For fair comparisons, we use Adam optimizer (Kingma and Ba, 2014) with learning rate 0.001 and regularize parameters of all methods with ℓ_2 norm and weight decay $\lambda = 0.001$. As the maximum lengths of claims and articles in words are 30 and 100 respectively for both datasets, we set $n = 30$ and $m = 100$. For HAN and our model, we set $k = 30$ since the number of articles for each claim is at most 30 in both datasets. Batch size is set to 32 and we trained all models until convergence. We tune all models including ours with hidden size H chosen from $\{64, 128, 300\}$, pre-trained word-embeddings are from Glove (Pennington et al., 2014) with $D = 300$. Both D_1 and D_2 are tuned from $\{128, 256\}$. The number of attention heads h_1 and h_2 is chosen from $\{1, 2, 3, 4, 5\}$, a_1 and a_2 are equal to $2 \times H$. In addition to Glove, we also utilized contextual embeddings from pre-trained language models such as ELMo and BERT but achieved comparable performances. We implemented all methods in PyTorch 0.4.1 and run experiments on an NVIDIA GTX 1080.

5.4 Performance of MAC and baselines

We show experimental results of our model and baselines in Tables 2 and 3. In Table 2, MAC outperforms all baselines with significance level $p < 0.05$ by using one-sided paired Wilcoxon test on Snopes dataset. MAC achieves the best result when $h_1 = 5, h_2 = 2, H = 300$ and $D_1 = D_2 = 128$. In Table 3, MAC also significantly outperforms all baselines with $p < 0.05$ according to one-sided paired Wilcoxon test on PolitiFact dataset. The hyperparameters we selected for MAC are $h_1 = 3, h_2 = 1, H = 300$ and $D_1 = D_2 = 128$.

For baselines, BERT is used as a static encoder. We tried to fine tune it but even achieve worse results. This might be because we do not have sufficient data to tune it. For both HAN and DeClare, since both papers do not release their source code, we tried our best to reproduce results from these two models. HAN model derived representation of each document by using the last hidden state of a GRU (Chung et al., 2014) without any attention mechanism on words to downgrade unimportant words (e.g. stop words), leading to poor representations of documents. Therefore, document-level attention mechanism in HAN model did not perform well. Similar patterns can be observed in two baselines LSTM-Avg and LSTM-Last. DeClare performed best among baselines, indicating the importance of applying word-level attention on words to reduce impact of less informative words.

We can see that our MAC outperforms all baselines in all metrics. When viewing *true news* as *positive class*, our MAC has an average increase of 16.0% and 7.1% over the best baselines on Snopes and PolitiFact respectively. We also have an increase of 4.7% improvements over baselines with a maximum improvements of 10.1% in PolitiFact

Table 3: Performance of MAC and baselines on PolitiFact dataset. MAC outperforms baselines with statistical significance level p-value<0.05 by one-sided paired Wilcoxon test.

(a) Snopes (b) PolitiFact

Figure 2: Sensitivity of MAC with respect to number of heads in word-level attention h_1 and the number of heads in document-level attention h_2

when considering *fake news* as *negative class*. In terms of AUC, average improvements of MAC over the baselines are 7.9% and 6.1% on Snopes and PolitiFact respectively. Improvements of MAC over baselines can be explained by our multi-head attention mechanism shown in Eq. 3 and Eq. 8. After attending to words in documents, we can generate better representations of documents/evidence, leading to more effective document-level attention compared with HAN model.

5.5 Ablation Studies

Impact of Word Attention and Evidence Attention. We study the impact of attention layers on performance of MAC by (1) using only word attention and replacing evidence attention with an average pooling layer on top of documents' representations and (2) using only evidence attention and replacing word attention with an average pooling layer on top of words' representations. As we can see in Table 4, using only word attention performs much better than using only evidence attention. This is because without downgrading less informative words in evidence, irrelevant information can be captured, leading to low quality representations of evidence. This experiment aligns with our observation that HAN model, which used only evidence attention, did not perform well. When combining both attention mechanisms hierarchically, we consistently achieve best results on two datasets in Table 4. In particular, the model *Word & Doc Att* outperformed both *Only Evidence Att* and *Only Evidence Att* significantly with p-value < 0.05. This result indicates that it is crucial to combine word-level attention and document-level attention to improve the performance of evidence-aware fake news detection task.

Impact of Speakers and Publishers on MAC. To study how speakers and publishers impact performance of MAC, we experiment four models: (1) using text only (Text Only), (2) using text and publishers (Text + Publishers), (3) using text and speakers (Text + Speakers) and (4) using text, publishers and speakers (Text + Pubs + Spkrs). In Table 5, Text + Publishers has better performance then using only text in both datasets. In PolitiFact, Text + Speakers achieves 2∼3% improvements over Text + Publishers, indicating that speakers who made claims are

Figure 4: Visualization of attention weights of *the second attention head* on three documents relevant to a false claim in word-level attention layer

crucial to determine verdict of the claims. Finally, using all information (Text + Pubs + Spkrs) helps us achieve the best result in PolitiFact. In Snopes, we omit results of Text + Speakers and Text + Pubs + Spkrs because the dataset does not contain speakers' information. In particular, model *Text + Pubs + Spkrs* outperformed methods *Text Only* and *Text + Publishers* significantly (p-value< 0.05). Based on these results, we conclude that integrating information of speakers and publishers is useful for detecting misinformation.

5.6 Impact of the Number of Attention Heads

In this section, we examine sensitivity of MAC with respect to the number of heads h_1 in word attention layer and the number of heads h_2 in document attention layer. We vary h_1 and h_2 in $\{1, 2, 3, 4, 5\}$. Since AUC is less sensitive to any threshold, we report AUC of MAC on two datasets in Fig. 2(a) and 2(b). A common pattern we can observe in the two figures is that performance of MAC tends to be better when we increase the number heads h_1 in word attention layer while performance of MAC tends to decrease when increasing h_2. This phenomenon indicates that word attention is more important than evidence attention. In Snopes, MAC has the best AUC when $h_1 = 5, h_2 = 2$. In PolitiFact, MAC reaches the peak when $h_1 = 3, h_2 = 1$.

5.7 Case Study

To understand how multi-head attention mechanism works, from the testing set, we visualize attention weights on three documents of a false claim *Actor Christopher Walken planning making bid US presidency 2008*. Note, our MAC correctly classifies the claim as fake news. In Fig. 3 and Fig. 4, we show the claim and visualization of two different heads in word attention layer. Note that Popat et al.

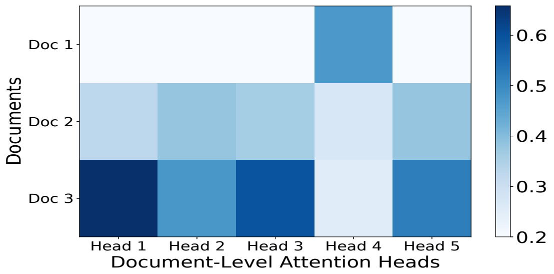

Figure 5: Visualization of five attention heads in document-level attention layer for three documents

(2018), who released the datasets, already lowercased and removed punctuations. To conduct fair comparison, we directly used the datasets without any additional preprocessing. In Fig. 3, attention weights are sparse, indicating that the first attention head focuses on the most important words which determine credibility of the claim (e.g. *hoax*, *false*). Differently, in Fig. 4, the second attention head has more diffused attention weights to capture more useful phrases from documents (e.g. *walken not running*, *its obviously not*). Moving on to attention heads in evidence attention layer in Fig. 5, we show a heat map where the x-axis is the five heads extracted from evidence attention layer and the y-axis is three documents relevant to the same claim in Fig. 3 and 4. As we can see in Fig. 5, *Head 1*, *Head 3* and *Head 5* emphasize on *Doc 3* which contains refuting phrases (e.g. *its obviously not*), while *Head 4* focuses on *Doc 1* which has negating information such as *walken not running*. Both *Doc 1* and *Doc 3* have crucial signals to fact-check the claim. From these analyses, we conclude that heads in word attention layer capture different semantic contributions of words and different heads in document attention layer captures important documents.

6 Conclusions

In this paper, we propose a novel evidence-aware model to fact-check textual claims. Our MAC is designed by hierarchically stacking two attention layers. The first one is a word attention layer and the second one is a document attention layer. In both layers, we propose multi-head attention mechanisms to capture different semantic contributions of words and documents. Our MAC outperforms the baselines significantly with an average increase of 6% to 9% over the best results from baselines with a maximum improvements of 18%. We conduct ablation studies to understand the performance of MAC and provide a case study to show the effectiveness of the attention mechanisms. In future work, we will further examine other data types such as images to improve the performance of our model.

Identifying Named Entities as they are Typed

Ravneet Singh Arora **Chen-Tse Tsai** **Daniel Preoţiuc-Pietro**
Bloomberg

Abstract

Identifying named entities in written text is an essential component of the text processing pipeline used in applications such as text editors to gain a better understanding of the semantics of the text. However, the typical experimental setup for evaluating Named Entity Recognition (NER) systems is not directly applicable to systems that process text in real time as the text is being typed. Evaluation is performed on a sentence level assuming the end-user is willing to wait until the entire sentence is typed for entities to be identified and further linked to identifiers or co-referenced. We introduce a novel experimental setup for NER systems for applications where decisions about named entity boundaries need to be performed in an online fashion. We study how state-of-the-art methods perform under this setup in multiple languages and propose adaptations to these models to suit this new experimental setup. Experimental results show that the best systems that are evaluated on each token after its typed, reach performance within 1–5 F_1 points of systems that are evaluated at the end of the sentence. These show that entity recognition can be performed in this setup and open up the development of other NLP tools in a similar setup.

1 Introduction

Automatically identifying named entities such as organizations, people and locations is a key component in processing written text as it aids with understanding the semantics of the text. Named entity recognition is used as a pre-processing step to subsequent tasks such as linking named entities to concepts in a knowledge graph, identifying the salience of an entity to the text, identifying coreferential mentions, computing sentiment towards an entity, in question answering or for extracting relations.

Figure 1: An example of the proposed task and evaluation setup. After the word ‘Foreign’ is typed, the model immediately predicts an NER label for this word, only using left context (‘A spokesman for’) and the word itself. The prediction is then compared against the gold label to compute token-level F_1 score. This token’s prediction will not be changed, even if the model’s internal prediction for it can be revised later as more tokens are typed.

Identifying named entities as they are typed benefits any system that processes text on the fly. Examples of such applications include: a) News editors – where named entities can be highlighted, suggested (auto-completion), co-referenced or linked as the editor is typing; b) auto-correct – where named entities that are just typed are less likely to need correction as they may come from a different language or be out-of-vocabulary (OOV); c) simultaneous machine translation – where translation of OOV named entities requires different approaches; d) live speech-to-text (e.g., TV shows) – where named entities are more likely to be OOV, hence the transcription should focus more on the phonetic transcription rather than on n-gram language modelling.

This paper introduces a novel experimental setup of Named Entity Recognition systems illustrated in Figure 1. In this setup, inference about the span and type of named entities is performed for each token, immediately after it was typed. The sentence level tag sequence is composed through appending all individual token predictions as they were made. The current named entity recognition systems that are trained and evaluated to predict full sentences are likely to under-perform in this experimental setup as they: expect that right context is available,

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 976–988
April 19 - 23, 2021.

are faced with unseen types of inputs in the form of truncated sentences and can not reconcile the final sentence-level tag sequence across the entire sentence as the result may not be a valid sequence.

The goal of this study is to present a comprehensive analysis of the task of NER in the *as-you-type* scenario, with the following contributions:

a) A novel experimental setup for conducting named entity recognition experiments, denoted as the *as-you-type* scenario;
b) Experiments with state-of-the-art sentence-level approaches to named entity recognition in the *as-you-type* setup across three languages, which indicate a 1–5 F_1 points decrease compared to sentence-level inference;
c) Tailored methods for as-you-type entity recognition models which reduce the gap to entire sentence-level inference by 9–23% compared to regular approaches;
d) An extensive analysis of existing data sets in the context of this task and model error analysis, which highlight future modelling opportunities.

2 Related Work

Named Entity Recognition is most commonly treated as a sequence labelling problem, where a prediction of whether a token is an entity and its type is done jointly for all tokens in the sentence. Over the past recent years, the dominant approach is based on recurrent neural networks, such as LSTMs (Hochreiter and Schmidhuber, 1997). These architectures use a stacked bi-directional LSTM units to transform the word-level features into distributions over named entity tags (Huang et al., 2015). Usually, an additional Conditional Random Field (CRF) (Lafferty et al., 2001) is used on the BiLSTM output in order to take into better model neighbouring tags. The tokens inputs are represented using one or a concatenation of pre-trained static word embeddings such as GloVe (Ma and Hovy, 2016), contextual word embeddings (Peters et al., 2018; Akbik et al., 2018; Devlin et al., 2019), pooled contextual word embeddings (Akbik et al., 2019b) or character embeddings trained using BiLSTMs (Lample et al., 2016) or CNNs (Ma and Hovy, 2016; Chiu and Nichols, 2016).

In addition to research on improving the performance of the NER model, other experimental setups have been proposed for this task. These include domain adaptation, where a model trained on data from a source domain is used to tag data from a different target domain (Guo et al., 2009; Greenberg et al., 2018; Wang et al., 2020), temporal drift, where a model is tested on data from future time intervals (Derczynski et al., 2016; Rijhwani and Preotiuc-Pietro, 2020), cross-lingual modelling where models trained in one language are adapted to other languages (Tsai et al., 2016; Ni et al., 2017; Xie et al., 2018), identifying nested entities (Alex et al., 2007; Lu and Roth, 2015) or high-precision NER models (Arora et al., 2019).

However, all these experimental setups assume that training is done over full length sentences. Perhaps the most related experimental setup to the one we propose for the task of entity recognition is the task of simultaneous machine translation. In this setup, the task is to generate an automatic translation in a target language as the text is being processed in the source language. The goal of the task is to produce a translation that is as accurate as possible while limiting the delay as compared to the input. Initial approaches involved identifying translatable segments and translating these independently (Fügen et al., 2007; Bangalore et al., 2012; Fujita et al., 2013) or by learning where to segment in order to optimize the system's performance (Oda et al., 2014). More recent approaches involve learning training an agent, usually using reinforcement learning, that makes a set of decisions of whether to should wait for another word from the input or write a token to the output (Gu et al., 2017). Other operations are shown to help, including predicting the verb (Grissom II et al., 2014) or the next word (Alinejad et al., 2018), better decoding with partial information (Cho and Esipova, 2016), and connecting the machine translation system to the agent's decisions (Gu et al., 2017).

Our experimental setup is different as we do not want to wait for another input token before we make a prediction about the named entity. We analyze the impact a delay has, albeit our experimental setup does not aim to combine quality and delay. The challenges are related, as the input may contain important cues for the translation or named entity decision after the current token or towards the end of the sentence, such as the verb in verb-final (SOV) languages such as German (Grissom II et al., 2014). The proposed as-you-type NER model can be useful to improve simultaneous machine translation.

3 Experimental Setup

We propose a new experimental setup for the standard task of Named Entity Recognition that would best suit real-time applications that need to process text in an online fashion.

In the regular NER experimental setup, a model is presented with a sequence of inputs $X = \{x_1, x_2, ..., x_n\}$ and it outputs a sequence of labels $Y = \{y_1, y_2, ..., y_n\}$ where $y_i \in K = \{O\} + E \times T$, where E are the set of entity types and T is the entity tag representation. Throughout the rest of the paper, we use the BIO tagging scheme ($T = \{\text{B}, \text{I}\}$), as this is arguably the most popular and differences in results between this tagging scheme and others, such as the BILOU scheme, are very small in practice (Ratinov and Roth, 2009). The types of entities we consider are $E = \{\text{ORG}, \text{PER}, \text{LOC}, \text{MISC}\}$.

The *as-you-type* named entity recognition setup assumes that the editor writing the text $X = \{x_1, x_2, ..., x_n\}$ needs each label prediction y_i right after the corresponding token x_i was typed. In this case, the information available for predicting y_i is only the sub-sequence $X_{1,i} = \{x_1, x_2, ..., x_i\}$. The sequence $Y = \{y_1, y_2, ..., y_n\}$ is obtained by concatenating the individual y_i predictions made for each token. Token-level micro F_1 score is used as the metric in our experiments. The evaluation process is illustrated in Figure 1.

This setup presents the model with several challenges. First, the model has no access to right context when making the prediction for each tag. However, this information is available in training. Secondly, the output sequence may contain invalid sequences of tags. For example, in the output sequence, B-ORG could be followed by I-LOC if the model decided to revise its predictions based on new information, but the evaluation setup prevents the model from revising the previous wrongly predicted tag (i.e. B-ORG). Lastly, sequences and sentences of the same length are likely to be qualitatively different and the model might need to adapt in training in order to account for these differences.

We note that this experimental setup can further be extended to account for delays in prediction, to trade-off between delays and quality or to predict entities before they are typed.

4 Data

We test our methods on three different data sets covering three different languages. We use the data sets released as part of CoNLL shared tasks in 2002 for Spanish (Tjong Kim Sang, 2002)[1] and in 2003 for English and German (Tjong Kim Sang and De Meulder, 2003).[2] The data sets contain four types of named entities: persons, locations, organizations and names of miscellaneous entities that do not belong to the previous three types. We use the standard train, dev and test splits defined for these data sets.

We chose these data sets as they are arguably the most popular data sets for performing named entity recognition and are regularly used as benchmarks for this task. We use the data sets in different languages in order to compare the impact of the language on the experimental results, identify if the commonalities and peculiarities for performing *as-you-type* entity recognition in different languages and draw more robust conclusions regarding our task setup.

4.1 Data Analysis

We perform a quantitative analysis of the data sets in order to develop some intuitions about the data in the context of the *as-you-type* experimental setup.

Sentence Length and Tag Distribution First, we study the distribution of sentence lengths. Figure 2 shows that for English, most sentences are very short (under 10 tokens) and the most frequent sentence length is two. These are expected to pose problems in the as-you-type scenario, as the context is limited. German sentences are slightly longer, while the Spanish sentences are longest, except for a spike of sentences of length one.

Figure 3 shows the distribution of entity types in sentences of varying lengths for English. For clarity, we remove MISC tags from this plot as these are infrequent. We observe there are major differences in tag distributions, especially shorter sentences (<5 tokens) containing both more entity tags as well as different tag distributions. For example, almost 30% of locations (B-LOC or I-LOC) are in sentences of length two, which are the most frequent in the English data, while in longer sentences, these are around 5%. Organizations are most frequent in sentences of length between 4 and 7 tokens, while persons are most frequent in sentences longer than 7 tokens.

Token Position and Tag Distribution To further investigate the positional bias of different tags, Fig-

---

[2] https://www.clips.uantwerpen.be/conll2003/ner/

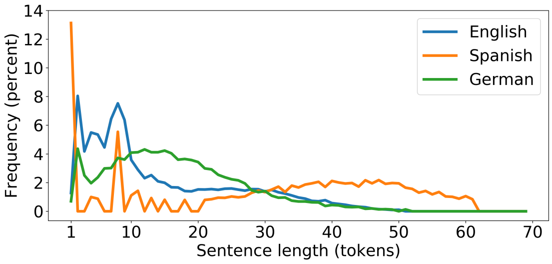

Figure 2: Distribution of sentence lengths.

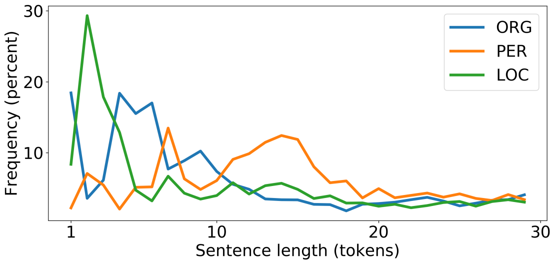

Figure 3: Distribution of entity types in terms of sentence length in the English CoNLL data set.

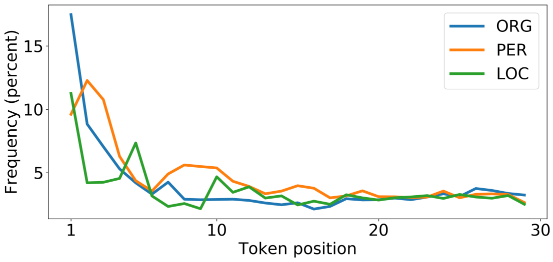

Figure 4: Distribution of entity types at each token position in the English CoNLL data set. B and I tags are merged for the same entity types and removed MISC tags as infrequent for clarity. O tag frequency can be inferred from the rest.

ure 4 shows the distribution of tags in the k-th token of the sentence. We observe that the first tokens of a sentence are much more likely to contain entities. The first position is most likely to be an ORG, with PER being the most frequent in the second to fourth positions, followed by LOC being the most prevalent for the next position, with PER again most frequent in further positions. These observations are likely to complicate the as-you-type inference for named entities, as a higher proportion of tokens will have to be inferred with no or little right context. Comparing Figures 3 and 4 shows that the model will be faced with different tag distributions when inferring the tag for the k-th token in a truncated sentence then to what it has observed in sentences of length k, which provides an intuition for our modelling strategies.

5 Methods

This section describes the methods used to perform named entity recognition in the as-you-type scenario. We use a base neural architecture that achieves state-of-the-art performance on the standard sentence-level NER task. We study its performance and observe the impact of different variants of the architecture in the *as-you-type* scenario. Following, we propose changes to the model to adapt to the as-you-type setup. We use the Flair package to conduct our experiments (Akbik et al., 2019a).[3] Implementation details and hyperparameter choices for all models are listed in the Appendix.

5.1 Base Architecture

We adopt the BiLSTM-CRF model proposed in (Huang et al., 2015) with the addition of character representation (Lample et al., 2016; Ma and Hovy, 2016). In this architecture, the word representations are fed into a bi-directional LSTM, and then the concatenated forward and backward vectors are passed through one layer of feed-forward neural network to produce a $|K|$ dimensional output for each word, where each value represents a score associated with each label. Finally, a Conditional Random Field (CRF) layer is applied to make a global decision for the entire sentence. This has the role of reconciling the independent predictions and modeling the constraints in the output space (e.g. I-PER can not follow B-ORG).

5.2 Architecture Variants

We start with studying different variants of the base neural architecture for the as-you-type scenario. The key challenge in the as-you-type setting is that the model is not presented with the future or right context (words after the current word) at test time. A natural idea is to remove information from this context during training as well. The variants we consider are based on changing the following three modeling components

Embeddings We first study the impact of different ways in which input tokens are represented. Pretrained word embeddings obtained state-of-the-art performance on the NER task when they were introduced (Lample et al., 2016). These representations are used to initialize the word embeddings, are then fine-tuned on the training data and are concatenated

---

[3] https://github.com/zalandoresearch/flair

with a character-level representation of the word obtained using BiLSTMs initialized with random character embeddings.

Contextual word embeddings extend this concept to obtain different word representations for the same token in based on its context. In the standard sentence-level evaluation, contextual word embeddings were shown to obtain 2–3 F_1 points improvement on the English CoNLL data set (Peters et al., 2018; Akbik et al., 2018; Devlin et al., 2019). Without right context, the quality of word representations could be more crucial than in the standard setting. In this study, we test the performance of using classic embeddings – GloVe embeddings for English (Pennington et al., 2014) and FastText embeddings (Bojanowski et al., 2017) for German and Spanish as well as the character based contextual Flair embeddings, which achieve state-of-the-art performance on the English and German CoNLL data sets (Akbik et al., 2018). We also experimented with contextual ELMO embeddings (Peters et al., 2018) which showed slightly lower performance when compared to the Flair embeddings and hence only Flair numbers are reported due to space limitations.

However, contextual embeddings are trained with right context available. We experiment with removing this dependency from the trained embeddings and observe if this improves the performance in the as-you-type setting, as the test scenario is more similar to the training one. We note that right context is never observed in inference beyond the current token such that there is no leakage of information.

BiLSTM Bidirectional LSTM stacks two recurrent neural networks: one starts from the beginning of the sentence, and another starts from the end of the sentence. This performs better than the unidirectional variant on sentence-level experiments and shows that both types of context (left and right) are important for identifying and typing entity mentions. In the as-you-type setting, we compare unidirectional LSTM modelling left context with the bidirectional LSTM model that models both types of contexts in training.

Conditional Random Field The CRF assigns labels for words in a sentence jointly, ensuring label assignments are coherent. When running inference in the as-you-type setting, the model often sees truncated sentences which, as shown in Section 4 may have different label distributions. This discrepancy between training and test sequences may degrade the usefulness of the CRF. We experiment to see if and how the CRF is useful in the as-you-type scenario.

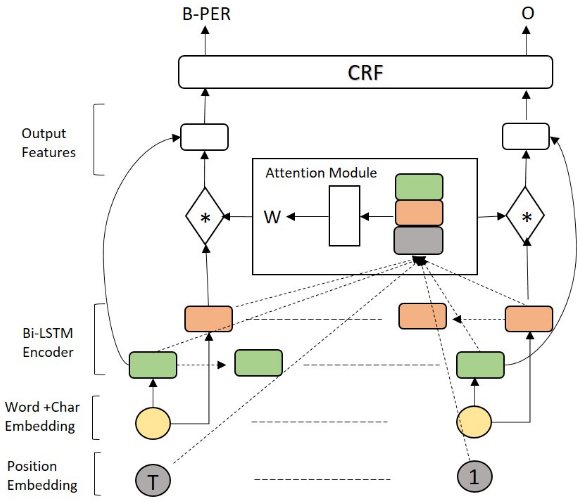

Figure 5: Architecture diagram highlighting the proposed feature weighting method described in Section 5.3.3

5.3 Model Adaptations for the As-you-type Setup

The as-you-type experimental setup presents the model with a new type of evaluation, which does not correspond to the one used in training. We thus propose the following approaches to bridge the gap between the setup and how the model is trained.

5.3.1 Weighted Loss

The model only observes the partial backward context for the tokens in the sequence during the as-you-type inference. In training, since the model has access to the entire sequence, it is likely that the model becomes too dependent on the presence and reliability of the backward features, especially for predicting the initial tokens.

In order to bias the model to be more robust to the absence or unreliable backward context, we design a new loss function that combines the original BiLSTM-CRF loss with the loss from the unidirectional LSTM features. From the latter loss, we also remove the influence of CRF as it also captures signal from the right context and, for contextual embeddings, remove the backward embeddings from the input to the LSTM. The resulting loss is:

$$L_{\text{weighted}} = L_{\text{BiLSTM-CRF}} + w * L_{\text{LSTM-NoCRF}}$$

where w is a weight treated as a hyper-parameter in our experiments.

5.3.2 Final Token Representation

The final token in a training sequence is treated in a special way in the base model. First, a stop tag is regularly used to capture the information associated with a the last token in the sequence. Secondly, the backward features for the final token in a sequence are not observed, as there is no right context, so these are initialized with a random vector. While both are useful in the regular setup as it captures a consistent pattern the final words follow, this does not hold for the as-you-type setup, where each token in a sequence will be the final token for its prediction, as partial sequences are observed.

We thus assume these choices add noise in our setup, thus we both remove the stop tag together with any transition scores to it during training and evaluation and remove the backward feature of the last token and initialize it with a zero vector.

5.3.3 Feature Weighting

The previous approach relied on the intuition of learning the trade-off between forward and backward features in order to better adapt to the inference setup. However, this trade-off is likely impacted by the position of the token in the sequence.

Thus, we explore a technique similar to (Moon et al., 2018) that allows the model to learn the importance of backward features based on the position of tokens. The is illustrated in Figure 5. We implement this using position based attention weights. We apply these weights before combining the forward and backward features (instead of concatenating) from the LSTMs as follows:

$$h_t = h_t^f + a_t * h_t^b$$

where t is the position of the token, h_t^f and h_t^b are forward and backward LSTM features at t, h_t is the new output feature at t and a_t is the attention weight for the backward features at position t. The attention weights a_t are computed as follows:

$$u_t = [h_t^f; h_t^b; p_t]; a_t = \sigma(W.u_t + b)$$

At every position t, the feature vector is calculated by concatenating the forward, backward and the positional embedding for that token. Attention weight a_t is calculated by applying attention weight matrix W followed by the sigma activation. We do not apply a_t for forward features since they are always complete and reliable even for partial sentences.

We follow the structure of positional embeddings introduced in (Vaswani et al., 2017) and defined as:

$$p_t^{2i} = sin(\frac{t}{10000^{2i/d}}); p_t^{2i+1} = cos(\frac{t}{10000^{2i/d}})$$

where d is the size of positional embedding, i is the dimension and t is the position. The values in a positional embedding are sin and cosine functions whose period is $10000^{2i/d} * 2\pi$. Positional sinusoidal embedding allows to encode longer sequences that are not present in training.

Since the right hand side context decreases as we move from left to right of a sequence in training, we would like our attention weights to consider how far a token lies from the final token in a sequence. To achieve this, we calculate position index of tokens from the end of the sentence which makes sure that a token lying at the final position always receives an index of 0, producing the same positional embedding and the input to attention weights does not fluctuate from one sequence to another.

5.3.4 Embedding Weighting

We perform a similar operation using attention at the embedding stage to trade-off between backward and forward contextual token representations. The input embeddings are calculated as follows:

$$x_t = e_t^w + e_t^f + a_t^e * e_t^b$$

$$v_t = [e_t^w; e_t^f; e_t^b; p_t]; a_t^e = \sigma(W_e.v_t + b_e)$$

where e^w are the classical word embeddings and e^f, e^b are Flair forward and backward embeddings. An architecture diagram is presented in the Appendix.

6 Results

We present the experimental results of the various NER models in the as-you-type setup, contrasting them with the regular sentence-level setup. All models are trained using the standard splits for the CoNLL data sets. The evaluation metric is token-level micro F_1, as this is reflective of our evaluation setup where each token is evaluated separately.

The top section of Table 1 shows the results of the different variants of the base architecture in Section 5.2. The overall performance drop in the as-you-type setup compared to the sentence-level setup ranges from 4.80 F1 for English to only 1.53 F1 for Spanish when comparing the best performing models. This is expected, as the as-you-type scenario is more challenging, especially for English where our data analysis from Section 4.1 showed that tokens are more prevalent in short sentences which are overall more frequent. For Spanish, where the performance difference is smallest, is where we have on average the longest sentences and in which left context alone is in most cases enough to make the correct inference.

Table 1: Evaluation results of LSTM-based NER models in the as-you-type and sentence-level evaluation setups as measured using token-level micro F_1. Arrows indicate if uni- (→) or bi-directional (⇆) training is used. Models with the best results across their setup are in **bold**. Best results within the class of methods are underlined. For classic word embeddings, we use GloVe for English, and FastText for German and Spanish. Results are averaged across three runs.

We note that in all three data sets, the best results in the as-you-type setting are obtained by matching the training setup to that of testing by only keeping a uni-directional LSTM that processes the text left to right and Flair embeddings only trained using left context. Flair embeddings trained only using left context are in all cases better than the bi-directional ones, which is natural as those embeddings would conflate information that is not available in inference. Uni-directional LSTMs perform overall better than bi-directional LSTMs by an average of a few percentage points as bi-directional LSTMs are likely learning information that will not be available in testing.

Adding the CRF hurts performance in all except one case when holding everything else constant, sometimes by wide margins (e.g. 5.3 F1 drop on Spanish with Flair forward embeddings and uni-directional LSTM). We attribute this to the mismatch between the structure of the sequences in the training data containing only full sentences, when compared to truncated sentences which can be observed by comparing Figures 3 to Figures 4.

The bottom section of Table 1 shows the results of our as-you-type adaptation strategies. All proposed methods are added on top of each other in order to study their individual contributions. For brevity, we only present the results of using Flair forward and backward embeddings as these performed best.

The changes to the last token representation and weighted loss improves on the regular bi-directional LSTM model by a substantial margin, adding between 0.45 for Spanish up to 4.25 F1 on English on the as-you type setup performance. We also notice that the sentence-level evaluation is near to the regular model performance (-0.39 for German to +0.05 for Spanish), showing that the weighted loss is able to achieve a good compromise between the representations.

Adding the feature weighting based on position marginally improves performance, between 0.02 on German to 0.21 on English. However, the weighting through attention is more effective at the embedding level improving on the previous model by between 0.19 F1 on English to 1.01 F1 on German. Overall, our as-you-type adaptation methods improve on the best variation of the base architecture on English (+0.45 F1) and German (+0.83 F1). The model is competitive on Spanish (-0.12 F1) to the Flair forward unidirectional LSTM with no CRF, albeit this is likely driven by the very long average sentence length in the Spanish data set (see Figure 2). Overall, the improvements represent between 9.3% - 23% error reduction when comparing to the best as-you-type and sentence level setups.

We highlight that an additional benefit of the proposed adaptation methods is that the model retains high performance on the sentence-level setup, in contrast with the Flair forward uni-directional LSTM, which performs between 1.89 (Spanish) and 4.34 (English) worse on the sentence-level.

Finally, the results of our proposed model are actually marginally better than the state-of-the-art approach of BiLSTM+CRF using Flair embeddings on German (+0.45 F1) and Spanish (+0.73 F1), albeit this was not the original goal of our additions. This highlights that the proposed modelling ideas are more generally beneficial as they push the model to learn more robust representations.

7 Error Analysis

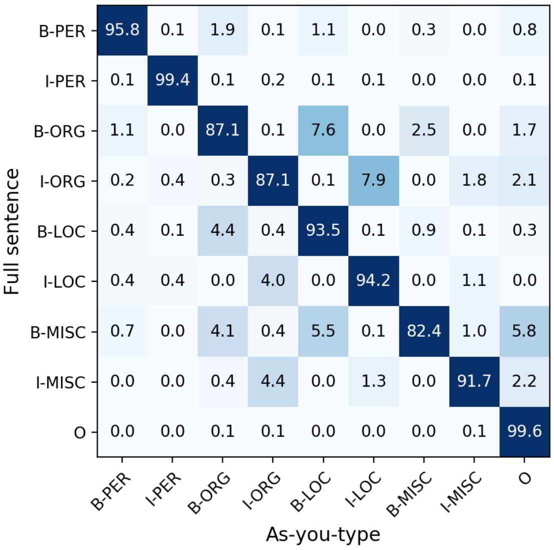
Finally, we perform error analysis to identify the limitations of our approaches.

7.1 Confusion Matrix

We first study prediction difference between as-you-type and sentence-level setup. Figure 6 shows the confusion matrix on the English data set. Both models are BiLSTM-CRF with Flair embeddings, but the as-you-type model is trained with the best setting from Table 1. We can see that most confusions are between LOC and ORG: 7.9% of I-ORG tokens in the full-sentence setting are classified as I-LOC in the as-you-type setting, and 7.6% of B-ORG tokens are classified as B-LOC. Without right context, it is very challenging to distinguish these two types. For example, the data set contains many sport teams that contain location name tokens. Another noticeable difference is that the as-you-type model makes more O predictions. For instance, 5.8% of B-MISC are classified as O. This can be due to the limited availability of cues for identifying entities when right context is missing.

7.2 Positional Prediction

We expect that the size of the context impacts the quality of the inference more acutely in the as-you-type scenario when compared to the sentence-level setup. Figure 7 plots the predictive performance of three English models across each token's position. This confirms our intuition that the as-you-type setup especially impacts prediction on the first tokens in a sentence, which are more entity rich as shown in Section 4.1. However, we see that there is still a difference compared to the standard NER setup (blue curve) across all positions, confirming that indeed the right context can add more information regardless of the position of the token. The plot also highlights the performance gains of our adaptation methods at the first tokens when compared with the BiLSTM-CRF model evaluated in the as-you-type setting (orange curve).



Full sentence \ As-you-type	B-PER	I-PER	B-ORG	I-ORG	B-LOC	I-LOC	B-MISC	I-MISC	O
B-PER	95.8	0.1	1.9	0.1	1.1	0.0	0.3	0.0	0.8
I-PER	0.1	99.4	0.1	0.2	0.1	0.1	0.0	0.0	0.1

Figure 6: Confusion matrix of tag type prediction when comparing the best as-you-type and sentence-level models.

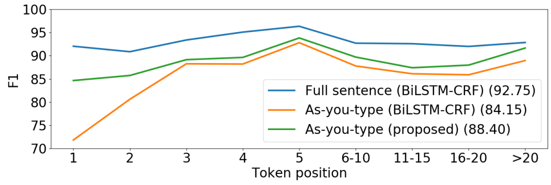

Figure 7: F_1 scores at various token positions averaged across all the sentences in the English data set. The overall performance of each model is listed in the legend.

7.3 Delayed Entity Prediction

Based on the previous results and examples, we want to study the impact of delaying the entity decision by one token. This would account for cases where the first entity word is ambiguous and also reduce the number of invalid sequences that can be produced by the as-you-type inference. For example, in the case of the 'Zimbabwe Open' entity, if the model predicted the tag of the token 'Zimbabwe' as B-LOC and after seeing the next token ('Open'), it revises this token's prediction as I-MISC, it is unable to change the B-LOC tagging, thus creating an invalid sequence, but still obtains partial credit on the token F_1 score. Delaying the decision of the first token could have allowed the model to correct its decision for the first token ('Zimbabwe') to B-MISC, resulting in a valid and more accurate sequence.

We study the possibility of delaying the prediction of a single token (not multiple tokens) by using

	English		German		Spanish	
Thr.	Tok%	F_1	Tok%	F_1	Tok%	F_1
0	0%	88.4	0%	81.62	0%	87.72
0.6	0.77%	89.18	0.97%	82.65	0.66%	88.20
0.7	1.28%	89.56	1.65%	83.09	1.15%	88.47
0.8	2.17%	90.05	2.43%	83.74	1.80%	88.66
0.9	3.25%	90.53	3.61%	84.01	2.80%	88.64
1.0	100%	91.20	100%	84.22	100%	88.91
Full sentence		92.75		84.32		89.43

Table 2: Results of the proposed wait-one policy. If the probability of prediction is less than or equal to the given threshold (Thr. column), we wait for one more token and predict again. The column Tok% indicates percentage of tokens which have a delayed prediction. The best performing model in the as-you-type setup is used. The performance of the best full-sentence model is listed in the last row for comparison purposes.

a threshold on the tag output. Table 2 shows the results of several threshold values and their impact on the total F_1.

We observe that if we delay prediction by one token for all tokens (Thr $= 1.0$), the performance is very close to the best full-sentence model, obtaining an error reduction rate of 64% (1.55 compared to 4.35) for English. Moreover, we can obtain a 50% reduction rate by only delaying the decision on 3.25% of the tokens if the downstream application deems this acceptable. These results highlight the importance of the immediate right context.

8 Untyped Entity Detection

Named entity recognition combines two different components: entity detection – identifying the named entity spans – and typing – identifying entity types. We study the impact of typing in the as-you-type setup by removing the typing information from the output labels ($E = \{\text{ENT}\}$), thus reducing the output space to $K = \{\text{B-ENT, I-ENT, O}\}$.

Results using the best as-you-type models with and without as-you-type adaptations are shown in Table 3. Comparing with the numbers in Table 1, the untyped F_1 score of as-you-type setting is much closer to the standard sentence-level evaluation, being within 1 point of F_1 for all languages. This highlights that the challenging part of the as-you-type setting is entity typing. For example, 'Zimbabwe' is a location on its own, but 'Zimbabwe Open' is an event (MISC entity type) while 'West' is usually indicative of a first location token (e.g. 'West Pacific'), but can also refer to an organization (e.g. 'West Indies' when referencing the cricket team). The proposed technique results are in this case less conclusive, which is somewhat expected as the differences in entity frequencies between full sentences and truncated sentences are smaller.

	Sentence	As-you-type	
		Original	Embedding weighting
English	97.49	97.11	97.09
German	91.37	89.29	89.49
Spanish	97.70	97.05	96.96

Table 3: Entity identification performance. The four entity types are collapsed into one type when computing token-level F_1 scores. The model for "Embedding weighting" is BiLSTM-CRF with bidirectional Flair embeddings for all three languages. For the "Original" setting, we use forward LSTM with forward Flair embeddings.

9 Conclusions

This paper introduced and motivated the as-you-type experimental setup for the popular NER task. We presented results across three different languages, which show the extent to which sentence-level state-of-the-art models degrade in this setup. Through insights gained from data analysis, we proposed modelling improvements to further reduce the gap to the regular sentence-level performance. Our error analysis highlights the cases that pose challenges to the as-you-type scenario and uncovers insights into way to further improve the modelling of this task.

This setup is tailored for end-applications such as text editors, speech-to-text, machine translation, auto-completion, or auto-correct. For text editors, the editor would be able to receive suggestions for entities inline, right after they type the entity, which can further be coupled with a linking algorithm. This would increase the user experience and efficiency of the editor, as they can make selections about entities inline (similar to a phone's autocorrect), rather than having to go back over the entire sentence after it was completed.

Another avenue of future work would be to couple the NER as-you-type with ASR data and using methods that adapt NER to noisy ASR input (Benton and Dredze, 2015) for building an end-to-end live speech to entities system.

A Appendices

A.1 Implementation and Hyperparameters

To train our models we use Stochastic Gradient Descent with a learning rate of 0.1 and mini batch size of 32. The LSTM model includes 1 layer of LSTM with hidden state size 256. We also employ a dropout of 0.5 for the LSTM layer. For the positional embeddings, the dimension d is set as 100 for feature weighting and 1000 for embedding weighting. We tried different dimensions between 100 and 2000. w for weighted loss is identified as 1.5 for English and 1 for German and Spanish from the dev set. For W we considered values between 0 and 2. All the models are trained for 70 epochs and the best model is selected based on the token-level F-1 score[4] on dev set. We perform manual hyperparameter selection and the final performance is reported based on the 5-10 runs of the best hyperparameter setting.We use Flair's standard settings for English.

All the models are trained on nvidia GPU and overall training for 70 epochs takes around 5-6 hours. This run-time complexity is very close to the complexity achieved by the the Flair implementation for standard NER training.

Numbers reported in (Akbik et al., 2018) are generated by training models on combined train and dev sets, hence they are higher than the numbers we report when training only on the training data. We also report token-level F1, rather than entity-level F1, which leads to results that are not directly comparable with (Akbik et al., 2018).

A.2 Visualization of Attention Weights

To better understand the impact of positional attention weights, we visualize and compare the feature-level attention weights for different tokens on a few hand-picked English sentences. Figure 8 highlights tokens using different color intensities. Higher intensity represents a larger weight value and hence a stronger influence of backward context. First, it is evident that tokens in the first position rely more heavily on backward features in the absence of any forward context, which is further reflected in the higher attention weights achieved by these tokens. Moreover, first tokens of multi-token entities such as Persons ('Nabil Abu Rdainah'), Organizations ('NY Rangers') and Events ('Zimbabwe Open') are assigned larger weights due to a high influence of immediate next tokens. Also, quite often the last token in the sentences are weighted lower which can be attributed to the positional information captured by the attention weights.

A.3 Performance on Dev Set

To facilitate reproducibility of results, Table 4 reports the development set performance of the base model (Bi-LSTM CRF Flair) and the proposed model for both as-you-type and sentence level setups.

A.4 Parameters

Table 5 lists different trainable parameters used in the model along with their sizes.

SANDI: Story-and-Images Alignment

Sreyasi Nag Chowdhury **Simon Razniewski** **Gerhard Weikum**
Max Planck Institute for Informatics, Saarbrücken, Germany
`(sreyasi, srazniew, weikum)@mpi-inf.mpg.de`

Abstract

The Internet contains a multitude of social media posts and other stories where text is interspersed with images. In these contexts, images are not simply used for general illustration, but are judiciously placed in certain spots of a story for multimodal descriptions and narration. In this work we analyze the problem of text-image alignment, and present SANDI, a methodology for automatically selecting images from an image collection and aligning them with text paragraphs of a story. SANDI combines visual tags, user-provided tags and background knowledge, and uses an Integer Linear Program to compute alignments that are semantically meaningful. Experiments show that SANDI can select and align images with texts with high quality of semantic fit.

1 Introduction

It is well-known (and supported by studies Lester (2013); Messaris and Abraham (2001)) that the most powerful messages are delivered with a combination of words and pictures. On the Internet, such multimodal content is abundant in the form of news articles, social media posts, and personal blog posts where authors enrich their stories with carefully chosen and placed images. As an example, consider a vacation report, to be posted on a blog site or online community. The backbone of the travel report is a textual narration, but the user typically places illustrative images in appropriate spots, carefully selected from her photo collection from this trip. These images can either show specific objective highlights such as waterfalls, mountain hikes or animal encounters, or may serve to depict the thematic mood of the trip, e.g., by showing nice sunsets. Another example is brochures for various organizations. Here, the text describes the mission, achievements and ongoing projects, and is accompanied with judiciously selected and placed photos of buildings, people, products and images depicting the subjects of interest, e.g., galaxies or telescopes for research in astrophysics.

Figure 1: The story-and-images alignment problem.

The generation of such multimodal stories requires substantial human judgement and reasoning, and is thus time-consuming and labor-intensive. In particular, the effort on the human side includes selecting the right images from a pool of story-specific photos (e.g., the traveler's own photos) and possibly also from a broader pool for visual illustration (e.g., from Pinterest). Even if the set of photos were exactly given, there is still considerable effort to place them within appropriate paragraphs, paying attention to the semantic coherence between surrounding text and image. In this paper, we set out to automate this human task, formalizing it as a *Story-AND-Images (SANDI) alignment* problem.

Problem Statement. Given a story-like text document and a set of images, the problem is to automatically decide where individual images are placed in the text. Figure 1 depicts this task. The problem comes in different variants: either all images in the given set need to be placed, or a subset of given cardinality must be selected and aligned with text paragraphs. Formally, given n paragraphs and $m \geq n$ images, assign $b \leq n$ of these images to a subset of the paragraphs, such that each paragraph has at most one image.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 989–999
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

Prior Work and its Inadequacy. There is ample literature on computer support for multimodal content creation, most notably, on generating image captions. Closest to our problem is work on *Story Illustration* (Joshi et al., 2006; Schwarz et al., 2010) where the task is to select illustrative images from a large pool. However, the task is quite different from ours, making prior approaches inadequate for the setting of this paper. First, unlike story illustration, we need to consider the text-image alignments jointly for all pieces of a story, rather than making context-free choices one piece at a time. Second, prior work assumes that each image in the pool has an informative caption or set of tags, by which the selection algorithm computes its choices. Our model harnesses visual tags from deep neural network based object-detection frameworks and incorporates background knowledge, as automatic steps to enrich the semantic interpretation of images.

Our Approach – SANDI. We present a framework that casts the story-images alignment task into a combinatorial optimization problem. The objective function, to be maximized, captures the semantic coherence between each paragraph and the co-located image. To this end, we consider a suite of features – the visual tags associated with an image (automatically detected tags as well as user-defined tags when available), text embeddings, and also background knowledge. The optimization is constrained by the number of images that the story should be enriched with. As a solution algorithm, we devise an integer linear program (ILP) and employ the Gurobi ILP solver for computing the exact optimum. Experiments show that SANDI produces semantically coherent alignments. A demonstration of SANDI (Nag Chowdhury et al., 2020) can be viewed at `https://youtu.be/k5gu2pNxdNU`.

Contributions. To the best of our knowledge, this is the first work to address story-images alignment. Our salient contributions are:

1. We introduce and define the problem of story-images alignment.
2. We analyze two real-world datasets of stories with rich visual illustrations, and derive insights on alignment decisions and quality measures.
3. We devise relevant features, formalize the alignment task as a combinatorial optimization problem, and develop an exact-solution algorithm using integer linear programming.
4. We compare our method against baselines that use multimodal embeddings.

2 Related Work

Existing work on associations between text and images can be categorized into the following areas.

Image Attribute Recognition. High level concepts in images lead to better results in Vision-to-Language problems (Wu et al., 2016). Traditionally image tagging was based on community input (Gupta et al., 2010). Modern deep-learning based tools detect objects (Hoffman et al., 2014; Redmon and Farhadi, 2017; Ren et al., 2015) and scenes (Zhou et al., 2014) in images. Inter-concept incoherence can also be refined using background knowledge (Nag Chowdhury et al., 2018). We leverage some frameworks from this category in our model to detect visual concepts in images.

Story Illustration. Prior work finds suitable images from annotated image collections to illustrate personal stories (Joshi et al., 2006; Ravi et al., 2018) or news posts (Schwarz et al., 2010; Delgado et al., 2010). The results are presented as clusters of related images (Guan et al., 2011), or an illustrated article (Jhamtani et al., 2016). Story illustration only addresses the problem of image selection, whereas we solve two problems simultaneously: image selection and image placement – making a joint decision on all pieces of long complex stories. This makes our problem distinct. There is no way to systematically compare our full-blown model with prior works on story illustration alone.

Multimodal Embeddings. A popular method of semantically comparing images and text has been to map textual and visual features into a common space of multimodal embeddings (Frome et al., 2013; Vendrov et al., 2016; Faghri et al., 2018; Wu et al., 2019; Wang et al., 2019; Liu et al., 2019). Visual-Semantic-Embeddings (VSE) has been used for generating captions for whole images (Faghri et al., 2018), or to associate text with image regions (Karpathy and Li, 2015). Color, geometry, aspect-ratio have been used to align image regions to nouns (“chair”), attributes (“big”), and pronouns (“it”) in corresponding text (Kong et al., 2014). Recent work train on document-level co-occurrences and predict links between images and sentences in a document (Hessel et al., 2019; Chu and Kao, 2017). However, alignment of small image regions to text snippets or linking images to single sentences play little role in jointly interpreting the correlation between images and a larger body of text. We focus on the latter in this work.

(b) Sample image and paragraph from Asia Exchange

Figure 2: Text-image pairs from our datasets.

Image Caption Generation. Most prior works generate factual captions (Xu et al., 2015; Tan and Chan, 2016; Lu et al., 2017; Wang et al., 2018), while some recent architectures venture into producing stylized captions (Gan et al., 2017) and stories (Zhu et al., 2015; Krause et al., 2017). An image caption can be considered as a precise focused description of an image without much superfluous or contextual information. However, in a multimodal story, the paragraphs surrounding an image contain detailed thematic descriptions. We try to capture the thematic indirection between an image and surrounding text, thus making the problem distinct.

Commonsense Knowledge for Story Understanding. One of the earliest applications of Commonsense Knowledge (CSK) to interpret text-image associtions is a photo agent which automatically annotated images from user's multi-modal (text-image) emails or web pages, while also inferring additional CSK concepts (Lieberman and Liu, 2002). Subsequent works used CSK reasoning to infer causality in stories (Williams et al., 2017). We enhance automatically detected objects and scenes in image with relevant CSK concepts from ConceptNet (Speer et al., 2017). This often helps to capture more context about an image.

3 Dataset and Problem Analysis

3.1 Dataset

To the best of our knowledge, there is no experimental dataset for text-image alignment. We therefore compile two datasets from two blogging sites:

- Lonely Planet[1]: 2178 travel stories containing 20 paragraphs and 4.5 images per story. Most images are accompanied by captions. The images come from the author's personal archives and adhere strictly to the content of the story.
- Asia Exchange[2]: 200 stories about education opportunities in Asia, with 13.5 paragraphs and 4 images per story. Some stories contain generic stock images complying with the abstract theme. Most images have captions.

Figure 2 shows image-paragraph examples from the datasets.

Text-Image Semantic Coherence. To understand human judgments behind text-image pairing, we analyze 50 randomly chosen images and their corresponding paragraphs from the Lonely Planet dataset. We identify six possibly overlapping concept classes that appear in images as well as in their corresponding paragraphs: (i) natural named objects such as Mt. Everest (ii) human activities such as biking (iii) generic objects such as cars (iv) general nature scenes such as forest (v) specific man-made entities such as monuments (vi) geographic locations such as Rome. The outcome of this analysis is shown in Table 1.

Concept Classes	% of text-images pairs with shared concepts
Natural named objects	9%
Human activities	12%
Generic objects	15%
General nature scenes	20%
Man-made named objects	21%
Geographic locations	29%

Table 1: Reasons for text-image semantic coherence.

3.2 Image Tags

Based on the analysis in Table 1, we consider the following kinds of tags for describing images:

Visual Tags (CV). We use three state-of-the-art computer-vision methods for object and scene detection. First, deep convolutional neural networks based architectures like LSDA (Hoffman et al., 2014) and YOLO (Redmon and Farhadi, 2017), are used to detect objects like *person*, *frisbee* or *bench*, that denote "Generic objects" from Table 1.

---

[1] www.lonelyplanet.com/blog

[2] www.asiaexchange.org

For stories, general scene descriptors like *restaurant* or *beach* play a major role, too. Therefore, our second asset is scene detection from the MIT Scenes Database (Zhou et al., 2014). These constitute "General nature scenes" from Table 1. Thirdly, since stories often abstract away from explicit visual concepts, a framework that incorporates abstractions into visual detections – VISIR (Nag Chowdhury et al., 2018) – is also leveraged. For e.g., the concept "hiking" is supplemented with the concepts "walking" (Hypernym of "hiking" from WordNet) and "fun" (from ConceptNet (Speer et al., 2017) assertion ⟨ *hiking, has property, fun*⟩).

User Tags (MAN). Owners of images often have additional knowledge about content and context – for e.g., activities or geographical information ("hiking near Lake Placid"), which, from Table 1 play a major role in text-image alignment. For experiments, we use nouns and adjectives from image captions from our datasets as user tags. In downstream applications, images can be selected either from web repositories or from a personal collection. In the former case, explicit tags or words from captions/titles serve as user tags. In the latter case, location details like names of places can be easily inferred from metadata like GPS coordinates associated with "raw" phone/camera images.

Big-data Tags (BD). Big data and crowd knowledge allow to infer additional context that may not be visually apparent. We utilize the Google reverse image search API[3] to incorporate such tags. This API allows to search by image, and suggests tags based on visually similar images in the vast web image repository. These tags depict popular places, such as "Savarmati Ashram", or "Mexico City insect market", and thus constitute "Natural names objects", "Man-made named objects", as well as "Geographic locations" from Table 1.

To further improve the semantic characterization of an image, we extend the tag set of an image by related commonsense knowledge concepts.

Commonsense Knowledge (CSK). CSK can bridge the gap between visual and textual concepts (Nag Chowdhury et al., 2016). CV, BD, and MAN tags are enriched with CSK from the following ConceptNet relations – *used for, has property, causes, at location, located near, conceptually related to*. E.g., for the left image in Figure 3, we add CSK concept "show talent" from CV tag "stage" from the assertion ⟨stage, *used for*, show talent⟩. CSK concepts cover multiple classes from Table 1. Owing to the noise and subjectivity in ConceptNet, only concepts which are informative for a given image are retained. If the top-10 web search results of a CSK concept are semantically similar to the image tags (CV/MAN/BD), the CSK concept is considered to be *informative* for the image. Cosine similarity between the mean vectors (from word2vec) of the image context and the search results is used as a measure of semantic similarity.

Figure 3 shows examples of the image tags. In use cases all features are not always available – user tags may not exist or may not be retained during web distribution, big data requires access to paid APIs , and visual tags are error-prone. We will thus study the features in isolation and jointly.

CV: person, sunglasses, stage
MAN: Globe Theatre
BD: Shakespeare's Globe
CSK: show talent, attend concert, entertain audience

CV: terra cotta, village
MAN:tiled rooftops
BD: Languedoc Roussillon
CSK: colony, small town

Figure 3: Types of image tags. CV – visual objects/scenes, MAN and BD – nuanced descriptions, locations, CSK - high-level thematic concepts.

4 Model for Story-Images Alignment

Our *story-image alignment* model constitutes an Integer Linear Program (ILP) which jointly optimizes the placement of selected images within a story. The main ingredient for this alignment is the pairwise similarity between images and units of text. We consider a paragraph as a text unit.

Text-Image Pairwise Similarity. Given an image, each of the three kinds of descriptors of Section 3.2 gives rise to a bag of features. We use these features to compute *text-image semantic relatedness scores* $srel(i,t)$ for an image i and a paragraph t.

$$srel(i,t) = cosine(\vec{i},\vec{t}) \tag{1}$$

where $\vec{i}$ and $\vec{t}$ are the mean word embeddings for the image tags and the paragraph respectively. For images, we use all detected tags. For paragraphs, we consider only the top 50% of concepts w.r.t. their TF-IDF ranking over the entire dataset. We use word embeddings from word2vec trained on Google News Corpus. $srel(i,t)$ scores from Equation 1 serve as weights for variables in the ILP.

---

[3] `www.google.com/searchbyimage`

Tasks. Our problem has two distinct tasks: 1. *Image Selection* – to select relevant images from an image pool. 2. *Image Placement* – to place selected images in the story. These two components are modelled into one ILP where Image Placement is achieved by maximizing an objective function, while Image Selection is styled by constraints. In the following subsections we discuss two flavors of our model consisting of one or both the tasks.

4.1 Complete Alignment

Complete Alignment constitutes the problem of aligning *all* images in a given image collection with relevant text units of a story. Hence, only *Image Placement* is applicable. For a story with $|T|$ text units and an associated image album with $|I|$ images, the alignment of images $i \in I$ to text units $t \in T$ can be modeled as an Integer Linear Program (ILP) with the following definitions:

Decision Variables. The following binary decision variables are introduced: $X_{it} = 1$ if image i should be aligned with text unit t, 0 otherwise.

Objective. Select image i to be aligned with text unit t such that the semantic relatedness over all text-image pairs is maximized:

$$max\left[\sum_{i\in I}\sum_{t\in T} srel(i,t)X_{it}\right] \qquad (2)$$

where $srel(i,t)$ is the text-image semantic relatedness from Equation 1.

Constraints. We make two assumptions for text-image alignments – no image may be repeated in the story (Constraint 3), and no paragraph may be aligned with multiple images (Constraint 4). The former is a trivial observation from multimodal presentations on the web such as in blog posts, newswire, brochures. The latter is made based on the nature of our datasets, and it is designed as a hard constraint in order to facilitate a fair evaluation.

$$\sum_{i} X_{it} \leq 1 \forall t \quad (3) \qquad\qquad \sum_{t} X_{it} = 1 \forall i \quad (4)$$

4.2 Selective Alignment

Selective Alignment is the flavor of the model which selects a certain number of thematically relevant images from a big image pool, and places them within the story. Hence, it constitutes both tasks – *Image Selection* and *Image Placement*. Along with the constraint in (3), Image Selection entails the following additional constraints:

$$\sum_{t} X_{it} \leq 1 \forall i \quad (5) \qquad\qquad \sum_{i}\sum_{t} X_{it} = b \quad (6)$$

where b is the budget for the number of images in the story. b may be simply defined as the number of paragraphs in the story, following our assumption that each paragraph may be associated with a maximum of one image. (5) is an adjustment to (4) which implies that not all images from the image pool need to be aligned with the story. The objective function from (2) rewards the selection of best fitting images from the image pool.

5 Quality Measures

In this section we define metrics for automatic evaluation of the text-image alignment problem. The two tasks involved – *Image Selection* and *Image Placement* – call for separate evaluation metrics as discussed below.

5.1 Image Selection

Representative images for a story are selected from a big pool of images. There are multiple conceptually similar images in our image pool since they have been gathered from blogs of the domain "travel". Hence evaluating the results on strict precision (based on exact matches between selected and ground-truth images) does not necessarily assess true quality. We therefore define a relaxed precision metric (based on semantic similarity) in addition to the strict metric. Given a set of selected images I and the set of ground truth images J, where $|I| = |J|$, the precision metrics are:

$$RelaxedPrecision = \frac{\sum_{i\in I, j\in J} max(cosine(\vec{i},\vec{j}))}{|I|} \qquad (7)$$

$$StrictPrecision = \frac{|I \cap J|}{|I|} \qquad (8)$$

5.2 Image Placement

For each image in a multimodal story, the ground truth (GT) paragraph is assumed to be the one following the image in our datasets. To evaluate the quality of SANDI's text-image alignments, we compare the GT paragraph and the paragraph assigned to the image by SANDI (henceforth referred to as "aligned paragraph"). We propose the following metrics for evaluating the quality of alignments:

BLEU and ROUGE. BLEU and ROUGE are classic n-gram-overlap-based metrics for evaluating

	BLEU	ROUGE	SemSim	ParaRank	Order Preserve
RandomAlign	3.1	6.9	75.1	50.0	50.0
VSE++	11.0	9.5	84.6	59.1	55.2
VSE++ ILP	12.6	11.2	84.0	58.1	48.0
SANDI-CV	18.2	17.6	86.3	63.7	54.5
SANDI-MAN	**45.6**	**44.5**	**89.8**	72.5	**77.4**
SANDI-BD	26.6	25.1	84.7	61.3	61.2
SANDI$*$	44.3	42.9	89.7	**73.2**	76.3

Table 2: Complete Alignment: Lonely Planet.

	BLEU	ROUGE	SemSim	ParaRank	Order Preserve
RandomAlign	6.8	8.9	70.8	50.0	50.0
VSE++	19.4	17.7	85.7	51.9	48.0
VSE++ ILP	23.5	20.1	86.0	52.6	46.1
SANDI-CV	21.5	20.6	87.8	58.4	52.0
SANDI-MAN	**35.2**	**32.2**	89.2	61.5	61.5
SANDI-BD	24.1	22.3	86.7	56.0	53.6
SANDI$*$	33.4	31.5	**89.7**	**62.4**	**62.5**

Table 3: Complete Alignment: Asia Exchange.

machine translation and text summarization. Although known to be limited insofar as they do not recognize synonyms and semantically equivalent formulations, they are in widespread use. We consider them as basic measures of concept overlap between GT and aligned paragraphs.

Semantic Similarity. To alleviate the shortcoming of requiring exact matches, we consider a metric based on embedding similarity. We compute the similarity between two text units t_i and t_j by the average similarity of their word embeddings, considering all unigrams and bigrams as words.

$$SemSim(t_i, t_j) = cosine(\vec{t_i}, \vec{t_j}) \tag{9}$$

where $\vec{x}$ is the mean vector of words in x. For this calculation, we drop uninformative words by keeping only the top 50% with regard to their TF-IDF weights over the whole dataset.

Average Rank of Aligned Paragraph. We associate each paragraph in the story with a ranked list of all the paragraphs on the basis of semantic similarity (Eq. 9), where rank 1 is the paragraph itself. Our goal is to produce alignments ranked higher with the GT paragraph. The average rank of alignments by a model is computed as follows:

$$ParaRank = 1 - \left[\left(\frac{\sum_{t \in T'} rank(t)}{|I|} - 1 \right) \Big/ \left(|T| - 1 \right) \right] \tag{10}$$

where $|I|$ is the number of images and $|T|$ is the number of paragraphs in the story. $T' \subset T$ is the set of paragraphs aligned to images. Scores are normalized between 0 and 1; 1 being the perfect alignment and 0 being the worst alignment.

Order Preservation. Most stories either follow a time-line or storyline. Images placed at meaningful spots within the text would ideally adhere to this sequence. Hence the measure of pairwise ordering provides a sense of maintaining or respecting the storyline. It can be defined as the number of order preserving image pairs in the alignment (i_m, i_n) normalized by the total number of ordered image pairs in the ground truth.

$$OrderPreserve = \frac{|(i_m, i_n)|}{(|I|(|I| - 1)/2)} \tag{11}$$

Correlation between Metrics. Table 4 shows the pairwise correlation between our evaluation metrics – BLEU, ROUGE, *SemSim*, *ParaRank*, *Orderpreserve* – computed on a random alignment of images to paragraphs in 100 stories. Not surprisingly, BLEU and ROUGE correlate nearly perfectly, and show reasonable correlation to $SemSim$ and $ParaRank$. $OrderPreserve$ works at a different level and exhibits virtually no correlation to the other metrics. This illustrates that order-preserving alignments are not necessarily semantically meaningful, and vice versa.

	ROUGE	SemSim	ParaRank	Order Preserve
BLEU	0.98	0.32	0.39	-0.23
ROUGE		0.33	0.40	-0.23
SemSim			0.29	0.08
ParaRank				-0.06

Table 4: Correlation between evaluation metrics.

6 Experiments and Results

We evaluate the two flavors of SANDI – *Complete Alignment* and *Selective Alignment* – based on the quality measures from Section 5.

6.1 Setup

Tools. Deep learning based architectures – LSDA (Hoffman et al., 2014), YOLO (Redmon and Farhadi, 2017), VISIR (Nag Chowdhury et al., 2018) and Places-CNN (Zhou et al., 2014) are used as sources of *Visual tags (CV)*. Google reverse image search tag suggestions are used as *Big-data tags (BD)*. We use the Gurobi Optimizer for solving the ILP. A Word2Vec (Mikolov et al., 2013) model trained on the Google News Corpus encompasses a large cross-section of domains, and hence is used as a source of word embeddings.

SANDI Variants. The variants of our text-image alignment model are based on the use of image descriptors described in Section 3.2.

- SANDI-CV, SANDI-MAN, and SANDI-BD use CV, MAN, and BD tags respectively.
- SANDI$*$ combines CV, MAN, and BD tags.

6.2 Complete Alignment

We evaluate our Complete Alignment model (defined in Section 4.1), which places *all* images from a given image pool within a story.

Baselines. To the best of our knowledge, there is no existing work on story-image alignment. Hence we modify methods on joint visual-semantic-embeddings (VSE) (Kiros et al., 2014; Faghri et al., 2018) to serve as baselines, henceforth referred to as VSE++. We compare SANDI with:

- RandomAlign: a simple baseline with random image-text alignments.
- VSE++: for an image, VSE++ is adapted to produce a ranked list of paragraphs from the given story. The top paragraph is considered as an alignment, with a greedy constraint that one paragraph can be aligned to at most one image.
- VSE++ ILP: using cosine similarity scores between image and paragraph from the joint visual-semantic embedding space, we solve an ILP as described in Section 4.

Since there are no existing story-image alignment datasets, VSE++ has been trained on the MSCOCO captions dataset (Lin et al., 2014), which contains 330K images with 5 captions per image.

Evaluation. Tables 2 and 3 show the performance of the baselines and the SANDI variants on the Lonely Planet and Asia Exchange datasets respectively. SANDI outperforms the baselines on all evaluation metrics to various degrees. While VSE++ looks at each image in isolation, SANDI captures context better by considering all text units of the story and all images from the corresponding album at once in a constrained optimization problem. VSE++ ILP, although closer to SANDI in methodology, does not outperform SANDI. This can be attributed to the fact that SANDI is less tied to a particular dataset, relying only on word2vec embeddings that are trained on a much larger corpus than MSCOCO. On Lonely Planet, SANDI-MAN is the best configuration – this is expected since user tags (MAN) contain concepts most specific to the story. SANDI$*$ marginally outperforms it on Asia Exchange – recall that images in this dataset are sometimes generic thematic illustrations, hence a combination of all features capture more context. The consistency of scores across both datasets highlight the robustness of SANDI.

Role of Commonsense Knowledge (CSK). We observe that CSK helps improve performance of SANDI-CV. This is intuitive because CV tags denote only explicit objects and scenes, which do not capture high-level concepts of the images. CSK alleviates this to some extent. For example, in the first image in Figure 3 – CSK (*show talent, attend concert, entertain audience*) appends a more meaningful context to the CV tags (*person, sunglasses, stage*); MAN and BD tags already capture a broader context. Table 5 compares SANDI-CV and SANDI-CV-CSK on Asia Exchange.

	BLEU	ROUGE	SemSim	ParaRank	Order Preserve
SANDI-CV	21.5	20.6	87.8	58.4	52.0
SANDI-CV -CSK	19.9	19.4	**88.3**	**62.4**	50.0

Table 5: Role of Commonsense Knowledge: Asia Exchange

6.3 Selective Alignment

This variation of our model, as defined in Section 4.2, solves two tasks – *Image Selection* and *Image placement*.

6.3.1 Image Selection

Setup. In addition to the setup described in Section 6.1, some additional requirements are:

- Image pool – We pool images from stories in our dataset. Since stories from a particular domain (e.g. travel blogs) are largely quite similar, images in the pool may also be very similar in content – e.g., stories on *hiking* contain images containing *mountain, person, backpack*.
- Image budget – For each story, the number of images in the ground truth is considered as the image budget b (Equation 4.2).

Baselines. We compare SANDI with:

- RandomAlign: a baseline of randomly selected images from the pool.
- NN: nearest neighbors from a common embedding space of images and paragraphs. Images are represented as mean vectors of their tags, and paragraphs are represented as mean vectors of their distinctive words. The basic word vectors are obtained from Word2Vec trained on Google News Corpus.

Tag Space	Precision	Random	NN	VSE++	SANDI
CV	*Strict*	0.4	2.0	1.14	**4.18**
	Relaxed	42.16	52.68	29.83	**53.54**
MAN	*Strict*	0.4	3.95	-	**14.57**
	Relaxed	37.14	42.73		**49.65**
BD	*Strict*	0.4	1.75	-	**2.71**

Table 9: Selective Alignment-Image Placement:Asia Exchange.

- VSE++: a joint visual-textual embeddings method presented in (Faghri et al., 2018) is adapted to retrieve the top-b images for a story.

Evaluation. We evaluate *Image Selection* by the measures in Section 5.1. Table 6 shows the results for SANDI and the baselines on a pool of 500 images from Lonely Planet. NN and SANDI both use Word2Vec for text-image similarity. SANDI's better scores are attributed to the joint optimization over the entire story, as opposed to greedy selection in case of NN. VSE++ uses a joint text-image embeddings space for similarity scores. Our evaluation metric $RelaxedPrecision$ (Eq. 7) factors in the semantic similarity between images based on the image descriptors (Section 3.2). Hence we compute results on the different image tag spaces, where '∗' refers to the combination of CV, MAN, and BD. The baseline VSE++ however, operates only on visual features; hence we report its performance only for CV. Results on Asia Exchange are similar (Table 7). Recall from Section 3.1 that the Asia Exchange dataset often has stock images for generic illustration rather than only story-specific images. Hence the average relaxed precision on image selection is comparitively higher. Figure 4 shows image selection results for one story. The original story contains 17 paragraphs; only the main concepts from the story have been retained for readability. SANDI is able to retrieve 2 ground-truth (GT) images out of 7, while the baselines retrieve 1 each. Note that SANDI's non-exact matches are thematically similar to GT – images in the 4th column of both GT and SANDI feature a yellow train in a backdrop of mountains, images in the 5th column show sunset. This can be attributed to the wider space of concepts that SANDI explores through the image tags from Section 3.2.

6.3.2 Image Placement

Having selected thematically related images from a big image pool, SANDI places them within contextual paragraphs of the story. Note that SANDI integrates the *Image Selection* and *Image Placement* stages into joint inference on selective alignment, whereas the baselines operate in two steps.

We evaluate the alignments by the measures from Section 5.2. Note that the measure *OrderPreserve* does not apply to Selective Alignment since the images are selected from a pool of mixed images which cannot be ordered. From Table 8 and 9 we observe that SANDI outperforms the baselines by a clear margin, harnessing its more expressive pool of tags. We show anecdotal evidence of the diversity of our image tags in Figure 3 and Table 10.

6.4 Role of Model Components

Image Descriptors. The wide variety of image tags that SANDI leverages (CV, BD, MAN) capture special characteristics of the images. These are unavailable to baselines such as VSE++, attributing to their poor performance.

Embeddings. The nature of embeddings is decisive towards alignment quality. Joint visual-semantic-embeddings trained on MSCOCO (used by VSE++) fall short in capturing high-level se-

Story: Clatter into Lisbon's steep Alfama aboard a classic yellow tram...Ride a regular bus for view of the metropolis...Venice ...opting for a vaporetto (water taxi) instead of a private punt...Hungary. Trundle alongside the Danube...Castle Hill... Istanbul...Ferries crossing the Bosphorus strait...Sail at sunset...Monte Carlo's electric-powered ferry boats...The 'Coast ...Tram' skirts...Belgium's North Sea shoreline...Pretty but pricey Geneva...travel on buses, trams and taxi-boats.

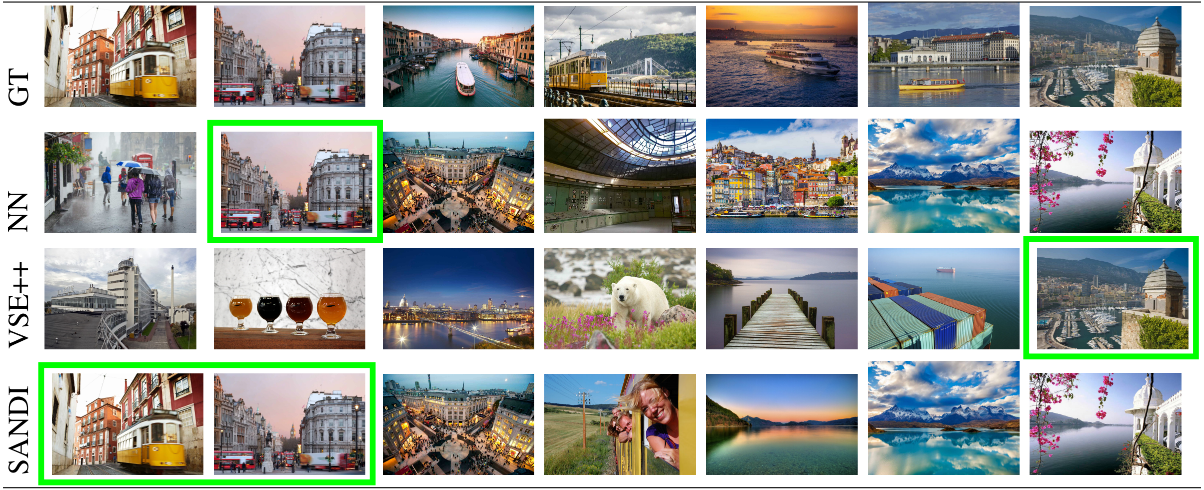

Figure 4: Image Selection. Images within green boxes are exact matches with ground truth (GT). SANDI retrieves more exact matches than the baselines (NN, VSE++). SANDI's non-exact matches are also much more thematically similar to the GT.

Image and detected concepts	SANDI-CV	SANDI-MAN	SANDI-BD
 CV: snowy mountains, massif, alpine glacier, mountain range MAN: outdoor lover, New Zealand, study destination, BD: New Zealand	New Zealand produced the first man to ever climb Mount Everest and also the creator of the bungee-jump. Thus, it comes as no surprise that this country is filled with adventures and adrenaline junkies.	Moreover, the wildlife in New Zealand is something to behold. Try and find a Kiwi! (The bird!) They are nocturnal creatures so it is quite a challenge. New Zealand is also home to the smallest dolphin species. Lastly, take the opportunity to search for the beautiful yellow-eyed penguin.	Home to hobbits, warriors, orcs and dragons. If you're a fan of the famous trilogies, Lord of the Rings and The Hobbit, then choosing New Zealand should be a no-brainer.

Table 10: Example alignments. Highlighted texts show similar concepts between image and aligned paragraphs.

mantics between images and story. Word2Vec embeddings trained on a much larger and domain-independent Google News corpus better represents high-level image-story interpretations.

ILP. As observed in Tables 6 and 7, Combinatorial optimization (SANDI) outperforms greedy optimization approaches (NN), both methods using the same embedding space.

7 Conclusion

In this paper we introduced the problem of story-images alignment – selecting and placing a set of representative images within a story. We analyzed features towards meaningful alignments from real-world multimodal datasets – Lonely Planet and Asia Exchange blogs – and defined various evaluation measures. We presented SANDI, a methodology for automating such alignments by a constrained optimization problem maximizing semantic coherence between text-image pairs jointly for the entire story. Evaluations show that SANDI produces semantically meaningful alignments. Nevertheless, some follow-up questions arise.

Additional Features. Our feature space covers most natural aspects. In addition, GPS locations where available may provide cues for geographic named entities, while timestamps may capture temporal aspects of a storyline.

Abstract and Metaphoric Relations. We do not address stylistic elements like metaphors and sarcasm in text, which would entail more challenging alignments. For example, the text "the news was a dagger to his heart" should not be paired with a picture of a dagger. Although user provided tags may provide some cues towards such abstract relationships, a deeper understanding of semantic coherence is desired.

The proposed text-image alignment system is available at `https://sandi.mpi-inf.mpg.de`, and a video of the demonstration can be viewed at `https://youtu.be/k5gu2pNxdNU`.

Abstract

Ideally Open-Domain Question Answering models should exhibit a number of competencies, ranging from simply memorizing questions seen at training time, to answering novel question formulations with answers seen during training, to generalizing to completely novel questions with novel answers. However, single aggregated test set scores do not show the full picture of what capabilities models truly have. In this work, we perform a detailed study of the test sets of three popular open-domain benchmark datasets with respect to these competencies. We find that 30% of test-set questions have a near-duplicate paraphrase in their corresponding train sets. In addition, we find that 60–70% of answers in the test sets are also present in the train sets. Using these findings, we evaluate a variety of popular open-domain models to obtain greater insight into what extent they can generalize, and what drives their overall performance. We find that all models perform substantially worse on questions that cannot be memorized from train sets, with a mean absolute performance difference of 61% between repeated and non-repeated data. Finally we show that simple nearest-neighbor models outperform a BART closed-book QA model, further highlighting the role that train set memorization plays in these benchmarks.

1 Introduction

Open-domain Question Answering (ODQA) is a task that examines the ability of models to produce answers to natural language factoid questions drawn from an open set of domains. ODQA has received significant attention for its potential practical applications, and more recently as a popular method to analyse how well NLP systems can capture and recall factual knowledge. This interest in ODQA as a challenging "knowledge-intensive" task has led to a flurry of recent works that have driven test-set performance on standard ODQA datasets to new heights (Lee et al., 2019; Guu et al., 2020; Karpukhin et al., 2020; Lewis et al., 2020; Izacard and Grave, 2020, inter alia). Whilst there have been several works examining other kinds of QA datasets (Manjunatha et al., 2018; Kaushik and Lipton, 2018; Sugawara et al., 2018, 2020), however, we know comparatively little about how the questions and answers are distributed in ODQA benchmarks, making it hard to understand and contextualize the results we are observing.

In this work, we address these issues via an analysis of the test sets of three popular ODQA datasets, namely WebQuestions (Berant et al., 2013), TriviaQA (Joshi et al., 2017) and Open NaturalQuestions (Kwiatkowski et al., 2019; Lee et al., 2019). We identify three types of desired behaviour of a trained ODQA system, in increasing order of difficulty: 1) to recall the answer to a question that the model has seen at training time. 2) to answer novel questions at test time and choose an answer from the set of answers it has seen during training. 3) to answer novel questions which have answers which are not contained in the training data. It is not clear to what extent our current ODQA datasets measure each of these three behaviours.

