) in-cell token relations; (*red, dash-dotted*) cross-column header relations; (*orange, dotted*) cross-row header relations.

3.1.3 Pretraining

The main motivation for applying the original BERT model to table encoding is to use contextualized embeddings that are pretrained on a large amount of data. The new relation biases incorporated as part of the proposed table encoding are randomly initialized, starting from a standard transformer model pre-trained on text. Since these parameters are added for each layer, they can significantly change the activations of the pretrained model. In order to derive a better initialization point for the additional bias terms, we pretrain a GNN model with the masked LM objective used in BERT on the Wikitables dataset (Bhagavatula et al., 2013), which contains 1.6M tables from English Wikipedia. In order to limit the amount of overfitting on that table set, we freeze all original BERT parameters while updating only the bias terms introduced in the GNN. We tune the model using perplexity on a subset of the Wikitables dataset.

3.2 Context-aware Table Representation

We hypothesize that text in the article of a Web page containing a table can help build an improved representation of the table for QA. Recent work has explored building encoders over large input sequences. Ravula et al. (2020) scaled input sequence length to more than 8,000 tokens for the NQ dataset. However, to make the model efficient, encodings of individual text or table segments communicate through single-vector global memories. Here, we take the approach of using asymmetric attention from table token representations to a small number of relevant text token representations, that are pre-computed independently. Our approach is more similar to the handling of prior segment context in Transformer-XL (Dai et al., 2019), but relevant context is selected based on word overlap and not contiguity.

The two components of our approach, described next, include the definition of relevant text context for table elements and the mechanism for using contextualized embeddings of the relevant text to enrich the table token representations.

3.2.1 Table-Textual Context Linking

Let a table cell that contains a sequence of input tokens be defined as $(u_0^t \dots u_K^t)$, with the corresponding s sub-word units (wordpieces in BERT or byte-pair encodings in RoBERTa) for the k-th word to be defined as $(x_0^{t,k} \dots x_{S_k}^{t,k})$, and let the textual context of the article surrounding the table be defined as $(u_0^c \dots u_N^c)$, with the corresponding sub-word units for the n-th word be as $(x_0^{c,n} \dots x_{S_n}^{c,n})$. For each word in the table u_i^t, we find the corresponding context in the text using the exact match of the lower-case sequence of tokens, starting with the trigram matches, following with bigram and unigram matches.[2] For example, a trigram match for a word u_i^t is $\alpha_3(u_i^t) = u_j^c$ if a lower-case expression $(u_i^t, u_{i+1}^t, u_{i+2}^t)$ equals to the lower-case expression $(u_j^c, u_{j+1}^c, u_{j+2}^c)$. For each of the table tokens u_k^t we collect up to 6 corresponding matches from the text, $u_{s1}^c \dots u_{s6}^c$, and extract their sub-word embeddings represented by the last layer of pretrained RoBERTa, $e(x_0^{c,s1}) \dots e(x_s^{c,s6})$. Then, we stack all the sub-word unit embeddings associated with u_k^t to get a text-aware representation for word k in the

---

[2] Function words are frequent in multi-word expressions. To avoid exact match of expressions solely consisting of function words, matching expressions must contain at least one non-frequent word, defined based on the 200 most frequent words in the training set and the NLTK stop-word list.

table $e(u_k^t) = [e_0(x_0^{c,s1}); \dots; e_r(x_s^{c,s6})] \in \mathbb{R}^{r \times d}$, with d being the size of the hidden RoBERTa embedding and r being the total number of sub-word units corresponding to $u_{s1}^c \dots u_{s6}^c$. For simplicity of implementation, we use $r = 12$, where we prune any extra word-piecies or use padding for the cases where $r \neq 12$.

3.2.2 Enriching Table Representations

In order to incorporate text context $e(u_i^t)$ into a table representation of $x_s^{t,i}$, we use a slightly modified version of self-attention in the transformer, with the goal of generating an additional text context head, concatenated with the rest of the attention heads across multiple transformer layers that would be aware of the broader text context.

In the original transformer, self-attention is calculated between an input at position i using a query projection $W^Q x_i$ and the rest of the inputs in positions $j \in 0 \dots N$ using key and value projections, $W^K x_j$ and $W^V x_j$, correspondingly. Now, when calculating a text-aware head for each of the sub-word units $x_i^{t,k}$, we use attention between a query of $x_i^{t,k}$ and all of the sub-word units of the corresponding text context $e(u_k^t)$ using the key and value projections $W_e^K e(u_k^t)$ and $W_e^V e(u_k^t)$, correspondingly:

$$Att(Q_e, K_e, V_e) = \\ softmax(\frac{(W_e^Q Q)^T (W_e^K e(K))}{\sqrt{d_k}}) W_e^V e(V)$$

Then, we concatenate the new text-aware head with the rest of the heads in the layer h, resulting in a total of $m+1$ heads ($m = 16$ for RoBERTa$_{\text{large}}$), each of a size $k = 64$. In addition, we extend the current projection layer from a size $km \times km$ to $k(m+1) \times km$ in order to fit the additional head, randomly initializing the additional $k \times km$ parameters. For computational efficiency, we incorporate the text-aware representation only at layers 12, 16, 20 and 24.

3.3 Combining Text and Table Answer Predictions

In question answering, both text and table contexts can be used to support meeting the user information need. Question answering systems should therefore be able to consider both sources of information to present the most suitable answer. So far we have presented enriched table representations that can be used for question answering from tables. We now consider approaches for the full document-level QA task, where an answer may be found in either or none of the two modalities.

Since a text-based QA model would not benefit from the architecture and pre-training extensions for our table representations, we use a standard text-based representation for QA from text. We combine predictions from two separate models for the full document-level QA task. Specifically, we train a generic model for full article question answering following (Alberti et al., 2019). This model assigns scores to candidate answers in both text and tables using a standard pre-trained text representation (RoBERTa). We also train a separate model which uses enriched table representations and pre-training, and focuses on predicting answers in tables. The two model predictions are combined using a late fusion approach detailed below.

3.3.1 Calculating Prediction and Confidence Scores

We follow Alberti et al. (2019) to define a loss function for training and an answer span prediction method. More specifically, at inference time the scores that correspond to the start and end of a possible answer span are defined as follows:

$$\begin{aligned} g(c,s,e) &= f_{start}(s,c;\theta) + f_{end}(e,c;\theta) \\ &- f_{start}(s = [\text{CLS}], c; \theta) \\ &- f_{end}(e = [\text{CLS}], c; \theta) \end{aligned}$$

where c is a context of 512 sub-word unit ID's (including question and document tokens), $s, e \in \{0, 1, ..., 511\}$ are inclusive indices pointing to the start and end of the target answer span, θ is our model parameters, and f_{start}, f_{end} are two different outputs derived from the last layer of our model using linear projections. Following this work, the `[CLS]` token is used at training time to predict no answer instances, making $g(c,s,e)$ the log-odds of the likelihood of an answer span and the `[CLS]` span. All the contexts from each document are scored and document spans (s,e) are ranked to return the highest scoring span that does not exceed 30 tokens. We denote the highest scoring span for the generic model as g_c, and the highest scoring span for table model as g_t.

In addition to the prediction score, we also calculate a confidence score κ for each span:

$$\kappa(c, s, e) = \log(\frac{\exp(f_{start}(s, c; \theta))}{\sum_{s'} \exp(f_{start}(s', c; \theta))}) + \log(\frac{\exp(f_{end}(e, c; \theta))}{\sum_{e'} \exp(f_{end}(e', c; \theta))})$$

3.3.2 Combining Predictions

To combine the scores of the generic model g_c and the table model g_t, we use grid search on three parameters: a scaling factor α, a bias β, and a confidence threshold γ associated with the confidence of the table prediction κ_t:

$$g = \begin{cases} \max_{t,c}(g_c, \alpha \cdot g_t + \beta) & \text{if } g_c^l \in \text{t}, \kappa_t > \gamma \\ g_c & \text{otherwise} \end{cases}$$

where $g_c^l \in$ t indicates whether the long answer span that is predicted by the generic model points to a table. The search for parameters α, β, and γ is done on a validation set.

4 Experiments

We evaluate our model on the Natural Questions (NQ) corpus (Kwiatkowski et al., 2019) that consists of questions and paired Wikipedia pages, with the task of finding the exact location of the answer that is present in the article, if any. The NQ dataset is large (300k training samples) and answers (if present) can appear in either or both text and tables. NQ contains one human annotation for every question in the training set, and 5 annotations for every question in the development and test sets. Based on the statistics of the development set, around 14% of questions contain a short answer in a table. Only 48% of the questions have a long answer annotation (a paragraph or a table that contains an answer), while only 33% contain a short answer annotation (an exact location of a short answer phrase). In this work we first evaluate our models on a subset of questions that contain at least one short answer in tables, referred as NQTables, and then further evaluate the model on the full dataset, referred as FullNQ.

For the questions in NQTables, we further evaluate in two settings: (*i*) NQTables$_{\text{Tab}}$, where systems are limited to predict answer spans only from tables, and (*ii*) NQTables, where systems can predict answer spans from both text and tables. Note that although all questions in NQTables have at least one answer in a table, they might also have answers in text, and systems operating in the full NQTables setting have more chances to arrive at a correct answer than systems in NQTables$_{\text{Tab}}$ setting. While our primary focus in this work is on improving the short answer prediction, we also report the long answer prediction results for our best model used for the full NQ dataset, according to official metrics.

The development set (DEV) for NQTables used in this work contains 1118 questions where the short answer can be found in a table. Since the official test set of the corpus is not public, all our experiments use the official development set as our test set, while splitting the training set into training (90%) and 2 validation sets (each contains 4% of the data). The first validation set (VAL-1) is used for tuning the parameters of the table-based models, while the second validation set (VAL-2) is used for tuning the parameters to combine text-based and table-based models. For clarity, in all the experiment variations we use the notation defined above where NQTables$_{\text{Tab}}$-Dev/Val-1/Val-2 is limited to predict answer spans only from tables, and NQTables-Dev/Val-1/Val-2 is able to predict answer spans from both text and tables.

The official evaluation script computes F1 scores and considers any questions that have at least 2 annotated answers as being answerable, while questions with 1 or no answer are unanswerable. An F1 score is calculated on the ability to predict a span that matches at least one of the annotations for the answerable questions, and to correctly predict unanswerable ones. Since the validation sets contain only a single annotation, the F1 score measure based on 5-way annotation cannot be used directly on VAL-1 or VAL-2. Therefore, in the table-based experiments on the VAL-1, we report both accuracy (percent of correctly predicted answers) and modified F1 score (F1*), where modified F1 is based on the match of the predicted answer to a single annotation. Finally, we report a string-based F1 score that accepts any exact string match of a predicted span to an answer when combining text and table models.

4.1 Table-based Results

First, we evaluate the proposed table representation approaches on the NQTables subset. In this set of experiments, we use the article's tables as our input, omitting direct usage of the article's text except in the form of context-aware updates of the model used in Section 3.2. The results on NQTables$_{\text{Tab}}$-

Model	Pretrained on WikiTables	Finetuned on	VAL-1		DEV
			F1*	Acc	F1
RoBERTa baseline	no	FullNQ	49.1	48.2	53.3
RoBERTa tables	no	tables only	52.5	51.2	56.8
`[SEP]` encoding	no	tables only	53.2	51.1	57.5
GNN	no	tables only	52.6	51.2	55.0
GNN	yes	tables only	54.4	52.9	56.7
GNN	yes	FullNQ → tables only	55.7	54.3	58.9
Context-aware + GNN	yes	FullNQ → tables only	56.7	55.4	60.0

Table 1: Evaluation of the table encodings and context-aware table representation on NQTables$_{\text{Tab}}$-Val$_1$ (VAL-1) and NQTables$_{\text{Tab}}$-Dev (DEV) sets of NQTables that contains tables input exclusively.

Val$_1$ and NQTables$_{\text{Tab}}$-Dev are presented in Table 1. First, we evaluate our model using a RoBERTa baseline, following (Alberti et al., 2019) with a RoBERTa pretrained model instead of BERT (line 1). This baseline is trained using the FullNQ corpus and contains both text and table inputs. We improve this baseline by finetuning on the NQTables part of the training dataset (line 2). Previous work on table representations using BERT has shown improvement from using `[SEP]` tokens to highlight cell boundaries (Hwang et al., 2019). This is the additional baseline we report in line 3. Since this baseline performs well, we combine the usage of `[SEP]` tokens with our models for the rest of the table-encoding experiments (lines 3-7). We evaluate our table representation in lines 4-6, where results in lines 5 and 6 are obtained by initially pretraining the additional weights introduced by the GNN using WikiTables, as described in Section 3.1.3. We also found that by finetuning on the full NQ dataset first and further finetuning on the NQTables subset, the results are substantially improved (lines 6 and 7). Finally, our context-aware model combined with the table encoding from line 6 achieves the best result in this set of experiments. The improvements of the GNN and textual context-aware models are statistically significant with $p < 0.01$ according to a Wilcoxon signed-rank test. In the Appendix we provide two examples — one where context-aware model prediction improves, and the other one where adding textual context hurts.