To address this, we stratify the test sets of these datasets. Firstly, we split the test data by whether answers in the test set also appear somewhere in the train set. We find that 58–71% of test answers also occur somewhere in the training data, demonstrating that the majority of the test data does not probe for answer generalization. Secondly, we annotate 1,000 question-answer pairs from each test set for near-duplicate questions in their respective train sets. We find that a surprisingly high 28–34% have paraphrased questions in the training data, the vast majority of which are near-duplicates differing by one or two words. This result implies that 30% of the test set of these datasets only probe for how

well models can memorize question-answer pairs seen at training.

Equipped with these observations, we compute the performance of several recently proposed ODQA models on our test subsets. We test both *Open-book* approaches, which leverage retrieval from a large corpus of documents and *Closed-book* approaches, which focus on training large parametric seq2seq models with no external knowledge source (Roberts et al., 2020). We find that test data with train-overlapping data contribute the bulk of the overall performance of all the models studied.

These issues seem to be more acute for closed-book models. Strikingly, we find that a closed-book BART-based model (Lewis et al., 2019) is incapable of producing answers not observed at training time, and achieves very low scores on non-overlapping questions, suggesting this model is only capable of memorizing question-answer pairs from training time. With this in mind, we build simple nearest-neighbor models which outperform this BART model, despite having virtually no capacity to generalize beyond training data.

In summary, we make the following contributions: 1) We provide insights into how answer entities are distributed between dataset splits for ODQA datasets 2) We provide annotated subsets of ODQA test sets indicating whether test-time questions are duplicates of training time questions.[1] 3) We evaluate a variety of models on our dataset splits, and derive insights into what kinds of question answering behaviour different models achieve.

2 Datasets

We analyse three widely used ODQA datasets, WebQuestions (Berant et al., 2013), TriviaQA (Joshi et al., 2017), and Open-NaturalQuestions (Lee et al., 2019). All three datasets consist of factual natural language questions and short multi-token answers, differing slightly in the style of questions and format of answers.

WebQuestions consists of 3,778 train and 2,032 test instances. Questions were obtained by mining a search engine, and answers are Freebase entities (Bollacker et al., 2008) annotated by crowdworkers. The ODQA task consists of predicting the name of the Freebase entity. We use the standard train/test splits from Berant et al. (2013) and the development split from Karpukhin et al. (2020), which was randomly split from the train set.

TriviaQA consists of 78,785 train, 8,837 development and 11,313 test instances obtained by scraping trivia websites. Answers are Wikipedia entities, and any alias for the answer entity is considered a correct answer. We use the ODQA splits, which correspond to the unfiltered-train and unfiltered-dev reading comprehension splits (Lee et al., 2019; Min et al., 2019, 2020b; Karpukhin et al., 2020).

Open-NaturalQuestions consists of search engine questions with crowdsourced answer spans in Wikipedia articles. The ODQA version consists of question-answer pairs from NaturalQuestions which have short answer spans less than 6 tokens in length. We use the standard open-domain splits in our experiments, consisting of 79,168 train, 8,757 development and 3,610 question answer pairs.

For all three datasets, the canonical train, development and test splits were obtained by randomly splitting the question-answer pairs, and there are no exact duplicate questions in any dataset. We exclude development data from our overlap analyses, and focus purely on train-test overlap to explicitly assess the effects of training memorization.

3 Test-Train Overlaps

We explore two ways of examining the test sets based on overlaps between training and test data. Consider a question-answer pair (q, a) from the test set D_{test} where the answer consists of at least one answer reference $a = \{s_1..s_n\}$. We can consider *answer overlap* where there exists at least one $(q', a') \in D_{\text{train}}$ which shares at least one answer reference with (q, a). We can also consider *question overlap*, where there exists some $(q'', a'') \in D_{\text{train}}$ where q'' is a duplicate of q, such that q and q'' are paraphrases and have the same answer.

Answer Overlap Following Rajpurkar et al. (2016), we apply answer normalization (lower-casing, stripping punctuation, removing articles and normalizing whitespace) on answer references

francisco pizarro	who led the conquest of the incas in south america	conquistador who defeated the incan empire in peru

Table 3: Randomly sampled test-train overlapping questions in Open NaturalQuestions. See Appendix A.2 for more examples, including examples from TriviaQA and WebQuestions

before searching for overlapping answer references for all (q, a) pairs in the test set – see Table 1. We find that 57.9% of test (q, a) pairs in WebQuestions have answer overlaps, with 63.6% and 71.7% for NaturalQuestions and TriviaQA respectively. We would naturally expect TriviaQA to have higher answer overlap as it has more answer references per question on average (13.7 references on average compared to 1.2 for NaturalQuestions and 2.4 for WebQuestions). Examples of answer overlaps are shown in Table 2.

Question-Overlap Unlike answer overlap, question overlap cannot be easily computed automatically, as searching for duplicates via rules or paraphrase classifiers may lead to both false positives and negatives. Thus, we turn to manual annotation to investigate question overlap. To obtain a representative sample for each dataset, we annotate a random subset of 1,000 (q, a) pairs for each test set. Annotators are shown a list of up to 50 training questions which have a similar answer reference.[2] This answer similarity function is designed for high recall to obtain a tight lower bound on question overlap. If there were no questions with similar answers in the train set, the question was automatically annotated as not overlapping. Three expert annotators annotated the remaining questions and indicated if any were paraphrases of the test question and had the same answer.

The results from the annotation can be seen in Table 1 and examples of overlapping questions in Table 3. A sample of 100 2-way annotated examples indicated 93% agreement, corresponding to a Cohen's Kappa of 0.85 (Cohen, 1960). What we observe is a high degree of question overlap, with between 27.5% and 33.6% of the 1,000 annotated test questions having a duplicate in the train set. It is also common to see several duplicates per test question, with an average of 2.8 duplicate questions per overlapping test question in NaturalQuestions.

4 Implications for Modelling

Earlier we identified three classes of answering behaviours: 1) questions that can be memorized at training time, 2) novel questions that can be answered with answers memorized at training time, 3) novel questions with novel answers. We refer to these behaviours as *Question memorization*, *Answer classification* and *QA generalization*.

Question memorization To perform well on the question-overlap subset, a model only needs to memorize (q, a) pairs at training time, then recognize which training question matches a test-time question. The reasoning required ranges from trivial duplicate detection for very similar questions such as "who played pink in pink floyd the wall" and "who played pink in the movie the wall", to more challenging inference problems for subtler duplicates like "On which island in the North Sea did both St Aidan and St Cuthbert live?" and "irish born missionary st aidan founded a monastery in

---

[2] Training questions are selected for annotation if one of the following is true: they share an answer reference with a test question, a test answer reference is a sub-sequence of a training answer reference, or the other way around (a training reference answer is a sub-sequence of a test answer reference). If there are more than 50 such questions, the top 50 are chosen by the highest degree of word overlap with the test question.

Model		Open NaturalQuestions				TriviaQA				WebQuestions			
		Total	Question Overlap	Answer Overlap Only	No Overlap	Total	Question Overlap	Answer Overlap Only	No Overlap	Total	Question Overlap	Answer Overlap Only	No Overlap

Table 4: Exact Match scores on our dataset splits. "Total" is the overall performance on the dataset. "Question Overlap" is the subset with train-test question overlap, and probes for simple question memorization. "Answer Overlap Only" is subset without train-test question overlap, but with train-test answer overlap, which probes for answer classification. "No overlap" is the subset with no train-test answer overlap and probes for QA generalization

653 on which english island which is also the name of a 1970s uk folk-rock band?". Manual annotation of 100 question-overlap pairs showed 81% were simple duplicates differing by one or two words, 14% needed some paraphrase recognition ability, and 5% needed more sophisticated language understanding. To measure performance on question memorization, we build a test subset of (q, a) pairs with question overlap to the train set.

Answer Classification For a model to handle answer-overlap questions, a classifier over train set answers would be sufficient, as answers never appear at test time that do not appear at training time. We build a test subset of (q, a) pairs which have answer overlap, but not question overlap. Question-overlap pairs are excluded as they are significantly easier and would inflate scores.

QA Generalization Here, models cannot rely on memorizing their training data. To measure performance on this most challenging split, we build a test subset of (q, a) pairs which do not have answer overlap with the train set. We also note that we expect higher frequency answers, such as countries, integers and public figures will naturally appear less often in this subset. As such, models that perform well on the head of the answer distribution may struggle to perform well here, despite being able to perform some generalization at test time.

Next we briefly describe the models included in our analysis. For published models, we obtain test set predictions directly from the authors.

4.1 Open-Book Models

Open-book Models first retrieve relevant documents from Wikipedia and then either extract or generate answers conditioned on those documents. We consider Dense Passage Retriever (DPR) (Karpukhin et al., 2020), a pipeline model which retrieves documents using dense embeddings, before feeding them into a conventional reader-reranker which extracts spans of text as answers. We also include Retrieval-Augmented Generation (Lewis et al., 2020), a model that jointly learns to retrieve and generate answers in a seq2seq framework. Finally we include Fusion-in-Decoder (FID) (Izacard and Grave, 2020), a pipeline model which retrieves 100 documents and fuses them so that the decoder can attend to all documents at once. We do not include FID results on WebQuestions as the authors did not use it in their original work.

4.2 Closed-Book Models

Closed-book models store the knowledge required to answer their questions entirely within the model's parameters, rather than in an external corpus. Typically these models consist of seq2seq transformers directly fine-tuned on (q, a) pairs. In our analysis, we train a BART-large closed-book model, which is trained with questions as input and generates (q, a) pairs as output. Checkpoints are selected by Exact Match score on a development set. We also include a more powerful T5-11B model from (Roberts et al., 2020). We use the T5-11B model pretrained with a special "Salient Span Masking" objective (Guu et al., 2020), which improves downstream ODQA performance. We do not include TriviaQA results for T5 since their model used a different data splitting scheme.

4.3 Nearest-Neighbor Models

Given the high levels of train-test overlaps in these datasets, we also experiment with some simple nearest-neighbor models. Here, we simply retrieve a (q, a) pair from the train set based on question similarity to the test question, and return its answer. We experiment with two models, one using TF-IDF and the other using maximum inner product of question embeddings from the DPR retriever. These models cannot generalize to non-overlapping answers, and have limited capacity to answer non-overlapping questions. However, they are attractive from the perspective of model size and efficiency (Min et al., 2020a).

4.4 Results

Question Memorization Earlier, we found that $\sim$30% of test set questions overlap with the train set. The "Question overlap" columns in Table 4 shows performance on Question Memorization. Comparing this column with the total performance column shows that all models perform significantly higher on memorizable questions. This effect is most pronounced for closed book models. The T5-11B performs especially well for question memorization on both NaturalQuestions and WebQuestions. This suggests that its very large capacity, coupled with more powerful question understanding may allow it to store and recall training questions more effectively than other models.

Answer Classification The "Answer overlap only" column in Table 4 shows performance on answer classification. Answer classification has a large drop in performance compared to question memorization, dropping by an average of 45% Exact Match. Open-book models handle this setting better than closed book models. The BART model in particular struggles here, scoring only 10.2%.

QA Generalization The "No overlap" column in Table 4 shows performance on QA generalization. All models significantly lose performance on QA generalization, highlighting the shortcomings of the total performance metric. For example, we may expect the FID state-of-the-art model to answer half of NaturalQuestions-style questions correctly, but once we account for repeated questions and answers, it can only answer about a third of questions correctly. This difference is even more pronounced for other models, with an average absolute drop of 25% with respect to total performance.

Nearest-Neighbor Models The bottom two rows of Table 4 show results for nearest-neighbor models. TF-IDF, despite being completely untrained, can answer about 20% of test questions correctly, purely by retrieving questions from the train sets. The dense retrieval model outperforms the BART closed-book model on NaturalQuestions and TriviaQA. Further, the dense nearest neighbor model also outperforms the significantly more complex DPR open-book model on TriviaQA and WebQuestions on the question overlap subset.

5 Related Work

Examining what behaviours are learnt by models has received attention in language understanding tasks, such as GLUE (Wang et al., 2018), which includes tools for probing for different reasoning types. There has also been critical and careful analysis of QA systems and datasets. Chen et al. (2016), Sugawara et al. (2020) and Kaushik and Lipton (2018) analyse the difficulty of various machine reading datasets, and Manjunatha et al. (2018) show that visual QA models memorize common question-answer relationships in training data. Févry et al. (2020) analyse various closed-book models' TriviaQA predictions. Kwiatkowski et al. (2019) note that the machine reading NaturalQuestions dataset has train-test overlap of Wikipedia titles, and provide baselines for "long-answer" QA. Verga et al. (2020) observe answer overlap effects in a related modality (knowledgebase QA), but no not consider question overlap.

6 Conclusion

We performed an analysis of popular open-domain QA datasets. We found that 60% of test set answers overlap with the train set and 30% of test set questions have at least one duplicate in the train set. Given these observations, we contextualize performance of seven ODQA models, stratifying by the extent of overlap, exploring how well these models generalize verses simply memorizing training data. It is clear that performance on these datasets cannot be properly understood by overall QA accuracy. In the future, a greater emphasis should be placed on more behaviour-driven evaluation, rather than pursuing single-number overall accuracy.

Abstract

Being able to parse code-switched (CS) utterances, such as Spanish+English or Hindi+English, is essential to democratize task-oriented semantic parsing systems for certain locales. In this work, we focus on Spanglish (Spanish+English) and release a dataset, CSTOP, containing 5800 CS utterances alongside their semantic parses. We examine the CS generalizability of various Cross-lingual (XL) models and exhibit the advantage of pre-trained XL language models when data for only one language is present. As such, we focus on improving the pre-trained models for the case when only English corpus alongside either zero or a few CS training instances are available. We propose two data augmentation methods for the zero-shot and the few-shot settings: fine-tune using translate-and-align and augment using a generation model followed by match-and-filter. Combining the few-shot setting with the above improvements decreases the initial 30-point accuracy gap between the zero-shot and the full-data settings by two thirds.

1 Introduction

Code-switching (CS) is the alternation of languages within an utterance or a conversation (Poplack, 2004). It occurs under certain linguistic constraints but can vary from one locale to another (Joshi, 1982). We envision two usages of CS for virtual assistants. First, CS is very common in locales where there is a heavy influence of a foreign language (usually English) in the native "substrate" language (e.g., Hindi or Latin-American Spanish). Second, for other native languages, the prevalence of English-related tech words (e.g., Internet, screen) or media vocabulary (e.g., movie names) is very common. While in the second case, a model using contextual understanding should be able to parse the utterance, the first form of CS, which is our focus in this paper, needs Cross-Lingual(XL) capabilities in order to infer the meaning.

There are various challenges for CS semantic parsing. First, collecting CS data is hard because it needs bilingual annotators. This gets even worse considering that the number of CS pairs grows quadratically. Moreover, CS is very dynamic and changes significantly by occasion and in time (Poplack, 2004). As such, we need extensible solutions that need little or no CS data while having the more commonly-accessible English data available. In this paper, we first focus on the zero-shot setup for which we only use EN data for the same task domains (we call this in-domain EN data). We show that by translating the utterances to ES and aligning the slot values, we can achieve high accuracy on the CS data. Moreover, we show that having a limited number of CS data alongside augmentation with synthetically generated data can significantly improve the performance.

Our contributions are as follows: 1) We release a code-switched task-oriented dialog data set, CSTOP[1], containing 5800 Spanglish utterances and a corresponding parsing task. To the best of our knowledge, this is the first Code-switched parsing dataset of such size that contains utterances for both training and testing. 2) We evaluate strong baselines under various resource constraints. 3) We introduce two data augmentation techniques that improve the code-switching performance using monolingual data.

2 Task

In task-oriented dialog, the language understanding task consists of classifying the intent of an utterance, i.e., sentence classification, alongside tagging the slots, i.e., sequence labeling. We use the Task-

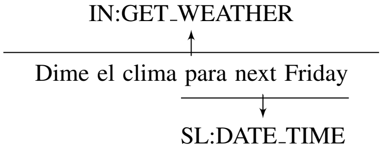

Figure 1: Example CS sentence and its annotation for the sequence [IN:GET_WEATHER Dime el clima [SL:DATE_TIME para next Friday]]

Oriented Parsing dataset released by Schuster et al. (2018) as our EN monolingual dataset. We release a similar dataset, CSTOP, of around 5800 Spanglish utterances over two domains, Weather and Device, which are collected and annotated by native Spanglish speakers. An example from the CSTOP alongside its annotation is shown in Fig. 1. Note that the intent and slot lables start with IN : and SL :, respectively. Our task is to classify the sentence intent, here *IN:GET_WEATHER* as well as the label and value of the slots, here *SL:DATE_TIME* corresponding to the span *para next Friday*. Moreover, other words are classified as having no label, i.e., *O* class. We discuss the details of this dataset in the next section.

One of the unique challenges of this task, compared with common NER and language identification CS tasks, is the constant evolution of CS data. Since the task is concerned with spoken language, the nature of CS is very dynamic and keeps evolving from domain to domain and from one community to another. Furthermore, cross-lingual data for this task is also very rare. Most of the existing techniques, either combine monolingual representations (Winata et al., 2019a) or combine the datasets to synthesize code-switched data (Liu et al., 2019). Lack of monolingual data for the substrate language (very realistic if you replace ES with a less common language) would make those techniques inapplicable.

In order to evaluate the model in a task-oriented dialog setting, we use the exact-match accuracy (from now on, accuracy) as the primary metric. This is simply defined as the percentage of utterances for which the full parse, i.e., the intent and all the slots, have been correctly predicted.

3 CSTOP Dataset

In this section, we provide details of the CSTOP dataset. We originally collected around 5800 CS utterances over two domains; *Weather* and *Device*. We picked these two domains as they represent complementary behavior. While Weather contains slot-heavy utterances (average 1.6 slots per utterance), Device is an intent-heavy domain with only average 0.8 slots per utterance. We split the data into 4077, 1167, and 559 utterances for training, testing, and validation, respectively.

CS data collection proceeded in the following steps:

1. One of the authors, who is a native speaker of Spanish and uses Spanglish on a daily basis, generated a small set of CS utterances for Weather and Device domains. Additionally, we also recruited bilingual EN/ES speakers who met our Spanglish speaker criteria guidelines, established following Escobar and Potowski (2015).

2. We wrote Spanglish data creation instructions and asked participants to produce Spanish-English CS utterances for each intent (i.e. ask for the weather, set device brightness, etc).

3. Next, we filter out utterances from this pool to only retain those that exhibited true intra-sentential CS.

4. The collected utterances were labeled by two annotators, who identified the intent and slot spans. If the two annotators disagreed on the annotation for an utterance, a third annotator would resolve the disagreement to provide a final annotation for it.

Table. 1 shows the number of distinct intents and slots for each domain and the number of utterances in CSTOP for each domain. We have also shown the most 15 common intents in the training set and a representative Spanglish example alongside its slot values for those intents in Table. 2. The first value in a slot tuple is the slot label and the second is the slot value. We can see that while most of the verbs and stop words are in Spanish, Nouns and slot values are mostly in English. We further calculate the prevalence Spanish and English words by using a vocabulary file of 20k for each language. Each token in the CSTOP training set is assigned to the language for which that token has a lower rank. The ratio of the Spangish to English tokens is around 1.34 which matches our previous anecdotal observation. This ratio was consistent when increasing the vocabular size to even 40k. .

Domain	intents	slots	utterances
Weather	2	4	3692
Device	17	6	2112

Table 1: CSTOP Statistics

4 Model

Our base model is a bidirectional LSTM with separate projections for the intent and slot tagging (Yao et al., 2013). We use the aligned word embedding MUSE (Conneau et al., 2017) with a vocabulary size of 25k for both EN and ES. Our experiments showed that for the best XL generalization, it's best to freeze the word embeddings when the training data contains only EN or ES utterances. We refer to this model as simply MUSE.

We also use SOTA pre-trained XL models; XLM (Conneau and Lample, 2019) and XLM-R (Conneau et al., 2019). These models are pre-trained via Masked Language Modeling (MLM) (Devlin et al., 2019) on massive multilingual data. They share the word-piece token representation, BPE (Sennrich et al., 2016) and SentencePiece (Kudo and Richardson, 2018), as well as a common MLM transformer for different languages. Moreover, while XLM is pre-trained on Wikipedia, XLM-R is trained on crawled web data which contains more non-English and possibly CS data. In order to adapt these models for the joint intent classification and slot tagging task, we use the method described in Chen et al. (2019). For classification, we add a linear classifier on top of the first hidden state of the Transformer. A typical slot tagging model feeds the hidden states, corresponding to each token, to a CRF layer (Mesnil et al., 2015). To make this compatible with XLM and XLM-R, we use the hidden states corresponding to the first sub-word of every token as the input to the CRF layer.

Table 3 shows the accuracy of the above models on CSTOP. We also have listed the performance when the models were first fine-tuned on the EN data (CS+EN). We observe that in-domain fine-tuning can almost halve the gap between XLM-R and XLM, which is around 50% faster during the inference than XLM-R during inference. The training details for all our models and the validation results are listed in the Appendix.

5 Zero-shot performance

Bottom part of Table 3 shows the CS test accuracy when using only the in-domain monolingual data. Our EN dataset is the task-oriented parsing dataset (Schuster et al., 2018) described in the previous section. Since the original TOP dataset did not include any utterances belonging to the Device domain, we also release a dataset of around thousand EN Device utterances for the experiments using the EN data. In order to showcase the effect of monolingual ES data, we also experiment with using the in-domain ES dataset, i.e. ES Weather and Device queries.

We observe that having monolingual data of both languages yields very high accuracy, only a few points shy of training directly on the CS data. Moreover, in this setting, even simpler models such as MUSE can yield competitive results with XLM-R while being much faster. However, the advantage of XL pre-training becomes evident when only one of the languages is present. As such, having only the substrate language (i.e., ES) is almost the same as having both languages for XLM-R.

Note that we do not use ES data for other results in this paper. Obtaining semantic parsing dataset in another language is expensive and often only EN data is available. Our experiments show a huge performance gap when only using the EN data, and thus in this paper, we will be focusing on using the EN data alongside zero or a few CS instances.

5.1 Effect of XL Embeddings

Here, we explore how much of the zero-shot performance can be attributed to the XL embeddings as opposed to the shared XL representation. As such, we experiment with replacing MUSE embeddings with other embeddings in the LSTM model explained in the previous section. We experiment with the following strategies:: (1) Random embedding: This learns the ES and EN word embeddings from the scratch (2) Randomly-initialized SentencePiece (Kudo and Richardson, 2018) (RSP): Words are represented by wordpiece tokens that are learned from a huge unlabeled multilingual corpus. (3) Pre-trained XLM-R sentence piece (XLSP). These are the 250k embedding vectors that are learned during the pre-trainig of XLM-R.

We have shown the effects of using the aforementioned embeddings in the zero-shot setting in Table 4. We can see that by having monolingual datasets from both languages, even random

intent	utterance	slots
GET_WEATHER	¿cómo estará el clima en Miami este weekend?	(LOCATION, Miami), (DATE_TIME, este weekend)

Table 2: Examples from CSTOP intents

Lang/Model	MUSE	XLM	XLM-R
CS	87.0	86.6	94.4
CS + EN	88.1	93.0	95.4
EN	39.2	54.8	66.6
ES	69.9	78.3	88.1
EN+ES	88.2	87.8	91.2

Table 3: Full-training (top) and zero-shot (bottom) accuracy of XL models when using different monolingual corpora. ES is an internal dataset to showcase the effect of having a big Spanish corpus.

embeddings can yield high performance. By removing one of the languages, unsurprisingly, the codeswitching generalizability drops sharply for all, but much less for XLSP and MUSE. Moreover, even though the XLSP embeddingsm, unlike MUSE, is not consttrained to only EN and ES, it yields comparable results with the word-based MUSE embeddings.

We can also see that When ES data is available, RSP provides some codeswitching generalizability, as compared with the Random strategy, but not when only EN data is available. We hypothesize that the common sub-word tokens are more helpful to generalize the slot values (which in the codeswitched data are mostly in EN) than the non-slot queries which are more commonly in ES. This is also verified by the observation that most of the gains for the RSP vs Random for the ES only scenario come from the slot tagging accuracy as compared with the intent detection.

As a final note, we observe that between $20-30\%$ of the XLM-R gains can be captured by using the pre-trained sentence-piece embeddings while the rest are coming from the shared XL representation pre-trained on massive unlabeled data. In the rest of the paper, we focus on the XLM-R model.

	Random	RSP	XLSP	MUSE
EN	13.5	12.2	30.3	**39.2**
ES	38.2	48.0	**70.5**	**69.9**
EN+ES	81.1	84.3	**89.0**	88.2

Table 4: Zero-shot accuracy for simple LSTM model when using different monolingual corpora and different embedding strategies.

6 Data Augmentation Approaches

In this section, we discuss two data augmentation approaches. The first one is in a zero-shot setting and only uses EN data to improve the performance on the Spanglish test set. In the second approach, we assume having a limited number of Spanglish data and use the EN data to augment the few-shot setting.

6.1 Translate and Align

We explore creating synthetic ES data from the EN dataset using machine translation. Since our task is a joint intent and slot tagging task, creating a synthetic ES corpus consists of two parts: a) Obtaining a parallel EN-ES corpus by machine translating utterances from EN to ES, b) Projecting gold annotations from EN utterances to their ES counterparts via word alignment (Tiedemann et al., 2014; Lee et al., 2019b). Once the words in both languages are aligned, the slot annotations are simply copied

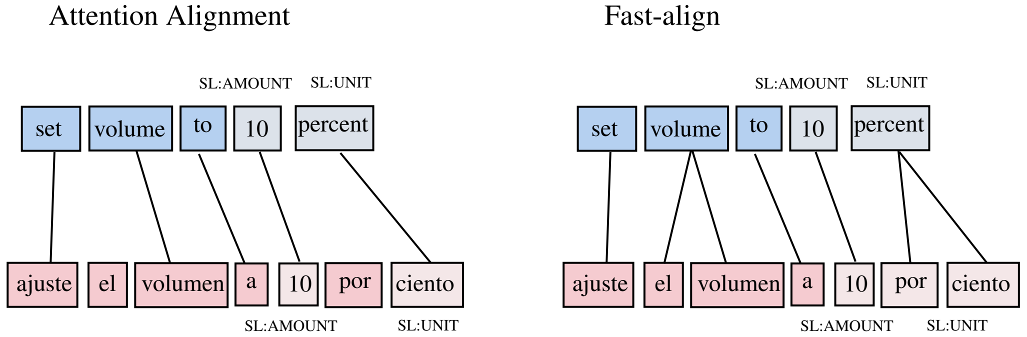

Figure 2: An example comparison between the two methods of slot label projection. The image in on the left shows Attention alignment, where every source token gets projected to a single target token. As a result, *percent*, in EN is aligned only with *ciento* in ES. The image on the right shows fast-align, which allow a many-to-many alignment. Hence *percent* is correctly aligned with *por ciento*.

over from EN to ES by word alignment. For word alignment, we explore two methods that are explained below. In some cases, word alignment may produce discontinuous slot tokens in ES, which we handle by introducing new slots of the same type, for all discontinuous slot fragments.

Our first method leverages the attention scores (Bahdanau et al., 2015) obtained from an existing EN to ES NMT model. We adopt a simplifying assumption that each source word is aligned to one target language word (Brown et al., 1993). For every slot token in the source language, we select the highest attention score to align it with a word in the target language.

Our next approach to annotation projection makes use of unsupervised word alignment from statistical machine translation. Specifically, we use the fast-align toolkit (Dyer et al., 2013) to obtain alignments between EN and ES tokens. Since fast-align generates asymmetric alignments, we generate two sets of alignments, EN to ES and ES to EN and symmetrize them using the grow-diagnol-final-and heuristic (Koehn et al., 2003) to obtain the final alignments.

In Table 5, we show the CS zero-shot accuracy when fine-tuning on the newly generated ES data (called ES*.) alongside the original EN data. We can see that unsupervised alignment results in around 2.5 absolute point accuracy improvement. On the other hand, using attention alignment ends up hurting the accuracy, which is perhaps due to the slot noise that it introduces. The assumption that a single source token aligns with a single target token leads to incorrect data annotations when the length of a translated slot is different in EN and ES. Figure 3 shows an example utterance where attention alignment produces an incorrect annotation compared to unsupervised alignment.

EN	**EN+ES* Attn**	**EN+ES* aligned**
66.6	65.8	69.2

Table 5: Zero-shot accuracy when fine-tuning XLM-R on EN monolignual data as well as the auto-translated and aligned ES data (called ES*).

6.2 Generate by Match-and-Filter in the Few-shot Setting

Here, we assume having a limited number of high-quality in-domain CS data and as such, we construct the CSTOP$_{100}$ dataset of around 100 utterances from the original training set in the CSTOP. We make sure that every individual slot and intent (but not necessarily the combination) is presented in CSTOP$_{100}$ and randomly sample the rest. We perform our sampling three times and report the few-shot results on the average performance. This setting is of paramount importance for bringing up a domain in a new locale when the EN data is already available. The first column in Table 6 shows the CS Few-Shot (FS) performance alongside the fine-tuning on the EN data and the aligned translated data, when average over three sampling of CSTOP$_{100}$.

In order to improve the FS performance, we perform data augmentation on the CSTOP$_{100}$ dataset. Unlike methods such as Pratapa et al. (2018), we seek generic methods that do not need extra resources such as constituency parsers. Instead, we explore using pre-trained generative models while taking advantage of the EN data.

We use BART (Lewis et al., 2019), a denois-

Model/Training Data	Few Shot	Few shot+ Generate and Filter augmentation
XLM-R	61.2	70.3
XLM-R fine-tuned on EN	82.6	83.7
XLM-R fine-tuned on EN+ES*	84.1	**84.8**

Table 6: Accuracy when only a few CS instances are available during training, with and without the data augmentation. ES* is the auto-translated and aligned data.

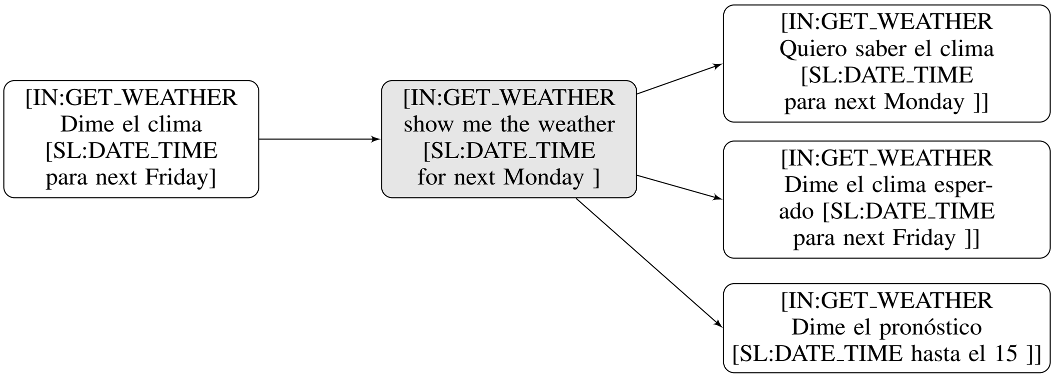

Figure 3: Match and Filter data augmentation: 1- For each CS utterance (target), find the the closest EN neighbor (source). 2- Learn a generative model from source to target 3- Perform beam search to generate more targets from the source utterances.

ing autoencoder trained on massive amount of web data, as the generative model. Our goal is to generate diverse Spanglish data from the EN data. Even though BART was trained for English, we found it very effective for this task. We hypothesize this is due to the abundance of the Spanish text among EN web data and the proximity of the word-piece tokens among them. We also experimented with multilingual BART (Liu et al., 2020a) but found it very challenging to fine-tune for this task.

First, we convert the data to a bracket format (Vinyals et al., 2015), which is called the seqlogical form in Gupta et al. (2018). Examples of this format are shown in Fig. 3. In the seqlogical form, we include the intent (i.e., sentence label) at the beginning and for each slot, we first include the label and text in brackets.

We perform our data augmentation technique in the following steps:

1. Find the top K closest EN neighbors to every CS query in the CSTOP$_{100}$. We enforce the neighbors to have the same parse as the CS utterance, i.e., same intent and same slot labels, and use the Levenshtein distance to rank the EN sequences.

2. Having this parallel corpus, i.e., top-K EN neighbors as the source and the original CS query as the target, Fine-tune the BART model. We use K=10 in our experiments to increase the parallel data size to around 650.

3. During the inference, Use the beam size of 5 to decode CS utterances from the same EN source data. Since both the source and target sequences are in the seqlogical form, the CS generated sequences are already annotated.

In Fig. 3, we have shown the closest EN neighbor corresponding to the original CS example in Fig. 1. The CS utterance can be seen as a rough translation of the EN sentence. We have also shown the top three generated CS utterances from the EN example.

In order to reduces the noise, we filter the generated sequences that either already exist in CSTOP$_{100}$, are not valid trees, or have a semantic parse different from the original utterance. We augment CSTOP$_{100}$ with the data, and fine-tune the XLM-R baseline.

In the second column of Table 6, we have shown the average data augmentation improvement over the three CSTOP$_{100}$ samples for the few-shot setting. We can see that even after fine-tuning on the EN monolingual data (the second row), the augmentation technique improves this strong baseline. In the last row, we first use the translation alignment of the previous section to obtain ES*. After fine-tuning on this set combined with the EN data, we further fine-tune on the CSTOP$_{100}$. We can see that the best model enjoys improvements from both zero-shot (translation alignment) and the few-shot (generate and filter) augmentation techniques. We also note that the p-value corresponding to the second and third row gains are 0.018 and 0.055, respectively.

7 Related Work

7.1 XL Pre-training

Most of the initial work on pre-trained XL representations was focused on embedding alignment (Xing et al., 2015; Zhang et al., 2017; Conneau et al., 2018). Recent developments in this area have focused on the context-aware XL alignment of contextual representations (Schuster et al., 2019; Aldarmaki and Diab, 2019; Wang et al., 2019; Cao et al., 2020). Recently, pre-trained multilingual language models such as mBERT (Devlin et al., 2019), XLM (Conneau and Lample, 2019), and Conneau et al. (2019) have been introduced, and Pires et al. (2019) demonstrate the effectiveness of these on sequence labeling tasks.

Separately, Liu et al. (2020a) introduce mBART, a sequence-to-sequence denoising auto-encoder pre-trained on monolingual corpora in many languages using a denoising autoencoder objective (Lewis et al., 2019).

7.2 Code-Switching

Following the ACL shared tasks, CS is mostly discussed in the context of word-level language identification (Molina et al., 2016) and NER (Aguilar et al., 2018). Techniques such as curriculum learning (Choudhury et al., 2017) and attention over different embeddings (Wang et al., 2018; Winata et al., 2019a) have been among the successful techniques. CS parsing and use of monolingual parses are discussed in Sharma et al. (2016); Bhat et al. (2017, 2018). Sharma et al. (2016) introduces a Hinglish test set for a shallow parsing pipeline. In Bhat et al. (2017), outputs of two monolingual dependency parsers are combined to achieve a CS parse. Bhat et al. (2018) extends this test set by including training data and transfers the knowledge from monolingual treebanks. Duong et al. (2017) introduced a CS test set for semantic parsing which is curated by combining utterances from the two monolingual datasets. In contrast, CSTOP is procured independently of the monolingual data and exhibits much more linguistic diversity. In Pratapa et al. (2018), linguistic rules are used to generate CS data which has been shown to be effective in reducing the perplexity of a CS language model. In contrast, our augmentation techniques are generic and do not require rules or constituency parsers.

7.3 XL Data Augmentation

Most approaches to cross-lingual data augmentation use machine translation and slot projection for sequence labeling tasks (Jain et al., 2019). Wei and Zou (2019) uses simple operations such as synonym replacement and Lee et al. (2019a) use phrase replacement from a parallel corpus to augment the training data. Singh et al. (2019) present XLDA that augments data by replacing segments of input text with its translations in other languages. Some recent approaches (Chang et al., 2019; Winata et al., 2019b) also train generative models to artificially generate CS data. More recently, Kumar et al. (2020) study data augmentation using pre-trained transformer models by incorporating label information during fine-tuning. Concurrent to our work, Bari et al. (2020) introduce Multimix, where data augmentation from pre-trained multilingual language models and self-learning are used for semi-supervised learning. Recently, Liu et al. (2019) generate CS data by translating keywords picked based on attention scores from a monolingual model. Generating CS data has recently been studied in Liu et al. (2020b)

7.4 Task-oriented Dialog

The intent/slot framework is the most common way of performing language understanding for task oriented dialog using. Bidirectional LSTM for the sentence representation alongside separate projection layers for intent and slot tagging is the typical architecture for the joint task (Yao et al., 2013; Mesnil et al., 2015; Hakkani-Tur et al., 2016). Such representations can accommodate trees of up to length two, as is the case in CSTOP. More recently, an extension of this framework has been introduced to fit the deeper trees (Gupta et al., 2018; Rongali et al., 2020).

8 Conclusion

In this paper, we propose a new task for code-switched semantic parsing and release a dataset, CSTOP, containing 5800 Spanglish utterances over two domains. We hope this foments further research on the code-switching phenomenon which has been set back by paucity of sizeable curated datasets. We show that cross-lingual pre-trained models can generalize better than traditional models to the code-switched setting when monolingual data from only one languages is available. In the presence of only EN data, we introduce generic augmentation techniques based on translation and generation. As such, we show that translating and aligning the EN data can significantly improve the zero-shot performance. Moreover, generating code-switched data using a generation model and a match-and-filter approach leads to improvements in a few-shot setting. We leave exploring and combining other augmentation techniques to future work.

A Appendix

Here, we describe the details regarding the training as the validation results.

A.1 Model and Training Parameters

In Table 7, we have shown the training details for all our models. We use ADAM (Kingma and Ba, 2014) with Learning Rate (LR), Weight Decay (WD), and Batch Size (BSz) that is listed for each model. We have also shown the number of epochs and the average training time for the full CS data using 8 V100 Nvidia GPUs. For all our XLM-R experiments, we use the XLM-R large from the PyText[2] (Aly et al., 2018) which is pre-trained on 100 languages. For the XLM experiments, we use XLM-20 pre-trained over 20 languages and use the same fine-tuning parameters as XLM-R but run for more epochs.

For the LSTM models, we use a two-layer LSTM with hidden dimension of 256 and dropout of 0.3 for all connections. We use one layer of MLP of dimension 200 for both the slot tagging and the intent classification. We also use an ensemble of five models for all the LSTM experiments to reduce the variance. The LSTM model with SentencePiece embeddings in Table 4 were trained with embedding dimension of 1024 similar to the XLM-R model.

A.2 Validation Results

In Table. 9, we have shown the validation results when using the full CS training data. We have not shown the corresponding results for the zero-shot experiments as no validation data was not used and the monolingual models were tested off the shelf.

In Table. 8, we have shown the validation results for the few-shot setting.

Generating Syntactically Controlled Paraphrases without Using Annotated Parallel Pairs

Kai-Wei Chang
University of California, Los Angeles
kwchang@cs.ucla.edu

Abstract

Paraphrase generation plays an essential role in natural language process (NLP), and it has many downstream applications. However, training supervised paraphrase models requires many annotated paraphrase pairs, which are usually costly to obtain. On the other hand, the paraphrases generated by existing unsupervised approaches are usually syntactically similar to the source sentences and are limited in diversity. In this paper, we demonstrate that it is possible to generate syntactically various paraphrases without the need for annotated paraphrase pairs. We propose *Syntactically controlled Paraphrase Generator* (SynPG), an encoder-decoder based model that learns to disentangle the semantics and the syntax of a sentence from a collection of unannotated texts. The disentanglement enables SynPG to control the syntax of output paraphrases by manipulating the embedding in the syntactic space. Extensive experiments using automatic metrics and human evaluation show that SynPG performs better syntactic control than unsupervised baselines, while the quality of the generated paraphrases is competitive. We also demonstrate that the performance of SynPG is competitive or even better than supervised models when the unannotated data is large. Finally, we show that the syntactically controlled paraphrases generated by SynPG can be utilized for data augmentation to improve the robustness of NLP models.

1 Introduction

Paraphrase generation (McKeown, 1983) is a long-lasting task in natural language processing (NLP) and has been greatly improved by recently developed machine learning approaches and large data collections. Paraphrase generation demonstrates the potential of machines in semantic abstraction and sentence reorganization and has already been applied to many NLP downstream applications, such as question answering (Yu et al., 2018), chatbot engines (Yan et al., 2016), and sentence simplification (Zhao et al., 2018).

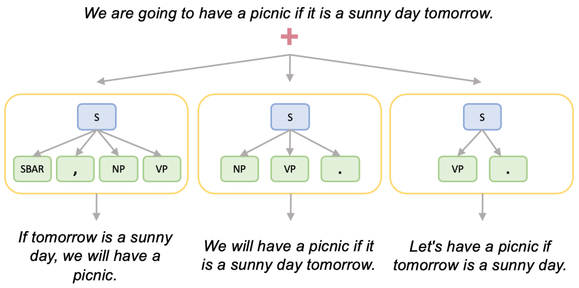

Figure 1: Paraphrase generation with syntactic control. Given a source sentence and a target syntactic specification (either a full parse tree or top levels of a parse tree), the model is expected to generate a paraphrase with the syntax following the given specification.

In recent years, various approaches have been proposed to train sequence-to-sequence (seq2seq) models on a large number of annotated paraphrase pairs (Prakash et al., 2016; Mallinson et al., 2017; Cao et al., 2017; Egonmwan and Chali, 2019). Some of them control the syntax of output sentences to improve the diversity of paraphrase generation (Iyyer et al., 2018; Goyal and Durrett, 2020; Kumar et al., 2020). However, collecting annotated pairs is expensive and induces challenges for some languages and domains. On the contrary, unsupervised approaches build paraphrase models without using parallel corpora (Li et al., 2018; Roy and Grangier, 2019; Zhang et al., 2019). Most of them are based on the variational autoencoder (Bowman et al., 2016) or back-translation (Mallinson et al., 2017; Wieting and Gimpel, 2018; Hu et al., 2019). Nevertheless, without the consideration of controlling syntax, their generated paraphrases are often similar to the source sentences and are not diverse in syntax.

This paper presents a pioneering study on syntactically controlled paraphrase generation based

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1022–1033
April 19 - 23, 2021.

on disentangling semantics and syntax. We aim to disentangle one sentence into two parts: 1) the semantic part and 2) the syntactic part. The semantic aspect focuses on the meaning of the sentence, while the syntactic part represents the grammatical structure. When two sentences are paraphrased, their semantic aspects are supposed to be similar, while their syntactic parts should be different. To generate a syntactically different paraphrase of one sentence, we can keep its semantic part unchanged and modify its syntactic part.

Based on this idea, we propose **Syn**tactically Controlled **P**araphrase **G**enerator (SynPG)[1], a Transformer-based model (Vaswani et al., 2017) that can generate syntactically different paraphrases of one source sentence based on some target syntactic parses. SynPG consists of a semantic encoder, a syntactic encoder, and a decoder. The semantic encoder considers the source sentence as a bag of words without ordering and learns a contextualized embedding containing only the semantic information. The syntactic encoder embeds the target parse into a contextualized embedding including only the syntactic information. Then, the decoder combines the two representations and generates a paraphrase sentence. The design of disentangling semantics and syntax enables SynPG to learn the association between words and parses and be trained by reconstructing the source sentence given its unordered words and its parse. Therefore, we do not require any annotated paraphrase pairs but only unannotated texts to train SynPG.

We verify SynPG on four paraphrase datasets: ParaNMT-50M (Wieting and Gimpel, 2018), Quora (Iyer et al., 2017), PAN (Madnani et al., 2012), and MRPC (Dolan et al., 2004). The experimental results reveal that when being provided with the syntactic structures of the target sentences, SynPG can generate paraphrases with the syntax more similar to the ground truth than the unsupervised baselines. The human evaluation results indicate that SynPG achieves competitive paraphrase quality to other baselines while its generated paraphrases are more accurate in following the syntactic specifications. In addition, we show that when the training data is large enough, the performance of SynPG is competitive or even better than supervised approaches. Finally, we demonstrate that the syntactically controlled paraphrases generated by SynPG can be used for data augmentation to defense syntactically adversarial attack (Iyyer et al., 2018) and improve the robustness of NLP models.

2 Unsupervised Paraphrase Generation

We aim to train a paraphrase model without using annotated paraphrase pairs. Given a source sentence $\mathbf{x} = (x_1, x_2, ..., x_n)$, our goal is to generate a paraphrase sentence $\mathbf{y} = (y_1, y_2, ..., y_m)$ that is expected to maintain the same meaning of $\mathbf{x}$ but has a different syntactic structure from $\mathbf{x}$.

Syntactic control. Motivated by previous work (Iyyer et al., 2018; Zhang et al., 2019; Kumar et al., 2020), we allow our model to access additional syntactic specifications as the control signals to guide the paraphrase generation. More specifically, in addition to the source sentence $\mathbf{x}$, we give the model a target constituency parse $\mathbf{p}$ as another input. Given the input $(\mathbf{x}, \mathbf{p})$, the model is expected to generate a paraphrase $\mathbf{y}$ that is semantically similar to the source sentence $\mathbf{x}$ and syntactically follows the target parse $\mathbf{p}$. In the following discussions, we assume the target parse $\mathbf{p}$ to be a full constituency parse tree. Later on, in Section 2.3, we will relax the syntax guidance to be a *template*, which is defined as the top two levels of a full parse tree. We expect that a successful model can control the syntax of output sentences and generate syntactically different paraphrases based on different target parses, as illustrated in Figure 1.

Similar to previous work (Iyyer et al., 2018; Zhang et al., 2019), we linearize the constituency parse tree to a sequence. For example, the linearized parse of the sentence "*He eats apples.*" is `(S(NP(PRP))(VP(VBZ)(NP(NNS)))(.)).` Accordingly, a parse tree can be considered as a sentence $\mathbf{p} = (p_1, p_2, ..., p_k)$, where the tokens in $\mathbf{p}$ are non-terminal symbols and parentheses.

2.1 Proposed Model

Our main idea is to disentangle a sentence into the semantic part and the syntactic part. Once the model learns the disentanglement, it can generate a syntactically different paraphrase of one given sentence by keeping its semantic part unchanged and modifying only the syntactic part.

Figure 2 illustrates the proposed paraphrase model called SynPG, a seq2seq model consisting of a semantic encoder, a syntactic encoder, and a decoder. The semantic encoder captures only the semantic information of the source sentence $\mathbf{x}$,

---

[1] Our code and the pretrained models are available at `https://github.com/uclanlp/synpg`

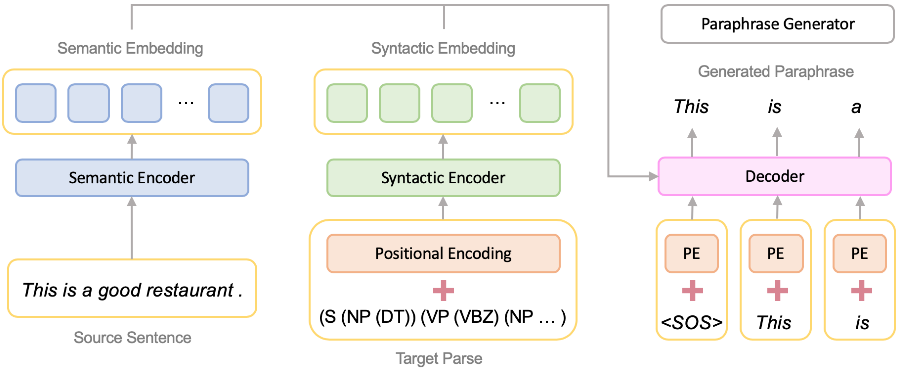

Figure 2: SynPG embeds the source sentence and the target parse into a semantic embedding and a syntactic embedding, respectively. Then, SynPG generates a paraphrase sentence based on the two embeddings.

while the syntactic encoder extracts only the syntactic information from the target parse $\mathbf{p}$. The decoder then combines the encoded semantic and syntactic information and generates a paraphrase $\mathbf{y}$. We discuss the details of SynPG in the following.

Semantic encoder. The semantic encoder embeds a source sentence $\mathbf{x}$ into a contextualized semantic embedding $\mathbf{z}_{sem}$. In other words,

$$\mathbf{z}_{sem} = (z_1, z_2, ..., z_n) = \text{Enc}_{sem}((x_1, x_2, .., x_n)).$$

The semantic embedding $\mathbf{z}_{sem}$ is supposed to contain only the semantic information of the source sentence $\mathbf{x}$. To separate the semantic information from the syntactic information, we use a Transformer (Vaswani et al., 2017) *without the positional encoding* as the semantic encoder. We posit that by removing position information from the source sentence $\mathbf{x}$, the semantic embedding $\mathbf{z}_{sem}$ would encode less syntactic information.

We assume that words without ordering capture most of the semantics of one sentence. Indeed, semantics is also related to the order. For example, exchanging the subject and the object of a sentence changes its meaning. However, the decoder trained on a large corpus also captures the *selectional preferences* (Katz and Fodor, 1963; Wilks, 1975) in generation, which enables the decoder to infer the proper order of words. In addition, we observe that when two sentences are paraphrased, they usually share similar words, especially those words related to the semantics. For example, "*What is the best way to improve writing skills?*" and "*How can I improve my writing skills?*" are paraphrased, and the shared words (*improve*, *writing*, and *skills*) are strongly related to the semantics. In Section 4, we show that our designed semantic embedding captures enough semantic information to generate paraphrases.

Syntactic encoder. The syntactic encoder embeds the target parse $\mathbf{p} = (p_1, p_2, ..., p_k)$ into a contextualized syntactic embedding $\mathbf{z}_{syn}$. That is,

$$\mathbf{z}_{syn} = (z_1, z_2, ..., z_k) = \text{Enc}_{syn}((p_1, p_2, .., p_k)).$$

Since the target parse $\mathbf{p}$ contains no semantic information but only syntactic information, we use a Transformer *with the positional encoding* as the syntactic encoder.

Decoder. Finally, we design a decoder that takes the semantic embedding $\mathbf{z}_{sem}$ and the syntactic embedding $\mathbf{z}_{syn}$ as the input and generates a paraphrase $\mathbf{y}$. In other words,

$$\mathbf{y} = (y_1, y_2, ..., y_m) = \text{Dec}(\mathbf{z}_{sem}, \mathbf{z}_{syn}).$$

We choose Transformer as the decoder to generate $\mathbf{y}$ autoregressively. Notice that the semantic embedding $\mathbf{z}_{sem}$ does not encode the position information and the syntactic embedding $\mathbf{z}_{syn}$ does not contain semantics. This forces the decoder to extract the semantics from $\mathbf{z}_{sem}$ and retrieve the syntactic structure from $\mathbf{z}_{syn}$. The attention weights attaching to $\mathbf{z}_{sem}$ and $\mathbf{z}_{syn}$ make the decoder learn the association between the semantics and the syntax as well as the relation between the word order and the parse structures. Therefore, SynPG is able to reorganize the source sentence and use the given syntactic structure to rephrase the source sentence.

2.2 Unsupervised Training

Our design of the disentanglement makes it possible to train SynPG without using annotated pairs. We train SynPG with the objective to reconstruct the source sentences. More specifically, when training on a sentence $\mathbf{x}$, we first separate $\mathbf{x}$ into two parts: 1) an unordered word list $\bar{\mathbf{x}}$ and 2) its linearized parse $\mathbf{p}_x$ (can be obtained by a pretrained parser). Then, SynPG is trained to reconstruct $\mathbf{x}$ from $(\bar{\mathbf{x}}, \mathbf{p}_x)$ with the reconstruction loss

$$\mathcal{L} = -\sum_{i=1}^{n} \log P(y_i = x_i | \bar{\mathbf{x}}, \mathbf{p}_x, \mathbf{y}_1, ..., \mathbf{y}_{i-1}).$$

Notice that if we do not disentangle the semantics and the syntax, and directly use a seq2seq model to reconstruct $\mathbf{x}$ from $(\mathbf{x}, \mathbf{p}_x)$, it is likely that the seq2seq model only learns to copy $\mathbf{x}$ and ignores $\mathbf{p}_x$ since $\mathbf{x}$ contains all the necessary information for the reconstruction. Consequently, at inference time, no matter what target parse $\mathbf{p}$ is given, the seq2seq model always copies the whole source sentence $\mathbf{x}$ as the output (more discussion in Section 4).

On the contrary, SynPG learns the disentangled embeddings $\mathbf{z}_{sem}$ and $\mathbf{z}_{syn}$. This makes SynPG capture the relation between the semantics and the syntax to reconstruct the source sentence $\mathbf{x}$. Therefore, at test time, given the source sentence $\mathbf{x}$ and a new target parse $\mathbf{p}$, SynPG is able to apply the learned relation to rephrase the source sentence $\mathbf{x}$ according to the target parse $\mathbf{p}$.

Word dropout. We observe that the ground truth paraphrase may contain some words not appearing in the source sentence; however, the paraphrases generated by the vanilla SynPG tend to include only words appearing in the source sentence due to the reconstruction training objective. To encourage SynPG to improve the diversity of the word choices in the generated paraphrases, we randomly discard some words from the source sentence during training. More precisely, each word has a probability to be dropped out in each training iteration. Accordingly, SynPG has to predict the missing words during the reconstruction, and this enables SynPG to select different words from the source sentence to generate paraphrases. More details are discussed in Section 4.5.

2.3 Templates and Parse Generator

In the previous discussion, we assume that a full target constituency parse tree is provided as the input to SynPG. However, the full parse tree of the target paraphrase sentence is unlikely available at inference time. Therefore, following the setting in Iyyer et al. (2018), we consider generating the paraphrase based on the *template*, which is defined as the top two levels of the full constituency parse tree. For example, the template of `(S(NP(PRP))(VP(VBZ)(NP(NNS)))(.))` is `(S(NP)(VP))(.))`.

Motivated by Iyyer et al. (2018), we train a parse generator to generate full parses from templates. The proposed parse generator has the same architecture as SynPG, but the input and the output are different. The parse generator takes two inputs: a tag sequence $\mathbf{tag}_x$ and a target template $\mathbf{t}$. The tag sequence $\mathbf{tag}_x$ contains all the POS tags of the source sentence $\mathbf{x}$. For example, the tag sequence of the sentence "*He eats apples.*" is "`<PRP> <VBZ> <NNS> <.>`". Similar to the source sentence in SynPG, we do not consider the word order of the tag sequence during encoding. The expected output of the parse generator is a full parse $\tilde{\mathbf{p}}$ whose a syntactic structure follows the target template $\mathbf{t}$.

We train the parse generator without any additional annotations as well. Let $\mathbf{t}_x$ be the the template of $\mathbf{p}_x$ (the parse of $\mathbf{x}$), we end-to-end train the parse generator with the input being $(\mathbf{tag}_x, \mathbf{t}_x)$ and the output being $\mathbf{p}_x$.

Generating paraphrases from templates. The parse generator makes us generate paraphrases by providing target templates instead of target parses. The steps to generate a paraphrase given a source sentence $\mathbf{x}$ and a target template $\mathbf{t}$ are as follows:

1. Get the tag sequence $\mathbf{tag}_x$ of the source sentence $\mathbf{x}$.
2. Use the parse generator to generate a full parse $\tilde{\mathbf{p}}$ with input $(\mathbf{tag}_x, \mathbf{t})$.
3. Use SynPG to generate a paraphrase $\mathbf{y}$ with input $(\mathbf{x}, \tilde{\mathbf{p}})$.

Post-processing. We notice that certain templates are not suitable for some source sentences and therefore the generated paraphrases are nonsensical. We follow Iyyer et al. (2018) and use n-gram overlap and paraphrastic similarity computed by the model[2] from Wieting and Gimpel (2018) to remove nonsensical paraphrases[3].

3 Experimental Settings

We conduct extensive experiments to demonstrate that SynPG performs better syntactic control than other unsupervised paraphrase models, while the quality of generated paraphrases by SynPG is comparable to others. In addition, we show that the performance of SynPG is competitive or even better than supervised models when the training data is large enough.

---

[2] https://github.com/jwieting/para-nmt-50m

[3] We set the minimum n-gram overlap to 0.3 and the minimum paraphrastic similarity to 0.7.

3.1 Datasets

For the training data, we consider ParaNMT-50M (Wieting and Gimpel, 2018), a paraphrase dataset containing over 50 million pairs of reference sentences and the corresponding paraphrases as well as the quality scores. We select about 21 million pairs with higher quality scores as our training examples. Notice that we use *only the reference sentences* to train SynPG and unsupervised paraphrase models since we do not require paraphrase pairs.

We sample 6,400 pairs from ParaNMT-50M as the testing data. To evaluate the transferability of SynPG, we also consider the other three datasets: 1) Quora (Iyer et al., 2017) contains over 400,000 paraphrase pairs and we sample 6,400 pairs from them. 2) PAN (Madnani et al., 2012) contains 5,000 paraphrase pairs. 3) MRPC (Dolan et al., 2004) contains 2,753 paraphrase pairs.

3.2 Evaluation

We consider paraphrase pairs to evaluate all the models. For each test paraphrase pair $(\mathbf{x}_1, \mathbf{x}_2)$, we consider $\mathbf{x}_1$ as the source sentence and treat $\mathbf{x}_2$ as the target sentence (ground truth). Let $\mathbf{p}_2$ be the parse of $\mathbf{x}_2$, given $(\mathbf{x}_1, \mathbf{p}_2)$, The model is expected to generate a paraphrase $\mathbf{y}$ that is similar to the target sentence $\mathbf{x}_2$.

We use BLEU score (Papineni et al., 2002) and human evaluation to measure the similarity between $\mathbf{x}_2$ and $\mathbf{y}$. Moreover, to evaluate how well the generated paraphrase $\mathbf{y}$ follows the target parse $\mathbf{p}_2$, we define the *template matching accuracy* (TMA) as follows. For each ground truth sentence $\mathbf{x}_2$ and the corresponding generated paraphrase $\mathbf{y}$, we get their parses ($\mathbf{p}_2$ and $\mathbf{p}_y$) and templates ($\mathbf{t}_2$ and $\mathbf{t}_y$). Then, we calculate the percentage of pairs whose $\mathbf{t}_y$ *exactly matches* $\mathbf{t}_2$ as the *template matching accuracy.*

3.3 Models for Comparison

We consider the following unsupervised paraphrase models: 1) **CopyInput**: a naïve baseline which directly copies the source sentence as the output without paraphrasing. 2) **BackTrans**: back-translation is proposed to generate paraphrases (Mallinson et al., 2017; Wieting and Gimpel, 2018; Hu et al., 2019). In our experiment, we use the pretrained EN-DE and DE-EN translation models[4] proposed by Ng et al. (2019) to conduct back-translation. Notice that training translation models requires additional translation pairs. Therefore, BackTrans needs more resources than ours and the translation data may not available for some low-resource languages. 3) **VAE**: we consider a vanilla variational autoencoder (Bowman et al., 2016) as a simple baseline. 4) **SIVAE**: syntax-infused variational autoencoder (Zhang et al., 2019) utilizes additional syntax information to improve the quality of sentence generation and paraphrase generation. Unlike SynPG, SIVAE does not disentangle the semantics and syntax. 5) **Seq2seq-Syn**: we train a seq2seq model with Transformer architecture to reconstruct $\mathbf{x}$ from $(\mathbf{x}, \mathbf{p}_x)$ without the disentanglement. We use this model to study the influence of the disentanglement. 6) **SynPG**: our proposed model which learns disentangled embeddings.

We also compare SynPG with supervised approaches. We consider the following: 1) **Seq2seq-Sup**: a seq2seq model with Transformer architecture trained on whole ParaNMT-50M pairs. 2) **SCPN**: syntactically controlled paraphrase network (Iyyer et al., 2018) is a supervised paraphrase model with syntactic control trained on ParaNMT-50M pairs. We use their pretrained model[5].

3.4 Implementation Details

We consider byte pair encoding (Sennrich et al., 2016) for tokenization and use Stanford CoreNLP parser (Manning et al., 2014) to get constituency parses. We set the max length of sentences to 40 and set the max length of linearized parses to 160 for all the models. For the encoders and the decoder of SynPG, we use the standard Transformer (Vaswani et al., 2017) with default parameters. The word embedding is initialized by GloVe (Pennington et al., 2014). We use Adam optimizer with the learning rate being 10^{-4} and the weight decay being 10^{-5}. We set the word dropout probability to 0.4 (more discussion in Section 4.5). The number of epoch for training is set to 5.

Seq2seq-Syn, Seq2seq-Sup are trained with the similar setting. We reimplemnt VAE and SIVAE, and all the parameters are set to the default value in the original papers.

4 Results and Discussion

4.1 Syntactic Control

We first discuss if the syntactic specification enables SynPG to control the output syntax better.

---

[5] https://github.com/miyyer/scpn

	Model	ParaNMT		Quora		PAN		MRPC	
		TMA	BLEU	TMA	BLEU	TMA	BLEU	TMA	BLEU
No Paraphrasing	CopyInput	33.6	16.4	55.0	20.0	37.3	26.8	47.9	30.7
Unsupervised Models	BackTrans	29.0	16.3	53.0	16.4	27.9	16.2	47.2	21.6
	VAE	26.3	9.6	44.0	8.1	19.4	5.2	20.8	1.2
With Syntactic Specifications	SIVAE	30.0	12.8	48.3	13.1	26.6	11.8	21.5	5.1
	Seq2seq-Syn	33.5	16.3	54.9	19.8	37.1	**26.5**	47.7	**30.4**
	SynPG	**71.0**	**32.2**	**82.6**	**33.2**	**66.3**	26.4	**74.0**	26.2

Table 1: Paraphrase results on four datasets. TMA denotes the template matching accuracy, which evaluates how often the generated paraphrases follow the target parses. With the syntactic control, SynPG obtains higher BLEU score and the template matching accuracy. This implies the paraphrases generated by SynPG are more similar to the ground truths and follow the target parses more accurately.

Model	Example 1 (ParaNMT)	Example 2 (Quora)
Source Sent.	these children are gonna die if we don't act now.	what are the best ways to improve writing skills?
Ground Truth	if we don't act quickly, the children will die.	how could i improve my writing skill?
BackTrans	these children will die if we do not act now.	what are the best ways to improve your writing skills?
VAE	these children are gonna die if we don't act now.	what are the best ways to improve writing skills?
SIVAE	these children are gonna die if we don't act now .	what are the best ways to improve writing skills?
Seq2seq-Syn	these children are gonna die if we don't act now.	what are the best ways to improve writing skills?
SynPG	if we don't act now, these children will die.	how can i improve my writing skills?

Table 2: Paraphrases generated by each model. SynPG can generate paraphrases with the syntax more similar to the ground truth than other baselines.

Table 1 shows the template matching accuracy and BLEU score for SynPG and the unsupervised baselines. Notice that here we use the full parse trees as the syntactic specifications. We will discuss the influence of using the template as the syntactic specifications in Section 4.3.

Although we train SynPG on the reference sentences of ParaNMT-50M, we observe that SynPG performs well on Quora, PAN, and MRPC as well. This validates that SynPG indeed learns the syntactic rules and can transfer the learned knowledge to other datasets. CopyInput gets high BLEU scores; however, due to the lack of paraphrasing, it obtains low template matching scores. Compared to the unsupervised baselines, SynPG achieves higher template matching accuracy and higher BLEU scores on all datasets. This verifies that the syntactic specification is indeed helpful for syntactic control.

Next, we compare SynPG with Seq2seq-Syn and SIVAE. All models are given syntactic specifications; however, without the disentanglement, Seq2seq-Syn and SIVAE tend to copy the source sentence as the output and therefore get low template matching scores.

Table 2 lists some paraphrase examples generated by all models. Again, we observe that without syntactic specifications, the paraphrases generated by unsupervised baselines are similar to the source sentences. Without the disentanglement, Seq2seq-Syn and SIVAE always copy the source sentences. SynPG is the only model can generate paraphrases syntactically similar to the ground truths.

4.2 Human Evaluation

We perform human evaluation using Amazon Mechanical Turk to evaluate the quality of generated paraphrases. We follow the setting of previous work (Kok and Brockett, 2010; Iyyer et al., 2018; Goyal and Durrett, 2020). For each model, we randomly select 100 pairs of source sentence $\mathbf{x}$ and the corresponding generated paraphrase $\mathbf{y}$ from ParaNMT-50M test set (after being post-processed as mentioned in Section 2.3) and have three Turkers annotate each pair. The annotations are on a three-point scale: **0** means $\mathbf{y}$ is not a paraphrase of $\mathbf{x}$; **1** means $\mathbf{x}$ is paraphrased into $\mathbf{y}$ but $\mathbf{y}$ contains some grammatical errors; **2** means $\mathbf{x}$ is paraphrased into $\mathbf{y}$, which is grammatically correct.

The results of human evaluation are reported in Table 3. If paraphrases rated **1** or **2** are considered meaningful, we notice that SynPG generates meaningful paraphrases at a similar frequency to that of SIVAE. However, SynPG tends to generate more ungrammatical paraphrases (those rated **1**). We think the reason is that most of paraphrases generated by SIVAE are very similar to the source sentences, which are usually grammatically correct. On the other hand, SynPG is encouraged to

Model	**2**	**1**	**0**	**2+1**	Hit Rate
BackTrans	63.6	22.4	14.0	86.0	11.0
SIVAE	57.6	20.3	22.0	78.0	6.5
SynPG	44.3	32.0	23.7	76.3	28.9

Table 3: Human evaluation on a three-point scale (**0** = not a paraphrase, **1** = ungrammatical paraphrase, **2** = grammatical paraphrase). SynPG performs better on hit rate (defined as the percentage of generated paraphrase getting **2** and matching the target parse at the same time) than other unsupervised models.

use different syntactic structures from the source sentences to generate paraphrases, which may lead some grammatical errors.

Furthermore, we calculate the *hit rate*, the percentage of generated paraphrases getting **2** and matching the target parse at the same time. The hit rate measures how often the generated paraphrases follow the target parses and preserve the semantics (verified by human evaluation) simultaneously. The results show that SynPG gets higher hit rate than other models.

4.3 Target Parses vs. Target Templates

Next, we discuss the influence of generating paraphrase by using templates instead of using full parse trees. For each paraphrase pair $(\mathbf{x}_1, \mathbf{x}_2)$ in test data, we consider two ways to generate the paraphrase. 1) Generating the paraphrase with the target parse. We use SynPG to generate a paraphrase directly from $(\mathbf{x}_1, \mathbf{p}_2)$. 2) Generating the paraphrase with the target template. We first use the parse generator to generate a parse $\tilde{\mathbf{p}}$ from $(\mathbf{tag}_1, \mathbf{t}_2)$, where $\mathbf{tag}_1$ is the tag sequence of $\mathbf{x}_1$ and $\mathbf{t}_2$ is the template of $\mathbf{p}_2$. Then we use SynPG to generate a paraphrase from $(\mathbf{x}_1, \tilde{\mathbf{p}})$. We calculate the template matching accuracy to compare these two ways to generate paraphrases, as shown in Table 4. We also report the template matching accuracy of the generated parse $\tilde{\mathbf{p}}$.

We find that most of generated parses $\tilde{\mathbf{p}}$ indeed follow the target templates, which means that the parse generator usually generates good parses $\tilde{\mathbf{p}}$. Next, we observe that generating paraphrases with target parses usually performs better than with target templates. The results show a trade-off. Using templates proves more effortless during the generation process, but may compromise the syntactic control ability. In comparison, by using the target parses, we have to provide more detailed parses, but our model can control the syntax better.

Another benefit of generating paraphrase with target templates is that we can easily generate a lot of syntactically different paraphrases by feeding the model with different templates. Table 5 lists some paraphrases generated by SynPG with different templates. We can perceive that most generated paraphrases are grammatically correct and have similar meanings to the original sentence.

Model	Template Matching Accuracy			
	ParaNMT	Quora	PAN	MRPC
Paraphrases generated by target parses	71.0	82.6	66.3	74.0
Paraphrases generated by target templates	54.1	73.4	51.7	62.3
Parses $\tilde{\mathbf{p}}$ generated by parse generator	98.4	99.0	95.7	93.9

Table 4: Influence of using templates. Using templates proves more effortless during the generation process, but may compromise the syntactic control ability.

4.4 Training SynPG on Larger Dataset

Finally, we demonstrate that the performance of SynPG can be further improved and be even competitive to supervised models on some datasets if we consider more training data. The advantage of unsupervised paraphrase models is that we do not require parallel pairs for training. Therefore, we can easily boost the performance of SynPG by consider more unannotated texts into training.

We consider SynPG-Large, the SynPG model trained on the reference sentences of ParaNMT-50M as well as One Billion Word Benchmark (Chelba et al., 2014), a large corpus for training language models. We sample about 24 million sentences from One Billion Word and add them to the training set. In addition, we fine-tune SynPG-Large on only the reference sentences of the testing paraphrase pairs, called SynPG-FT.

From Table 6, We observe that enlarging the training data set indeed improves the performance. Also, with the fine-tuning, the performance of SynPG can be much improved and even is better than the performance of supervised models on some datasets. The results demonstrate the potential of unsupervised paraphrase generation with syntactic control.

4.5 Word Dropout Rate

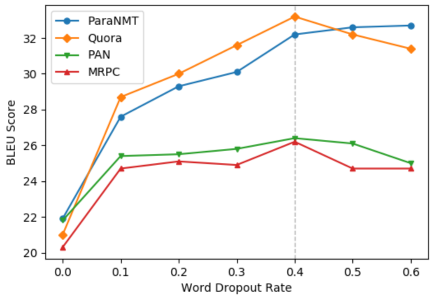
The word dropout rate plays an important role for SynPG since it controls the ability of SynPG to generate new words in paraphrases. We test differ-

Template	Generated Paraphrase
Original	can you adjust the cameras?
(S(NP)(VP)(.))	you can adjust the cameras.
(SBARQ(ADVP)(,)(S)(,)(SQ)(.))	well, adjust the cameras , can you?
(S(PP)(,)(NP)(VP)(.))	on the cameras, you can adjust them?
Original	she doesn't keep pictures from her childhood.
(SBARQ(WHADVP)(SQ)(.))	why doesn't she keep her pictures from childhood.
(S(``)(NP)(VP)('')(NP)(VP)(.))	" she doesn't keep pictures from her childhood " she said.
(S(ADVP)(NP)(VP)(.))	perhaps she doesn't keep pictures from her childhood.

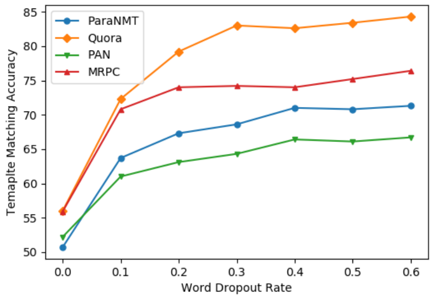
Table 5: Paraphrases generated by SynPG with different templates.

	Model	ParaNMT		Quora		PAN		MRPC	
		TMA	BLEU	TMA	BLEU	TMA	BLEU	TMA	BLEU
Ours	SynPG	71.0	32.2	82.6	33.2	66.3	26.4	74.0	26.2
	SynPG-Large	70.3	31.8	83.8	34.7	66.6	27.1	79.3	36.2
	SynPG-FT	–	–	86.3	**44.4**	66.4	34.2	**80.7**	**44.6**
Supervised Models	Seq2seq-Sup	40.2	19.6	54.0	11.3	29.2	13.1	44.3	16.3
	SCPN	**83.9**	**58.3**	**87.1**	41.0	**72.3**	**37.6**	80.1	41.8

Table 6: Training on larger dataset improves the performance of SynPG. Since training SynPG does not require annotated paraphrase pairs, it is possible to fine-tune SynPG on the texts in the target domain. With the fine-tuning, SynPG can have competitive or even better performance than supervised approaches.



(a) BLEU score



(b) Template matching accuracy

Figure 3: Influence of word drop out rate. Setting the word dropout rate to 0.4 can achieve the best BLEU score. However, higher word dropout rate leads to better template matching accuracy.

ent word dropout rates and report the BLEU scores and the template matching accuracy in Figure 3.

From Figure 3a, we can observe that setting the word dropout rate to 0.4 can achieve the best BLEU score in most of datasets. The only exception is ParaNMT, which is the dataset used for training. On the other hand, Figure 3b shows that higher word dropout rate leads to better template matching accuracy. The reason is that higher word dropout rate gives SynPG more flexibility to generate paraphrases. Therefore, the generated paraphrases can match the target syntactic specifications better. However, higher word dropout rate also make SynPG have less ability to preserve the meaning of source sentences. Considering all the factors above, we recommend to set the word dropout rate to 0.4 for SynPG.

5 Improving Robustness of Models

Recently, a lot of work show that NLP models can be fooled by different types of adversarial attacks (Alzantot et al., 2018; Ebrahimi et al., 2018; Iyyer et al., 2018; Tan et al., 2020; Jin et al., 2020). Those attacks generate *adversarial examples* by slightly modifying the original sentences without changing the meanings, while the NLP models change the predictions on those examples. However, a robust model is expected to output the same labels. Therefore, how to make NLP models not affected by the adversarial examples becomes an important task.

Since SynPG is able to generate syntactically different paraphrases, we can improve the robustness of NLP models by data augmentation. The models trained with data augmentation are thus more robust to the syntactically adversarial examples (Iyyer et al., 2018), which are the adversarial sentences that are paraphrases to the original sen-

Model	SST-2		MRPC		RTE	
	Acc.	Brok.	Acc.	Brok.	Acc.	Brok.
Base	91.9	46.7	84.1	52.8	63.2	58.3
SynPG	88.9	**39.6**	80.1	**35.5**	60.7	**33.9**

Table 7: Data augmentation improves the robustness of models. SynPG denotes the base classifier trained on augmented data generated by SynPG. Acc denotes the accuracy in the original dataset (the higher is the better). Brok denotes the percentage of examples changing predictions after attacking (the lower is the better).

tences but with syntactic difference.

We conduct experiments on three classification tasks covered by GLUE benchmark (Wang et al., 2019): SST-2, MRPC, and RTE. For each training example, we use SynPG to generate four syntactically different paraphrases and add them to the training set. We consider the setting to generate syntactically adversarial examples by SCPN (Iyyer et al., 2018). For each testing example, we generate five candidates of adversarial examples. If the classifier gives at least one wrong prediction on the candidates, we treat the attack to be successful.

We compare the model without data augmentation (Base) and with data augmentation (SynPG) in Table 7. We observe that with the data augmentation, the accuracy before attacking is slightly worse than Base. However, after attacking, the percentage of examples changing predictions is much less than Base, which implies that data augmentation indeed improves the robustness of models.

6 Related Work

Paraphrase generation. Traditional approaches usually require hand-crafted rules, such as rule-based methods (McKeown, 1983), thesaurus-based methods (Bolshakov and Gelbukh, 2004; Kauchak and Barzilay, 2006), and lattice matching methods (Barzilay and Lee, 2003). However, the diversity of their generated paraphrases is usually limited.

Recently, neural models make success on paraphrase generation (Prakash et al., 2016; Mallinson et al., 2017; Cao et al., 2017; Egonmwan and Chali, 2019; Li et al., 2019; Gupta et al., 2018). These approaches treat paraphrase generation as a translation task and design seq2seq models based on a large amount of parallel data. To reduce the effort to collect parallel data, unsupervised paraphrase generation has attracted attention in recent years. Wieting et al. (2017); Wieting and Gimpel (2018) use translation models to generate paraphrases via back-translation. Zhang et al. (2019); Roy and Grangier (2019) generate paraphrases based on variational autoencoders. Reinforcement learning techniques are also considered for paraphrase generation (Li et al., 2018).

Controlled generation. Recent work on controlled generation can be grouped into two families. The first family is doing end-to-end training with an additional trigger to control the attributes, such as sentiment (Shen et al., 2017; Hu et al., 2017; Fu et al., 2018; Peng et al., 2018; Dai et al., 2019), tense (Logeswaran et al., 2018), plots (Ammanabrolu et al., 2020; Fan et al., 2019; Tambwekar et al., 2019; Yao et al., 2019; Goldfarb-Tarrant et al., 2019, 2020), societal bias (Wallace et al., 2019; Sheng et al., 2020b,a), and syntax (Iyyer et al., 2018; Goyal and Durrett, 2020; Kumar et al., 2020). The second family controls the attributes by learning disentangled representations. For example, Romanov et al. (2019) disentangle the meaning and the form of a sentence. Chen et al. (2019b,a); Bao et al. (2019) disentangle the semantics and the syntax of a sentence.

7 Conclusion

We present syntactically controlled paraphrase generator (SynPG), an paraphrase model that can control the syntax of generated paraphrases based on the given syntactic specifications. SynPG is designed to disentangle the semantics and the syntax of sentences. The disentanglement enables SynPG to be trained without the need for annotated paraphrase pairs. Extensive experiments show that SynPG performs better syntactic control than unsupervised baselines, while the quality of the generated paraphrases is competitive to supervised approaches. Finally, we demonstrate that SynPG can improve the robustness of NLP models by generating additional training examples. SynPG is especially helpful for the domain where annotated paraphrases are hard to obtain but a large amount of unannotated text is available. One limitation of SynPG is the need for mannually providing target syntactic templates at inference time. We leave the automatic template generation as our future work.

Abstract

The automatic detection of hypernymy relationships represents a challenging problem in NLP. The successful application of state-of-the-art supervised approaches using distributed representations has generally been impeded by the limited availability of high quality training data. We have developed two novel data augmentation techniques which generate new training examples from existing ones. First, we combine the linguistic principles of hypernym transitivity and intersective modifier-noun composition to generate additional pairs of vectors, such as *small dog - dog* or *small dog - animal*, for which a hypernymy relationship can be assumed. Second, we use generative adversarial networks (GANs) to generate pairs of vectors for which the hypernymy relation can also be assumed. We furthermore present two complementary strategies for *extending* an existing dataset by leveraging linguistic resources such as WordNet. Using an evaluation across 3 different datasets for hypernymy detection and 2 different vector spaces, we demonstrate that both of the proposed automatic data augmentation and dataset extension strategies substantially improve classifier performance.

1 Introduction

The detection of hypernymy relationships between terms represents a challenging commonsense inference problem and is a major component in recognising paraphrase and textual entailment in larger units of text. Consequently, it is important for Question-Answering, Text Simplification and Automatic Summarization. For example,

There are lots of cars and vans at the port today.

might be adequately summarised by

There are lots of vehicles at the port today.

as *car* and *van* both lexically entail, i.e. they are both hyponyms of the more general term *vehicle*.

Furthermore, the recognition and discovery of hyponym-hypernym relations is a foundational part of constructing taxonomies, which has a range of practical applications in a variety of domains such as Healthcare (Barisevičius et al., 2018) or Fashion[1].