4.2 Combining Tables and Text

In this section, we describe experiments of combining text and table predictions. Since the official development set contains up to 5 annotations, some of those annotations can be associated with tables, while others are associated with text. Unlike in the previous section, where text-related answers are ignored, here we allow a match to either text- or table-based answers. For this purpose, we need to combine scores from the text-based and table-based models. For text predictions, we use the RoBERTa baseline that was trained on the FullNQ dataset; for the table predictions we use our best GNN model and the context-aware model (lines 6 and 7 in Table 1, respectively). Oracle analysis on the development set suggests that a linear score transformation in the case of the FullNQ is not effective. To combine the scores of the text model g_c and the table model g_t, we use grid search, as described in Section 3.3. The search for parameters α, β, and γ is done on VAL-2 containing questions with table answers, questions with text answers, and questions without answers, using the string-based F1 score instead of the span-based one to compensate for the lack of multiple annotations in the validation set. According to this metric, both answers in tables and text are considered correct if they have exact string match with the gold answer span in a table annotated in VAL-2.

We evaluate those models on both the NQTables-Dev and FullNQ-Dev, allowing both text and table answers. The results are presented in Table 2. Results from our RoBERTa baseline that was trained on FullNQ are shown in line 1. Then, as mentioned above, we combine this generic model with table-only models (lines 2 and 3). Our experiments suggest that our proposed best model that uses table encoding improves the F1 score on NQTables by 1.5 points. When the table+text model combination is used on the full NQ dataset, there is a small improvement from both table models, but the textual context attention model is comparable to the GNN model, increasing recall at the cost of reducing precision. This might be explained by the relatively small fraction of questions that have

	NQTables (span)			FullNQ (span)			FullNQ (str)

answers only in tables (8% of all questions) and the difficulty in calibrating answers from tables and text against each other.

4.2.1 Impact of Relation Types

In order to investigate which of the five types of table relations (defined in Section 3.1.2) help table representation the most we perform an ablation study where we use the baseline of the pretrained GNN model (line 6), but remove each type of relation. The results are presented in Table 3. The ablation study shows a clear importance of cell-column and cell-row relation types, where the performance of the model without each of those relations degrades. While the F1 score for the experiment without in-cell relation is higher, the accuracy is much lower. The cross-column relation does not seem to contribute to the overall performance while the cross-row relation degrades the accuracy.

4.2.2 Impact of Negative Sampling

In all our experiments using models finetuned on tables only data (lines 2-7 in Table 1 and lines 2-3 in Table 2), during training we used an equal proportion of positive and negative samples,[4] where all negative samples were taken from the articles in NQTables-Train, which contain an answer in a table. This approach is successful when models were evaluated on their ability to predict answers in tables, for articles that are known to contain such answers. On the other hand, when the table-based models are asked to make predictions for articles not known to contain answers in tables (or any answers), they tended to be over-confident in comparison to a generic text-based model, trained with negative examples across all articles. This over-confidence is evident from the extremely high selected confidence parameters of $\gamma = -0.005$ for GNN model (line 2 in Table 2) and $\gamma = -0.0025$ for context-aware model (line 3 in Table 2), suggesting that only high-value and high-confidence scores are considered from the table-based model.

To investigate the effect of the negative sampling method we perform an ablation study that compares three techniques: 1) sampling negative samples from within articles that contain an answer in tables, 2) random sampling of negatives across all NQ articles, in the proportion used by Alberti et al. (2019), and 3) sampling negatives with equal proportion from articles that contain answer in tables, and articles that do not. The results for the GNN model are shown in Table 4. While the first sampling strategy works best when a table-based model is used to predict answers from tables in NQTables, sampling negatives from a more diverse set of articles improves the overall FullNQ results for the combination of text and table-based models, by allowing better calibration between text and table models. The threshold values γ are seen to be much lower in these cases. However, the second and third strategies reduce performance on QA from tables. When optimizing the random sampling strategy for highest performance on FullNQ, no benefit was found from contextual text attention for table representations.

Finally, we compare the performance of our model to other work on the Natural Questions on both the short and long answer prediction tasks. In our model, the long answer is predicted based on

the segment that corresponds to the short answer prediction. The results are presented in Table 5. As we can see, our method obtains a substantial improvement over the baseline of Alberti et al. (2019) in short answer F1, and a smaller improvement in long answer F1. Advances in long answer F1 from state-of-the-art recent works are likely complementary to our method and can be integrated for additive gain.

5 Conclusion

Tables in Web documents are pervasive and can be directly used to answer many search queries. In this work, we presented an approach to enrich table representations using information from article text, and showed that it improves a state-of-the-art pretrained structure-aware table representation for question answering from tables. We also studied how to effectively combine text-based and table-based approaches. Finally, we performed the first study focusing on table QA for the Natural Questions dataset, and showed that improved representations of tables lead to performance gains. In future work, our methods can be applied to other QA datasets, such as WikiTableQuestions (Pasupat and Liang, 2015) and HybridQA (Chen et al., 2020).

A Examples

Question: What kind of poisonous snakes are in Michigan?

List of reptiles of Michigan

From Wikipedia, the free encyclopedia

Michigan, one of the fifty United States, is home to two types of lizards, nineteen types of snakes and eleven types of turtles, all members of the class Reptilia.[1] Reptiles are found throughout Michigan, although the only venomous species, the eastern massasauga rattlesnake, is seen only in the Lower Peninsula.[2] Reptiles are cold-blooded, and so usually pass the cold winters of Michigan in frost-free areas, such as burrows (for snakes and land-

Scientific name	Common name	Description	Image	Notes
Cnemidophorus sexlineatus	Six-lined racerunner	Adults are 6 to 10.5 inches (15 to 27 cm) in length and colored olive, gray, brown or black with six lighter-colored stripes.[9]		Found only in Tuscola County in eastern Michigan,[9] considered a threatened species[7]
Sistrurus catenatus catenatus	Eastern massasauga rattlesnake	Adults are 2 to 3 feet (0.61 to 0.91 m) in length and colored gray or brown with dark brown patches. Venomous.		A candidate species for listing on the federal endangered species list,[8] and a species of special concern in Michigan[7]

Figure 2: Example where incorporating textual context helps. In red square the prediction was made by GNN model without context attention (Table 1, line 6), in green square the prediction was made by context-aware GNN (Table 1, line 7).

The correct answer "Easter massasauga rattlesnake" was correctly predicted from the table when context-aware attention was used. The same answer can be extracted based on the textual information in the introduction paragraph. By propagating relevant information from the textual context to the table entries, the model was able to predict correctly the answer from the table. On the other hand, the table-only model which does not use the surrounding textual context incorrectly predicted "Cnemidophorus sexlineatus".

Question: Who sings the intro for the Phineas and Ferb?

Background [edit]

The artists on the soundtrack all are in *Phineas and Ferb* except for Bowling for Soup who performs the theme tune for the series. The song "Gitchee Gitchee Goo" performed by Vincent Martella & Ashley Tisdale featured in the episode "Flop Starz", was also included in the 2009 album *Disney Channel Playlist*.[2]

Length	38:04
Label	Walt Disney
Cast - Phineas and Ferb chronology	
Phineas and Ferb Soundtrack (2009)	*Phineas and Ferb Christmas Vacation!* (2009)

Release [edit]

The original report cited that the initial February 10, 2009 release date had been pushed back to August 4.[3] On June 26, 2009 the release date was pushed back to September 22, 2009.[4] Later this has been confirmed on the official website.[5] The soundtrack was released in the United Kingdom on October 10, 2009 via EMI Music.[6]

Track listing [edit]

No.	Title	Writer(s)	Performer(s)	Length
1.	"Today is Gonna Be a Great Day"	Dan Povenmire, Jeff "Swampy" Marsh, Michael Culross, Michael Walker, Carl Williams	Bowling for Soup	3:01
2.	"Gitchee Gitchee Goo"	Dan Povenmire, Jeff "Swampy" Marsh, Jon Colton Barry	Vincent Martella, Ashley Tisdale, Laura Dickinson, Danny Jacob	1:58
3.	"Backyard Beach"	Dan Povenmire, Danny Jacob	Danny Jacob	0:47
4.	"Busted"	Dan Povenmire, Jeff "Swampy"	Ashley Tisdale, Olivia Olson	1:38

Figure 3: Example where incorporating textual context hurts. In red square the incorrect prediction was made by context-aware GNN model (Table 1, line 7), in green square the correct prediction was made by GNN without context attention (Table 1, line 6).

The correct answer ”Bowling for Soup” was correctly predicted from the table by the model that does not use context attention, while the context-aware model predicts the answer that has higher number of links to the textual context.

PPT: Parsimonious Parser Transfer for Unsupervised Cross-Lingual Adaptation

Abstract

Cross-lingual transfer is a leading technique for parsing low-resource languages in the absence of explicit supervision. Simple 'direct transfer' of a learned model based on a multilingual input encoding has provided a strong benchmark. This paper presents a method for unsupervised cross-lingual transfer that improves over direct transfer systems by using their output as implicit supervision as part of self-training on unlabelled text in the target language. The method assumes minimal resources and provides maximal flexibility by (a) accepting any pre-trained arc-factored dependency parser; (b) assuming no access to source language data; (c) supporting both projective and non-projective parsing; and (d) supporting multi-source transfer. With English as the source language, we show significant improvements over state-of-the-art transfer models on both distant and nearby languages, despite our conceptually simpler approach. We provide analyses of the choice of source languages for multi-source transfer, and the advantage of non-projective parsing. Our code is available online.[1]

1 Introduction

Recent progress in natural language processing (NLP) has been largely driven by increasing amounts and size of labelled datasets. The majority of the world's languages, however, are low-resource, with little to no labelled data available (Joshi et al., 2020). Predicting linguistic labels, such as syntactic dependencies, underlies many downstream NLP applications, and the most effective systems rely on labelled data. Their lack hinders the access to NLP technology in many languages. One solution is cross-lingual model transfer, which adapts models trained on high-resource languages to low-resource ones. This paper presents a flexible framework for cross-lingual transfer of syntactic dependency parsers which can leverage *any* pre-trained arc-factored dependency parser, and assumes no access to labelled target language data.

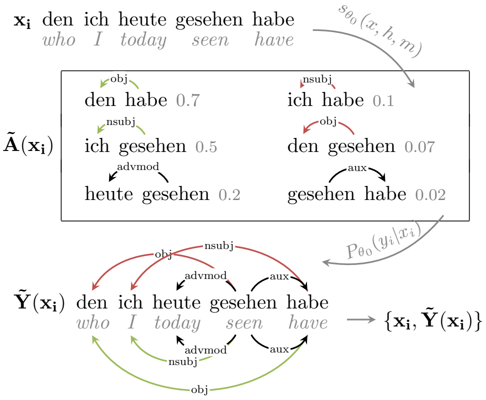

Figure 1: Illustration of our technique. For a target language sentence (x_i), a source parser P_{θ_0} predicts a set of candidate arcs $\tilde{A}(x_i)$ (subset shown in the figure), and parses $\tilde{Y}(x_i)$. The highest scoring parse is shown on the bottom (green), and the true gold parse (unknown to the parser) on top (red). A target language parser P_θ is then fine-tuned on a data set of ambiguously labelled sentences $\{x_i, \tilde{Y}(x_i)\}$.

One straightforward method of cross-lingual parsing is direct transfer. It works by training a parser on the source language labelled data and subsequently using it to parse the target language directly. Direct transfer is attractive as it does not require labelled target language data, rendering the approach fully unsupervised.[2] Recent work has shown that it is possible to outperform direct transfer if unlabelled data, either in the target lan-

[2] Direct transfer is also called zero-shot transfer or model transfer in the literature.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2907–2918
April 19 - 23, 2021.

guage or a different auxiliary language, is available (He et al., 2019; Meng et al., 2019; Ahmad et al., 2019b). Here, we focus on the former setting and present flexible methods that can adapt a pre-trained parser given unlabelled target data.

Despite their success in outperforming direct transfer by leveraging unlabelled data, current approaches have several drawbacks. First, they are limited to generative and projective parsers. However, discriminative parsers have proven more effective, and non-projectivity is a prevalent phenomenon across the world's languages (de Lhoneux, 2019). Second, prior methods are restricted to single-source transfer, however, transfer from multiple source languages has been shown to lead to superior results (McDonald et al., 2011; Duong et al., 2015a; Rahimi et al., 2019). Third, they assume access to the source language data, which may not be possible because of privacy or legal reasons. In such source-free transfer, only a pre-trained source parser may be provided.

We address the three shortcomings with an alternative method for unsupervised target language adaptation (Section 2). Our method uses high probability edge predictions of the source parser as a supervision signal in a self-training algorithm, thus enabling unsupervised training on the target language data. The method is feasible for discriminative and non-projective parsing, as well as multi-source and source-free transfer. Building on a framework introduced in Täckström et al. (2013), this paper for the first time demonstrates their effectiveness in the context of state-of-the-art neural dependency parsers, and their generalizability across parsing frameworks. Using English as the source language, we evaluate on eight distant and ten nearby languages (He et al., 2019). The single-source transfer variant (Section 2.1) outperforms previous methods by up to 11 % UAS, averaged over nearby languages. Extending the approach to multi-source transfer (Section 2.2) gives further gains of 2 % UAS and closes the performance gap against the state of the art on distant languages. In short, our contributions are:

1. A conceptually simple and highly flexible framework for unsupervised target language adaptation, which supports multi-source and source-free transfer, and can be employed with any pre-trained state-of-the-art arc-factored parser(s);
2. Generalisation of the method of Täckström et al. (2013) to state-of-the-art, non-projective dependency parsing with neural networks;
3. Up to 13 % UAS improvement over state-of-the-art models, considering nearby languages, and roughly equal performance over distant languages; and
4. Analysis of the impact of choice of source languages on multi-source transfer quality.

2 Supervision via Transfer

In our scenario of unsupervised cross-lingual parsing, we assume the availability of a pre-trained source parser, and unlabelled text in the target language. Thus, we aim to leverage this data such that our cross-lingual transfer parsing method out-performs direct transfer. One straightforward method is self-training where we use the predictions from the source parser as supervision to train the target parser. This method may yield decent performance as direct transfer is fairly good to begin with. However, we may be able to do better if we also consider a set of parse trees that have high probability under the source parser (cf. Fig. 1 for illustration).

If we assume that the source parser can produce a set of possible trees instead, then it is natural to use all of these trees as supervision signal for training. Inspired by Täckström et al. (2013), we formalise the method as follows. Given an unlabelled dataset $\{x_i\}_{i=1}^{n}$, the training loss can be expressed as

$$\mathcal{L}(\theta) = -\frac{1}{n}\sum_{i=1}^{n} \log \sum_{y \in \tilde{Y}(x_i)} P_\theta(y|x_i) \qquad (1)$$

where θ is the target parser parameters and $\tilde{Y}(x_i)$ is the set of trees produced by the source parser. Note that $\tilde{Y}(x_i)$ must be smaller than the set of all trees spanning x (denoted as $\mathcal{Y}(x_i)$) because $\mathcal{L}(\theta) = 0$ otherwise. This training procedure is a form of self-training, and we expect that the target parser can learn the correct tree as it is likely to be included in $\tilde{Y}(x_i)$. Even if this is not the case, as long as the correct arcs occur quite frequently in $\tilde{Y}(x_i)$, we expect the parser to learn a useful signal.

We consider an arc-factored neural dependency parser where the score of a tree is defined as the sum of the scores of its arcs, and the arc scoring function is parameterised by a neural network. The probability of a tree is then proportional to its score.

Formally, this formulation can be expressed as

$$P_\theta(y|x) = \frac{\exp s_\theta(x, y)}{Z(x)} \tag{2}$$

$$s_\theta(x, y) = \sum_{(h,m)\in A(y)} s_\theta(x, h, m) \tag{3}$$

where $Z(x) = \sum_{y\in\mathcal{Y}(x)} \exp s_\theta(x, y)$ is the partition function, $A(y)$ is the set of head-modifier arcs in y, and $s_\theta(x, y)$ and $s_\theta(x, h, m)$ are the tree and arc scoring function respectively.

2.1 Single-Source Transfer

Here, we consider the case where a single pre-trained source parser is provided and describe how the set of trees is constructed. Concretely, for every sentence $x = w_1, w_2, \dots, w_t$ in the target language data, using the source parser, the set of high probability trees $\tilde{Y}(x)$ is defined as the set of dependency trees that can be assembled from the high probability arcs set $\tilde{A}(x) = \bigcup_{m=1}^{t} \tilde{A}(x, m)$, where $\tilde{A}(x, m)$ is the set of high probability arcs whose dependent is w_m. Thus, $\tilde{Y}(x)$ can be expressed formally as

$$\tilde{Y}(x) = \{y|y \in \mathcal{Y}(x) \wedge A(y) \subseteq \tilde{A}(x)\}. \tag{4}$$

$\tilde{A}(x, m)$ is constructed by adding arcs (h, m) in order of decreasing arc marginal probability until their cumulative probability exceeds a threshold σ (Täckström et al., 2013). The predicted tree from the source parser is also included in $\tilde{Y}(x)$ so the chart is never empty. This prediction is simply the highest scoring tree. This procedure is illustrated in Fig. 1.

Since $\mathcal{Y}(x)$ contains an exponential number of trees, efficient algorithms are required to compute the partition function $Z(x)$, arc marginal probabilities, and the highest scoring tree. First, arc marginal probabilities can be computed efficiently with dynamic programming for projective trees (Paskin, 2001) and Matrix-Tree Theorem for the non-projective counterpart (Koo et al., 2007; McDonald and Satta, 2007; Smith and Smith, 2007). The same algorithms can also be employed to compute $Z(x)$. Next, the highest scoring tree can be obtained efficiently with Eisner's algorithm (Eisner, 1996) or the maximum spanning tree algorithm (McDonald et al., 2005; Chu and Liu, 1965; Edmonds, 1967) for the projective and non-projective cases, respectively.

The transfer is performed by initialising the target parser with the source parser's parameters and then fine-tuning it with the training loss in Eq. (1) on the target language data. Following previous works (Duong et al., 2015b; He et al., 2019), we also regularise the parameters towards the initial parameters to prevent them from deviating too much since the source parser is already good to begin with. Thus, the final fine-tuning loss becomes

$$\mathcal{L}'(\theta) = \mathcal{L}(\theta) + \lambda||\theta - \theta_0||_2^2 \tag{5}$$

where θ_0 is the initial parameters and λ is a hyperparameter regulating the strength of the L_2 regularisation. This single-source transfer strategy was introduced as ambiguity-aware self-training by Täckström et al. (2013). A difference here is that we regularise the target parser's parameters against the source parser's as the initialiser, and apply the technique to modern lexicalised state-of-the-art parsers. We refer to this transfer strategy as PPT hereinafter.

Note that the whole procedure of PPT can be performed even when the source parser is trained with monolingual embeddings. Specifically, given a source parser trained *only on monolingual embeddings*, one can align pre-trained target language word embeddings to the source embedding space using an offline cross-lingual alignment method (e.g., of Smith et al. (2017)), and use the aligned target embeddings with the source model to compute $\tilde{Y}(x)$. Thus, our method can be used with any pre-trained monolingual neural parser.

2.2 Multi-Source Transfer

We now consider the case where multiple pre-trained source parsers are available. To extend PPT to this multi-source case, we employ the ensemble training method from Täckström et al. (2013), which we now summarise. We define $\tilde{A}(x, m) = \bigcup_k \tilde{A}_k(x, m)$ where $\tilde{A}_k(x, m)$ is the set of high probability arcs obtained with the k-th source parser. The rest of the procedure is exactly the same as PPT. Note that we need to select one source parser as the main source to initialise the target parser's parameters with. Henceforth, we refer to this method as PPTX.

Multiple source parsers may help transfer better because each parser will encode different syntactic biases from the languages they are trained on. Thus, it is more likely for one of those biases to match that of the target language instead of using just a single source parser. However, multi-source transfer may also hurt performance if the languages have very different syntax, or the source parsers are of poor quality, which can arise from poor quality cross-lingual word embeddings.

3 Experiments

3.1 Setup

We run our experiments on Universal Dependency Treebanks v2.2 (Nivre et al., 2018). We reimplement the self-attention graph-based parser of Ahmad et al. (2019a) that has been used with success for cross-lingual dependency parsing. Averaged over 5 runs, our reimplementation achieves 88.8 % unlabelled attachment score (UAS) on English Web Treebank using the same hyperparameters,[3] slightly below their reported 90.3 % result.[4] We select the run with the highest labelled attachment score (LAS) as the source parser. We obtain cross-lingual word embeddings with the offline transformation of Smith et al. (2017) applied to fastText pre-trained word vectors (Bojanowski et al., 2017). We include the universal POS tags as inputs by concatenating the embeddings with the word embeddings in the input layer. We acknowledge that the inclusion of gold POS tags does not reflect a realistic low-resource setting where gold tags are not available, which we discuss more in Section 3.3. We evaluate on 18 target languages that are divided into two groups, distant and nearby languages, based on their distance from English as defined by He et al. (2019).[5]

During the unsupervised fine-tuning, we compute the training loss over all trees regardless of projectivity (i.e. we use Matrix-Tree Theorem to compute Eq. (1)) and discard sentences longer than 30 tokens to avoid out-of-memory error. Following He et al. (2019), we fine-tune on the target language data for 5 epochs, tune the hyperparameters (learning rate and λ) on Arabic and Spanish using LAS, and use these values[6] for the distant and nearby languages, respectively. We set the threshold $\sigma = 0.95$ for both PPT and PPTX following Täckström et al. (2013). We keep the rest of the hyperparameters (e.g., batch size) equal to those of Ahmad et al. (2019a). For PPTX, unless otherwise stated, we consider a leave-one-out scenario where we use all languages except the target as the source language. We use the same hyperparameters as the English parser to train these non-English source parsers and set the English parser as the main source.

3.2 Comparisons

We compare PPT and PPTX against several recent unsupervised transfer systems. First, HE is a neural lexicalised DMV parser with normalising flow that uses a language modelling objective when fine-tuning on the unlabelled target language data (He et al., 2019). Second, AHMAD is an adversarial training method that attempts to learn language-agnostic representations (Ahmad et al., 2019b). Lastly, MENG is a constrained inference method that derives constraints from the target corpus statistics to aid inference (Meng et al., 2019). We also compare against direct transfer (DT) and self-training (ST) as our baseline systems.[7]

3.3 Results

Table 1 shows the main results. We observe that fine-tuning via self-training already helps DT, and by incorporating multiple high probability trees with PPT, we can push the performance slightly higher on most languages, especially the nearby ones. Although not shown in the table, we also find the PPT has up to 6x lower standard deviation than ST, which makes PPT preferrable to ST. Thus, we exclude ST as a baseline from our subsequent experiments. Our results seem to agree with that of Täckström et al. (2013) and suggest that PPT can also be employed for neural parsers. Therefore, it should be considered for target language adaptation if unlabelled target data is available. Comparing to HE (He et al., 2019), PPT performs worse on distant languages, but better on nearby languages. This finding means that if the target language has a closely related high-resource language, it may be better to transfer from that language as the source and use PPT for adaptation. Against AHMAD (Ahmad et al., 2019b), PPT performs better on 4 out of 6 distant languages. On nearby languages, the average UAS of PPT is higher, and the average LAS is on par. This result shows that leveraging unlabelled data for cross-lingual parsing without access to the source data is feasible. PPT also performs

---

[3] Reported in Table 4.

[4] UAS and LAS are reported excluding punctuation tokens.

[5] We exclude Japanese and Chinese based on Ahmad et al. (2019a), who reported atypically low performance on these two languages, which they attributed to the low quality of their cross-lingual word embeddings. In subsequent work they excluded these languages (Ahmad et al., 2019b).

[6] Reported in Table 5.

[7] ST requires significantly less memory so we only discard sentences longer than 60 tokens. Complete hyperparameter values are shown in Table 5.