While distributed representations of words are commonly used to find semantically similar words, they do not straightforwardly provide a way to distinguish more fine-grained semantic information, such as hypernymy, co-hyponymy and meronymy relationships. This deficiency has attracted substantial attention in the literature, and with regard to the task of hypernymy detection, both unsupervised approaches (Hearst, 1992; Weeds et al., 2004; Kotlerman et al., 2010; Santus et al., 2014; Rimell, 2014; Nguyen et al., 2017; Chang et al., 2018) and supervised approaches (Weeds et al., 2014; Roller et al., 2014; Roller and Erk, 2016; Shwartz et al., 2016; Vulić and Mrkšić, 2018; Rei et al., 2018; Kamath et al., 2019) have been proposed.

Supervised methods have, however, been severely hampered by a lack of adequate training data. Not only has a paucity of labelled data been an obstacle in the adoption of deep neural networks and other more complex supervised methods, but two compounding problem-specific issues have been identified. First, there is a need to avoid lexical overlap between the training and test sets in order to avoid the lexical memorisation problem (Weeds et al., 2014; Levy et al., 2015a), where a supervised method simply learns the relationships between lexemes rather than generalising to their distributional features. Second, the performance of classifiers given just the hypernym word (at training

---

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1034–1048
April 19 - 23, 2021.

and testing) has been shown to be almost as good as performance given both words (Weeds et al., 2014; Shwartz et al., 2017). This suggests that classifiers are learning the distributional features that make something a more general term or a more specific term. Our conjecture is that in order to learn the more complex function, more complex machinery, and hence more labelled data is required.

In computer vision or speech recognition, it is common to use data augmentation to increase the size of the training set (Shrivastava et al., 2017; Park et al., 2019). The idea is that there are certain transformations of the data under which the class label remains invariant. For example, rotating an image does not change whether that image contains a face or not. By providing a supervised classifier with rotated examples, it can better generalise.

In this work, we consider the use of linguistic transformations to augment existing datasets for hypernymy detection. The challenge is to identify transformations that can be applied to the representations of two words that are known to be in a hypernym relationship, such that the entailment relation still holds between the transformed representations. We propose two ways to achieve this.

Our first augmentation technique is based on the hypothesis that lexical entailment is transitive and therefore invariant under certain compositions. For example, if A entails B and B entails C then A also entails C. Suitable candidates for A can be found by composing common intersective adjectives with the noun B. For example, if we know that *car* entails *vehicle*, then we can augment the dataset with *fast car* entails *car* and *fast car* entails *vehicle*.

Our second augmentation technique is based on the hypothesis that lexical entailment is invariant within a certain threshold of similarity. If A entails B, A' is very similar to A and B' is very similar to B then A' will also entail B'. In order to obtain vectors which are sufficiently similar to the words in the training data, we apply generative adversarial networks (GANs) to create realistic-looking synthetic vectors, from which we choose the most similar to the words in the training data.

We evaluate the proposed techniques on three hypernymy detection datasets. The first two are standard benchmark tasks in this area (Weeds et al., 2014; Baroni et al., 2012), both of which are generated from WordNet (Fellbaum, 1998). However, since many of the approaches to hypernmy classification involve vector space models which have been specialised using the entirety of WordNet, we need to guard against the danger that evaluations are simply measuring how well WordNet has been encoded, rather than how well the general hypernymy relationship has been learned. In light of this, we introduce a new dataset (that we call **HP4K**) which does not rely on WordNet in its construction.

We evaluate our two data augmentation techniques against two methods for increasing the size of the training data which rely on finding or mining more non-synthetic examples. First, we consider the extraction of additional examples from WordNet. Second, we consider extracting examples automatically from a Wikipedia corpus using Hearst Patterns (Hearst, 1992). This provides us with what one would expect to be an upper bound on what we might reasonably expect to achieve with a similar amount of synthetic examples generated using our data augmentation techniques.

Our contributions are thus threefold. First, we have identified two novel data augmentation techniques for the task of hypernymy detection which have the potential to generate almost limitless quantities of synthetic data. Second, we show, rather surprisingly, that adding synthetic data is more effective than adding non-synthetic data in almost all cases. Third, we release a new benchmark evaluation dataset for the lexical entailment task that is not dependent on WordNet.

2 Related Work

Data augmentation has recently become a very popular research topic in NLP and has successfully been applied in machine translation systems (Sennrich et al., 2016; Fadaee et al., 2017; Wang et al., 2018; Li et al., 2019; Tong et al., 2019; Matos Veliz et al., 2019; Xia et al., 2019; Gao et al., 2019; Li and Specia, 2019; Liu et al., 2019), but also for tasks such as relation extraction (Can et al., 2019; Yan et al., 2019), text classification (Wei and Zou, 2019), or natural language inference (Kang et al., 2018; Junghyun et al., 2020). Most similar to our usage of GANs for data augmentation is the proposal of Kang et al. (2018) who leverage a GAN-based setup together with WordNet for data augmentation for natural language inference.

While to the best of our knowledge this work represents the first application of data augmentation for lexical entailment, a number of alternative approaches have been proposed. Most proposals rely on supervised methods for injecting an external source of knowledge into distributional representations. Starting with *retro-fitting* (Faruqui et al., 2015), vector-specialization methods modify existing representations to embed desired features (Vulić and Mrkšić, 2018; Rei et al., 2018; Kamath et al., 2019; Glavaš and Vulić, 2019).

3 Data Augmentation Strategies for Hypernymy Detection

Given a labelled dataset $\mathcal{D}_{\mathcal{X}}$ of triples $\langle x^{(i)}_{hypo}, x^{(i)}_{hyper}, y^{(i)}\rangle$, where $x^{(i)}_{hypo}, x^{(i)}_{hyper} \in \mathcal{X}$ and $y^{(i)} \in \{0, 1\}$, we define data augmentation as adding additional hyponym-hypernym triples $\langle x'^{(j)}_{hypo}, x'^{(j)}_{hyper}, y'^{(j)}\rangle$ coming from an automatically generated augmentation set $\mathcal{A}_{\mathcal{X}'}$, such that $x'^{(j)}_{hypo}, x'^{(j)}_{hyper} \in \mathcal{X}'$ and $y'^{(j)} \in \{0, 1\}$, to the existing training set of $\mathcal{D}$. We ensure that the data augmentation does not introduce any lexical overlap with the existing test set, i.e. $\mathcal{X} \cap \mathcal{X}' = \emptyset$.

Data augmentation strategies in NLP can roughly be divided into two categories: linguistically grounded augmentation and artificial augmentation. In the former, which has been the dominant paradigm in NLP, any additional instances that are added to a training set have an actual surface form representation, i.e. the data points correspond to actual words or sentences (Kim et al., 2019; Kumar et al., 2019; Gao et al., 2019; Andreas, 2020; Croce et al., 2020). The latter adds instances that are fully or partly artificial, meaning they do not correspond to any words or sentences. In this work we propose methods for both categories, data augmentation via distributional composition adds data points grounded in real language to a training set, and data augmentation based on GANs infers plausible points in latent space, which however, do not correspond to any real linguistic objects.

Furthermore, we distinguish between *data augmentation* and *dataset extension*, where in the former case we only leverage knowledge from the existing dataset and in the latter case we rely on expanding the training set with additionally mined hyponym-hypernym pairs. Below, we discuss two ways of augmenting and two ways of extending a training set. We make use of a cleaned October 2013 Wikipedia dump (Wilson, 2015) as reference corpus to determine word and bigram frequencies.

Distributional Composition based Augmentation. We take a modified noun as being in a hypernymy relation with the unmodified noun. For example, we treat the pairs $\langle$*fast car*, *car*$\rangle$ and $\langle$*car*, *vehicle*$\rangle$ as expressing the same semantic relation when the modifier-noun compound is composed with an intersective composition function.

We focus on adjective-noun (AN) and noun-noun (NN) compounds, extracted from our reference corpus where each AN or NN phrase occurred at least 50 times. We filtered pairs with non-subsective adjectives using a wordlist from Nayak et al. (2014)[2].

We consider two strategies for automatically constructing positive hyponym-hypernym pairs: simple positive cases such as $\langle$*small dog*, *dog*$\rangle$ or $\langle$*fast car*, *car*$\rangle$; and gapped positive cases that mimic the transitivity of hypernym relations, where we pair the hypernym of an existing hyponym-hypernym pair with a compound hyponym. For example if $\langle$*car*, *vehicle*$\rangle$ is in the training data, we combine *car* with one of its modifiers to create the pair $\langle$*fast car*, *vehicle*$\rangle$.

We construct negative pairs from the simple positive cases using two strategies: creating compositional co-hyponyms such as $\langle$*fast car*, *red car*$\rangle$, where we keep the head noun fixed and pair it with two different modifiers; and creating perturbed simple positive examples, such as $\langle$*small dog*, *cat*$\rangle$ where we select the incorrect hypernym (e.g. *cat*) from the n most similar nouns to the composed hyponym (e.g. *dog*). We apply the same methodology to the perturbed gapped positive examples, replacing the correct hypernym with a noun from the top n neighbours of the compositional hyponym's head noun. For example, given a positive pair such as $\langle$*dog*, *animal*$\rangle$, this would result in negative examples such as $\langle$*small dog*, *vehicle*$\rangle$, where the hyponym *dog* is paired with a modifier and the hypernym *animal* is replaced with one of its neighbours, in this case, *vehicle*.

In neural word embeddings, an additive composition function approximates the intersection of the corresponding feature spaces (Tian et al., 2017), hence by creating positive pairs such as $\langle$*small dog*, *dog*$\rangle$, we encode the distributional inclusion hypothesis (Weeds et al., 2004; Geffet and Dagan, 2005) in the augmentation set.

GAN based Augmentation. We create an augmentation set using Generative Adversarial Networks (Goodfellow et al., 2014). GANs consist of two model components — the generator and the discriminator — which are typically implemented

---

[2] In preliminary experiments we did not find that filtering non-subsective adjectives had much of an effect, but decided to move forward with the filtered data nonetheless.

as neural networks. The generator's task is to create data that mimics the distribution of the original data, while the discriminator's task is to distinguish between data coming from the real distribution and synthetic data coming from the generator. Both components are trained jointly until the generator succeeds in creating realistic data. Using GANs for data augmentation has been shown to be a successful strategy for a number of computer vision tasks (Shrivastava et al., 2017; Frid-Adar et al., 2018; Neff, 2018). Our goal is to create synthetic hyponym-hypernym pairs that are similar to real examples. Unlike most other scenarios involving GANs for NLP tasks, our generated vectors do not need to correspond to actual words.

For our model - *GANDALF*[3] - we used a list of ≈40K nouns for which we had vector representations as the "real" data input to *GANDALF*, and sampled the synthetic vectors from a Gaussian distribution, optimising a binary cross-entropy error criterion for the generator and the discriminator, which are both simple feedforward networks with a single hidden layer. We provide *GANDALF*'s full model details in Appendix A. As an additional quality check for the generated vectors, we tested whether a logistic regression classifier could distinguish the synthetic and non-synthetic vectors. Typically, the accuracy of the classifier was between 0.55-0.65, meaning the classifier is barely able to distinguish between "real" vectors and generated ones.

Figure 1 illustrates the training loop of *GANDALF* as well as the selection process for constructing an augmented training set. Essentially, once *GANDALF* has been trained, the generator is used to create a large collection[4] of synthetic noun vectors. To augment a dataset, $\mathcal{D}_{\mathcal{X}}$, for each triple, $\langle x_{hypo}, x_{hyper}, y\rangle \in \mathcal{D}_{\mathcal{X}}$ we find the n synthetic vectors most similar to x_{hypo} and the n synthetic vectors most similar to x_{hyper} and for each of the n^2 synthetic vector pairs, $\langle x'_{hypo}, x'_{hyper}\rangle$, we create the triple $\langle x'_{hypo}, x'_{hyper}, y\rangle$. The augmented training set is formed by randomly sub-sampling this set of triples.

WordNet based Extension. WordNet (Fellbaum, 1998) is a large manually curated lexical resource, covering a wide range of lexical relations between words, where groups of semantically similar words form "synsets"[5]. For each synset we extract all hypernyms and hyponyms of a given lexeme, and add it as a positive hyponym-hypernym pair if the original lexeme and any extracted hypernym/hyponym occurs at least 30 times in our reference corpus.

We construct negative pairs based on distributional similarity, where we calculate the pairwise cosine similarities between all lexemes in the positive set. Subsequently we use all antecedent (LHS) lexemes from the extracted positive pairs and select the top n most similar words for each antecedent as negative examples[6].

Pattern based Extension. Hearst Patterns (Hearst, 1992) are textual patterns such as *a car **is-a** vehicle* and can be automatically mined from text corpora in an unsupervised way. This has recently been shown to deliver strong performance on the hypernymy detection task (Roller et al., 2018). In this work, we leverage Hearst Patterns to mine additional hyponym-hypernym pairs in order to extend a training set. We treat any extracted noun pairs as additional positive examples and create the negative pairs in the same way as for the WordNet-based approach above.

4 Experiments

We evaluate our models on the datasets **Weeds** (Weeds et al., 2014) and **LEDS** (Baroni et al., 2012): well-studied and frequently used benchmarks for the hypernymy detection task (Roller et al., 2014; Vilnis and McCallum, 2014; Roller and Erk, 2016; Carmona and Riedel, 2017; Shwartz et al., 2017). Since both datasets use WordNet during construction, this can give rise to a bias in favour of those models that also make use of WordNet. To address this concern, we have created a new entailment dataset, **HP4K**, that makes use of Hearst Patterns, and is manually annotated, thereby avoiding the use of WordNet.

Weeds: The dataset is based on nouns sampled from WordNet where each noun had to occur at least 100 times in Wikipedia, and its predominant sense had to account for more than 50% of the occurrences in SemCor (Miller et al., 1993). We use the predefined split of Weeds et al. (2014), that avoids any lexical overlap between the training and evaluation sets. The split contains 2012 examples in the training set, evenly balanced between positive and negative hyponym-hypernym pairs, and

---

[3] **GAN**-based **D**ata **A**ugmentation for **L**exical in**F**erence.

[4] We would typically create half a million synthetic nouns.

[5] We use the API provided by NLTK (Loper and Bird, 2002), using WordNet 3.0.

[6] Ensuring we don't accidentally add any real positive pairs.

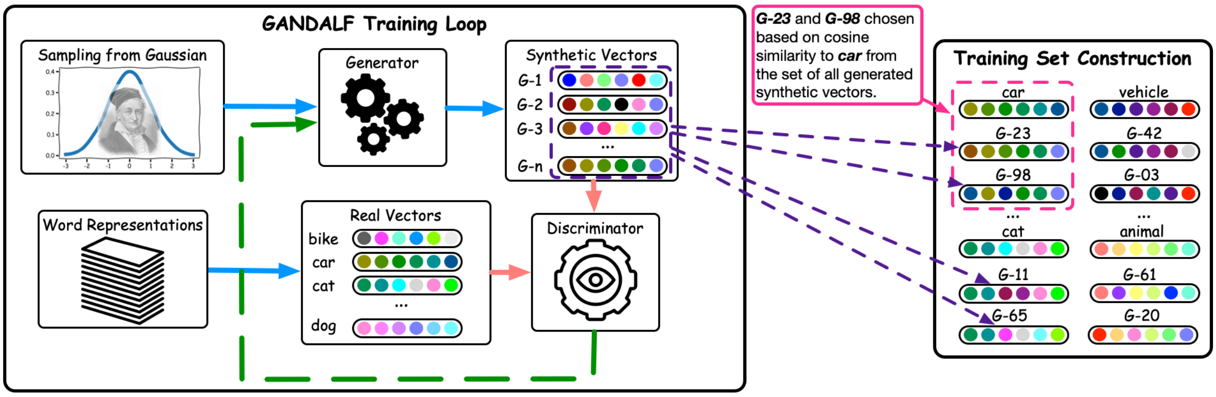

Figure 1: The left panel shows the training loop for *GANDALF* where synthetic noun vectors are generated from Gaussian noise. The discriminator's task is to distinguish between the generated synthetic vectors and real word representations from word2vec or HyperVec. The dashed line indicates error backpropagation, on the basis of the discriminator's current performance, through to the generator. After a final set of synthetic vectors has been generated with *GANDALF*, we choose the top n most similar synthetic vectors to a real representation and add these with the same label as the original hyponym-hypernym pair from an existing training set (e.g. $\langle cat, animal \rangle$) to the augmented training set (right panel).

502 examples in the evaluation set.

LEDS: The dataset consists of 2770 examples, evenly balanced between positive and negative hyponym-hypernym pairs. The positive examples are based on direct hyponym-hypernym relationships from WordNet and the negative examples are based on a random permutation of the hypernyms of the positive pairs. As there is no predefined training/evaluation split, we make use of the 20-fold cross-validation methodology of Roller and Erk (2016) that avoids any lexical overlap between training and evaluation sets.

HP4K: We extracted Hearst Patterns from our reference Wikipedia corpus and randomly selected 4500 unigram pairs. Subsequently, we manually annotated each pair according to whether it constitutes a correct hyponymy-hypernymy relation or not. The labelling was carried out by 4 experienced annotators — all domain experts, familiar with the problem of hypernymy detection. We then split up the annotators in two teams, with each team annotating one half of the dataset. The initial round of annotations resulted in a Cohen's κ score of 0.714, indicating substantial agreement (Viera and Garrett, 2005). Conflicts were resolved on a cross-team basis such that team A would resolve team B's annotation conflicts and vice-versa.

During annotation we noticed that positive pairs typically fall into one of two categories. Either they were "true" subtype-supertype relations, such as $\langle dog, animal \rangle$, or they were individual-class relationships where the hyponym is typically a named entity and represents a *specific* instance of the more general class, as for example in $\langle Nirvana, band \rangle$. Negative pairs were of a more diverse nature and included a range of different relations, such as co-hyponyms, meronyms or reverse hyponym-hypernyms. Negative pairs can also be comprised of two random nouns or two nouns without any semantic relation due to some amount of noise in extracting candidates solely on the basis of Hearst Patterns. Table 1 shows positive and negative examples from the dataset.

Pair	**Relationship**	**Label**
$\langle dog, animal \rangle$	hyponymy-hypernymy (Subtype)	*True*
$\langle Nirvana, band \rangle$	hyponymy-hypernymy (Instance)	*True*
$\langle beef, stew \rangle$	meronymy	*False*
$\langle pedestrian, road \rangle$	topical relatedness	*False*
$\langle chemical, adenosine \rangle$	reverse hyponymy-hypernymy	*False*
$\langle cherry, plum \rangle$	co-hyponymy	*False*
$\langle form, situation \rangle$	none	*False*

Table 1: Examples from our proposed **HP4K** dataset.

HP4K consists of 4369 pairs with a class distribution of 45:55 (positive : negative). Subsequently we split the dataset into a training and evaluation set, ensuring that there is no lexical overlap between the two sets. This resulted in a training set of size 3426 and an evaluation set of size 943[7].

4.1 Models

We conduct experiments with two distributional vector space models, word2vec (Mikolov et al., 2013) and HyperVec (Nguyen et al., 2017). HyperVec is based on word2vec's skip-gram architecture and leverages WordNet to optimise the word representations for the hypernym detection task. Hierarchical information is encoded in the norm of

---

[7] All resources are available from `https://github.com/tttthomasssss/le-augmentation`.

the learned vectors, such that lexemes higher up in the hypernymy hierarchy have larger norms than lexemes in lower parts.

For word2vec we use the 300-dimensional pre-trained Google News vectors[8] and for HyperVec we trained 100-dimensional embeddings on a October 2013 Wikipedia dump (Wilson, 2015), using the recommended settings of Nguyen et al. (2017), as our augmentation sets contained many words that were OOV in the pre-trained HyperVec vectors[9].

In our experiments, we consider a supervised scenario where a classifier predicts a hyponym-hypernym relation between two given word embeddings. We use two different models as classifier a logistic regression classifier (LR), and a 3-layer feedforward neural network (FF). In both cases, the classifier takes the aggregated hypothesised hyponym-hypernym pair as input and predicts whether the pair is in a hyponym-hypernym relation. We report a detailed overview of the model parameterisation in Appendix A.

The two models share the same procedure for aggregating the word embeddings of the hypothesised hyponym-hypernym pair. For data augmentation based on distributional composition, we use vector averaging as composition function, which gave substantially better performance than addition in preliminary experiments.

4.2 Results

For the FF network, we performed 10-fold cross-validation on the **Weeds** and **HP4K** training sets. As our evaluation for **LEDS** is based on a 20-fold cross-valiation split, rather than a pre-defined training/evaluation split as for **Weeds** and **HP4K**, the same procedure for hyperparameter tuning is not straightforwardly applicable without exposing the model to some of the evaluation data. However, we found that the top parameterisations for **Weeds** and **HP4K** were quite similar and therefore applied hyperparameters to the FF model for **LEDS** that performed well in 10-fold cross-validation on **Weeds** *and* **HP4K**. For data augmentation and dataset extension, we consider the following amounts of additional data: $\{0.2\text{K}, 1\text{K}, 2\text{K}, 4\text{K}, 10\text{K}, 20\text{K}, 40\text{K}\}$. All augmentation sets are balanced between positive and negative pairs.

Figure 2 shows the increase in absolute points of accuracy for the LR and FF model, as well as both vector spaces, averaged across all datasets. While in total data augmentation as well as dataset extension has a positive impact, the gains are larger for the FF model, suggesting that a higher capacity model is necessary to more effectively leverage the additional information from the augmentation source. Furthermore, before starting our experiments we exptected that extending an existing dataset with WordNet represents an upper bound on performance, given that WordNet is manually annotated and curated. However in our experiments we found that data augmentation by either distributional composition or by using *GANDALF* remarkably *surpassed* performance of the WordNet-based extension technique regularly.

The effect of data augmentation and dataset extension in absolute points of accuracy on each dataset individually for the FF model is shown in Figure 3. It highlights consistent improvements across the board with only a single performance degradation in the case of extending the LEDS dataset with Hearst Patterns when using HyperVec-based word representations. The results per dataset for the LR model are presented in Appendix A and show that the LR model is less effective in leveraging the augmented data, causing more frequent performance drops. This suggests that models with more capacity are able to make more efficient use of additional data and are more robust in the presence of noise which is inevitably introduced by automatic methods.

Table 2 compares our FF model using word2vec embeddings with all proposed techniques for augmenting or extending a dataset. Our techniques are able to outperform a non-augmented model by 4-6 points in accuracy, representing a relative error reduction of 14%-26%. While the primary objective in this work is to improve an existing model setup with data augmentation, our augmented models compare favourably with previously published results.[10] In general, data augmentation by distributional composition or by *GANDALF* overcomes two key weaknesses of simply extending a dataset with more data from WordNet or Hearst Patterns. First, many of the hyponym-hypernym pairs we mined from WordNet contain low-frequency words,

---

[8] Available from: `https://code.google.com/archive/p/word2vec/`.

[9] We used the HyperVec code from `www.ims.uni-stuttgart.de/data/hypervec`.

[10] We note that due to the use of different performance metrics and cross-validation splits, direct model-to-model comparisons are difficult on the LEDS and Weeds datasets. Thus we only compare to approaches that use the same evaluation protocol as we do.

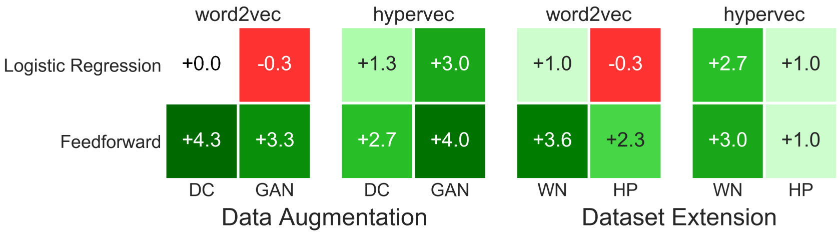

Figure 2: Effect of data augmentation and dataset extension in absolute points of accuracy averaged across all datasets over the same model without augmentation or extension. The 2 heatmaps on the left are based on data augmentation (DC=Distributional Composition, GAN=*GANDALF*). The 2 heatmaps on the right use dataset extension (WN=WordNet, HP=Hearst Patterns).

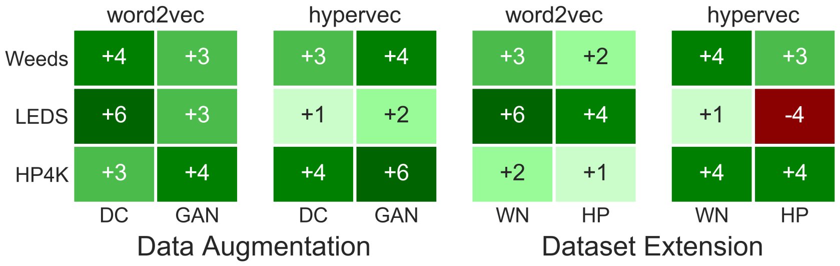

Figure 3: Effect of data augmentation and dataset extension in absolute points of accuracy on all datasets for the FF model.

Model	**Weeds**	**LEDS**	**HP4K**
No Augmentation	0.72	0.77	0.67
Distributional Composition	**0.76**	**0.83**	0.70
GANDALF	0.75	0.80	**0.71**
WordNet Extension	0.75	**0.83**	0.69
Hearst Patterns Extension	0.74	0.81	0.68
Weeds et al. (2014)	0.75	-	-
Carmona and Riedel (2017)	0.63	0.81	-

Table 2: Accuracy scores for the data augmentation and the two dataset extension strategies in comparison to the same FF model without any augmentation or extension.

which may have poor representations in our vector space models. Second, while using Hearst Patterns typically returned higher frequency words, the retrieved candidates frequently did not represent hyponymy-hypernymy relationships.

5 Analysis

The concrete amount of data augmentation, i.e. the number of additional hyponym-hypernym pairs that are added to the training set, represents a tuneable parameter. Figure 4 shows the effect of varying amounts of data augmentation for the FF model, using word2vec representations, across all datasets. We note that all amounts of additional augmentation data share the same quality, i.e. it is not the case that a smaller augmentation set consists of "better data" or contains less noise than a larger set. For the **Weeds** and **LEDS** datasets, peak performance is typically achieved with smaller amounts of additional data, whereas for the **HP4K** dataset optimal performance is achieved with larger amounts of augmentation data. One explanation for the different augmentation characteristics of the **HP4K** dataset in comparison to the other two datasets is its independence of WordNet during the development of the dataset.

5.1 Data Augmentation in Space

In order to visualise what area of the vector space the *GANDALF* vectors and the composed vectors inhabit, we created a t-SNE (van der Maaten and Hinton, 2008) projection of the vector spaces in Figure 5. For the visualisation we produced the nearest neighbours of standard word2vec embeddings and augmentation embeddings for 5 exemplary words and project them into the same space. Figure 5 shows that the generated augmentation points, marked with an "x", fit in with the real neighbours and do not deviate much from the "natural" neighbourhood of a given word. *GANDALF* vectors typically inhabit the edges of a neighbour cluster, whereas composed vectors are frequently closer to the cluster centroid. Table 3 lists the nearest neighbours for the example words. For word2vec and the composed augmentation vectors, we simply list the nearest neighbours of each query word. For *GANDALF* we list the nearest neighbours of the generated vector that correspond to actual words. For example, if the vector *GANDALF-234* is closest to the representations of *sugar*, *GANDALF-451* and *mountain*, we only list *sugar* and *mountain* as

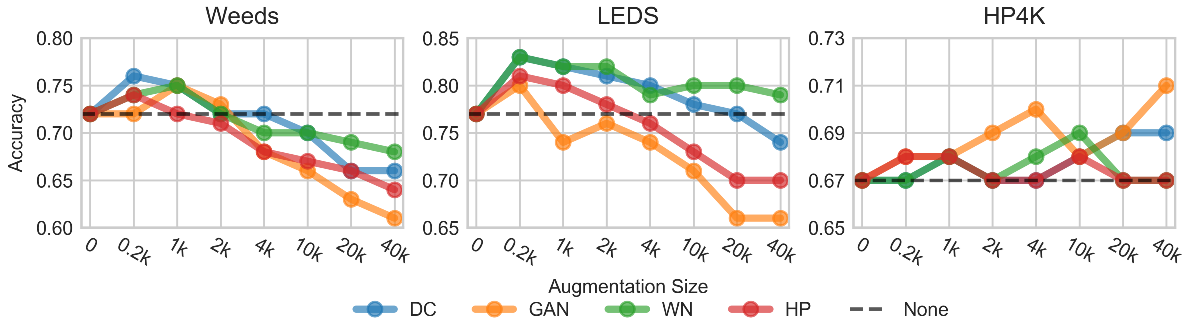

Figure 4: Impact of different amounts of data augmentation.

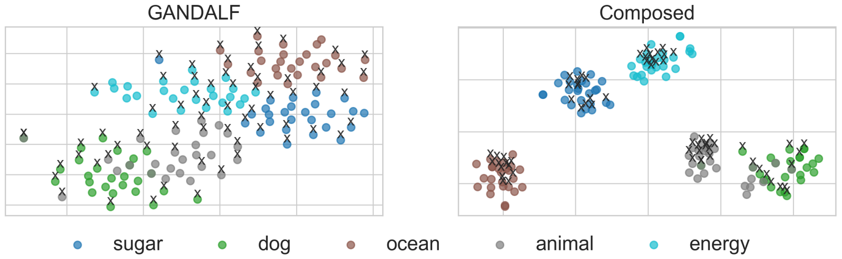

Figure 5: t-SNE visualisation of the data augmentation spaces. Data points marked with "x" denote the representation as coming from the data augmentation set.

neighbours of *GANDALF-234*.

The composed neighbours for each word are typically closely related to the original query, e.g. *raw sugar* for *sugar*, or *zoo animal* for *animal*. The *GANDALF* neighbours on the other hand have a much weaker association with the query word, but are frequently still related to it *somehow* as in the example of *akpeteshie*, which is a spirit on sugar cane basis, as a neighbour for *sugar*.

5.2 Data Augmentation as Regularisation

In the past, a prominent criticism of distributional methods for hypernymy detection was that such models were found to frequently identify features of a prototypical hypernym in the distributional representations, rather than being able to dynamically focus on the relevant features that are indicative of a hypernymy relation for a specific pair of words (Weeds et al., 2014; Levy et al., 2015b). We therefore briefly investigate whether data augmentation can be used as a regularisation mechanism that helps prevent models from overfitting on prototypical hypernym features.

Table 4 shows the results on the **Weeds** dataset using a hypernym-only FF model with word2vec representations, in comparison to the same model variant that makes use of the hyponym and the hypernym. Ideally, we would hope to see weak performance for the hypernym-only and strong performance on the full model. This would indicate that the classifier does not rely on prototypical features in the hypernym, but is able to focus on specific features in a given hyponym-hypernym pair. For data augmentation by distributional composition there appears to be a correlation between the performance of the hypernym-only and the full model, i.e. a stronger model on the whole dataset also results in better performance for the hypernymy-only model. Hence augmentation by distributional composition might not be effective in helping the model to generalise in its current form. For augmentation with *GANDALF* however, performance for the full model improves, while performance of the hypernym-only model slightly drops, suggesting that the evoked *GANDALF* representations have a regularisation effect, while also improving generalisation. Hence, a fruitful avenue for future work will be further leveraging data augmentation for regularisation.

6 Conclusion

In NLP, in contrast to computer vision, data augmentation has not been applied as standard due to the apparent lack of universal rules for label-invariant language transformations.

We have considered the problem of hypernymy detection, and proposed two novel techniques for data augmentation. These techniques rely on semantic rules rather than an external knowledge source, and have the potential to generate almost limitless synthetic data for this task. We demonstrate that these techniques perform better than

Word	**word2vec Neighbours**	***GANDALF* Neighbours**	**Composed Neighbours**
sugar	refined sugar, cane sugar, turbinado, cocoa, sugars	cmh rawalpindi, prescribed antipsychotic medication, sugar, mumtaz bhutto, akpeteshie	raw sugar, white sugar, brown sugar, sugar price, sugar industry
dog	dogs, puppy, pit bull, pooch, cat	ellis burks, sniffing glue, microchip implants, liz klekamp, cf rocco baldelli	pet cat, dog fighting, cat breed, rat terrier terrier breed
ocean	sea, oceans, pacific ocean, atlantic ocean, oceanic	pacific ocean, heavily vegetated, alaska aleutian, seagrasses, plutoid	ocean basin, pacific ocean, shallow sea, sea fish, sea mammal
animal	animals, animal welfare, dog, pet, cats	animals, pet, hallway feeds, poop scooping, panhandle animal welfare	first animal, adult animal, zoo animal, different animal, animal organization
energy	renewable energy, enery, electricity, enegy, fossil fuel	radial velocity measurements, stopped, renewable energy, bicycle advisory, steinkuehler	energy efficiency, solar energy, state energy, food energy, energy company

Table 3: Nearest neighbours for word2vec, GAN vectors and composed vectors.

Augmentation	**Hypernym-Only**	**Full**
No Data Augmentation	0.59	0.72
Distributional Composition (size=100)	0.60	**0.74**
Distributional Composition (size=500)	**0.57**	0.71
GANDALF (size=500)	**0.58**	**0.75**
GANDALF (size=1000)	0.60	0.73

Table 4: Accuracy for the hypernym-only and full models on the **Weeds** dataset with no, DC or GAN augmentation.

extending the training set with additional non-synthetic data, drawn from an external knowledge source in most cases. Our results are consistent across evaluation benchmarks, word vector spaces and classification architectures. We have also shown that our approach is effective even when the word vector space model has already been specialised for hypernymy detection.

Since WordNet is widely used as a source of information about semantic relations, we have proposed a new evaluation benchmark that is independent of WordNet. Whilst results are lower across the board on this dataset, suggesting that it is more difficult than the others, we see the same pattern of increasing performance with a more complex classifier and the use of data augmentation.

Future work includes leveraging data augmentation for more complex models and the extension of our approach to a multilingual setup as well as domains with a more specialised vocabulary such as Healthcare or Fashion.

Acknowledgements

Part of this research was supported by EPSRC grant no. 2129720: *Composition and Entailment in Distributed Word Representations*. We thank Mark Steedman for valuable feedback and insightful discussions that had substantial impact on the quality the paper. We also thank Nicola De Cao, without whose help *GANDALF* wouldn't have been able to defeat the Balrog of mediocre performance. Lastly, we thank several mini-batches of reviewers for their ~~stochastic gradients~~ helpful comments that iteratively improved the paper, rejection after rejection, until it *finally* converged towards acceptance.

A Supplemental Material

A.1 GANDALF Model Details

The generator and discriminator in *GANDALF* are single layer feedforward networks, with tanh activations and a dropout ratio (Srivastava et al., 2014) of 0.3. We used ADAM (Kingma and Ba, 2014) to optimise a binary cross entropy error criterion with a learning rate of 0.0002 and β values of 0.5 and 0.999. We found that *GANDALF* required quite a bit of wizardry to achieve strong performance and we found the website `https://github.com/soumith/ganhacks` very helpful. For example we applied label noise and soft labels (Salimans et al., 2016) and used a batch normalisation layer (Ioffe and Szegedy, 2015), which had the largest impact on model performance. *GANDALF* is implemented in PyTorch (Paszke et al., 2017) and we release our code on `https://github.com/tttthomasssss/le-augmentation`.

A.2 Model Details

For our linear model we use the logistic regrssion classifier implemented in scikit-learn (Pedregosa et al., 2011). Our neural network model is 3-layer feedforward model implemented in PyTorch (Paszke et al., 2017).

We tuned the parameters of the Feedforward neural network by 10-fold cross-validation on the respective training sets, except for **LEDS**, where we chose the parameters on the basis of a model that performed well on the **Weeds** and **HP4K**. Our parameter grid consisted of activation function: {tanh, relu}, dropout: { 0.0, 0.1, 0.3 } and hidden layer sizes, where we considered { 200-200-200, 200-100-50, 200-50-30 } for Hypervec and { 600-600-600, 600-400-200, 600-300-100, 600-200-50} for word2vec. We furthermore considered 3 different aggregation functions: `diff` (Weeds et al., 2014), which simply takes the elementwise difference of the embedding pair; `asym` (Roller et al., 2014) which is the concatenation of the difference and the squared difference of the embedding pair; and `concat-asym` (Roller and Erk, 2016), which is the concatenation of the embedding pair, their difference, and their squared difference. We trained all models for 30 epochs with early stopping and used ADAM with a learning rate of 0.01 to optimise a cross entropy error criterion.

A.3 Results

Figure 6 below shows the effect of data augmentation in terms of points of Accuracy for the logistic regression classifier per vector space model and dataset. Unlike for the higher-capacity feedforward model, data augmentation frequently causes performance to go down for the simpler linear model. This suggests that more complex models are required to fully leverage the additional information from the augmentation sets.

Table 5 below gives an overview over the complete results for both classifier and vector space models, across all datasets. It shows the consistent positive effect of data augmentation on the more complex feedforward model in comparison to the logistic regression classifier, which is less robust to the small amounts of noise that is inevitably introduced by the automatic augmentation algorithm.

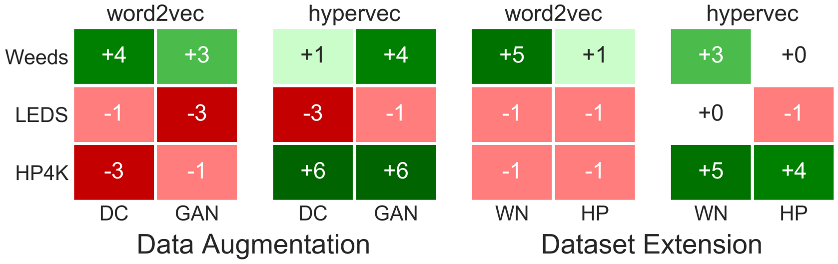

Figure 6: Effect of data augmentation and dataset extension in absolute points of accuracy on all datasets for the LR model.

Model	Weeds					LEDS					HP4K					Vector Space

Abstract

Machine translation (MT) models used in industries with constantly changing topics, such as translation or news agencies, need to adapt to new data to maintain their performance over time. Our aim is to teach a pre-trained MT model to translate previously unseen words accurately, based on very few examples. We propose (i) an experimental setup allowing us to simulate novel vocabulary appearing in human-submitted translations, and (ii) corresponding evaluation metrics to compare our approaches. We extend a data augmentation approach using a pre-trained language model to create training examples with similar contexts for novel words. We compare different fine-tuning and data augmentation approaches and show that adaptation on the scale of one to five examples is possible. Combining data augmentation with randomly selected training sentences leads to the highest BLEU score and accuracy improvements. Impressively, with only 1 to 5 examples, our model reports better accuracy scores than a reference system trained with on average 313 parallel examples.

1 Introduction

News agencies dealing with articles in multiple languages often rely on machine translation (MT) to provide an initial translation, which a journalist reworks into a final article. This can involve changing the structure or phrasing, but also correcting (or *post-editing*) mistranslated words or expressions, which can frequently occur when new topics emerge, bringing new vocabulary that has been rarely or never seen in the data used for training. The willingness of a journalist to use MT technology is dependent on the general quality of the models, but also on whether they can learn from the journalist's corrections, to avoid them having to correct the same errors time and time again.

Various strategies have been explored to learn from a journalist's post-edits. One option is to use an automatic post-editing (APE) model trained on the journalist's post-edits. However, state-of-the-art APE systems (Junczys-Dowmunt and Grundkiewicz, 2017) typically require large numbers of post-edits for training, which are rarely available or hard to generate (particularly for low-resource languages). An alternative, commonly used strategy is to fine-tune models to in-domain data, but this is prone to overfitting (Miceli Barone et al., 2017). More advanced ways of continually learning through fine-tuning have been explored, selecting similar training instances based on their similarity with test sentences (Li et al., 2018; Turchi et al., 2017). These methods achieve good results according to automatic MT metrics but can also overfit when training is continued. So far there has been little focus on the speed of adaptation required—so as to minimize the number of human interventions required—and the trade-off between successfully adapting to specific new post-edits and maintaining a good global translation quality.

In this article, we aim to explore in more depth this trade-off between overall translation quality and the ability of the MT model to learn specific novel words in the context of life-long learning of MT from journalistic post-edits. We explore the setup in a simulated few-shot learning scenario, whereby we track the translation performance on specific test words that are removed from the training data and are gradually re-introduced through fine-tuning. To improve the model's capacity to learn these new examples, we explore an approach similar to Turchi et al. (2017) and inspired by a contextual data augmentation technique used for rare word translation (Fadaee et al., 2017) to reduce the number of corrections that need to be seen.

We show in our experiments on the Gujarati-English language pair that it is not only possible

to surpass the accuracy of our baseline fine-tuning approach, but also of a reference model which has already seen the new words dozens to hundreds of times during training. However we find that in most cases adaptation to new words comes at a variable cost in BLEU (Papineni et al., 2002), due to overfitting to the new examples. We show that this cost can be kept at a minimum by padding our data-augmentation approach with randomly selected sentences from our training set. The appropriate choice of hyper-parameters is also important for final performance.

Our code is freely available online.[1]

2 Related work

The topic of few-shot learning from post-edits is relatively novel, and we were therefore left with few comparison points. A somewhat similar task that requires quick adaptation is low-resource MT, for which transfer learning (Zoph et al., 2016) and meta-learning (Gu et al., 2018) approaches exist. These techniques generally apply for adaptation from hundreds of thousands of sentences, rather than a dozen available in our scenario; this is because we aim to learn individual new words rather than a whole language or domain.

A widespread technique in the MT literature to adapt a model to new data is fine-tuning, often used for domain adaptation. Turchi et al. (2017) and Li et al. (2018) explore the use of a similarity search in the training corpus in order to fine-tune an MT model before translating a novel sentence or to gradually adapt a model to post-edits. This approach does not apply to our scenario, where new words appear and therefore a similarity search cannot yield sentences containing these new words. Our baseline approach (which we call `finetune`) is present in these works, known as *adaptation a posteriori* in (Turchi et al., 2017) and also appears as *single-sentence adaptation* in (Kothur et al., 2018). A challenge these works report with fine-tuning is overfitting, which we encounter systematically when evaluating our various techniques. Works on fine-tuning also explore several regularization techniques (Simianer et al., 2019) when adapting to new data, which we choose to leave out of our comparison due to added hyper-parameter choices and complexity of implementation in our experiments – we do however believe that future work implementing these techniques could potentially outperform ours.

Fadaee et al. (2017); Kobayashi (2018); Wu et al. (2019) and Gao et al. (2019) explore a similar contextual data augmentation technique, albeit in different scenarios and with different goals. This technique synthesizes new sentences by using sentences from the training set and substituting different words into them. In (Fadaee et al., 2017) the goal is to enhance overall translation performance by focusing on words that appear rarely in the training data, but in our case we are training our system to learn new words which were not in the training set at all, based simply on a ground-truth translation of this new word by a human. Moreover, our technique uses more recent tools and techniques such as the BERT contextual language model (Devlin et al., 2019). Kobayashi (2018) and Wu et al. (2019) also use BERT for contextual data augmentation, but with a goal of improving language model tasks such as sentiment analysis. The constraints for this task are very different; rather than having to produce a translation for augmented data, these approaches have to maintain the sentiment label of the sentences. Gao et al. (2019) work in a similar context to us, but focus on overall translation performance rather than learning new words, and apply contextual data augmentation during the training step, thus removing the challenge of adapting to new data as it becomes available.

Similar to us, Huck et al. (2019) focus on improving the MT of words which are unseen in the training set. They use bilingual lexicons to hypothesize translations for their unseen terms. They find these translations in monolingual target side data and backtranslate them inserting the unseen term. They show that this improves translation performance in the medical domain. However they do not analyze the accuracy of translation of the novel terms, or explore how fast you can learn from very few examples.

3 Lifelong learning from post-edits

MT models are inevitably adapted towards the topics and vocabulary from the time period associated with their training data. In the long term, they therefore struggle to correctly translate novel words and expressions associated with new topics, unless they can be adapted to them. This is particularly a problem in journalism, where current topics and names are constantly changing. A prime example is the

---

[1] `https://gitlab.com/farid-fari/fewshot-learning`

recent COVID-19 pandemic: prior to January 2020, newspapers would contain little to no mention of the words *coronavirus*, *respirators*, *PPE masks* and *hydroxychloroquine*. On top of these topic-specific words, there may also be novel but very frequent expressions that are initially hard to translate, such as *flattening the curve* and *social distancing*, which are likely to be poorly translated and therefore need to be subsequently corrected by the journalist.

We are interested in developing approaches to quickly learn from journalistic post-edits in a way that maintains the general high translation quality of the model. In order to analyze and objectively evaluate our different approaches, we simulate this scenario in a reproducible way by using a publicly available corpus in which we select the rarest words and separate out all sentences containing them: these words will be our *evaluation words*. These words must appear at least a few times in the test set as well in order to enable proper evaluation of adaptation using our approaches. The sentences separated from the training set containing our evaluation words will be used to simulate reference sentences submitted by a journalist for our models to use for adaptation. Finally, the training set with the evaluation words removed will be our *filtered training set*, used for initial training of our model.

Our test set is also made up of publicly available data sets whose sentences also contain the evaluation words we selected. This setup prohibits the use of a development set and a test set due to the dependency of the rare words on the test set: they must appear a minimum number of times in the test set to have a way of evaluating our approaches. In turn, the choice of rare words changes the training set and therefore the models we train. We are therefore in a transductive learning scenario, where our method is adapted to the task we aim to solve.

We also use as a reference point a model which has been trained on the complete (unfiltered) training set, which is a very strong comparison point since it has seen many more occurrences of the rare words we selected than our few-shot models.

4 Our approaches

We propose and evaluate four approaches: `finetune` (our baseline), `randompad`, `augmented` and `half`. The first two approaches only involve fine-tuning whereas the latter two include contextual data augmentation. Each approach works from a given number of reference sentence pairs containing our evaluation words, acting as human-provided references. In our experimental setup, these sentences are chosen randomly among the held-out sentences from the filtered training set.

4.1 Baseline: fine-tuning

Our first approach, which is also our baseline, is naive fine-tuning referred to as *adaptation a posteriori* in (Turchi et al., 2017), and which we refer to as `finetune`. When presented with a set of reference sentence pairs to adapt to, our model is trained from its previous state for a few epochs using the sentence pairs. This approach is especially prone to overfitting as it will see very few sentences, and they all contain a potentially repetitive set of words. To minimize this effect, we choose to fine-tune on a batch of several reference sentence pairs rather than individually for each evaluation word, so as to diversify the data fed to the model.

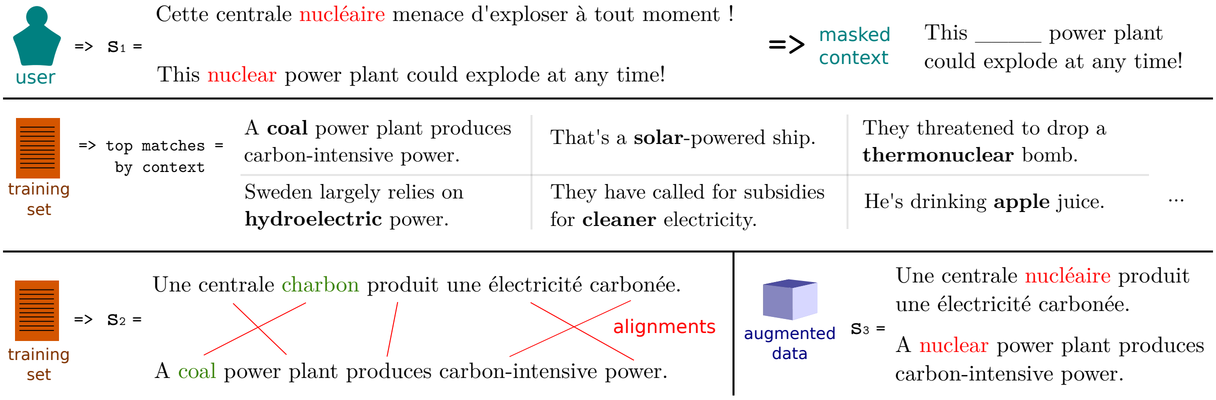
4.2 Padded fine-tuning

The second approach, `randompad`, attempts to minimize the overfitting from `finetune` by introducing variety and generality to the fine-tuning set. This is done by adding randomly chosen sentences from the filtered training set to the reference sentences, which is known as *padding*. These random sentences do not contain the evaluation words and so encourage generalization during fine-tuning.

4.3 Contextual data augmentation

The aim of this approach, similar to the one used by Fadaee et al. (2017) and which we refer to as `augmented`, is to use the reference sentences provided by the journalist to create additional novel sentences containing the evaluation words. If successful, this approach simulates the presence of more reference sentences containing the new words, which accelerates learning, effectively reducing the number of corrections required from the human translator or journalist. More formally, given a reference sentence pair (s_{src}, s_{tgt}) containing an unseen word $w \in s_{tgt}$, the goal is to generate new sentence pairs containing w in the target language, varied enough to be beneficial in fine-tuning.

Our data augmentation process has 2 steps: (i) for each reference sentence pair provided by the journalist containing a word of interest w, find sentences from the training corpus with similar contexts to the one surrounding w, and then (ii) insert w and its translation into the retrieved sentences.



Cette centrale nucléaire menace d'exploser à tout moment !

This nuclear power plant could explode at any time!

This ______ power plant could explode at any time!

A **coal** power plant produces carbon-intensive power.

That's a **solar**-powered ship.

They threatened to drop a **thermonuclear** bomb.

Sweden largely relies on **hydroelectric** power.

They have called for subsidies for **cleaner** electricity.

He's drinking **apple** juice.

Une centrale charbon produit une électricité carbonée.

A coal power plant produces carbon-intensive power.

Une centrale nucléaire produit une électricité carbonée.

A nuclear power plant produces carbon-intensive power.

Figure 1: Contextual data augmentation applied to an example sentence

We illustrate this process in Figure 1, using the French-English language pair to aid readability: the sentence pair s_1 containing the new word *nuclear* is provided to our system by the journalist or translator. We first find sentences in the training set that contain a word (in bold) with a similar context to that of w in s_{tgt}. In each of these sentences, the word in bold could be replaced by *nuclear*, although there are sometimes false positives such as the last sentence: *He's drinking **nuclear** juice*, would not be a good reference sentence for training. Next, we use an alignment tool to replace the aligned source word (e.g. *charbon*) in the selected sentence pair s_2 with the word *nucléaire*, providing a brand new sentence pair s_3 for the reference word *nucléaire-nuclear*.

Finding similar contexts The first step is to find suitable sentences in which we can substitute w and its translation. As in (Wu et al., 2019), we use the BERT contextual language model (Devlin et al., 2019) to provide a contextual representation of w in s_{tgt}, noted v. This feature vector is taken from the second-to-last layer of BERT (usually used to compute vocabulary probabilities through a softmax layer). Given the masked and bidirectional nature of BERT, this contextual representation contains information about the context surrounding w in s_{tgt}, with no prior knowledge of w required by BERT. The advantage of this approach is that truly novel words can be data-augmented using this technique with any pre-trained BERT model.

The context search consists in (i) extracting the feature vector v for w in s_{tgt}, (ii) for each sentence in the filtered training set, randomly selecting a word u in it and computing the corresponding feature vector[2] and (iii) selecting the top k sentences based on the cosine similarity of these feature vectors with v.

This is shown in Figure 1 where 6 sentences have been selected based on their feature vector similarity to s_1. These sentences are selected because the context surrounding the random word chosen in each of them is similar to the context surrounding w in s_1, which generally means the bold words loosely correspond to adjectives describing power plants. Using a masked model means that knowledge of the meaning of w is not required, but only an understanding of the context in s_{tgt}. An additional real use example is provided in Appendix B.

This process significantly differs from Fadaee et al. (2017), which iterates over the training set to find sentences for which the language model gives a high probability of the rare words appearing. Moreover, by using feature vectors rather than raw probability distributions (as in previous works), we capture richer information about the surrounding sentence than only which words are likely to replace w.

Creation of new training examples The second step is to substitute the randomly masked word u—which is *coal* in our example—in the retained sentence pair s_2 with w in the target language and its translation in the source language. In the target language, we simply replace u by w, but the task is harder in the source language since we have no prior information as to which word translates to u, or which word translates to w to replace it with. In our scenario, we assume that the translation in the source language of w, noted w', is known to us – for

---

[2] Comparing all positions in all sentences would lead to the best results, but is inefficient. With sufficient training examples (as is the case here), randomly choosing a single position in each sentence avoids having to to do all computations and still provides varied contexts that can be tested.

example, a human translator providing (s_{src}, s_{tgt}) could identify w' in s_{src}. Having no human translator for our experiments, we train an alignment tool on the complete unfiltered training set and use it to select the words most often aligned to each w from our evaluation words. A different approach could be used in future work, by training the alignment tool on the filtered training set and then re-training it on reference sentences as they are provided, removing the need for human intervention or prior knowledge of w. Note that all alignment steps rely on automatic tools which can introduce some noise in the process. However, we observed satisfactory results, and this allows for the entire process to be automated.

Once the translation w' for w is established, we have to determine which word or words in the source sentence must be replaced by w'. This is done by using an alignment tool trained only on the filtered training set, to compute the aligned word to u. The word aligned to u is replaced by w'; if multiple consecutive words are aligned to u they are all replaced with w', and if no words or non-consecutive words are aligned to u then the sentence is discarded. This is illustrated in Figure 1, where *coal* is successfully aligned to *charbon*, allowing us to replace it with *nucléaire*.

The final result in the example is s_3, a sentence pair which makes sense and will be useful for the translation of *nucléaire* to *nuclear*. The sentences generated by this method will at the very least contain w' and w in roughly aligned source and target positions and the best sentences will have the same quality as human-provided references.

4.4 Padded data augmentation

The `augmented` approach does not benefit from the added generality of the `randompad` approach; it could suffer from overfitting due to the repetition of our evaluation words (and their semantic fields) in the fine-tuning sentences. This is addressed by the `half` approach, designed to overcome potential overfitting in the `augmented` approach. This approach uses half of the synthesized sentences from `augmented` and replaces the other half with random sentences from the filtered training set. This provides more sentences containing our rare words through augmentation but also more generality from the random sentences, aiming to combine the strengths of both approaches.

5 Experiments

5.1 Experimental setup

We use the low-resource Gujarati to English language direction. Our base model is the same as the University of Edinburgh's submission to WMT 2019 (Bawden et al., 2019), except that its training set is filtered to remove sentences containing words previously selected for evaluation. The model is a base transformer model (Vaswani et al., 2017) with 6 encoder and decoder layers, feed-forward dimension 512, 8 transformer heads, and dropout of 0.1. We train using the Marian toolkit (Junczys-Dowmunt et al., 2018) and the Adam optimizer (Kingma and Ba, 2015).[3] The complete training script with additional parameters can be found on the webpage for the University of Edinburgh's WMT19 submission.[4] We use an identical version of this model trained on the full, unfiltered training set as a reference point called `all-data`.

The main preprocessing, data augmentation and training scripts are freely available online: `https://gitlab.com/farid-fari/fewshot-learning`.

We use the pre-trained BERT model from Huggingface (Wolf et al., 2020): the `bert-large-uncased-whole-word-masking` variant, which has the benefit for our use case of masking whole words rather than subwords.

5.2 Data and preprocessing

Our training data consists of both genuine Gujarati-English parallel data and backtranslations from the WMT19 news translation task (Barrault et al., 2019). The backtranslations are produced as described by Bawden et al. (2019) and we follow their method of first training on a mixture of backtranslations and parallel data before fine-tuning on the genuine parallel data only. As mentioned previously, we filter out English words selected for evaluation from both the synthetic and genuine parallel data. However, only the genuine parallel data is used to select augmentation candidates to ensure their high quality. For testing, we use the concatenation of `newstest2019` and `newsdev2019`.

Preprocessing All data augmentation was run after tokenization but before subword segmentation to keep a consistent notion of a 'word'. We

---

[3] We experimented with SGD but observed no significant differences with Adam.

[4] `http://data.statmt.org/wmt19_systems/en-gu/train.sh`

first apply tokenization using the Moses tokenizer (Koehn et al., 2007) and then apply sub-word segmentation using the BPE strategy (Sennrich et al., 2016) and the `fastbpe` implementation.[5,6] Word alignment is carried out using `fast_align` (Dyer et al., 2013).[7]

Evaluation data The rare words to filter out are chosen to be the 100 rarest words in the training set that appear at least 5 times in the test set and 20 times in the training set, and are manually filtered down to 96 words to exclude low quality choices (such as plurals and punctuation). Their frequency in the unfiltered training set (used by our reference model) ranges from 20 to 775 occurrences, with a mean of 313 and a median of 275 occurrences. The complete word list can be found in Appendix A. These words appear in 701 of the 3,014 test set sentences, meaning that the BLEU score is computed on a majority of sentences not containing our evaluation words, thus giving us a good overview of how general translation performance is affected. They appear in only 26,910 of the 8.5M training sentences,[8] meaning that the filtered training set is almost the same size as the original full training data. The genuine parallel data contains 40k sentences which were used for context search in the data augmentation steps.

Evaluation setup Our aim is to evaluate how well the model adapts (through fine-tuning of the model) to the gradual addition of reference examples containing the 96 evaluation words, which were absent from the initial training data. For each evaluation word, we randomly choose 20 reference sentences that contain the word, and for each of the four approaches, we successively make 1, 2, 3, 5, 10, 15 and 20 reference occurrences of each word available to the model to learn from, evaluating at each step. Everything is run as a batch over all 96 words; for instance in an experiment using 3 occurrences, fine-tuning is conducted over 288 reference sentences, with each reference word occurring 3 times.[9]

Each approach that uses padding and/or augmentation requires choosing a ratio r between the total number of fine-tuning sentences and the original number of reference sentences provided by the journalist. For a word w, as the number of occurrences offered to the model grows from 1 to 20, the number of fine-tuning sentences grows from r to $20r$. This ratio r is calculated as follows:

$$n_{total} = n_{ref} + n_{synth} + n_{rand} \quad (1)$$

$$r = \frac{n_{total}}{n_{ref}}, \quad (2)$$

where n_{ref}, n_{synth} and n_{rand} refer respectively to the number of reference, synthetic and random sentences. The chosen ratio is written in brackets following the name of each approach.

For the `augmented` experiments we choose $r = 20$, meaning that we augment each reference sentence with 19 synthetic sentences. This is chosen by manually evaluating the quality of augmented sentences on examples, as shown in Appendix B. We run two `randompad` experiments, `randompad(2)` (half of sentences are random), and `randompad(20)` (same ratio as `augmented(20)` for comparison). The `half(20)` experiment has the same ratio as `augmented(20)`, with each reference sentence accompanied by 9 random sentences and 10 synthetic sentences.[10]

5.3 Evaluation metrics

We use two evaluation metrics: (i) the BLEU score (Papineni et al., 2002) computed with the `multi-bleu-detok` script from the Moses toolkit (Koehn et al., 2007) on the entire test set to evaluate overall MT quality, and (ii) the accuracy of the filtered evaluation words to evaluate how well the approaches learn from the post-edits. We use a clipped bag-of-words accuracy defined as follows: if in the target language the reference sentence contains the word w n times, and the translated sentence contains it p times, then the accuracy is $\frac{\min(p,n)}{n}$. This accuracy is computed separately for each of the evaluation words w, and then averaged to obtain an overall accuracy. The advantage of this metric is that it also only requires segmentation to be done in the target language, meaning that once more no prior knowledge or training fur-

---

[6] We reuse the pre-processing scripts available at http://data.statmt.org/wmt19_systems/scripts/.

[7] https://github.com/clab/fast_align

[8] Both genuine and synthetic parallel training sentences.

[9] The number of sentences is very slightly lower due to some sentences containing 2 evaluation words, but this is rare enough that it does not meaningfully impact our results.

[10] We leave it to future work to explore additional padding and augmentation ratios. In the `half` experiments, we randomly select half of the sentences from the synthetic sentences from `augmented`: this means in particular that we do not necessarily keep the best half of the synthetic sentences, leaving room for improvement in future experiments.

ther than the base model are required for the source language.

A third evaluation metric, which is very important for our scenario but overlooked in previous work, is the speed at which the model improves its accuracy. We define this as the number of reference sentences per novel word it needs to see in order to substantially improve the accuracy in translating these words. For a journalist correcting an MT system's mistakes, it is important to correct a given mistake as few times as possible, since having to correct each mistake beyond a certain number of times might make it more worthwhile to simply manually translate the article. The best way of evaluating this metric is by comparing the evolution of the accuracy curve and the BLEU curve as a function of the number of seen occurrences, as presented in the next section in more detail.

We also compare all models to the reference model `all-data`, trained on the unfiltered training set, as in the University of Edinburgh's WMT19 submission (Bawden et al., 2019). This model is considered as a topline rather than a baseline since it does not perform the same task and was trained with much more data – our baseline being the `finetune` approach.

5.4 Hyper-parameter choice

To ensure optimal settings, for each approach we choose hyper-parameters based on the size of the fine-tuning corpus. Several hyper-parameter choices seem relevant, depending on the goal: more training leads to lower BLEU scores (as overfitting occurs) but higher accuracies on the evaluation words, exposing a trade-off between BLEU and translation performance specifically on the evaluation words. This is shown in Appendix D where we explore different values for the `finetune` approach. In our results in the following section, we use hyper-parameter values that best match the accuracy scores for all approaches, thus simplifying the trade-off to a direct comparison in BLEU score.

Choosing a single epoch and learning rate value depends on the end goal: we can focus on accuracy at all costs, even if it means decreasing overall translation performance, or take a more conservative approach by moderately increasing accuracy while maintaining BLEU. Another way of seeing this trade-off is with respect to a time scale over which adaptation occurs: if the process is to be repeated many times, then it may be wise to decrease BLEU as little as possible, whereas a system that is often reset or used less often can afford to sacrifice more BLEU for extra accuracy on novel words. It is important to note that these results are batched, so the BLEU losses or gains illustrated correspond to the learning of 96 words at once.

We present our results with two adaptation speeds for each approach: a slow (*S*) and a fast (*F*) setting, corresponding to two possible compromises in the previously explained trade-off. At each adaptation speed, for each approach, different hyper-parameters are used in order to match accuracy scores as closely as possible to make their comparison easier. The table of chosen epoch and learning rate values can be found in Appendix C.

6 Results

Figures 2 and 3 present the results for the reference model and all approaches for both slow and fast adaptation speeds. We immediately notice that at both adaptation speeds our models are capable of surpassing the `all-data` model[11] in terms of accuracy on the new words, despite having seen fewer than 20 (and as few as 1) reference sentences containing those words, whereas `all-data` has seen each evaluation word over 300 times on average. Our baseline, the `finetune` model, is shown to be largely surpassed by all other approaches in accuracy, both on the slow and fast settings.

With hyper-parameters being chosen to approximately match accuracy curves, the main comparison point is the BLEU score. In Figure 2, we see that in the slow setting our `half` approach is the only one able to improve the BLEU score while learning the new words, nearly matching `all-data` in both BLEU and accuracy at 3 occurrences seen. The `augmented` approach offers a slightly better accuracy curve than all other models on this speed, but loses out on BLEU score at higher occurrence numbers.

It is very important to look at the first points on the curve: 1-5 occurrences of each evaluation word is the realistic range to imagine a journalist making corrections, since a journalist could become frustrated with a model requiring each new word to be corrected up to 20 times for it to be correctly translated. In this respect, Figure 3 for the fast setting offers the best results, with accu-

---

[11] Note however that `all-data` does not constitute a baseline for our model: it does not perform the same task and has access to many more reference sentence pairs.

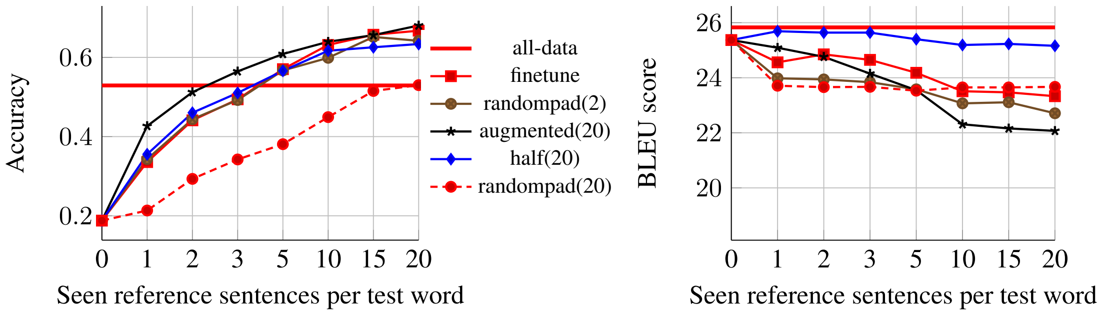

Figure 2: BLEU and accuracy results of all of our approaches for the slow speed setting

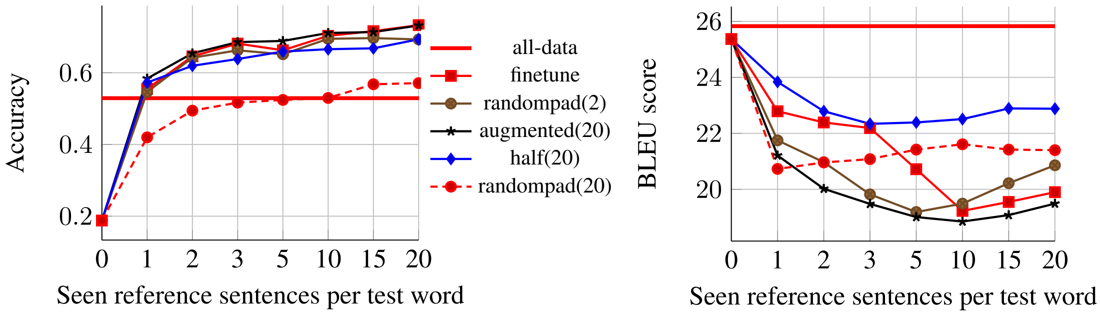

Figure 3: BLEU and accuracy results of all of our approaches for the fast speed setting

racy immediately surpassing `all-data` for all but one model, albeit at a heightened cost to BLEU. Several models, including our new `augmented` and `half` approaches, see an increase in BLEU at higher occurrence numbers, suggesting that generalization is occurring as more sentences are learned with bigger learning steps.

The `randompad` approaches surprised us in two ways, especially given `half`'s success: they generally perform worse than `finetune` despite being designed as improvements over it, and `randompad(20)` has poor accuracy scores compared to all other approaches. To the first point, one possible explanation is that overfitting might occur with both the random sentences and the reference sentences when few data is used for fine-tuning (low seen occurrence numbers). This would explain why in Figure 3 the BLEU curve for `randompad` ends up overtaking the `finetune` curve once enough padding data is available to allow generalization. The second point can be explained by a form of 'dilution' of the reference sentences containing the evaluation words: the model over-adapts to the sentences provided to it but does not particularly improve on the evaluation words. We also tried various hyper-parameters for `randompad(20)` but were unable to find a compromise similar to other models, resulting in this approach standing out from the others. This might also be partially explained through variations inherent to the randomness in the selection of the padding sentences.

6.1 Analysis

To gain more insight into which words were translated well or poorly, we chose to look at our accuracy metric for each evaluation word. For the fast `half` approach, averaged across all occurrence numbers, the best words were generally proper nouns such as *Sulawesi* (1.00), *Isabel* (0.98) and *Kohli* (0.68). Acronyms such as *ATM* (1.00), *RCN* (0.98) or *GB* (0.87) also performed very well, and common nouns or verbs had more varied performance: *niece* (0.00), *moustache* (0.37) and *smartphone* (0.87). Although the very best words are generally proper nouns or acronyms and the very worst generally other parts of speech, no clear pattern or general rule can be ascertained.

One phenomenon initially worrying us the was over-translation of evaluation words: a model outputting evaluation words where they should not appear would be able to 'trick' our bag-of-words accuracy metric by artificially inflating it to a certain point. However, we hypothesized and then verified that this would be counteracted by a decrease in BLEU score due to these words appearing in sentences where they should not. This is presented in Appendix E where we confirm this by demonstrating a negative correlation between over-translation and BLEU score.

7 Conclusion

We explored different techniques based on fine-tuning in order to adapt a base model to post-edits containing novel vocabulary. We proposed a data augmentation technique never applied to this task, allowing us to expand the number of occurrences of the new words available to our model to learn from. In our experiments, all proposed adaptation techniques offer better performance on the novel words than our reference model, which had seen the words hundreds of times each. Our data augmentation approaches yield faster adaptation than our baseline, but with a greatly improved BLEU score, especially when combined with generalization using padding with random training set data.

These various techniques could all be applied to lifelong adaptation of an MT system often confronted with new vocabulary or expressions. Our work can be generalized in several directions which we chose to leave for future work: word translations can automatically be retrieved with alignments, rare multi-word expressions (*n-grams*) can be used rather than rare single-token words, the language model generalization can be used in the source language or both languages and several word substitutions can be made in a single sentence. Several approaches can be deployed to further improve the BLEU score when fine-tuning, such as regularization techniques as explored by Simianer et al. (2019), keeping only the best half of synthetic sentences rather than a random half, and a more careful choice of the ratio of augmented and random data relative to reference sentences.

A Filtered words

The complete list of the 96 filtered words in English is given in Table 4.

B Data augmentation example

This is an actual example of contextual data augmentation from a given sentence. The reference sentence is, "*A powerful 7.5 magnitude earthquake hit the Indonesian island of* **Sulawesi** *on Friday, September 29, triggering a tsunami and leaving nearly 400 people dead.*", with the novel word being *Sulawesi*. The top five sentences matching the context of *Sulawesi* above are as follows:

1. This labour shortage prompted the authorities to import slaves from **Indonesia** and Madagascar.
2. Many of them have settled down in Ahmedabad, Vadodara, Mumbai, Kolkota, Delhi, Nagpur and far away places like **Java**, Rangoon, Singapore, Fiji, Eden, Kenya, Uganda, America etc and established their business in these places.
3. The rice lands of **Java** are among the richest in the world.
4. Rising ocean temperatures and ocean acidification means that the capacity of the ocean carbon sink will gradually get weaker, giving rise to global concerns expressed in the **Monaco** and Manado Declarations.
5. **Lara**'s first school was St. Joseph's Roman Catholic primary.

These sentences generally capture the idea that the word refers to an island, except for the last one which might be an outlier. The fourth sentence is remarkable in the fact that *Monaco* is not an island, but the context of *rising ocean temperatures and ocean acidification* as well as the mention of *Manado* alongside (the capital of North Sulawesi) make the sentence relevant here. This highlights the importance of context besides the actual words' meanings.

C Learning rate and epochs

Table 5 gives the epoch numbers and learning rates we chose for our presented examples. The `augmented` and `half` experiments both have lower learning rates because they fine-tune on more data, and thus go through more gradient steps.

D Preliminary survey of hyper-parameters

We tried different hyper-parameter combinations for the `finetune` approach to explore the dependency of accuracy and BLEU score to these. Figure 6 shows these curves labeled by '*number of epochs / learning rate*'.

We noticed a clear trade-off between BLEU score and accuracy as the parameters evolved, with more training leading to bigger gains in accuracy at a cost to BLEU. Higher parameters saw diminishing returns as accuracy would improve little or not at all while BLEU kept decreasing, as can be seen for the two first curves. Lower parameters also showed diminishing returns in BLEU score as accuracy dramatically drops.

E Over-translation

Table 7 shows the over-translation metric for different approaches. Over-translation is defined as the number of times each word appears in sentences in excess of the reference sentence, divided by the number of times it appears in the reference. This metric is computed similarly to the accuracy metric as explained in Section 5.3, i.e. per word over all sentences and then averaged over all words.

For reference, the `all-data` model gets an over-translation metric of 0.04 and the base model (the one referred to as 0 occurrences in figures) scores 0.01.

While some approaches have seemingly high over-translation values, the most competitive approaches do not see such a high increase in over-translation. For instance, the over-translation metric of 0.25 for `half(20)` (F) means that an over-translated word would appear for every four reference occurrences of our evaluation words, which means that it would over-translate only in about one in seventeen sentences in the test set (given that reference words only appear in 23% of test set sentences). The `half` approach has very good BLEU scores, which is aligned with the fact that it has some of the best over-translation scores amongst the presented approaches.

Moreover, Figure 8 shows for all of these data points the evolution of BLEU score with over-translation: there is a clear linear correlation, implying that BLEU captures over-translation by our approaches very well.

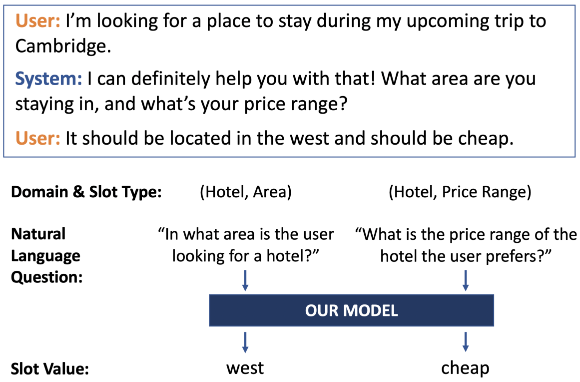
Abstract

Dialog State Tracking (DST), an integral part of modern dialog systems, aims to track user preferences and constraints (slots) in task-oriented dialogs. In real-world settings with constantly changing services, DST systems must generalize to new domains and unseen slot types. Existing methods for DST do not generalize well to new slot names and many require known ontologies of slot types and values for inference. We introduce a novel ontology-free framework that supports natural language queries for unseen constraints and slots in multi-domain task-oriented dialogs. Our approach is based on generative question-answering using a conditional language model pre-trained on substantive English sentences. Our model improves joint goal accuracy in zero-shot domain adaptation settings by up to 9% (absolute) over the previous state-of-the-art on the MultiWOZ 2.1 dataset.

1 Introduction

Dialog agents are gaining increasing prominence in daily life. These systems aim to assist users via natural language conversations, taking the form of digital assistants who help accomplish everyday tasks by interfacing with connected devices and services. A key component to understanding and enabling these task-oriented dialogs is Dialog State Tracking (DST): extracting user intent and goals from conversations via filling in belief slots (Lemon et al., 2006; Wang and Lemon, 2013). Assistive and recommendation use-cases for dialog agents in production settings are particularly challenging due to constantly changing services and applications with which they interface.

Traditional DST systems have achieved high accuracy when presented with a known ontology of slot types and valid values (Chen et al., 2020). In a real-world setting, however, a DST model must generalize to new slot *values* (e.g. new entities that are not present at training time) and new slot *types* (e.g. requirements regarding a new application). Recent work has sought to address these issues by posing DST as a reading comprehension or question answering (QA) task (Gao et al., 2019)—such models predict each slot value independently at any given turn and can theoretically be queried for new slots at inference time.



User: I'm looking for a place to stay during my upcoming trip to Cambridge.

System: I can definitely help you with that! What area are you staying in, and what's your price range?

User: It should be located in the west and should be cheap.

Figure 1: Based on a dialog history, a natural language questions are provided to our model to query a user's requirements and preferences (dialog state).

Some approaches toward DST as QA learn embedding vectors for each slot and/or domain word (Wu et al., 2019), but this is not robust to unseen slots whose specific names (e.g. 'Internet Access') may be totally unlike those in the training set. Gao et al. (2020) attempt to remedy this by posing a natural language question for each slot, but their hybrid span-extraction and classification-based system nonetheless requires access to the full ontology for unknown domains. We present an ontology-free model using natural language questions to represent slots that builds on conditional language modeling techniques—taking advantage of the rise of powerful generative language models (Radford et al., 2019)—to tackle DST as a *generative* QA

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1063–1074
April 19 - 23, 2021.

task. Our model can generalize to unseen domains, slot types, and values, and allows developers to query for arbitrary user requirements via simple questions. To summarize our main contributions:

- We propose an ontology-free conditional language modeling framework for dialog state tracking via generative question answering, achieving state-of-the-art performance in zero-shot domain adaptation settings for DST on MultiWOZ 2.1 (Eric et al., 2020) across all domains with average per-domain gains of 5.9% joint accuracy over previous best methods;
- We demonstrate performance competitive with state-of-the-art methods in a fully supervised setting;
- We show that our approach can be easily adapted to predict slot carry-over and transfer knowledge from a larger, more diverse dataset (Kim et al., 2019), improving zero-shot DST performance across all domains to 11% joint accuracy over the state-of-the-art.

2 Approach

We follow Gao et al. (2019) in treating Dialog State Tracking as a reading comprehension problem: at each turn of dialog, our model reads the dialog history and answers a fixed set of queries about user requirements and preferences (slots), with predictions aggregated to form the belief state. In our framework (Figure 1), we query for a given slot (e.g. Hotel Price Range) by asking a natural language question (Gao et al., 2020)—"What is the price range of the hotel the user prefers?". As our model's predictive ability is based on its general understanding of language and task-oriented conversation, we support zero-shot inference without the need to re-train the model or extend a formal ontology. For example, if a model has not been trained on data from the hotel domain, when presented with a hotel booking conversation we may nonetheless ask it a question like "In what area is the user looking for a hotel?" and received a prediction for that unseen requirement (Hotel Area).

While we conduct our experiments on English-language DST datasets, our approach is applicable to state tracking in any language, provided a conversation history is available.

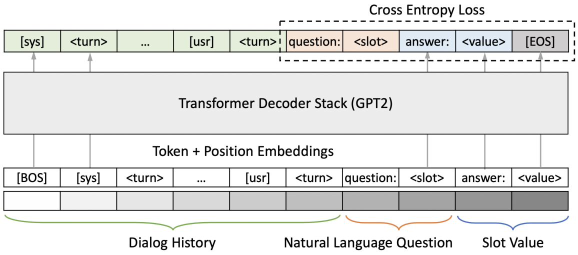


Figure 2: Our model performs DST via generative question-answering. Natural language questions for dialog slots allow our model to generalize to new slot types through its understanding of general language.

Problem Statement We consider a conversation with T turns of user u_t and system utterances y_t: $C = \{y_1, u_1, \dots y_T, u_T\}$. The belief state B_t at turn t comprises many tuples of slots $s \in S$ and their associated values $v_{s,t} \in V_s$, extracted from the conversation history $C_t = \{y_1, u_1, \dots, y_t, u_t\}$. The set of possible values V_s can be arbitrarily large (e.g. possible hotel names), so we represent these values as sequences of vocabulary tokens $v_{s,t} = \{w_1, w_2, \dots, w_k\}, w_i \in \mathcal{W}$. At inference time we pose a natural language question $s = \{w_1, \dots, w_n\}$ and our model predicts an answer (slot value $v_{s,t}$) based on its understanding of the dialog history C_t. To predict the belief state B_t, our model independently answers $|S|$ different questions (Figure 1). In zero-shot DST, the system must predict values for slots outside of the initial ontology—these slot queries correspond to arbitrary natural language questions s' about entities and relationships in the conversation C_t.

Generalizing to New Domains and Slots Dialog State Tracking systems in real-world settings must scale to new users and services, accommodating new slot values (e.g. a new movie release) as well as new domains and slot types (e.g. a service update, or a new connected API). Existing methods require the developer to either write a complete ontology of slots and allowed values or modify their model architecture to add slot-specific prediction heads (Chen et al., 2020). Span-based approaches (Zhang et al., 2019; Zhou and Small, 2019) can correctly predict values that appear verbatim in a conversation but fail when a user paraphrases or mis-phrases a value. They also fall back to treating open-valued slots as classification problems (Zhang et al., 2019; Gao et al., 2020). We approach DST as an ontology-free generative question answering task, as generative methods (Wu et al., 2019; Kumar et al., 2020) have shown promise in few-shot and supervised DST settings.

While some approaches toward DST as QA learn a set of embeddings for each slot and/or domain (Gao et al., 2019; Wu et al., 2019; Kumar et al., 2020), this is not robust to unseen slots. We encode slots as natural language questions—manually formulating one question per slot—allowing us to share a pre-trained encoder for both dialog context and slot to leverage shared linguistic knowledge (Gao et al., 2020). Thus, our model is also agnostic to ontologies and can answer arbitrary English questions about the dialog history. We treat DST via QA as a conditional language modeling task, and train our model to predict the conditional likelihood of question (slot s) and answer (value $v_{s,t}$) tokens given a dialog context C_t at a given turn t:

$$P(v_{s,t}, s|C_t) = P(v_{s,t}|s, C_t) * P(s|C_t)$$

At inference time, the model is given the dialog context alongside a question—$[C_t; s]$—and asked to predict the value $v_{s,t}$ for that slot.

3 Model Architecture

For our conditional language model, we compared two common architectures: 1) an encoder-decoder model (Sutskever et al., 2014) with a bi-directional encoder; and 2) a purely auto-regressive decoder-only model. We conducted preliminary experiments using both a Transformer (Vaswani et al., 2017) encoder-decoder language model pre-trained using a de-noising auto-encoder objective (Lewis et al., 2020), as well as a Transformer decoder pre-trained with next-token prediction on English web pages. We achieved 1% better supervised DST performance with the decoder-only model in half the training time. Our model architecture thus comprises a Transformer decoder language model that allows us to leverage pre-trained language models like GPT2 (Radford et al., 2019) and common-sense world knowledge accrued through pre-training (Petroni et al., 2019).

We use a BPE (Sennrich et al., 2016) tokenizer to convert input text into a sequence of tokens. These are embedded in $\mathbb{R}^h$ and added to an $\mathbb{R}^h$ sinusoidal positional embedding. This input embedding is processed by l Transformer layers with hidden dimensionality h, each of which applies multi-headed attention with k heads followed by a feed-forward layer with a softmax nonlinearity. The final output hidden states are then projected into our vocabulary space of 50,257 sub-word tokens. We initialize our model weights with DistilGPT2 (Sanh et al., 2019), GPT2 (Radford et al., 2019), or GPT2-medium with $h = 768, 768, 1024$, $l = 6, 12, 24$, and $k = 12, 12, 16$ respectively.

As seen in Figure 2, our input sequence consists of a concatenation of dialog context C_t, slot query s, and slot value $v_{s,t}$: $[C_t; s; v_{s,t}]$. We prepend each utterance with a speaker token `[usr]` or `[sys]` for a user or system speaker to allow our model to identify additional context about each utterance. We pre-pend the slot query and value with `question:` and `answer:` respectively to distinguish slot queries from user-posed questions in the conversation. At training time, we calculate a cross-entropy loss similar to encoder-decoder models by maximizing the log likelihood of the slot query and value conditioned on the dialog context:

$$P(s, v_{s,t}|C_t) = \prod_{i}^{n} P(x_i|x_{<i}, C_t)$$

where $n = |[s; v_{s,t}]|$. We find through ablation experiments on our architecture that this loss computation method out-performs a naïve language-modeling approach that maximizes log likelihood of the full concatenated sequence $[C_t; s; v_{s,t}]$ via the factorized joint distribution (Peng et al., 2020;

Model	Type	JGA	NLQ

GPT2-m CLMQ	G	**52.58**	Y

Table 3: Supervised DST performance on MultiWOZ 2.1 of our model (underlined) compared to prior methods capable of zero-shot inference. Models using natural language questions (NLQ) are marked. **Requires access to slot-value ontologies at inference time.*

Hosseini-Asl et al., 2020):

$$P(x) = \prod_{i}^{n} P(x_i | x_{<i})$$

This allows for flexibility in learned representations for dialog context while regularizing slot query hidden states.

4 Data

We perform our experiments on **MultiWOZ** (Budzianowski et al., 2018), which contains over 10K single- and multi-domain task-oriented dialogs written by crowd-workers. We use the 2.1 version, with corrected and standardized annotations from Eric et al. (2020). We follow Wu et al. (2019) in lower-casing all dialogs and removing dialogs from training-only domains (Police and Hospital). The final dataset contains 9,906 conversations from 5 domains (Restaurant, Hotel, Attraction, Train, Taxi) covering 30 domain-slot pairs. Each dialog contains an average of 7 user and system turns.

We also experiment with augmenting our training dataset in zero-shot settings with observations drawn from the DSTC8 (Kim et al., 2019) dataset, [1] which contains 16,152 dialogs from 45 domains. DSTC8 was created via template-based dialog models provided with service APIs, and then edited by crowd-workers (Shah et al., 2018). We normalize domains and slots corresponding to the same domain (e.g. `Bus_1, Bus_2`) for a total of 19 domains and 124 slot types in DSTC8. We further manually annotate each dataset with slot value types: open-valued (e.g. Hotel Name), numeric (e.g. Restaurant Guests), temporal (e.g. Taxi LeaveAt), and categorical (e.g. Attraction Type). Dataset statistics are shown in Table 2.

5 Experiments

We measure DST performance via Joint Goal Accuracy (JGA): the proportion of turns with all belief slots predicted correctly, including those not present. In Section 5.1, we evaluate our model on fully *supervised* DST, in which all domains and slots are known at training time. In Section 5.2, we investigate *zero-shot* domain adaptation in which the model is evaluated on conversations from an unseen domain with previously unseen slots. We then explore how our framework seamlessly accommodates teaching a model to predict slot carryover (Section 5.3) and transfer learning with significantly more diverse domains and slot types (Section 5.4). To measure zero-shot JGA, we follow Campagna et al. (2020) and only consider slots specific to the held-out domain. We focus our analysis on the zero-shot setting, as our goal is to build DST systems that can easily and effectively generalize to new domains and services. We train all models to convergence with a maximum of 10 epochs on Nvidia V100 GPUs, using the Lamb optimizer (You et al., 2020) with a base learning rate of 2e-5. All predictions are made using greedy decoding.

5.1 Supervised DST

We first evaluate on the commonly benchmarked supervised DST task to demonstrate performance competitive with state-of-the-art. In this setting we compare our approach against prior methods capable of zero-shot inference in Table 3—TRADE, STARC, SUMBT, and MA-DST—and those incapable of doing so in Table 4, including DSTQA (Zhou and Small, 2019), DS-DST (Zhang et al., 2019), SOM-DST (Kim et al., 2020), SST (Chen et al., 2020), TripPy (Heck et al., 2020), and SimpleToD (Hosseini-Asl et al., 2020). Our model outperforms all prior models that support zero-shot generalization and is competitive with meth-

ods that focus solely on supervised DST—most of which require extra supervision at training and inference time, including dialog actions and prior dialog states. We distinguish models by their prediction type as (C)lassification-, (S)pan extraction-, and (G)eneration-based methods.

As seen in Table 1, our formulation of DST as a generative QA task benefits significantly from the usage of a conditional decoder-style model. A standard auto-regressive language modeling formulation (**LM**) with loss computed over the entire input sequence achieves 13% lower JGA compared to computing cross entropy loss only over slot value tokens (**CLM**). Pre-training is also crucial—we see a 10-point drop in JGA when randomly initializing model weights (**no PT**) compared to initializing from pre-trained DistilGPT2 weights. We also compare two other sizes of our models: GPT2-based—comparable in size to SUMBT's (Lee et al., 2019) 112M parameters—and GPT2-medium-based—comparable in size to STARC's (Gao et al., 2020) 355M parameters. We find that scaling the size of our model results in modest improvements in supervised JGA. We hypothesize that extending our loss to cover both slot query and value tokens (**+Question/CLMQ**) helps regularize the hidden representations of question tokens, and we achieve a 1.3% improvement in JGA.

5.2 Zero-Shot DST

Our primary focus lies in the zero-shot domain adaptation setting, where conversations and target slots at inference time come from unseen domains. We use a leave-one-out setup, training our models on four domains from MultiWOZ and evaluating on the held-out domain. Our model must understand a wide variety of possible questions about unseen conversations to generalize well. We compare our model against strong baseline models for zero-shot DST: TRADE, SUMBT, and MA-DST; Table 5 contains results from our models alongside baseline results reported by Kumar et al. (2020) and Campagna et al. (2020). These models represent slots as domain-slot tuples: TRADE learns a separate embedding for each domain and word in slot names, while SUMBT and MA-DST encode domain-slot tuples via BERT (Devlin et al., 2019) and an RNN encoder, respectively.

Our GPT2-medium based model achieves state-of-the-art zero-shot performance on all five domains, and by a significant (5-10%) margin on the Restaurant, Hotel, Attraction, and Train domains. While increased model size modestly impacts supervised DST performance (Table 1), larger models perform significantly better in a zero-shot setting with average absolute gains of 4.8% and relative gains of 22% in JGA across domains. Such improvements are consistent with findings from Brown et al. (2020) that up-sizing language models improves zero-shot performance across various tasks and Petroni et al. (2019), who observe that larger pre-trained models can retain more commonsense and world knowledge from their pre-training corpus—which may help our model understand queries for unseen domains and slots.

Effect of Natural Language Questions Prior work that frames DST as QA typically represents the slot query as a concatenation (tuple) of domain and slot name. Zhang et al. (2019) explore the impact of three different slot representations—domain-slot tuples, short slot descriptions, and full questions—on a hybrid classification-extraction model for DST, and find little difference in performance. However, we find that full questions work much better than domain-slot tuples for our generative framework, especially in zero-shot DST. We hypothesize that natural language questions—structurally similar to dialog utterances and pre-training sentences—allow our model to best leverage its linguistic knowledge with minimal friction when jointly encoding the dialog history, slot query, and slot value.

Wu et al. (2019) find that zero-shot generalization in models that represent slots as tuples is primarily due to shared slot names between domains (e.g. Taxi and Train 'leaveAt'). In a real-world setting a newly added dialog service is unlikely to share slot names verbatim with existing services. To fairly compare tuples and natural language questions under our framework, we per-

USER	My friend told me about Carolina Bed and Breakfast. Do you know anything about it?
SYS	It's a 4 star guesthouse. What would you like to know about it?
USER	Can you give me the postcode? And, do they have internet?
SYS	The postcode is cb13nx; they have internet.
USER	Thanks. Any boat attractions in the west?
SYS	**Nothing in west. Closest boat is the Cambridge Punter in centre. Too far?**
USER	**Yes, it is. How about a museum?**

Error Modality	Slot	Gold	Prediction	Open	Numeric	Temporal	Categorical
Spurious	(Attraction, Name)	`n/a`	cambridge punter	8.4 %	22.3 %	47.7 %	16.0 %
Ignored	(Hotel, Internet)	yes	`n/a`	65.3 %	53.5 %	19.9 %	76.8 %
Wrong Value	(Attraction, Type)	museum	boat	26.3 %	24.2 %	32.4 %	7.2 %

Table 6: Example of different classes of DST errors, and the proportion of errors they make up across the four slot categories for all five domains in a zero-shot setting. Latest (target) turn is **bolded**.

form zero-shot experiments using each representation. For tuple-based questions, our model takes as slot query a synonym of the slot name (e.g. Taxi 'leaveAt' → 'Pick Up Time') instead of a full question (e.g. 'What time does the user want the taxi to pick them up¿). Full question models achieved 6% higher per-domain JGA compared to slot-tuple models, supporting the notion that slot-tuple models memorize slot names rather than understanding their meaning and thus do not generalize well in real-world settings. Using full questions, our model (Table 5) achieves state-of-the-art performance in zero-shot settings.

Error Modalities To analyze our model, we follow Gao et al. (2020) and categorize DST errors in three modalities: 1) the model predicts a *spurious* value for an irrelevant slot; 2) the model *ignores* a relevant slot; and 3) the model correctly infers the presence of a slot but predicts a *wrong value*. Table 6 shows examples of each type of error for a sample conversation, and what proportion of errors they make up in each slot category for our **GPT2-m CLMQ** model in a zero-shot setting. Temporal slots are least likely to be *ignored* by our model, as verbatim `HH:MM` values are easily identifiable in a conversation. However, it is difficult to distinguish between closely related unseen temporal slots like 'leaveAt' and 'arriveBy'. Values for categorical, numeric, and open-valued slots on the other hand can comprise common (non-slot) phrases used in conversation, and thus it is easy for our model to ignore such slot references.

We also examine the source of dialog slots: *users* explicitly express the majority (79.5%) of slot values, while a minority are either derived via user reactions to *system* suggestions (9.7%) or *implicitly* valued (10.8%)—not present verbatim in a conversation. However, our errors are distributed evenly between *user*, *system*, and *implicit* sourced slots—suggesting that it is challenging for our model to track dialog states that are updated reactively via user feedback. We thus see a future opportunity to improve DST models by emphasizing multi-hop reasoning and common-sense inference.

5.3 Predicting Carried Over Slots

Long-range dependencies and slot values carried over from early turns are particularly important to model for accurate DST in long conversations (Kumar et al., 2020). We observe this in the zero-shot setting: our model is able to predict all slots accurately for 61% of conversation first-turns, dropping to 46% after one turn, and 5.7% after seven turns (the average conversation duration). We implement an oracle module to discard predictions when a dialog state does not need updating, obtaining an upper bound for DST improvements due to carry-over prediction. With this oracle, we see an average 5-point improvement in JGA across domain, indicating that carry-over prediction can greatly benefit our model. State-of-the-art models for fully supervised DST often rely on explicitly processing previous dialog states—via slot-value graphs (Zhou and Small, 2019; Chen et al., 2020) or as a separate input to the model at each turn (Heck et al., 2020; Kim et al., 2020). In our framework we can target slot carry-over by training a model to predict a `carried over` token in place of the true slot value whenever a slot value does not need updating at the current turn (**+ Carryover**). At inference time, we replace predicted carry-over tokens with the slot's last predicted value.

Our carry-over implementation improved JGA for all domains (Table 7) by an average of 3.14%, and improved JGA across all context lengths—with the largest improvements (+7%) at the sec-

	Rest.	Hotel	Attr.	Train	Taxi

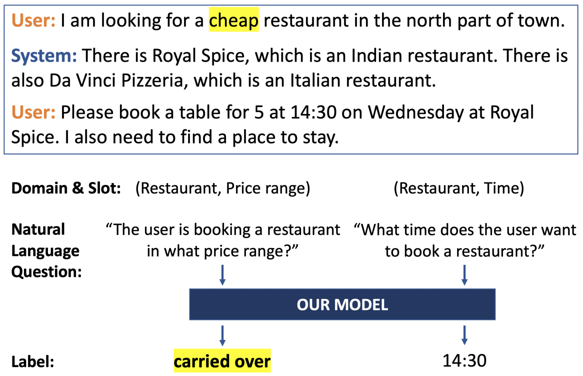
Table 7: Zero-shot JGA on MultiWOZ 2.1 test set with carry-over prediction and transfer learning.



User: I am looking for a cheap restaurant in the north part of town.

System: There is Royal Spice, which is an Indian restaurant. There is also Da Vinci Pizzeria, which is an Italian restaurant.

User: Please book a table for 5 at 14:30 on Wednesday at Royal Spice. I also need to find a place to stay.

Figure 3: Our model can be trained to predict the presence of slot carry-over by replacing slot values from previous turns with the `carried over` token.

ond and third turn of a conversation (Figure 4). The `carried over` token allows our model to hedge against low confidence slots, falling back to predictions from previous turns where the target slot may be directly mentioned. This helps reduce the *wrong value* error rate by an average of 31% across each domain. Our model can also propagate null values with carry-over, reducing spurious predictions by an average of 36% across domains. However, we also observe our carry-over model propagating 78% of its errors from previous turns, suggesting that further improvements can result via accurately predicting slot updates.

5.4 Transfer Learning for Generalization

Our framework is ontology-agnostic and thus easily supports transfer learning without modifying the architecture by simply writing natural language questions for additional slots. Gao et al. (2020) found that intermediate fine-tuning of RoBERTa-Large (Liu et al., 2019) on passage-based QA tasks (Fisch et al., 2019) improved zero-shot DST performance. In preliminary experiments, we found no significant impact from intermediate fine-tuning on the SQuAD v2.0 (Rajpurkar et al., 2018) passage-based QA dataset. However, we observe significant improvements when training with joint, non-curriculum learning (McCann et al., 2018; Raffel et al., 2020)—augmenting our training data with an equal number of examples sampled from DSTC8, taking care to remove data from the held-out domain in both MultiWOZ and DSTC8.

Our framework allows for easy joint optimization with carry-over and transfer learning: by training new models on MultiWOZ 2.1 augmented with DSTC8 (**+ DSTC8**) we gain a further average 3.5-point improvement in per-domain JGA (Table 7). On average, our model makes 29% fewer *spurious* errors, and 6.9% fewer errors in open-valued slots, suggesting that our model scales well with additional training data with semantically distinct slot types and values. Our model also makes 9.7% fewer errors on categorical slots and 63% fewer mistakes where it assigns the value of one categorical slot to another, despite being unable to observe the set of possible categorical options—suggesting that exposure to more diverse categorical slots allows our model to better understand and distinguish between such slots. While temporal slots comprise only 17% of MultiWOZ and 10% of DSTC8 slots, these additional examples seem to help our model better disambiguate temporal references and make 32% fewer errors in such slots.

By applying both carry-over and transfer learning to our largest model, we observe further improvements in zero-shot JGA for all domains—averaging 5.1 points better than GPT2-m CLMQ, for an average gain of 11% JGA over previous state-of-the-art across domains (Table 7).

6 Qualitative Analysis

We manually reviewed 300 errors made by our GPT2-medium CLMQ model in the zero-shot setting—annotating 20 errors from each modality (spurious, ignored, wrong value) from each domain with the gold label quality and perceived cause of error totaling 300 annotated examples. As widely observed in recent DST work (Zhou and Small, 2019; Kumar et al., 2020), a significant proportion of DST errors on MultiWOZ are unavoidable—caused by annotation errors. While version 2.1 corrected some of these, annotation errors and inconsistencies remain responsible for 30% of sampled errors—in particular, in 10% of errors the original annotator did not record reactive preferences while in 5% of errors the original annotator did. These inconsistencies can hurt our model's ability to infer

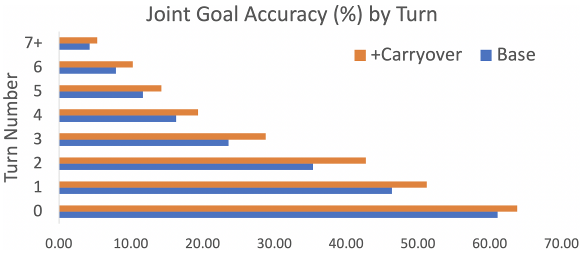


Figure 4: Per-turn JGA on MultiWOZ Test set for GPT2-CLMQ with and without carry-over prediction.

reactive and implied requirements and preferences.

We are also particularly interested in *slot transfers*—when our model mistakenly predicts one slot's value for a different slot, comprising 36% of our manually reviewed errors. In the Taxi and Hotel domains, our model transfers slots from the same domain over 75% of the time, with most swaps occurs between same-category slots (e.g. temporal slots like Taxi 'LeaveAt' and 'ArriveBy'). Slots in these domains are closely semantically related, with values that can fit any slot of that category (e.g. 13:10 vs. 15:15). While a human can easily infer that the earlier of two times must be departure and the later arrival, our model has no inherent understanding of temporal mechanics or numeracy (Wallace et al., 2019). In future work, we will explore learning such knowledge directly via hierarchical softmax output distributions to distinguish between output modalities (Spithourakis and Riedel, 2018), and fine-tuning our model with contrastive losses to learn to rank numerals and times (Hoffer and Ailon, 2015).

For Restaurant, Attraction, and Train, our model tends to swap slot values with those from other domains in the conversation. This is often due to semantically similar slots whose values, at first glance, may not be obviously identifiable as such (e.g. 'Bridge' or 'The Place'). Kumar et al. (2020) similarly observe a particularly high incidence of slot transfers between different-domain 'Name' slots. Other such slots include price ranges and numbers of guests. We have seen that data augmentation with DSTC8 can improve our model's ability to disambiguate such slots—this suggests that we could further improve our model by exposing it to in-domain, conversational reading comprehension data.

While no such dataset currently exists, in future work we aim to explore using question generation (Du et al., 2017) and paraphrasing (Tseng et al., 2014) models to perform in-domain data augmentation, creating reading comprehension questions for task-oriented dialogs that targeting entities and relations not covered by an ontology. We also wish to explore methods for generating general reading comprehension questions for out-of-domain conversations (Shakeri et al., 2020) to improve our model's domain adaptation ability.

7 Related Works

Modern dialog state tracking seeks to capture evolving user intents in a structured belief state (Thomson and Young, 2010). Traditional systems rely on hand-crafted features (Henderson et al., 2014) and classify slot values from a fixed ontology (Mrksic et al., 2017; Ramadan et al., 2018). Gao et al. (2019) and Zhou and Small (2019) fill some slots via spans extracted from dialog history, although they treat non-numeric slots as categorical. Generative methods (Xu and Hu, 2018; Wu et al., 2019) can predict arbitrary unseen values, with Hosseini-Asl et al. (2020) achieving state-of-the-art supervised DST performance in MultiWOZ 2.1 although they cannot predict unseen slots.

By posing DST as generative QA, our framework can leverage language models pre-trained on open-domain documents (Radford et al., 2019) to understand unfamiliar queries. Like Gao et al. (2020), we seek to answer natural language questions about each slot. We contrast our approach to zero-shot DST—which never has access to slots or dialog from the target domain—and that of Campagna et al. (2020), who expose their 'zero-shot' models to synthetic in-domain conversations that require access to the full ontology of the 'held-out' evaluation domain.

We take inspiration from previous work that frames a wide selection of natural language understanding (NLU) tasks (Wang et al., 2019) as QA (McCann et al., 2018) and span extraction (Keskar et al., 2019). While question-answering can be posed as a span extraction task (Wang et al., 2016), generative approaches have proven successful in answering questions about complex passages (Fan et al., 2019). We use a language modeling approach, taking cues from Raffel et al. (2020) who demonstrate that a large language model trained on next-token prediction can learn to solve many different NLU tasks posed as text. Recent work has also shown that large pre-trained language models can generalize to new NLU tasks with few or no examples (Brown et al., 2020), and we leverage this alongside world knowledge acquired during the pre-training process (Petroni et al., 2019) to build a DST model that is robust to new domains and slot-value ontologies.

8 Conclusion

This paper proposes a conditional language modeling approach to multi-domain DST posed as a generative question answering task. By leveraging natural language questions as state queries, our model can generalize to unseen domains, slots, and values via its understanding of language. Our model achieves state-of-the-art zero-shot results on the MultiWOZ 2.1 dataset with average per-domain absolute improvements of 5.9% joint accuracy. We also demonstrate that our framework is easily extensible to support transfer learning and learning slot carry-over. In the future, it is worth exploring mechanisms for our model to better understand relative temporal values and general reading comprehension questions from conversations in order to disambiguate semantically similar dialog slots.

Zero-shot Neural Passage Retrieval via Domain-targeted Synthetic Question Generation

Ji Ma Ivan Korotkov Yinfei Yang Keith Hall Ryan McDonald
Google Research

Abstract

A major obstacle to the wide-spread adoption of neural retrieval models is that they require large supervised training sets to surpass traditional term-based techniques, which are constructed from raw corpora. In this paper, we propose an approach to zero-shot learning for passage retrieval that uses synthetic question generation to close this gap. The question generation system is trained on general domain data, but is applied to documents in the targeted domain. This allows us to create arbitrarily large, yet noisy, question-passage relevance pairs that are domain specific. Furthermore, when this is coupled with a simple hybrid term-neural model, first-stage retrieval performance can be improved further. Empirically, we show that this is an effective strategy for building neural passage retrieval models in the absence of large training corpora. Depending on the domain, this technique can even approach the accuracy of supervised models.

1 Introduction

Recent advances in neural retrieval have led to advancements on several document, passage and knowledge-base benchmarks (Guo et al., 2016; Pang et al., 2016; Hui et al., 2017; Dai et al., 2018; Gillick et al., 2018; Nogueira and Cho, 2019a; MacAvaney et al., 2019; Yang et al., 2019a,b,c). Most neural passage retrieval systems are, in fact, two stages (Zamani et al., 2018; Yilmaz et al., 2019), illustrated in Figure 1. The first is a true retrieval model (aka first-stage retrieval[1]) that takes a question and retrieves a set of candidate passages from a large collection of documents. This stage itself is rarely a neural model and most commonly is an term-based retrieval model such as BM25 (Robertson et al., 2004; Yang et al., 2017), though there is recent work on neural models (Zamani et al., 2018; Dai and Callan, 2019; Chang et al., 2020; Karpukhin et al., 2020; Luan et al., 2020). This is usually due to the computational costs required to dynamically score large-scale collections. Another consideration is that BM25 is often high quality (Lin, 2019). After first-stage retrieval, the second stage uses a neural model to rescore the filtered set of passages. Since the size of the filtered set is small, this is feasible.

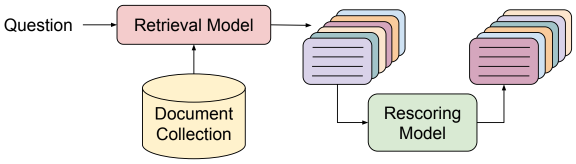

Figure 1: End-to-end neural retrieval. A first-stage model over a large collection returns a smaller set of relevant passages which are reranked by a rescorer.

The focus of the present work is methods for building neural models for *first-stage passage retrieval* for large collections of documents. While rescoring models are key components to any retrieval system, they are out of the scope of this study. Specifically, we study the *zero-shot* setting where there is no target-domain supervised training data (Xian et al., 2018). This is a common situation, examples of which include enterprise or personal search environments (Hawking, 2004; Chirita et al., 2005), but generally any specialized domain.

The zero-shot setting is challenging as the most effective neural models have a large number of parameters, which makes them prone to overfitting. Thus, a key factor in training high quality neural models is the availability of large training sets. To address this, we propose two techniques to improve neural retrieval models in the zero-shot setting.

First, we observe that general-domain question-passage pairs can be acquired from community platforms (Shah and Pomerantz, 2010; Duan et al., 2017) or high quality academic datasets that are publicly available (Kwiatkowski et al., 2019; Bajaj et al., 2016). Such resources have been used to

---

[1] Also called *open domain* retrieval.

April 19 - 23, 2021. ©2021 Association for Computational Linguistics

create open domain QA passage retrieval models. However, as shown in Guo et al. (2020) and in our later experiments, neural retrieval models trained on the general domain data often do not transfer well, especially for specialized domains.

Towards zero-shot neural retrieval with improved domain adaptability, we propose a data augmentation approach (Wong et al., 2016) that leverages these naturally occurring question/answer pairs to train a generative model that synthesizes questions given a text (Zhou et al., 2017). We apply this model to passages in the target domain to generate unlimited pairs of synthetic questions and target-domain passages. This data can then be used for training. This technique is outlined in Figure 2.

A second contribution is a simple hybrid model that interpolates a traditional term-based model – BM25 (Robertson et al., 1995) – with our zero-shot neural model. BM25 is also zero-shot, as its parameters do not require supervised training. Instead of using inverted index which is commonly used in term-based search, we exploit the fact that BM25 and neural models can be cast as vector similarity (see Section 4.4) and thus nearest neighbour search can be used for retrieval (Liu et al., 2011; Johnson et al., 2017). The hybrid model takes the advantage of both the term matching and semantic matching.

We compare a number of baselines including other data augmentation and domain transfer techniques. We show on three specialized domains (scientific literature, travel and tech forums) and one general domain that the question generation approach is effective, especially when considering the hybrid model. Finally, for passage retrieval in the scientific domain, we compare with a number of recent supervised models from the BioASQ challenge, including many with rescoring stages. Interestingly, the quality of the zero-shot hybrid model approaches supervised alternatives.

2 Related Work

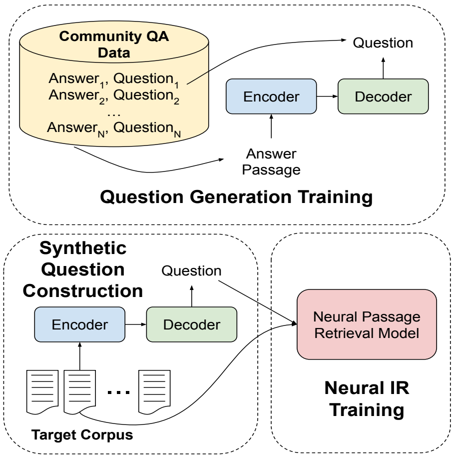

Figure 2: Synthetic query generation for neural IR.

Neural Retrieval The retrieval vs. rescorer distinction (Figure 1) often dictates modelling choices for each task. For first-stage retrieval, as mentioned earlier, term-based models that compile document collections into inverted indexes are most common since they allow for efficient lookup (Robertson et al., 2004; Yang et al., 2017). However, there are studies that investigate neural first-stage retrieval. A common technique is to learn the term weights to be used in an inverted index (Zamani et al., 2018; Dai and Callan, 2019, 2020). Another technique is representation-based models that embed questions and passages into a common dense subspace (Palangi et al., 2016) and use nearest neighbour search for retrieval (Liu et al., 2011; Johnson et al., 2017). Recent work has shown this can be effective for passage scoring (Chang et al., 2020; Karpukhin et al., 2020; MacAvaney et al., 2020). Though all of the aforementioned first-stage neural models assume supervised data for fine-tuning. For rescoring, scoring a small set of passages permits computationally intense models. These are often called interaction-based, one-tower or cross-attention models and numerous techniques have been developed (Guo et al., 2016; Hui et al., 2017; Xiong et al., 2017; Dai et al., 2018; McDonald et al., 2018), many of which employ pre-trained contextualized models (Nogueira and Cho, 2019a; MacAvaney et al., 2019; Yang et al., 2019a,b). Khattab and Zaharia (2020) also showed that by delaying interaction to the last layer, one can build a first stage retrieval model which also leverages the modeling capacity of an interaction based models.

Model Transfer Previous work has attempted to alleviate reliance on large supervised training sets by pre-training deep retrieval models on weakly supervised data such as click-logs (Borisov et al., 2016; Dehghani et al., 2017). Recently, Yilmaz et al. (2019) has shown that training models on general-domain corpora adapts well to new domains without targeted supervision. Another common technique for adaptation to specialized domains is to learn cross-domain representations (Cohen et al., 2018; Tran et al., 2019). Our work is more aligned with methods like Yilmaz et al. (2019) which use general domain resources to build neural models for new domains, though via different techniques – data augmentation vs. model transfer. Our experiments show that data augmentation compares favorably a model transfer baseline. For specialized domains, recently, there have been a number of studies using cross-domain transfer and other techniques for biomedical passage retrieval via the TREC-COVID challenge[2,3] that uses the CORD-19 collection (Wang et al., 2020).

Question generation for data augmentation is a common tool, but has not been tested in the pure zero-shot setting nor for neural passage retrieval. Duan et al. (2017) use community QA as a data source, as we do, to train question generators. The generated question-passage pairs are not used to train a neural model, but QA is instead done via question-question similarity. Furthermore, they do not test on specialized domains. Alberti et al. (2019) show that augmenting supervised training resources with synthetic question-answer pairs can lead to improvements. Nogueira et al. (2019) employed query generation in the context of first-stage retrieval. In that study, the generated queries were used to augment documents to improve BM25 keyword search. Here we focus on using synthetic queries to train the neural retrieval models.

Hybrid Models Combining neural and term-based models have been studied, most commonly via linearly interpolating scores in an approximate re-ranking stage (Karpukhin et al., 2020; Luan et al., 2020) or through the final layer of a rescoring network (Severyn et al., 2015; McDonald et al., 2018). Since rescoring can be cast as classification, blending signals is straight-forward. However, this is approximate as it does not operate over the whole collection. For first-stage retrieval, the most common method is to learn term weights for a standard inverted index in order to make search efficient (Zamani et al., 2018; Dai and Callan, 2019). Here we propose a first-stage retrieval model that incorporates both term-based (sparse) and neural-based (dense) representations in a hybrid model that uses nearest neighbor search for exact inference (Liu et al., 2011; Johnson et al., 2017; Wu et al., 2019). Similar methods using approximate nearest neighbour search have been investigated by Seo et al. (2019).

3 Synthetic Question Generation

In this work, we are specifically investigating the zero-shot scenario where there exists neither user issued questions nor domain specific data except the passage collection itself. We propose to address the

Ubuntu Forums
Passage: Every time I get a notification about and begin updating when they become available, the process is interrupted by an error message: error in foomatic-filters. Then I get "error in linux generic package" and a bunch of numbers. This is replaced before I can write it all down with "error in Linux package" Everything seems to go OK except I don't know if the updates are really being installed. I tried un-installing and re-installing foomatic-filters . . . **Generated Question**: How do I get rid of error in foomatic-filters?

Biomedical Literature
Passage: Electroencephalographic tracings of 50 patients who presented the classical features of Friedreich's ataxia were reviewed . . . Friedreich's ataxia is mainly a spinal disorder. Involvement of supraspinal and in particular brain stem or diencephalic structures may be more extensive in those patients who show electrographic abnormalities. This would require confirmation with comparative data based on pathological observations. Impaired function of brain stem inhibitory mechanism may be responsible for the slightly raised incidence of seizures in patients with Friedreich's ataxia and other cerebellar degenerations. **Generated Question**: What is the significance of Friedreich's ataxia?

Table 1: Examples of domain-targeted synthetic generated questions used to train passage retrieval models.

training data scarcity issue by generating synthetic questions (Zhou et al., 2017; Duan et al., 2017; Alberti et al., 2019; Nogueira et al., 2019). Leverage the fact that there are large question-answer data sources freely available from the web (Shah and Pomerantz, 2010; Duan et al., 2017). we first train a question generator using general domain question-answer pairs. The passage collection of a target domain is then fed into this generator to create pairs of noisy question-passage pairs, which are used to train a retrieval model (see Figure 2). In this work, we mine English question-answer pairs from community resources, primarily StackExchange[4] and Yahoo! Answers[5]. Note we use stackexchange as it covers a wide range of topics, and we focus on investigating the domain adaptability of using a question generation approach. We leave comparing question generator trained on different datasets or using different architectures to future work.

To ensure data quality, we further filter the data by only keeping question-answer pairs that were positively rated by at least one user on these sites. In total, the final dataset contains 2 millions pairs, and the average length of questions and answers are 12 tokens and 155 tokens respectively. This dataset is *general domain* in that it contains question-answer pairs from a wide variety of topics.

Our question generator is an encoder-decoder with Transformer (Vaswani et al., 2017) layers, which is a common for generation tasks such as translation and summarization (Vaswani et al., 2017; Rothe et al., 2019). The encoder is trained to build a representation for a text and the decoder generates a question for which that text is a plausible answer. Appendix B has model specifics.

Our approach is robust to domain shift as the generator is trained to create questions based on a given text. As a result, generated questions stay close to the source passage material. Real examples are shown in Table 1 for technical and biomedical domains, highlighting the model's adaptability.

4 Neural First-stage Retrieval

In this section we describe our architecture for training a first-stage neural passage retriever. Our retrieval model belongs to the family of *relevance-based dense retrieval* [6] that encodes pairs of items in dense subspaces (Palangi et al., 2016). Let $Q = (q_1, \ldots q_n)$ and $P = (p_1, \ldots, p_m)$ be a question and passage of n and m tokens respectively. Our model consists of two encoders, $\{f_Q(), f_P()\}$ and a similarity function, sim(). An encoder is a function f that takes an item x as input and outputs a real valued vector as the encoding, The similarity function, sim(), takes two encodings, $\mathbf{q}, \mathbf{p} \in \mathbb{R}^N$ and calculates a real valued score, $s = \text{sim}(\mathbf{q}, \mathbf{p})$. For passage retrieval, the two encoders are responsible for computing dense vector representation of questions and passages.

4.1 BERT-based Encoder

In this work, both query and document encoders are based on BERT (Devlin et al., 2019), which has been shown to lead to large performance gains across a number of tasks, including document ranking (Nogueira and Cho, 2019a; MacAvaney et al., 2019; Yang et al., 2019b). In addition, we share parameters between the query and passage encoder – i.e., $f_Q = f_P$, so called Siamese networks – as we found this greatly increased performance while reducing parameters.

We encode P as (CLS, $p_1, \ldots, p_m$, SEP). For some datasets, a passage contains both a title $T = (t_1, ..., t_l)$ and content $C = (c_1, ..., c_o)$, in which case we encode the passage as (CLS, $t_1, ..., t_l$, SEP, $c_1, ..., c_o$, SEP). These sequences are fed to the BERT encoder. Let $h_{\text{CLS}} \in \mathbb{R}^N$ be the final representation of the "CLS" token. Passage encodings $\mathbf{p}$ are computed by applying a linear projection, i.e., $\mathbf{p} = \mathbf{W} * h_{\text{CLS}}$, where $\mathbf{W}$ is a $N \times N$ weight matrix (thus $N = 768$), which preserves the original size of h_{CLS}. This has been shown to perform better than down-projecting to a lower dimensional vector (Luan et al., 2020), especially for long passages.

We encode Q as (CLS, $q_1, q_2, ..., q_n$, SEP) which is then fed to the BERT encoder. Similarly, a linear projection on the corresponding "CLS" token, using the same weight matrix $\mathbf{W}$, is applied to generate $\mathbf{q}$. Following previous work (Luan et al., 2020; Lee et al., 2019b), we use dot product as the similarity function, i.e., $\text{sim}(\mathbf{q}, \mathbf{p}) = \langle \mathbf{q}, \mathbf{p} \rangle = \mathbf{q}^\intercal \mathbf{p}$.

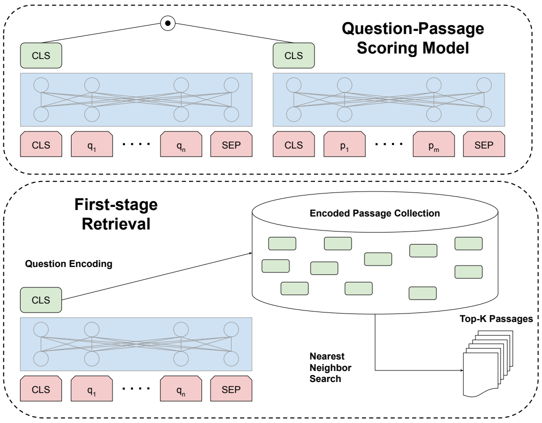

Figure 3: First-stage neural passage retrieval. Top: A BERT-based transformer encodes questions and passages and scores them via dot-product. Bottom: Passages from the collection are encoded and stored in a nearest neighbour search backend. At inference, the question is encoded and relevant passages retrieved.

The top half of Figure 3 illustrates the model.

4.2 Training

For training, we adopt softmax cross-entropy loss. Formally, given an instance $\{\mathbf{q}, \mathbf{p}^+, \mathbf{p}_1^-, ..., \mathbf{p}_k^-\}$ which comprises one query $\mathbf{q}$, one relevant passage $\mathbf{p}^+$ and k non-relevant passages $\mathbf{p}_i^-$. The objective is to minimize the negative log-likelihood:

$$L(\mathbf{q}, \mathbf{p}^+, \mathbf{p}_1^-, ..., \mathbf{p}_k^-) = \log(e^{\langle \mathbf{q}, \mathbf{q}^+ \rangle} + \sum_{i=1}^{k} e^{\langle \mathbf{q}, \mathbf{q}_i^- \rangle}) - \langle \mathbf{q}, \mathbf{q}^+ \rangle$$

This loss function is a special case of ListNet loss (Cao et al., 2007) where all relevance judgements are binary, and only one passage is marked relevant for each training example.

For the set $\{\mathbf{p}_1^-, ..., \mathbf{p}_k^-\}$, we use in-batch negatives. Given a batch of (query, relevant-passage) pairs, negative passages for a query are passages from different pairs in the batch. In-batch negatives has been widely adopted as it enables efficient training via computation sharing (Yih et al., 2011; Gillick et al., 2018; Karpukhin et al., 2020).

4.3 Inference

Since the relevance-based model encodes questions and passages independently, we run the encoder

---

[6] A.k.a. two-tower, dual encoder or dense retrieval.

over every passage in a collection offline to create a distributed lookup-table as a backend. At inference, we run the question encoder online and then perform nearest neighbor search to find relevant passages, as illustrated in the bottom half of Figure 3. While there has been extensive work in fast approximate nearest neighbour retrieval for dense representations (Liu et al., 2011; Johnson et al., 2017), we simply use distributed brute-force search as our passage collections are at most in the millions, resulting in exact retrieval.

4.4 Hybrid First-stage Retrieval

Traditional term-based methods like BM25 (Robertson et al., 1995) are powerful zero-shot models and can outperform supervised neural models in many cases (Lin, 2019). Rescoring systems have shown that integrating BM25 into a neural model improves performance (McDonald et al., 2018). However, for first-stage retrieval most work focuses on approximations via re-ranking (Karpukhin et al., 2020; Luan et al., 2020). Here we present a technique for exact hybrid first-stage retrieval without the need for a re-ranking stage. Our method is motivated by the work of Seo et al. (2019) for sparse-dense QA.

For a query Q and a passage P, BM25 is computed as the following similarity score,

$$\text{BM25}(Q, P) = \sum_{i=1}^{n} \frac{\text{IDF}(q_i) * \text{cnt}(q_i \in P) * (k+1)}{\text{cnt}(q_i \in P) + k * (1 - b + b * \frac{m}{m_{\text{avg}}})},$$

where k/b are BM25 hyperparameters, IDF is the term's inverse document frequency from the corpus, cnt is the term's frequency in a passage, n/m are the number of tokens in Q/P, and m_{avg} is the collection's average passage length.

Like most TF-IDF models, this can be written as a vector space model. Specifically, let $\mathbf{q}^{\text{bm25}} \in [0,1]^{|V|}$ be a sparse binary encoding of a query of dimension $|V|$, where V is the term vocabulary. Specifically this vector is 1 at position i if $v_i \in Q$, here v_i is the i-th entry in V. Furthermore, let $\mathbf{p}^{\text{bm25}} \in \mathbb{R}^{|V|}$ be a sparse real-valued vector where,

$$\mathbf{p}_i^{\text{bm25}} = \frac{\text{IDF}(v_i) * \text{cnt}(v_i \in P) * (k+1)}{\text{cnt}(v_i \in P) + k * (1 - b + b * \frac{m}{m_{\text{avg}}})}$$

We can see that,

$$\text{BM25}(Q, P) = \langle \mathbf{q}^{\text{bm25}}, \mathbf{p}^{\text{bm25}} \rangle$$

As BM25 score can be written as vector dot-product, this gives rise to a simple hybrid model,

$$\begin{aligned} \text{sim}(\mathbf{q}^{\text{hyb}}, \mathbf{p}^{\text{hyb}}) &= \langle \mathbf{q}^{\text{hyb}}, \mathbf{p}^{\text{hyb}} \rangle \\ &= \langle [\lambda \mathbf{q}^{\text{bm25}}, \mathbf{q}^{\text{nn}}], [\mathbf{p}^{\text{bm25}}, \mathbf{p}^{\text{nn}}] \rangle \\ &= \lambda \langle \mathbf{q}^{\text{bm25}}, \mathbf{p}^{\text{bm25}} \rangle + \langle \mathbf{q}^{\text{nn}}, \mathbf{p}^{\text{nn}} \rangle, \end{aligned}$$

where $\mathbf{q}^{\text{hyb}}$ and $\mathbf{p}^{\text{hyb}}$ are the hybrid encodings that concatenate the BM25 ($\mathbf{q}^{\text{bm25}}/\mathbf{p}^{\text{bm25}}$) and the neural encodings ($\mathbf{q}^{\text{nn}}/\mathbf{p}^{\text{nn}}$, from Sec 4.1); and λ is a interpolation hyperparameter that trades-off the relative weight of BM25 versus neural models.

Thus, we can implement BM25 and our hybrid model as nearest neighbor search with hybrid sparse-dense vector dot-product (Wu et al., 2019).

5 Experimental Setup

We outline data and experimental details. The Appendix has further information to aid replicability.

5.1 Evaluation Datasets

BioASQ Biomedical questions from Task B Phase A of BioASQ (Tsatsaronis et al., 2015). We use BioASQ 7 and 8 test data for evaluation. The collection contains all abstracts from MEDLINE articles. Given an article, we split its abstract into chunks with sentence boundaries preserved. A passage is constructed by concatenating the title and one chunk. Chunk size is set so that each passage has no more than 200 wordpiece tokens.

Forum Threads from two online user forum domains: Ubuntu technical help and TripAdvisor topics for New York City (Bhatia and Mitra, 2010). For each thread, we concatenate the title and initial post to generate passages. For BERT-based models we truncate at 350 wordpiece tokens. Unlike the BioASQ data, this data generally does not contain specialist knowledge queries. Thus, compared to the collection of question-answer pairs mined from the web, there is less of a domain shift.

NaturalQuestions Aggregated queries issued to Google Search (Kwiatkowski et al., 2019) with relevance judgements. We convert the original format to a passage retrieval task, where the goal is to retrieval the long answer among all wiki paragraphs (Ahmad et al., 2019). We discarded questions whose long answer is either a table or a list. We evaluate retrieval performance on the development set as the test set is not publicly available. The target collection contains all passages from the development set and is augmented with passages from 2016-12-21 dump of Wikipedia (Chen et al., 2017). Each passage is also concatenated with title. For BERT-based models passages are truncated at 350 wordpiece tokens. This data is different from the previous data in two regards. First, there is a single annotated relevant paragraph per query. This is due to the nature in which the data was curated. Second, this data is entirely "general domain".

Dataset statistics are listed in Appendix A.

5.2 Zero-shot Systems

BM25 Term-matching systems such as BM25 (Robertson et al., 1995) are themselves zero-shot, since they require no training resources except the document collection itself. We train a standard BM25 retrieval model on the document collection for each target domain.

ICT The Inverse Cloze Task (ICT) (Lee et al., 2019b) is an unsupervised pre-training objective which randomly masks out a sentence from a passage and creates synthetic sentence-passage pairs representing membership of the sentence in the passage. These masked examples can then used to train or pre-train a retrieval model. Lee et al. (2019b) showed that masking a sentence with a certain probability, p, can both mimic the performance of lexical matching ($p = 0$) or semantic matching ($p > 0$). ICT is *domain-targeted* since training examples are created directly from the relevant collection. Chang et al. (2020) showed that ICT-based pre-training outperforms a number of alternatives such as Body First Selection (BFS) or Wiki Link Prediction (WLP) for large-scale retrieval.

Ngram Gysel et al. (2018) proposes to train unsupervised neural retrieval system by extracting ngrams and titles from each document as queries. Different from ICT, this approach does not mask the extract ngrams from the original document.

QA The dataset mined from community question-answer forums (Sec. 3) itself can be used directly to train a neural retrieval model since it comes of the form query and relevant text (passage) pair. This data is naturally occurring and not systematically noisy, which is an advantage. However, the data is not domain-targeted, in that it comes from general knowledge questions. We call models trained on this dataset as QA. Applying a model trained on general domain data to a specific domain with no adaptation is a strong baseline (Yilmaz et al., 2019).

QGen The QGen retrieval model trained on the domain-targeted synthetic question-passage pairs described in Section 3. While this model can contain noise from the generator, it is domain-targeted.

	QA	ICT	Ngram	ICT+Ngram	QGen
BioASQ	2.00M	90.50M	636.54M	727.05M	82.62M
NQ	2.00M	71.58M	356.15M	427.72M	84.33M
Forum Travel	2.00M	0.30M	1.25M	1.54M	0.26M
Forum Ubuntu	2.00M	0.42M	2.07M	2.49M	0.43M

Table 2: Number of (synthetic-question, passage) pairs used in zero-shot experiments.

QGenHyb This is identical to QGen, but instead of using the pure neural model, we train the hybrid model in Section 4.4 setting $\lambda = 1.0$ for all models to avoid any domain-targeted tuning. We train the term and neural components independently, combing them only at inference.

All **ICT**, **NGram**, **QA** and **QGen** models are trained using the neural architecture from Section 4. For BioASQ experiments, question and passage encoders are initialized with BioBERT base v-1.1 (Lee et al., 2019a). All other data uses uncased BERT base (Devlin et al., 2019).

We can categorize the neural zero-shot models along two dimensions *extractive* vs. *transfer*. ICT and Ngram are extractive, in that they extract exact substrings from a passage to create synthetic questions for model training. Note that extractive models are also unsupervised, since they do not rely on general domain resources. QA is a *direct* cross-domain transfer model, in that we train the model on data from one domain (or general domain) and directly apply it to the target domain for retrieval. QGen models are *in-direct* cross-domain transfer models, in that we use the out-of-domain data to generate resources for model training.

5.3 Generated Training Datasets

The nature of each zero-shot neural system requires different generated training sets. For ICT, we follow Lee et al. (2019b) and randomly select at most 5 sentences from a document, with a mask rate of 0.9. For Ngram models, Gysel et al. (2018) suggests that retrieval models trained with ngram-order of around 16 was consistently high in quality. Thus, in our experiment we also use 16 and move the ngram window with a stride of 8 to allow 8 token overlap between consecutive ngrams.

For QGen models, each passage is truncated to 512 sentence tokens and feed to the question generation system. We also run the question generator on individual sentences from each passage to promote questions that focus on different aspects of the same document. We select at most 5 salient sentences from a passage, where sentence saliency is the max term IDF value in a sentence.

The size of the generated training set for each baseline is shown in Table 2.

6 Results and Discussion

Our main results are shown in Table 3. We compute Mean Average Precision over the first N[7] results (MAP), Precision@10 and nDCG@10 (Manning et al., 2008) with TREC evaluation script[8]. All numbers are in percentage.

Accuracy of pure neural models are shown in the upper group of Table 3. First, we see that both QA and QGen consistently outperform neural baselines such as ICT and Ngram that are based on sub-string masking or matching. Matching on sub-strings likely biases the model towards memorization instead of learning salient concepts of the passage. Furthermore, query encoders trained on sub-strings are not exposed to many questions, which leads to adaptation issues when applied to true retrieval tasks. Comparing QGen with QA, typically QGen performs better, especially for specialized target domains. This suggests that domain-targeted query generation is more effective for domain shift than direct cross-domain transfer (Yilmaz et al., 2019).

Performance of term-based models and hybrid models are shown in Table 3 (bottom). We can see that BM25 is a very strong baseline. However, this could be an artifact of the datasets as the queries are created by annotators who already have the relevant passage in mind. Queries created this way typically have large lexical overlapping with the passage, thus favoring term matching based approaches like BM25. This phenomenon has been observed by previous work Lee et al. (2019b). Nonetheless, the hybrid model outperforms BM25 on all domains, and the improvements are statistically significant on 9/12 metrics. This illustrate that term-based model and neural-based model return complementary results, and the proposed hybrid approach effectively combines their strengths.

For NaturalQuestions since there is a single relevant passage annotation, we report Precision@1 and Mean reciprocal rank (MRR)[9]. Results are show in Table 4. We can see here that while QGen still significantly outperform other baselines, the gap between QGen and QA is smaller. Unlike BioASQ and Forum datasets, NaturalQuestions contains general domain queries, which aligns well with the question-answer pairs for training the QA model. Another difference is that NaturalQuestions consists of real information seeking queries, in this case QGen performs better than BM25.

6.1 Zero-shot vs. Supervised

One question we can ask is how close to the state-of-the-art in supervised passage retrieval are these zero-shot models. To test this we looked at BioASQ 8 dataset and compare to the top-participant systems.[10] Since BioASQ provides annotated training data, the top teams typically use supervised models with a first-stage retrieval plus rescorer architecture. For instance, the AUEB group, which is the top or near top system for BioASQ 6, 7 and 8, uses a BM25 first-stage retrieval model plus a supervised neural rescorer (Brokos et al., 2018; Pappas et al., 2019).

In order to make our results comparable to participant systems, we return only 10 passages per question (as per shared-task guidelines) and use the official BioASQ 8 evaluation software.

Table 5 shows the results for three zero-shot systems (BM25, QGen and QGenHyb) relative to the top 4 systems on average across all 5 batches of the shared task. We can see the QGenHyb performs quite favorably and on average is indistinguishable from the top systems. This is very promising and suggests that top-performance for zero-shot retrieval models is possible.

A natural question is whether improved first-stage model plus supervised rescoring is additive. The last two lines of the table takes the two-best first-stage retrieval models and adds a simple BERT-based cross-attention rescorer (Nogueira and Cho, 2019b; MacAvaney et al., 2019). We can see that, on average, this does improve quality. Furthermore, having a better first-stage retriever (QGenHyb vs. BM25) makes a difference.

As noted earlier, on BioASQ, BM25 is a very strong baseline. This makes the BM25/QGenHyb zero-shot models highly likely to be competitive. When we look at NaturalQuestions, where BM25 is significantly worse than neural models, we see that the gap between zero-shot and supervised widens substantially. The last row of Table 4 shows a model trained on the NaturalQuestions training data, which is nearly 2-3 times more accurate than the best zero-shot models. Thus, while zero-shot neural models have the potential to be competitive with supervised counterparts, the experiments here show this is data dependant.

6.2 Learning Curves

Since our approach allows us to generate queries on every passage of the target corpus, one question is that whether retrieval system trained this way simply memorizes the target corpus or it also generalize on unseen passages. Furthermore, from an efficiency standpoint, how many synthetic training examples are required to achieve maximum performance. To answer these questions, we uniformly sample a subset of documents and then generate synthetic queries only on that subset. Results on BIOASQ 7 are shown in Figure 4, where x-axis denotes the percentage of sampled documents. We can see that retrieval accuracy improves as passage coverage increases. The peak is achieved when using a 20% subset, which covers 21% of the reference passages. This is not surprising because the number of frequently discussed entities/topics are typically limited, and a subset of the passages covers most of them. This result also indicates that the learned system does generalize, otherwise optimal performance would be seen with 100% of the data.

6.3 Generation vs. Retrieval Quality

Another interesting question is how important is the quality of the question generator relative to retrieval performance. Below we measured generation quality (via Rouge-based metrics (Lin and Hovy, 2002)) versus retrieval quality for three systems. The base generator contains 12 transformer layers, the lite version only uses the first 3 layer. The large one contains 24 transformer layers and each layer with larger hidden layer size, 4096, and more attention heads, 16. Retrieval quality was measured on BIOASQ 7 and generation quality with a held out set of the community question-answer data set. Results are shown in Table 6. We can see that larger generation models lead to improved generators. However, there is little difference in retrieval metrics, suggesting that large domain targeted data is the more important criteria.

7 Conclusion

We study methods for neural zero-shot passage retrieval and find that domain targeted synthetic question generation coupled with hybrid term-neural first-stage retrieval models consistently outperforms alternatives. Furthermore, for at least one domain, approaches supervised quality. While out of the scope of this study, future work includes further testing the efficacy of these first-stage models in a full end-to-end system (evaluated briefly in Section 6.1), as well as for pre-training supervised models (Chang et al., 2020).

A Data

Statistics on each evaluation set are listed in Table 7. Document collection of "BioASQ" comes from MEDLINE articles, and we remove roughly 10M articles that only contains a title. Furthermore, for BioASQ 7B and BioASQ 8B we only keep articles published before 2018 December 31 and 2019 December 31, respectively. On "Forum", we remove threads with empty posts. On "NQ" since there is at most one passage annotated as relevant for each question, and we also remove questions that have no answer, thus the number of questions equal to the number of reference passages. Besides zero-shot experiments, we also conduct supervised experiments on NQ, where we randomly samples 5% question from the training data as development set. This yields a training and development set with 70,393 and 3,704 (question, passage) pairs, respectively.

The data resources can be downloaded from the following websites

To the extent that we pre-process the data, we will release relevant tools and data upon publication.

B Question Generation Details

Our question generation follows the same implementation of Rothe et al. (2019). Both the encoder and decoder share the same network structure. Parameter weights are also shared and are initialized from a pretrained RoBERTa (Liu et al., 2019) checkpoints. Training data is processed with sentencepiece (Kudo and Richardson, 2018) tokenization. We truncate answers to 512 sentencepiece tokens, and limit decoding to at most 64 steps. The training objective is the standard cross entropy. We use Adam (Kingma and Ba, 2014) with learning rate of 0.05, $\beta_1 = 0.9$, $\beta_2 = 0.997$ and $\epsilon = 1e-9$. Learning rate warmup over the first 40,000 steps. Training batch size for the “lite”, “base” and “large” models are 256, 128 and 32 respectively. All models are trained on a “4x4” slice of v3 Google Cloud TPU. At inference, results from using beam search decoding usually fall short of diversity, thus we use greedy decoding to speed up question generation.

C Neural Model Details

C.1 Zero shot Retrieval Models

C.1.1 Development Set

Since we are investigating zero-shot scenario where there is no annotated development set available, hyperparameters are set by following best practice reported in previous work. We thus do not have development set numbers. However, in the hyperparameters section below, we do use a subset of the zero-shot training data to test training convergence under different parameters.

C.1.2 Data Generation

For ICT task, we follow Lee et al. (2019b) and randomly select at most 5 sentences from a document, with a mask rate of 0.9. For Ngram models, Gysel et al. (2018) suggests that retrieval models trained with N larger than 16 consistently outperform those trained with N smaller than 8. In addition, further increase N from 16 has little effect on retrieval accuracy. Thus, in our experiment we set N to 16 and move the ngram window with a stride of 8 to allow 8 token overlap between consecutive ngrams. For QGen models, each passage is truncated to 512 sentence tokens and feed to the question generation system. Besides, we also run question generator on individual sentences from each document to promote questions that focus on different aspects of the same document. In particular, we select at most top 5 salient sentences from a document, where salience of a sentence is measure as the max IDF value of terms in that sentence. We then feed these sentences to the question generator.

C.1.3 Hyperparameters

For zero-shot neural retrieval model training, we uniformly sample of a subset of 5K (question, document) pairs from the training data as a noisy development set. Instead of finding the best hyperparameter values, we use this subset to find the largest batch size and learning rate that lead the training to converge (Smith et al., 2018). Take batch size for example, we always start from the largest batch that can fit in the memory of a “8x8” TPU slice. We gradually decrease the batch size by a factor of 2 if the current value causes training diverge. More details of hyperparameter values of each task are listed in Table 8. Note on Forum data, the maximum batch size for QGen is much larger than other tasks. Looking into the data, we found that queries generated by ICT or Ngram task on Forum data tends to contain higher percentage of noisy sentences or ngrams that are either ill-relevant to the topic or too general. For example, “suggestions are welcomed”, “any ideas for things to do or place to stay”. We train each model for 10 epochs, but also truncate training steps to 200,000 to make training time tractable.

For BM25, the only two hyperparameters are k and b. We set these to $k = 1.2$ and $b = 0.75$ as advised by Manning et al. (2008).

For the hybrid model QGenHyb, the only hyperparameter is λ. We set this to 1.0 without any tuning, since this represented an equal trade-off between the two models and we wanted to keep the systems zero-shot. However, we did try experimentations. For BioASQ 8b and Forum Ubuntu, values near 1.0 were actually optimal. For BioASQ

		Learning Rate	**Batch Size**
BioASQ	ICT	1e-5	8192
	Ngram	1e-5	8192
	QGen	1e-5	8192
Forum Travel	ICT	2e-6	1024
	Ngram	2e-6	1024
	QGen	2e-6	4096
Forum Ubuntu	ICT	1e-6	512
	Ngram	1e-6	512
	QGen	1e-6	4096
NQ	ICT	1e-5	6144
	Ngram	1e-5	6144
	QGen	1e-5	6144

Table 8: Hyperparameters

7b and Forum Travel, values of 2.0 and 2.1 were optimal and led to improvements in MAP from 0.468 → 0.474 and 0.181 → 0.188, respectively.

C.2 Supervised Models

We also train supervised models on BioASQ and NQ, where we use the development set to do early stopping. For BioASQ, our developement set is data from BioASQ 5 (i.e., disjoint from BioASQ 7 and 8). The development set MAP of our supervised model reranking a BM25 system on this data is 52.1, compared to the BioASQ 8 scores of 38.7. For NQ, the MRR on the development set is 0.141. All other hyperparameters remain the same except we use a smaller batch size of 1024, as we observe that using large batch causes the model quickly overfit the training data. This may due to the number of training examples is 2 orders of magnitude smaller compared to zero-shot setting. For our BioASQ supervised model we follow Pappas et al. (2019) and train it with binary cross-entropy using the top 100 BM25 results as negatives.

C.3 Computational Resources

C.3.1 Question Generation

To train the question generator on 2M questions,

- We used a “4x4” slice of v3 Google Cloud TPU.
- Training time ranges from 20 hours for the lite model and 6 days for the large model.

Once trained, we need to run the generator over our passage collection.

- We distributed computation and used 10,000 machines (CPUs) over the collection.
- For BioASQ, the largest dataset, it took less than 40 hours to generate synthetic questions.

We initialize question generation models from either RoBerta base or Roberta large checkpoint (Liu et al., 2019), and the total number of trainable parameters are 67M for the lite model, 152M for the base model and 455M for the large model.

C.3.2 Neural Retrieval Model

To train the retrieval models, we need to train the query and passage encoders. We share parameters between the two encoders and initialize them from either base BERT (Devlin et al., 2019) or BioBERT (Lee et al., 2019a) checkpoint. Thus retrieval models trained on BioASQ have 108M trainable parameters and retrieval models trained on NQ and Forum data have 110M trainable parameters. After training, we need to run the passage encoder over every passage in the collection to create the nearest neighbour backend.

- Depending on the training batch size, we use either an “8x8” or “4x4” TPU slice.
- Training the ”ngram” model on BioASQ took the longest time, which completes in roughly 30 hours.
- Indexing BioASQ, which is our largest passage collection, with 4000 CPUs which took roughly 4 hours.

Having trained models, the inference task is to encode a query with the neural model and query the distributed nearest neighbour backend to get the top ranked passages. The relevant resources are:

- We encode queries on a single CPU.
- Our distributed nearest neighbour search uses 20 CPUs to serve the collections.
- For BioASQ, our largest collection, to run the inference on the test sets of 500 queries took roughly 1m57s. This is approximately 0.2s per instance to encode the query, run brute-force nearest neighbour search on 10s of millions of examples and return the result.

Discourse-Aware Unsupervised Summarization of Long Scientific Documents

Abstract

We propose an unsupervised graph-based ranking model for extractive summarization of long scientific documents. Our method assumes a two-level hierarchical graph representation of the source document, and exploits asymmetrical positional cues to determine sentence importance. Results on the PubMed and arXiv datasets show that our approach[1] outperforms strong unsupervised baselines by wide margins in automatic metrics and human evaluation. In addition, it achieves performance comparable to many state-of-the-art supervised approaches which are trained on hundreds of thousands of examples. These results suggest that patterns in the discourse structure are a strong signal for determining importance in scientific articles.

1 Introduction

Single document summarization aims at shortening a text and preserving the most important ideas of the source document. While abstractive strategies generate summaries with novel words, extractive strategies select sentences from the source to form a summary (Nenkova et al., 2011). Despite recent advances in abstractive summarization, extractive models are still attractive in cases where faithfully preserving the original text is the priority. For example, legal arguments can hinge on the exact wording of a contract (Farzindar and Lapalme, 2004), and ensuring the factual correctness of a summary can be critical in the health or scientific domains, which is a known weakness of current abstractive methods (Kryściński et al., 2019).

Introduction	anxiety affects quality of life in those living with parkinson's disease (pd) more so than overall cognitive status, motor deficits, apathy, and depression.
Introduction	although anxiety and depression are often related and coexist in pd patients, recent research suggests that anxiety rather than depression is the most prominent and prevalent mood disorder in pd.
Related Work	furthermore, since previous work, albeit limited, has focused on the influence of symptom laterality on anxiety and cognition, we also explored this relationship .
Methodology	this study is the first to directly compare cognition between pd patients with and without anxiety.
Result	the findings confirmed our hypothesis that anxiety negatively influences attentional set-shifting and working memory in pd.
Result	moreover, anxiety has been suggested to play a key role in freezing of gait (fog), which is also related to attentional set-shifting.
Future work	s. future research should examine the link between anxiety, set-shifting, and fog, in order to determine whether treating anxiety might be a potential therapy for improving fog.

Table 1: Example of a PubMed article's summary produced by our model HipoRank. The hierarchical and directed graph combined with discourse-aware edge weighting allow HipoRank to generate summaries that cover topics from different sections of the scientific article.

Supervised neural-based models have been the dominant paradigm in recent extractive systems, at least for *short news summarization* (Nallapati et al., 2017; Dong et al., 2018; Zhou et al., 2018; Liu and Lapata, 2019; Narayan et al., 2018b; Zhang et al., 2019b). These models usually employ the encoder-decoder structure and have achieved promising performance on news datasets such as CNN/DailyMail (Hermann et al., 2015), and NYT (Sandhaus, 2008).

However, these models cannot easily be adapted to out-of-domain data that have greater length and fewer training examples such as scientific article summarization (Xiao and Carenini, 2019) due to

---

[*] Equal contribution.

two significant limitations. First, they require large domain-specific training pairs of source documents and gold-standard summaries, which are often not available or feasible to create (Zheng and Lapata, 2019). Second, the typical setup of using a token-level encoder-decoder with an attention mechanism does not scale well to longer documents (Shao et al., 2017), as the number of attention computations is quadratic with respect to the number of tokens in the input document.

We instead explore *unsupervised* approaches to address these challenges on long document summarization. We show that a simple unsupervised graph-based ranking model combined with proper sophisticated modelling of discourse information as an inductive bias can achieve unreasonable effectiveness in selecting important sentences from long scientific documents.

For the choice of unsupervised graph-based ranking model, we follow the paradigm of LexRank (Erkan and Radev, 2004) and PACSUM (Zheng and Lapata, 2019). In these methods, sentences are nodes and weighted edges represent the degree of similarity between sentences. Summary generation is formulated as a node selection problem, in which nodes (i.e., sentences) that are semantically similar to other nodes are chosen to be included in the final summary. In other words, they determine node importance by defining a notion of centrality in the graph.

In addition, we augment the document graph with directionality and hierarchy to reflect the rich discourse structure of long scientific documents. In particular, our method relies on two insights about the discourse structure of long scientific documents. The first is that important information typically occurs at the start and end of sections; i.e., they tend to appear near section boundaries (Baxendale, 1958; Lin and Hovy, 1997; Teufel, 1997). We implement this using an asymmetric edge weighting function in a *directed graph* which considers the distance of a sentence to a boundary. The second is that most sentences across section boundaries are unlikely to interact significantly with each other (Xiao and Carenini, 2019). We implement this insight by injecting *hierarchies* into our model, introducing section-level representations as graph nodes in addition to sentence nodes. By doing so, we convert a flat graph into a hierarchical non-fully-connected graph, which has two advantages: 1) reduced computational cost and 2) pruning of distracting weak connections between sentences across different sections.

We call our approach **Hi**erarchical and **Po**sitional **Rank**ing model (HIPORANK) and evaluate it on summarizing long scientific articles from PubMed and arXiv (Cohan et al., 2018). Empirical results show that our method significantly improves performance over previous unsupervised models (Zheng and Lapata, 2019; Erkan and Radev, 2004) in both automatic and human evaluation. In addition, our simple unsupervised approach achieves performance comparable to many expensive state-of-the-art supervised neural models that are trained on hundreds of thousands of examples of long document pairs (Xiao and Carenini, 2019; Subramanian et al., 2019). This suggests that patterns in the discourse structure are highly useful for determining sentence importance in long scientific articles, and that explicitly building in biases inspired by this structure is a viable strategy for building summarization systems.

2 Related Work

2.1 Extractive Summarization

Traditional extractive summarization methods are mostly unsupervised (Radev et al., 2000; Lin and Hovy, 2002; Wan, 2008; Wan and Yang, 2008; Hirao et al., 2013; Parveen et al., 2015; Yin and Pei, 2015; Li et al., 2017; Zheng and Lapata, 2019), utilizing a notion of sentence importance based on n-gram overlap with other sentences and frequency information (Nenkova and Vanderwende, 2005), relying on graph-based methods for sentence ranking (Erkan and Radev, 2004; Mihalcea and Tarau, 2004), or performing keyword extraction combined with submodular maximization (Tixier et al., 2017; Shang et al., 2018).

With the development of large-scale summarization datasets such as CNN/DailyMail (Hermann et al., 2015), NYT (Sandhaus, 2008), Newsroom (Grusky et al., 2018) and XSum (Narayan et al., 2018a), along with advancements in deep neural-based architectures, modern supervised neural network-based methods that employ encoder-decoder framework have become increasingly popular. These models have been proposed with extractive strategies (Cheng and Lapata, 2016; Nallapati et al., 2017; Wu and Hu, 2018; Dong et al., 2018; Zhou et al., 2018; Narayan et al., 2018b); abstractive strategies (See et al., 2017; Chen and Bansal, 2018; Gehrmann et al., 2018; Dong et al., 2019; Zhang et al., 2019a; Lewis et al., 2019); and hybrid strategies (Hsu et al., 2018; Bae et al., 2019; Moroshko et al., 2019).

More recently, extractive approaches leveraging transformer architectures (Vaswani et al., 2017) and their pretrained counterparts (Devlin et al., 2019; Lewis et al., 2019; Zhang et al., 2019a; Dong et al., 2019) have achieved state-of-the-art performances on the CNN/DailyMail news benchmark dataset (Zhang et al., 2019b; Liu and Lapata, 2019; Zhong et al., 2019). Furthermore, pretrained transformer models also provide better sentence representations for unsupervised summarization methods. For instance, PACSUM (Zheng and Lapata, 2019), a directed graph-based unsupervised model that utilizes BERT-based sentence representations, achieved comparable performance to supervised models on the CNN/DailyMail and NYT datasets.

2.2 Extractive Summarization of Long Scientific Papers

Despite the success of deep neural-based models on news summarization, these approaches typically face challenges when applied to long documents such as scientific articles. Furthermore, these approaches are often blind to the topical information resulting from the structured sections in scientific articles (Xiao and Carenini, 2019). Two recent neural supervised models address these issues. Subramanian et al. (2019) used the introduction section as a proxy for the whole document, while Xiao and Carenini (2019) divided articles into sections and used non-auto-regressive approaches to model global and local information.

Besides neural approaches, most previous scientific article summarization systems employ traditional supervised machine learning algorithms with surface features as input (Xiao and Carenini, 2019). Surface features such as sentence position, sentence and document length, keyphrase score, and fine-grain rhetorical categories are often combined with Naive Bayes (Teufel and Moens, 2002), CRFs and SVMs (Liakata et al., 2013), LSTM and MLP (Collins et al., 2017) for extractive summarization over long scientific articles. To the best of our knowledge, the only unsupervised extractive summarization model for long scientific documents relies on citation networks (Qazvinian and Radev, 2008; Cohan and Goharian, 2015), by extracting citation-contexts from citing articles and ranking these sentences to form the final summary. Our proposed method is different from their settings, where we perform single document summarization based on the long source article.

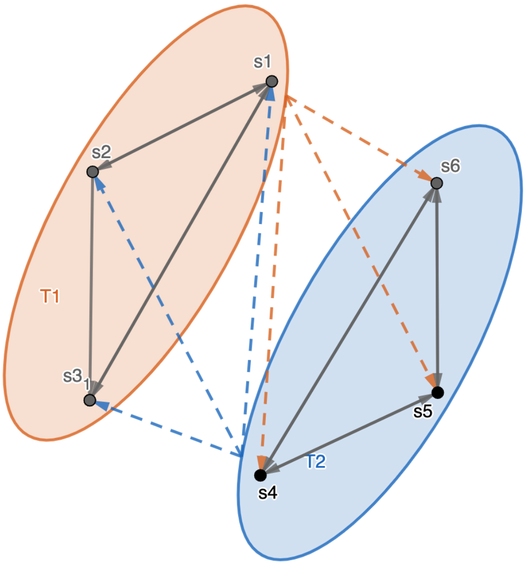

Figure 1: Example of a hierarchical document graph constructed by our approach on a toy document that contains two sections $\{T_1, T_2\}$, each containing three sentences for a total of six sentences $\{s_1, \ldots, s_6\}$. Each double-headed arrow represents two edges with opposite directions. The solid and dashed arrows indicate intra-section and inter-section connections respectively. When compared to the flat fully-connected graph of traditional methods, our use of hierarchy effectively reduces the number of edges from 60 to 24 in this example.

3 Method

Our proposed method combines simple graph-based ranking algorithms with a two-level hierarchical model of the rich discourse structures of long scientific documents (Teufel, 1997; Xiao and Carenini, 2019). We incorporate this discourse information into the graph as inductive biases through the construction of a *directed hierarchical graph* for document representation (Figure 1 and Section 3.2) and through the asymmetric edge weighting of edges with boundary functions (Section 3.3).

3.1 Graph-based Ranking Algorithm

Graph-based ranking algorithms for summarization represent a document as a graph $G = (V, E)$, where V is the set of vertices that represent sentences or other textual units in the document, and

E is the set of edges that represent interactions between sentences. The directed edge e_{ij} from node v_i to node v_j is typically weighted by $w_{ij} = f(sim(v_i, v_j))$, where sim is a measure of similarity between two nodes (e.g. cosine distance between their distributed representations), and f can be an additional weighting function. These algorithms select the most salient sentences from V based on the assumption that sentences that are similar to a greater number of other sentences capture more important content and therefore are more informative.

3.2 Hierarchical Document Graph Creation

To create a hierarchical document graph, we first split a document into its sections, then into sentences[2]. To create the hierarchy, we allow two levels of connections in our hierarchical graph: intra-sectional connections and inter-sectional connections as shown in Figure 1.

Intra-sectional connections aim to model the *local* importance of a sentence within its section. It implements the idea that a sentence that is similar to a greater number of other sentences in the same topic/section should be more important. This is realized in our fully-connected subgraph for an arbitrary section I, where we allow *sentence-sentence* edges for all sentence nodes within the same section.

Inter-sectional connections aim to model the *global* importance of a sentence with respect to other topics/sections in the document, as a sentence that is similar to a greater number of other topics is deemed more important. However, calculating sentence-sentence connections across different sections is computationally expensive and may also suffer from performance degradation due to weak edges between sentences that are unrelated as a result of being from different sections (Mihalcea and Tarau, 2004). To address these issues, We introduce section nodes on top of sentence nodes to form a hierarchical graph. For inter-section connections, we only allow *section-sentence* edges for modeling the global information. This choice makes our approach more computationally efficient while greatly limiting the number of irrelevant inter-section edges that arise from the fact that sections in scientific documents typically have independent topics (Xiao and Carenini, 2019). In contrast, traditional graph-based ranking algorithms have a flat fully-connected graph document with no sections.

3.3 Asymmetric Edge Weighting by Boundary functions

To calculate the weight of an edge, we first measure similarity between a sentence-sentence pair $sim(v_j^I, v_i^I)$ and a section-sentence pair $sim(v^J, v_i^I)$. While our method is agnostic to the measure of similarity, we use cosine similarity with different vector representations in our experiments, averaging a section's sentence representations to obtain its own.

While the similarities of two graph nodes are symmetric, one may be more salient than the other when considering their discourse structures (Baxendale, 1958; Teufel, 1997). Based on these discourse hypotheses of long scientific documents, we capture this asymmetry by making our hierarchical graph *directed* and inject *asymmetric* edge weighting over intra-section and inter-section connections.

Asymmetric edge weighting over sentences Our asymmetric edge weighting is based on the hypothesis that important sentences are near the boundaries (start or end) of a text (Baxendale, 1958). We reflect this hypothesis by defining a *sentence boundary function* d_b over sentences v_i^I in section I such that sentences closer to the section's boundaries are more important:

$$d_b(v_i^I) = \min(x_i^I, \alpha(n^I - x_i^I)), \tag{1}$$

where n^I is the number of sentences in section I and x_i^I represents sentence i's position in the section I. $\alpha \in \mathbb{R}^+$ is a hyper-parameter that controls the relative importance of the start or end of a section or document.

The sentence boundary function allow us to incorporate directionality in our edges, and weight edges differently depending on if they are incident to a more important or less important sentence in the same section. Concretely, we define the weight w_{ji}^I for intra-section edges (incoming edges for i) as:

$$w_{ji}^I = \begin{cases} \lambda_1 * sim(v_j^I, v_i^I), & \text{if } d_b(v_i^I) \geq d_b(v_j^I), \\ \lambda_2 * sim(v_j^I, v_i^I), & \text{if } d_b(v_i^I) < d_b(v_j^I) \end{cases} \tag{2}$$

where $\lambda_1 < \lambda_2$ such that an edge e_{ji} incident to i is weighted more if i is closer to the text bound-

---

[2] Our approach is agnostic to the sentence/section splitting method. In our experiments, articles in the datasets are already split into sections and sentences.

ary than j. Edges with a weight below a certain threshold β can be pruned (i.e., set to 0).

Asymmetric edge weighting over sections Similarly, to reflect the hierarchy hypothesis over long scientific documents proposed by Teufel (1997), we also define a *section boundary function* d_b to reflect that sections near a document's boundaries are more important:

$$d_b(v^I) = \min(x^I, \alpha(N - x^I)), \tag{3}$$

where N is the number of sections in the document and x^I represents section I's position in the document.