Table 1: Test UAS and LAS (avg. 5 runs) on distant (top) and nearby (bottom) languages, sorted from most distant (fa) to closest (de) to English. PPTX is trained in a leave-one-out fashion. The numbers for He, Ahmad, and Meng are obtained from the corresponding papers, direct transfer (DT) and self-training (ST) are based on our own implementation. † indicates languages used for hyper-parameter tuning, and thus have additional supervision through the use of a labelled development set.

better than Meng (Meng et al., 2019) on 4 out of 7 distant languages, and slightly better on average on nearby languages. This finding shows that PPT is competitive to their constrained inference method.

Also reported in Table 1 are the ensemble results for PPTX, which are particularly strong. PPTX outperforms PPT, especially on distant languages with the average UAS and LAS absolute improvements of 7 % and 6 % respectively. This finding suggests that PPTX is indeed an effective method for multi-source transfer of neural dependency parsers. It also gives further evidence that multi-source transfer is better than the single-source counterpart. PPTX also closes the gap against the state-of-the-art adaptation of He et al. (2019) in terms of average UAS on distant languages. This result suggests that PPTX can be an option for languages that do not have a closely related high-resource language to transfer from.

Treebank Leakage The success of our cross-lingual transfer can be attributed in part to treebank leakage, which measures the fraction of dependency trees in the test set that are isomorphic to a tree in the training set (with potentially different words); accordingly these trees are not entirely unseen. Such leakage has been found to be a particularly strong predictor for parsing performance in monolingual parsing (Søgaard, 2020). Fig. 2 shows the relationship between treebank leakage and parsing accuracy, where the leakage is computed between the English training set as source and the target language's test set. Excluding outliers which are Korean and Turkish because of their low parsing accuracy despite the relatively high leakage, we find that there is a fairly strong positive correlation ($r = 0.57$) between the amount of

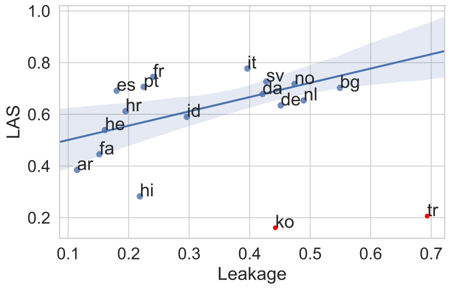

Figure 2: Relationship between treebank leakage and LAS for PPTX. Shaded area shows 95 % confidence interval. Korean and Turkish (in red) are excluded when computing the regression line.

leakage and accuracy. The same trend occurs with DT, ST, and PPT. This finding suggests that cross-lingual parsing is also affected by treebank leakage just like monolingual parsing is, which may present an opportunity to find good sources for transfer.

Use of Gold POS Tags As we explained in Section 3.1, we restrict our experiments to gold POS tags for comparison with prior work. However, the use of gold POS tags does not reflect a realistic low-resource setting where one may have to resort to automatically predicted POS tags. Tiedemann (2015) has shown that cross-lingual delexicalised parsing performance degrades when predicted POS tags are used. The degradation ranges from 2.9 to 8.4 LAS points depending on the target language. Thus, our reported numbers in Table 1 are likely to decrease as well if predicted tags are used, although we expect the decline is not as sharp because our parser is lexicalised.

3.4 Parsimonious Selection of Sources for PPTX

In our main experiment, we use all available languages as source for PPTX in a leave-one-out setting. Such a setting may be justified to cover as many syntactic biases as possible, however, training dozens of parses may be impractical. In this experiment, we consider the case where we can train only a handful of source parsers. We investigate two selections of source languages: (1) a representative selection (PPTX-REPR) which covers as many language families as possible and (2) a pragmatic selection (PPTX-PRAG) containing truly high-resource languages for which quality pre-trained parsers are likely to exist. We restrict the selections to 5 languages each. For PPTX-REPR, we use English, Spanish, Arabic, Indonesian, and Korean as source languages. This selection covers Indo-European (Germanic and Romance), Afro-Asiatic, Austronesian, and Koreanic language families respectively. We use English, Spanish, Arabic, French, and German as source languages for PPTX-PRAG. The five languages are classified as exemplary high-resource languages by Joshi et al. (2020). We exclude a language from the source if it is also the target language, in which case there will be only 4 source languages. Other than that, the setup is the same as that of our main experiment.[8]

We present the result in Fig. 3 where we also include the results for PPT, and PPTX with the leave-one-out setting (PPTX-LOO). We report only LAS since UAS shows a similar trend. We observe that both PPTX-REPR and PPTX-PRAG outperform PPT overall. Furthermore, on nearby languages except Dutch and German, both PPTX-REPR and PPTX-PRAG outperform PPTX-LOO, and PPTX-PRAG does best overall. In contrast, no systematic difference between the three PPTX variants emerges on distant languages. This finding suggests that instead of training dozens of source parsers for PPTX, training just a handful of them is sufficient, and a "pragmatic" selection of a small number of high-resource source languages seems to be an efficient strategy. Since pre-trained parsers for these languages are most likely available, it comes with the additional advantage of alleviating the need to train parsers at all, which makes our method even more practical.

Analysis on Dependency Labels Next, we break down the performance of our methods based on the dependency labels to study their failure and success patterns. Fig. 4 shows the UAS of DT, PPT, and PPTX-PRAG on Indonesian and German for select dependency labels.

Looking at Indonesian, PPT is slightly worse than DT in terms of overall accuracy scores (Table 1), and this is reflected across dependency labels. However, we see in Fig. 4 that PPT outperforms DT on `amod`. In Indonesian, adjectives follow the noun they modify, while in English the opposite is true in general. Thus, unsupervised target language adaptation seems able to address these kinds of discrepancy between the source and target language. We find that PPTX-PRAG outperforms both DT and PPT across dependency labels, especially on `flat` and `compound` labels as shown in Fig. 4. Both labels are related to multi-word expressions (MWEs), so PPTX appears to improve parsing MWEs in Indonesian significantly.

For German we find that both PPT and PPTX-PRAG outperform DT on most dependency labels, with the most notable gain on `nmod`, which appear in diverse, and often non-local relations in both languages many of which do not structurally translate, and fine-tuning improves performance as expected. Also, we see PPTX-PRAG significantly underperforms on `compound` while PPT is better than DT. German compounds are often merged into a single token, and self-training appears to alleviate over-prediction of such relations. The multi-source case may contain too much diffuse

---

[8] Hyperparameters are tuned; values are shown in Table 5.

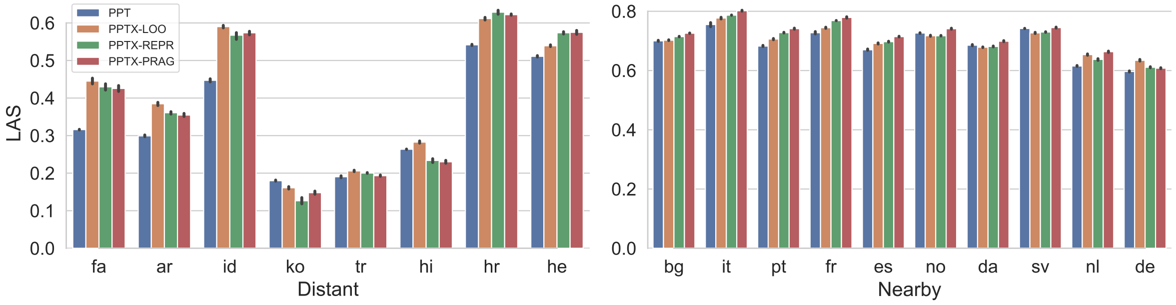

Figure 3: Comparison of selection of source languages for PPTX on distant and nearby languages, sorted from most distant (fa) to closest (de) to English. PPTX-LOO is trained in a leave-one-out fashion. PPTX-REPR uses the representative source language set, while PPTX-PRAG is adapted from five high-resource languages. A source language is excluded from the source if it is also the target language.

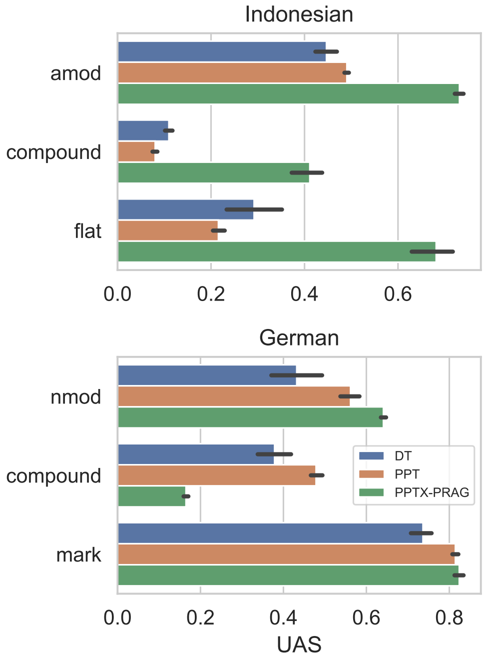

Figure 4: Comparison of direct transfer (DT), PPT, and PPTX-PRAG on select dependency labels of Indonesian (top) and German (bottom).

signal on `compound` and thus the performance is worse than that of DT. We find that PPT and PPTX improves over DT on `mark`, likely because markers are often used in places where German deviates from English by becoming verb-final (e.g., subordinate clauses). Both PPT and PPTX-PRAG seem able to learn this characteristic as shown by their performance improvements. This analysis suggests that the benefits of self-training depend on the syntactic properties of the target language.

Model	Target				AVG
	id	hr	fr	nl	
	Non-projective				
DT	45.2	51.9	68.1	59.5	56.2
PPT	44.7	54.2	72.8	61.5	58.3

	Projective				
DT	45.7	52.1	68.4	59.6	56.4
PPT	45.0	54.0	72.3	61.7	58.3
PPTX-PRAG	57.5	61.1	78.1	67.7	66.1

Table 2: Comparison of projective and non-projective direct transfer (DT), PPT, and PPTX-PRAG. Scores are LAS, averaged over 5 runs.

3.5 Effect of Projectivity

In this experiment, we study the effect of projectivity on the performance of our methods. We emulate a projective parser by restricting the trees in $\tilde{Y}(x)$ to be projective. In other words, the sum in Eq. (1) is performed only over projective trees. At test time, we search for the highest scoring projective tree. We compare DT, PPT, and PPTX-PRAG, and report LAS on Indonesian (id) and Croatian (hr) as distant languages, and on French (fr) and Dutch (nl) as nearby languages. The trend for UAS and on the other languages is similar. We use the dynamic programming implementation provided by `torch-struct` for the projective case (Rush, 2020). We find that it consumes more memory than our Matrix-Tree Theorem implementation, so we set the length cutoff to 20 tokens.[9]

Table 2 shows result of our experiment, which suggests that there is no significant performance difference between the projective and non-projective

---

[9] Hyperparameters are tuned; values are shown in Table 5.

Model	Target	
	ar	es
DT	28.1	64.1
PPT	30.8	67.3
PPTX^{EN5}	30.9	66.3
PPTX-PRAG^{S}	36.5	70.3
PPTX-PRAG	36.5	71.9

Table 3: Comparison of LAS on Arabic and Spanish on the development set, averaged over 5 runs. PPTX^{EN5} is PPTX with 5 English parsers as source, each trained on 1/5 size of the English corpus. PPTX-PRAG^{S} is PPTX with the pragmatic selection of source languages (PPTX-PRAG) but each source parser is trained on the same amount of data as PPTX^{EN5}.

variant of our methods. This result suggests that our methods generalise well to both projective and non-projective parsing. That said, we recommend the non-projective variant as it allows better parsing of languages that are predominantly non-projective. Also, we find that it runs roughly 2x faster than the projective variant in practice.

3.6 Disentangling the Effect of Ensembling and Larger Data Size

The effectiveness of PPTX can be attributed to at least three factors: (1) the effect of ensembling source parsers (*ensembling*), (2) the effect of larger data size used for training the source parsers (*data*), and (3) the diversity of syntactic biases from multiple source languages (*multilinguality*). In this experiment, we investigate to what extent each of those factors contributes to the overall performance. To this end, we design two additional comparisons: PPTX^{EN5} and PPTX-PRAG^{S}.

PPTX^{EN5} is PPTX with only English source parsers, where each parser is trained on 1/5 of the English training set. That is, we randomly split the English training set into five equal-sized parts, and train a separate parser on each. These parsers then serve as the source parsers for PPTX^{EN5}. Thus, PPTX^{EN5} has the benefit of ensembling but not data and multilinguality compared with PPT.