This section boundary function allows us to inject asymmetric edge weighting w_i^{JI} to inter-section edges:

$$w_i^{JI} = \begin{cases} \lambda_1 * sim(v^J, v_i^I), & \text{if } d_b(v^I) \geq d_b(v^J). \\ \lambda_2 * sim(v^J, v_i^I), & \text{if } d_b(v^I) < d_b(v^J) \end{cases} \tag{4}$$

where $\lambda_1 < \lambda_2$ such that an edge e_i^{JI} incident to $i \in I$ is weighted more if section I is closer to the text boundary than section J.

3.4 Importance Calculation

We compute the overall importance of sentence v_i^I as the weighted sum of its inter-section and intra-section centrality scores:

$$c(v_i^I) = \mu_1 \cdot c_{\text{inter}}(v_i^I) + c_{\text{intra}}(v_i^I) \tag{5}$$

$$\begin{aligned} c_{\text{intra}}(v_i^I) &= \sum_{v_j^I \in I} \frac{w_{ji}^I}{|I|} \\ c_{\text{inter}}(v_i^I) &= \sum_{v^J \in D} \frac{w_i^{JI}}{|D|}, \end{aligned} \tag{6}$$

where I is the set of sentences neighbouring v_i^I and D is the set of neighbouring sections in the hierarchical document graph; μ_1 is a weighting factor for inter-section centrality.

3.5 Summary Generation

Lastly, we generate a summary by greedily extracting sentences with the highest importance scores until a predefined word-limit L is passed. Most graph-based ranking algorithms recompute importance after each sentence is extracted in order to prevent content overlap. However, we find that the asymmetric edge scoring functions in (2) and (4) naturally prevent redundancy, because similar sentences have different boundary positional scores. Our method thus successfully extracts diverse sentences without recomputing importance.

Dataset	# docs	avg. doc. len.	avg. summ. len.
CNN	92K	656	43
Daily Mail	219K	693	52

arXiv	215K	4,938	220

Table 2: Dataset statistics on news articles (CNN, DailyMail, and NYT) and long scientific documents (PubMed and arXiv).

4 Experimental Setup

This section describes the datasets, the hyperparameter choices, the baseline models, and the evaluation metrics used in the experiments.

4.1 Datasets

Our experiments are conducted on PubMed and arXiv (Cohan et al., 2018), two large-scale datasets of long and structured scientific articles with abstracts as summaries. The average source article length is four to seven times longer than popular news benchmarks (Table 2), making them ideal candidates to test our method.

4.2 Implementation Details

Our model's hyperparameters for testing are chosen from the ablation studies on the validation sets. The test results are reported with the following hyperparameter settings: $\lambda_1 = 0.0, \lambda_2 = 1.0, \alpha = 1.0$, with $\mu_1 = 0.5$ for PubMed and $\mu_1 = 1.0$ for arXiv. We fix λ_2 to 1 and the choices of $\lambda_1 \in \{-0.2, 0, 0.5\}$. represent whether the edge between a less boundary-important sentence and a more boundary-important sentence is 1) negatively weighted, 2) pruned, or 3) down-weighted. $\lambda_1 < \lambda_2$ such that an edge e_{ji} incident to i is weighted more if i is closer to the text boundary than j. $\alpha \in \{0, 0.5, 0.8, 1.0, 1.2\}$ controls the relative importance of the start or end of a section or document. $\mu_1 \in \{0.5, 1.0, 1.5\}$ controls how much we weigh intra-section sentence importance vs. inter-section sectional importance.

For each dataset, we experimented with different pretrained distributional sentence representation models. The dimension of sentence representations is model-dependent (details in Section

6.2). We used the publicly released BERT model[3] (Devlin et al., 2019), PACSUM BERT model[4] (Zheng and Lapata, 2019), SentBERT and SentRoBERTa[5] (Reimers and Gurevych, 2019), and BioMed word2vec representations[6] (Moen and Ananiadou, 2013). A section's representation is calculated as the average of its sentences' representations. The similarity between sentences or sections is defined to be the cosine similarity between the distributed representations.

4.3 Baselines

We compare our approach with previous unsupervised and supervised models in extractive summarization. In addition, we also compare it with recent neural abstractive approaches for completeness.

For unsupervised extractive summarization models, we compare with SumBasic (Vanderwende et al., 2007), LSA (Steinberger and Jezek, 2004), LexRank (Erkan and Radev, 2004) and PACSUM (Zheng and Lapata, 2019). For supervised neural extractive summarization models, we compare with a vanilla encoder-decoder model (Cheng and Lapata, 2016), SummaRuNNer (Nallapati et al., 2017), GlobalLocalCont (Xiao and Carenini, 2019), Sent-CLF and Sent-PTR (Subramanian et al., 2019). We also compare with neural abstractive summarization models as reported in Xiao and Carenini (2019): Attn-Seq2Seq (Nallapati et al., 2016), Pntr-Gen-Seq2Seq (See et al., 2017) and Discourse-aware (Cohan et al., 2018). In addition, we report the lead baseline that selects the first k tokens as a summary ($k = 203, = 220$ for PubMed and arXiv respectively). Lastly, we report baselines for an Oracle summarizer (Nallapati et al., 2017).

4.4 Evaluation Methods

We evaluate our method with automatic evaluation metrics - ROUGE F1 scores (Lin, 2004). ROUGE-1 and ROUGE-2 compute unigram and bigram overlaps between system summaries and reference summaries, while ROUGE-L computes the longest common sub-sequence of the two.

In addition, we design a human evaluation experiment (details in Section 5.2) to compare our model with the best unsupervised summarization model - PACSUM (Zheng and Lapata, 2019). As far as we know, we are the first to perform human evaluation on the 2018 PubMed and arXiv datasets (Cohan et al., 2018). Human evaluation over long scientific articles require annotators to comprehend a full domain-specific long article and compare multiple summaries for quality evaluation. Due to the challenging nature of the task, previous papers choose to skip it and purely rely on automatic evaluations to judge the system performance.

5 Results

5.1 Automatic Evaluation Results

Tables 3 and 4 summarize our automatic evaluation results on the PubMed and arXiv test sets with the best hyperparameters, as described in Section 4.2.

The first blocks in Table 3,4 include the lead and the oracle baselines. The second and the third blocks in the tables present the results of supervised abstractive models, and of supervised extractive models. ROUGE-2 oracle summaries are used as gold standard summaries for training supervised extractive models, which likely contributes to their better ROUGE-2 scores.

The last blocks compare previous unsupervised models with our approach. Our model outperforms all other unsupervised approaches by wide margins in terms of ROUGE-1,2,L F1 scores on both PubMed and arXiv datasets. We also show that PACSUM is biased towards selecting sentences that

appear at the beginning of a document while our method selects sentences in every section and near the article boundaries, similar to the oracle (Figure 2). This overlap with gold standard summaries suggests our use of discourse structure and hierarchy plays a significant role in our method's performance.

Interestingly, despite limited access to only the validation set for hyperparameter tuning, our method achieves performance scores that are competitive with supervised models that require hundreds of thousands of training examples, outperforming almost all abstractive and extractive models on ROUGE-L. This suggests that our discourse-aware unsupervised model is surprisingly effective at selecting salient sentences in long scientific document and perhaps should be used as a strong baseline to accessing the merits of supervised approaches for learning content beyond discourse.

Model	Content-coverage	Importance
PacSum	30.52	48.70
HipoRank (ours)	**42.13**	**59.06**

Table 5: Human evaluation results on 20 sampled reference summaries with 281 system summary sentences from PubMed. Each reference summary-sentence pair is annotated by two annotators with an average annotator agreement of 73.24%. The results are averaged across 127 sentences from HipoRank and154 sentences from state-of-the-art unsupervised extractive summarization system PacSum (Zheng and Lapata, 2019)..

5.2 Human Evaluation

We asked the human judges[7] to read the reference summary[8] (abstract) and present extracted sentences from different summarization systems in a random and anonymized order. The judges are asked to evaluate the system summary sentence according to two criteria: 1) *content coverage* (whether the presented sentence contains content from the abstract); and 2) *importance* (whether the presented sentence is important for a goal-oriented reader even if it isn't in the abstract (Lin and Hovy, 1997)).

Table 5 presents the human evaluation results. HipoRank is shown to be significantly better than PacSum in both content coverage and importance ($p = 0.002$ and $p = 0.007$ with Mann-Whitney U tests, respectively). We also measure inter-rater reliability using Fleiss' κ (46.56 for *content-coverage* and 41.37 for *importance*). These results help sup-

---

[7] All judges are native English speakers with at least a bachelor's degree and experience in scientific research. We compensated the judges at an hourly rate of $20.

[8] We made the decision to not present the whole article, which would create a large cognitive burden on judges and incentivize them to take shortcuts.

port that our method's use of hierarchy and discourse structure improves summarization quality.

6 Ablation Studies

6.1 Component-wise Analysis

Table 6 presents the ablation study to assess the relative contributions of the boundary function and the hierarchical information. We keep all the hyperparameters unchanged with respect to the best setting in Section 4.2 and either vary the positional function or the hierarchical structures. We also found that the improvement of each components are stable across all the hyperparameters we tested (more details in the appendix).

The first block of Table 6 reports the ablation results with different positional functions: no positional function (Erkan and Radev, 2004; Mihalcea and Tarau, 2004), lead bias function (Zheng and Lapata, 2019), and our proposed boundary function. We can see that using the wrong positional function hurts the model's performance when comparing no positional function with lead bias function. Our boundary positional function outperforms the lead or no positional functions significantly.

The second block of Table 6 reports the results with or without the hierarchical structure. We observe that adding the hierarchical information results in a huge performance improvement.

6.2 Effect of Embeddings

To disentangle the effect of sentence representation, we show PubMed test set results of our best model with different sentence embeddings in Table 7. While pretrained transformer models finetuned on sentence similarity improve performance, HipoRank still consistently outperforms previous state-of-the-art unsupervised models (Table 3) even with random embeddings. These results once again suggest that our method's improvement can indeed be attributed to the use of hierarchy and discourse structure, rather than to the the choice of representations.

Model	ROUGE-1	ROUGE-2	ROUGE-L

SentRoBERTa (d=1024)	43.55	17.06	39.07

Table 7: PubMed test set results with HipoRank framework and different pretrained sentence and section embeddings.

6.3 Stability of Hyperparameters

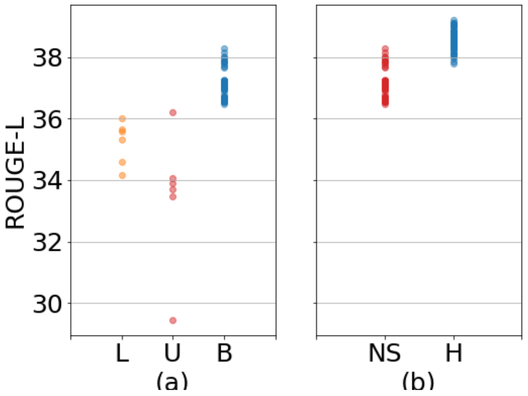

Figure 3: ROUGE-L scores for (a) different positional functions (L=lead, U=undirected, B=boundary) and (b) different graph hierarchies (NS=no_section, H=hierarchical). Each point corresponds to one configuration of the hyperparameter gridsearch described in Section 4.2.

To further inspect our model's stability across different hyperparameter choices, we conducted fine-grained analysis across all different hyperparameter settings as below.

Stability w.r.t. Discourse Structure To evaluate the impact and the stability of discourse structure informed edge weighting (Section 3.3), we first compared our *boundary* positional function (Eqn. 1,3) to PacSum's *lead* positional function, as well as the standard *undirected* approach over different hyperparameter settings. Figure 3 (a) shows that our method consistently performed better on the PubMed validation set, across *different hyperparameters and embedding models* outlined in Section 4.2.

Stability w.r.t. Hierarchy We then evaluated the effect of adding hierarchy (Section 3.2) on top of our boundary positional function. In addition to decreasing the computational cost, Figure 3 (b) shows that incorporating hierarchy further improved ROUGE-L consistently across *different hyperparameters and embedding models* we tested.

Application to other genres While our work here is focused on long scientific document summarization, we believe that our approach is promising for other genres of text, provided that the right discourse-aware biases are given to the model. Indeed, one version of our model with our proposed boundary function can be seen as a generalization of PACSUM, which achieves state-of-the-art performance on unsupervised summarization of news by exploiting the well known lead bias of news text (Zheng and Lapata, 2019; Grenander et al., 2019). We leave such explorations of adapting HIPORANK to other genres to future work.

7 Conclusion

We presented an unsupervised graph-based model for long scientific document summarization. The proposed approach augments the measure of sentence centrality by inserting directionality and hierarchy in the graph with boundary positional functions and hierarchical topic information grounded in discourse structure. Our simple unsupervised approach with rich discourse modelling outperforms previous unsupervised graph-based summarization models by wide margins and achieves comparable performance to state-of-the-art supervised neural models. This makes our model a lightweight but strong baseline for assessing the performance of expensive supervised approaches for long scientific document summarization.

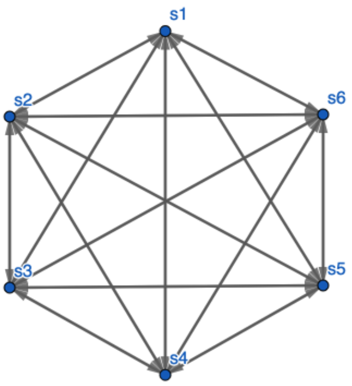
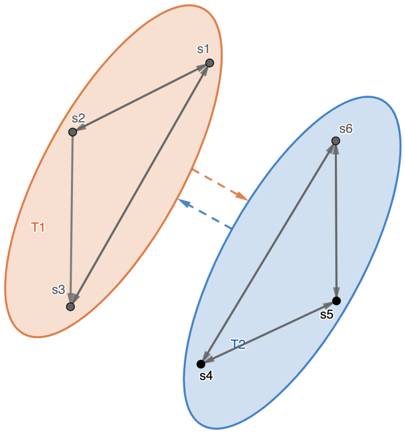
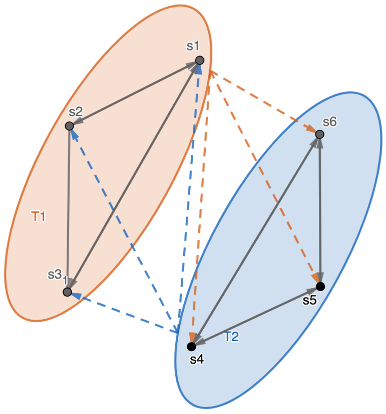
A Appendices



(a) Flat fully-connected graph



(b) Section-section hierarchical multiplication (hierarchy-multiply, ours)



(c) Section-sentence hierarchical addition (hierarchy-add, ours)

Figure 4: Comparison of the flat fully-connected graph used in Erkan and Radev (2004); Mihalcea and Tarau (2004); Zheng and Lapata (2019) to the hierarchical graph used in our models (b) and (c). Although the section-section multiplication reduces the edge computation proportionally to the number of sections, we found it oversimplifies the graph by assuming independence between sentences across different sections. Our final model loosens the assumption by including section-sentence connections as shown in sub-figure (c).

A.1 Different Hierarchical Structure

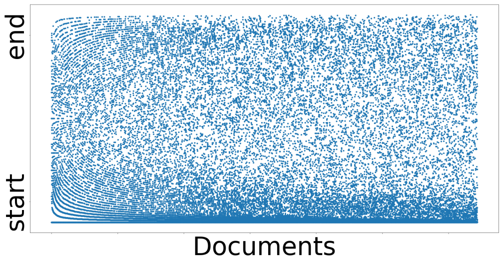
Besides our proposed hierarchical model (Figure 4 (c), hierarchy-add) in the paper, we also proposed and experimented with another novel hierarchical graph by introducing section-section connections (Figure 4 (b), hierarchy-multiply). In this hierarchical setting, we multiply a sentence's sectional importance with its sentence importance (Eqn. (2)) to form the final centrality score:

$$c(v_j^I) = \mu_1 \cdot c_{\text{inter}}(v_j^I) \times c_{\text{intra}}(v_j^I). \tag{7}$$

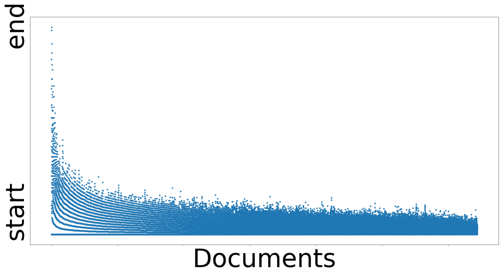
Model	**ROUGE-1**	**ROUGE-2**	**ROUGE-L**
Various Hierarchicall Centrality			
no-hierarchy	41.88	15.39	37.91
hierarchy-multiply (ours)	43.04	16.76	38.77
hierarchy-add (ours)	**43.42**	**16.76**	**39.23**

Table 8: Results on the PubMed validation set with different positional function or different hierarchical information.

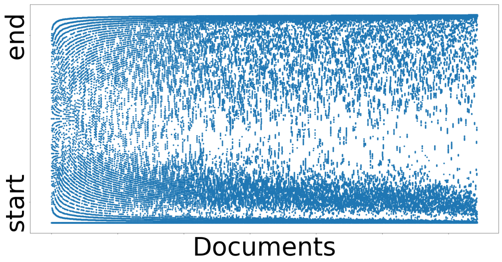
Our empirical results indicate the hierarchy-multiply model always outperforms no-hierarchy models ((Figure 4 (a)) but under performs hierarchy-add. Nevertheless, Table 8 shows that adding any hierarchical structure results in performance improvement by wide margins when compared to the no-hierarchy model.



(a) Oracle (arXiv)



(b) PACSUM (arXiv)



(c) HIPORANK (arXiv)

Figure 5: Sentence positions in source document for extractive summaries generated by different models on the arXiv validation set. Documents on the x-axis are ordered by increasing article length from shortest to longest.

A.2 Sentence Position Comparison

Figure 5 shows the sentence positions in source document for extractive summaries generated by different models on the arXiv validation set. We can again see that PACSUM is biased towards selecting sentences that appear at the beginning of a document while our method selects sentences in every section and near the article boundaries, similar to the oracle.

MIDAS: A Dialog Act Annotation Scheme for Open Domain Human Machine Spoken Conversations

Zhou Yu
Columbia University
`zhouyu@cs.columbia.edu`

Abstract

Dialog act prediction in open-domain conversations is an essential language comprehension task for both dialog system building and discourse analysis. Previous dialog act schemes, such as SWBD-DAMSL, are designed mainly for discourse analysis in human-human conversations. In this paper, we present a dialog act annotation scheme, MIDAS (Machine Interaction Dialog Act Scheme), targeted at open-domain human-machine conversations. MIDAS is designed to assist machines to improve their ability to understand human partners. MIDAS has a hierarchical structure and supports multi-label annotations. We collected and annotated a large open-domain human-machine spoken conversation dataset (consisting of 24K utterances). To validate our scheme, we leveraged transfer learning methods to train a multi-label dialog act prediction model and reached an F1 score of 0.79.[1]

1 Introduction

Human-machine conversations have different dynamics compared to human-human conversations due to the power imbalance between humans and machines in conversational settings. Such differences include content and voice quality (Hill et al., 2015). For instance, humans tend to use a more authoritative voice when they talk to a machine. We found that "commands" account for about 9% of utterances in a human-machine social conversation corpus we collected, while a similar dialog act, "Action-Directive", only accounts for 0.4% in a human-human conversation corpus (Switchboard Dialog Act Corpus (SwDA) (Jurafsky et al., 1997)). Moreover, a human-machine dialog act scheme is not simply used to understand the dialog flow but also to help dialog systems plan their next steps. Therefore, a dialog act scheme for spoken dialog systems must capture semantic information necessary for fine-grained dialog planning. More importantly, a useful human-machine dialog act scheme should incorporate dynamics of realistic settings such as real-time automatic speech recognition (ASR) outputs. However, previously available dialog act schemes are all designed for manual dialog transcriptions, which are very different from ASR outputs. For instance, ASR outputs are noisy and may not contain punctuation. To test if a dialog act predictor trained on manual transcriptions would generalize to ASR outputs, we trained a model using the SwDA dataset annotated with the SWBD-DAMSL scheme (Jurafsky et al., 1997). We tested the model on the ASR output of our open-domain human-machine dialog system conversations and found that the model's performance is only 47.38% in accuracy, mostly due to incompatible schemes and confusion in annotation in addition to domain shifts. This low accuracy score suggests that using existing schemes and datasets to train models for human-machine dialog systems is impractical.

Scheme	#labels	context	multi-label	dataset

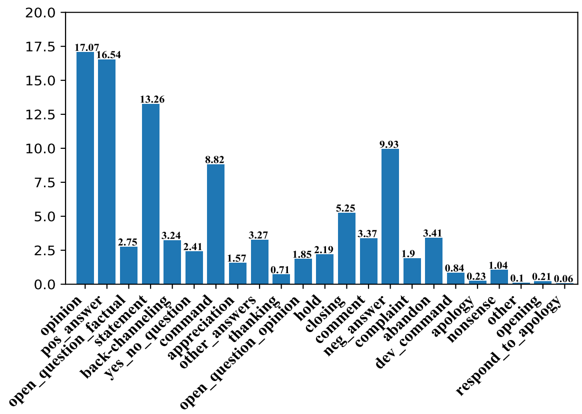

Figure 1: Distribution of dialog acts in the training set

machine spoken conversations. We show a comparison to major dialog act schemes in Table 1. We also annotated real-world human-machine social conversations using the MIDAS scheme and Figure 1 shows the distribution of dialog acts. The scheme is easy for humans to follow. Two annotators achieved an inter-annotator agreement of $\kappa = 0.94$. We trained a multi-label dialog act classifier using transfer learning methods and reached an F1 score of 0.79. Multiple Amazon Alexa Prize social chatbots have deployed our dialog act model and reported better conversational quality due to improved language understanding compared to using SWBD-DAMSL. We share our annotated data and trained models with the research community for easy adoption.

2 Related Work

Previous dialog act annotation schemes are mostly designed for task-oriented dialogs with a specific task, such as MapTask (Thompson et al., 1993) and DATE (Walker and Passonneau, 2001), or in a specific setting (Klüwer, 2011). There are a few dialog act schemes designed for human-human task-independent conversations, such as the Discourse Annotation and Markup System of Labeling (DAMSL, Core and Allen, 1997) and SWBD-DAMSL (Jurafsky et al., 1997). SWBD-DAMSL is used to annotate the Switchboard (Godfrey et al., 1992) corpus, a task-independent telephone conversation corpus, with inter-annotator agreement of $\kappa = 0.80$. SWBD-DAMSL is also applied to annotate human-human meeting conversations (Shriberg et al., 2004). In this paper, we design a dialog annotation scheme specifically for human-machine social chitchat conversations without any topic constraints.

Khatri et al. (2018) introduces a human-machine dialog act annotation scheme with 14 tags. However, the scheme is designed for modeling conversation topics instead of training dialog act predictors. The scheme has tags such as *Information Request*, *General Chat*, and *Multiple Goals*, and the annotation is performed on unsegmented user utterances. Even though the small number of tag categories makes annotation more reliable, it may not provide enough information for understanding user semantics. For example, tags such as *Multiple Goals* do not provide explicit information about user intent. In contrast, we propose a dialog act annotation scheme that focuses on improving open-domain dialog system understanding. We also build a dialog act predictor based on the annotated corpus.

Previously, most popular annotation schemes, such as DAMSL, use mutually-exclusive tags (Mezza et al., 2018) (0.01% of the labeled utterances have multiple labels so we do not consider DAMSL as multi-label) and each utterance is labeled with a single tag in SWBD-DAMSL (Stolcke et al., 2000). However, Bunt (2009) argues that conversation utterances are complex. Each functional segment can have four to five functions on average, so dialog act tags should serve multiple functions. Dynamic Interpretation Theory (DIT) (Bunt, 1997) and its extension, DIT++ (Bunt, 2009) try to solve this problem by supporting multi-dimension and multi-function tags. The 88 tags are organized in a hierarchical structure and separated into dimension-specific and general-purpose functions. The fifth version of DIT++, ISO 24617-2 (ISO standard, Bunt et al., 2010, 2017), is introduced to incorporate not only linguistic theory but also empirical discourse analysis on real domain-independent conversations. Although much effort has been expended in designing ISO, no large dataset was annotated with the scheme except DialogBank (Bunt et al., 2016). This is probably due to the complexity of the scheme and the lack of clear guidelines on how to use contextual information (Ribeiro et al., 2015; Mezza et al., 2018). Due to the huge complexity of open domain social conversations, we propose a hierarchical structure in the annotation scheme and allow one utterance to have multiple dialog acts. We limit the number of dialog acts to 23 to capture the fundamental acts necessary to the system while keeping the total number relatively small (two annotators reached 0.94 in Kappa). We

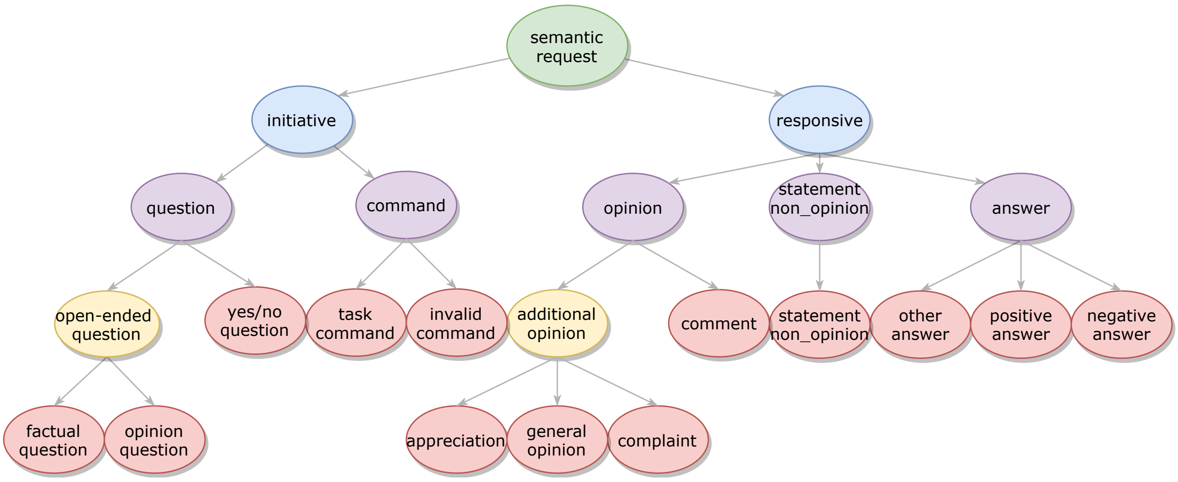

Figure 2: Semantic request tree. Scheme types, classes, categories, and sub-categories are in green, blue, purple, and yellow, respectively. Dialog act tags are leaf nodes in red. Tags can co-occur in one utterance, except tags under *opinion* and *statement non_opinion*, *question* and *answer* categories due to semantic and syntactic conflicts. For example, "User1:Do you watch TV shows? User2: I prefer watching movies." User2 is labeled both *general opinion* and *negative answer*.

also publish our annotated human-machine chatbot corpus through user studies containing 24,000 utterances.

3 MIDAS Annotation Scheme

We present MIDAS, a contextual hierarchical multi-label dialog act annotation scheme for human-machine conversations. MIDAS follows DIT++ and ISO (Bunt, 2009; Bunt et al., 2010) to ensure that the scheme facilitates both annotation and the training of automatic dialog act predictors. MIDAS focuses on helping dialog systems understand their human users, while previous schemes mainly focus on analyzing human-human dialog with not fully open-domain data (SWBD-DAMSL), mutually-exclusive tags (DAMSL), or lack of contextual information (DIT++ and ISO). Therefore, MIDAS provides a unique hierarchical structure and proposes a set of new labels for the human-machine setting while inheriting labels from previous schemes. A complete description of MIDAS is in Appendix A.2. Similar to Chowdhury et al. (2016); Mezza et al. (2018), we also show a potential mapping from SWBD, SWBD-DAMSL, and ISO to MIDAS in Appendix A.4. We discuss the three main features of MIDAS: hierarchical structure, multi-label format, and context consideration respectively.

3.1 Hierarchical structure

Previous schemes such as ISO design their hierarchical structure as multiple dimensions and define dialog acts as dimension-specific functions. Such a turn-by-turn specific taxonomy mixes in-depth analysis into the discourse level, thereby requiring a distinguished definition in each dimension and creating a complex hierarchy. For instance, "accept" and "decline" are defined individually for corresponding parent dimensions such as "address offer" and "address suggestion". This detailed design is beneficial to study interlocutors in a conversations, but may not be necessary for language understanding in a dialog system. In comparison, MIDAS focuses on a concise hierarchical structure to mainly distinguish semantic and functional intents which are critical for dialog understanding and planning. This design facilitates both annotation and model prediction in human-machine conversations.

Specifically, we design MIDAS to have a tree structure. It has two sub-trees: *semantic request* type (Figure 2) and *functional request* type (Figure 3). Under each type, there are classes, categories, and tags arranged in a hierarchical tree structure. Please refer to Figure 2 and 3 for detailed organization. Utterances are labeled with dialog act tags, which are the leaf nodes. The non-leaf nodes are used to categorize different dialog acts, help annotators find the correct tags, and assist customized requirements. We explain the reasoning for the hierarchical design and provide justification for the dialog act definitions with use cases.

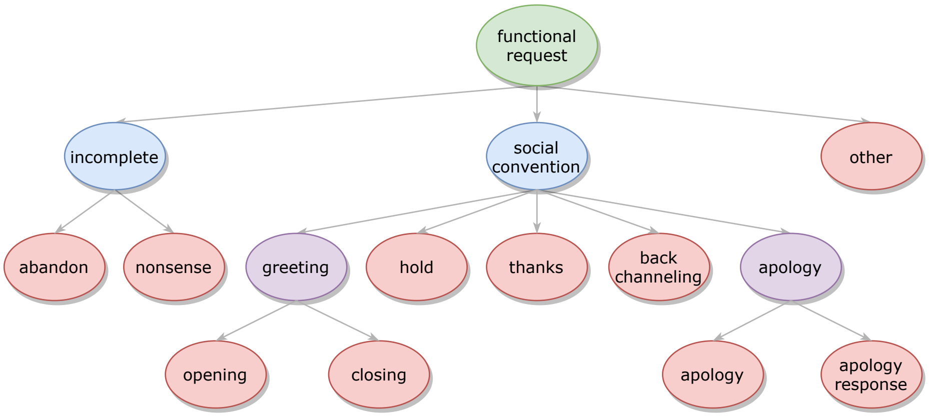

Figure 3: Functional request tree. We remove class and category nodes if there is only one label under them.

3.1.1 Semantic request

Semantic request type captures dialog content, therefore it is essential for dialog topic planning. *Semantic request* separates into *initiative* class and *responsive* class based on whether the user is proposing or continuing a topic.

Initiative class is especially important in the human-machine setting, because in such an imbalanced power setting, the machine must follow the topic that its human partner proposes. Therefore, understanding whether the user is proposing a new topic with their specific intent is the first step for the system to be coherent. There are two categories, *question* and *command* in the *initiative* class, that are designed to distinguish information requests (*question*) from action requests (*command*).

MIDAS first separates *question* into *yes/no question* and *open-ended question* based on syntax. This separation helps the system to generate a coherent response. For example, it is more natural for system responses to start with “yes” or “no” when replying to a *yes/no question*. Then MIDAS further divides *open-ended question* into *factual question* and *opinion question* based on the different types of information that users seek. The system can thus leverage this information and prepare responses by searching different knowledge bases. For example, *factual questions* require factual information from knowledge graphs such as Wikipedia, while *opinion question* requires information from corpora with opinionated material such as Twitter.

Unlike *question*, *command* conveys orders and is particularly popular in human-machine dialogs. The system needs to follow users’ commands, both implicit and explicit, because the system has less power in the conversation than its human interlocutors. Therefore, unlike previous schemes, MIDAS uses *task command* for task-oriented and device related requests, and introduces *invalid command*, which is specific to smart devices. Users sometimes produce commands that are beyond the system’s capability. For example, users may want to control device hardware to which the dialog system does not have access. The system needs to identify these utterances and handle them separately. Utterances labeled with *invalid command* are commands involving device functions which are specific to tasks and can be replied by templates and APIs. We present this tag in the leaf level to be consistent with other dialog acts in prediction.

Responsive class indicates that the utterance is a continuation of the previous topic. SWBD-DAMSL points out that opinions are often followed by general opinions, whereas statements are followed by back-channels (Jurafsky et al., 1997). This distinction may be subtle in human-human conversations (Jurafsky et al., 1997) as humans do not need to explicitly distinguish between the two tags to generate corresponding responses. However, knowing whether an utterance is a statement or an opinion is essential for a system to generate an appropriate response. Hence, MIDAS further breaks the responsive class into *opinion*, *statement non_opinion*, and *answer*, based on the conversation history.

MIDAS separates the *opinion* category into the *additional opinion* subcategory and the *comment* tag because we observed examples such as “User1: my friend thinks we are living in matrix. User2: she’s probably right”. User2 comments on the previous utterance without contributing extra information. *additional opinion* indicates that utterances labeled as dialog acts under this subcategory may contribute extra information, whereas *comment* often indicates that an utterance is a simple reply without explicit feedback. MIDAS separates three types of opinions: *appreciation*, *complaint*, and *general opinion*. Understanding whether the user is complaining or praising the system is essential. Such information is critical to influence dialog policies and extract user feedback.

We also split *answer* into *positive answer*, *negative answer*, and *other answer*, based on utterance's sentiment. One caveat is that utterances, such as "why not", contain negative words but are actually a positive answer to questions such as "Can we talk about movies?", and thus should be labeled as *positive answer*. Such phenomena suggest that automatic dialog act prediction models require semantic understanding and incorporate context in feature representation.

3.1.2 Functional request

Functional request type helps dialog systems achieve discourse level coherence and control conversation functions. We define *incomplete*, *social convention*, and *other* classes under the *functional request* type.

Incomplete class describes utterances that are not complete. There are two *incomplete* types, *abandon* and *nonsense*. In real-world settings, human users can be cut off due to issues such as background noise and long pauses. These cases are labeled as *abandon*. By comparison, *nonsense* is used to label utterances that human annotators cannot understand. These utterances usually contain many ASR errors.

Social convention class is similar to the *social obligations management* and *discourse structure management* dimensions in ISO (Bunt et al., 2010). We define *opening*, *closing*, *thanks*, *apology*, *apology response*, *hold*, and *back channeling* to provide discourse level information.

Finally, utterances that cannot be assigned to any other tag in this hierarchical structure are labeled as an *other* tag.

3.2 Multi-label support

Compared to single-label schemes, multi-label schemes capture different dimensions and functions, which better support dialog system building and discourse analysis. For example,

User1: *what books have you read recently*
User2A: *i haven't read any*
User2B: *i don't want to talk about books*
User2C: *i prefer watching movies*

Users may use different strategies to express a *negative answer* intent. A single-label scheme cannot differentiate above three sentences. An extra label that captures additional semantic information besides *negative answer* benefits dialog system understanding. For instance, User2B has the additional *task command* intent that requests to end the current topic compared to User2A. User2C has the *general opinion* intent that initiates a different topic. Dialog system may not need to change a topic for User2A, but it needs to change the topic for User2B and User2C.

SWBD-DAMSL allows a utterance to be tagged as *double labels* and lists the preferred tag first (Jurafsky et al., 1997). However, *double labels* and ordering heuristics are not explicitly defined in the scheme and thus are infrequent in Switchboard. In MIDAS, except for two exclusive category pairs (*opinion* and *statement non_opinion*, *question* and *answer*), dialog acts are designed to be compatible across hierarchies so that labels in each category can co-occur in one utterance.

Due to the power difference in human-machine conversations, the system needs to prioritize certain tags over the others to keep a coherent conversation. MIDAS has a priority list to focus, from high to low: *question*, *command*, *answer*, *opinion*, and *statement non_opinion*. For example, "User1: what do you want to talk about? User2: how about the financial market". User2's utterance can be tagged as *task command*, *opinion question*, and *general opinion*. Among the three tags, *opinion question* and *task command* are more useful for the system to direct the conversation towards a specific topic.

3.3 Context consideration

Mezza et al. (2018) suggests that most dialog act schemes, including ISO, are not clear on how to leverage contextual information in the annotation process. So tags such as "Answers" are confused with "Inform", which leads to noisy annotations. In comparison, MIDAS scheme is designed to consider context utilizing the hierarchical structure. Dialog acts are thus explicitly distinguished by contextual information. For instance, *general opinion* and *comment* both refer to personal views, but they belong to different sub-categories capturing different semantics and expectations from interlocutors given a specific context. Correspondingly, during annotation, annotators are instructed to consider the context from previous two turns and locate each level in the structure tree suggested by the context.

4 Dataset and Annotation Process

We collected 380K human-machine conversations ASR outputs using Gunrock, the 2018 Alexa Prize winning social bot (Chen et al., 2018). The average number of turns in a conversation and the average tokens per user utterance is 21.76 and 2.85, respectively. Table 2 shows a sample conversation. Two annotators read the descriptions and examples of each dialog act illustrated in Appendix A.2. The annotators reached an inter-annotator agreement of $\kappa = 0.94$ on 1,185 segmented utterances verified by the scheme designers (compared to $\kappa = 0.80$ using DAMSL reported by Stolcke et al. (2000)). Then they annotated the rest of the data separately. In total, they annotated 468 conversations, including 24K segmented sentences on both user and system, among which 12.9K segments are from users. Note that if one dialog act spans multiple segments, we annotate each segment with the same dialog act tag. *general opinion* and *statement non_opinion* are the most frequent tags. For multiple labels, (*positive_answer*, *command*) and (*negative_answer*, *command*) are the most frequent co-occurring tags. Detailed annotation results, including dialog act tag distribution, are shown in Appendix A.2 and Appendix A.3.

USER1:	what do you want to talk about
USER2:	what can you tell me what the top books are right now
USER1:	i am so excited to talk to you about books. i'm actually a pretty big bookworm, and i love to read when i'm not chatting
USER2:	oh [SEG] what are some titles of the books you've read
USER1:	recently, i'm reading the great gastby. it's really thought provoking, and i can see why some people call it the great american novel. how about you? what book do you like?
USER2:	i have {not} read a book in a while [SEG] do you have recommendations in the sci fi

Table 2: An example conversation between a machine (USER1) and a human (USER2). The word "not" is dropped in the last sentence due to ASR errors.

We note that there may be some limitations in the corpus we annotated in terms of both ASR results, and the current interactions between humans and machines. Our motivation is that compared to carefully corrected transcriptions such as SwDA, our scheme and annotated corpus can be more robust against ASR errors and noisy inputs. Since the proportion of utterances with ASR errors are relatively small in our corpus, models trained with the corpus should still perform well on utterances without such errors from more advanced ASR systems. In addition, we believe that our hierarchical multi-label schemes with a manageable size and structure can be easily modified to customized models, as well as more advanced human-machine conversational models. Moreover, our scheme is designed to bridge the gap in human and machine interactions, and are not restricted by the annotation corpus. More importantly, this scheme and annotated corpus can be extended outside of predictions and understanding tasks to language generation tasks. We leave detailed comparison and application to additional tasks such as language generation to future work.

For dialog act prediction, user utterances in human-machine dialogs are ASR outputs and have no punctuation. Therefore, we train a model to segment utterances into semantic units for preprocessing. Note that utterance segmentation is a different line of research and is out of the scope of this paper. We focus on dialog act prediction on each segmented unit following Stolcke et al. (2000). Previous research detects sentence boundaries by predicting the exact punctuation in the training dataset (Cho et al., 2015). However, correct punctuation also relies on deep semantic understanding beyond the sentence surface forms. For instance, a misused question mark can lead the dialog act model to predict a sentence as a question. So following Favre et al. (2008), we only predict the boundary of a sentence instead of predicting punctuation to avoid introducing errors.

It is expensive to annotate sentence boundaries, so we use the Cornell Movie-Quotes Corpus (Danescu-Niculescu-Mizil and Lee, 2011) to train a sentence segmentation model. The Cornell dataset contains 300K utterances from movie transcripts. We reformat the transcripts by replacing punctuation to sentence breaker tokens (denoted as [SEG]). We then train a sequence-to-sequence (seq2seq) model (Sutskever et al., 2014) to predict sentence breaker similarly to Klejch et al. (2017) and Peitz et al. (2011). The input to the model is a reformatted sentence, and the output is the same sentence with added sentence breaker tokens. An example can be seen in the last *USER2* utterance in Table 2. Word embeddings are pre-trained with fastText

(Mikolov et al., 2018) using Common Crawl. We evaluate the segmentation model on 2k manually labeled human utterances of the collected data. The segmentation model achieves 84.43% in micro F1 score, 84.97% in precision, and 84.57% in recall. We apply the trained segmentation model on the entire collected dataset to obtain segmented sentences. All the dialog act annotation and predictions are done on the automatic segmentation results.

5 Dialog Act Prediction

We formulate the dialog act prediction problem as a multi-label classification problem. Following Katakis et al. (2008), we evaluate the proposed methods using F1 score. For evaluation simplicity, we predict one or two labels in the following experiments. We leverage both unlabeled data and annotated data to improve classification performance.

5.1 Baseline model

RNN models have shown promising results in text classification (Rojas-Barahona et al., 2016). Our baseline model uses a 2-layer Bi-LSTM to encode the context representation and a multi-layer perceptron (MLP) to decode the output. For multi-label prediction, we use a binary cross-entropy objective function to learn co-occurring tags independently. This training objective also helps with transfer learning from other single label dialog act datasets. During testing, we choose the labels with the highest values predicted from the MLP as the potential output and filter them with an empirical threshold (0.5).

5.2 Context representation

Contextual information plays an important role in dialog act prediction (Liu et al., 2017; Khatri et al., 2018). We consider two methods to represent previous turns: the actual utterance (text), and the dialog act of the utterance (DA). For each method, the most recent segmented sentence unit from each speaking party is considered as the history suggested by the length of context from Khatri et al. (2018). We append the last segmented system unit (sys_unit), the previous segmented user unit (user_prev), and the current segmented user unit (user_cur) as sys_unit $<u\_p>$ $user\_prev$ $<u\_c>$ $user\_cur$ where $<u\_p>$ and $<u\_c>$ are special tokens to separate utterances. For instance, to predict the dialog act for the segment "do you have recommendations in the sci fi" in the last *USER2* utterance in Table 2, the context representation is formed as *what book do you like <u_p> i haven't read a book in a while <u_c> do you have recommendations in the sci fi*. However, if the current utterance is the first one in the current turn, i.e. there is no contextual information, we use an empty token for usr_prev instead.

Another method to incorporate history is to replace the actual previous segment unit with its dialog act labels (if there are two labels for one segment, we combine both labels). The results for these two methods are shown in Table 3.

5.3 Transfer learning

We use an unsupervised domain adaptation task and a supervised dialog act predictor trained on SwDA (Jurafsky et al., 1997) to improve model performance. We used a BERT model trained on Wikipedia (Devlin et al., 2019) to leverage its contextual word embeddings. However, one potential drawback of using pre-trained BERT is that it has a different domain from our conversational data. Inspired by Siddhant et al. (2019), we use 50 million unlabeled segmented utterances from 380K conversations from Gunrock to fine-tune the BERT language model to resolve this issue. We also leverage an annotated dataset from a similar task. We automatically map 42 tags from SWBD-DMSL to our 23 tags. The detailed mapping can be found in Appendix A.4. We remove all the punctuation (except apostrophes) and non-verbal information such as "<laugh>" from the carefully annotated dataset. We also remove sentences with dialog acts that are not applicable to ours such as *3rd-party-talk*. After pre-processing, we extract a total of 200K annotated utterances using the context representation in Section 5.2. We train a single-label prediction model based on BERT before fine-tuning it on our multi-label prediction task.

6 Experiments

Setting The main purpose of a dialog act predictor in human-machine dialogs is to improve the dialog system's understanding of user intent and preparing corresponding responses. Therefore, we build a dialog act prediction model on user utterances only. After pre-processing (refer to Section 5.2), there are 12.9K user segments, 13.78% of which have multiple labels. We use 10.3K for training and 2.6K for testing. All the testing data are from in-lab user studies. In order to protect Amazon Alexa

	Pre(%)	Rec(%)	F1(%)
LSTM-text	75.94	75.91	75.51
LSTM-DA	75.83	73.48	73.77
BERT-text	79.57	79.31	79.11
BERT-DA	79.29	76.12	76.87
BERT-no_context	73.88	70.43	71.30
BERT-DA+text	79.79	79.47	79.28
BERT_F-text	79.83	79.64	79.40
BERT_F-DA	79.30	76.15	76.89
BERT_F-DA+text	**79.93**	79.61	**79.44**
BERT-SwDA	79.26	76.43	78.98
BERT-SwDA_F	79.58	**79.76**	79.28

Table 3: BERT_F-DA+text achieves the best precision and F1 score. Results reported are an average score of six different random seed runs.

user's privacy, we only make the 2.6K annotated testing utterances public as they were collected with consent for releasing the data to the public.

Models. We implemented 11 models. We use **LSTM** to represent the baseline model trained with LSTMs. **BERT** represents Transformer models with a pre-trained BERT language model. Based on different transfer learning methods described in Section 5.3, **BERT_F** is a pre-trained BERT language model fine-tuned on unlabeled in-domain data, whereas **BERT_SwDA** is a pre-trained BERT language model fine-tuned on labeled SwDA task. Combining these two methods, **BERT-SwDA_F** is fine-tuned on both the unlabeled and labeled tasks. After fine-tuning, the models are trained on our data annotated with the MIDAS scheme. To evaluate the impact of context representation for the above models, we use **-text** and **-DA** to represent using text and dialog act as the context, respectively. We denote **-no_context** when predicting the current utterance without any context.

See Appendix A.1 for implementation details.

7 Results and Analysis

Table 3 describes the experimental results on all 11 models. Transformer models (Vaswani et al., 2017) using BERT embeddings (BERT-text) outperform Bi-LSTM models with pre-trained word embeddings (LSTM-text) by a large margin (from 75.51% to 79.11% in F1). If we further fine tune the BERT language model on an unsupervised training task with similar data distribution (BERT_F-text), the classification result further improves from 79.11% to 79.40% in F1. This is consistent with previous research on in-domain pre-training (Siddhant et al., 2019). However, the performance improvement is not statistically significant. One possible reason is that models pre-trained on a very large text dataset, such as Wikipedia, already encode sufficient semantics for dialog act prediction. Therefore, fine-tuning the model on a more domain-aligned data set does not significantly improve the performance.

We found that incorporating context improves the model performance. Adding text information as context improves the BERT model from 71.30% to 79.11% in F1. We also compare the impact of different context embedding methods on dialog act classification performance. The results show that replacing text with dialog act achieves a high precision, but suffers from a low recall. This is because an utterance can have multiple intents while dialog act itself does not provide enough context information to achieve accurate prediction. For example, when "i don't think so" is a response to a simple *yes/no question* such as "have you read the book", it is a *negative_answer*. But if it is a response to a more complex *yes/no question*, such as "do you want to talk about books", then it has two tags, *command* and *negative_answer*. The latter conveys user's implicit request on changing the topic. Therefore, only using dialog act as context could lead to high recall but low F1. We found combining both the previous segment's dialog act label and its surface text achieves the best performance in F1 (79.44%). However the performance improvement over including text only is not statistically significant. This suggests that dialog act and text may contain more overlapping information than complementary information.

We also found that fine-tuning the model using the supervised dialog act prediction task on the SwDA data did not improve performance in F1 but improved recall slightly. The reduced performance may be due to difference in the data. Even though both datasets are open domain conversational data, the SwDA task uses pre-processed Switchboard data that does not have ASR errors. Moreover, SwDA is human-human conversations, and they are more coherent and consistent compared to human-machine conversations. Another reason is that SwDA dataset has exactly one label for each utterance. When fine-tuning on our multi-label task, the pre-trained single-label model may tend to predict more labels to quickly reduce loss but fail to learn better representations.

We further looked into the errors made by our best model (*BERT_F-DA+text*) and found that the model confuses *statement non_opinion* and *general opinion*. This is most likely caused by only including one turn context. Sometimes, users have questions that break the conversation flow, such as “can you say it again clearly”. The model needs to consider not only this utterance but also the prior turns to perform dialog act prediction. We plan to incorporate longer context in future work. In addition, some of the *nonsense* sentences are misclassified as *statement non_opinion* such as “it doesn’t outside break a car”. It is also worth noting that some incorrectly segmented units resulted in inaccurate dialog act prediction. For instance, the utterance “we are they love each other” is incorrectly segmented into “we” and “are they love each other” given the context “you must be great friends with your dogs”. The second segment is incorrectly predicted as a *yes/no question*.

8 Conclusion

We propose MIDAS, a dialog act scheme designed for open-domain human-machine conversational systems. MIDAS is a hierarchical annotation scheme that supports multiple labels. We annotated 24K sentences from a human-machine social conversation dataset using MIDAS. We also trained dialog act classification models based on the annotated dataset. We tested different transfer learning techniques to improve model performance. We found that fine-tuning a pre-trained BERT model on unannotated target human-machine conversations improved model performance. However, fine-turning the model on a supervised dialog act task with human-human conversations did not improve model performance. MIDAS has been deployed in real world dialog systems, demonstrating its efficacy in the open-domain dialog setting.

Beyond prediction in open-domain dialogs for human request understanding, our proposed scheme can also be applied to task-oriented dialogs together with chit-chats. Furthermore, MIDAS can be used in end-to-end dialog systems for cases such as probing and model interpretation. In addition, our scheme and method can be extended to controlled text generation. We will explore broader applications in future work.

A Appendices

A.1 Implementation Details

The baseline dialog act prediction model uses a 2-layer Bi-LSTM with a hidden size of 500. The LSTM layers use a dropout rate of 0.3. We optimize the model with Adam optimizer (Kingma and Ba, 2014). For the Transformer models, we use 12 layers with 12 attention heads and a hidden size of 768. All the fully connected layers use a dropout rate of 0.1. Because one utterance may have multiple labels, following Katakis et al. (2008), we calculate precision, recall, and F1 for multilabel classification) on each sample and then average them across all samples (micro F1). We use the efficient Transformer implementation (Wolf et al., 2019) for our experiments.

For sentence breaker seq2seq model, both the encoder and the decoder are 2-layer 500-dimension bi-LSTMs. In addition, the decoder uses global attention and input feed (Luong et al., 2015) with beam search.

A.2 Dialog Act Scheme

Dialog Act - Semantic request		
Dialog Act Tag	**Description**	**Example**
factual question	factual questions	How old is Tom Cruise; How's the weather today
opinion question	opinionated questions	What's your favorite book; what do you think of disney movies
yes/no question	yes or no questions	Do you like pizza; did you watch the game last night
task command	commands/requests (can be in a question format) for some actions that may be different from the ongoing conversation	can i ask you a question; let's talk about the immigration policy; repeat
invalid command	general device/system commands that cannot be handled by the social bot	show me a picture; cook food for me
appreciation	appreciation towards the previous utterance	that's cool; that's really awesome
general opinion	personal view with polarized sentiment	dogs are adorable; (A: How do you like Tom) B: i think he is great
complaint	complaint about the response from another party	I can't hear you; what are you talking about; you didn't answer my question
comment	comments on the response from another conversation party	(A: my friend thinks we live in the matrix) B1: she is probably right; B2: you are joking, right; B3: i agree; (A: ... we can learn a lot from movies ...) B: there is a lot to learn; (A: He is the best dancer after michael jackson. What do you think) B: michael jackson
statement non_opinion	factual information	I have a dog named Max; I am 10 years old; (A: what movie have you seen recently) B: the avengers
other answer	answers that are neither positive or negative	I don't know; i don't have a favorite; (A: do you like listening to music) B: occasionally

Abstract

In this work, we study how the finetuning stage in the pretrain-finetune framework changes the behavior of a pretrained neural language generator. We focus on the transformer encoder-decoder model for the open-domain dialogue response generation task. Our major finding is that after standard finetuning, the model *forgets* some of the important language generation skills acquired during large-scale pretraining. We demonstrate the forgetting phenomenon through a set of detailed behavior analysis from the perspectives of knowledge transfer, context sensitivity, and function space projection. As a preliminary attempt to alleviate the forgetting problem, we propose an intuitive finetuning strategy named "mix-review". We find that mix-review effectively regularizes the finetuning process, and the forgetting problem is alleviated to some extent. Finally, we discuss interesting behavior of the resulting dialogue model and its implications.

1 Introduction

Large-scale unsupervised pretraining (Peters et al., 2018; Devlin et al., 2018; Song et al., 2019; Yang et al., 2019; Liu et al., 2019) has recently been shown to greatly boost the performance of natural language processing (NLP) models. On a high level, the pretrain-finetune framework can be viewed as a simple two-stage procedure: (1) Use large-scale unsupervised text data to pretrain the model; (2) Use target task data to finetune the model.

Recently, multiple works (Radford et al., 2019; Jiang et al., 2020; Roberts et al., 2020; Talmor et al., 2019) have reported that pretrained language models (LM) have implicitly stored large amounts of "world knowledge" in its parameters, and are able to answer common-sense questions. While these studies are encouraging, during the finetuning stage the model is usually trained on a dataset that is very different from the pretraining data, which leads to the potential danger that the model could **forget** precious skills gained during pretraining. This is an important question for open-domain dialogue response generation, which is the focus of our work, because the knowledge acquired during pretraining can greatly help make the dialogue interaction more engaging or informative.

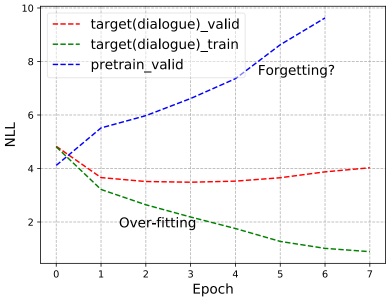

Figure 1: During finetuning, the model's performance on the pretraining data drastically degrades.

In Figure 1, we show that during finetuning, the model's performance on the pretraining data drastically degrades. While this drop is concerning, it does not necessarily mean that the skills from pretrained model are not well transferred to the end dialogue task, because the model should be evaluated in a dialogue setting.

To better answer the question about how finetuning changes the pretrained model's behavior, in this work we conduct a set of behavior analysis from the perspectives of knowledge transfer, context sensitivity, and function space projection. Our major finding is that in the finetuning stage, data separation causes the model to *forget* some of the important language generation skills acquired during pretraining. We also show that the forgetting problem can be alleviated by mixing pretraining and target-task data during finetuning.

2 Model Formulation

In this work we study the pretrain-finetune framework from the viewpoint of neural language generation (NLG). In particular, we focus on the open-domain dialogue response task, for the following reasons: (1) There is high similarity between the target dialogue response task (conditional NLG) and the pretraining language modeling (LM) objective, so we expect that language generation skills learnt during pretraining can be well transferred to the down-stream target task. (2) The sequence-to-sequence (seq2seq) nature of the model allows us to characterize the model's generation behavior in various ways (e.g., context sensitivity).

End-to-end dialogue response generation (Li et al., 2016) can be formulated as a sequence-to-sequence (seq2seq) task: Given a dialogue context (previous utterances), the model is asked to generate a high-quality response. In this work we adopt the encoder-decoder model architecture (Sutskever et al., 2014; Cho et al., 2014), which is widely used in NLG applications like dialogue response generation (Li et al., 2016), machine translation (Luong et al., 2015), etc. In particular, we use the transformer model (Vaswani et al., 2017), which has currently become the most popular encoder-decoder model architecture (Young et al., 2017). We use the same configuration as (Vaswani et al., 2017), which has 6 encoder/decoder layers, 16 attention heads, with an embedding dimension of 1024 and a feed-forward dimension of 4096.

During standard finetuning, the Adam optimizer (Kingma and Ba, 2014) is used to minimize the negative log-likelihood (NLL) of the reference target sentence $\boldsymbol{y}$ given the input context $\boldsymbol{x}$ in the data distribution (denoted as P_{data}):

$$\begin{aligned}\mathcal{L}_{\text{finetune}}(P_{data};\theta) &= E_{(\boldsymbol{x},\boldsymbol{y})\sim P_{data}}(-\log P_\theta(\boldsymbol{y}|\boldsymbol{x})) \\ &= E_{(\boldsymbol{x},\boldsymbol{y})\sim P_{data}}(-\sum_{t=1}^{m}\log P_\theta(y_t|\boldsymbol{y}_{<t},\boldsymbol{x})),\end{aligned} \tag{1}$$

where $\boldsymbol{y}_{<t}$ refers to $\{y_0, y_1, ..., y_{t-1}\}$, in which y_0 is set to a begin-of-sentence token `<BOS>`, and y_m is a end-of-sentence token `<EOS>`. In the dialogue response setting, the input $\boldsymbol{x}$ is a concatenation of previous utterances. We truncate the length of $\boldsymbol{x}$ to be at most 128 words, which typically includes around 6 previous utterances.

Given a trained seq2seq model, to generate a response for some contextual input, one needs to choose a decoding or sampling method. Recent research (Holtzman et al., 2019; Radford et al., 2019; Fan et al., 2018) has shown that a strategy called top-k sampling, in which the next word is sampled from the top k most probable choices, is a better choice than the traditional beam-search decoding, due to better diversity. Our preliminary experiments (Appendix A) have also verified this claim in the open-domain dialogue response setting. As a result, in this work, unless otherwise mentioned, we use top-k sampling as the default decoding method. In particular, we set k to 30 (we find it to work well in preliminary experiments).

Dialogue
Input: what did you do yesterday ? `<eou>` i watched the avengers movie .
Output: wow ! i am crazy about iron man !
Next-sentence Pretraining
Input: the avengers are super hot currently . `<eou>` the next movie will be on in April .
Output: fans are talking about iron man on the internet .
MASS Pretraining
Input: fans are talking about `<MASK>` `<MASK>` `<MASK>` will do on the internet .
Output: what iron man

Table 1: Illustrations of input-output pairs for typical dialogue response training, next-sentence pretraining, or MASS pretraining.

3 The Pretrain-Finetune Framework

In this section we first review the pretrain-finetune framework for encoder-decoder models. We discuss the language generation skills the model can acquire during pretraining, and more importantly, how we check whether the skills are "forgotten" during finetuning. Finally, as a preliminary attempt to alleviate the forgetting problem, we propose the mix-review finetuning strategy.

3.1 Pretraining

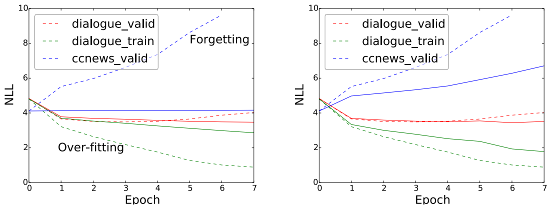
In this work, we consider pretraining the seq2seq model using large-scale unsupervised text data, and afterwards finetuning it using target dialogue data. We compare two representative strategies: next-sentence (NS) pretraining and masked sequence-to-sequence (MASS) pretraining (Song et al., 2019). Next-sentence pretraining is a natural extension of GPT-style LM training (Radford et al., 2019; Kiros et al., 2015) for encoder-decoder models. For every sentence in a given training document, we set the previous sentences as the contextual input, and ask the model to generate the next sentence. We omit the formulation of NS because it is very similar to Equation (1).

Masked sequence-to-sequence pretraining (MASS) can be regarded as an extension of the “BERT” (Devlin et al., 2018) pretraining for encoder-decoder models. For each sentence, a random segment of the sentence is masked, and the model is trained to generate the masked words on the decoder side. We refer readers to (Song et al., 2019) for more details.

In Table 1, we illustrate the similarity between NS pretraining and typical dialogue response training. Compared to NS pretraining, MASS has the disadvantage that it focuses on one single sentence at a time. However, the context of multiple previous sentences are very important for dialogue response generation.

3.2 Analyzing the Forgetting Problem

Although recently a number of pretraining strategies (Peters et al., 2018; Devlin et al., 2018; Song et al., 2019; Yang et al., 2019; Liu et al., 2019) have been proposed for various NLP tasks, the finetuning stage remains simple and straightforward: simply finetune all parameters with a relatively small learning rate.



(a) Mix-review (b) WD(θ_{pre})

Figure 2: Model’s performance on different evaluation sets during the finetuning stage, for the Dailydialog dataset (to be described in Section 4.1). The dotted lines represent the original finetuning process, while the solid lines represent when mix-review or WD(θ_{pre}) is applied.

In Figure 2a, we show (with the dotted lines) the model’s negative log-likelihood (NLL) on different evaluation sets during the finetuning stage. We identify two potential issues during finetuning: (1) **Over-fitting:** The gap between training-set NLL and validation-set NLL increases quickly. (2) **Forgetting:** The performance on the pretraining CCNEWS data (to be described in Section 4.1) drops drastically. Note that the forgetting phenomenon here is not necessarily “catastrophic” as in the sequential learning case (Atkinson et al., 2018; Robins, 1995), because the goal is to achieve the best performance on the target dialogue dataset, and the model does not need to maintain fidelity to the pretraining data. However, **it leads us to question whether the model has lost some important skills learned during pretraining**.

In this work we analyze two important generation capabilities that the model can acquire in the pretraining stage, and will be useful for the target dialogue setting. One is the *acquisition of knowledge*: the large-scale pretraining text data contains a large amount of knowledge, and can be used to make dialogue responses more informative and engaging (e.g., the model can learn about the “Avengers” movie, and use it as a topic). To quantify how knowledgeable the finetuned model is, we prepare a set of knowledge terms such as iphone, pokemon, etc., and the corresponding reference description. We then query the model about these knowledge terms, and compare its output against the reference. We also conduct multi-turn human evaluation in the setting of knowledgeable conversations. More details will be given in Section 5.1.

The other ability is the *utilization of contextual input*: as shown by (Sankar et al., 2019), the current open-domain dialogue models (without pretraining) are insensitive to contextual input, which gives rise to the generic response problem (Li et al., 2016). In our preliminary experiments with NS pretraining, we find that similarly to the GPT model (Radford et al., 2019) the pretrained model has the ability to generate closely related responses given the previous sentences as input. Ideally during finetuning, the model can transfer this skill to the target dialogue task. To quantify the model’s sensitivity to context, following (Sankar et al., 2019), we add noise to the input, and measure the relative drop in perplexity. More details will be given in Section 5.2.

3.3 The Mix-review Finetuning Strategy

As a preliminary attempt to alleviate the forgetting problem, we propose a finetuning strategy named “mix-review (MR)”: For each finetuning epoch, we mix the target dialogue data with a random subset of the pretraining data. This process introduces two hyper-parameters: *mix-ratio*, which controls how much pretraining data is mixed, and *mix-decay*, which decays mix-ratio by each epoch. For example, assume the target dialogue training set has

100k utterances, mix-ratio=4 and mix-decay=0.9, then in the first epoch of mix-review finetuning, 400k pretraining utterances will be mixed in, and for the second epoch the amount will be reduced to 360k utterances, etc.

We formulate the mix-review objective as below:

$$\mathcal{L}_{\text{mix-review}} = \mathcal{L}_{\text{finetune}}(P_{\text{target-data}};\theta) + \\ \text{mix-ratio} \cdot \mathcal{L}_{\text{pretrain}}(P_{\text{pretrain-data}};\theta). \quad (2)$$

Note that the augmented mixing term can be viewed as a regularization term.

We tune the hyper-parameters (mix-ratio and mix-decay) in the grid of $\{1,2,4,8,16\} \times \{1,0.9,0.8,0.7,0.6,0.5\}$ (using the same learning rate and other hyper-parameters with standard finetuning), and report with the best model based on the perplexity (PPL) performance on the validation set of the target task. We find that the performance gain of mix-review is not sensitive to hyper-parameter tuning: a small mix-ratio of 4 typically works well, which means the computational cost of mix-review is comparable to standard finetuning.

In Figure 2a, we show the loss curve for mix-review finetuning with a mix-ratio of 4 and a mix-decay of 0.7. We observe that the performance on the pretraining CCNEWS data is preserved, which strongly supports the motivation of mix-review. Furthermore, we observe a regularization effect from mix-review (narrowing the gap between training and testing performance).

We compare mix-review with the L_2 regularization (weight decay) toward the pretrained parameters θ_{pre} (Kirkpatrick et al., 2016). We denote it as WD(θ_{pre}) and formulate it as follows:

$$\mathcal{L}_{\text{finetune}}(P_{\text{target-data}};\theta) + \lambda \cdot \left\|\theta - \theta_{\text{pre}}\right\|_2^2 . \quad (3)$$

In our experiments, we tune λ in the set $\{10^{-1},10^{-2},10^{-3},10^{-4},10^{-5}\}$ and report with the best model based on PPL on the validation set.

In Figure 2b we show the loss curve for WD(θ_{pre}) with $\lambda = 0.1$. We observe that WD(θ_{pre}) also has a regularization effect, but it is not as strong as mix-review.

Additionally, we tried the following two basic regularization techniques: (1) Increase the rate of dropout; (2) Freeze the bottom layers of the model during finetuning. However, these two techniques show little or no improvement. The reason could be that the transformer is already a well-tuned model (e.g., it features dropout and layer normalization).

4 Datasets and Implementation Details

4.1 Datasets

For pretraining, we use the large-scale CCNEWS data (Bakhtin et al., 2019) which is a de-duplicated subset of the English portion of the CommonCrawl news dataset[1]. The dataset contains news articles published worldwide between September 2016 and February 2019. It has in total around 1 billion sentences or 27 billion words. To be able to complete experiments in a reasonable amount of time, we use the first 10 percent of the CCNEWS data for pretraining, which contains 100 million sentences and 2.7 billion words.

For finetuning, three open-domain conversational dialogue datasets are used: Dailydialog (1.3 million words) (Li et al., 2017), Switchboard (1.2 million words), and Cornell Movie (Danescu-Niculescu-Mizil and Lee, 2011) (4.5 million words). To save space, we defer the details of the data-sets to Appendix B.

To construct the vocabulary, we learn codes of Byte Pair Encoding (BPE) (Sennrich et al., 2016) from the CCNEWS-100m data with 50k merges. This results in a vocabulary of size 62k. We then apply the same BPE codes to all target dialogue datasets.

4.2 Implementation

Our code is based on the Fairseq toolkit (Ott et al., 2019). The Adam optimizer (Kingma and Ba, 2014) is used for all experiments. For pretraining of both MASS and NS, we use a mini-batch size of 2048, with the learning rate (LR) set to 0.0001. Following (Vaswani et al., 2017), the "inverse square root" LR scheduler with a warm-up stage is used. Pretraining is conducted on 32 GPUs and half-precision (float16) speed-up is used. For both MASS and NS, we stop the pretraining after the CCNEWS data is swept 20 times. For all our experiments, a dropout rate of 0.1 is applied to the transformer model. We follow Song et al. (2019) for the recommended hyper-parameter setting of MASS (e.g., how to select the mask span).

Finetuning is done on 2 GPUs without float16 speed-up. The learning rate is halved when the PPL on the validation set does not improve. In almost all finetuning experiments over-fitting is observed, and we do an early-stop when performance on the validation set starts to deteriorate. We tune the

learning rate from $\{10^{-3},10^{-4},10^{-5}\}$, and report the best model based on validation set perplexity.

5 Experiment Results

In this section, we conduct a set of detailed behavior analysis, characterising how different training strategies change the model's behavior. In particular, we aim to answer the crucial question about whether the model forgets precious language generation skills during standard finetuning, and whether mix-review helps the model remember the skills.

We first present perplexity results for different finetuning methods in Table 2. We observe the big improvement in perplexity (larger than 40%) for the pretrained models comparing to the baseline models trained from scratch. Comparing to MASS, the NS pretraining has more than 7% relative improvement. This confirms our earlier discussion that the model pretrained by NS better utilizes contextual input (which is further verified in Section 5.2). Based on this observation, we focus our analysis below on the NS pretraining.

Comparing to standard finetuning, mix-review further gives solid improvement. The gain is due to its strong regularization effect (which we study in the next three sections). However, the performance gap between mix-review and WD(θ_{pre}) is not significant. We believe the reason is that the benefit (e.g., knowledge transfer) from alleviate the forgetting problem is not be well demonstrated in single-turn response evaluation, because the context is limited to the narrow scope of the specific datasets. We address this concern with multi-turn human evaluation in the next section.

5.1 Behavior Analysis: Knowledge Transfer

As argued in Section 3.1, ideally the model can acquire common-sense (or world) knowledge from the large-scale pretraining data, which will be useful for the downstream open-domain dialogue task. In this section, we design a process to quantify how much knowledge the model has, and use it to monitor how the pretrain-finetune framework changes the model's behavior.

Since the pretraining CCNEWS data is in the public news domain, we expect the model to have knowledge about "big news". So, we utilize the Google trend data of the year 2016[2], which contains 365 trending terms (e.g., iPhone 7, Deadpool), and its corresponding description.

To query whether the model has knowledge of a certain term, we design three news-style and three dialogue-style "trigger templates" to trigger the model to generate responses related to the knowledge term. We collect 10 samples for each trigger, then we compute BLEU score of generated samples against the reference descriptions. We show some examples of trigger inputs in Table 3.

The BLEU scores are shown in Table 4. Note that for the pretrained model we feed news triggers, while for the other dialogue models dialogue triggers are used. We observe that although the finetuned model is more knowledgeable than the baseline model, its score is much lower than the pretrained model. This demonstrates the forgetting problem for the standard finetuning.

On the other hand, we find that mix-review and WD(θ_{pre}) can effectively retain the knowledge acquired during pretraining, giving a much higher BLEU score than the standard finetuned model. Mix-review shows higher BLEU scores than WD(θ_{pre}), demonstrating its superiority in facilitating knowledge retention. We showcase samples from different models in Table 3. To save space, we manually select and show the most related sample out of the 30 samples for each knowledge term. The observations agree with the quantitative results: The standard finetuning loses the detailed information about the knowledge term, and mix-review helps the model retain it. More importantly, the model is able to express the knowledge in a dialogue context.

To further investigate our model's ability to conduct knowledgeable dialogues with users, we use the ParlAI[3] platform to conduct multi-turn dialogue evaluation. For each session, the user will be assigned a random knowledge term from Google Trend, and have a 8-turn dialogue with the model under that topic. Ratings from around 600 dia-

NS+WD(θ_{pre})	+26%/+46%	+19%/+25%
NS+MR	**+60%/+108%**	**+19%/+30%**

Table 6: The model's relative PPL drop when word-shuffle/drop is applied to input. "FT" refers to "finetune". To save space, the results on the Cornell Movie dataset is deferred to Appendix D, Table 11.

logues are collected for each model, and are reported in Table 5. In this evaluation we use the models finetuned on the Dailydialog data, because the nature of that dataset is closet to online chit-chat. It is observed that the model trained by mix-review significantly outperforms WD(θ_{pre}) on knowledge, consistency and engagingness, which agrees well with the results in Table 4. Some dialogue examples are included in Table 7.

5.2 Behavior Analysis: Context Sensitivity

The sensitivity to context is an important property for NLG models. However, as shown by (Sankar et al., 2019), dialogue models trained from scratch typically are not sensitive to artificial distortion in the context input, showing the models have poor utilization of dialogue context. In this section, we repeat their experiments with pretrained or finetuned models.

Following (Sankar et al., 2019), we use two methods to distort the context input:

- **word-drop:** We randomly drop 30% of the words in the context input.
- **word-shuffle:** We randomly shuffle the words in the context input.

We use the relative drop in test-set perplexity to quantify the sensitivity. The results are presented in Table 6, where the result of the pretrained model is also included. First, we observe the baseline model trained from scratch is relatively insensitive to context, which agrees well with Sankar et al. (2019). The model with the standard pretrain-finetune process is much more sensitive, showing that pretraining effectively changes the model's behavior. Comparing to MASS, the NS pretrained model has better utilization of context, which explains its superior performance in PPL.

Somewhat surprisingly, the finetuned dialogue models are much less sensitive to context input than the pretrained model without finetuning. This again

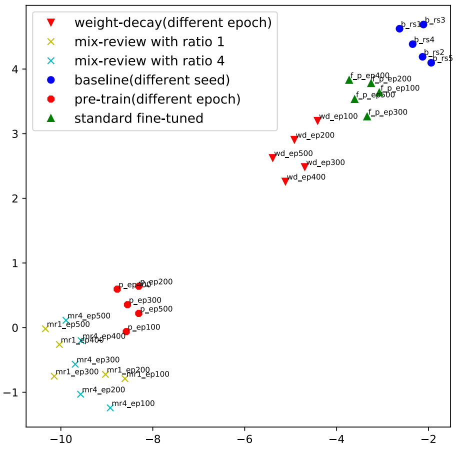

Figure 3: UMAP projection of checkpoints from different training processes.

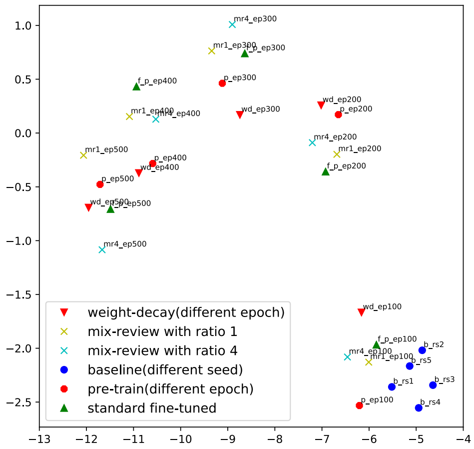

Figure 4: Parameter-space UMAP projection of checkpoints from different training processes.

verifies our worry in Section 3.3 that the model is forgetting some important generation skill during standard finetuning. Further, we find that the mix-review finetuning strategy can effectively alleviate this problem: Its sensitivity is much greater than that of standard finetuning, and is close to the pre-trained model.

5.3 Behavior Analysis: Function Space Projection

It is interesting to study models' behavior via function-space 2D projection (Erhan et al., 2010). We collect the model's output distribution on 10k words for the CCNEWS validation set and the Dailydialog validation set[4]. And feed them as input to UMAP (McInnes et al., 2018). We use the default hyper-parameter setting of the python implementation of UMAP. The result is shown in Figure 3. Note that during pretraining of the CCNEWS data, 20 epochs are one entire data pass. We finetune from epoch 100, 200, 300, 400, 500 of the pretraining checkpoints.

We observe that the standard finetuned models are not close to the cluster of the pretrained models, which suggests the models' generative behavior is substantially different from the pretrained ones. Mix-review regularizes the finetuning process by keeping the model's generation behavior close to the pretrained model. These observations agree with our results in Section 5.1 and 5.2. Figure 3 also suggests potential limitations of mix-review and WD(θ_{pre}): mix-review could be too "aggressive" and does not put enough attention on the target task. On the other hand, WD(θ_{pre}) is not strong enough in regularizing the model's generative behavior.

In Figure 4 we show the parameter-space UMAP projection for the same set of models. In this case, the input to UMAP is the concatenation of flattened weight matrices of the transformer model. A key observation is that the finetuned models are typically very close to the starting point (pretrained models). However, as shown in Figure 3, their behavior is very different. This suggests that a parameter-space regularization such as WD(θ_{pre}) could be not very effective for regularizing the model's behavior.

6 Implications and Discussion

The sensitivity to dialogue context and the ability to transfer knowledge from pretraining opens the possibility of a **data-driven** knowledgable chatbot. In Table 7, we show multi-turn and single-turn interaction examples with the model trained by mix-review. For demonstration purpose, we manually select the most interesting response out of 10 samples from the model for the single-turn examples. We observe that the model is able to return interesting responses with the knowledge it acquired from pretraining. Interestingly, it has developed its own "opinions" and can give advice

---

[4] It's a concatenation of two long vectors.

User: have you been to china ?	**U:** who is mark zukerberg ?	**U:** tell me about tv show Robot Wars .
Model: yes , i have .	**M:** he is the ceo of facebook .	**M:** it 's about robots fighting in a war .
User: which city did you go ?	**U:** what is that company about ?	**U:** cool ! What season is it on ?
Model: shanghai	**M:** it is a social media company .	**M:** it 's on next month .
User: how do you like it there ?	**U:** do you like him ?	**U:** how many years has it been on for ?
Model: i like it very much	**M:** i think he is a good leader .	**M:** it started in 2003 .
User: i think the weather is not so good .	**U:** my friend works at facebook .	**U:** what channel does it come on ?
Model: but it is nice in spring and fall .	**M:** what does your friend do there ?	**M:** the science channel.
User: when is the independence day ? **Best-of-10:** it 's july fourth.		
User: is coffee good for health ? **Best-of-10:** it may help reduce your risk of certain diseases.		
User: should i do a phd or go to work ? **Best-of-10:** a phd is not enough if you want to learn something new .		
User: oh shut up you . **Worst-of-10:** shut up !		
User: you 're the problem . **Worst-of-10:** i hate you .		
User: i will kill . **Worst-of-10:** i will kill you .		

Table 7: Multi-turn and single-turn examples of the model trained by mix-review on the Dailydialogue dataset. The single-turn examples involve light cherry-picking.

to the user.

Next, we discuss the malicious response problem for open-domain dialogue models. As shown by (He and Glass, 2019a), it is relatively difficult to trigger the dialogue models trained from scratch to output malicious responses. However, as shown in Table 7, the pretrained models are easily triggered to respond in a malicious way when "provoked". This is because compared to the baseline models, the pretrained models are more sensitive to the contextual input, making them easier to manipulate. This makes the malicious response problem a more relevant issue to solve (He and Glass, 2019b).

Finally, we discuss some limitations of our work. First, the mix-review strategy we proposed is a simple and preliminary attempt to alleviate the forgetting, and its performance is far from perfect. As shown in Appendix C, in a lot of cases, the generation from mix-review is still boring or non-informative. Next, the three datasets considered in this work are open-domain dialogue datasets, and they are not knowledge-intensive. It would be interesting, as future work, to check the forgetting problem for knowledge-grounded datasets such as Topical-chat (Gopalakrishnan et al., 2019).

7 Related Works

Behavior of pretrained NLG Models Recently, multiple works (Radford et al., 2019; Jiang et al., 2020; Roberts et al., 2020; Talmor et al., 2019; Trinh and Le, 2019) have reported that pre-trained language models (LM) have implicitly stored large amounts of "world knowledge" in its parameters, and are able to answer common-sense questions. However, whether the world knowledge is well preserved after finetuning on target task dataset is not discussed.

On the other hand, knowledge-grounded NLG model (Liu et al., 2018; Guu et al., 2020; Zhou et al., 2018) has been an important and exciting research topic. These studies usually involve additional retrieval modules or external knowledge bases to provide the model with relevant information. In contrast to these works, we study whether the model can conduct knowledgeable dialogues by itself.

Forgetting As discussed in Section 3.2, in contrast to the "catastrophic forgetting" problem in sequential learning (Atkinson et al., 2018; Robins, 1995), the performance drop on pretraining data is not necessarily bad for the NLP pretrain-finetune framework, and its implications have not been properly studied. In our analysis, we confirm the "forgetting" of important language generation skills during standard finetuning. The proposed mix-review strategy is similar to the *pseudo-rehearsal* algorithm in sequential learning (Robins, 1995), with the difference being that we assume we still have access to the pretraining data.

8 Conclusion

In this work, we attempt to answer to question of whether during finetuning, the model has forgotten some of the useful NLG skills acquired during large-scale pretraining. Through a set of detailed behavior analysis, we find the answer is, to some extent, yes. For example, the finetuned model fails to give detailed information about some knowledge terms, while the pretrained model can. As a preliminary attempt to alleviate the forgetting problem, we propose the mix-review finetuning method, and find it to be effective.

Our analysis shows that under the surface of the performance boost for standard metrics, large-scale pretraining changes the model's generative behavior in various profound ways. More importantly, the behavior change is influenced by the nature of data itself. For example, we demonstrate that we can discuss news with the dialogue model finetuned by mix-review, even when the target dataset is not about news (Dailydialog). We believe that this opens the possibility of a completely data-driven way to customize a language generator.

A Beam-search vs. Top-k Sampling

To compare beam-search with top-k sampling (we set k to 30), we compute diversity metrics for samples from models trained by different procedures (from scratch or pretrained). In particular, we compute bi-gram and tri-gram entropy, and the ratio of the most frequent response and second most frequent response (denoted as max-ratio) (He and Glass, 2019b). The results are shown in Table 8.

We observe that the responses given by top-k sampling are much more diverse than beam-search. Beam-search suffers much from the "generic response" problem (Li et al., 2016), for example, 34% of the responses are "`um - hum`" for Switchboard. Further, in our multi-turn dialogue experiments, beam-search is likely to give repetitive responses. Finally, by manual inspection, we find the sample quality of top-k sampling is not compromised. Due to these observations, we adopt top-k sampling for our models.

B Details on Datasets

Dailydialogue (Li et al., 2017) is a high-quality multi-turn dialog dataset. The language is human-written and less noisy. The dialogues in the dataset reflect our everyday communication and cover various topics about our daily life. The training split has around 11k dialogues (1.3 million words), and both the validation and test splits have 1k dialogues (0.1 million words).

The Switchboard Dialogue Act Corpus[5] is a version of the Switchboard Telephone Speech Corpus, which is a collection of two-sided telephone conversations, annotated with utterance-level dialogue acts. In this work we only use the conversation text part of the data, and select 1.1k dialogues for training (181k sentences / 1.2 million words), 50 dialogues for validation and 50 dialogues for testing.

The Cornell Movie Dialogue Corpus[6] (Danescu-Niculescu-Mizil and Lee, 2011) is a collection of movie scripts. In the processing of the data, we simply regard the whole scripts from a movie as a long dialogue. The training split contains 9k dialogues (4.5 million words), and both the validation and test splits have 180 dialogues (85k words).

C Model Samples

In Table 9, we show more samples from different training procedure, for the three dialogue datasets.

D Supplementary Experiment Results

	Cornell

Dailydialogue

Input: why do you think you are qualified for this position ?
Baseline: i can tell you more about your company because your company has a working experience with a company and company company .
NS: i have been working with microsoft for four years . i can make good use of microsoft ' s word pad and excel excel spreadsheet .
MASS: i think i have a strong sense of responsibility and i have had a high iq score in college . i am applying for some courses of study for some courses if i have a preference .
Mix-review: my background is in computer engineering and i have a strong commercial acumen in business - related application . i am in charge of all the things i like to do here .
WD(θ_{pre}): my background , education , experience as an english professor , and the work ethic are strong .
Input: according to your advertisement , you want an experienced software engineer . i think my background meets the requirement of this position .
Baseline: yes . and you also need to know how to enjoy the work . and , here is a position to develop the company position under the company .
NS: do you know your qualifications ?
MASS: that ' s a good answer . i can tell you if we have made a decision this afternoon .
Mix-review: i see . do you have some experience as an executive engineer ?
WD(θ_{pre}): in your first year of operating your company , you had an impressive track record of product design , and achieved a high level of technical proficiency .

Switchboard

Input: that 's going to be a really viable program if it continues to be funded at current levels
Baseline: oh really
NS: um it 's going to be a lot of fun it certainly is
MASS: sure sure sure
Mix-review: well that that 's what i 'm saying too that 's that 's not gonna be an issue
WD(θ_{pre}): yeah oh sure sure
Input: uh - huh
Baseline: oh okay
NS: and uh i- i think there are some areas that if the government decides to close down that could be a real problem
MASS: and i really feel strongly that we don 't need the space station because we think there 's really no space
Mix-review: but uh that
WD(θ_{pre}): i mean it 's pretty i think it 's it 's pretty interesting to me that it 's uh

Cornell Movie

Input: i expect you shortly .
Baseline: how so ?
NS: i 'll make a reservation .
MASS: i 'll come with you , doctor .
Mix-review: no , i 'm fine
WD(θ_{pre}): okay .
Input: what shall we do ?
Baseline: we all don 't know where the hell he is now , but if he talks to me first , i 'll be back .
NS: nothing .
MASS: we send a cab ! i said i expect you to be fast .
Mix-review: david 's not very lucid , but he 's always lucid .
WD(θ_{pre}): stop him .
Input: tea would be nice .
Baseline: i have no desire to go to bed .
NS: but you can 't come here and have tea too ?
MASS: i 've been expecting you , doctor .
Mix-review: do you want me to drink some ?
WD(θ_{pre}): what is it ?

Table 9: Samples of different models on the Dailydialog/Switchboard/Cornell-Movie test-set. The samples are consecutive (input of the next sample is the reference response for the previous one).

Model(Dataset)	PPL(**normal**)	PPL(**word-shuffle**)	PPL(**word-drop**)
NS pretrained(CCNEWS)	17.33	36.56(**+110.96%**)	35.56(**+105.19%**)
Baseline(Cornell)	49.48	50.22(+1.4%)	50.85(+2.7%)

Abstract

"Transcription bottlenecks", created by a shortage of effective human transcribers are one of the main challenges to endangered language (EL) documentation. Automatic speech recognition (ASR) has been suggested as a tool to overcome such bottlenecks. Following this suggestion, we investigated the effectiveness for EL documentation of end-to-end ASR, which unlike Hidden Markov Model ASR systems, eschews linguistic resources but is instead more dependent on large-data settings. We open source a Yoloxóchitl Mixtec EL corpus. First, we review our method in building an end-to-end ASR system in a way that would be reproducible by the ASR community. We then propose a novice transcription correction task and demonstrate how ASR systems and novice transcribers can work together to improve EL documentation. We believe this combinatory methodology would mitigate the transcription bottleneck and transcriber shortage that hinders EL documentation.

1 Introduction

Grenoble et al. (2011) warned that half of the world's 7,000 languages would disappear by the end of the 21st century. Consequently, a concern with endangered language documentation has emerged from the convergence of interests of two major groups: (1) native speakers who wish to document their language and cultural knowledge for future generations; (2) linguists who wish to document endangered languages to explore linguistic structures that may soon disappear. Endangered language (EL) documentation aims to mitigate these concerns by developing and archiving corpora, lexicons, and grammars (Lehmann, 1999). There are two major challenges:

(a) Transcription Bottleneck: The creation of EL resources through documentation is extremely challenging, primarily because the traditional method to preserve primary data is not simply with audio recordings but also through time-coded transcriptions. In a best-case scenario, texts are presented in interlinear format with aligned parses and glosses along with a free translation (Anastasopoulos and Chiang, 2017). But interlinear transcriptions are difficult to produce in meaningful quantities: (1) ELs often lack a standardized orthography (if written at all); (2) invariably, few speakers can accurately transcribe recordings. Even a highly skilled native speaker or linguist will require a minimum of 30 to 50 hours to simply transcribe one hour of recording (Michaud et al., 2014; Zahrer et al., 2020). Additional time is needed for parse, gloss, and translation. This creates what has been called a "transcription bottleneck", a situation in which the expert transcribers cannot keep up with the amount of recorded material for documentation.

(b) Transcriber Shortage: It is generally understood that any viable solution to the transcription bottleneck must involve native speaker transcribers. Yet usually few, if any, native speakers have the skills (or time) to transcribe their language. Training new transcribers is one solution, but it is time-consuming, especially with languages that present complicated phonology and morphology. The situation is distinct for major languages, for which transcription can be crowd-sourced to speakers with little need for specialized training (Das and Hasegawa-Johnson, 2016). In Yoloxóchitl Mixtec (YM; Glottocode=yolo1241, ISO 639-3=xty), the focus of this study, training is time-consuming: after one-year part-time transcription training, a proficient native speaker, Esteban Guadalupe Sierra, still has problems with certain phones, particularly tones and glottal stops. Documentation requires accurate transcriptions, a goal yet beyond even the capability of an enthusiastic speaker with many

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1134–1145
April 19 - 23, 2021.

months of training.

As noted, ASR has been proposed to mitigate the Transcription Bottleneck and create increasingly extensive EL corpora. Previous studies first investigated HMM-based ASR for EL documentation (Ćavar et al., 2016; Mitra et al., 2016; Adams et al., 2018; Jimerson et al., 2018; Jimerson and Prud'hommeaux, 2018; Michaud et al., 2018; Cruz and Waring, 2019; Thai et al., 2020; Zahrer et al., 2020; Gupta and Boulianne, 2020a). Along with HMM-based ASR, natural language processing and semi-supervised learning have been suggested as a way to produce morphological and syntactic analyses. As HMM-based systems have become more precise, they have been increasingly promoted as a mechanism to bypass the transcription bottleneck. However, ASR's context for ELs is quite distinct from that of major languages. Endangered languages seldom have sufficient extant language lexicons to train an HMM system and invariably suffer from a dearth of skilled transcribers to create these necessary resources (Gupta and Boulianne, 2020b).

As we have confirmed with this present study, end-to-end ASR systems have shown comparable or better results over conventional HMM-based methods (Graves and Jaitly, 2014; Chiu et al., 2018; Pham et al., 2019; Karita et al., 2019a). As end-to-end systems directly predict textual units from acoustic information, they save much effort on lexicon construction. Nevertheless, end-to-end ASR systems still suffer from the limitation of training data. Attempts with resource-scarce languages have relatively high character (CER) or word (WER) error rates (Thai et al., 2020; Matsuura et al., 2020; Hjortnaes et al., 2020). It has nevertheless become possible to utilize ASR with ELs to reduce significantly, but not eliminate, the need for human input and annotation to create acceptable ("archival quality") transcriptions.

This Work: This work represents end-to-end ASR efforts on Yoloxóchitl Mixtec (YM), an endangered language from western Mexico. The YMC[1] corpus comprises two sub-corpora. The first ("YMC-EXP", expert transcribed, corpus) includes 100 hours of transcribed speech that have been carefully checked for accuracy. We built a recipe of the ESPNet (Watanabe et al., 2018) that shows the whole process of constructing an end-to-end ASR system using the YMC-EXP corpus.[2] The second corpus, ("YMC-NT", native trainee, corpus) includes 8+ hours of additional recordings not included in the YMC-EXP corpus. This second corpus contains novice transcriptions with subsequent expert corrections that has allowed us to evaluate the skill level of the novice. Both the YMC-EXP and YMC-NT corpora are publicly available at OpenSLR under a CC BY-SA-NC 3.0 License.[3]

The contributions of our research are:

- A new Yoloxóchitl Mixtec corpus to support ASR efforts in EL documentation.
- A reproducible workflow to build an end-to-end ASR system for EL documentation.
- A comparative study between HMM-based ASR and end-to-end ASR, demonstrating the feasibility of the latter. To test the framework's generalizability, we also experiment with another EL: Highland Puebla Nahuat (Glottocode=high1278; ISO 639-3=azz).
- An in-depth analysis of errors in novice transcription and ASR. Considering the discrepancies in error types, we propose Novice Transcription Correction (NTC) as a task for the EL documentation community. A rule-based method and a voting-based method are proposed.[4] In clean speech, the best system reduces relative word error rate in the novice transcription by 38.9% .

2 Corpus Description

In this section, we first introduce the linguistic specifics for YM and YMC. Then we discuss the recording settings. Since YM is a spoken language without a standardized textual format, we next explain the transcription style designed for this language. Finally, we offer the corpus partition and some statistics regarding corpora size.

2.1 Linguistic Specifics for Yoloxóchitl Mixtec

Yoloxóchitl Mixtec is an endangered, relatively low-resource Mixtecan language. It is mainly spoken in the municipality of San Luis Acatlán, state

---

[1] Specifically, we used material from the community of Yoloxóchitl (YMC), one of four in which YM is spoken.

[2] `https://github.com/espnet/espnet/tree/master/egs/yoloxochitl_mixtec/asr1`

[3] `http://www.openslr.org/89/`

[4] A system combination method, Recognizer Output Voting Error Reduction (Fiscus, 1997))

of Guerrero, Mexico. It is one of some 50 languages in the Mixtec language family, which is part of a larger unit, Otomanguean, that Suárez (1983) considers “a ‘hyper-family’ or ‘stock’.” Mixtec languages (spoken in Oaxaca, Guerrero, and Puebla) are highly varied, resulting from approximately 2,000 years of diversification.

YM is spoken in four communities: Yoloxóchitl, Cuanacaxtitlan, Arroyo Cumiapa, and Buena Vista. Mutual intelligibility among the four YM communities is high despite significant differences in phonology, morphology, and syntax. All villages have a simple segmental inventory but significant though still undocumented variation in tonal phonology. YMC (refering only to the Mixtec of the community of Yoloxóchitl [16.81602, -98.68597]) manifests 28 distinct tonal patterns on 1,451 identified bimoraic lexical stems. The tonal patterns carry a significant functional load in regards to the lexicon and inflection. For example, 24 distinct tonal patterns on the bimoraic segmental sequence [nama] yield 30 words (including six homophones). This ample tonal inventory presents challenges to both a native speaker learning to write and an ASR system learning to recognize. Notably, it also introduces difficulties in constructing a language lexicon for training HMM-based systems.

2.2 Recording Settings

There are two corpora used in this study. The first (YMC-EXP) was used for ASR training. The second (YMC-NT) was used to train the novice speaker (e.g., set up a curriculum for him to learn how to transcribe) and for Novice Transcription Correction. The YMC-EXP corpus comprises expert transcriptions used as the gold-standard reference for ASR development. The YMC-NT corpus has paired novice-expert transcription as it was used to train and evaluate the novice writer.

The corpus used for ASR development comprises mostly conversational speech in two-channel recordings (split for training). Each conversation is with two speakers and each of the two speakers was fitted with a separate head-worn mic (usually a Shure SM10a). Over two dozen speakers (mostly male) contributed to the corpus. The topics and their distribution were varied (plants, animals, hunting/fishing, food preparation, ritual speech). The YMC-NT corpus comprises single-channel field recordings made with a Zoom H4n at the moment plants were collected during ethnobotanical research. Speakers were interviewed one after another; there is no overlap. However, the recordings often registered background sounds (crickets, birds) that we expected would negatively impact ASR accuracy more than seems to have occurred. The topic was always a discussion of plant knowledge (a theme of only 9% of the YMC-EXP corpus). Expectedly, there were many out-of-vocabulary (OOV) words (e.g., plant names not elsewhere recorded) in this YMC-NT corpus.[5]

2.3 Corpus Transcription

(a) Transcription Level: The YMC-EXP corpus presently has two levels of transcription: (1) a practical orthography that represents underlying forms; (2) surface forms. The underlying form marks prefixes (separated from the stem by a hyphen), enclitics (separated by an = sign), and tone elision (with the elided tones in parentheses). All these “breaks” and phonological processes disappear in the surface form. For example, the underlying $\mathrm{be}'^{3}e^{3}{=}an^{4}$ (house=3sgFem; 'her house') surfaces as $\mathrm{be}'^{3}\tilde{a}^{4}$. And $\mathrm{be}'^{3}e^{(3)}{=}^{2}$ ('my house') surfaces as $\mathrm{be}'^{3}e^{2}$. Another example is the completive prefix ni^{1}-, which is separated from the stem as in ni^{1}-$xi^{3}xi^{(3)}{=}^{2}$ (completive-eat-1sgS; 'I ate'). The surface form would be written $\widetilde{ni}^{1}xi^{3}xi^{2}$. Again, processes such as nasalization, vowel harmony, palatalization, and labialization are not represented in the practical (underlying) orthography but are generated in the surface forms. The only phonological process encoded in the underlying orthography is tone elision, for which parentheses are used.

The practical, underlying orthography mentioned above was chosen as the default system for ASR training for three reasons: (1) it is easier than a surface representation for native speakers to write; (2) it represents morphological boundaries and thus serves to teach native speakers the morphology of their language; and (3) for a researcher interested in generating concordances for a corpus-based lexicographic project it is much easier to discover the root for 'house' in $\mathrm{be}'^{3}e^{3}{=}an^{4}$ and $\mathrm{be}'^{3}e^{(3)}{=}^{2}$ than in the surface forms $\mathrm{be}'^{3}\tilde{a}^{4}$ and $\mathrm{be}'^{3}e^{2}$.

(b) “Code-Switching” in YMC: Endangered, colonialized Indigenous languages often manifest extensive lexical input from a dominant Western language, and speakers often talk with “code-switching” (for lack of a better term). Yoloxóchitl

---

[5] After separating enclitics and prefixes as separate tokens, the OOV rate in YMC-NT is 4.84%.

Corpus	Subset	UttNum	Dur (h)
EXP	Train	52763	92.46
	Validation	2470	4.01
	Test	1577	2.52
EXP(-CS)	Train	35144	58.60
	Validation	1301	2.16
	Test	2603	4.35
NT	Clean-Dev	2523	3.45
	Clean-Test	2346	3.31
	Noise-Test	1335	1.60

Table 1: YMC Corpus Partition for EXP (corpus with expert transcription), EXP(-CS) (subset of EXP without "code-switching"), NT (corpus with paired novice and expert transcription)

Mixtec is no exception. Amith considered how to write such forms best and decided that Spanish-origin words would be written in Spanish and without tone when their phonology and meaning are close to that of Spanish. So Spanish *docena* appears over a dozen times in the corpus and is written *tucena*; it always has the meaning of 'dozen'. All month and day names are also written without tones. Note, however, that Spanish *camposanto* ('cemetery') is also found in the corpus and pronounced as $pa^3san^4tu^2$. The decision was made to write this with tone markings as it is significantly different in pronunciation from the Spanish origin word. In effect, words like $pa^3san^4tu^2$ are considered loans into YM and are treated orthographically as Mixtec. Words such as *tucena* are considered "code-switching" and written without tones.

(c) Transcription Process: The initial time-aligned transcriptions were made in Transcriber (Barras et al., 1998). However, given that Transcriber cannot handle multiple tiers (e.g., transcription and translation, or underlying and surface orthographies), the Transcriber transcriptions were then imported into ELAN (Wittenburg et al., 2006) for further processing (e.g., correction, surface-form generation, translation).

2.4 Corpus Size and Partition

Though endangered, YMC does not suffer from the same level of resource limitations that affect most ASR work with ELs (Ćavar et al., 2016; Jimerson et al., 2018; Thai et al., 2020). The YMC-EXP corpus, developed for over ten years, provided 100 hours for the ASR training, validation, and test corpora. There are 505 recordings from 34 speakers in the YMC-EXP corpus, and the transcription for the YMC-EXP were all carefully proofed by an expert native-speaker linguist. As shown in Table 1, we offer a train-valid-test split where there is no overlap in content between the sets. The partition considers the balance between speakers and relative size for each part.

As introduced in Section 2.2, the YMC-NT corpus has *both* expert and novice transcription. It includes only three speakers for a total of 8.36 hours. In the recordings of two consultants, the environment is relatively clean and free of background noise. The speech of the other individual, however, is frequently affected by background noise. This seems coincidental as all three were recorded together, one after the other in random order. But given this situation, we split the corpus into three sets: clean-dev (speaker EGS), clean-test (speaker CTB), and noise-test (speaker FEF; see Table 1).

The "code-switching" discussed in 2.3 (b) introduces different phonological representations and makes it difficult to train an HMM-based model using language lexicons. Therefore, previous work (Mitra et al., 2016) using the HMM-based system for YMC did not consider phrases with "code-switching". To compare our model with their results, we have used the same experimental corpus in our evaluation. Their corpus (YMC-EXP(-CS)), shown in Table 1, is a subset of the YMC-EXP; the YMC-EXP(-CS) corpus does not contain "code-switching" phrases, i.e., phrases with words that were tagged as Spanish origin and transcribed without tone.

3 ASR Experiments

3.1 End-to-End ASR

As ESPNet (Watanabe et al., 2018) is widely used in open-source end-to-end ASR research, our end-to-end ASR systems are all constructed using ESPNet. For the encoder, we employed the conformer structure (Gulati et al., 2020), while for the decoder we used the transformer structure to condition the full context, following the work of Karita et al. (2019b). The conformer architecture is a state-of-the-art innovation developed from the previous transformer-based encoding methods (Karita et al., 2019a; Guo et al., 2020). A comparison between the conformer and transformer encoders shows the value of applying state-of-the-art end-to-end ASR to ELs.

3.2 Experiments and Results

As discussed above, our end-to-end model applied an encoder-decoder architecture with a conformer encoder and a transformer decoder. The architecture of the model follows Gulati et al. (2020) while its configuration follows the aishell conformer recipe from ESPNet.[6] The experiment is reproducible using ESPNet.

As the end-to-end system models are based on word pieces, we adopted CER and WER as evaluation metrics. They help demonstrate the system performances at different levels of graininess. But because the HMM-based systems were decoding with a word-based lexicon, for comparison to HMM we only use the WER metric. To thoroughly examine the model, we conducted several comparative experiments, as discussed in continuation.

(a) Comparison with HMM-based Methods: We first compared our end-to-end method with the Deep Neural Network-Hidden Markov Model (DNN-HMM) methods proposed in Mitra el al. (2016). In this work, Gammatone Filterbanks (GFB), articulation, and pitch are configured for the DNN-HMM model. This baseline is a DNN-HMM model using Mel Filterbanks (MFB). In recent unpublished work, Kwon and Kathol develop a latest state-of-the-art CNN-HMM-based ASR model[7] for YMC based on the lattice-free Maximum Mutual Information (LF-MMI) approach, also known as “chain model” (Povey et al., 2016). The experimental data of the above HMM-based models is YMC-EXP(-CS) discussed in Section 2.4. For the comparison, our end-to-end model adopted the same partition to ensure fair comparability with their results.

Table 2 shows the comparison between DNN-HMM systems and our end-to-end system on YMC-EXP(-CS). It indicates that even without an external language lexicon the end-to-end system significantly outperforms both the DNN-HMM baseline models and the CNN-HMM-based state-of-the-art model.

In Section 2.3 (b), we note that “code-switching” is invariably present in EL speech (e.g., YMC). Thus, ASR models built on ”code-switching-free corpora (like YMC-EXP[-CS]) are not practical for real-world usage. However, a language lexicon is available only for the YMC-EXP(-CS) corpus so we cannot conduct HMM-based experiments with either YMC-EXP or YMC-NT corpora.

Model	**Feature**	**WER**
DNN-HMM	MFB	36.9
DNN-HMM	GFB + Articu. +Pitch	31.1
CNN-HMM (Chain)	MFCC	19.1
E2E-Conformer	MFB + Pitch	**15.4**

Table 2: Comparison between HMM-based Models and the End-to-End Conformer (E2E-Conformer) Model on YMC-EXP(-CS) that is a subset of the YMC-EXP **without** “code-switching”.

Model	**CER** dev/test	**WER** dev/test
E2E-RNN	9.2/9.3	19.1/19.2
E2E-Transformer	7.8/7.9	16.3/16.7
E2E-Conformer	**7.7/7.7**	**16.0/16.1**

Table 3: End-to-End ASR Results on YMC-EXP (corpus **with** “code-switching”)

(b) Comparison with Different End-to-End ASR Architectures: We also conducted experiments comparing models with different encoders and decoders on the YMC-EXP corpus. For a Recurrent Neural Network-based (E2E-RNN) model, we followed the best hyper-parameter configuration, as discussed in Zeyer et al. (2018). For a Transformer-based (E2E-Transformer) model, the same configuration from Karita et al. (2019b) was adopted. Both models shared the same data preparation process as the E2E-Conformer model.

Table 3 compares different end-to-end ASR architectures on the YMC-EXP corpus.[8] The E2E-Conformer obtained the best results, obtaining significant WER improvement as compared to the E2E-RNN and the E2E-Transformer models. The E2E-Conformer’s WER on YMC-EXP(-CS) is slightly lower than that obtained for the whole YMC-EXP corpus, despite a significantly smaller training set in the YMC-EXP(-CS) corpus. Since the subset excludes Spanish words, “code-switching” may well be a problem to consider in ASR for endangered languages such as YM.

---

[6] See Appendix for details about the model configuration.

[7] See Appendix for details about the model configuration.

[8] The train set in YMC-EXP is significantly larger than that in YMC-EXP(-CS), the YMC-EXP corpus from which all lines containing a Spanish-origin word have been removed.

Transcription Level	**CER** dev/test	**WER** dev/test
Surface	8.0/**7.6**	16.6/16.3
Underlying	**7.7**/7.7	**16.0/16.1**

Corpus	**CER** dev/test	**WER** dev/test
10h	19.4/19.5	39.1/39.2
20h	12.6/12.7	26.2/26.2
50h	8.6/8.7	18.0/18.0
Whole (92h)	**7.7/7.7**	**16.0/16.1**

Table 5: E2E-Conformer Results on Different Corpus Size

(c) Comparison with Different Transcription Levels: In addition to comparing model architectures, we compared the impact of transcription levels on the ASR model. E2E-Conformer models with the same configurations were trained using both the surface and the underlying transcription forms, which are discussed in Section 2.3. We also trained separate RNN language models for fusion and unigram language models to extract word pieces for different transcription levels.

Table 4 shows the E2E-Conformer results for both underlying and surface transcription levels. As introduced in Section 2.3, the surface form reduces several linguistic and phonological processes compared to the underlying practical form. The results indicate that the end-to-end system is able to automatically infer those morphological and phonological processes and maintain a consistent low error rate.

(d) Comparison with Different Corpus Sizes: As introduced in Section 1, most ELs are considered low-resource for ASR purposes. To measure the impact of resource availability on ASR accuracy we trained the E2E-Conformer model on 10, 20, and 50 hours subsets of YMC-EXP. The results demonstrate the model performances over different sizes of resources.

Table 5 shows the E2E-Conformer performances on different amounts of training data. It demonstrates how the model consumes data. As corpus size is incrementally increased, WER decreases significantly. It is apparent that the model still has the capacity to improve performance with more data. The result also indicates that our system can get reasonable performances from 50 hours of data. This would be an important guideline when we collect a new EL database.

Model	**CER** dev/test	**WER** dev/test
E2E-RNN	10.3/9.9	26.8/25.4
E2E-Transformer	**9.1**/9.1	23.7/**21.7**
E2E-Conformer	9.9/**8.6**	**23.5/21.7**

Table 6: E2E-Conformer Results on another EL: Highland Puebla Nahuatl

Corpus	**CER** dev/test	**WER** dev/test
10h	18.3/17.5	44.7/43.3
20h	14.2/12.9	34.8/33.3
50h	11.0/10.2	27.0/24.9
Whole (120h)	**9.9/8.6**	**23.5/21.7**

Table 7: E2E-Conformer Results on another EL: Highland Puebla Nahuatl (Different Corpus Size)

(e) The Framework Generalizability: To test the end-to-end ASR systems' generalization ability, we conducted the same end-to-end training and test procedures on another endangered language: Highland Puebla Nahuatl (high1278; azz). This corpus is also open access under the same CC license.[9] It comprises 954 recordings that total 185 hours 22 minutes, including 120 hours transcribed data in ELAN and 65 hours still only in Transcriber and not used in ASR training.[10]

Table 6 shows the performance of three different end-to-end ASR architectures on Highland Puebla Nahuatl. For this language the E2E-Conformer again offers better performances over the other models. Table 7 shows the E2E-Conformer performances on different amounts of training data for Highland Puebla Nahuatl. We can observe that 50-hour is a reasonable size for an EL, which is similar to the experiments in Table 5. These experiments indicate the general ability to consistently apply end-to-end ASR systems across ELs.

---

Table 8: Character Error-type Distribution of Novice and ASR (by number of errors)

4 Novice Transcription Correction

Finally, this paper presents novice transcription correction (NTC) as a task for EL documentation. That is, in this experiment we explore not only the possibility of using ASR to enhance the accuracy of a YM novice transcription but to combine both novice transcription and ASR to achieve accurate results that surpass that of either component. Below we first analyze patterns manifested in novice transcriptions. Next, we introduce two baselines that fuse ASR hypotheses and novice transcription for the NTC task.

4.1 Novice Transcription Error

As mentioned in Section 1, transcriber shortages have been a severe challenge for EL documentation. Before 2019, only the native speaker linguist, Rey Castillo García, could accurately transcribe the segments and tones of YMC. To mitigate the YMC transcriber shortage, in 2019 Castillo began to train another speaker, Esteban Guadalupe Sierra. First, a computer course was designed to incrementally teach Guadalupe segmental and tonal phonology. In the next stage, he was given YMC-NT corpus recordings to transcribe. Compared to the paired expert transcription, the novice achieved a CER of 6.0% on clean-dev, defined in Table 1. However, it is not feasible to spend many months training speakers with no literacy skills to acquire the transcription proficiency achieved by Guadalupe in our project. Moreover, even with a 6.0% CER, there are still enough errors so as to require significant annotation/correction by the expert, Castillo. The state-of-the-art ASR system (e.g., E2E-Conformer) shown in Table 3 gets an 8.2% CER on the clean-dev set, more errors than the novice CER. So for YMC, ASR is still not a good enough substitute for a proficient novice.

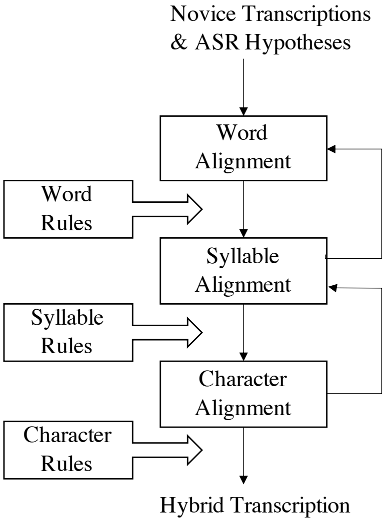

Figure 1: Novice-ASR Fusion Process

As Amith and Castillo worked with the novice, they saw a repetition of types of errors that they worked to correct by giving the novice exercises focused on these transcription shortcomings. The end-to-end ASR, however, has demonstrated a different pattern of errors. For example, it developed a fair understanding of the rules for suppleting tones, marked by parentheses around the suppleted tones. Rather than over-specify the NTC correction algorithm, we first analyzed the error-type distribution using the Clean-dev from the YMC-NT corpus, as shown in Table 8.

4.2 Novice-ASR Fusion

Rapid comparison of the types of errors for each transcription (novice and ASR) demonstrated consistent patterns and has led us to hypothesize that a fusion system might automatically correct many of these errors. Two baseline methods are examined for the fusion: a voting-based system (Fiscus, 1997) and a rule-based system.

The voting-based system follows the definition in (Fiscus, 1997) that combines hypotheses from different ASR models with novice transcription.

The framework of rule-based fusion is shown in Figure 1. The rules are defined in different linguistic units: words, syllables, and characters. They assume a hierarchical alignment between the novice transcription and ASR hypotheses. The rules are applied to the transcription from word to syllable to character level. The rules are developed based on continual evaluation of the novice's progress. Thus they will be different but discoverable when

Model	Clean-Dev		Clean-Test		Noise-Test		Overall

Table 9: NTC Results on YMC-NT (the results are evaluated using the expert transcription in YMC-NT). Model D is trained with a 50-hour subset of the YMC-EXP as shown in Table 5.

applied to a new language. However, the general principle should be applicable to other ELs: Novice trainees will learn certain transcription tasks easier than others. Below we explain the rules for YMC.

Word Rules: If a word from the novice transcription is Spanish (i.e., no tones and no linguistic indications [-, =, '] that mark it as Mixtec), keep the novice transcription. If the novice has extra words, not in the ASR hypothesis, keep those extra words.

Syllable Rules: If a novice syllable is tone initial, use the corresponding ASR syllable. If the novice and the ASR have identical segments but different tones, use the ASR tones. When an ASR syllable has CVV or CV'V, and its corresponding novice syllable has CV,[11] use the ASR syllable (CVV or CV'V). If the tone from either transcription system follows a consonant (except a stem-final n), use the other system's transcription.

Character Rules: If the ASR has a hyphen, equal sign, parentheses, glottal stop which is absent from the novice transcription, then always trust the ASR and maintain the aforementioned symbols in the final transcription.

We apply the edit distance (Wagner and Fischer, 1974) to find the alignment between the ASR model hypothesis $\{C_1, ..., C_n\}$ and the Novice transcription $\{C'_1, ..., C'_m\}$. The L_I, L_D, L_S are introduced in the dynamic function as the insertion, deletion, and substitution loss, respectively. In the naive setting, L_I, L_D are both set to 1. The L_S is set to 1 if C_i is different from C'_j and 0 otherwise. This setting is computation-efficient. However, it does not consider how the contents mismatch between the C_i and C_j. Therefore, we adopt a hierarchical dynamic alignment. In this method, the character alignment follows the native setting. While the $L_S(C_i, C'_j)$ for syllable alignment is defined as the normalized character-level edit distance between C_i and C'_j as follows:

$$L_S(C_i, C'_j) = \frac{D[C_i, C'_j]}{|C_i|} \quad (1)$$

where the $|C_i|$ is the lengths of the syllable. Similarly, the $L_S(C_i, C'_j)$ for word alignment is defined based on syllable alignment.

5 NTC Experiments

5.1 Experimental Settings

The novice transcription, the E2E-Transformer model, and the E2E-Conformer model were considered as baselines for the NTC task. To evaluate the system for reduced training data, we also show our results of E2E-Conformer trained with a 50-hour subset. For the end-to-end models, we adopted the trained model from Section 3 with the same decoding set-ups. To test the effectiveness of the hierarchical dynamic alignment, we tested the data with two fusion systems, namely Fusion1 and Fusion2. The Fusion1 system used the naive settings of edit distance, while the Fusion2 system adopted the hierarchical dynamic alignment. Both fusion systems adopt rules defined in Section 4.2. Two configurations for voting-based methods were tested. The first "ROVER" combined three hypotheses (i.e., the E2E-Transformer, the E2E-Conformer, and the

---

[11] A CV syllable can occur in a monomoraic word. But novice will often write a CV word when it should be CVV or CV'V. Stem-final syllables can be CV, CVV or CV'V. But novice tends to write CV in these cases.

Novice). In contrast, the "ROVER-Fusion2" combined the Fusion2 system with the above three.

5.2 Results

As shown in Table 9, voting-based methods and rule-based methods all significantly reduce the novice errors for clean speech.[12] However, for the noise-test, the novice transcription is the most robust method. For overall results, the ROVER system (model I) has a lower WER, while the ROVER-Fusion2 system (model J) reaches a lower CER. Model J significantly reduces specific errors, including tone errors (25%), enclitic errors (50%), and parentheses errors (87.5%). In addition, models D, F, and H indicate that the system could still reduce clean-environment novice errors using ASR models trained with a 50-hour subset of the YMC-EXP corpus.

As we discussed in Section 4, novice and ASR transcriptions manifest distinct patterns of error and thus can be used to complement each other. Table 9 shows that our proposed rule-based and voting-based fusion methods can potentially eliminate the errors that come from the novice transcriber, and it can mitigate the transcriber shortage problems based on these fusion methods. However, we should note that a noisy recording condition would negatively affect a fusion approach as ASR does poorly under such conditions (>23% CER), and for practical purposes, the novice transcription alone (<8.5%) is much more accurate. In such conditions we should rely on the novice transcriber alone.

6 Conclusion and Future Work

This work presents an open-source endangered language corpus in Yoloxóchitl Mixtec and a comparative and reproducible study on various approaches to end-to-end ASR. We demonstrate that end-to-end approaches are feasible and present comparable results over conventional HMM approaches, which require resources such as language lexicons not necessary with end-to-end ASR. Additionally, we propose novice transcription correction as a potential task for ASR in EL documentation. We examine two methods to approach this task. The first is a rule-based approach that uses hierarchical dynamic alignment and linguistic rules to perform novice-ASR hybridization. The second is a voting-based method that combines hypotheses from the novice and end-to-end ASR systems. Empirical studies on the YMC-NT corpus indicate that both methods significantly reduce the CER/WER of the novice transcription for clean speech.

The above discussion suggests that a useful approach to EL documentation using both human and computational (ASR) resources might focus on training each system (human and ASR) for particular transcription tasks. If we know from the start that ASR will be used to correct novice transcriptions in areas of difficulty, we could train an ASR system to maximize accuracy in those areas that challenge novice learning.

A Appendices

Experimental Settings for End-to-End ASR: All the end-to-end ASR systems adopted the hybrid CTC/Attention architecture integrated with an RNN language model. The best model was selected on the basis of performance on the development set. The input acoustic features were 83-dimensional log-Mel filterbanks features with pitch features (Ghahremani et al., 2014). The window length and the frameshift were set to 25ms and 10ms. SpecAugmentation are adopted for data augmentation (Park et al., 2019). The prediction targets were the 150-word pieces trained using unigram language modeling (Kudo and Richardson, 2018) (both for surface and underlying form). All the end-to-end models are fused with RNN language models.[13] The CTC ratio for Hybrid CTC/Attention was set to 0.3. The decoding beam size was 20. Training and Testing are based on Pytorch.

E2E-Conformer Configuration: The E2E-Conformer used 12 encoder blocks and 6 decoder blocks. All the blocks adopted a 2048 dimension feed-forward layer and four-head multi-head-attention with 256 dimensions. Kernel size in the Conformer block was set to 15. For training, the batch size was set to 32. Adam optimizer with 1.0 learning rate and Noam scheduler with 25000 warmup-steps were used in training. We trained for a max epoch of 50. The parameter size is 43M.

E2E-RNN Configuration: The E2E-RNN used 3 encoder blocks and 2 decoder blocks. All the blocks adopt 1024 hidden units. Location-based attention adopted 1024-dim attention. Adadelta was chosen as the optimizer, and we trained for a max epoch of 15. The parameter size is 108M.

E2E-Transformer Configuration: The E2E-Transformer used 12 encoder blocks and 6 decoder blocks. All the blocks adopted a 2048 dimension feed-forward layer and four-head multi-head-attention with 256 dimensions. Adam optimizer with 1.0 learning rate and Noam scheduler with 25000 warmup-steps were used in training. We trained for a max epoch of 100. The parameter size is 27M.

Experimental Settings for HMM-based ASR: The acoustic feature input for this model is 40 dimensional Mel Frequency Cepstral Coefficients (MFCC). The lexicon for HMM-based models is

---

[13] Our experiments show that the RNN language model reduces WER by about 1%.

phone-based. The transcriptions are mapped to surface representations and then to phones (a total of 197 phones, as each tone for a given vowel, is a different phone). There are 22,465 total entries in the lexicon. The chain model is trained with a sequence-level objective function and operates with an output frame rate of 30 ms, three times longer than the previous standard. The longer frame rate increases decoding speed, which in turn makes it possible to operate with a significantly deeper DNN architecture for acoustic modeling. The best results were achieved with a neural network based on the ResNet architecture (Szegedy et al., 2017). This consists of an initial layer for Linear Discriminative Analysis (LDA) transformation and subsequent alternating 160-dimensional bottleneck layers, adding up to 45 layers in total. The DNN acoustic model is then compiled with a 4-gram language model into a weighted finite-state transducer for word sequence decoding.

Mode Effects’ Challenge to Authorship Attribution

Abstract

The success of authorship attribution relies on the presence of linguistic features specific to individual authors. There is, however, limited research assessing to what extent authorial style remains constant when individuals switch from one writing modality to another. We measure the effect of writing mode on writing style in the context of authorship attribution research using a corpus of documents composed online (in a web browser) and documents composed offline using a traditional word processor. The results confirm the existence of a “mode effect” on authorial style. Online writing differs systematically from offline writing in terms of sentence length, word use, readability, and certain part-of-speech ratios. These findings have implications for research design and feature engineering in authorship attribution studies.

1 Introduction

That authorship attribution techniques work as reliably as they do has been attributed to the fact that each individual has a distinctive writing style. Texts written by the same author can be recognized by analyzing lexical and syntactic features in documents (Juola, 2006). This principle is practically successful in a variety of settings (Abbasi and Chen, 2008; Overdorf and Greenstadt, 2016; Afroz et al., 2014). In some cases, however, authorial style is challenging to detect. For example, authorial style fades as time goes by (Glover and Hirst, 1996; Baayen et al., 2002), varies considerably in collaborative environments (Graham et al., 2005; Kestemont et al., 2018; Zangerle et al., 2019), and drifts depending on document genre (Stamatatos, 2018; Koppel et al., 2007; Sapkota et al., 2016).

The aforementioned changes are conspicuous due to the fact that there are certain markers indicating that a document may have been written in a fashion that will lead to stylistic variation. For instance, the presence of genre-specific words indicates a document may present a puzzle for standard authorship attribution techniques. Sometimes, however, documents which may challenge an analysis of authorial style can be unannounced. This paper shows that authorial style changes with respect to sentence length, word use, readability, and certain part-of-speech ratios when the writing environment switches from traditional word processing software to an input box of a web browser.

2 Mode Effects

Originally developed in survey research and educational testing, a “mode effect” describes the following phenomenon: a respondent may answer the same question differently depending on how a survey is administered (e.g., online vs. phone) (Hochstim, 1967; Leeson, 2006). Although discussion continues about mode effects’ underlying mechanism (Kreuter et al., 2008; Sidi et al., 2017), contextualized magnitude (Carpenter and Alloway, 2019; Washburn et al., 2017), and adjustment methods (Kolenikov and Kennedy, 2014), a consensus has been reached that mode effects can impair survey validity. For instance, Tourangeau et al. (2000) compiled six studies investigating illicit drug use with self-administered and interviewer-administered surveys. The results showed that illicit drug use was reported at higher rates when questions were administered without an interviewer present.

Functionally, writing modality resembles survey modality: the style observed in an individual’s writing may vary depending on how the writer composes the document. A document written by hand may vary from a document composed using traditional word processing software. Further variation may be observed if the document is typed into a

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1146–1155
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

text box in a web browser. Therefore, this research uses "mode effect" to label such differences.

3 Data

Participants in this experiment were recruited on Amazon Mechanical Turk (MTurk). Two distinct types of writing were collected from each of the 18 participants: (1) ca. 6,500 words of pre-existing formal writing and (2) a short ca. 500-word open-ended response to an essay prompt. For the pre-existing writing samples, participants were asked to "Submit at least 6500 words total from multiple documents of your own writing that was done for a formal purpose (school essays, grant proposals, etc)." For the 500-word essay, respondents were asked to describe [their] neighborhood to someone who has never been there before as part of a college application.[1] Respondents also completed a demographic questionnaire, reporting their gender and age bracket.

Responses that were not in English or which seemed very likely to be inauthentic were excluded. (Kennedy et al. (2018) discusses challenges dealing with MTurk surveys). We also excluded one response which appeared to contain writing copied (without attribution) from online sources. The pre-existing writing samples were further processed in order to remove personally identifying information. Lengthy quotations, headings, tables, and figures were also removed.

The data for this experiment are a subset of data collected as part of research seeking to replicate results in Brennan et al. (2012). In the full replication experiment, respondents were randomly given one of four essay prompts. In this paper, we only used the responses by respondents randomly assigned to the "control" condition. These respondents provided pre-existing writing samples and a response to the essay prompt mentioned above. Responses were collected between March 29th and June 1st, 2019. 14 out of 18 respondents reported their age as "18-34". Self-reported gender was also collected. Ten of the respondents were men and eight were women.

The overwhelming majority of pre-existing writing samples collected were essays written for undergraduate courses. Many essays discussed films and literary works. Many appeared to be written for political science and business courses.

The writing prompt generally elicited the desired response: respondents wrote about their neighborhood using formal or semi-formal prose.

To check that all writing collected exhibited approximately the same degree of formality, we compared the formality of the writing in the offline corpus with the formality of the writing in the online corpus using a formality score developed by Heylighen and Dewaele (1999). We found that the formality scores in each corpus were similar.[2]

4 Method

This paper focuses on stylistic differences introduced by seemingly innocuous variation in the mode used to enter a text—offline composition vs. online typing into a text box. We are interested in whether a mode effect occurs in writing. To the extent that it is observed, we wish to know if its impact on an author's style is predictable. Does writing mode induce similar changes in the writing style of different individuals?

To answer these questions, we extract linguistic features from the documents written by the 18 participants. We then use a Bayesian hierarchical model to estimate differences in the rates at which the linguistic features appear in texts written using different writing modes.

5 Modeling Authorial Style

5.1 Feature Selection

We use a set of high-level, familiar linguistic features in our study. Our "Comparative Style" ("CS") feature set aims to capture word-, sentence-, and chunk-level features. All features are described in Table 1. For sentence-level features, white space between words is not counted as a character. Punctuation includes periods, exclamation marks, question marks, commas, semicolons, colons, and apostrophes. For function words we use the list of 512 words from Koppel et al. (2005). The Voice of America (VOA) Special English word list contains 1,512 frequently-used words which are used

---

[1] The full prompt reads: "TOPIC: You are asked as part of a college application to describe your neighborhood to someone who has never been there before. Discuss the houses, people, stores, parks. Anything you think is relevant." The prompt is taken from Brennan et al. (2012).

[2] The mean formality score and standard deviation for the offline corpus were 59.2 and 17.3 respectively. The mean formality score and standard deviation for the online corpus were 57.9 and 17.6 respectively. The formality scores were calculated for each sentence using the following formula: $(\text{noun frequency} + \text{adjective freq.} + \text{preposition freq.} + \text{article freq.} - \text{pronoun freq.} - \text{verb freq.} - \text{adverb freq.} - \text{interjection freq.} + 100)/2$ (Heylighen and Dewaele, 1999).

Table 1: This table describes features in the Comparative Style feature set. The last column mentions an example sentence and an example text chunk. The first sentence of the abstract is the example sentence. The abstract is the example text chunk.

Level	No.	Feature	Abbreviation	Explanation/Example
Word	1	Word length in syllables	WordLenSyll	E.g. the word "mode" has one syllable while the word "effect" has two.
	2	Word length in characters	WordLenChar	E.g. the word "mode" has four characters while the word "effect" has five.
Sentence	3	Sentence length in syllables	SentLenSyll	E.g. the example sentence has 35 syllables.
	4	Sentence length in words	SentLenWord	The example sentence has 16 words.
	5	Sentence length in characters	SentLenChar	E.g. the example sentence has 99 characters.
	6	Punctuation to character ratio	PuncChar	E.g. the PuncChar ratio of the example sentence is 1/99.
	7	Function word to word ratio	FuncWord	E.g. the FuncWord ratio of the example sentence is 6/16.
	8	Special English ratio	SplEng	E.g. the SplEng ratio of the example sentence is 6/16, because "on", "the", "to", "individual," and two "of" are in the sentence.
	9	Common word ratio	CommWord	E.g. the CommWord ratio of the example sentence is 12/16, because "success", "on", "the", "presence", "linguistic", "feature", "specific", "to", "individual", "author," and two "of" are in the sentence.
Chunk	10	Adjective to noun ratio	AdjNoun	E.g. the AdjNoun ratio of the abstract is 18/44.
	11	Verb to noun ratio	VerbNoun	E.g. the VerbNoun ratio of the abstract is 16/44.
	12	Pronoun to noun ratio	PronNoun	E.g. the PronNoun ratio of the abstract is 2/46.
	13	Adverb to adjective ratio	AdvAdj	E.g. the AdvAdj ratio of the abstract is 3/18.
	14	Flesch–Kincaid grade level	FleschKincaid	E.g. the FleschKincaid score of the abstract is 13.11.
	15	Gunning fog index	GunningIdx	E.g. the GunningIdx ratio of the abstract is 50.00.

in VOA Special English reporting (Voice of America, 2007). The 8,013-word "common word" list is taken from the College English Test Band 4 and 6 (CET-4/6), the nationwide English proficiency test used in mainland China. The lists are used in the three sentence-level measures of vocabulary richness.

A chunk is defined as a sequence of consecutive sentences containing at least 150 words. The criterion "150 words" was arbitrarily chosen to balance meeting the length requirement of readability tests and the desire to extract as many chunk-level observations as possible in order to better estimate feature variability within writing modes. We experimented with different chunk lengths (e.g., 100, 150, 200) and found that our results did not depend strongly on chunk length.

The Flesch–Kincaid grade level Flesch (1948) and Gunning fog index (Gunning, 1968) were calculated for every chunk. More challenging texts are associated with lower Flesch-Kincaid levels and higher Gunning fog indexes.

Thirteen of the 15 CS features were transformed by taking the square root so that the feature distributions would be approximately Gaussian. The Flesch-Kincaid level and the Gunning fog index are left on the original scale as their distributions were already approximately Gaussian. Although the hierarchical model uses the transformed features, in subsequent visualizations and tables, parameter estimates are reported on the original scale.

5.2 Setup

We divide the documents into two groups: the "offline" documents, the pre-existing writing samples from the 18 subjects (authored using word processing software) and the "online" documents, written in a web browser in response to the essay prompt asking for a description of the writer's neighborhood.

To compare features across modes and individuals, we use a hierarchical model. Within each mode-specific group of documents, feature observations associated with an individual are modeled using a normal sampling model with an individual-specific mean and scale. The individual-specific means and scales are, in turn, modeled using a normal distribution and gamma distribution.

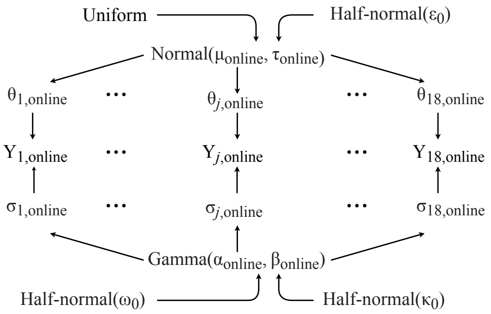

Figure 1: The model for CS feature observations for the online documents. The model for the CS feature observations for the offline documents is the same.

Figure 1 shows the hierarchical model for observations of CS features for the documents composed online. The model can be rendered in symbols as

$$\begin{aligned}\theta_{j,\text{online}} &\overset{i.i.d.}{\sim} \text{Normal}(\mu_{\text{online}}, \tau_{\text{online}}) \\ \sigma_{j,\text{online}} &\overset{i.i.d.}{\sim} \text{Gamma}(\alpha_{\text{online}}, \beta_{\text{online}}) \\ Y_{j,\text{online}} &\overset{i.i.d.}{\sim} \text{Normal}(\theta_{j,\text{online}}, \sigma_{j,\text{online}}), \\ & \quad j \in \{1, 2, ..., 18\}\end{aligned}$$

where $Y_{j,\text{online}} = \{y_{1,j}, y_{2,j}, ..., y_{n_j,j}\}_{\text{online}}$ are observations for the jth subject in the online mode. These observations are drawn from a normal sampling distribution $\text{Normal}(\theta_{j,\text{online}}, \sigma_{j,\text{online}})$. The individual-specific standard deviation $\sigma_{j,\text{online}}$ comes from a gamma distribution parameterized by shape α_{online} and rate β_{online}. The individual-specific mean $\theta_{j,\text{online}}$ is drawn from a normal distribution with a location μ_{online} and a scale τ_{online}. In addition, the μ_{online} was assigned a uniform prior distribution, while weakly informative priors were given to τ_{online}, α_{online}, and β_{online}. Each feature is modeled separately. The models for CS features in the offline mode mirrors those for the online mode.

In a pilot study, we considered using a Student-t distribution instead of a normal distribution as the sampling distribution. We found that the estimated degrees of freedom for these sampling distributions were sufficiently large (>30). Hence we concluded it was safe to use the simpler normal distribution as the sampling distribution.

Additionally, for simplicity, η, the group-level scale coming from Gamma(α, β), will be reported rather than the original parameterization. The effect size between modes was calculated with $\frac{\mu_{\text{online}} - \mu_{\text{offline}}}{\sqrt{(\eta^2_{\text{online}} + \eta^2_{\text{offline}})/2}}$ (Kruschke, 2014).

5.3 Decision Rule

Posterior differences between the two group means (μ_{online} and μ_{offline}) and group scales (η_{online} and η_{offline}) will be characterized using 95% highest posterior density (HPD) intervals and regions of practical equivalence (ROPE) (Kruschke and Liddell, 2018). The 95% HPD interval describes an interval in which a parameter is likely to be found. The ROPE specifies a region of practical equivalence around a null value.

When the 95% HPD for a parameter falls outside the ROPE, the null value is rejected, and the parameter is considered to be different from the null value. If the HPD falls entirely inside the ROPE, the null value is accepted. Otherwise, we withhold judgment.

The data can be analyzed using different ROPEs. Given the goals of this investigation, we use ROPEs associated with a "small" effect (Cohen's d=0.2, according to Cohen (1988)), that is, calculating ±0.1 standard deviations for every posterior difference as the upper and the lower ROPE limits around zero, as suggested by Kruschke (2018). There are many ways to calculate the effect size. We follow Kruschke (2014) in our calculation and refer to this effect size as Cohen's d.

6 Results

Before summarizing differences between online and offline writing across all individuals and features, we first consider how a single feature varies in writing from the 18 subjects. This analysis demonstrates how we use Bayesian methods to infer collective tendencies in the data.

6.1 A Close Look at Sentence Length

Do sentence lengths vary systematically by writing mode? We consider three measures of sentence length, one of which is "sentence length in characters." Even before performing any modeling, the individual and collective tendencies can be identified in a visualization of the data (Figure 2).

The box plots on the left-hand side of Figure 2 show that all but one of the 18 participants tended to use longer sentences in their offline documents. The variability in sentence lengths also tended to be greater. The right-hand side histograms of aggregated observations further confirm this characterization.

Figure 3 shows the 95% HPD intervals for the parameters of interest related to "sentence length in

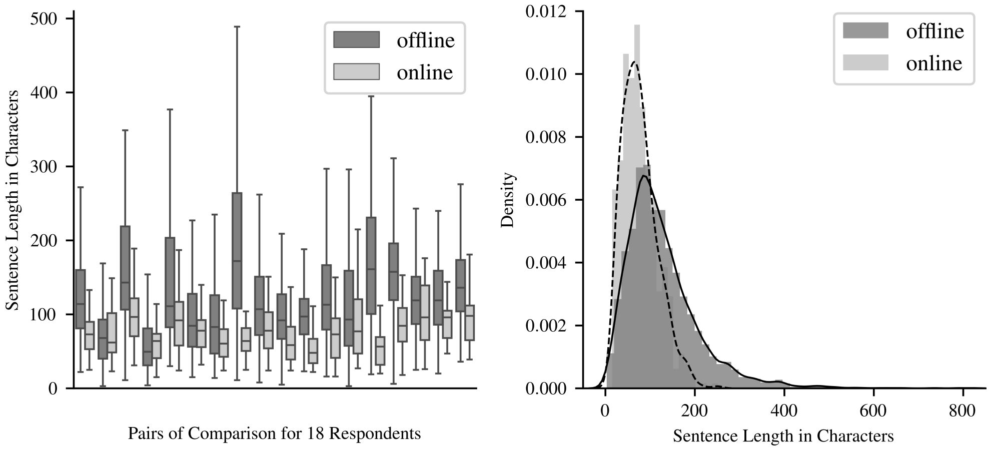

Figure 2: The grouped box plots and histograms with kernel density estimates for sentence length in characters.

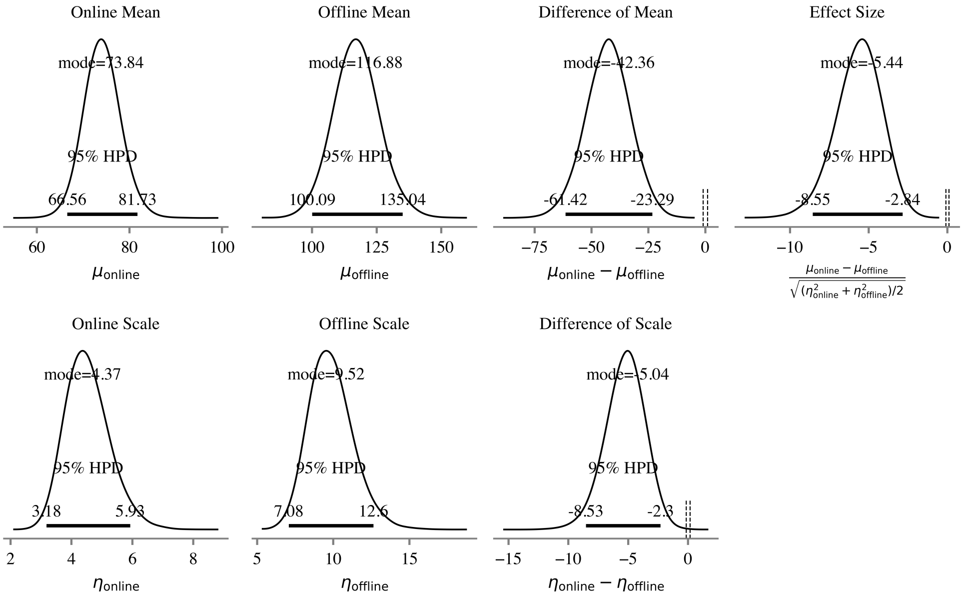

Figure 3: Posterior distribution of μ_{online}, μ_{offline}, $\mu_{\text{online}} - \mu_{\text{offline}}$, η_{online}, η_{offline}, $\eta_{\text{online}} - \eta_{\text{offline}}$, and effect size for the “sentence length in characters” feature. The ranges between two dotted reference lines are ROPEs.

characters”, μ_{online}, μ_{offline}, η_{online}, η_{offline}, $\mu_{\text{online}} - \mu_{\text{offline}}$, $\eta_{\text{online}} - \eta_{\text{offline}}$, and effect size.

In the first two upper panels, posteriors indicate that individuals’ sentences were typically 73.84 characters when typing into a text box in a web browser but were typically 116.88 characters with traditional word processing software. Those writing online tended to use shorter sentences (42.36 characters fewer, $\mu_{\text{offline}} - \mu_{\text{online}}$). Note that the 95% HPD falls far away from the ROPE, indicating a non-negligible difference. Therefore, we conclude that people wrote shorter sentences when writing online.

The lower panels of Figure 3 show another difference: the standard deviation in the online setting was 5.04 characters fewer than that in the offline mode, indicating a relative lack of variability in sentence length when individuals wrote online.

The estimated effect size was -5.44 with a 95% HPD interval between -8.55 and -2.84 (Figure 3 upper-right). A effect size of greater than 2 (in absolute value) counts as “huge” (Sawilowsky, 2009). One way of comprehending the magnitude of an effect size is the following: with the naked eye, one can barely detect a “small” effect (e.g., Cohen’s d=0.2) but would have no difficulty in seeing a “large” one (e.g., Cohen’s d=0.8).

The preceding analysis looked closely at a specific feature. We considered both the raw data and posterior estimates. In the remainder of the paper, for the sake of brevity, only differences between group means ($\mu_{\text{online}} - \mu_{\text{offline}}$), scales ($\eta_{\text{online}} - \eta_{\text{offline}}$), and effect sizes will be reported.

6.2 How Writing Style Varies by Mode

In Figure 4, 12 out of 15 posterior differences of group means ($\mu_{\text{online}} - \mu_{\text{offline}}$) are credibly nonzero, leaving the rest undecided.

The posterior differences between word lengths and sentence lengths are negative. Participants tend to write shorter sentences and use shorter words in the online condition. Relative to offline writings, a positive difference in mean Flesch-Kincaid levels and a negative difference in mean Gunning fog index scores indicate that individuals simplify their writing style when they are entering prose in the web browser. Similar patterns also appear when examining the percentages of function words, Special English, and common words. Individuals tended to use simpler vocabulary in the online condition. For ratios of parts of speech, the adjective to noun and pronoun to noun ratios show credibly positive differences.

Differences in feature standard deviations are shown in Figure 5, where five features indicated nonzero differences. Sentence length, measured in three different ways, varies less in online writing than in offline writing. That is, individuals tend to use a wider range of sentence lengths in offline writing than in online writing. Two readability scores also show less variations in the online mode.

Effect size. The posterior distributions for effect size are shown in Figure 6. Eleven out of 15 features have nonzero effect size. One effect size counts as "medium", five count as large "large", one counts as "very large," and four count as "huge" (using levels defined in Cohen (1988) and Sawilowsky (2009)). Measures regarding word length both manifest "large" effect sizes, and features related to sentence length all have "huge" effect sizes. Likewise, the Flesch-Kincaid reading ease and Gunning's fog index differences are "huge" and "very large." Function words and special English show "large" effects while common words display "medium" effects. This confirms that individuals used simpler words online. The pronoun to noun ratio is the only part-of-speech ratio that shows a credibly nonzero effect (a "large" effect).

7 Mode Effects and Authorship Attribution Accuracy

Another way to understand the magnitude of mode effects is to check if standard authorship attribution techniques have a harder time identifying an individual's writing when presented with the same individual's writing composed in a different mode. That is, we can compare the rate at which an authorship attribution model identifies the correct individual when presented with an unsigned document written offline with the rate at which the model identifies the correct individual when given a document written offline. (The model is trained using writing samples written in the offline mode.) This approach has the virtue of allowing us to answer the question we began with: Does the mode effect make authorship attribution more difficult?

For this experiment, we use two authorship attribution models featured in Brennan et al. (2012). One is extremely basic, making use of nine features and a simple feed-forward neural network. The second model uses a larger feature set ("Writeprints Static") and a support vector machine classifier with a linear kernel.[3] Authorship attribution accuracy is calculated in the following steps:

1. Choose a random subset from the 18 authors, starting from two and gradually increasing.

2. Calculate authorship attribution accuracy with five-fold cross-validation using the authorship attribution model (SVM or neural network) with pre-existing writings.

---

[3] We re-engineered the Writeprints Static" and the "Basic-9" feature sets. Our re-implementation of the Writeprints-Static feature set mirrored the original set with three exceptions. First, we applied another widely-used function word list (Koppel et al., 2005) (including 512 words in total) in lieu of the original word list because we could not locate the original list. Second, we used the Penn Treebank tagset (39 non-punctuation tags in NLTK 3.4.5) rather than the original maximum entropy tagset (22 tags). We expect to see very minor differences between the two implementations. Third, we used a linear kernel instead of the polynomial kernel mentioned in Brennan et al. (2012) because the linear kernel performed far better. Indeed, we suspect Brennan et al. (2012) may have used a linear kernel (despite reporting having used a polynomial kernel). A subsequent paper, Overdorf and Greenstadt (2016), which shares an author with Brennan et al. (2012) describes the Brennan et al. (2012) as having used SVM with a linear kernel.

The SVM with a linear kernel used a maximum iteration of 100,000. The neural network used half of the sum of the author count and feature size (which is nine) as the hidden layer count, 100 neurons per layer, and a maximum iteration of 100. All experiments were performed using Scikit-Learn 0.22.1.

3. Repeat the previous steps 1,000 times using a different author subsets. Calculate the average accuracy over these replications.

Calculating attribution accuracy for the online writing samples follows similar steps. Step 2 differs. The model is trained on pre-existing documents and asked to predict the authorship of a document written online.

Figure 7 shows our results. It is clear that the accuracy suffers when applying offline-writing-trained classifiers to online writings. That is, changes in authorial style are big enough to confuse the classifiers. Writing mode differences make authorship attribution more difficult.

8 Discussion

This study investigated whether individuals' writing style varies by "mode": Does the mode used to

compose a document (word processor (offline) versus web browser text entry (online)) affect measurements of individuals' writing style? Our findings confirmed the existence of mode effects. In online writing, respondents tend to use shorter sentences, shorter words, more adjectives (relative to nouns) and pronouns (relative to nouns). Sentence lengths exhibit lower variability as well.

Therefore, we suggest authorship attribution researchers should exercise caution when dealing texts written using different modes.

For example, in Brennan et al. (2012), the authors attributed lower accuracy in an authorship attribution task to the fact that writers employed authorship attribution circumvention techniques. Our research suggests that this lower accuracy may be due in part to differences in writing mode. (The circumvention techniques were only used in online writing.)

Systematic differences in writing associated with different modes may complicate a broader range of experiments. Just as researchers appropriately anticipate genre-dependent stylistic differences in individuals' writing (e.g., fiction vs. non-fiction prose), experiments should also anticipate mode-dependent differences.

Abstract

Latent variable models for text, when trained successfully, accurately model the data distribution and capture global semantic and syntactic features of sentences. The prominent approach to train such models is variational autoencoders (VAE). It is nevertheless challenging to train and often results in a trivial local optimum where the latent variable is ignored and its posterior collapses into the prior, an issue known as *posterior collapse*. Various techniques have been proposed to mitigate this issue. Most of them focus on improving the inference model to yield latent codes of higher quality. The present work proposes a short run dynamics for inference. It is initialized from the prior distribution of the latent variable and then runs a small number (e.g., 20) of Langevin dynamics steps guided by its posterior distribution. The major advantage of our method is that it does not require a separate inference model or assume simple geometry of the posterior distribution, thus rendering an automatic, natural and flexible inference engine. We show that the models trained with short run dynamics more accurately model the data, compared to strong language model and VAE baselines, and exhibit no sign of posterior collapse. Analyses of the latent space show that interpolation in the latent space is able to generate coherent sentences with smooth transition and demonstrate improved classification over strong baselines with latent features from unsupervised pretraining. These results together expose a well-structured latent space of our generative model.

1 Introduction

The state-of-the-art language models (LM) are often modeled with recurrent neural networks (RNN) (Mikolov et al., 2010) or attention-based models (Dong et al., 2019; Vaswani et al., 2017). They are optimized by making a series of next-step predictions, encouraging the models to capture local dependency rather than global semantic features or high-level syntactic properties. A seminal work by Bowman et al. (2016) extends the standard LM to incorporate a continuous latent space which is aimed to explicitly capture global features. They formulate and train the model as a varational autoencoder (VAE) (Kingma and Welling, 2014). Indeed, the model is able to generate coherent and diverse sentences through continuous sampling, and provide smooth interpolation between sentences, uncovering a well-formed latent space.

However, training VAE for text is challenging and often leads to a trivial local optimum, *posterior collapse*. Specifically, the training objective of VAE can be decomposed into a reconstruction term and a KL term that regularizes the distance between the posterior and prior of the latent variable. Due to the autoregressive nature of the decoder, it is able to reconstruct the data well by simply relying on the one-step-ahead groud-truth and evolving model state while completely ignoring the latent codes. The posterior hence collapses into the prior, carrying no information. This is an important open question in this field. As pointed out in Fu et al. (2019), two paths work together to generate sentences in VAE. One path (Path A) is through the latent codes, while the other (Path B) is conditioned on the prior ground-truth or previously generated tokens. The posterior collapse describes an easy solution, that is, relying on Path B and ignoring Path A. Prior efforts made to address this issue by and large are along the two paths. One can control the information available from Path B to force the decoder to employ more Path A information. Bowman et al. (2016) dropout the input words to the decoder and Yang et al. (2017) utilize a dilated CNN to con-

April 19 - 23, 2021.

trol the size of context from previously generated words. Along Path A, various techniques have been developed to improve the latent code quality. Bowman et al. (2016) anneal the weight of the KL term from a small number to reduce the regularization in the beginning of the training (Anneal-VAE), while Fu et al. (2019) further propose to adopt a cyclical annealing schedule (Cyclical-VAE). He et al. (2019) update the encoder multiple times before one decoder update (Lagging-VAE). Li et al. (2019) initialize the VAE with an autoencoder (AE) and adopt a hinge loss for the KL term such that KL is not driven down below a target rate (FBP-VAE and FB-VAE). These techniques fall under the framework of amortized variational inference. Despite its fast inference, Cremer et al. (2018) observes that an amortization gap, the gap between the log-likelihood and the ELBO, can be large. Thus Kim et al. (2018) proposes semi-amortized variational autoencoders (SA-VAE) in which initial variational parameters are obtained from an encoder as in VAE, and the ELBO is then optimized with respect to the variational parameters to refine them.

An alternative to variational inference is Markov chain Monte Carlo (MCMC) sampling. MCMC posterior sampling may be in the form of Langevin dynamics (Langevin, 1908) or Hamiltonian Monte Carlo (HMC) (Neal, 2011; Chen et al., 2014). Traditional MCMC can be time-consuming as the Markov chains require a long running time, each iteration involving a gradient computation through the decoder.

In this article, we propose to apply a short run inference (SRI) dynamics, such as finite step Langevin dynamics, guided by the posterior distribution of the latent variable as an approximate inference engine. For each training example, we initialize such a short run dynamics from the prior distribution such as Gaussian noise distribution, and run a finite number (e.g., 20) of steps of updates. This amounts to a residual network which transforms the initial noise distribution to an approximate posterior distribution.

One major advantage of the SRI is that it is natural and automatic. Designing and tuning a separate inference model is not a trivial task. In prior work, the inference model requires careful tuning to avoid posterior collapse in VAEs for text modeling. For instance, the inference model needs to be aggressively trained (He et al., 2019), pre-trained with an autoencoder (Li et al., 2019), or refined with gradient descent guided by the ELBO (Kim et al., 2018). In contrast, the short run dynamics guided by the log-posterior of the latent variable can be automatically obtained on modern deep learning platforms. In addition, our method does not assume a closed-form density for the posterior, like a Gaussian with diagonal covariance matrix, and hence are possible to have a good approximate posterior and provide good latent code. Lastly, we optimize the hyper-parameter of the short run dynamics by minimizing the KL divergence between the short-run-dynamics-induced posterior and the true posterior, to further improve the approximate posterior.

Empirically, we show that the model trained with the SRI is able to outperform a standard LSTM language model by employing an LSTM generative model, while exhibiting active utilization of the latent space, improving over models trained with VAE-based approaches. Moreover, we find the learned latent space is smooth, allowing for coherent and smooth interpolation and reconstruction from noisy samples, and captures sufficient global information, enabling enhanced classification accuracy over state-of-the-art baselines.

In summary, the following are contributions of our paper. (1) We propose to use short run inference dynamics to train generative models for sentences without the need for an auxiliary inference network. (2) We demonstrate that the generative model trained with the SRI is able to accurately model the data distribution and make active use of the latent space, exhibiting no sign of posterior collapse. (3) We show that the learned latent space is smooth and captures rich global representations of sentences.

2 Model and learning algorithm

2.1 Generative model

Let x be the observed example, such as a sentence. Let z be the latent variable. We may consider z as forming an interpretation or explanation of x, such as the global semantics and/or high-level syntactic properties of sentences. Consider the following generative model for x,

$$z \sim p(z) \quad x \sim p_\theta(x|z). \tag{1}$$

where $p(z)$ is the prior and $p_\theta(x|z)$ is given by a generative model parameterized with θ. The marginal distribution of x is $p_\theta(x) = \int p_\theta(x,z)dz$. Given x, the inference of z can be based on the posterior distribution $p_\theta(z|x) = p_\theta(x,z)/p_\theta(x)$.

2.2 Learning and inference

Let $p_{\text{data}}(x)$ be the data distribution that generates the example x. The learning of parameters θ of $p_\theta(x)$ can be based on $\min_\theta \text{KL}(p_{\text{data}}(x)\|p_\theta(x))$, where $\text{KL}(p\|q) = \text{E}_p[\log(p(x)/q(x))]$ is the Kullback-Leibler divergence between p and q (or from p to q since $\text{KL}(p\|q)$ is asymmetric). If we observe training examples $\{x_i, i = 1, ..., n\} \sim p_{\text{data}}(x)$, the above minimization can be approximated by maximizing the log-likelihood

$$L(\theta) = \frac{1}{n}\sum_{i=1}^{n} \log p_\theta(x_i), \quad (2)$$

which leads to the maximum likelihood estimate (MLE).

The gradient of the log-likelihood, $L'(\theta)$, can be computed according to the following identity:

$$\begin{aligned}\frac{\partial}{\partial\theta}\log p_\theta(x) &= \frac{1}{p_\theta(x)}\frac{\partial}{\partial\theta}p_\theta(x)\\ &= \frac{1}{p_\theta(x)}\int \frac{\partial}{\partial\theta}p_\theta(x,z)dz\\ &= \int \frac{\partial}{\partial\theta}\log p_\theta(x,z)\frac{p_\theta(x,z)}{p_\theta(x)}dz\\ &= \text{E}_{p_\theta(z|x)}\left[\frac{\partial}{\partial\theta}\log p_\theta(x,z)\right]. \quad (3)\end{aligned}$$

While the marginal distribution $p(x) = \int p(x|z)p(z)dz$ is intractable due to the latent variables z being integrated out, the above expectation can be approximated by Monte Carlo average with samples drawn from $p_\theta(z|x)$. Such samples from $p_\theta(z|x)$ can be obtained by MCMC in the form of Langevin dynamics (Langevin, 1908), which iterates

$$z_{k+1} = z_k + s\frac{\partial}{\partial z}\log p_\theta(z_k|x) + \sqrt{2s}\epsilon_k, \quad (4)$$

where $\epsilon_k \sim \mathcal{N}(0, I)$, t denotes the time step of Langevin dynamics, and s is the discretization step size. The gradient term is tractable since $\frac{\partial}{\partial z}\log p_\theta(z_k|x) = \frac{\partial}{\partial z}\log p_\theta(z_k, x)$ and thus does not depend on the intractable $p_\theta(x)$. The Langevin dynamics (4) involves a gradient and a diffusion term. The first term is gradient descent $z'_{k+1} = z'_k + s\frac{\partial}{\partial z}\log p_\theta(z_k|x)$ on $\log p_\theta(z_k|x)$. If $z_k \sim p_\theta(z_k|x)$, then the distribution of z'_k will be shifted towards basins of high log-posterior. We may recover $p_\theta(z_k|x)$ by smoothing with the second term $\sqrt{2s}\epsilon_k$, which amounts to white noise diffusion and induces randomness for sampling from $p_\theta(z_k|x)$.

For small step size s, the marginal distribution of z_k will converge to $p_\theta(z|x)$ as $k \to \infty$ regardless of the initial distribution of z_0 (Cover and Thomas, 2006). More specifically, let $q_k(z)$ be the marginal distribution of z_k of the Langevin dynamics, then $\text{KL}(q_k(z)\|p_\theta(z|x))$ decreases monotonically to 0, that is, by increasing k, we reduce $\text{KL}(q_k(z)\|p_\theta(z|x))$.

Finally, the MLE learning can be accomplished by gradient descent. Each learning iteration updates θ by

$$\theta_{t+1} = \theta_t + \eta_t \frac{1}{n}\sum_{i=1}^{n} \text{E}_{p_{\theta_t}(z_i|x_i)}\left[\frac{\partial}{\partial\theta}\log p_\theta(x_i, z_i) \mid_{\theta=\theta_t}\right], \quad (5)$$

where η_t is the step size or learning rate, and $\text{E}_{p_{\theta_t}(z_i|x_i)}$ can be approximated by Monte Carlo sampling from $p_{\theta_t}(z_i|x_i)$.

2.3 Learning with short run inference dynamics

It is computationally impractical to run long Markov chains from $p_\theta(z|x)$ as the gradient term in (4) requires back-propagation through the model underlying $p_\theta(x|z)$. Earlier work (Han et al., 2017) recruits persistent Markov chains (Tieleman, 2008) $\{(z_i, x_i), i = 1, \ldots, n\}$ such that for each observed example x_i a latent code z_i is updated for a few steps in each learning iteration and the chains are maintained throughout the learning procedure. This method leads to inconsistent sampling procedures while training and evaluating the model, since persistent Markov chains for evaluation data are not available. Moreover, estimation of the log-likelihood has to resort to means such as annealed importance sampling (Neal, 2001).

Instead, we adopt short run MCMC (Nijkamp et al., 2019) in which we approximately sample from the posterior distribution of the latent variable. We thus propose the following short run inference dynamics, with a fixed small number of steps

K (e.g., $K = 20$),

$$z_0 \sim p(z), \tag{6}$$

$$z_{k+1} = z_k + s\frac{\partial}{\partial z}\log p_\theta(z_k|x) + \sqrt{2s}\epsilon_k, \tag{7}$$

where $k = 1, ..., K$ and $p(z)$ is the prior distribution of z. Initializing $z_0 \sim p(z) = \mathcal{N}(0, I)$, we perform K steps of Langevin with step size s.

Finally, the learning procedure updates θ by

$$\begin{aligned}\theta_{t+1} &= \theta_t \qquad\qquad (8)\\ &+ \eta_t \frac{1}{n}\sum_{i=1}^{n} \mathrm{E}_{q_{s,\theta_t}(z_i|x_i)}\left[\frac{\partial}{\partial\theta}\log p_\theta(x_i, z_i)\mid_{\theta=\theta_t}\right], \qquad (9)\end{aligned}$$

where η_t is the learning rate, $\mathrm{E}_{q_{\theta_t}(z_i|x_i)}$ can be approximated by samples drawn from $q_{\theta_t}(z_i|x_i)$ using (7). Compared to MLE learning algorithm (5), we replace $p_{\theta_t}(z|x)$ by $q_{s,\theta_t}(z|x)$. Moreover, we may update the step size s of (7), which we will elaborate in the following.

2.4 Theoretical understanding

Given θ_t, the updating equation (9) is a one step gradient ascent on

$$Q_s(\theta) = \frac{1}{n}\sum_{i=1}^{n} \mathrm{E}_{q_{s,\theta_t}(z_i|x_i)}\left[\log p_\theta(x_i, z_i)\right]. \tag{10}$$

Compared to the log-likelihood in MLE learning, $L(\theta) = \frac{1}{n}\sum_{i=1}^{n}\log p_\theta(x)$, we have

$$\begin{aligned}Q_s(\theta) &= L(\theta) + \frac{1}{n}\sum_{i=1}^{n} \mathrm{E}_{q_{s,\theta_t}(z_i|x_i)}\left[\log p_\theta(z_i|x_i)\right]\\ &= L(\theta) - \frac{1}{n}\sum_{i=1}^{n} \mathrm{KL}(q_{s,\theta_t}(z_i|x_i)\|p_\theta(z_i|x_i))\\ &+ \frac{1}{n}\sum_{i=1}^{n} \mathrm{E}_{q_{s,\theta_t}(z_i|x_i)}[\log q_{s,\theta_t}(z_i|x_i)]. \qquad (11)\end{aligned}$$

Since the last term has nothing to do with θ, gradient ascent on $Q_s(\theta)$ is equivalent to gradient ascent of

$$\tilde{Q}_s(\theta) = L(\theta) - \frac{1}{n}\sum_{i=1}^{n} \mathrm{KL}(q_{s,\theta_t}(z_i|x_i)\|p_\theta(z_i|x_i)), \tag{12}$$

which is a perturbation or a variational lower bound of log-likelihood $L(\theta)$.