PPTX-PRAG^{S} is PPTX whose source language selection is the same as PPTX-PRAG, but each source parser is trained on the training data whose size is roughly the same as that of the training data of PPTX^{EN5} source parsers. In other words, the training data size is roughly equal to 1/5 of the English training set. To obtain this data, we randomly sub-sample the training data of each source language to the appropriate number of sentences. Therefore, PPTX-PRAG^{S} has the benefit of ensembling and multilinguality but not data.

Table 3 reports their LAS on the development set of Arabic and Spanish, averaged over five runs. We also include the results of PPTX-PRAG that enjoys all three benefits. We observe that PPT and PPTX^{EN5} perform similarly on Arabic, and PPTX^{EN5} has a slightly lower performance on Spanish. This result suggests a negligable effect of ensembling on performance. On the other hand, PPTX-PRAG^{S} outperforms PPTX^{EN5} remarkably, with approximately 6 % and 4 % LAS improvement on Arabic and Spanish respectively, showing that multilinguality has a much larger effect on performance than ensembling. Lastly, we see that PPTX-PRAG performs similarly to PPTX-PRAG^{S} on Arabic, and about 1.6 % better on Spanish. This result demonstrates that data size has an effect, albeit a smaller one compared to multilinguality. To conclude, the effectiveness of PPTX can be attributed to the diversity contributed through multiple languages, and not to ensembling or larger source data sets.

4 Related Work

Cross-lingual dependency parsing has been extensively studied in NLP. The approaches can be grouped into two main categories. On the one hand, there are approaches that operate on the data level. Examples of this category include annotation projection, which aims to project dependency trees from a source language to a target language (Hwa et al., 2005; Li et al., 2014; Lacroix et al., 2016; Zhang et al., 2019); and source treebank reordering, which manipulates the source language treebank to obtain another treebank whose statistics approximately match those of the target language (Wang and Eisner, 2018; Rasooli and Collins, 2019). Both methods have no restriction on the type of parsers as they are only concerned with the data. Transferring from multiple source languages with annotation projection is also feasible (Agić et al., 2016).

Despite their effectiveness, these data-level methods may require access to the source language data, hence are unusable when it is inaccessible due to privacy or legal reasons. In such source-free transfer, only a model pre-trained on the source language data is available. By leveraging parallel data, annotation projection is indeed feasible without access to the source language data. That said, parallel data is limited for low-resource languages or may have a poor domain match. Additionally, these methods involve training the parser from scratch for every new target language, which may be prohibitive.

On the other hand, there are methods that operate on the model level. A typical approach is direct transfer (aka., zero-shot transfer) which trains a parser on source language data, and then directly uses it to parse a target language. This approach is enabled by the shared input representation between the source and target language such as POS tags (Zeman and Resnik, 2008) or cross-lingual embeddings (Guo et al., 2015; Ahmad et al., 2019a). Direct transfer supports source-free transfer and only requires training a parser once on the source language data. In other words, direct transfer is unsupervised as far as target language resources.

Previous work has shown that unsupervised target language adaptation outperforms direct transfer. Recent work by He et al. (2019) used a neural lexicalised dependency model with valence (DMV) (Klein and Manning, 2004) as the source parser and fine-tuned it in an unsupervised manner on the unlabelled target language data. This adaptation method allows for source-free transfer and performs especially well on distant target languages. A different approach is proposed by Meng et al. (2019), who gathered target language corpus statistics to derive constraints to guide inference using the source parser. Thus, this technique also allows for source-free transfer. A different method is proposed by Ahmad et al. (2019b) who explored the use of unlabelled data from an auxiliary language, which can be different from the target language. They employed adversarial training to learn language-agnostic representations. Unlike the others, this method can be extended to support multi-source transfer. An older method is introduced by Täckström et al. (2013), who leveraged ambiguity-aware training to achieve unsupervised target language adaptation. Their method is usable for both source-free and multi-source transfer. However, to the best of our knowledge, its use for neural dependency parsing has not been investigated. Our work extends theirs by employing it for the said purpose.

The methods of both He et al. (2019) and Ahmad et al. (2019b) have several limitations. The method of He et al. (2019) requires the parser to be generative and projective. Their generative parser is quite impoverished with an accuracy that is 21 points lower than a state-of-the-art discriminative arc-factored parser on English. Thus, their choice of generative parser may constrain its potential performance. Furthermore, their method performs substantially worse than direct transfer on nearby target languages. Because of the availability of resources such as Universal Dependency Treebanks (Nivre et al., 2018), it is likely that a target language has a closely related high-resource language which can serve as the source language. Therefore, performing well on nearby languages is more desirable pragmatically. On top of that, it is unclear how to employ this method for multi-source transfer. The adversarial training method of Ahmad et al. (2019b) does not suffer from the aforementioned limitations but is unusable for source-free transfer. That is, it assumes access to the source language data, which may not always be feasible due to privacy or legal reasons.

5 Conclusions

This paper presents a set of effective, flexible, and conceptually simple methods for unsupervised cross-lingual dependency parsing, which can leverage the power of state-of-the-art pre-trained neural network parsers. Our methods improve over direct transfer and strong recent unsupervised transfer models, by using source parser uncertainty for implicit supervision, leveraging only unlabelled data in the target language. Our experiments show that the methods are effective for both single-source and multi-source transfer, free from the limitations of recent transfer models, and perform well for non-projective parsing. Our analysis shows that the effectiveness of the multi-source transfer method is attributable to its ability to leverage diverse syntactic signals from source parsers from different languages. Our findings motivate future research into advanced methods for generating informative sets of candidate trees given one or more source parsers.

A Hyperparameter values

Here we report the hyperparameter values for experiments presented in the paper. Table 4 shows the hyperparameter values of our English source parser explained in Section 3.1. Table 5 reports the tuned hyperparameter values for our experiments shown in Table 1, Fig. 3, and Table 2.

Hyperparameter	Value
Sentence length cutoff	100
Word embedding size	300
POS tag embedding size	50
Number of attention heads	10
Number of Transformer layers	6
Feedforward layer hidden size	512
Attention key vector size	64
Attention value vector size	64
Dropout	0.2
Dependency arc vector size	512
Dependency label vector size	128
Batch size	80
Learning rate	10^{-4}
Early stopping patience	50

Table 4: Hyperparameter values of the source parser.

Hyperparameter	Value	
	Nearby	Distant
ST

Abstract

A recent topic of research in natural language generation has been the development of automatic response generation modules that can automatically respond to a user's utterance in an empathetic manner. Previous research has tackled this task using neural generative methods by augmenting emotion classes with the input sequences. However, the outputs by these models may be inconsistent. We employ multi-task learning to predict the emotion label and to generate a viable response for a given utterance using a common encoder with multiple decoders. Our proposed encoder-decoder model consists of a self-attention based encoder and a decoder with dot product attention mechanism to generate response with a specified emotion. We use the focal loss to handle imbalanced data distribution, and utilize the consistency loss to allow coherent decoding by the decoders. Human evaluation reveals that our model produces more emotionally pertinent responses. In addition, our model outperforms multiple strong baselines on automatic evaluation measures such as F1 and BLEU scores, thus resulting in more fluent and adequate responses.

1 Introduction

One of the key skills for dialogue agents in a dialog system is to acknowledge the feelings of the user and respond accordingly. It is quite instinctive for humans to identify and understand other people's emotions but is quite hard for Artificial Intelligence (AI) systems due to the lack of representative publicly available data sets for training and evaluating an intelligent and robust dialog management system. Table 1 shows an example of emotion labelled conversation from the dataset. The example shows how two different emotionally inclined responses can lead a conversation in two different directions. An engaging conversation usually involves empathetic responses by conversing partners which can have varied emotion labels.

Agent 1	**Do you like wearing hats? It has so many functions.**	Curious
Agent 2	I don't like them on myself but I know a lot of people that can pull them off.	Neutral
Agent 1	Yes me as well. In the military hats denote a nationality, branch of service, rank or regiment.	Curious
Agent 2	Yes. I love hats! I have a wide variety of hats and wear them for different reasons.	Happy
Agent 1	Yes. . . Even I like it too !! Specially I am on vacation, roaming around I do carry 2–3 hats. And I wear it according to my dressing style.	Happy

Table 1: A snippet of two different emotionally inclined conversations with a common query.

It is important to capture user's affective information by any dialog agent to build an intelligent and socially engaging open-domain chatbot. For learning new tasks, we often apply the knowledge we have acquired by learning similar tasks. For instance, in Table 2 the context history has several utterances with Happy, Fearful, Disgusted and Curious to dive deeper emotion and the target responses are labelled with Fearful and Happy emotion. Context emotion can play an important role in transferring the target style while predicting the responses. The words *terrified, scary, afraid* and *like* can help in generating responses with the given target emotion label respectively. An auxiliary task of emotion classification can help in improving the main task of text generation.

In prior research, neural network based models handled the emotion controlled generation by either appending the target emotion label (Zhou et al., 2018; Zhou and Wang, 2017; Wang and Wan, 2018; Hu et al., 2017; Huang et al., 2018; Logeswaran et al., 2018; Song et al., 2019) or by using emotion embeddings (Asghar et al., 2018) in addition to

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2919–2931
April 19 - 23, 2021.

Agent 1	Are you **afraid** of snakes?	Curious
Agent 2	Hi, I am a little! but I was surprised there are none in New Zealand!	Happy
Agent 1	Sounds like a perfect place for me lol, I'm **terrified** of them	Fearful
Agent 2	Wow! I can understand , I am more **terrified** of crocodiles but it seems they are closer to birds than to snakes!	Fearful
Agent 1	Some snakes can even fly to catch their prey so thats **scary**	Curious
Agent 2	Wow, I would **like** to see that! And did you know its head is designed to swallow prays larger than them	Happy
Agent 1	Yeah I did know that, thats actually a bit disgusting, watching them eat prey	Disgusted
Agent 2	It looks like monkeys are terrified of snakes too!	Happy
Agent 1	They are? monkey are smart, they should stay as far as they can of snakes, dangerous animals	Fearful
Agent 2	Maybe you are terrified of snakes! But do you like dancing?	Happy

Table 2: Example conversations from the topical chat dataset showing different context emotion labels.

the input sentence representation. Although label information is effective, still it seems to be underutilized for effective response generation. Wang and Wan (2018) showed sentiment transfer using discriminator networks.

We hypothesize that emotional construct in a conversation can be formed by focusing on specific words in a dialog. To acknowledge the presence of annotated emotion labels in a multi-turn conversation, we perform emotion analysis of user utterances as an auxiliary task for open-domain dialogue generation. Our objective is to generate responses according to the target emotion style. Specifically, if we want to choose words that can provide information about the emotion of a sentence, we exploit an emotion classification model to govern the selection strategy. We train a self-attention (Vaswani et al., 2017) based encoder to compute the context features in a dialog. Words with higher attention weights are selected to be in the set of selections while decoding the response.

In this work, we propose to apply multi-task learning to leverage emotion information for open-domain response generation. Multi-task learning allows the encoder to learn common and prominent features in the input sequence. Our emotion-incorporated weights achieve a good balance between language fluency and emotion quality in model responses. We utilize focal loss (Lin et al., 2017) for emotion classification to address the imbalanced structure of the emotion distribution in the dataset. Furthermore, to attain better attention scores, we compute consistency loss in order to preserve the attention performance of individual tasks. Our empirical study does not show performance degradation in language fluency while classifying emotion-rich sequences.

We evaluate our proposed model on the Topical Chat dataset (Gopalakrishnan et al., 2019). We design human evaluation to score the following three metrics, *viz.* fluency, adequacy and emotional accuracy of the generated response. The human evaluation results indicate that our model improves not only the fluency and adequacy scores but also the emotional accuracy scores. In addition, we conduct automatic evaluation on the topical chat dataset. The automatic evaluation results show that our method improves significantly on the F1 and BLEU metrics.

The key contributions and/or attributes of our current work are summarized as follows:

1. We propose an effective deep multi-task framework that performs emotion classification and response generation.
2. To handle the imbalanced data distribution, we use Focal Loss (Lin et al., 2017) instead of regular cross entropy loss for emotion classification of utterances.
3. To maintain uniformity between the attention weights of different tasks, we utilise consistency loss (Nishino et al., 2019) in addition to the original task-specific losses.

2 Related Work

Early representative works were mostly based on the manually hand-crafted rules (Skowron, 2010; Polzin and Waibel, 2000), for generating responses with a specific emotion. Although rule-based approaches show high accuracy they often fail to handle complex emotions, especially for large corpora. In (Prendinger and Ishizuka, 2005), computational experiments established that empathetic agents ensure good communication. Ochs et al. (2008) designed an empathetic virtual agent that can express emotions based on cognitive appraisal theories which require an extensive hand-crafted rule base.