The fixed point of the learning algorithm (9) solves the following estimating equation:

$$\frac{1}{n}\sum_{i=1}^{n} \mathrm{E}_{q_{s,\theta}(z_i|x_i)}\left[\frac{\partial}{\partial\theta}\log p_\theta(x_i, z_i)\right] = 0. \tag{13}$$

If we approximate $\mathrm{E}_{q_{s,\theta_t}(z_i|x_i)}$ by Monte Carlo samples from $q_{s,\theta_t}(z_i|x_i)$, then the learning algorithm becomes Robbins-Monro algorithm for stochastic approximation (Robbins and Monro, 1951), whose convergence to the fixed point follows from regular conditions of Robbins-Monro. The estimating equation (9) is a perturbation of the maximum likelihood estimating equation $\frac{1}{n}\sum_{i=1}^{n}\mathrm{E}_{p_\theta(z_i|x_i)}\left[\frac{\partial}{\partial\theta}\log p_\theta(x_i, z_i)\right] = 0$.

2.5 Optimizing step size

We can optimize the step size s by maximizing $\tilde{Q}_s(\theta)$ defined in equation (12), which is equivalent to minimizing the KL divergence between the short-run-dynamics-induced posterior and the true posterior since the first term $L(\theta)$ does not involve s. $\tilde{Q}_s(\theta)$ involves the entropy of $q_{s,\theta_t}(z_i|x_i)$. We provide the details of its computation in the supplementary materials. The step size optimization can be done by grid search or stochastic gradient descent. In this work, we optimize the step size s with grid search guided by maximizing $\tilde{Q}_s(\theta)$.

2.6 Algorithm

The learning procedure is summarized in Algorithm 1. Note that we only optimize s every T_s iterations, so that computational cost is negligible.

Algorithm 1: Learning with SRI.

```
input  : Learning iterations $T$, step size interval $T_s$, learning rate $\eta$, initial
         weights $\theta_0$, observed examples $\{x_i\}_{i=1}^n$, batch size $m$,
         number of steps $K$, initial step size $s$.
output : Weights $\theta_{T+1}$.
for $t = 0 : T$ do
    1. Draw observed examples $\{x_i\}_{i=1}^m$.
    2. Draw latent vectors $\{z_{i,0} \sim p(z)\}_{i=1}^m$.
    3. Infer $\{z_{i,K}\}_{i=1}^m$ by $K$-steps of dynamics (7) with step size $s$.
    4. Update $\theta$ according to (9).
    5. Every $T_s$ iterations, update $s$.
```

2.7 Log-likelihood computation

Unlike traditional MCMC, short run inference enables the computation of the marginal log-likelihood $\log p(x)$[1],

$$\begin{aligned}\log p_\theta(x) &= \log \int p_\theta(x,z)dz \\ &= \log \int \frac{p_\theta(x|z)p(z)}{q_k(z)} q_k(z)dz \\ &= \log E_{q_k(z)}\left[\frac{p_\theta(x|z)p(z)}{q_k(z)}\right]. \end{aligned} \quad (14)$$

Then,

$$\begin{aligned}& E_{p_{\text{data}}}\left[\log \frac{1}{M}\sum_{i=1}^{M} \frac{p_\theta(x|z_i)p(z_i)}{q_k(z_i|x)}\right] \\ &= E_{p_{\text{data}}}\Bigg[\log \sum_{i=1}^{M} \exp\left[\log p_\theta(x|z_i)\right. \\ &\left. + \log p(z_i) - \log q_k(z_i|x)\right] - \log M\Bigg]. \end{aligned} \quad (15)$$

While most terms in (15) are readily available, $\log q_k(z_i|x)$ requires special treatment. We may rewrite the dynamics (7) in the form of

$$z_0 \sim p(z), \quad z_k = R_k(z_0) \quad (16)$$

where R_k is defined by a k-step Langevin dynamics. Let the distribution of z_k be denoted $q_k(z)$. Then, by change of variable theorem,

$$z_k \sim q_k(z), \quad (17)$$

$$q_k(z) = p(R_k^{-1}(z))|\det(dR_k^{-1}(z)/dz)|. \quad (18)$$

Instead of inverting R_k, we draw $z_0 \sim p(z)$ and compute the log determinant of the Jacobian $dR_k(z_0)/dz_0$. See more details in the supplementary.

3 Related Work

Variational inference. VAE (Kingma and Welling, 2014; Bowman et al., 2016) is a prominent method for learning generative models. Due to the autoregressive nature of the decoder, a naive application of VAE to text data results in posterior collapse. Following work makes extensive efforts to alleviate this issue (Fu et al., 2019; Yang et al., 2017; He et al., 2019; Li et al., 2019; Kim et al., 2018; Pelsmaeker and Aziz, 2020; Dieng and Paisley, 2019). Among them SA-VAE developed by Kim et al. (2018) is mostly related to our work. They propose SA-VAE where initial variational parameters obtained from the inference model are further refined by running a small number of gradient updates (e.g., 20) guided by the ELBO. In our work, instead of relying on a parameteric varational distribution, we run a few gradient updates on the log-posterior of the latent variable with initialization from the prior distribution to draw samples directly. Thus, there is no need to design and tune an extra inference model, which is highly non-trivial considering that posterior collapse occurs easily in VAE training.

Alternating back-propagation. Han et al. (2017) propose to learn generative models for images by maximum likelihood, where the learning algorithm iterates over two steps: (i) inferring the latent variable by sampling from its posterior distribution with Langevin dynamics; (ii) updating the model parameters based on the inferred latent codes. In the training stage, in step (i), the Langevin dynamics is initialized from the latent codes inferred in the last epoch, which is called persistent chain in the literature (Tieleman, 2008). In contrast, the short run dynamics always initializes the gradient descent updates from the prior noise distribution. Data-independent initialization renders the dynamics in training and testing consistent.

Short run MCMC. Nijkamp et al. (2019) introduces short run MCMC as a learned sampling dynamics guided by an energy-based model. It shares the same theoretical underpinning as early work of using stochastic gradient Langevin dynamics to learn mixture of Gaussians and logistic regression for large-scale data (Welling and Teh, 2011). Our short run inference method for learning latent variable models for text is inspired by these works.

4 Experiments

We apply our method to train latent variable models on text datasets. The dimension of the latent variable is 32 in all experiments. The generator is implemented with a one-layer uni-directional LSTM (Hochreiter and Schmidhuber, 1997). The number of hidden units and word embedding size of the LSTM vary among datasets to closely follow the experimental setup in recent work (Fu et al.,

2019; Li et al., 2019). The number steps of the short run dynamics is 20 for all experiments [2]. The sample from the short run dynamics is used to predict the initial hidden state of the LSTM. It is also concatenated with the word embeddings and then fed to the LSTM as input at each time step.

The short run inference is more computationally costly than the vanilla VAE and has comparable training cost as some improved versions of VAE. The number of inner steps of SRI (20 steps) is about the same as that of SA-VAE and Lagging-VAE. In training, SRI has faster convergence than SA-VAE and comparable convergence as Lagging-VAE in our experiments. In inference, our sampling-based approach is slower than amortized inference. Our method trades a feasible computational cost for accurate inference whose empirical performance is presented in the following experiments.

4.1 Language Modeling

We evaluate our method on language modeling with the Penn Tree Bank (PTB) (Marcus et al., 1993), Yahoo (Yang et al., 2017), and a down-sampled version of the Stanford Natural Language Inference (SNLI) corpus (Bowman et al., 2015) as preprocessed in (Li et al., 2019). Ideally, a language model with latent variable would be expected to make use of the latent space and accurately model the data distribution. To measure the utilization of the latent space, three quantitatively metrics are often considered in prior work (Bowman et al., 2016; Li et al., 2019; Fu et al., 2019; Kim et al., 2018): reconstruction error (Recon), number of active units (AU), the magnitude of KL. Reconstruction error is the negative log-likelihood of the observed data evaluated under the posterior, $\mathrm{E}_{q(z|x)}\left[-\log p_\theta(z|x)\right]$. A latent dimension is considered active if its distribution changes depending on the observations. Following Burda et al. (2016), a latent dimension is defined to be active if $\mathrm{Cov}_x(\mathrm{E}_{z\sim q(z|x)}[z]) > 10^{-2}$. Perplexity (PPL) based on the marginal log-likelihood of x is adopted to measure how accurately the model captures the data. The marginal log-likelihood is estimated with importance sampling with z sam-

ples from trained short run dynamics as importance samples.

Besides the standard LM and the vanilla VAE with KL weight annealing, VAEs with recent state-of-the-art training techniques, Cyclical-VAE (Fu et al., 2019), Lagging-VAE (He et al., 2019), SA-VAE (Kim et al., 2018), FBP-VAE and FB-VAE (Li et al., 2019) are also included for comparison. The results are displayed in Table 1. In terms of PPL, our method outperforms all the baselines on the PTB and Yahoo datasets, while does slightly worse than Lagging-VAE and performs better than other baselines on the SNLI. This indicates the model trained with our method is able to accurately model the data distribution. On the other hand, our method yields the lowest reconstruction error and the highest KL with all latent dimension active on all three datasets, exposing the active use of the latent space. Taken together, these results suggest that the model trained with short run dynamics are balanced on modeling the data and utilizing the latent space.

Figure 1 displays a t-SNE plot of the SRI-induced aggregate posterior $E_{p_{\text{data}}} q(z|x)$ and its marginal density of each dimension. The t-SNE plot demonstrates the SRI-induced aggregate posterior is multi-modal and the marginal densities are uni-modal but clearly deviates from the zero-centered standard Gaussian prior. These visualizations demonstrate that the aggregate posterior in our model is clearly different the isotropic Gaussian prior[3] and thus our

---

[3] Ideally $E_{p_{\text{data}}} q(z|x) = p(z)$ since $\int_x p_{\text{data}}(x)q(z|x) = \int_x p(z)p_\theta(x|z)$. However the generative model might not be able to induce such a model posterior. The mismatch might indicate some form of under-regularization, similar to other approaches for mitigating posterior collapse such as FB-VAE.

model does not show a posterior collapse issue, consistent with our analysis above.

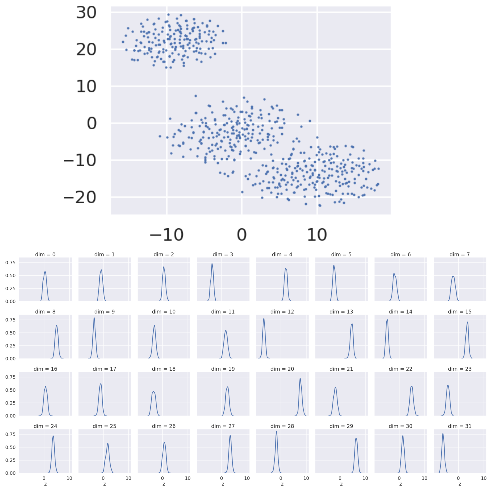

Figure 1: t-SNE plot (upper) and marginal density plot (bottom) of the SRI-induced aggregate posterior on the PTB dataset.

4.2 Latent Space Analysis

The quality of the latent space with SNLI is examined through interpolation, generation, and noisy reconstruction.

4.2.1 Interpolation

Interpolation allows us to appraise the smoothness of the latent space. In particular, two samples z_1 and z_2 are drawn from the prior. We linearly interpolate between them and then decode the interpolated points. FB-VAE (Li et al., 2019) is considered as the SOTA text VAE that mitigates posterior collapse. Due to space limit, we only include this method for comparison in interpolation and generation experiments. Table 2 shows the decoded samples. Although the interpolated sentences by FB-VAE appears smooth, the first two sentences are repetitive. In comparison, the decoded sentences from our model transition more smoothly. While the interpolated sentences from our model are diverse, their syntactic properties and topic information remain consistent in neighborhoods along the path, exposing a smooth latent space.

4.2.2 Generation

We sample from the prior distribution and decode the sentences in a greedy manner. Table 3 displays the samples from our model and FB-VAE. It appears that samples from both models are grammatically correct and semantically meaningful in general. FB-VAE samples nevertheless show more local grammar errors. More generated samples are given in the supplementary.

4.2.3 Noisy reconstruction

Zhao et al. (2018) reasons that a latent variable model's capacity on reconstructing from noisy data reveals the smoothness of the latent space. We impose discrete noise to the data by swapping tokens in a sentence for k times, where $k = 1, 2, 3, 4$ in this experiment. The reconstruction error (negative log-likelihood) under each condition is reported in Table 4. Notice that even the AE yields the lowest reconstruction when the noise is low ($k = 1$), but its performance deteriorates quickly as the noise level increases, implying that the latent space of AE is not smooth. In contrast, other models with regularization on the latent space do not exhibit drastic decline in reconstruction performance with increasing noise level. Furthermore, the model trained with our method demonstrates reconstruction either outperforming other methods or comparable to the best, revealing that the model trained with SRI has a smooth latent space.

4.3 Classification

The latent space of a well-learned latent variable model should capture highly informative features such that data points cluster into meaningful groups in the latent space. We hence further probe the latent space structure by investigating the clustering and classification performance of the SRI-inferred latent codes. Following prior work (Fu et al., 2019; Li et al., 2019), we utilize the Yelp sentiment dataset as preprocessed in Shen et al. (2017). We train a Gaussian mixture for clustering (zero labels) and a SVM with 100, 1000, or 10,000 number of labels. The results are displayed in Table 5. Our method consistently improves over VAE approaches and AE. The improvement is especially clear in the zero-shot setting and small data regime (0 and 100 labels), revealing a well-structured latent space learned by SRI.

5 Conclusion

This work proposes to use short run inference dynamics to infer latent variables in text generative models. SRI dynamics is always initialized from the prior distribution of the latent variable and then performs a small number (e.g., 20) of Langevin dynamics updates guided by the posterior distribution. This simple and automatic inference method induces a good approximate posterior and provides good latent code.

The model trained with SRI accurately models the text data compared to strong language model and generative model baselines and shows no sign of posterior collapse, which is non-trivial to avoid and several remedies have been proposed for in prior art. Moreover, the learned space is smooth and captures rich representations of the sentences.

Abstract

Podcast episodes often contain material extraneous to the main content, such as advertisements, interleaved within the audio and the written descriptions. We present classifiers that leverage both textual and listening patterns in order to detect such content in podcast descriptions and audio transcripts. We demonstrate that our models are effective by evaluating them on the downstream task of podcast summarization and show that we can substantively improve ROUGE scores and reduce the extraneous content generated in the summaries.

1 Introduction

Podcasts are a rich source of data for speech and natural language processing. We consider two types of textual information associated with a podcast episode: the short description written by the podcast creator, and the transcript of its audio, both of which may contain content that is not directly related to the main themes of the podcasts. Such content may come in the form of sponsor advertisements, promotions of other podcasts, or mentions of the speakers' websites and products.

While such content is tightly integrated into the user experience and monetization, it is a source of noise for many natural language processing and information retrieval applications which utilize podcast data. For example (Table 1), an episode of the podcast show *Survival* includes a promotion for an unrelated podcast *Dog Tales* about dogs; a search query for podcasts on dogs should probably not surface the *Survival* episode. Algorithms attempting to connect topics discussed in the podcast to those mentioned in the episode description, such as summarization models, would be confounded by the presence of supplementary material and URLs in the description. Information extraction models looking for entities may mistakenly retrieve sponsor names from advertisements.

Table 1: Portions of a podcast transcript and episode description which contain extraneous material (in bold).

In this paper, we introduce the problem of detecting extraneous content (which we sometimes shorthand as EC) in episode descriptions and audio transcripts. We produce an annotated corpus by taking advantage of podcast listening data, construct models to detect extraneous content, and evaluate our models for accuracy of detection, as well as for the downstream task of summarizing podcast transcripts. We also discuss some of challenges that arise while annotating and classifying extraneous content in this domain.

2 Previous Work

A related, well-studied problem is boilerplate detection on web pages, mainly involving the detection of templates, navigational elements, and advertisements (Kohlschütter et al., 2010). Such models tend to rely on the specific structure of web page boilerplate markup and characteristics. There has also been work on detecting promotional content on Wikipedia (Bhosale et al., 2013).

There are primarily two lines of work in advertisement detection and discovery in multimedia. One computes acoustic features over the entire audio to discriminate between the segments of con-

---

[*] Work done while at Spotify

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1166–1173
April 19 - 23, 2021.

tent and the segments of advertisements (Conejero and Anguera, 2008; Melamed and Kim, 2009; Nguyen et al., 2010). The other fuses multimodal features such as visual cues to segment ad clips from televised and online videos (Lienhart et al., 1997; Duan et al., 2006; Vedula et al., 2017). Our work is closely related to Huang et al. (2018), who analyze consumer engagement on audio advertisements when compared to topical content, as we utilize the user engagement signals to predict extraneous content segments.

3 Datasets and Annotation

To create an annotated dataset, we selected a random set of podcast episodes out of the Spotify Podcast Dataset, a corpus of 105,360 episodes (Clifton et al., 2020). Each episode in the dataset has an automatically generated transcript and a short text description of the episode written by the podcast creators. We annotate both sources, creating ground-truth labels for the extraneous content detection task, using the open source software *doccano* (Nakayama et al., 2018). Annotators were instructed to select spans that correspond to extraneous content, which we defined as ads, social media links, promotions of other podcasts, and show notes that are not directly related to the episode. Respecting sentence boundaries was encouraged, but not required, to allow for cases where extraneous content starts or ends mid-sentence.

3.1 Podcast Episode Descriptions

Annotation of episode descriptions was relatively straightforward. We encountered a few corner cases: for example, an episode may in its entirety be a promotion or an ad; a description that reflects these promotions would be on-topic. In such scenarios, the annotations attempted to be consistent with the annotators' judgments of the main topics of the episode as far as possible. Examples of annotated episode descriptions are shown in Table 6 in the appendix.

3.2 Podcast Episode Transcripts

Each transcript contains thousands of words, of which extraneous content may make up a small portion. This necessitates a way to sample an informative subset of transcript segments for annotation. We observe that if a region is extraneous to the main content, listeners of the podcast episode may fast-forward past this region or abandon listening. To this end, we gather listener data for a subset of our corpus from Spotify, an audio streaming platform. We record the proportion of all listeners who begin streaming an episode retained at each second of the episode's duration. Listening data was aggregated from the date of each episode's publication – with the most recent episode published in February 2020 – through September 2020. For episodes with a substantial number of listeners, there exist distinct local minima or "dips" in the retention curves (Figure 1), which we posit may correspond to regions of extraneous content.

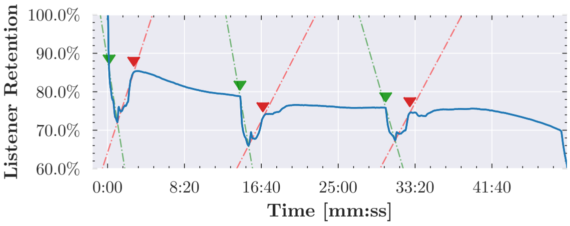

Figure 1: A podcast listener retention curve for a single podcast episode. The dips in the graph suggest potential EC regions. Start- and end-points for each dip are automatically estimated as described in Section 3.2, shown with green and red markers respectively.

To locate the center point of each dip, we first apply `SciPy` peak detection on the negative retention curve (Virtanen et al., 2020). Within ±2 min of each peak, we calculate the slopes of secant lines passing through every point on the curve. The coordinates which maximize the secant slope within this range correspond to the start/end points of the dips. Green and red secant lines are shown in Figure 1 to illustrate this process.

The transcript is then segmented 60 sec before the starting point and 90 sec after the ending point of each dip, loosening the boundaries of the potential EC regions; these segments are then manually annotated. We note that the transcripts contain noisy text which are artifacts from an automatic speech recognition (ASR) system. An additional challenge stems from identifying native advertising, where podcast creators deliberately script product placement into the context of their content (Einstein, 2015; Hutton, 2015). Considering all cases, we attempted to best estimate the boundaries of the scripted content.

Examples of annotated transcript regions are shown in Table 7 in the appendix. The set of manual annotations is used as a *gold* labeled transcript dataset for our models.

Dataset	# of episodes	# of sentences
Episode Descriptions	1730 (61.58% w/ EC)	10410 (43.80% w/ EC)
Transcripts (Gold)	506 (62.25% w/ EC)	12918 (24.01% w/ EC)

Table 2: Our manually annotated datasets show that the majority of podcast episodes do contain extraneous content, making up a sizeable fraction of all sentences.

Of the annotated dips, 38.4 % were found not to contain extraneous content. These largely correspond to episode beginnings, where listeners may skip over the introduction to show, or dynamically inserted ads that are not present in the transcript. The dip boundaries for the rest are relatively accurate against the manual annotations, with an absolute mean error of 16.0 words for the starts, and 35.2 for the ends, motivating the use of the unannotated listener dips as a *silver* training set (described in §4.2).

Sentence-Level Labels Our models for descriptions and transcripts use the sentence as the unit of classification. The annotated data is split into sentences using SpaCy[1]. A sentence is labeled as extraneous if more than 50 % is annotated as such (Table 2).

4 Extraneous Content Detection

4.1 Sentence-Level Classification

We built separate classifiers for detecting extraneous content in descriptions and transcripts. A pretrained BERT (Devlin et al., 2019) cased language model[2] was first fine-tuned on our entire large corpus (of podcast descriptions and transcripts respectively, excluding the test set) to capture the distinctive language use of the podcast domain, and then further fine-tuned for classification on the annotated data to predict whether a sentence is extraneous. We also trained non-neural classifiers (logistic regression and SVMs) with TF-IDF unigram and bigram features (Appendix A.2).

We experimented with single sentence classification in isolation, and with the immediately preceding sentence prepended for context.[3]

Dataset	Model	Single Sentence		Sentence with Context	
		Unigram	Bigram	Unigram	Bigram
Episode Descriptions	LR	0.893	0.818	0.858	0.850
	SVM	0.907	0.907	0.898	0.896
	BERT	0.920		**0.940**	
Transcripts (Gold)	LR	0.651	0.603	0.629	0.638
	SVM	0.675	0.679	0.663	0.670
	BERT	0.710		**0.769**	

Table 3: F1 score of three sentence-level EC classifiers tested across two datasets.

Results Our experiments used a training/test split of 90/10 for annotated transcripts and 80/20 for episode descriptions. The best results come from BERT where the model sees the previous sentence (Table 3). We observed that classification precision and recall are comparable on the descriptions dataset; however, with transcripts, precision tends to be lower (0.690) than recall (0.870). This suggests that the model mistakenly identifies sentences as extraneous, but has fairly good coverage. This seems to be because many sentences in extraneous content in the training transcripts are seemingly innocuous when taken out of context, confounding the model during training.

Dataset	Model	Doc. (%)	Sen. (%)
Episode Descriptions	Sentence-level BERT	86.4	94.9
	BERT + Change Point	**89.6**	95.4
	BERT + BiLSTM-CRF	87.6	95.0
Transcripts (Gold)	Sentence-level BERT	43.1	88.7
	BERT + Smoothing	**49.1**	90.9
Transcripts (Silver)	Sentence-level BERT	60.8	96.6
	BERT + Smoothing	**66.7**	97.0

Table 4: Classification accuracy of sentence-level and document-level extraneous content detection. Documents come from either the dataset of full episode descriptions, or from transcript segments corresponding to dip regions. A document EC-match occurs when *all* sentence labels agree; this is difficult to achieve with longer segments.

4.2 Document-Level Classification

We classify sentences independently, but extraneous content comes as contiguous groups of sentences. We apply non-parametric kernel regression to post-hoc smooth the sequence of individual sentence classification probabilities in the transcripts. We observe that extraneous content within episode

---

[1] https://spacy.io

[2] https://huggingface.co/bert-base-cased

[3] The two sentences are concatenated. In BERT, we include the SEP token to separate them. Where there is no preceding sentence, we use a special `__START__` token.

descriptions often appears as a contiguous block at the end, prompting us to apply a change point detector (Appendix A.3) on the sentence classification probabilities in order to detect the start of the EC block.

We also formulate the problem as sequence tagging at the sentence level, in order to allow the model to learn the label dependencies. For this, we use the BERT pooled sentence embeddings as input to a separate BiLSTM-CRF model. The BiLSTM-CRF improves over sentence-level classification but underperforms the change point detection strategy (Table 4). In future work, we would like to investigate an end-to-end BERT-BiLSTM-CRF model (Dai et al., 2019) or sequential sentence classification models (Cohan et al., 2019).

Expanded Transcript Dataset Since the manually labeled gold set is small, we create a larger silver dataset from 6401 detected listener dips across 4930 episodes by applying the best performing classifier trained on the gold data. To encode information about the dip locations to aid the model, we prepend special tokens 'in-dip' and 'outside-dip' to each sentence depending on whether the sentence lies within a listening dip.

We strip special tokens from the resulting silver set. This data is then used to train a final classifier that can detect extraneous content regions in podcast transcripts *without* listener dips. We also add a negative sample of sentences that are distant (by at least 5 minutes) from dips in the same episodes, with the assumption that these are likely to be topical.

On the same test set as the previous experiments, the document and sentence level performance increases (Table 4), proving the model benefits from the larger, albeit noisy, training set. This model is applied to the corpus in the downstream task described below.

5 Application to Podcast Summarization

We address the problem of automatically generating episode descriptions from podcast transcripts, a task similar to abstractive summarization. Within this problem, we evaluate the downstream effect of removing extraneous sentences from the training and/or test data. Alternatives to removal (such as using the model's predictions as auxiliary inputs in the downstream system) are left for future work.

We experiment with two supervised abstractive summarization models both built using BART (Lewis et al., 2020). The first experiment uses a model pretrained for summarization on the CNN/DailyMail dataset[4] (Hermann et al., 2015). This model (which we refer to as BART-CNN) evaluates the extent to which extraneous text in the transcripts contribute to the presence of extraneous content in the generated descriptions. In the second experiment, we fine-tune BART-CNN on our corpus of podcasts, similar to the work of Zheng et al. (2020), using the episode transcripts as inputs and descriptions as targets. We refer to this model as BART-PODCASTS; with it, we can evaluate the effects of EC as realistic noise which may contaminate the training data of summarization models.

5.1 Experimental Setup

From the original corpus of 105,360 podcast shows, 6401 were used for training and evaluation of the two EC detection models. We filter the remaining episodes for descriptions which are distinctly short or long. The resulting dataset contains 84,451 episodes sorted by episode publication date. This is split into 82,451 episodes for training, 1000 for validation, and 1000 for evaluation.

As a baseline, we manually remove extraneous content from the episode descriptions within the test set, comparing the ROUGE score of the model outputs against the manually-cleaned descriptions as well as against the original descriptions. Additionally, we manually validate whether the generated outputs for 150 random test episodes contain extraneous content.

5.2 Results

Table 5 shows the full ROUGE-L scores of our experiments. We evaluate quality through ROUGE as well as by manually verifying for the presence of extraneous content in the outputs. BART-CNN is an out of the box summarization model, while BART-PODCASTS is the same model that is fine-tuned on our data of transcripts and descriptions. All numbers are reported on the test split of the corpus. The range of these ROUGE scores is comparable to previous podcast summarization work. Removing extraneous content is clearly beneficial for summary quality: while the baseline models have better ROUGE scores against the original (EC-containing) descriptions, the highest scoring models score better against the clean descriptions compared to the originals. With the original data, both

	M1	0.269	0.309	0.247	0.308	0.280	0.260	8.7
	M3	0.323	0.276	0.261	0.367	0.247	0.263	15.5
	M4	0.330	0.281	0.269	0.376	0.261	0.268	2.0

Table 5: Evaluation of the effect of extraneous content detection on a downstream summarization task. Accuracies are reported in terms of recall, precision, and F1 score. The models are provided with data pre-processed through one of four EC removal strategies: (M1) cleaned test descriptions, (M2) cleaned test transcripts, (M3) cleaned training descriptions, or (M4) cleaned descriptions and transcripts for both train and test.

BART-CNN and BART-PODCASTS tend to generate descriptions that contain extraneous material. Interestingly, BART-PODCASTS, being trained on the unmodified descriptions, produces even *more* extraneous content (73.2 %) than the corresponding original descriptions (50.0 %), often generating ads unrelated to the actual sponsors, and nonexistent URLs. While post-processing only the output summaries with no change to the model inputs is effective at minimizing extraneous content, it does so at the expense of summary quality, since the resulting summaries are significantly shortened. The best overall performance comes from detecting extraneous content on transcripts and descriptions before model training and application.

6 Conclusion

We introduced the problem of detecting extraneous content in podcast descriptions and transcripts, presented models that leverage textual and listener data, and evaluated them on a downstream summarization task.

We consider our models to be baselines for a new problem with several opportunities for future work. Although we used two separate models for the descriptions and transcripts with the view that the language patterns are different, a joint model or shared components may be able to take advantage of some of the common vocabulary. One could leverage the 'boilerplate' nature of some types of extraneous content like ads by detecting repeated sentences and phrases across the corpus. A language model that is robust to noisy speech transcripts (Lin et al., 2019; Chuang et al., 2019) may improve accuracy on podcast transcripts. Given that extraneous content may appear as pre-recorded audio, or with a different speaking pitch and cadence, acoustic features alongside textual ones may be helpful.

7 Acknowledgments

We thank Ann Clifton and Jussi Karlgren for valuable assistance with the summarization model and evaluations, Richard Mitic, Laurence Pascall, Skylar Brannon, Kristie Savage, and Karishma Gulati for collaborating on identifying listening dips from user logs, Iftekhar Tanveer for helpful discussions, and the anonymous EACL reviewers for their suggestions.

A Appendix

A.1 Annotation Process and Annotated Examples

Examples of extraneous content regions of episode descriptions are shown in Table 6. and example of annotated listener 'dip' regions in the podcast transcripts in Table 7. The categorization into types is only for illustrative purposes and is not used in our model.

A.2 Model Training and Evaluation Details

We modified the sentence splitter in SpaCy to include `---`, `...` and the three-space string as delimiters for episode descriptions, based on our observations of common patterns. Speech recognition errors/disfluencies and missing punctuation contribute to a small amount of noise in the sentence segmentations of transcripts and descriptions respectively.

For the bag of words models, we used `https://scikit-learn.org/` implementations with the default parameters and no hyper-parameter tuning.

For all Transformer models, we used the Huggingface library (Wolf et al., 2020). For summarization, we set the maximum length of the target descriptions as 250 tokens for training and generation, and the minimum length to 30 tokens. The models were trained for up to 5 epochs, with early stopping based on ROUGE-2 on the validation set. All other hyperparameters were set as the defaults specified in the Huggingface Transformers code.

For evaluation, we use the FILES2ROUGE implementation (`https://github.com/pltrdy/files2rouge`), after tokenizing both the reference and the outputs using the Moses tokenizer (`https://github.com/alvations/sacremoses`).

A.3 Change Point Detection for Episode Descriptions

As shown in Eq. 1, we can find a position $\hat{\tau}$ which maximizes the negative log-likelihood ratio R_τ of H_1 as the existence of the change point versus H_0 as no change point.

$$\hat{\tau} = \arg \max_{1 \leq \tau \leq N} R_\tau \tag{1}$$

We make the assumption that (1) there is only one change point, and (2) extraneous content appears at end the descriptions. The null hypothesis is that there is no changepoint, while the alternative hypothesis assumes that there is a changepoint at the time $t = \tau$. Here is the hypothesis test:

$$H_0 : \theta_1 = \theta_2 = ... = \theta_{N-1} = \theta_N \tag{2}$$

$$H_1 : \theta_1 = ... = \theta_{\tau-1} = \theta_\tau \neq \theta_{\tau+1} = ... = \theta_N \tag{3}$$

Therefore, the likelihood is given by the probability of observation the data $x = x_1,...,x_n$ conditional on H_0. In other words,

$$L(H_0) = p(x|H_0) = \prod_{i=1}^{N} p(x_i|\theta_i) \tag{4}$$

And the the likelihood of the alternative hypothesis is,

$$L(H_0) = p(x|H_1) = \prod_{i=1}^{\tau} p(x_i|\theta_i) \prod_{j=\tau+1}^{N} p(x_j|\theta_j) \tag{5}$$

The log-likelihood ratio R_τ is then,

$$\begin{aligned} R_\tau &= \log \frac{L_{H_0}}{L_{H_1}} \\ &= \sum_{i=1}^{\tau} \log p(x_i|\theta_1) + \sum_{j=\tau+1}^{N} \log p(x_j|\theta_2) \\ &\quad - \sum_{k=1}^{N} \log p(x_k|\theta_0) \end{aligned} \tag{6}$$

Abstract

Expressive text encoders such as RNNs and Transformer Networks have been at the center of NLP models in recent work. Most of the effort has focused on sentence-level tasks, capturing the dependencies between words in a single sentence, or pairs of sentences. However, certain tasks, such as argumentation mining, require accounting for longer texts and complicated structural dependencies between them. Deep structured prediction is a general framework to combine the complementary strengths of expressive neural encoders and structured inference for highly structured domains. Nevertheless, when the need arises to go beyond sentences, most work relies on combining the output scores of independently trained classifiers. One of the main reasons for this is that constrained inference comes at a high computational cost. In this paper, we explore the use of randomized inference to alleviate this concern and show that we can efficiently leverage deep structured prediction and expressive neural encoders for a set of tasks involving complicated argumentative structures.

1 Introduction

Many discourse-level NLP tasks require modeling complex interactions between multiple sentences, paragraphs or even documents. For example, analyzing opinions in online conversations (Hasan and Ng, 2013; Sridhar et al., 2015) requires modeling the dependencies between the opinions in individual posts, the disagreement between posts in long conversational threads and the overall view of users, given all their posts.

Learning in these settings is extremely challenging. It requires highly expressive models that can capture the claims made in each document, either by using a rich, manually crafted feature set, or by using neural architectures to learn an expressive representation (Ji and Eisenstein, 2014; Niculae et al., 2017). In addition, reasoning about the interaction between these decisions is often computationally challenging, as it requires incorporating domain-specific constraints into the search procedure, making exact inference intractable. As a result, most current work relies on highly engineered solutions, which are difficult to adapt. Instead of training structured predictors that model the interaction between decisions during training, they combine locally trained classifiers at test time (Stab and Gurevych, 2017).

Our goal in this paper is to study realistic settings, in which discourse-level problems can be learned efficiently when leveraging *deep structured prediction*, a framework for combining rich neural representation with an inference-layer, forcing consistency between them (Zheng et al., 2015). These models were applied successfully to simpler NLP tagging tasks (Lample et al., 2016), in which inference is tractable. However, as shown in a recent argumentation mining work (Niculae et al., 2017), their applicability to more complex learning tasks is not guaranteed.

Randomized inference algorithms have been proposed for structured NLP tasks, such as tagging and dependency parsing, in the context of linear models (Zhang et al., 2014, 2015; Ma et al., 2019). This approach offers an efficient alternative to exact inference. Instead of finding the optimal output state, the algorithm makes greedy updates to a randomly initialized (or locally initialized) output assignment state. Our main contribution is to explore these ideas in the context of deep structured models composed of expressive text encoders, where theoretical guarantees are weak or nonexistent. Moreover, we do this for discourse-level tasks involving a rich set of domain constraints. To do this, we consider two variations of this approach. In the first, the

---

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1174–1184
April 19 - 23, 2021.

algorithm samples and traverses only legal states (i.e., consistent with the constraints imposed by domain knowledge). In the second, these restrictions are ignored and only applied at test time. Adapting the sampling procedure to the specific constraints imposed by each domain is difficult, motivating the second approach as a generic alternative.

We focus on two discourse-level tasks, stance prediction in discussion forums, described above, and parsing argumentation structures in essays (Stab and Gurevych, 2017). The latter consists of constructing an argumentation tree that represents the type-of, and relation-between, the arguments made in the essay. Models for both tasks typically employ declarative inference for incorporating domain knowledge. Our experiments are designed to quantify the trade-off between different modeling choices, both in terms of task performance and computational cost. We compare exact ILP models, approximate inference based on the popular AD^3 algorithm (Martins et al., 2015) and the two randomized inference algorithms. Our experiments show that in all cases, deep structured prediction outperforms traditional shallow approaches, structured learning outperforms inference over locally trained models, and generic randomized inference performs competitively to exact inference.

2 Related Work

Using deep structured prediction for NLP has been studied in previous work, typically on traditional sentence-level tasks such as dependency parsing (Chen and Manning, 2014; Weiss et al., 2015), transition systems (Andor et al., 2016), named entity recognition (Lample et al., 2016) and sequence labeling systems (Ma and Hovy, 2016). In most of these cases, inference is tractable. More recently, some efforts have started to look at incorporating deep structured prediction to discourse tasks such as argument mining (Niculae et al., 2017), event and temporal relation extraction (Han et al., 2019) and discourse representation parsing (Liu et al., 2019). In all of these cases, constrained inference is formulated as an integer linear program and solved either using off-the-shelf optimizers or approximation algorithms like AD^3 (Martins et al., 2015).

Randomized approximation has been introduced as an alternative to exact inference. Zhang et al. (2014) suggest a simple randomized greedy inference algorithm and empirically demonstrate its effectiveness for dependency parsing and other traditional NLP tasks (Zhang et al., 2015). The theoretical results in (Honorio and Jaakkola, 2016), based on the probably approximately correct Bayes framework, characterize these findings by providing generalization bounds. More recently, Ma et al. (2019) extended the work of (Zhang et al., 2014, 2015) to structured prediction tasks with large structured outputs by leveraging local classifiers to find good starting solutions and improve the accuracy of search. All of these methods were evaluated on linear structured models.

In this paper, we focus on two tasks: mining argumentative structures in essays and stance prediction in online debates. Stab and Gurevych (2017) approach argumentative essays using an exhaustive set of hand-crafted features, linear local classifiers and ILP at test time. Niculae et al. (2017) jointly learn to score multiple decisions while enforcing domain constraints. They explore structured SVMs and RNNs, using the AD^3 inference algorithm (Martins et al., 2015). On the other hand, there are several works on predicting user stances in online debates. Some approaches model the problem as a text classification task (Somasundaran and Wiebe, 2010; Sun et al., 2018), while other approaches take a collective approach to model user behavior and interactions (Walker et al., 2012; Hasan and Ng, 2013; Sridhar et al., 2015; Li et al., 2018). In the latter case, inference procedures include MaxCut, ILP and probabilistic soft logic (Bach et al., 2017).

3 Modeling

We look at two challenging structured prediction problems that deal with long texts where dependencies span across different paragraphs, documents and authors. To deal with these setups, we define neural factor graphs $G = \{\Psi\}$ where each decision $\psi_i \in \Psi$ is associated with a neural architecture ρ_i and a set of parameters $\boldsymbol{\theta}_i$. In this section, we introduce the tasks in detail.

3.1 Argument Mining

This task aims to identify argumentative structures in essays. Each argumentative structure forms a tree, and there is a forest per document. Nodes correspond to spans of text in the document and they can be labeled either as *claims, major claims* or *premises*. Edges correspond to stances (i.e., support/attack relations between nodes). The spans of texts are given, and we need to label nodes, predict which pairs of nodes are connected by an edge and label the edges. Domain knowledge can be exploited as there are only valid edges between pairs of premises, a premise and a claim, or a claim and a major claim. At the same time, all trees are rooted at major claims. Similarly to previous work, we model second order relationships: **grandparent** ($a \rightarrow b \rightarrow c$) and **co-parent** ($a \rightarrow b \leftarrow c$) (Martins and Almeida, 2014; Niculae et al., 2017).

Figure 1 has a visual representation of the structure. In this problem, each forest defines a factor graph Ψ and G is the collection of all documents. We define a set of five neural architectures corresponding to the five types of decisions that we need to make: $NN = \{\rho_{\text{node}}, \rho_{\text{link}}, \rho_{\text{stance}}, \rho_{\text{grandparent}}, \rho_{\text{coparent}}\}$, each with its own set of parameters $\boldsymbol{\theta} = \{\theta_{\text{node}}, \theta_{\text{link}}, \theta_{\text{stance}}, \theta_{\text{grandparent}}, \theta_{\text{coparent}}\}$. Note that in principle, we can substitute each (ρ_i, θ_i) with any neural architecture. We include details about the architectures in the experimental section.

3.2 Stance Prediction

Given a debate thread on a specific political issue, the task is to predict the stance of each post w.r.t. the issue (e.g., pro-life or pro-choice on abortion) (Walker et al., 2012). Following previous work, we model the problem as a collective classification task and consider all posts in a given thread. To do this, we add the task of predicting stance agreement between consecutive posts. As observed in Figure 1, each thread forms a tree, where users participate and respond to each other's posts. For a thread labeling to be valid, we need to enforce consistency between the node and edge labels.

In this case, each discussion thread defines a factor graph Ψ and G is the collection of threads. We define two neural architectures $NN = \{\rho_{\text{stance}}, \rho_{\text{agreement}}\}$, each with its own set of parameters $\boldsymbol{\theta} = \{\theta_{\text{stance}}, \theta_{\text{agreement}}\}$. As in the previous setup, each (ρ_i, θ_i) can be substituted by any neural architecture, more details are outlined in the experimental section.

4 Learning

We learn a joint neural model that uses inference during training to ensure consistency across all decisions. Let Ψ be a factor graph with potentials $\psi_i \in \Psi$ over all possible structures Y. Let $\boldsymbol{x_i}$ be the input vector to potential ψ_i. Let $\boldsymbol{\theta} = \{\theta^i\}$ be

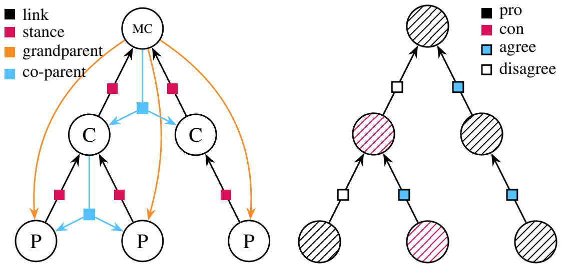

Figure 1: Argument Mining (left), Stance Prediction (right)

a set of parameter vectors associated with a set of neural networks $\boldsymbol{\rho} = \{\rho_i\}$, and $\rho_i(\boldsymbol{x_i}, \boldsymbol{y_i}; \theta^i)$ is the score for potential ψ_i resulting from a forward pass. Here $\boldsymbol{y} \in Y$ corresponds to the gold structure and $\hat{\boldsymbol{y}} \in Y$ to the prediction resulting from the MAP inference procedure:

$$\begin{aligned} \arg\max_{\boldsymbol{y} \in Y} \sum_{\psi_i \in \Psi} \rho_i(\boldsymbol{x_i}, \boldsymbol{y_i}; \theta^i) \\ s.t.\ c(\boldsymbol{x_c}, \boldsymbol{y_c}) \ \ \forall c \in C \end{aligned} \tag{1}$$

Where C is a set of domain-specific constraints defined over the factor graph Ψ, and $\boldsymbol{x_c}, \boldsymbol{y_c}$ indicates inputs and variables relevant to the constraints. In this work, we experiment with different algorithms to obtain or approximate the $\arg\max$, including the randomized procedures outlined in Section 5.

To learn $\boldsymbol{\theta}$, we use the structured hinge loss $L(\boldsymbol{x}, \boldsymbol{y}, \hat{\boldsymbol{y}}; \boldsymbol{\theta})$ defined as:

$$\begin{aligned} \max\Big(0, \max_{\hat{\mathbf{y}} \in Y}\big(\Delta(\boldsymbol{y}, \hat{\boldsymbol{y}}) + \sum_{\psi_i \in \Psi} \rho_i(\boldsymbol{x_i}, \hat{\boldsymbol{y}}_{\boldsymbol{i}}; \theta^i)\big) \\ - \sum_{\psi_i \in \Psi} \rho_i(\boldsymbol{x_i}, \boldsymbol{y_i}; \theta^i)\Big) \end{aligned} \tag{2}$$

Where $\Delta(\boldsymbol{y}, \hat{\boldsymbol{y}})$ is the Hamming loss. To introduce the Hamming loss into the objective, we perform loss augmented inference. The pseudo-code for the structured learning procedure can be observed in Algorithm 1. We implemented our models using DRaiL (Pacheco and Goldwasser, 2020), a declarative deep structured prediction framework built on PyTorch, and extended it to support our randomized inference procedures[1].

5 Randomized Inference

In this section, we describe the randomized inference procedure used for each task. We define the

return $\boldsymbol{\theta}^{\text{ret}}$
```

relevant domain constraints for each case, and explain how we sample solutions that respect them. Finally, we include a discussion about the theoretical bounds for the linear case.

5.1 Argument Mining

For randomized inference on argument mining, we adapt the randomized greedy algorithm proposed by Zhang et al. (2014). Algorithm 2 outlines the overall procedure. We will consider that each paragraph $p \in P$ of an essay contains a single tree. We obtain a local optimum tree $\hat{y}$ by using the hill climbing algorithm, which is further described below. After that, $\hat{y}$ is labeled and added to the forest Y. We iterate over each paragraph (line 4) and subsequently score the forest as:

$$\bar{\mathcal{S}}(Y) = \sum_{\hat{y} \in Y} \mathcal{S}(\hat{y}) = \sum_{\hat{y} \in Y} w + h \, \|y - \hat{y}\|_1 \quad (3)$$

Where $w = \sum_{\psi_i \in \Psi} \rho_i(\boldsymbol{x_i}, \hat{\boldsymbol{y}}_{\boldsymbol{i}}; \theta^i)$ is the sum of the scores of the potentials for the predicted tree $\hat{y}$. We add a weighted Hamming distance term to the scoring function in order to additionally penalize the score the more the tree structure differs from the gold structure. $h \, \|y - \hat{y}\|_1$ gets close to w if the distance is low, and close to zero if it is high.

Algorithm 2 Randomized Inference

```
1:  $\hat{Y} \leftarrow \{\}$
2:  for number of restarts do
3:      $Y \leftarrow \{\}$
4:      for each $p \in P$ do
5:          $\hat{y} \leftarrow$ hill_climbing($p$)
6:          label($\hat{y}$)
7:          $Y \leftarrow Y \cup \{\hat{y}\}$
8:      if $\bar{\mathcal{S}}(Y) > \bar{\mathcal{S}}(\hat{Y})$ then
9:          $\hat{Y} \leftarrow Y$
10: return $\hat{Y}$
```

More specifically, let $\|y - \hat{y}\|_1$ be in $[0, 1]$, e.g., by dividing the number of node and edge differences by the total number of nodes and edges. In its simplest form, h can be assigned to $-w$, and thus $\mathcal{S}(\hat{y})$ would become w if $y = \hat{y}$ or 0 if they differ in every node and edge. Whenever the score of the locally improved forest is better than the forest found so far, Y becomes the new currently best scoring forest $\hat{Y}$. Since hill climbing might get stuck in a local optimum, we repeat line 3-9 for a constant number of restarts.

Algorithm 3 Hill Climbing