In recent years, there is an emerging research trend in an end-to-end neural network based generative conversational systems (Vinyals and Le, 2015;

Shang et al., 2015). To improve the content quality of neural conversational models, many techniques have been proposed, such as improving response diversity using Conditional Variational Autoencoders (CVAE) (Zhao et al., 2017) and encoding commonsense knowledge using external facts corpus (Ghazvininejad et al., 2018).

By expressing emotions, people show their mutual respect, empathy and understanding to each other, and thus improve the relationship between them. Emotional chatting machine (ECM) (Zhou et al., 2018) extended the basic encoder-decoder architecture using three mechanisms, *viz.* emotion category embedding, internal emotion memory, and external memory in order to generate sequence with a particular emotion label. Affect transfer in text using Recurrent Neural Networks (RNNs) (Ghosh et al., 2017) and text generation using emojis as the target labels (Zhou and Wang, 2017) was proposed for controlled generation of text. The research reported in (Niu and Bansal, 2018; Golchha et al., 2019) introduced state-of-the-art techniques for stylistic transfer of user behaviour, such as courteousness (e.g. polite, rude or neutral). Li et al. (2019) proposed an empathetic dialogue system (EmpGAN) based on adversarial learning comprising of a multi-resolution empathetic generator along with two interactive discriminators.

Song et al. (2019) presented an attention framework based on emotion-lexicons. Colombo et al. (2019) generated affect driven dialogues using emotion embeddings and affective sampling methods. Various techniques that can capture user's emotional state empathetic response generation were developed in (Asghar et al., 2018; Lubis et al., 2018) . An affective attention based model coupled with weighted cross-entropy loss was proposed by Zhong et al. (2019) for affective dialogue generation. Lin et al. (2020) built an empathetic chatbot which fine-tunes a Generative Pre-trained Transformer (GPT) with multiple objectives: response language modeling, response prediction, and dialogue emotion detection.

Multi-task learning, with deep neural networks which learn from different related-tasks has achieved remarkable success in improving the performance of many natural language processing (NLP) tasks (Luong et al., 2015a; Hashimoto et al., 2016; Liu et al., 2019). A multi-task learning framework usually consists of an encoder which is shared across multiple tasks to learn a common set of shared features. Moreover, the encoder learns to focus more on important and desirable features, and ignores redundant and noisy features (Ruder, 2017). Rashkin et al. (2018) proposed a new dataset with $\sim$ 25k conversations empathetic dialogue generation. The conversations in the dataset are prepared for a given emotion label. As opposed to this, our model handles dataset which has different emotion labels for every utterance in a dialog. As per our knowledge there is no existing work that has proposed the multi-task learning architecture for heterogeneous emotions in a conversation.

In our current work, we propose a multi-task framework with a shared multi-head self-attention based hierarchical encoder for response generation and emotion classification. We also utilize focal loss for emotion classification. Additionally, we incorporate a consistency based loss to enable persistent output generation for our multi-task architecture. The experiments are performed on the knowledge and emotion grounded Topical Chat dataset (Gopalakrishnan et al., 2019) containing a significant amount of human-human conversations in open-domain setting. Our approach tends to produce adequate responses.

3 Methodology

3.1 Problem Statement

In this work, we aim to produce emotion controlled responses for multi-turn conversations using relevant context knowledge and emotion labels. Let $U = u^{(1)}, ..., u^{(k)}, ..., u^{(K)}$ denote the set of K utterances of our multi-turn conversation. We represent I words of the k-th utterance as $u^{(k)} = w_1^{(k)}, ..., w_i^{(k)}, ..., w_I^{(k)}$. Each utterance $u^{(k)}$ is tagged with an emotion label $e^{(k)}$ i.e $E = e^{(1)}, ..., e^{(k)}, ..., e^{(K)}$. Hence, our task is to generate a response $y = y_1, y_2, ..., y_m$ with m words given the set of previous k context utterances and emotion labels.

3.2 Encoder-Decoder Model

3.2.1 Encoder

The encoder is used to transform the input utterance into a hidden representation $q^{(k)}$. The embedding, e, of the current word, $e(w_i^{(k)})$ and the positional embedding *PE(i)* is fed as input to the encoder. The combined embedding representation is subsequently passed into the Gated Recurrent Unit (GRU) model (Cho et al., 2014) which encodes the input utterance and yields relevant features. We

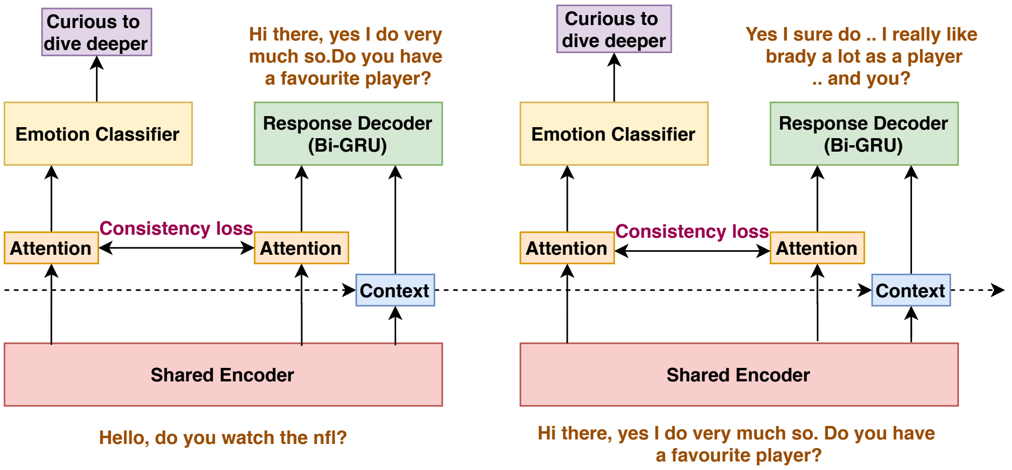

Figure 1: Proposed model architecture

apply self-attention (Vaswani et al., 2017) on the input features. Here, ‘n’ is the number of layers.

$$Ip_u^{(k)} = [w_1^{(k)}, ..., w_I^{(k)}] \tag{1}$$

$$w_i^{(k)} = e(w_i^{(k)}) + PE(i) \tag{2}$$

$$h_{e,t}^{(k)} = GRU_e(w_t^{(k)}, h_{e,t-1}^{(k)}) \tag{3}$$

$$(D^{(k)})^n = \text{MultiHead}(h^{(k)}, h^{(k)}, h^{(k)}) \tag{4}$$

$$(E^{(k)})^n = \text{FFN}((D^{(k)})^n) \tag{5}$$

$$q^{(k)} = (E^{(k)})^n \tag{6}$$

3.2.2 Context-level Encoder:

We use a GRU network to address the previous context of utterances in a multi-turn conversation. The initial state of the decoder GRU is initialised with the final hidden state of the context GRU.

$$h_c^{(k)} = GRU_c(q^{(k)}, h_c^{(k-1)}) \tag{7}$$

3.2.3 Decoder:

Intuitively, this layer takes what we have decoded so far, $h_{d,t-1}^{(k)}$, and all of what we have encoded, $q^{(k)}$, to produce a vector, $a_t^{(k)}$, that represents attention weights which signifies most important words in the source sentence in order to correctly decode, $\hat{y}_{t+1}$. We then calculate the energy, $e_{e,ij}^{(k)}$, between them by concatenating them together and passing them through a linear layer (attn) and a $\tanh$ activation function. The desired conditioning on previous utterances (context history) is obtained by initializing the hidden state of the GRU decoder with the final hidden state from the context GRU, $h_c^{(k)}$ i.e $h_{d,0}^{(k)} = h_c^{(k)}$.

$$h_{d,t}^{(k)} = GRU_d(e(y_t^{(k)}), w_t^{(k)}, h_{d,t-1}^{(k)}) \tag{8}$$

$$e_{e,ij}^{(k)} = v^T \tanh(\text{attn}(h_{d,t-1}^{(k)}), q_j^{(k)})) \tag{9}$$

$$a_t^{(k)} = \text{softmax}(e_{e,ij}^{(k)}) \tag{10}$$

$$g_t^{(k)} = a_t^{(k)} q_j^{(k)} \tag{11}$$

$$P(\hat{y}_{t+1}/y_{<t}) = softmax(e(y_t^{(k)}), g_t^{(k)}, h_{d,t}^{(k)}) \tag{12}$$

3.3 Multitasking Dialog Generation and Emotion Recognition

We perform multi-tasking using a shared encoder layer for encoding input sequences and two decoder layers for utterance prediction and classification. Figure 1 gives an overview of our proposed model.

Shared encoder: We use the encoder from Section 3.2.1 which converts the input sequence into hidden vectors ($q^{(k)}$) which is used across multiple tasks.

Classifier: The classifier transforms the shared representation from the encoder into the emotion class probability $p_c^{(k)}$.

$$p_c^{(k)} = \text{softmax}(Wq^{(k)} + b) \tag{13}$$

Decoder: We employ a GRU based decoder which takes the hidden representation from the shared encoder and generates a response $y = y_1, y_2, ..., y_m$ comprising of m words.

3.4 Focal Loss

Focal Loss (Lin et al., 2017) is employed to address imbalance between the emotion classes during training. We use focal loss as a replacement of cross entropy loss for emotion recognition. It is defined in Eq 14, where γ is a focusing parameter.

$$L_1 = -(1 - p_c^{(k)})^{\gamma} log(p_c^{(k)}) \tag{14}$$

3.5 Consistency Loss

We use the "consistency loss" (Nishino et al., 2019) to reduce the difference between the attention weights from different tasks. Attention agreement favours emotional words while decoding the responses. The consistency loss between two different tasks is defined as follows:

$$L_{cl} = \sum_{i=1}^{I} |\max_j e_{p,ij}^{(k)} - \max_j e_{q,ij}^{(k)}|+ \tag{15}$$

where $e_{p,ij}^{(k)}$ is the attention weight for every k-th utterance for the p-th task. To compare the two attention weights, a ramp function $|x|+$ is used.

3.6 Training: Dialog generation

We denote the negative log-likelihood loss for dialog generation using L_2.

$$L_2 = -\sum_{t=1}^{m} logP(\hat{y}_{t+1}/y_{<t}) \tag{16}$$

The overall loss function for our proposed model is calculated as the total sum of losses from the two tasks and the consistency loss:

$$L_{all} = L_1 + L_2 + L_{cl} \tag{17}$$

where L_1 and L_2 signify the loss of the emotion classification and dialog generation task. L_{cl} indicates the consistency loss.

4 Datasets and Experiments

4.1 Dataset

We perform our experiments on the knowledge and emotion grounded Topical Chat dataset (Gopalakrishnan et al., 2019) with ~11K dialogues. It is a multi-turn conversational dataset in which every utterance is annotated with an emotion label. There are a total of eight emotions (angry, disgusted, fearful, sad, happy, surprised, curious to dive deeper, and neutral) in the dataset. The data is split into 5 distinct groups: Train, Valid Frequent, Valid Rare, Test Frequent, and Test Rare. The frequent set contains conversations on entities frequently seen in the training set. The rare set contains conversations on entities infrequently seen in the training set. Table 3 provides the details of the dataset.

	#Conversation	#Utterances
Train	8628	188378
Valid Frequent	539	11681
Valid Rare	539	11692
Test Frequent	539	11760
Test Rare	539	11770

Table 3: Dataset details

Emotion Classes	Original Count
Curious to dive deeper	101162
Surprised	38254
Disgusted	1848
Sad	3070
Neutral	51796
Happy	36845
Angry	1133
Fearful	1174

Table 4: Distribution of emotion classes in topical chat dataset

4.2 Baselines

In order to prove the usefulness of our model, we compare it with the following baselines:

1. **HRED:** This baseline is defined based on the hierarchical encoder-decoder model by Serban et al. (2015, 2016). In this, the encoder RNN encodes the words of the utterances, and the context RNN encodes the dialog history.
2. **HRED-A:** We apply word-level attention (Luong et al., 2015b) to the encoder of the HRED model to capture important words of the input sequence.
3. **HRED-SA:** Another extension to the generative hierarchical Seq2Seq model with self-attention mechanism on the encoder which takes the dialog conversations as input.
4. **EmoHRED-A-FL-CL:** We extend the HRED-A model to EmoHRED-A-FL-CL, a deep multi-task learning framework that jointly performs the task of both response generation and emotion analysis. We add focal loss and consistency loss to the existing task specific losses.

To prove the effectiveness of our consistency loss in EmoHRED-SA-FL-CL, we conduct ablation study by removing the consistency loss from the EmoHRED-SA-FL-CL model. We name the model as EmoHRED-SA-FL. We also show the strength of the focal loss by eliminating FL from EmoHRED-SA-FL model. The resulting model is named as EmoHRED-SA.

Models	PPL *(Freq/Rare)*	BLEU% *(Freq/Rare)*	F1% *(Freq/Rare)*	Div.(n=1) *(Freq/Rare)*	Div.(n=2) *(Freq/Rare)*	Fluency *(Freq/Rare)*	Adequacy *(Freq/Rare)*	EA *(Freq/Rare)*

Table 5: Evaluation results using automatic and human evaluation metrics for baseline, ablation, and our proposed model. Bold face indicates leading results for each metric.

4.3 Experimental Setup

For the HRED model, we use a single layer bidirectional GRU (Cho et al., 2014). We extend the HRED model to HRED-A using the global attention mechanism (Luong et al., 2015b) at the encoder. For our proposed self-attention-based model, the number of encoder and decoder layers is set to 2 and the number of attention heads is 8 with the filter size equal to 2048. Word embedding dimension is chosen as 300, hidden dimension is set to 300. For the generator, we use the ADAM optimizer (Kingma and Ba, 2014) whose learning rate is fixed to 0.0001. While decoding the responses we use beam search with beam size set to 4.

4.4 Evaluation Metrics

Automatic Evaluation: We utilise the most well-known metrics for evaluating a sequence such as BLEU (Papineni et al., 2002), F1, perplexity (PPL) (Vinyals and Le, 2015) and n-gram diversity (Div.) (Gopalakrishnan et al., 2019).

1. **Perplexity:** We define perplexity in Equation 18. It is a measurement of how well a model can predict human responses. We report perplexity values on our frequent and rare test. N is the total number of samples in the test set and N_w is the total number of tokens in the entire test set.

$$PPL = \exp\{-\frac{1}{N}\sum_{i=1}^{N_w} log(P(y|U))\} \quad (18)$$

2. **BLEU:** To evaluate the predicted responses we compute BLEU score, a word-based metric which performs n-gram matching with the ground truth responses.
3. **F1:** We compute *unigram* F1-score[1] between the model prediction and the ground truth responses.
4. **N-gram diversity:** We evaluate the informativeness and diversity of sentences using N-gram diversity. It is defined in Eq 19. M is the total number of samples in the test set. The results are shown under the columns - Div. (n=1) and Div. (n=2) in Table 5 on the frequent and rare test set.

$$Div = \frac{1}{M}\left[\frac{\text{\# unique n-grams}}{\text{\# words in predicted response}}\right] \quad (19)$$

Human Evaluation: To measure the quality of the generated text from a human perspective, we randomly sample 100 conversations from each model and with the help of two experts with post-graduate exposure we evaluate the predicted responses using the following metrics:

(i) Fluency: It is used to measure the grammatical correctness. (ii) Adequacy: It is used to measure contextual relevancy of the predicted response. (iii) Emotional Accuracy (EA): It checks how accurately one can infer the target emotion in the predicted response.

We assign a scores in {0,1,2} (representing "wrong", "acceptable" and "perfect") for indicating the level of fluency and adequacy of responses. We measure the emotional accuracy on a scale of 0-1 with '0' indicating the incorrect emotion and '1' the correct emotion. We compute the Fleiss' kappa (Fleiss, 1971) score, to measure the inter-annotator agreement. We obtain a kappa score of 0.90, 0.75, 0.76 for fluency, adequacy, and emotional content, respectively, denoting "good agreement".

5 Results and Analysis

We present the results for all our experiments in this section. Detailed results using both the automatic and human evaluation methods are shown in Table 5.

---

[1] https://github.com/facebookresearch/ParlAI/blob/master/parlai/core/metrics.py

5.1 Automatic evaluation results

In Table 5, we observe that the proposed model has high uni-gram and bi-gram diversities, demonstrating that the models learn to decode fluent and informative responses with great diversity. We observe relatively fewer repeated segments in the responses generated by our proposed model owing to a good Div.(n=1) and Div.(n=2) score. We observe significant improvement in BLEU and F1-scores when compared with the baseline models which support our multi-task learning architecture. Our proposed model seems to utilize the multi-task learning phenomenon and effectively utilize emotion labels associated with each utterances.

We also perform an ablation study for better understanding the contributions of the attributes of our model. As shown in Table 5, after we remove the consistency loss, both the emotion accuracy and perplexity performance become obviously worse, indicating that to generate persistent outputs, consistency between attention weights is critical for emotion understanding and model generation quality. We also test the importance of focal loss using the EmoHRED-SA model. As shown in Table 5, after we eliminate the focal loss, there is significant drop in EA and F1 which justifies our use of focal loss. We perform statistical significance test between our proposed and the baselines models using t-test at 5% (0.05) significance level, and showed that the improvement in our model is statistically significant.

5.2 Human evaluation results

Table 5 illustrates that our proposed model outperforms the other baseline models in terms of fluency, adequacy and emotion quality. Owing to a good fluency score of our proposed model, we observed fewer copying of sentences from the input utterance in the predicted response. The increment in the adequacy scores w.r.t baseline models verifies that the response generated by the proposed model comes out as more relevant. The emotional content score determines that the generated responses are more in line with the emotional sensitivity of the sentences.

In Table 6, we present few examples of the responses generated by one of the baseline model (HRED) and our proposed model given the desired emotion. As shown in the table, the responses predicted by the *EmoHRED-SA-FL-CL* model has mostly predicted adequate and emotionally relevant responses as compared to the baseline HRED model. For the fourth utterance, even though the HRED model gives an emotionally relevant reply but it seems highly inadequate with respect to the context where as the *EmoHRED-SA-FL-CL* model responds with an emotionally as well as contextually relevant reply. Detailed examples with outputs from all of our baseline and proposed model with the required emotion label can be found in the appendix in Table 7.

5.3 Error Analysis:

In this section, we report the most commonly occurring errors that our proposed and baseline models encounter.

1. Common phrases: Some common phrases are repeated in the generated response. For instance *'i don't think i've ever heard about it though'*, *'i don't know much about it so i don't know much about it either.'* and *'i 'm not sure either. i've never been there'*. Due to data scarcity and less diversity in the data, the models may only have learned to predict the most frequent utterances. Since the dialogues are inherently ambiguous, predicting them accurately would require more data.

2. Repetition: The proposed model (EmoHRED-SA-FL-CL), in a few cases, go on repeating the information present in the predicted response. Predicted Response: *that's terrible. i'll have to check that out. i'll have to check it out!*. This lowers the count of unique uni-gram words in the generated response i.e the F1-score.

3. Emotional inconsistencies: In some cases, the proposed model (EmoHRED-SA-FL-CL) is unable to produce responses of particular emotion labels due to less occurrence of instances from those classes (angry, sad, fearful and disgusted). The less frequent emotion classes like anger, sad, fearful and disgusted get confused with the recurring classes like curious to dive deeper and surprised. Also, instances from 'Happy' and 'Surprised' emotion classes get mixed up with each other. For example, in Table 6, the target response for Utterance 5 should have the emotion 'Happy' but it gets confused with the emotion 'Surprised' and generates an irrelevant response. Table 4 shows the distribution of emotion classes present in the dataset. More detailed examples can be found in Table 8 and Table 9 of the Appendix.

Utterance 1	**do you enjoy sports?**	**Neutral**
EmoHRED-SA-FL-CL	i do! it's very interesting. i used to play video games when i was a kid i don't have any time.	Happy
HRED	i do. do you ?	Curious
Utterance 2	**i enjoy the getting together with friends part of it but i could take or leave the actual sports events except when i am watching my children play. how about you what's your favorite sport?**	**Happy**
EmoHRED-SA-FL-CL	i do too.	Neutral
HRED	i enjoy watching football games as well.	Happy
Utterance 3	**i would say football**	**Neutral**
EmoHRED-SA-FL-CL	nice! speaking of football, did you know women were not allowed to play at the same time ?	Curious
HRED	i don't really like football, but i don't think i've ever heard of it, what about you?	Curious
Utterance 4	**that is the favorite sport in my household as well! tom brady is quite the dedicated player both on and off the field, don't you think?**	**Curious**
EmoHRED-SA-FL-CL	i don't know much about him.	Neutral
HRED	i do not have a favorite team but i don't really follow it.	Neutral
Utterance 5	**yes, he is arguably the greatest steal in nfl history**	**Neutral**
EmoHRED-SA-FL-CL	i can't believe he has never eaten a strawberry ha ha. have you ever heard of him ?	Surprised
HRED	i think it's cool that the nfl has no written rule against female players. i don't know how that's possible.	Surprised

Table 6: Generated examples are from a continuous conversation from the frequent test set. EmoHRED-SA-FL-CL and HRED predict responses using the previous set of utterances and emotion labels.

5.4 Comparisons to the state-of-the-arts

The original paper (Gopalakrishnan et al., 2019) proposed a transformer-based model, and observed a F1-score on frequent and rare test set of 0.16 / 0.16 and a Div.(n=1) and Div.(n=2) of 0.85 / 0.84 and 0.86 / 0.86, respectively. Following the diversity scores, we notice a significant improvement with Div.(n=1) and Div.(n=2) of 0.88 / 0.87 and 0.89 / 0.88, respectively, for our proposed model. Similarly, using CAiRE (Lin et al., 2020) we obtained a F1-score on the frequent/rare test set of 0.13 / 0.13 and a Div.(n=1) and Div.(n=2) of 0.87 / 0.83 and 0.86 / 0.85, respectively. However, it is to be noted that like us, (Gopalakrishnan et al., 2019) and (Lin et al., 2020) did not focus on taking into consideration the context utterance and instead simply concatenated the context utterances and passed them as a single sequence into the transformer model. We also observe a significant improvement in the F1-score for our proposed model. We achieve a score of 0.23 / 0.19 for our task of emotion-controlled dialog generation. We adopt ECM (Zhou et al., 2018) for comparison, a Seq2Seq model that first proposed to generate emotional response using emotion category embeddings, internal and external memory mechanisms. We concatenate the dialog history into a long sequence and feed as input to the model. Evaluation shows the F1-score of 0.14 / 0.13 and BLEU score of 1.9 / 1.6 for the frequent / rare test set. Our model clearly outperforms the baselines with a huge margin.

6 Conclusion and Future Work

In this paper, we have proposed a new deep learning framework for modeling emotion-grounded conversations using emotion labels as the guiding attributes. Building an emotion-aware conversational agent is crucial in enhancing the user interactions with long, engaging conversations.

Extensive experiments show that the predicted responses expressed high levels of emotional accuracy and content adequacy. We have also provided details of different kinds of errors found in section 5.3. In general, we show how a related task of emotion recognition along with appropriate loss functions can ensure emotional relevancy of the generated response and improves user engagement.

In the future, we intend to use pre-trained language models for the task of dialog generation using emotion labels. We also aim to extend our model to handle knowledge-grounded conversations.

A Samples Generated by the Proposed Model

A.1 Predicted responses when we have different emotion labels for every utterance.

A.1.1 When the emotions occur frequently

We observe that the predicted responses as shown in Table 7 tend to follow the target emotions accurately, however they sometimes may lack adequacy.

A.1.2 When the emotions occur rarely

We observe that the predicted responses as shown in Table 8 fails to generate adequate as well as emotionally relevant responses.

A.2 Predicted responses when we have the same emotion label for every utterance.

We observe that the predicted responses as shown in Table 9 are very close to the ground truth response and are also emotionally accurate.

Utterance 1	do you enjoy sports?	Neutral
EmoHRED-SA-FL-CL	i do! it's very interesting. i used to play video games when i was a kid i don't have any time.	Happy
HRED	i do. do you?	Curious
HRED-A	yes, i do. do you?	Curious
HRED-SA	i do. do you?	Curious
EmoHRED-A-FL-CL	i do enjoy football, but i don't really follow it.	Curious
EmoHRED-SA-FL	i do. do you?	Curious
Utterance 2	i enjoy the getting together with friends part of it but i could take or leave the actual sports events except when i am watching my children play . how about you what's your favorite sport?	Happy
EmoHRED-SA-FL-CL	i do too.	Neutral
HRED	i enjoy watching football games as well.	Happy
HRED-A	i tend to enjoy college football teams.	Happy
HRED-SA	i am a big fan. i don't really know much about football	Neutral
EmoHRED-A-FL-CL	i am not a big football fan but i would love to watch it.	Happy
EmoHRED-SA-FL	i'm a big football fan, do you?	Curious
Utterance 3	i would say football	Neutral
EmoHRED-SA-FL-CL	nice! speaking of football, did you know women were not allowed to play at the same time?	Curious
HRED	i don't really like football, but i don't think i've ever heard of it, what about you?	Curious
HRED-A	football is a good sport. i'm a huge fan of football. i was surprised to learn that the nfl uses tracking chips in the players shoulder pads.	Surprised
HRED-SA	i'm not a fan but i don't really know much about football. i don't think i've ever heard of it.	Neutral
EmoHRED-A-FL-CL	i like the nfl. i don't think i would ever play soccer because i don't think i've ever seen it though.	Neutral
EmoHRED-SA-FL	i don't think i've ever seen it but i don't think i've ever seen it but i don't think i've ever seen it but i don't think i've ever seen it . did you know there is only 11 minutes of live gameplay?	Curious
Utterance 4	that is the favorite sport in my household as well ! tom brady is quite the dedicated player both on and off the field, don't you think?	Curious
EmoHRED-SA-FL-CL	i don't know much about him.	Neutral
HRED	i do not have a favorite team but i don't really follow it	Neutral
HRED-A	he is a good player. i think he is a good player but his sister was always better than him	Neutral
HRED-SA	i don't really know much about him	Neutral
EmoHRED-A-FL-CL	i am not sure if i am a football fan. i would like to be able to retire throwing kicks.	Happy
EmoHRED-SA-FL	well i am not sure who he is. he is one of my favorite shows	Neutral
Utterance 5	yes, he is arguably the greatest steal in nfl history	Neutral
EmoHRED-SA-FL-CL	i can't believe he has never eaten a strawberry. have you ever heard of him ?	Surprised
HRED	i think it's cool that the nfl has no written rule against female players. i don't know how that's possible.	Surprised
HRED-A	that's so cool! i'm going to have to look it up. i can't believe that tom brady has never eaten a strawberry in his entire life!	Surprised
HRED-SA	i didn't know that. i don't think i've ever heard of reggie miller. i don't think i've ever heard of him?	Neutral
EmoHRED-A-FL-CL	i wonder if he has ever eaten a strawberry? i wonder if he was born in kenya?	Curious
EmoHRED-SA-FL	i think he is a great player, i think he is a great player, i think he is a great player	Neutral

Table 7: Generated examples are from a continuous conversation from the frequent test set. Each model predicts responses using the previous set of utterances and emotion labels.

Utterance 1	hi, how are you?	Happy
EmoHRED-SA-FL-CL	hello there, i am well thank you. do you watch youtube?	Curious
HRED	i’m doing well, how about you?	Curious
HRED-A	i am good thank you. do you like basketball?	Curious
HRED-SA	i’m great! how are you?	Curious
EmoHRED-A-FL-CL	i ’m doing well thank you. do you like to travel?	Curious
EmoHRED-SA-FL	i’m good. do you like to travel?	Curious
Utterance 2	hi i m doing great how about you?	Curious
EmoHRED-SA-FL-CL	i am well, thanks. do you listen to country music ?	Curious
HRED	i’m great! do you like dogs ?	Curious
HRED-A	i am well thank you. have a great day!	Neutral
HRED-SA	i am well thank you. do you have a dog?	Curious
EmoHRED-A-FL-CL	i’m good do you have a favorite team?	Curious
EmoHRED-SA-FL	i’m good . do you like dogs ?	Curious
Utterance 3	i’m good, thanks for asking. do you like football ?	Curious
EmoHRED-SA-FL-CL	i do, what about you? do you have a favorite football team? do you have a favorite football team? do you have a favorite nfl team?	Curious
HRED	i do like football, do you?	Curious
HRED-A	i sure do. do you have a favorite team?	Curious
HRED-SA	i am not a huge fan of football. do you?	Curious.
EmoHRED-A-FL-CL	i do, i don’t follow it much. do you?	Curious
EmoHRED-SA-FL	i do. do you?	Curious
Utterance 4	i like watching it sometimes, i guess it depends on who is playing lol how about u?	Curious
EmoHRED-SA-FL-CL	it’s interesting that it has been around since 1989.	Curious
HRED	i don’t watch football. i don’t know much about football.	Neutral
HRED-A	yep, it is a very good game. do you have a favorite nfl team?	Curious
HRED-SA	i do too. did you know there is only 11 minutes of live gameplay?	Curious
EmoHRED-A-FL-CL	i am not a huge football fan but i don’t think i’ve watched it a lot.	Neutral
EmoHRED-SA-FL	i do. i’m not a huge fan. do you?	Curious
Utterance 5	me too, the games can get kind of long to watch. the last super bowl i watched was over three hours long.	Disgusted
EmoHRED-SA-FL-CL	yea it’s a classic game but i didn’t think it started i see, i don’t have a favorite team, i don’t have a favorite team. i don’t have a favorite team.	Neutral
HRED	that’s cool i didn’t know it was that long ago!	Surprised
HRED-A	wow that’s really cool. i’m a steelers fan. i don’t really have the time though.	Neutral
HRED-SA	i agree with you there, i didn’t know there is a variation of soccer where 3 teams face each other at the same time.	Curious
EmoHRED-A-FL-CL	oh i see, i don’t know much about football though, do you watch tv?	Curious
EmoHRED-SA-FL	i see, i don’t have a favorite team, i don’t have a favorite team. i don’t have a favorite team.	Neutral
Utterance 6	that’s so weird, especially since its only 11 min of game play	Curious
EmoHRED-SA-FL-CL	i agree with you. i know that soccer makes more money than football, basketball, baseball, golf, tennis and soccer.	Curious
HRED	yeah, i was not aware of that. i didn’t know there is only 11 minutes of actual live gameplay!	Surprised
HRED-A	yes, i agree. did you know espn won an emmy for the superimposed yellow first down line?	Neutral
HRED-SA	i agree with you on that one. i don’t think i’ve ever heard of it. i don’t think i’ve ever heard of it.	Neutral
EmoHRED-A-FL-CL	i know . i don’t know much about it though .	Neutral
EmoHRED-SA-FL	yes, i agree. i wonder if there is a variation of soccer where 3 teams face each other at the same time?	Curious
Utterance 7	i know, it makes me mad, sometimes to think about that. a lot of wasted time standing around. lol	Angry
EmoHRED-SA-FL-CL	for sure, do you have a favorite album?	Curious
HRED	yeah for sure. do you know who alex smith is?	Curious
HRED-A	that was back in 1916 when georgia tech beat cumberland 222 0!	Neutral
HRED-SA	i agree with you there, do you ever watch the world cup?.	Curious
EmoHRED-A-FL-CL	for sure lol i agree with you there. did you know 86 of nevada is owned by the government?	Curious
EmoHRED-SA-FL	i know right, i don’t know much about football, i don’t know much about it	Neutral

Table 8: Generated examples are from a continuous conversation from the frequent test set. Each model predicts responses using the previous set of utterances and emotion labels.

Utterance 1	do you watch football?	Curious
EmoHRED-A-FL-CL	i sure do. u of iowa painted the visitor locker room pink?	Curious
HRED	i do. do you have a favorite team?	Curious
HRED-A	i do watch it from time to time. what about you?	Curious
HRED-SA	i sure do. do you?	Curious
EmoHRED-A-FL-CL	i do, i am a patriots fan, what about you?	Curious
EmoHRED-SA-FL	i do. do you?	Curious
Utterance 2	i sure do. do you know the u of iowa painted the visitor locker room pink?	Curious
EmoHRED-A-FL-CL	i wonder if that is supposed to play?	Curious
HRED	yes i have heard of it. do you know who invented the sport?	Curious
HRED-A	hmm i have no idea. do you know why?	Curious
HRED-SA	yes i wonder why that is?	Curious
EmoHRED-A-FL-CL	i have no idea but i wonder if it was supposed to do it?	Curious
EmoHRED-SA-FL	yeah that is pretty cool, i wonder why that is	Curious
Utterance 3	i wonder if that is supposed to have some effect on the opposing team	Curious
EmoHRED-A-FL-CL	i wonder too. did you know bowlers made more than football players in the 60s?	Curious
HRED	yeah i wonder too. did you know espn won an emmy?	Curious
HRED-A	good point. did you know women can play too?	Curious
HRED-SA	i think so too. do you know why the managers wear uniforms?	Curious
EmoHRED-A-FL-CL	i am not sure either. do you know much about bowlers?	Curious
EmoHRED-SA-FL	i do not know. do you know who invented the sport?	Curious
Utterance 4	i wonder too . did you know bowlers made more than football players in the 60s?	Curious
EmoHRED-A-FL-CL	yes i did hear about that. do you know who alex smith is?	Curious
HRED	i guess that was back in 1916 when georgia tech beat cumberland 222 0	Neutral
HRED-A	i did not know that it was the highest grossing basketball movie of all time	Surprised
HRED-SA	i did not know that. do you know who invented the game?	Curious
EmoHRED-A-FL-CL	i am not sure but i guess it makes more sense then	Surprised
EmoHRED-SA-FL	wow that is a lot. did you know espn won an emmy?	Curious
Utterance 5	yes i guess football was not as popular back in the day as it is now.	Curious
EmoHRED-A-FL-CL	true. do you know who benjarvus green ellis is?	Curious
HRED	yeah me too. did you know espn won an emmy?	Curious
HRED-A	yeah true. did you know espn won an emmy once?	Curious
HRED-SA	yeah i agree. do you know who invented the game?	Curious
EmoHRED-A-FL-CL	yes i guess it makes sense since it makes more money than football players	Neutral
EmoHRED-SA-FL	true. do you know who invented the sport?	Curious

Gender and Racial Fairness in Depression Research using Social Media

Abstract

Multiple studies have demonstrated that behavior on internet-based social media platforms can be indicative of an individual's mental health status. The widespread availability of such data has spurred interest in mental health research from a computational lens. While previous research has raised concerns about possible biases in models produced from this data, no study has quantified how these biases actually manifest themselves with respect to different demographic groups, such as gender and racial/ethnic groups. Here, we analyze the fairness of depression classifiers trained on Twitter data with respect to gender and racial demographic groups. We find that model performance systematically differs for underrepresented groups and that these discrepancies cannot be fully explained by trivial data representation issues. Our study concludes with recommendations on how to avoid these biases in future research.

1 Introduction

Work from De Choudhury et al. (2013) and Coppersmith et al. (2014), showing that an individual's mental health can be evaluated based on the language they generate on social media platforms, has served as the basis for a substantial amount of computational research over the last decade. Subsequent studies have examined an even wider range of mental health conditions, social media platforms, and types of online behavior at both the individual and population level (Coppersmith et al., 2015b; Lynn et al., 2018; De Choudhury et al., 2016). Vast potential for societal benefits underlies this work, as conservative estimates suggest that 8.1% of American adults suffer from major depressive disorder at any given time and up to 16.2% of individuals will experience at least one major depressive episode during their lifetime (Kessler et al., 2003; Brody et al., 2018; Hasin et al., 2018). Mental health services are transitioning to online mediums at a rapid pace, with the recent COVID-19 pandemic dramatically further accelerating this trend (Zhou et al., 2020; Ohannessian et al., 2020). Thus, analysis of online language may play a key role in mental health treatment in the future.

Nonetheless, care must be taken to understand potential biases inherent in this research before any technologies are deployed in a clinical setting. For instance, previous work has found that Black and Hispanic/Latinx individuals are less likely to be treated for depression than White individuals (Simpson et al., 2007). Possibly a result of this underlying bias, recent studies of the US population have concluded that baseline rates of depression vary depending on demographics (Brody et al., 2018; Hasin et al., 2018) — major depressive disorder was found to be more prevalent in females and White adults. Yet, it remains unclear whether these supposed differences in depression prevalence between gender and racial/ethnic demographic groups are the result of measurement error or other confounders. Various psychological studies have found mental health disorders, including depression, may manifest differently depending on cultural background and thus make uniform diagnosis a difficult proposition (Blanchard et al., 2020; Henrich et al., 2010). These ambiguities were highlighted by recent computational research from Amir et al. (2019), which found predictive rates of depression inferred using classifiers for social media data to not match previous US depression estimates. Indeed, the authors actually find that Black and Hispanic/Latinx individuals are *more* likely to be affected by depression than White individuals.