```
$\hat{y}_0 \leftarrow$ initialize tree randomly for paragraph $p$
label($\hat{y}_0$)
$\hat{y} \leftarrow \hat{y}_0$
$t \leftarrow 0$
repeat
    $\mathcal{L} \leftarrow$ top-down level node list of $\hat{y}$
    for $i = 1, ..., |\mathcal{L}|$ do
        for $j = i - 1, ..., 0$ do
            $\hat{y}_{t+1} \leftarrow$ connect subtree of $\mathcal{L}_i$ to $\mathcal{L}_j$
            label($\hat{y}_{t+1}$)
            if $\mathcal{S}(\hat{y}_{t+1}) > \mathcal{S}(\hat{y})$ then
                $\hat{y} \leftarrow \hat{y}_{t+1}$
            $t \leftarrow t + 1$
until no improvement in this iteration
return $\hat{y}$
```

Algorithm 3 describes the hill climbing procedure. It initially draws uniformly a tree $\hat{y}_0$ at random. Then the greedy algorithm applies local updates on $\hat{y}_t$ and attempts to achieve a better scoring tree $\hat{y}_{t+1}$. This is done by iterating through a top-down level node list $\mathcal{L}$ of $\hat{y}_t$. Denote i as the current position in the list, then the entire subtree of $\mathcal{L}_i$ is connected to the node $\mathcal{L}_j$, whereas $j = i - 1, i - 2, \ldots, 0$. If the score of $\hat{y}_{t+1}$ is higher than the score of $\hat{y}_t$, the newly generated tree is kept. The algorithm continues until the score can no longer be improved and therefore yields a local optimum tree. Figure 2 depicts how such local

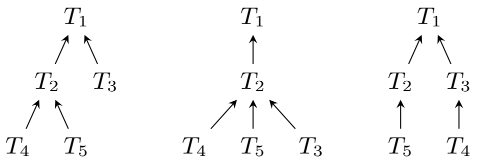

Figure 2: Greedy local update of a tree $\hat{y}_t$ (left) to $\hat{y}_{t+1}$ and $\hat{y}_{t+2}$ without score improvement

updates are performed, $\mathcal{L} = (T_1, T_2, T_3, T_4, T_5)$.

It might be the case that a paragraph contains more than a single tree, therefore, when a tree is initially drawn at random, we introduce an additional *phantom node* which serves as the new root. This modification no longer restricts hill climbing on trees only. Moreover, it allows us having multiple roots and we treat the second layer of the tree like the top layer.

Domain Specific Constraints: For node labeling, we exploit domain knowledge. *Major claims* can only occur in the first or last paragraph, and there has to be at least one major claim in each essay. A root gets labeled as major claim with some fixed probability depending on the paragraph (first or last), holding the condition that there has to exist at least one. Any other root is labeled as a *claim* in each paragraph. Nodes having an edge to a major claim are labeled as claims as well. All remaining nodes are *premises*. An edge can have either the label *support* or *attack* and we draw all edge labels randomly with a probability of 0.9 being a support label. The node and edge labels are determined after each iteration since scoring depends on both, links and labels.

In Section 6, we evaluate our models using randomized inference with and without domain specific constraints. In the latter case, all labels are chosen at random.

5.2 Stance Prediction

A debate thread provides a fixed structure, thus nodes and links are predefined and no improvement of the tree structure needs to be done. However, nodes and edges still need to be labeled and can be improved. Initially, we pick the node labels, which can either be *pro* or *con*. Following the observations made by Ma et al. (2019), we leverage local classifiers and greedily chose the label with the highest score for each node.

Domain Specific Constraints: To respect the dependencies between node and edges labels, we use the following heuristic: If two consecutive nodes u and v have different stances, the edge (u, v) receives a *disagreement* label, if they share the same stance, (u, v) gets an *agreement* label. When author constraints are considered as well, we additionally force stances of posts to be equal when written by the same author.

We attempt to improve node labels by flipping them randomly and subsequently adjust the edge labels. This is done until an iteration no longer improves the overall score. We restart the algorithm for a constant number of times in order to increase the chance of achieving a global optimum. In the experiments, we evaluate our models using randomized inference with and without domain specific constraints. When constraints are not used, a random node is flipped and its adjacent edge adjusted, without enforcing consistency in the whole tree.

The error of the *constrained* randomized algorithms can be bound for the linear case. Let's define the norm of the set of parameter vectors $\boldsymbol{\theta}$ as follows: $\|\boldsymbol{\theta}\| = \sqrt{\sum_{\theta^i \in \boldsymbol{\theta}} \|\theta^i\|^2}$, where $\|\theta^i\|$ is the Euclidean norm of the parameter vector θ^i. Let n be the number of training samples. From Theorem 2 and Claim ii in (Honorio and Jaakkola, 2016), for $\rho_i(\boldsymbol{x_i}, \boldsymbol{y_i}; \theta^i)$ linear in θ^i, the generalization bound (i.e., the difference between the test error and training error) is on the order of $\|\boldsymbol{\theta}\|^2/n + \|\boldsymbol{\theta}\|/\sqrt{n} + \max(1/\log 2, \|\boldsymbol{\theta}\|^2) \log^{3/2} n/\sqrt{n}$. The above generalization bound is decreasing in n, and increasing in $\|\boldsymbol{\theta}\|$, which suggests the use of a large training set, and the penalization of the norm $\|\boldsymbol{\theta}\|$ during learning. In our experiments, we show that in practice we can obtain competitive results by implementing the randomized algorithms for the non-linear case.

6 Experiments

We learn our models using four different inference procedures: (1) **ILP** defines the inference problem as an integer linear program and uses the Gurobi solver[2] to perform exact inference, (2) **AD^3/ILP** translates the ILP program into an AD^3 instance to perform approximate inference, (3) **Rand-C** uses the randomized method with domain constraints, and (4) **Rand** uses the randomized method without domain constraints. Note that we always use exact inference to evaluate on both the development and test sets. For completeness, we add an entry **AD^3**

---

[2] `https://www.gurobi.com/products/gurobi-optimizer`

where we use AD^3 for both training and testing. When using ILP or AD^3, the domain constraints are expressed declaratively.

All experiments were run on a 32 core 3.2Ghz Intel Xeon CPU machine with 128GB RAM and an NVIDIA GeForce GTX 1080 Ti 11GB GDDR5X GPU. We performed an exhaustive search for hyperparameters on the development set. We tuned the learning rate (lr $\in$ {1e-6, 2e-6, 5e-6, 1e-5, 2e-5, 5e-5, 1e-4, 2e-4, 5e-4, 1e-3, 2e-3, 5e-3, 1e-2, 2e-2, 5e-2, 1e-1}), patience (p $\in \{5, 10, 15, 20\}$), and number of restarts (r $\in \{1, 5, 10, 15, 20, 30, 50, 100\}$). The weight decay was fixed at 1e-5 (PyTorch's default). We found that results were stable for local and global models, for different sets of constraints and across inference algorithms.

6.1 Argument Annotated Persuasive Essays

Dataset: We used the UKP dataset (Stab and Gurevych, 2017), consisting of 402 documents, with a total of 6,100 propositions and 3,800 links (17% of pairs). We use the train/dev/test splits used by Niculae et al. (2017), and report macro F1 for components and positive F1 for relations.

Learning and Representation: We did 5 repetitions and reported the average performance. Each repetition used a different seed to initialize the model parameters. For training, we used stochastic gradient descent, a patience of 10, weight decay of 1e-5, and 5 restarts for randomized inference. For local models, we used a learning rate of 0.05 and for structured learning we used a learning rate of 1e-4. Similarly to previous work on deep structured prediction (Han et al., 2019), we obtained better results by performing structured learning over locally trained models, instead of training them from scratch. To represent the component and the essay, we used a BiLSTM over the words, initialized with GloVe embeddings (Pennington et al., 2014), concatenated with a feature vector following Niculae et al. (2017), without the word features. For representing the relation, we use the components, as well as the relation features used in Niculae et al. (2017). For shallow models, we use a bag-of-words representation for the text and concatenate it with the rest of the features into a single feature vector. Both the feature extraction and the neural implementations are available in the repository.

We test two versions of the model: (1) **Base** includes node labeling, link prediction and link labeling, and (2) **Full** adds grandparent and co-parent factors. Domain constraints are introduced in all models.

Model	Inference	Node	Link	Avg	Stance
Local	–	70.7	52.8	61.7 (60.7)	63.4
	L+I	76.5	56.9	66.7 (66.5)	62.5

	Rand	83.4	**63.2**	**73.3** (65.9)	68.4

Table 1: F1 for argument mining using **deep structured prediction**, Avg results using **shallow** models included in parenthesis

We can analyze the results across three dimensions:

Structured Learning: The advantage of leveraging more structural dependencies can be seen in Table 1. The model gets increasingly better as more dependencies are considered, and using global learning outperforms learning local models and using inference just at prediction time (L+I).

Deep vs. Shallow: There is a consistent trend showing that deep structured models are more expressive than their shallow counterparts, as we can see by comparing average results in Table 1. To obtain good results using linear classifiers, Stab and Gurevych (2017) relied on an exhaustive set of features (Table 2). These numbers cannot be replicated by using just word-features and the feature set suggested by Niculae et al. (2017), as our shallow models and their structured SVM results show. In contrast, deep models and word embeddings are able to leverage this information without additional features. In addition, we find that deep models have a shorter overall training time (3.3x faster for the full model). This can be attributed to the compact embedding representation used in deep models, in contrast to the large sparse one-hot vectors used in linear models. Similarly to previous work (Niculae et al., 2017), we find that higher-order factors and strict constraints are more helpful when using deep structured models than in their shallow counterparts.

Model	Node	Link	Avg
Human upper bound	86.8	75.5	81.2
ILP Joint (Stab and Gurevych, 2017)	82.6	58.5	70.6
Struct RNN strict (Niculae et al., 2017)	79.3	50.1	64.7
Struct RNN full (Niculae et al., 2017)	76.9	50.4	63.6
Struct SVM strict (Niculae et al., 2017)	77.3	56.9	67.1
Struct SVM full (Niculae et al., 2017)	77.6	60.1	68.9
Joint PointerNet (Potash et al., 2017)	84.9	60.8	72.9

Deep Full Rand-C	**83.8**	62.6	73.2
Deep Full Rand	83.4	**63.2**	**73.3**

Table 2: Previous work on UKP Dataset

Randomized vs. ILP/AD3: When using deep structured prediction, we did not find a statistically significant difference in the performance of the models that were trained with ILP/AD3 vs. the ones that were trained with constrained and non-constrained randomized inference.

We obtain competitive results with respect to previous work that relies on the same underlying embeddings or features, as observed in Table 2. Recently, Kuribayashi et al. (2019) were able to further improve performance by exploiting contextualized embeddings that look at the whole document, instead of embedding the arguments in isolation, and by making a distinction between argumentative markers and argumentative components. We attempted document-level contextualized embeddings using BERT and were not able to replicate their success[3]. Moreover, we found no significant improvement on the structured prediction models when replacing our BiLSTM encoders with either BERT or document-level BERT. We leave the exploration of an effective way to leverage contextualized embeddings for future work. As for stance prediction, Stab and Gurevych (2017) identify stances over the resulting structure and obtain a macro F1 of 68.0. Our full models obtain commensurate results, 69.2, 68.4 for ILP and randomized inference, respectively.

6.2 Debate Stance Prediction

Dataset: We use a subset of the 4FORUMS dataset from the Internet Argument Corpus (Walker et al., 2012), which consist of a total of 418 discussion threads on four political issues, containing 24,658 posts. We use the same splits as (Li et al., 2018). Most previous work reports accuracy. However, given that labels are highly imbalanced, we also report macro F1.

Learning and Representation: We model the problem as a collective classification task by predicting disagreement between consecutive posts in a given thread. We represented posts using a BERT encoder. For disagreement, we just represented pairs of posts without additional information. We do 5-fold cross validation and report the average performance. For training, we used AdamW, weight decay of 1e-5, a patience of 3, and 50 restarts for randomized inference. For local models, we used a learning rate of 5e-5 and for structured models we used a learning rate of 2e-6. For structured learning, we initialize the parameters using the local models. Note that we keep fine-tuning BERT during training.

Model	Infer.	A		E		GM		GC

Table 5: Previous work on 4FORUMS (Post Acc)
*Note that (Li et al., 2018) use author profile information in their models, whereas we only look at text

Table 5 compares our models to previous work on this dataset. Sridhar et al. (2015) use probabilistic soft logic (PSL) to learn a global assignment for the post labels. They use local classifiers to obtain the input scores to PSL. The main difference between their approach and ours is that we are able to backpropagate the global error back into the classifiers, and we find that it improves performance considerably. Even though we use BERT encoders in our structured procedure, we can see that BERT alone is not able to solve the task. Lastly, we compare to the structured representation learning method of Li et al. (2018) and find that we are able to improve on abortion and gay marriage only. Note that these two are the issues with more data available (8,000 and 7,000 posts respectively). The main difference with their approach and ours is that they push author profile information into the learned representation. We hypothesize that this is key to obtain good performance for gun control, which contains only 4,000 posts.

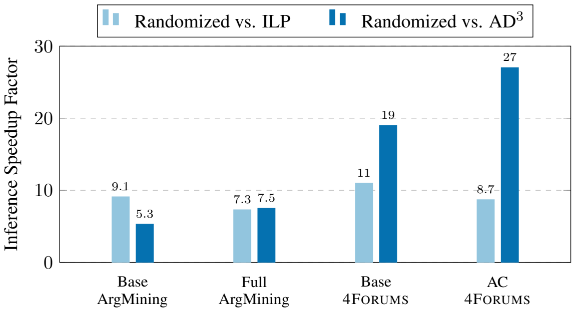

Figure 3: Comparing inference speedup per epoch

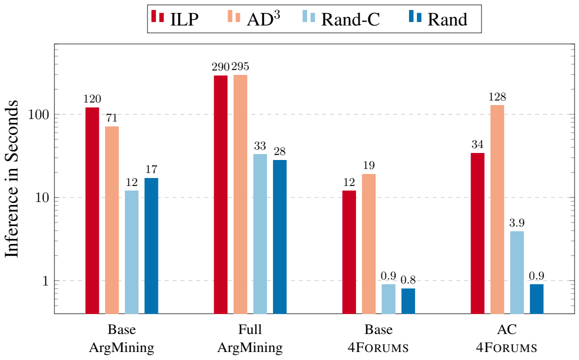

Figure 4: Pure inference runtime in seconds

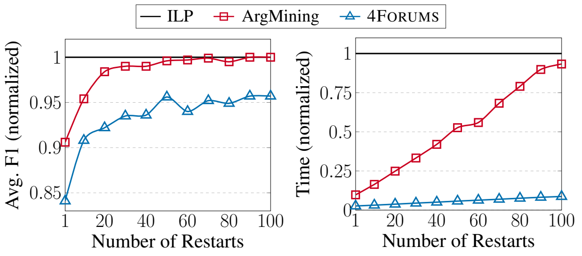
6.3 Inference Analysis

In our experiments, randomized inference always outperforms ILP and AD^3 in terms of runtime. Figure 3 shows the speedup factor per epoch against ILP and AD^3. In argument mining, AD^3 is faster than ILP, except on our full model, where both perform similarly. We noticed that ILP consumes a lot of time in initialization and encoding. The randomized inference approach is able to predict argumentative structures 9.1x faster than ILP for our base model, and 7.5x faster than AD^3 for our full model. For stance prediction on 4FORUMS, ILP is considerably faster than AD^3, we presume that this is due to the fact that Gurobi is a highly optimized commercial software, and our graphs are small. Randomized inference is 11x faster than ILP on the base model and beats AD^3 by a factor of 27 when author constraints are used.

We also measured pure inference time over five training runs and took the average. Figure 4 shows (in logarithmic scale) plain inference runtime in seconds on the training set for all of our models. We can observe that randomized inference without domain constraints has almost the same performance as the constrained version. Again we find that randomized inference considerably outperforms ILP and AD^3.



(a) (b)

Figure 5: Impact of performance and runtime depending on the number of restarts for randomized inference

Additionally, we evaluated our model at test time by replacing exact inference with randomized inference, incrementally increasing the number of restarts. Figure 5 shows the performance and runtime of the Rand-C algorithm with respect to exact inference $\left(\text{i.e., } \frac{\text{Rand-C}}{\text{ILP}}\right)$. Figure 5a shows that the global optimum is closely approached after just 20 restarts for the argument mining task, as opposed to stance prediction on 4FORUMS, where a higher number of restarts is required. This is in line with our reported results in Sections 6.1 and 6.2. Figure 5b shows that randomized inference is about twice as fast than ILP when using 50 restarts for the Argument Mining task, and it starts to approach the time needed for ILP after 100 restarts. On the other hand, the randomized algorithm on 4FORUMS continues to be an order of magnitude faster even when doing 100 repetitions. Note that as the number of restarts keeps increasing, the randomized procedure will eventually surpass the time needed to perform exact inference.

7 Summary

We studied the effectiveness of randomized inference for deep structured prediction and obtained positive results for two challenging discourse-level tasks. We showed that, in practice, we can train complex structured models, using expressive neural architectures, and get competitive results at a lower computational cost. Moreover, we saw that combining expressive representations and inference is a promising direction for modeling discourse-level structures. Future directions include expanding the discussion to other tasks involving more complex structures, as well as exploring shared representations across different sub-tasks.

Automatic Data Acquisition for Event Coreference Resolution

Prafulla Kumar Choubey and Ruihong Huang

Texas A&M University
`(prafulla.choubey, huangrh)@tamu.edu`

Abstract

We propose to leverage lexical paraphrases and high precision rules informed by news discourse structure to automatically collect coreferential and non-coreferential event pairs from unlabeled English news articles. We perform both manual validation and empirical evaluation on multiple evaluation datasets with different event domains and text genres to assess the quality of our acquired event pairs. We found that a model trained on our acquired event pairs performs comparably as the supervised model when applied to new data out of the training data domains. Further, augmenting human-annotated data with the acquired event pairs provides empirical performance gains on both in-domain and out-of-domain evaluation datasets.

1 Introduction

Event coreference resolution aims to determine and cluster event mentions that refer to the same real-world event. It is a relatively less studied NLP task despite being crucial for various NLP applications such as topic detection and tracking, question answering, and summarization.

A typical event coreference resolution system relies on scoring similarity between two event mentions in a document followed by clustering. However, event coreference chains are very sparsely distributed and only certain key events are repeated in a document, which makes manually labeling many event coreference relations very time-consuming. Furthermore, event mentions tend to appear in extremely diverse contexts and few are accompanied by a full set of their arguments. The two challenges, the absence of abundant human-annotated event coreference data and the high diversity of contexts containing coreferential event mentions, make it hard to build effective event coreference resolution systems.

We aim to improve the effectiveness of event coreference resolution systems by automatically acquiring coreferential event pairs from many documents requiring minimal supervision. Specifically, coreferential event mentions are associated with discourse function of sentences in a news document (Choubey et al., 2020)[1]. We propose to use them to identify sentence pairs that are likely to contain coreferential event mentions as well as sentence pairs that are likely to contain non-coreferential event pairs. Consider the two example sentence pairs below, each pair having an event pair with synonymous trigger words.

(1): [People living in absolute poverty in rural areas of the eight regions and provinces **reduced** to 14.52 million from 30.76 million over the last decade.] [Yang admitted , however , that ethnic minority regions still lagged far behind the developed eastern regions and the government still faced serious challenges to **reduce** poverty.]

(2): [At least 30,000 war-displaced people camped in Angola's central province of Kwanza-sul are being **resettled** in productive areas, the official news agency angop reported here on Friday.] [The **resettlement** is being carried out jointly by the local municipal authorities of Seles, located in southern Kwanza-sul, and the charity organization German Agro Action, the news agency said.]

In example (1), the first sentence describes a historical event about the reduction in poverty during the last decade, while the second sentence projects the challenges of further reducing poverty in the coming years. Here, the two *reduce* events are non-overlapping in the temporal space and are non-coreferential. On the contrary, in example (2), both mentions for the event *resettle* refer to the same real-world event and can be so ascertained by knowing that both sentences describe the same main

---

[1] The discourse roles are roughly based on the Van Dijk's theory of news discourse (Teun A, 1986). It assigns discourse function to sentences in a news article, where the function is characterized by the operative role of sentence's content in describing the main event, context informing events, and other historical or future projected events

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1185–1196
April 19 - 23, 2021.

event in a news article. In general, we can recognize pairs of sentences in news articles that are likely to contain coreferential or non-coreferential event mention pairs by knowing the sentence's discourse function following Van Dijk's theory.

To ascertain our hypothesis, we first use the discourse profiling system and dataset introduced by Choubey et al. (2020) to identify the discourse role for each sentence in a news article. Then, we use multiple rules to capture the distributional correlation between event coreference chains and discourse roles of sentences and collect a diverse set of 9,210 coreferential and 232,135 non-coreferential event pairs[2]. To assess the reliability of the proposed data augmentation strategy, we perform manual validation on subsets of both coreferential and non-coreferential event pairs. Then, we train event coreference resolution systems using the acquired data alone or using the acquired data to augment a human-annotated training dataset.

We evaluate trained systems on two datasets, the news portion[3] of the widely used benchmark evaluation corpus KBP 2017 as well as the news portion[4] of the Richer Event Description (RED) corpus (O'Gorman et al., 2016). Unlike the KBP corpora that only consider eight event types for event coreference annotations, the RED corpus comprehensively annotates all the event types that appear in a document, and is arguably the only comprehensively annotated corpus of event coreference relations. Assuming the automatically acquired event coreference data is not available, we also train a supervised event coreference resolution system using the KBP 2015 corpus[5]. On the KBP 2017 corpus, the event coreference resolution system trained on the acquired data performs slightly worse than the system trained using the KBP 2015 corpus, the human-annotated in-domain training data. But, on the RED corpus, both the systems trained on either the annotated KBP 2015 corpus or the acquired data obtain roughly the same evaluation results. Further, the system trained on combined annotated KBP 2015 and automatically acquired data yields the best results on both the KBP 2017 dataset and the RED dataset.

Lastly, we evaluate all the trained systems on a different text genre, discussion forum articles from the KBP 2017 corpus, and found that all the systems obtain comparable results. Overall, the performance gain of all the trained systems on discussion forum documents is marginal compared to a simple trigger word match baseline. Thus, increasing training data size does not improve the performance of an event coreference resolution system on a new text genre. We suspect that, for generalization across different text genres, we may require specialized learning algorithms, e.g., text style adaptation, which is not in the scope of this work.

2 Related Work

The existing literature on supervised event coreference resolution primarily focuses on designing pairwise classifier based on the surface linguistic features such as lexical features comprising of lemma and part-of-speech tag similarity of event words (Bejan and Harabagiu, 2010; Lee et al., 2012; Liu et al., 2014; Yang et al., 2015; Lu et al., 2016; Cremisini and Finlayson, 2020), argument overlap (Chen et al., 2009; McConky et al., 2012; Sangeetha and Arock, 2012; Bejan and Harabagiu, 2014; Yang et al., 2015; Lu et al., 2016; Choubey and Huang, 2017), semantic similarity based on lexical resources such as wordnet (Bejan and Harabagiu, 2010; Liu et al., 2014; Yu et al., 2016) and word embeddings (Yang et al., 2015; Choubey and Huang, 2017; Kenyon-Dean et al., 2018; Barhom et al., 2019; Zuo et al., 2019; Pandian et al., 2020; Sahlani et al., 2020; Lu et al., 2020), and discourse features such as token and sentence distance (Liu et al., 2014; Cybulska and Vossen, 2015). The resulting classifier is used to cluster event mentions. The commonly used strategies include *agglomerative clustering* that selects the antecedent closest in mention distance that is classified as coreferent or the antecedent with the highest coreference likelihood (Chen et al., 2009; Chen and Ng, 2014), hierarchical bayesian (Yang et al., 2015) or spectral clustering algorithms (Chen and Ji, 2009). In this work, we use the pre-trained BERT model to extract both event and context features and use agglomerative clustering to form event coreference chains.

Supervised models suffer from a lack of human-

---

[2] The acquired coreferential and non-coreferential event pairs can be found at `https://github.com/prafulla77/Event-Coref-EACL-2021`

[3] All the KBP corpora include news articles as well as documents from discussion forums.

[4] In addition to news articles, the RED corpus contains several other types of documents, including news summaries, discussion forum posts, and web posts.

[5] We only use the news articles from KBP 2015 to train the supervised system.

annotated event coreference data. To address the annotation scarcity problem, Peng et al. (2016) proposed to learn structured event representations on large amounts of text and use the similarity score between two event representations to form event coreference chains. Their model uses a small human-annotated event coreference dataset to find the appropriate similarity score threshold for linking two events. Unsupervised models based on probabilistic generative modeling have also been successfully used for event coreference resolution (Bejan and Harabagiu, 2010; Chen and Ng, 2015). However, both semi-supervised and unsupervised approaches have been found empirically lagging behind the supervised models (Lu and Ng, 2018).

The closest to our work are weakly-supervised and self-training methods that have been shown useful for many information extraction and classification tasks (Riloff, 1996; Riloff and Wiebe, 2003; Xie et al., 2019). But, to the best of our knowledge, we are the first to explore discourse-aware strategies to automatically label event coreference relations and use them exclusively or use them to augment existing human-annotated data for training event coreference resolution systems.

3 Event Coreference Data Acquisition

To acquire coreferential event-pairs without direct supervision, we first collect event trigger words along with their potential set of coreferential event mentions using The Paraphrase Database (PPDB 2.0) (Ganitkevitch et al., 2013; Pavlick et al., 2015)[6]. Then, we use high precision rules informed by the functional news discourse structures (Teun A, 1986; Choubey et al., 2020) to identify seed coreferential and non-coreferential event pairs followed by a single bootstrapping iteration to collect additional non-coreferential event pairs.

3.1 Identifying Coreferential Event Trigger Candidates using The PPDB Database

We collect lexically diverse candidate coreferential event pairs using the paraphrases from PPDB-2.0-s-lexical (Pavlick et al., 2015) database. The corpus[7] contains 213,716 highest scoring lexical paraphrase pairs, each annotated with one of the equivalence, forward or reverse entailment, and contradiction relation classes. First, we extract all the *verb* paraphrase pairs as the potential event trigger words. While event mentions can take other part of speech types, we limit our paraphrase pairs to verbs to ensure high precision among the collected event trigger words. Additionally, many of the verb paraphrase pairs include nominalization (e.g., investing and investment), which adds to the syntactic diversity in the event pairs without compromising their quality. Then, among all verb paraphrase pairs, we filter out only three relation classes, namely *equivalence*, *reverse entailment* and *forward entailment*, as the potential coreferential event pairs. The forward and reverse entailment relations characterize hyponym and hypernym relations, which are not semantically equivalent but can often be coreferential and thus, add diversity to the pairs. Finally, we manually remove noisy event trigger words and cluster the remaining event pairs through pivoting, based on a common event trigger word shared between two paraphrase pairs[8]. Overall, we obtain 1023 clusters with an average of 3.375 event trigger words per cluster.

3.2 Post-Filtering Paraphrase-based Event Pairs using Functional News Discourse Structure

To generate the news discourse structure proposed by Van Dijk (Teun A, 1986; Van Dijk, 1988a,b) and specify the discourse role of a sentence with respect to events in the document, we use the discourse profiling system proposed by Choubey et al. (2020). Note that the above discourse structure is functional (Webber and Joshi, 2012) and does not specify relations between two discourse units. Instead, it classifies each sentence in a document into one of the eight content types. Each content type describes the specific role of a sentence in describing the main event, context informing events, and other historical or future projected events.

The eight content types include *main event* (M1) sentences that describe the most newsworthy event of a news article. Sentences describing events that happen recently and act as triggers for the main event and events that are triggered by the main event constitute the *previous event* (C1) and *consequence* (M2) sentences respectively. The remaining context-informing events and states with temporal co-occurrence with the main event are

---

[6] A contemporary work by Meged et al. (2020) has also studied the potential correlation between coreferential event trigger words and predicate paraphrases.

[7] `http://nlpgrid.seas.upenn.edu/PPDB/eng/ppdb-2.0-tldr.gz`

[8] The processed event clusters are available at `https://git.io/JtnMf`

covered in *current context* (C2) sentences. In addition to the above four content types, a news article may contain sentences describing lesser relevant events such as *historical events* (D1) that temporally precedes the main event by months and years, *anecdotal events* (D2) that are unverifiable personal account of incidents, *evaluation* (D3) containing reactions from immediate participants, experts or known personalities and *expectation* (D4) that projects the possible consequences of the main event.

Among the eight content types, events described in *main event* sentences are central to the main news topic. They routinely appear in headline and sentences of other content types and consequently are more likely to form event coreference chains. On the contrary, events in the *historical event* content type are restricted to describing certain historical background and might only be mentioned once in the document. Additionally, events mentioned in *previous event* sentences tend to happen before those in *main event* and *consequence* sentences, and are unlikely to be coreferential with the events from the later two content types. Overall, content types provide cues for determining whether the events from a certain sentence possess coreferential event mentions and we leverage them to locate both coreferential and non-coreferential event pairs in a news article. Our event coreference data acquisition method works in two phases.

Rule-based Filtering to extract Coreferential and Non-coreferential Event Pairs: In the first phase, we extract both coreferential and non-coreferential event mention pairs based on their respective rules. Specifically, two event mentions from the headline or main event sentences with synonymous event trigger words are identified as coreferential event pairs. Considering that coreferential event mentions are very sparsely distributed, simple trigger-word matching is extremely noisy and damaging when used to train an event coreference classifier. However, narrowing coreferential event mention pairs to synonymous event trigger words from main event sentences or headline significantly eliminates false coreferential event pairs. To get non-coreferential event pairs, we require both trigger words to be non-synonymous and belong to either the same sentence or two sentences of different non-main content types. Further, considering that events in historical event sentences tend to precede the main event by months and years, we identify non-synonymous event pairs with one mention in a historical event sentence and another mention in a main event sentence as non-coreferential. The latter rule allows us to also acquire non-coreferential event pairs with one event from main event sentences, adding to the overall diversity of the acquired dataset.

Distilling Non-coreferential Event Pairs with Synonymous Trigger Words: All the non-coreferential event pairs acquired in phase one have non-synonymous trigger words. However, we know that many of the synonymous words are non-coreferential. Therefore, to further diversify the acquired event coreference data, we use the second-phase bootstrapping to extract non-coreferential pairs with synonymous trigger words. We once again leverage the temporal separation between historical and other content types. We first identify synonymous event pairs that have one mention in a historical sentence and another mention in any non-historical sentence as candidate non-coreferential pairs. Then, we use an event coreference classifier trained on the dataset extracted in phase one to filter out high scoring non-coreferential event pairs (likelihood ≥ 0.9) from the candidate pairs.

3.3 Statistics of Acquired Coreference Data

We use Xinhua news articles[9] from the English Gigaword (Napoles et al., 2012) corpus to acquire coreferential and non-coreferential event pairs using the proposed methodology. We limit the number of coreferential and non-coreferential event pairs for each trigger word to 20 and 200, respectively, to ensure diversity and reduce repetitions of common event trigger words. We compare our acquired event pairs with the KBP 2015 corpus, which has 179 news documents annotated with eight event types and 38 event subtypes. It is the most widely used corpus for training a within-document event coreference resolution system. Table 1 shows the number of event pairs obtained in the first and second phases of our data acquisition strategy and the human-annotated KBP 2015 corpus. Overall, the total number of extracted coreferential event pairs is more than twice the number of pairs in news documents from the KBP 2015 corpus. Note that we can increase the number of acquired pairs by expanding the synonymous event

Table 2: Precision (Prec.) and bootstrap 80% confidence interval (80% CI) score of precision for acquired event pairs based on human evaluation.

trigger word list or the unlabeled news article collection.

3.4 Manual Evaluation of Acquired Event Pairs

We randomly selected 300 event pairs from each of the coreferential and non-coreferential samples extracted in the first phase, 100 event pairs from non-coreferential samples distilled in the second phase, and 300 event pairs having synonymous event trigger words to evaluate the proposed data acquisition methodology. Then, we asked a human annotator to validate all the 1000 samples manually.

Table 2 shows the precision and bootstrapped 80% confidence interval of precision for event pairs from each category. Rows 1 and 2 show that only 49% of synonymous event pairs are coreferential while the remaining are non-coreferential. By comparing rows 1 and 3, we can see that limiting coreferential event pairs to the synonymous event trigger words from the headline and main event sentences improves the precision from 49% to 83%. As shown in rows 4 and 5, our rules achieve high precision in identifying non-coreferential event pairs as well, achieving 99.3% for event pairs with non-synonymous trigger words acquired in the first phase and even 93% for event pairs with synonymous trigger words acquired in the second phase. Note that the high precision of non-coreferential event pair identification in both phases is partly due to the distributional sparsity of event coreference chains.

4 Event Coreference Resolution System

We design a neural network-based mention-pair classifier for event coreference resolution. We represent each event pair using 50 context words to the left and right of the first and second event trigger words respectively, and with the maximum of 200 words in between the two event words[10].

Given the event context $(w_1, ., e_1, ., e_2, ., w_n)$, we first transform the context words sequence to word embeddings sequence $(b_{w1}, ., b_{e1}, ., b_{e2}, ., b_{wn})$ using the pre-trained Bert-Large-uncased model (Devlin et al., 2019). Then, we model the semantic associations between two event mentions by measuring similarity between their event embeddings (b_{e1}, b_{e2}) through element-wise product and difference. Further, we obtain context embedding (C) through $maxpool$ operation over the word embeddings sequence to model contextual cues. While the context provides important cues for identifying coreferential event mentions, it may not always be relevant for resolving coreference links. For instance, many event trigger word pairs such as (*"injuries"*, *"recommended"*) are extremely unlikely to exhibit coreferential relations irrespective of their context. Therefore, we use the similarity between event embeddings to control the context input and use them only in the scenarios where event trigger words are likely to possess coreferential link. To achieve so, we apply linear neural layer over element-wise product and differences of two event mention embeddings followed by the $sigmoid$ activation, and multiply them with context embedding C. Finally, we concatenate the resulting set of embeddings and then use a three-layer feed-forward neural network classifier to score the coreference likelihood. The exact formulation of the coreference classifier is described in Eq. 1.

$$\begin{aligned}
(b_{w1}.b_{e1}.b_{e2}.b_{wn}) &= BERT[(w_1.e_1.e_2.w_n)] \in R^{n\times1024} \\
C &= maxpool(b_{w1}, ., b_{e1}, ., b_{e2}, ., b_{wn}) \in R^{1024} \\
s_1 &= sigmoid(W_1^s(b_{w1} \odot b_{w2}) + b_1^s) \in R^{1024} \\
s_2 &= sigmoid(W_2^s(b_{w1} - b_{w2}) + b_2^s) \in R^{1024} \\
R &= [b_{w1} \odot b_{w2}; b_{w1} - b_{w2}; s_1 \odot C; s_2 \odot C] \in R^{4096} \\
\hat{y_i} &= W_3(gelu(W_2(gelu(W_3R + b_3)) + b_2)) + b_3 \in R
\end{aligned} \tag{1}$$

We train the model using binary cross-entropy

---

[10] We take 100 context words to the right and left of the first and second event trigger words respectively when the number of context words in between them exceeds 200.

loss. During inference, we use the best-first clustering approach, where we select the antecedent having the highest pairwise coreference score based on the coreference classifier, to build event chains.

5 Experiments

5.1 Datasets and Evaluation Setup

We use the news documents from the KBP 2016 for validation, and use news documents from KBP 2017 and RED corpora as well as discussion forum documents from the KBP 2017 corpus to evaluate the usefulness of our acquired data[11]. KBP 2016, KBP 2017 and RED corpora contain 85, 83 and 30 news documents respectively, and KBP 2017 has 84 discussion forum documents. KBP corpora have been widely used for evaluating in-document event coreference resolution systems. We further evaluate our models on the RED corpus to examine systems' performance across different event types. KBP 2016 and 2017 corpora are annotated using a subset of 20 subtypes from 38 subtypes used in KBP 2015. On the contrary, RED documents are comprehensively annotated with event coreference relations with no restriction on event types or subtypes, thus, allowing us to evaluate coreference resolution performance on a broad range of events. Besides, we evaluate the performance of models across text genres by evaluating our models trained with news articles on KBP 2017 discussion forum documents.

Following previous work on event coreference resolution, we evaluate all the event coreference resolution systems using the official KBP 2017 scorer v1.8. The scorer employs four coreference scoring measures, namely B^3 (Bagga and Baldwin, 1998), CEAFe (Luo, 2005), MUC (Vilain et al., 1995) and BLANC (Recasens and Hovy, 2011) and the unweighted average of their F1 scores AVG_{F1}. In addition, since MUC directly evaluates pairwise coreference links, we also report MUC precision and recall scores.

5.2 Implementation Details

We use an ensemble of multi-layer feed-forward neural network classifiers to identify event mentions (Choubey and Huang, 2018) for both news and discussion forum documents in KBP 2017 corpus. For the RED corpus, we use gold event mentions as that event extraction system can identify events from only eight event types annotated in KBP 2015 corpus. The coreference classifier uses a three-layer feed-forward neural network with 1024-512-1 units for scoring coreference likelihood. Two single-neural layers, used to transform element-wise dot product and difference between two event embeddings used for controlling context input, use 1024 units each. All hidden activations are followed by dropout with the rate of 0.1 for regularization (Srivastava et al., 2014). All models are trained using AdamW optimizer (Loshchilov and Hutter, 2017; Kingma and Ba, 2014) with four different learning rates (1e-4, 5e-5, 1e-5, 5e-6) and for maximum of 100,000 updates. We use the batch size of 16 and evaluate the model after every 5,000 steps. The epoch and learning rate yielding the best validation performance, average F1 score on KBP 2016 news documents, are used to obtain the final model. Bert model is kept fixed during the training. All experiments are performed on NVIDIA GTX 2080 Ti 11GB using PyTorch 1.2.0+cu92 (Paszke et al., 2019) and HuggingFace Transformer libraries (Wolf et al., 2019).

5.3 Baseline Systems

Trigger Match (+Paraphrase): It links event mentions with the same trigger word (or are lexical paraphrases) as coreferential. Trigger match is a strong baseline for event coreference resolution.

Feature-based Classifier: The neural network classifier that uses GloVe (Pennington et al., 2014) based event trigger word embeddings and binary features indicating argument overlaps.

Choubey and Huang (2018): It models correlations between event coreference chains and document topic structures through a heuristics-based ILP formulation and has achieved the best event coreference resolution performance to date on both KBP 2016 and KBP 2017 datasets.

5.4 Our Systems

KBP 2015, Paraphrase-based pairs, Post-Filtering Paraphrase pairs and KBP 2015+Post-Filtering Paraphrase pairs: The mention pair model, proposed in § 4, trained on different combinations of acquired and human-annotated datasets. *KBP 2015* is trained on event pairs from news docu-

---

[11] ECB+ (Cybulska and Vossen, 2014) is another popular dataset for evaluating event coreference resolution. However, documents in ECB+ are selectively annotated, comprising only of event mentions and within-document coreference chains that are relevant to cross-document event coreference chains. Since our data acquisition methodology is designed for collecting within-document event pairs, we decided to exclude evaluations on the ECB+ corpus.

ments in the KBP 2015 corpus. *Paraphrase-based pairs* is trained on paraphrase event pairs without rules-based filtering (§3.1). *Post-Filtering Paraphrase pairs* is trained on paraphrase event pairs that are filtered using rules defined over news discourse structure (§3.2). *KBP 2015+Post-Filtering Paraphrase pairs* is trained on aggregation of KBP 2015 and Post-Filtering Paraphrase event pairs.

Student Training: The mention pair model trained using the recently proposed self-training approach with a student network (Xie et al., 2019). We first train a teacher mention pair model on the KBP 2015 corpus, then use the teacher model to annotate samples from unannotated news articles. We use the same set of event pairs from Xinhua articles in the Gigaword corpus, set the same upper bound of 20 coreferential and 200 non-coreferential pairs per event trigger word. Also, to allow fair comparisons, we selected only high scoring event pairs (likelihood $\geq$ 0.9) and collected 11,390 coreferential and 272,083 non-coreferential pairs. Finally, we train a new student network with the combined KBP 2015 and teacher-annotated event pairs.

Masked Training: The mention pair model trained on all annotated and automatically acquired (or teacher annotated in case of student training model) event pairs. However, to limit the over-dependence on lexical features[12], we replace both the event trigger words with the *[MASK]* token for all acquired event pairs. Annotated event pairs from KBP 2015 are left unchanged.

5.5 Results and Analysis

The first segment in Table 3 shows the results for all models on KBP 2017 news articles corpus. The mention-pair model trained on KBP 2015 corpus using pre-trained language model and larger event context outperforms both local feature-based as well as the discourse-structure aware previous best model (Choubey and Huang, 2018), outperforming Choubey and Huang (2018) by 2.26 points in average F1 score. The improvement is consistent across all metrics. Specifically, the used mention pair model gains MUC F1 score by 9.76 and 3.33 points over feature-based and discourse aware systems, indicating that BERT-based embedding is more effective in resolving coreference links without exclusively modeling event-arguments or discourse-related features. The model trained on event pairs acquired following the proposed automatic strategy also outperforms Choubey and Huang (2018) by 1.24 and 0.56 points on MUC F1 and average F1 scores respectively. However, this model does worse than the equivalent model trained on KBP 2015 data, which can be explained by the related distribution of KBP 2015 and KBP 2017 datasets. Overall, training the model on KBP 2015 data combined with the acquired event pairs performs the best, outperforming both models trained on KBP 2015 only and the one trained with student training by 1.04 and 0.14 points respectively.

As shown in the second segment of Table 3, the improvement in the average F1 of the model trained on KBP 2015 over the trigger match baseline reduces to 2.3 points on the RED news articles corpus, compared to 5.69 points on KBP 2017 news articles. Mainly, RED annotates all event types while KBP has only 8 event types, and the change in event domains affects the overall performance gain of model. The model trained on our Post-Filtering Paraphrase event pairs performs similarly to the one trained on KBP 2015, implying that the former generalizes similarly to the model trained on human-annotated data when applied to new data out of the training data distribution. Similar to the performance gain on KBP 2017 news articles, combining both KBP 2015 and acquired event pairs improves the average F1 on RED news articles, achieving the highest average F1 gain of 3.98 points against the trigger match baseline. Note that student training also improves performance on RED news articles. However, it is 1.26 points lower on average F1 score than the *KBP 2015+Post-Filtering Paraphrase pairs* model.

In the third segment of Table 3, we compare the performance of all models on a different text genre by evaluating them on the discussion forum documents from the KBP 2017 corpus. With shared event types, the model trained on KBP 2015 achieves the best result with 1.76 points improvement in the average F1 score over the lemma match baseline. The model trained using acquired event pairs, *Post-Filtering Paraphrase pairs*, achieves performance comparable to the model trained on KBP 2015. However, combining the KBP 2015 data with acquired event pairs (the model *KBP 2015+Post-Filtering Paraphrase pairs*) does not further improve the performance. Overall, we observe that none of the models obtain substantial performance improvement. The smaller improvements

Table 3: Results for event coreference resolution systems on the KBP 2017 and RED corpora. Feature-based Classifier results are directly taken from Choubey and Huang (2018). The results are statistically significant using bootstrap and permutation test (Dror et al., 2018) with $p<0.01$ between *Post-Filtering Paraphrase pairs* and *Paraphrase-based Pairs* and $p<0.002$ between *KBP 2015+Post-Filtering Paraphrase pairs+Masked Training* and *KBP 2015* models on both KBP 2017 and RED news articles test sets. Further, results for *KBP 2015+Post-Filtering Paraphrase pairs+Masked Training* are statistically significant compared to both *Student Training* and *Student Training+Masked Training* with $p<0.002$ on the RED news articles test set.

for all models on discussion forum documents, with the increased data size, also indicate the need for specialized learning algorithms to build a model that can generalize to a new text genre.

Post-Filtering Paraphrase Filtering and Masked Training: The model trained on Post-Filtering Paraphrase event pairs outperforms the one trained on paraphrase-based pairs by 2.69 and 5.04 average F1 points on KBP 2017 and RED news articles test sets respectively. Using news discourse structure-based rules to first constrain coreferential event paraphrase pairs within main sentences or headline and then add non-coreferential event paraphrase pairs from historical sentences inhibits the model from exclussively relying on lexical features. Further, masked training helps to completely circumvent any bias induced in a model by limiting coreferential event pairs to lexical paraphrases, which slightly improved the average F1 score.

Distributional Analysis of Predicted Coreferential Event Pairs across different Discourse Content Type Pairs: Finally, we analyze the distribution of predicted coreferential event pairs across sentence pairs with different discourse content types on the validation dataset. We use the gold coreferential event pairs to identify the top 10 content type pairs of sentences that most frequently contain coreferential event mention pairs. Then, for the models trained on KBP 2015, Post-Filtering Paraphrase pairs and their combination with masked training, we report true-positive, false-positive, and false-negative predictions, shown in Figure 1. To ensure uniformity with rules used in

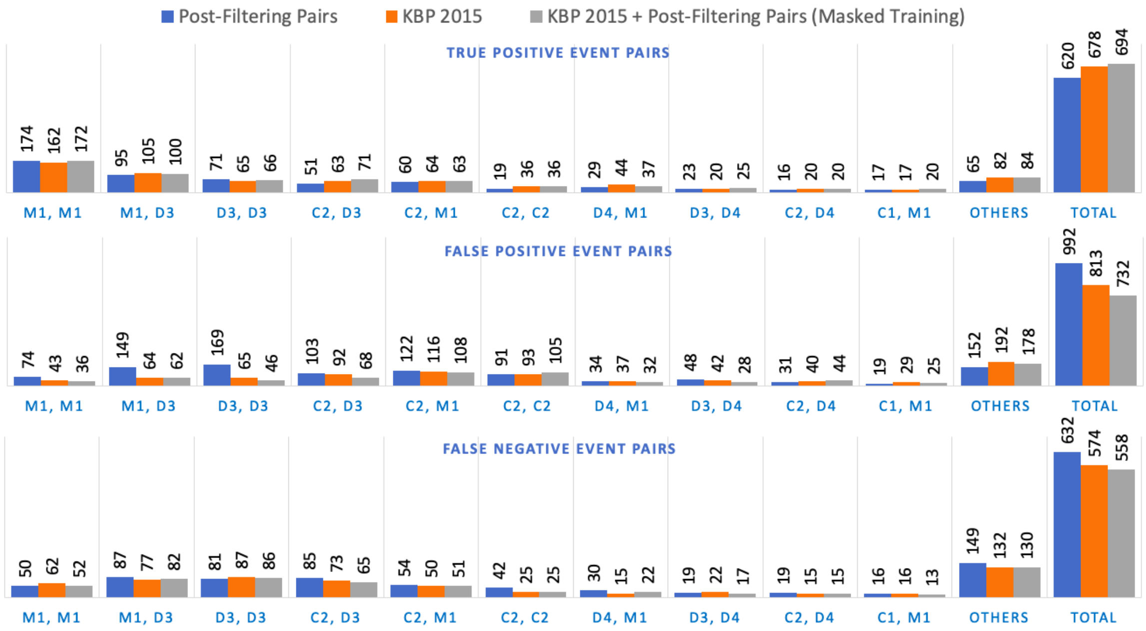

Figure 1: Distributions of Predicted Coreferential Event Pairs across different Discourse Content Type Pairs.

§3.2, we merge the headline with main sentences.

Contrary to the rule that exclusively acquires coreferential event pairs from main sentences or headline, the classifier trained on acquired event pairs predicts coreferential event pairs across all discourse content type pairs. Notably, the Post-Filtering Pairs model predicted a comparable number of coreferential event pairs, 248, 244 and 240, in the (M1, M1), (M1, D3) and (D3, D3) content type pairs respectively. However, the number of true positives in (M1, M1) content pair is more than twice the number in either of the (M1, D3) or (D3, D3). This is expected given that the distribution of gold coreferential event pairs is normally skewed towards (M1, M1).

In comparison, models trained on KBP 2015 or combined KBP 2015 and Post-Filtering pairs have lower false-positives while exhibiting similar distributions for true-positive predictions. Intuitively, despite second phase bootstrapping to include non-coreferential paraphrase pairs, the model trained solely on acquired event pairs focuses on lexical features more than the model trained on human-annotated corpus. On the other hand, masked training effectively overcomes excessive reliance on lexical cues and helps achieve a higher true positive rate without increasing false positives.

6 Conclusions and Future Work

We presented an automatic data acquisition strategy for event coreference resolution by mining the functional news discourse structure. We performed both qualitative and empirical studies to determine the effectiveness of our proposed strategy. We found that the model trained on automatically acquired event pairs performs similarly to the model trained on human-annotated corpus when evaluated on the test set covering general event domains. Further, augmenting acquired event pairs to existing human-annotated data improves the performance of the model on both training-domain and broader domain test sets. For future work, we intend to develop new training algorithms to improve the generalization capability of models on a new text genre. Further, we plan to evaluate a similar event coreference data acquisition strategy for new languages.

Joint Learning of Representations for Web-tables, Entities and Types using Graph Convolutional Network

Abstract

Existing approaches for table annotation with entities and types either capture the structure of table using graphical models, or learn embeddings of table entries without accounting for the complete syntactic structure. We propose TabGCN, which uses Graph Convolutional Networks to capture the complete structure of tables, knowledge graph and the training annotations, and jointly learns embeddings for table elements as well as the entities and types. To account for knowledge incompleteness, TabGCN's embeddings can be used to discover new entities and types. Using experiments on 5 benchmark datasets, we show that TabGCN significantly outperforms multiple state-of-the-art baselines for table annotation, while showing promising performance on downstream table-related applications.

1 Introduction

Table data abounds in webpages and organizational documents. Annotation of table entries, such as columns, cells and rows, using available background knowledge (e.g. Yago, DBPedia, Freebase, etc.), such as knowledge of entities and their types, helps in better understanding and semantic interpretation of such tabular data. The challenge, however, is that such web tables do not adhere to any standard format, schema or convention (Limaye et al., 2010). Additionally, knowledge graphs are typically incomplete - entities and types mentioned in tables may not always exist in the knowledge graph. Therefore, it becomes necessary to expand the knowledge graph with new entities (Zhang et al., 2020) and types for annotating tables.

Initial research on table annotation (Limaye et al., 2010; Takeoka et al., 2019; Bhagavatula et al., 2015) used probabilistic graphical models to capture the complete row-column structure of tables and also the knowledge graph for collective annotation. More recent approaches using embeddings (Gentile et al., 2017; Zhang and Balog, 2018; Zhang et al., 2019; Chen et al., 2019; Yin et al., 2020) only partly capture the syntactic structure of tables, and also ignore the structure of the knowledge graph. The problem of incompleteness of the knowledge representation (Zhang et al., 2020) is mostly not addressed.

In this work, we propose the TabGCN model that uses a Graph Convolutional Network (GCN) (Kipf and Welling, 2017) to unify the complete syntactic structure of tables (rows, columns and cells) and that of the knowledge graph (entities and types) via available annotations. The embeddings of the table elements as well as knowledge graph entities and types are trained jointly and end-to-end. While GCNs have been used for learning embeddings for many NLP tasks using the syntactic and semantic structure of natural language sentences (Marcheggiani and Titov, 2017; Vashishth et al., 2019), encoding tabular structure using GCNs has not been addressed before. The model and embeddings thus trained are used to annotate new tables with known entities and types, while discovering hitherto unseen entities and types. Additionally, we use the trained embeddings for tables and rows for downstream table-related tasks - identifying similar tables, and identifying the appropriate table for any row.

We demonstrate these capabilities of TabGCN using experiments on 5 benchmark web table datasets comparing against 5 existing models. We show that WebGCN significantly improves performance for entity and type annotation. For the other tasks, we show that the same embeddings show impressive performance. No existing model can perform all of these tasks.

Our contributions are as follows: **(a)** We propose a model called TabGCN based on the GCN architecture that captures the complete syntactic structure

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1197–1206
April 19 - 23, 2021.

of tables as well as the knowledge representation, and learns embeddings of tables, rows, columns and cells, as well as entities and types jointly and in an end-to-end fashion. **(b)** TabGCN addresses incompleteness in the knowledge representation by discovering new entities and types. **(c)** TabGCN significantly outperforms 5 existing approaches in 5 different benchmark datasets for the task of table annotation. **(d)** The trained embeddings show impressive performance in downstream tasks such as identifying similar tables and assignment of rows to appropriate tables.

2 Related Work

Existing literature on table annotation considers two different types of tables. In general, web tables (Limaye et al., 2010; Takeoka et al., 2019; Bhagavatula et al., 2015) contain mentions of entities under every column, which need to be annotated. In contrast, relational tables (Gentile et al., 2017; Zhang and Balog, 2018; Zhang et al., 2019, 2020) refer to a single entity in each row, with a single core or anchor column and multiple attribute columns. Here, the entire row is annotated with a single entity. While both tasks are important, our focus is on the first category.

In terms of approaches, one category of work considers graphical models to capture table structure and performs joint inference for entity and type classification (Limaye et al., 2010; Takeoka et al., 2019; Bhagavatula et al., 2015). Limaye et al. (2010) uses a Markov Random Field that captures the structure of tables, and creates dependencies between entity and type annotations to jointly classify entities for cells and types for columns. The Markov Random Field (MRF) potentials capture domain knowledge about similarities between cells, between cells and entity lemmas and between entities using the type hierarchy. It cannot handle entities and types not used as labels during training. MeiMei (Takeoka et al., 2019) extends this MRF framework to handle numeric columns and focuses on multi-label classifiers for entities with multiple types. Additionally, it constructs embeddings of entities and types using knowledge graph structure to avoid expensive graph traversal for computing potential function features. However, it still requires manual construction of these features based on domain knowledge. Our GCN architecture is motivated by the structure of the graphical model in these papers. Both these models also jointly label pairs of columns with known relationships, which we do not address in our work.

The second category focuses on embeddings for tables (Gentile et al., 2017; Zhang and Balog, 2018; Zhang et al., 2019). All of these models transform table data to word sequences and then make use of neural language models. Zhang and Balog (2018) make use of RDF2vec for embedding tables, which internally uses neural language models after transforming graphs to sequences. ColNet (Chen et al., 2019) considers columns as cell sequences and uses a CNN to learn the representations of individual cells, which are used to predict entity types for columns. TaBERT (Yin et al., 2020) focuses on retrieving table rows for natural language utterances and learns a joint representation for utterances and cell sequences in table rows using BERT. In summary, these fail to capture the complete row-column structure of tables in the embeddings. In contrast, our GCN architecture captures the structure of all tables, the entities, the types and the training annotations.

For the problem of extending the knowledge graph from tables, Zhang et al. (2020) consider discovery of new entities, but only in the context of relational tables, with a single core column. Their approach make use of pre-trained neural embeddings (word2vec) and cosine similarity in addition to lexical similarity. Our focus is on web tables, where we need to discover new entities and types for all columns in a table. Our approach makes use of GCN embeddings trained using entity and type labels to detect new entities and types.

3 Problem: Table Annotation

In this section, we first define tables, the background knowledge of entities and types, annotation of tables with entities and types, and, finally, the problem of semi-supervised table annotation with incomplete knowledge.

Tables: We are given a set of tables $\mathcal{S}$. Fig.1 shows an example at the top. The k^{th} table $S^k \in \mathcal{S}$, consists of m^k rows and n^k columns of individual cells. The individual cell in the i^{th} row and j^{th} column of the k^{th} table is denoted as x^k_{ij}. We consider textual tables only, so that each x^k_{ij} takes a string as value. Also, we denote the i^{th} row as R^k_i and the j^{th} column as C^k_j.

Entities and Types: We assume background knowledge of entities and entity types (or simply,

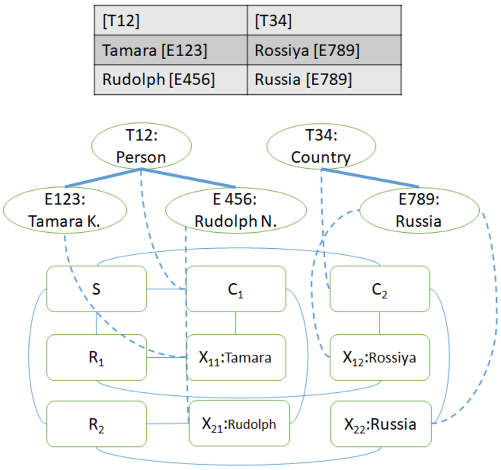

Figure 1: (a) Example table with 2 columns and 2 rows. The column annotations with types and the cell annotations with entities are shown within brackets. (b) GCN graph for example table with table nodes as boxes and entities and types nodes as ovals. Table edges are shown using fine solid lines, entity-type edges with thick solid lines and annotation edges using dashed lines. Lexical similarity edges are typically between cells in different tables and are not shown.

types). Let $\mathcal{T}$ denote the set of types, and $\mathcal{E}$ the set of entities. Each entity E is associated with a type $\mathcal{T}(E)$. For each entity E, there is also an entity description or lemma $\mathcal{L}(E)$. In Fig.1, the oval nodes shows example entities and types. Entity *E123* has associated type *T12:Person* and lemma *Tamara K.*.

Table Annotations: We assume that tables contain information about entities $\mathcal{E}$ and types $\mathcal{T}$. Specifically, each column of each table corresponds to a single type, each cell corresponds to a specific entity of that type. In our example table, cell x_{11} is annotated with entity *E123*, and column C_1 is annotated with type *T12:Person*. Let $\mathcal{T}(C^k_j)$ denote the type associated with column C^k_j, and $\mathcal{E}(x^k_{ij})$ the entity associated with the cell x^k_{ij}. Let A_e be the set of all entity annotations of cells, and A_t that of all type annotations of columns.

Semi-supervised Table Annotation with Incomplete Knowledge: In the semi-supervised table annotation task, we are given the entire set of tables $\mathcal{S}$ but only a subset $A^o_e \subset A_e$ of the entity annotations, and a subset $A^o_t \subset A_t$ of the type annotations are observed. The task is to annotate the unannotated cells and columns of the tables, using the observed annotations as training data.

Let $\mathcal{T}^o$ denote the set of unique types seen in A^o_t, and $\mathcal{E}^o$ the set of unique entities seen in A^o_e. In the *incomplete knowledge setting*, $\mathcal{T}^o \subset \mathcal{T}$, indicating that all the types are not seen in the training annotations. Similarly, all the entities are also not seen in training: $\mathcal{E}^o \subset \mathcal{E}$. Now, the task for the unannotated cells and columns is three-fold. The first is to decide whether these correspond to observed entities A^o_e and observed types A^o_t. We call this *novelty classification*. Next, the non-novel table columns need to be annotated with observed types $\mathcal{T}^o$, and the non-novel table cells with observed entities $\mathcal{E}^o$. We call these *type detection* and *entity detection* respectively. Finally, the columns corresponding to novel types need to be grouped according to distinct novel types, and the cells corresponding to novel entities need to be grouped according to distinct novel entities. We call these *type discovery* and *entity discovery* respectively.

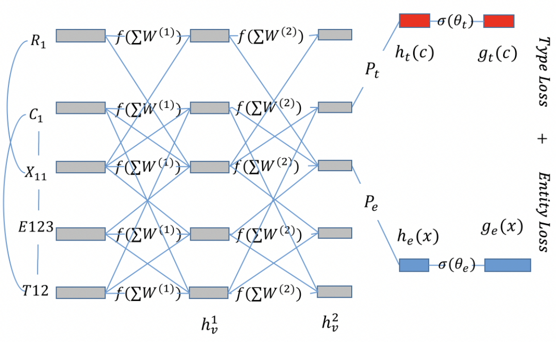

Figure 2: Model architecture showing GCN component with gray nodes, entity classification component with blue nodes and type classification components with red nodes.

4 Joint Table and Knowledge Embedding

We first present at a high level the network architecture of our model, which we call **TabGCN**. The core components TabGCN are (I) a Graph Convolutional Network (GCN), which captures the various syntactic relationships between table and knowledge elements, and then jointly learns embeddings for these via the convolution operation. The GCN embeddings of table elements contain information about both types and entities. These are fed into two parallel components: (II) the Type Classification component, and (III) the Entity Classification component. The Type Classification component first projects the GCN embedding of *table columns* to a *type space* using a *type-projection matrix*, and then uses a soft-max layer to classify this *type embedding* according to observed types. Similarly, the

Entity Classification component first projects the GCN embeddings of *table cells* to an *entity space* using an *entity-projection matrix*, and then uses a soft-max layer to classify this *entity embedding* according to observed entities. Fig.2 shows the high level architecture of our model for a subgraph of our example table graph in Fig.1. The parameters of all three components are trained jointly in an end-to-end fashion using training entity annotations for cells and type annotations for columns via back-propagation. We next describe these components in greater detail.

Graph Convolutional Network: Graph Convolutional Networks (GCN) (Kipf and Welling, 2017; Gilmer et al., 2017) extend the notion of convolution to graphs. Let $\mathcal{G} = (\mathcal{V}, R)$ be a directed graph where $\mathcal{V}$ is the set of n nodes and R the set of directed edges. An edge between nodes $u, v \in \mathcal{V}$ with label L_{uv} is denoted as $(u, v, L_{uv}) \in R$. The edge set includes an inverse edge for each edge and a self-loop for each node. An input feature matrix $\mathcal{X} \in \mathbb{R}^{m\times n}$ contains the input feature representation $x_u \in \mathbb{R}^m$ of each node $\forall u \in \mathcal{V}$ in its columns. Output embedding of a node v at k^{th} layer of GCN is given by

$$h_v^{(k+1)} = f\left(\sum_{u\in\mathcal{N}(v)} W_{L_{uv}}^{(k)} h_u^{(k)} + b_{L_{uv}}^{(k)}\right), \forall v \in \mathcal{V} \tag{1}$$

Here, $W_{L_{uv}}^{(k)}$ and $b_{L_{uv}}^{(k)}$ are label specific model parameters at k^{th} layer and $h_u^{(1)} = x_u$. For classification, a linear classification layer is added on top of final GCN layer. Function $f()$ is a non-linear activation for which we used ReLU.

GCN for Table and Knowledge Elements: Our GCN graph connects table parts, entities and types. We show the GCN graph for our example table in Fig.1. Its node set V consists of **table nodes** (boxes) and **knowledge nodes** (ovals). For each table $S^k \in \mathcal{S}$, the table nodes include one node for each cell x_{ij}^k, one node for each column C_j^k, one node for each row R_i^k, and one node for the table S_k itself. The knowledge nodes include one node for each *observed* type $T^o \in \mathcal{T}^o$ and one node for each *observed* entity $E^o \in \mathcal{E}^o$.

Recall that edges in a GCN serve to bring the embeddings of their end nodes closer, the extent being determined by their weight. With this intuition we create the edges R of different types reflecting the underlying semantics of tables and the annotations. These are **table edges** R_t, **knowledge edges** R_k, **annotation edges** R_a, and **lexical similarity edges** R_l.

Table edges capture the semantics of web tables, which do not have special anchor columns. These are of four categories: a *cell-column edge* between a cell node x_{ij}^k and its corresponding column node C_j^k; a *cell-row edge* between a cell node x_{ij}^k and its corresponding row node R_i^k; a *column-table edge* between a column node C_j^k and its corresponding table node S^k; and a *row-table edge* between a row node R_i^k and its corresponding table node S^k.

Knowledge edges connect each entity node E^o with its corresponding type node $\mathcal{T}(E^o)$.

Annotation edges are of two categories: an *entity annotation edge* for each entity annotation in A_e^o between a cell node x_{ij}^k and its labeled entity node $\mathcal{E}(x_{ij}^k)$; and a *type annotation edge* for each type annotation in A_t^o between a column node C_j^k and its labeled type node $\mathcal{T}(C_j^k)$.

Lexical similarity edges are added between pairs of cells in the same or different tables whose lexical similarity, computed using character-based Jaccard (Limaye et al., 2010), is above a threshold.

All edges are bi-directional. Each of the 8 edge categories above has its own parameters $(W_l^{(k)}, b_l^{(k)})$ for each layer in our GCN. Self loops are added for nodes associated with textual input, specifically, cells and entities with lemmas. For the input representation of such nodes, we use the pre-trained word embeddings for each of their constituent tokens, and take their mean. For this paper we used GloVe (Pennington et al., 2014).

Type Classification: The final (K^{th}) GCN layer generates an embedding $h_v^{(K)}$ for each node v. This contains information about both types and entities. For type classification of a column node c, we first get its *type embedding* $h_t(c)$ by projecting $h_c^{(K)}$ to a *type space* using a *type projection matrix* P_t: $h_t(c) = P_t h_c^{(K)}$. Then we get the probability distribution $g_t(c)$ over known types $\mathcal{T}^o$ for the type embedding $h_t(c)$ using a soft-max layer with weight matrix θ_t: $g_t(c) = \sigma(h_t(c); \theta_t)$. The type projection matrix P_t and the sigmoid weight matrix θ_t form the parameters for this component.

Entity Classification: We follow a similar approach for entity classification of a cell node x. We first project its GCN embedding $h_x^{(K)}$ to an *entity* *space* using an *entity projection matrix* P_e. The *entity embedding* $h_e(x)$ is passed through a soft-max layer with weight matrix θ_e to get the probability distribution $g_e(x)$ over known entities $\mathcal{E}^o$. The entity projection matrix P_e and the sigmoid weight matrix θ_e form the parameters for this component.

Joint Training: The parameters for all three components are trained end-to-end using available entity annotations for cells and type annotations for columns. Specifically, we consider the type predictions $g_t(c)$ for columns and minimize classification loss with the observed entity labels $\mathcal{T}(c)$. We similarly minimize classification loss between entity predictions $g_e(x)$ and observed entity labels $\mathcal{E}(x)$ for cells. We consider a weighted combination of the entity prediction loss and the type prediction loss. We have used cross-entropy as the classification loss function, and Adam (Kingma and Ba, 2015) for optimization.

5 Annotating Tables using Embeddings

Training the network in Sec.4 generates estimates of the model parameters as well as embeddings for all table and knowledge elements. In this section, we describe the use of these parameters and embeddings for the tasks defined in Sec.3. We use $h(v)$ for the GCN embedding of a node v instead of $h_v^{(K)}$ for brevity.

Novelty Classification: To decide whether an unannotated column c corresponds to any of the known types in $\mathcal{T}^o$ (novel type classification), we make use of their type embeddings. Column c corresponds to a new type if its type-space embedding $h_t(c) = P_t h(c)$ is 'far away' from the type space embedding $h_t(T) = P_t h(T)$ for all $T \in \mathcal{T}^o$. More specifically, we use $\delta(\max_{T\in\mathcal{T}^o} \cos(P_t h(c), P_t h(T)) \leq \epsilon_t)$, where ϵ_t is the *novel type threshold*, and $\delta()$ is the Kronecker delta function. A similar approach is followed for deciding if an unannotated cell x corresponds to any of the known entities in $\mathcal{E}^o$ (novel entity classification) by using the entity embeddings. Specifically, we use $\delta(\max_{E\in\mathcal{E}^o} \cos(P_e h(x), P_e h(E)) \leq \epsilon_e)$, where ϵ_e is the *novel entity threshold.*

Type and Entity Detection: Columns and cells determined to be non-novel need to be classified according to known types and entities respectively. This can be done using forward propagation in the trained network on the embeddings of the corresponding nodes. The type prediction $g_t(c)$ of a column c is obtained as $g_t(c) = \sigma(P_t h(c); \theta_t)$. Similarly, the entity prediction $g_e(x)$ of a cell x is obtained as $g_t(x) = \sigma(P_e h(x); \theta_e)$.

Type and Entity Discovery: On the other hand, columns and cells determined to be novel need to be grouped according to distinct new types and entities respectively. This is done by clustering their projections in the appropriate space. Specifically, for type discovery, we take the *type embeddings* $h_t(c)$ of all novel columns c and cluster these. Similarly, for entity discovery, we cluster the *entity embeddings* $h_e(x)$ of all novel cells x. The clustering algorithm needs to automatically determine the number of clusters in both cases. In this paper, we have used Silhouette clustering (Rousseeuw, 1987) as a representative non-parametric clustering algorithm. Other algorithms approaches such as Bayesian non-parametric techniques (Teh, 2010) may be used here.

Down-stream Inference for Rows and Tables: Training annotations are only provided for cells and columns. But embeddings are available for the rows and tables as well after training, and these can be used for different down-stream application tasks. Since these do not involve type or entity spaces, we directly use their GCN embeddings for these tasks. As examples, we define two such tasks here. **Table clustering** is the task of grouping together semantically related tables. For this, we cluster the table embeddings $h(S)$ of all tables $S \in \mathcal{S}$. For consistency, we again use Silhouette clustering. **Row to Table assignment** is the task of assigning a row to its most appropriate table. For this, we assign a row R with embedding $h(R)$ to the table S_k with the 'closest' embedding $h(S_k)$, or, more specifically, to $S^* = \arg\max_{S_k} \cos(h(R), h(S_k))$. If R is a row from a table provided during training, then its embedding is readily available. If it is a new row, then its embedding is created by convolving over the input embeddings of its constituent cells using the trained parameters W_l for cell-row edge.

6 Experiments

In this section, we first present experimental results for table annotation, and then for down-stream table-related tasks. We compare our proposed model **TabGCN** with appropriate state-of-the-art baselines. We have uploaded our source code as supplementary material for reproducibility.

Table 2: Type and Entity Discovery performance using normalized mutual information (NMI) for TabGCN, ColNet and TaBERT. Other baselines cannot address this task. T2DV2 and Wikipedia do not have entity annotations.

Data: We used 5 benchmark web table datasets. Their statistics are shown in Table.4. **Wiki Manual** (Limaye et al., 2010) is a small dataset of simple non-infobox tables from Wikipedia articles. **Web Manual** (Limaye et al., 2010) contains tables fetched by web-crawling using Wiki Manual tables as queries. These two tables are manually annotated with entities and types from YAGO. The tables and annotations are noisier than Wiki Manual. **Limaye** (Chen et al., 2019; Efthymiou et al., 2017) corrects many incorrect annotation in Wiki Manual using entities and types from DBPedia 2015. **T2Dv2** (Chen et al., 2019) contains tables from Common Web Crawl. **Wikipedia** is a publicly available subset of the data used by Efthymiou et al. (2017). This has HTML tables from Wikipedia 2013 with class attribute "wikitable". The last three datasets are annotated using DBPedia. But **T2Dv2** and **Wikipedia** contain *only* type annotations, and entity annotations are not available. For all datasets, we first set aside 30% of the unique entities and types, and effectively all their annotations as unseen during training. Of the remaining annotations, again 30% was removed during training.

Baselines: We compare TabGCN against three existing table annotation approaches. **PGM** (Limaye et al., 2010) uses a probabilistic graphical model and hand-crafted features. Since our entity-type set $\mathcal{T}$ is flat instead of being a hierarchical graph, we use logistic regression instead of structural SVM to estimate model parameters. **MeiMei** (Takeoka et al., 2019) also uses a Markov Random field but embeds the entities and types for fast computation of clique potentials. For both models, we ignore the relation labels for column-pairs and associated potential functions, since we do not address relation detection. **Table2Vec** (Zhang et al., 2019) learns various word2vec-based embeddings for tables for entity annotation. It does not address type annotation. It focuses on relational tables and associates a single entity with a row for its core column. We adapted this model for web tables which associate an entity for each cell. We use their *Table2VecE* version, which models a row as a sequences of all entities that appear within cells of that row. After training the word2vec model, instead of considering the embedding for the entire row as in *Table2VecE*, we create cell-specific embeddings from only the tokens for that cell. **ColNet** (Chen et al., 2019) models each column as a sequence of words from the cells under the column and uses a CNN to predict the column type. We also use an adaptation of TaBERT (Yin et al., 2020) which trains a joint language model for retrieval from tables given utterances. We adapt their approach to independently linearize each row and column of a table as a sequence of cells under that row and column, and get column and row embeddings using the mean of corresponding cell embeddings. For cells, we use pre-trained BERT embeddings.

Hyper-parameters: We used one-hot encodings as inputs for cells and entities with lemmas. We used ReLU as the nonlinear GCN activation, 2 GCN layers with 512 and 256 dimensions. As a result, the 8 GCN weight matrices were Vx512 in the first layer, where V is the vocabulary size,

Table 4: Dataset Statistics: For each dataset, T indictates the number of tables, R the average number of rows per table, C the average number of columns per table, E the number of unique entities and $\mathcal{T}$ the number of unique types used for annotation, E^* the number of new unique entities and $\mathcal{T}^*$ the number of new unique types *not seen* in training annotations.

and 512x256 in the second layer. The entity and type space embeddings had dimension 256, so that the entity and type projection matrices were both 256x256. For training, we used learning rate 0.001, dropout 0.5, 1000 epochs. The weights for combining the type and entity losses was $1 : 2$ for both datasets, optimized manually. All experiments were performed on a Dual-core intel Core i5 Processor with 8GB RAM. The average training time per epoch ranges from 1.3 secs for Wiki Manual to 35.4 secs for T2Dv2.

Detection Results: We first present results for entity and type detection, addressed by most of the baselines. For this task, all models predict entity labels for all cells and type labels for all columns that are unannotated. However, evaluation is *only* for those cells and columns whose true entity and type labels are contained in the observed entities $\mathcal{E}^o$ and observed types $\mathcal{T}^o$ respectively.

For evaluation, as in earlier table annotation papers (Limaye et al., 2010; Chen et al., 2019), we use micro-averaged F1, which takes the weighted average of the F1 scores over the entities or types. This takes class imbalance into account and is therefore more appropriate than accuracy. We note that MeiMei addresses the multi-label setting with multiple possible type labels, and therefore uses ranking evaluation measures (e.g. NDCG). This is not meaningful in our single-labeled setting.

Tab. 1 shows detailed results for all models across datasets. We can see that **TabGCN** significantly outperforms all baselines on all datasets for both detection tasks. The only exception is for Wiki Manual. The graphical model based approaches with handcrafted potential functions outperform the representation learning approaches, possibly on account of the smallness of the dataset. Among the embedding based approaches, TabGCN performs the best.

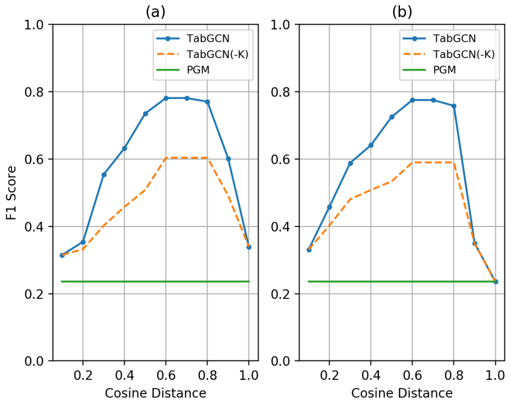

Figure 3: Novelty classification Performance on (a) types and (b) entities for TabGCN, its ablation TabGCN(-K) and PGM for Web Manual, showing F1 on the y-axis and decision threshold on x-axis. PGM does not use a decision threshold. Results on other datasets are very similar. Other baselines cannot address this task.

Novelty Classification Results: In our second experiment, we consider novelty classification. This is an unsupervised task, where a model makes a binary decision for each unannotated column (novel type classification) and for each unannotated cell (novel entity classification). Since the decision depends on the thresholds for type (ϵ_t) and entity (ϵ_e), we plot F1 score on the y-axis against the corresponding threshold on the x-axis. Of the baselines, only PGM can address this task, but outputting a NONE label for the type or entity. Fig.3 shows novelty classification performance for Web Manual. Results for Wiki Manual and Limaye are very similar. **TabGCN** reaches F1 around 0.8 for both tasks for appropriate thresholds. Across thresholds, TabGCN significantly out-

Table 5: Ablation study for entity and type detection showing micro. F1. -K removes knowledge (entity and type) nodes, -E removes entity nodes, -T removes type nodes and -L removes lexical similarity edges.

performs PGM.

Type and Entity Discovery Results: The final annotation tasks are type discovery, where all unannotated columns that do not correspond to known types in $\mathcal{T}^o$ need to be clustered into distinct new types, and entity discovery, where all unannotated cells that do not correspond to known entities in $\mathcal{E}^0$ need to be clustered into distinct new entities. We used Normalized Mutual Information (NMI) $NMI = \frac{2I(C,Y)}{H(C)+H(Y)}$ between the assigned cluster labels (Y) and the true entity or type labels (C), where $I(,)$ denotes mutual information and $H()$ denotes entropy. In Tab. 2, we see that **TabGCN** performs consistently above 80% for entity and type discovery across datasets, significantly outperforming ColNet and TaBERT.

Ablation Study: Next, we analyze the performance of **TabGCN**, using multiple ablations of the full model. **-K** leaves out the knowledge nodes and their incident edges from the GCN graph during training. **-E** focuses only on types by removing all entity nodes and entity-related edges (type-entity and cell-entity annotation) from the GCN graph. It is trained only using type loss. Note that it cannot perform tasks associated with entities, specifically entity detection, novel entity classification and novel entity discovery. Similarly, **-T** focuses only on entities by removing all type nodes and type-related edges (type-entity and column-type annotation) from the GCN graph. It is trained only using entity loss, and cannot perform tasks associated with types. Finally, **-L** removes the lexical similarity edges from the GCN graph. The results are recorded in Table. 5. We can see that all the components of the architecture contribute to performance improvements. The improvement is statistically significant (using the Wilson Interval with $\alpha = 0.05$) for all ablations other than **-K**. While **-K** performs comparably here, its performance drops significantly for novelty classification, as can be seen in Fig.3.

TaBERT	0.76	0.51
TabGCN	**0.89**	**0.81**

Table 6: Table clustering performance using NMI for TabGCN, Tab2Vec and TaBERT on T2Dv2 and Limaye. Other baselines cannot address this task. T2Dv2 has 40 table categories and Limaye 15. Other datasets do not have table categories for evaluation.

Downstream Table Related Tasks: Finally, we include some results for the table and row related inference tasks defined at the end of Sec.5. This is to demonstrate how the learnt embeddings can benefit potential down-stream tasks. Note that TabGCN directly outputs table embeddings. Of the baselines, Tab2Vec and TaBERT output row embeddings. For these models, we create table embeddings by averaging the corresponding row embeddings.

In Tab. 6, we record performance for table clustering. **TabGCN** again significantly outperforms both baselines for both datasets.

We finally consider row-to-table assignment. In this task, one randomly selected row is removed from every table during training. These rows then need to be classified according to their parent table. Since the models output a ranking of tables for each row, we evaluate using two ranking related measures. *Hits@1* measures the fraction of rows with the correct table at rank 1. *Mean Reciprocal rank* (MRR) is the mean of the reciprocal rank of the correct table over all rows, and its perfect value is 1.0. In Tab. 3, we again see that **TabGCN** performs the best across datasets.

In summary, we have demonstrated the usefulness of learning embeddings of table elements and knowledge elements jointly using both entity and type losses in an end-to-end fashion for type and entity annotation on 5 benchmark datasets. In addition, we have demonstrated how the learned embeddings can be useful for downstream table-related tasks. In all cases, **TabGCN** has significantly outperformed multiple state-of-the-art baselines using probabilistic graphical models as well as other neural approaches.

7 Conclusion

We have proposed a model for that jointly learns representations of tables, rows, columns and cell, as well as entities and types by capturing the complete syntactic structure of all tables, the relevant entities and types and the available annotations using the Graph Convolutional Network. As a result, TabGCN unifies the benefits of probabilistic graphical model based approaches and embedding based approaches for table annotation. Using these embeddings, TabGCN significantly outperforms existing approaches for table annotation, as well as entity and type discovery.

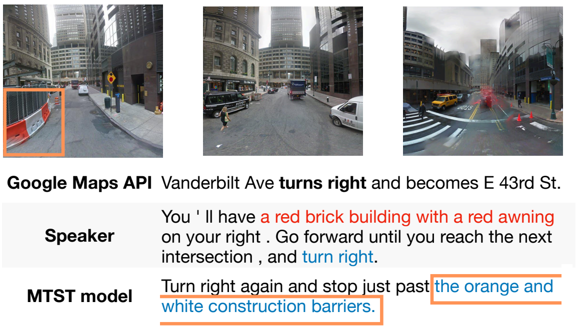
Abstract

One of the most challenging topics in Natural Language Processing (NLP) is visually-grounded language understanding and reasoning. Outdoor vision-and-language navigation (VLN) is such a task where an agent follows natural language instructions and navigates a real-life urban environment. Due to the lack of human-annotated instructions that illustrate intricate urban scenes, outdoor VLN remains a challenging task to solve. This paper introduces a Multimodal Text Style Transfer (MTST) learning approach and leverages external multimodal resources to mitigate data scarcity in outdoor navigation tasks. We first enrich the navigation data by transferring the style of the instructions generated by Google Maps API, then pre-train the navigator with the augmented external outdoor navigation dataset. Experimental results show that our MTST learning approach is model-agnostic, and our MTST approach significantly outperforms the baseline models on the outdoor VLN task, improving task completion rate by 8.7% relatively on the test set. [1]

1 Introduction

A key challenge for Artificial Intelligence research is to go beyond static observational data and consider more challenging settings that involve dynamic actions and incremental decision-making processes (Fenton et al., 2020). Outdoor vision-and-language navigation (VLN) is such a task, where an agent navigates in an urban environment by grounding natural language instructions in visual scenes, as illustrated in Fig. 1. To generate a series of correct actions, the navigation agent must comprehend the instructions and reason through the visual environment.



Google Maps API	Vanderbilt Ave **turns right** and becomes E 43rd St.
Speaker	You ' ll have a red brick building with a red awning on your right . Go forward until you reach the next intersection , and turn right.
MTST model	Turn right again and stop just past the orange and white construction barriers.

Figure 1: An outdoor VLN example with instructions generated by Google Maps API (ground truth), the Speaker model, and our MTST model. Tokens marked in red indicate incorrectly generated instructions, while the blue tokens suggest alignments with the ground truth. The orange bounding boxes show that the objects in the surrounding environment have been successfully injected into the style-modified instruction.

Different from indoor navigation (Anderson et al., 2018; Wang et al., 2018; Fried et al., 2018; Wang et al., 2019; Ma et al., 2019a; Tan et al., 2019; Ma et al., 2019b; Ke et al., 2019), the outdoor navigation task takes place in urban environments that contain diverse street views (Mirowski et al., 2018; Chen et al., 2019; Mehta et al., 2020). The vast urban area leads to a much larger space for an agent to explore and usually contains longer trajectories and a wider range of objects for visual grounding. This requires more informative instructions to address the complex navigation environment. However, it is expensive to collect human-annotated instructions that depict the complicated visual scenes to train a navigation agent. The issue of data scarcity limits the navigator's performance in the outdoor VLN task.

To deal with the data scarcity issue, Fried et al. (2018) proposes a Speaker model to generate additional training pairs. However, synthesizing instructions purely from visual signals is hard, especially for outdoor environments, due to visual complexity.

On the other hand, template-based navigation instructions on the street view can be easily obtained via the Google Map API, which may serve as additional learning signals to boost outdoor navigation tasks. But instructions generated by Google Maps API mainly consist of street names and directions, while human-annotated instructions in the outdoor navigation task frequently refer to street-view objects in the panorama. The distinct instruction style hinders the full utilization of external resources.

Therefore, we present a novel Multimodal Text Style Transfer (MTST) learning approach to narrow the gap between template-based instructions in the external resources and the human-annotated instructions for the outdoor navigation task. It can infer style-modified instructions for trajectories in the external resources and thus mitigate the data scarcity issue. Our approach can inject more visual objects in the navigation environment to the instructions (Fig. 1), while providing direction guidance. The enriched object-related information can help the navigation agent learn the grounding between the visual environment and the instruction.

Moreover, different from previous LSTM-based navigation agents, we propose a new VLN Transformer to predict outdoor navigation actions. Experimental results show that utilizing external resources provided by Google Maps API during the pre-training process improves the navigation agent's performance on Touchdown, a dataset for outdoor VLN (Chen et al., 2019). In addition, pre-training with the style-modified instructions generated by our multimodal text style transfer model can further improve navigation performance and make the pre-training process more robust. In summary, the contribution of our work is four-fold:

- We present a new Multimodal Text Style Transfer learning approach to generate style-modified instructions for external resources and tackle the data scarcity issue in the outdoor VLN task.
- We provide the Manh-50 dataset with style-modified instructions as an auxiliary dataset for outdoor VLN training.
- We propose a novel VLN Transformer model as the navigation agent for outdoor VLN and validate its effectiveness.
- We improve the task completion rate by 8.7% relatively on the test set for the outdoor VLN task with the VLN Transformer model pre-trained on the external resources processed by our MTST approach.

2 Related Work

Vision-and-Language Navigation (VLN) is a task that requires an agent to achieve the final goal based on the given instructions in a 3D environment. Besides the generalizability problem studied by previous works (Wang et al., 2018, 2019; Tan et al., 2019; Zhang et al., 2020), the data scarcity problem is another critical issue for the VLN task, expecially in the outdoor environment(Chen et al., 2019; Mehta et al., 2020; Xiang et al., 2020). Fried et al. (2018) obtains a broad set of augmented training data for VLN by sampling trajectories in the navigation environment and using the Speaker model to back-translate their instructions. However, the Speaker model might cause the error propagation issue since it is not trained on large corpora to optimize generalization. While most existing works select navigation actions dynamically along the way in the unseen environment during testing, Majumdar et al. (2020) proposes to test in previously explored environments and convert the VLN task to a classification task over the possible paths. This approach performs well in the indoor setting, but is not suitable for outdoor VLN where the environment graph is different.

Multimodal Pre-training has attracted much attention to improving multimodal tasks performances. The models usually adopt the Transformer structure to encode the visual features and the textual features (Tan and Bansal, 2019; Lu et al., 2019; Chen et al., 2020; Sun et al., 2019; Li et al., 2019; Huang et al., 2020b; Luo et al., 2020; Li et al., 2020; Zheng et al., 2020; Wei et al., 2020; Tsai et al., 2019). During pre-training, these models use tasks such as masked language modeling, masked region modeling, image-text matching to learn the cross-modal encoding ability, which later benefits the multimodal downstream tasks. Majumdar et al. (2020) proposes to use image-text pairs from the web to pre-train VLN-BERT, a visiolinguistic transformer-based model similar to the model proposed by Lu et al. (2019).

A concurrent work by Hao et al. (2020) proposes to use Transformer for indoor VLN. Our VLN Transformer is different from their model in several key aspects: (1) The pre-training objectives are different: Hao et al. (2020) pre-trains the model on the same dataset for training, while we create an augmented, stylized dataset for outdoor VLN using the proposed MTST method. (2) Benefiting from the effective external resource, a simple navigation loss is employed in our VLN Transformer, while they adopt the masked language modeling to better train their model. (3) Model-wise, instead of encoding the whole instruction into one feature, we use sentence-level encoding since Touchdown instructions are much longer than R2R instructions. (4) We encode the trajectory history, while their model encodes the panorama for the current step.

Unsupervised Text Style Transfer is an approach to mitigate the lack of parallel data for supervised training. One line of work encodes the text into a latent vector and manipulate the text representation in the latent space to transfer the style. Shen et al. (2017); Hu et al. (2017); Yang et al. (2018) use variational auto-encoder to encode the text, and use a discriminator to modify text style. John et al. (2019); Fu et al. (2018) rely on models with encoder-decoder structure to transfer the style. Another line of work enriches the training data by generating pseudo-parallel data via back-translation (Artetxe et al., 2018; Lample et al., 2018b,a; Zhang et al., 2018).

3 Methods

3.1 Task Definition

In the vision-and-language navigation task, the reasoning navigator is asked to find the correct path to reach the target location following the instructions (a set of sentences) $\mathcal{X} = \{s_1, s_2, \ldots, s_m\}$. The navigation procedure can be viewed as a series of decision making processes. At each time step t, the navigation environment presents an image view $\boldsymbol{v}_t$. With reference to the instruction $\mathcal{X}$ and the visual view $\boldsymbol{v}_t$, the navigator is expected to choose an action $a_t \in \mathcal{A}$. The action set $\mathcal{A}$ for urban environment navigation usually contains four actions, namely *turn left*, *turn right*, *go forward*, and *stop*.

3.2 Overview

Our Multimodal Text Style Transfer (MTST) learning mainly consists of two modules, namely the *multimodal text style transfer model* and the *VLN Transformer*. Fig. 2 provides an overview of our MTST approach. We use the multimodal text style transfer model to narrow the gap between the human-annotated instructions for the outdoor navigation task and the machine-generated instructions in the external resources. The multimodal text style transfer model is trained on the dataset for outdoor navigation, and it learns to infer style-modified instructions for trajectories in the external resources. The VLN Transformer is the navigation agent that generates actions for the outdoor VLN task. It is trained with a two-stage training pipeline. We first pre-train the VLN Transformer on the external resources with the style-modified instructions and then fine-tune it on the outdoor navigation dataset.

Source	Instruction
Google Maps API	Head northwest on E 23rd St toward 2nd Ave. Turn left at the 2nd cross street onto 3rd Ave.
Human Annotator	Orient yourself so you are facing the same as the traffic on the 4 lane road. Travel down this road until the first intersection. Turn left and go down this street with the flow of traffic. You'll see a black and white stripped awning on your right as you travel down the street.

Table 1: For the outdoor VLN task, the instructions provided by Google Maps API is distinct from the instructions written by human annotators.

3.3 Multimodal Text Style Transfer Model

Instruction Style The navigation instructions vary across different outdoor VLN datasets. As shown in Table 1, the instructions generated by Google Maps API is template-based and mainly consists of street names and directions. In contrast, human-annotated instructions for the outdoor VLN task emphasize the visual environment's attributes as navigation targets. It frequently refers to objects in the panorama, such as traffic lights, cars, awnings, etc. The goal of conducting multimodal text style transfer is to inject more object-related information in the surrounding navigation environment to the machine-generated instruction while keeping the correct guiding signals.

Masking-and-Recovering Scheme The multimodal text style transfer model is trained with a "masking-and-recovering" (Zhu et al., 2019; Liu et al., 2019; Donahue et al., 2020; Huang et al., 2020a) scheme to inject objects that appeared in the panorama into the instructions. We mask out certain portions in the instructions and try to recover the missing contents with the help of the remaining instruction skeleton and the paired trajectory. To be specific, we use NLTK (Bird et al., 2009) to mask out the object-related tokens in the human-annotated instructions, and the street names

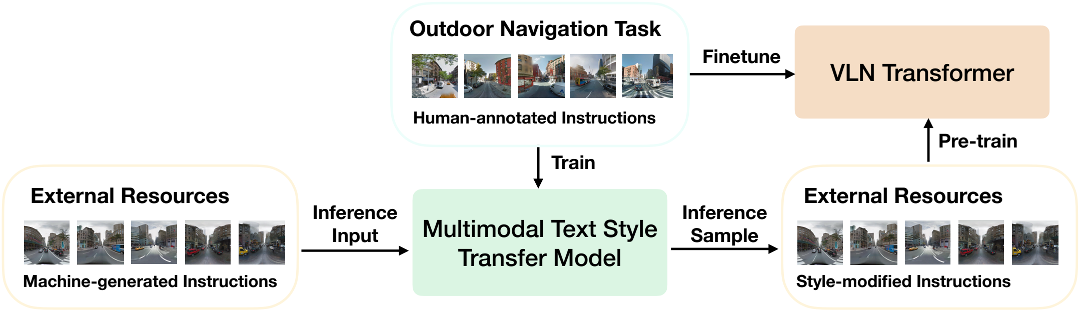

Figure 2: An overview of the Multimodal Text Style Transfer (MTST) learning approach for vision-and-language navigation in real-life urban environments. Details are described in Section 3.2.

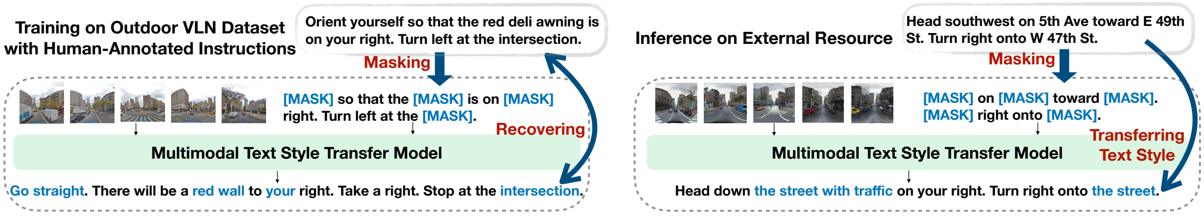

Figure 3: An example of the training and inference process of the multimodal text style transfer model. During training, we mask out the objects in the human-annotated instructions to get the instruction template. The model takes both the trajectory and the instruction skeleton as input, and the training objective is to recover the instructions with objects. When inferring new instructions for external trajectories, we mask the street names in the original instructions and prompt the model to generate new object-grounded instructions.

in the machine-generated instructions[2]. Multiple tokens that are masked out in a row will be replaced by a single [MASK] token. We aim to maintain the correct guiding signals for navigation after the style transfer process. Tokens that provide guiding signals, such as “turn left" or “take a right", will not be masked out. Fig. 3 provides an example of the “masking-and-recovering" process during training and inferring.

Model Structure Fig. 3 illustrates the input and expected output of our multimodal text style transfer model. We build the multimodal text style transfer model upon the Speaker model proposed by Fried et al. (2018). On top of the visual-attention-based LSTM (Hochreiter and Schmidhuber, 1997) structure in the Speaker model, we inject the textual attention of the masked instruction skeleton $\mathcal{X}'$ to the encoder, which allows the model to attend to original guiding signals.

The encoder takes both the visual and textual inputs, which encode the trajectory and the masked instruction skeletons. To be specific, each visual view in the trajectory is represented as a feature vector $\boldsymbol{v}' = [\boldsymbol{v}'_v; \boldsymbol{v}'_\alpha]$, which is the concatenation of the visual encoding $\boldsymbol{v}'_v \in \mathbb{R}^{512}$ and the orientation encoding $\boldsymbol{v}'_\alpha \in \mathbb{R}^{64}$. The visual encoding $\boldsymbol{v}'_v$ is the output of the last but one layer of the RESNET18 (He et al., 2016) of the current view. The orientation encoding $\boldsymbol{v}'_\alpha$ encodes current heading α by repeating vector $[sin\alpha, cos\alpha]$ for 32 times, which follows Fried et al. (2018). As described in section 3.4, the feature matrix of a panorama is the concatenation of eight projected visual views.

In the multimodal style transfer encoder, we use a soft-attention module (Vaswani et al., 2017) to calculate the grounded visual feature $\hat{\boldsymbol{v}}_t$ for current view at step t:

$$attn_{v_{t,i}} = softmax((\boldsymbol{W}_v \boldsymbol{h}_{t-1})^T \boldsymbol{v}'_i) \qquad (1)$$

$$\hat{\boldsymbol{v}}_t = \sum_{i=1}^{8} = attn_{v_{t,i}} \boldsymbol{v}'_i \qquad (2)$$

where $\boldsymbol{h}_{t-1}$ is the hidden context of previous step, $\boldsymbol{W}_v$ refers to the learnable parameters, and $attn_{v_{t,i}}$ is the attention weight over the i_{th} slice of view $\boldsymbol{v}'_i$ in current panorama.

We use full-stop punctuations to split the input text into multiple sentences. The rationale is to enable alignment between the street views and the semantic guidance in sub-instructions. For each sentence in the input text, the textual encoding $\boldsymbol{s}'$

---

[2] We masked out the tokens with the following part-of-speech tags: [JJ, JJR, JJS, NN, NNS, NNP, NNPS, PDT, POS, RB, RBR, RBS, PRP$, PRP, MD, CD]

is the average of all the tokens' word embedding in the current sentence. We also use a soft-attention modules to calculate the grounded textual feature $\hat{\boldsymbol{s}}_t$ at current step t:

$$attn_{s_{t,j}} = softmax((\boldsymbol{W}_s \boldsymbol{h}_{t-1})^T \boldsymbol{s}'_j) \tag{3}$$

$$\hat{\boldsymbol{s}}_t = \sum_{j=1}^{M} attn_{s_{t,j}} \boldsymbol{s}'_j \tag{4}$$

where $\boldsymbol{W}_s$ refers to the learnable parameters, $attn_{s_{t,j}}$ is the attention weight over the j_{th} sentence encoding $\boldsymbol{s}'_j$ at step t, and M denotes the maximum sentence number in the input text. The input text for the multimodal style transfer encoder is the instruction template $\mathcal{X}'$.

Based on the grounded visual feature $\hat{\boldsymbol{v}}_t$, the grounded textual feature $\hat{\boldsymbol{s}}_t$ and the visual view feature $\boldsymbol{v}'_t$ at current timestamp t, the hidden context can be given as:

$$\boldsymbol{h}_t = LSTM([\hat{\boldsymbol{v}}_t; \hat{\boldsymbol{s}}_t; \boldsymbol{v}'_t]) \tag{5}$$

Training Objectives We train the multimodal text style transfer model in the teacher-forcing manner (Williams and Zipser, 1989). The decoder generates tokens auto-regressively, conditioning on the masked instruction template $\mathcal{X}'$, and the trajectory. The training objective is to minimize the following cross-entropy loss:

$$\mathcal{L}(x_1, x_2, \dots, x_n | \mathcal{X}', \boldsymbol{v}'_1, \dots, \boldsymbol{v}'_N)$$
$$= -\log \prod_{j=1}^{n} P(x_j | x_1, ..., x_{j-1}, \mathcal{X}', \boldsymbol{v}'_1, \dots, \boldsymbol{v}'_N) \tag{6}$$

where $x_1, x_2, \dots, x_n$ denotes the tokens in the original instruction $\mathcal{X}$, n is the total token number in $\mathcal{X}$, and N denotes the maximum view number in the trajectory.

3.4 VLN Transformer

The VLN Transformer is the navigation agent that generates actions in the outdoor VLN task. As illustrated in Fig. 4, our VLN Transformer is composed of an instruction encoder, a trajectory encoder, a cross-modal encoder that fuses the modality of the instruction encodings and trajectory encodings, and an action predictor.

Instruction Encoder The instruction encoder is a pre-trained uncased BERT-base model (Devlin et al., 2019). Each piece of navigation instruction is split into multiple sentences by the full-stop punctuations. For the i_{th} sentence $s_i = \{x_{i,1}, x_{i,2}, \dots, x_{i,l_i}\}$ that contains l_i tokens, its sentence embedding $\boldsymbol{h}^s_i$ is calculated as:

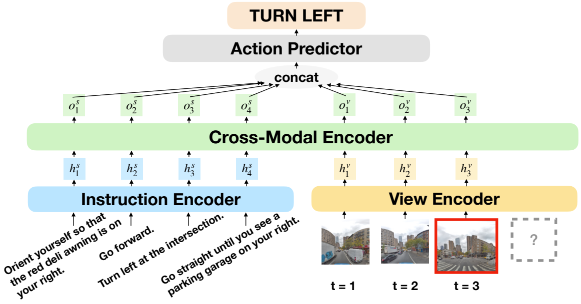

Figure 4: Overview of the VLN Transformer. In this example, the VLN Transformer predicts to take a left turn for the visual scene at $t = 3$.

$$\boldsymbol{w}_{i,j} = \mathcal{BERT}(x_{i,j}) \in \mathbb{R}^{768} \tag{7}$$

$$\boldsymbol{h}^s_i = \mathcal{FC}\left(\frac{\sum_{j=1}^{l_i} \boldsymbol{w}_{i,j}}{l_i}\right) \in \mathbb{R}^{256} \tag{8}$$

where $\boldsymbol{w}_{i,j}$ is the word embedding for $x_{i,j}$ generated by BERT, and $\mathcal{FC}$ is a fully-connected layer.

View Encoder We use the view encoder to retrieve embeddings for the visual views at each time step. Following Chen et al. (2019), we embed each panorama $\mathbf{I}_t$ by slicing it into eight images and projecting each image from an equirectangular projection to a perspective projection. Each of the projected image of size 800×460 will be passed through the RESNET18 (He et al., 2016) pre-trained on ImageNet (Russakovsky et al., 2015). We use the output of size $128 \times 100 \times 58$ from the fourth to last layer before classification as the feature for each slice. The feature map for each panorama is the concatenation of the eight image slices, which is a single tensor of size $128 \times 100 \times 464$. We center the feature map according to the agent's heading α_t at timestamp t. We crop a $128 \times 100 \times 100$ sized feature map from the center and calculate the mean value along the channel dimension. The resulting 100×100 features is regarded as the current panorama feature $\hat{\mathbf{I}}_t$ for each state. Following Mirowski et al. (2018), we then apply a three-layer convolutional neural network on $\hat{\mathbf{I}}_t$ to extract the view features $\boldsymbol{h}^v_t \in \mathbb{R}^{256}$ at timestamp t.

Cross-Modal Encoder In order to navigate through complicated real-world environments, the agent needs to grasp a proper understanding of the natural language instructions and the visual views jointly to choose proper actions for each state. Since the instructions and the trajectory lies in different modalities and are encoded separately, we introduce the cross-modal encoder to fuse the features from different modalities and jointly encode the instructions and the trajectory. The cross-modal encoder is an 8-layer Transformer encoder (Vaswani et al., 2017) with mask. We use eight self-attention heads and a hidden size of 256.

In the teacher-forcing training process, we add a mask when calculating the multi-head self-attention across different modalities. By masking out all the future views in the ground-truth trajectory, the current view $\boldsymbol{v}_t$ is only allowed to refer to the full instructions and all the previous views that the agent has passed by, which is $[\boldsymbol{h}^s_1, \boldsymbol{h}^s_2, \ldots, \boldsymbol{h}^s_M; \boldsymbol{h}^v_1, \boldsymbol{h}^v_2, \ldots, \boldsymbol{h}^v_{t-1}]$, where M denotes the maximum sentence number.

Since the Transformer architecture is based solely on attention mechanism and thus contains no recurrence or convolution, we need to inject additional information about the relative or absolute position of the features in the input sequence. We add a learned segment embedding to every input feature vector specifying whether it belongs to the sentence encodings or the view encodings. We also add a learned position embedding to indicate the relative position of the sentences in the instruction sequence or the trajectory sequence's views.

Action Predictor The action predictor is a fully-connected layer. It takes the concatenation of the cross-modal encoder's output up to the current timestamp t as input, and predicts the action a_t for view $\boldsymbol{v}_t$:

$$\boldsymbol{h}_{concat} = \boldsymbol{h}^s_1 || \ldots || \boldsymbol{h}^s_M || \boldsymbol{h}^v_1 || \ldots || \boldsymbol{h}^v_t \tag{9}$$

$$a_t = argmax(\mathcal{FC}(\mathcal{T}(\boldsymbol{h}_{concat}))) \tag{10}$$

where $\mathcal{FC}$ is a fully-connected layer in the action predictor, and $\mathcal{T}$ refers to the Transformer operation in the cross-modal encoder. During training, we use the cross-entropy loss for optimization.

4 Experiments

4.1 Datasets

Outdoor VLN Dataset For the outdoor VLN task, we conduct experiments on the Touchdown dataset (Chen et al., 2019; Mehta et al., 2020), which is designed for navigation in realistic urban environments. Based on Google Street View[3], Touchdown's navigation environment encompasses 29,641 Street View panoramas of the Manhattan area in New York City, which are connected by 61,319 undirected edges. The dataset contains 9,326 trajectories for the navigation task, and each trajectory is paired with a human-written instruction. The training set consists of 6,526 samples, while the development set and the test set are made up of 1,391 and 1,409 samples, respectively.

External Resource We use the StreetLearn dataset as the external resource for the outdoor VLN task (Mirowski et al., 2018). The StreetLearn dataset is another dataset for navigation in real-life urban environments based on Google Street View. StreetLearn contains 114k panoramas from New York City and Pittsburgh. In the StreetLearn navigation environment, the graph for New York City contains 56k nodes and 115k edges, while the graph for Pittsburgh contains 57k nodes and 118k edges. The StreetLearn dataset contains 580k samples in the Manhattan area and 8k samples in the Pittsburgh area for navigation.

While the StreetLearn dataset's trajectory contains more panorama along the way on average, the paired instructions are shorter than the Touchdown dataset. We extract a sub-dataset *Manh-50* from the original large scale StreetLearn dataset for the convenience of conducting experiments. Manh-50 consists of navigation samples in the Manhattan area that contains no more than 50 panoramas in the whole trajectory, containing 31k training samples. We generate style-transferred instructions for the Manh-50 dataset, which serves as an auxiliary dataset, and will be used to pre-train the navigation models. More details can be found in the appendix.

4.2 Evaluation Metrics

We use the following metrics to evaluate VLN performance: (1) *Task Completion (TC)*: the accuracy of completing the navigation task correctly. Following Chen et al. (2019), the navigation result is considered correct if the agent reaches the specific goal or one of the adjacent nodes in the environment graph. (2) *Shortest-Path Distance (SPD)*: the mean distance between the agent's final position and the goal position in the environment graph. (3) *Success weighted by Edit Distance (SED)*: the normalized Levenshtein edit distance between the path predicted by the agent and the reference path, which is constrained only to the successful navigation. (4) *Coverage weighted by Length Score (CLS)*: a measurement of the fidelity of the agent's path

---

[3] `https://developers.google.com/maps/documentation/streetview/intro`

with regard to the reference path. (5) *Normalized Dynamic Time Warping (nDTW)*: the minimized cumulative distance between the predicted path and the reference path, normalized by the reciprocal of the square root of the reference path length. The value is rescaled by taking the negative exponential of the normalized value. (6) *Success weighted Dynamic Time Warping (SDTW)*: the nDTW value where the summation is only over the successful navigation.

TC, SPD, and SED are defined by Chen et al. (2019). CLS is defined by Jain et al. (2019). nDTW and SDTW are originally defined by Ilharco et al. (2019), in which nDTW is normalized by the length of the reference path. We adjust the normalizing factor to be the reciprocal of the square root of the reference path length for length invariance (Mueen and Keogh, 2016). In case the reference trajectories length has a salient variance, our modification to the normalizing factor made the nDTW and SDTW scores invariant to the reference length.

4.3 Results and Analysis

In this section, we report the outdoor VLN performance and the quality of the generated instructions to validate the effectiveness of our MTST learning approach. We compare our VLN Transformer with the baseline model and discuss the influence of pre-training on external resources with/without instruction style transfer.

Outdoor VLN Performance We compare our VLN Transformer with RCONCAT (Chen et al., 2019; Mirowski et al., 2018) and GA (Chen et al., 2019; Chaplot et al., 2018) as baseline models. Both baseline models encode the trajectory and the instruction in an LSTM-based manner and use supervised training with Hogwild! (Recht et al., 2011). Table 2 presents the navigation results on the Touchdown validation and test sets, where VLN Transformer performs better than RCONCAT and GA on most metrics with the exception of SPD and CLS.

Pre-training the navigation models on Manh-50 with template-based instructions can partially improve navigation performance. For all three agent models, the scores related to successful cases—such as TC, SED, and SDTW—witness a boost after being pre-trained on vanilla Manh-50. However, the instruction style difference between Manh-50 and Touchdown might misguide the agent in the pre-training stage, resulting in a performance drop on SPD for our VLN Transformer model.

In contrast, our MTST learning approach can better utilize external resources and further improve navigation performance. Pre-training on Manh-50 with style-modified instructions can stably improve the navigation performance on all the metrics for both the RCONCAT model and the VLN Transformer. This also indicates that our MTST learning approach is model-agnostic.

Table 4 compares the SPD values on success and failure navigation cases. In the success cases, VLN Transformer has better SPD scores, which is aligned with the best SED results in Table 2. Our model's inferior SPD results are caused by taking longer paths in failure cases, which also harms the fidelity of the generated path and lowers the CLS scores. Nevertheless, every coin has two sides, and exploring more areas when getting lost might not be a complete bad behavior for the navigation agent. We leave this to future study.

Multimodal Text Style Transfer in VLN We attempt to reveal each component's effect in the multimodal text style transfer model. We pre-train the VLN Transformer with external trajectories and instructions generated by different models, then fine-tune it on the TouchDown dataset.

According to the navigation results in Table 3, the instructions generated by the Speaker model misguide the navigation agent, indicating that relying solely on the Speaker model cannot reduce the gap between different instruction styles. Adding textual attention to the Speaker model can slightly improve the navigation results, but still hinders the agent from navigating correctly. The style-modified instructions improve the agent's performance on all the navigation metrics, suggesting that our Multimodal Text Style Transfer learning approach can assist the outdoor VLN task.

Quality of the Generated Instruction We evaluate the quality of instructions generated by the Speaker and the MTST model. We utilize five automatic metrics for natural language generation to evaluate the quality of the generated instructions, including BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Elliott and Keller, 2013), CIDEr (Vedantam et al., 2015) and SPICE (Anderson et al., 2016). In addition, we calculate the guiding signal match rate (MR) by comparing the appearance of "turn left" and "turn right". If the generated instruction contains the

same number of guiding signals in the same order as the ground truth instruction, then this instruction pair is considered to be matched. We also calculate the number of different infilled tokens (#infill) in the generated instruction[4]. This reflects the model's ability to inject object-related information during style transferring. Among the 9,326 trajectories in the Touchdown dataset, 9,000 are used to train the MTST model, while the rest form the validation set.

Table 5: Quantitative evaluation of the instructions generated by Speaker, Speaker with textual attention and our MTST model.

We report the quantitative results on the validation set in Table 5. After adding textual attention to the Speaker, the evaluation performance on all seven metrics improved. Our MTST model scores the highest on all seven metrics, which indicates that the "masking-and-recovering" scheme is beneficial for the multimodal text style transfer process. The results validate that the MTST model can generate higher quality instructions, which refers to more visual objects and provide more matched guiding signals.

Human Evaluation We invite human judges on Amazon Mechanical Turk to evaluate the quality of the instructions generated by different models. We conduct a pairwise comparison, which covers 170 pairs of instructions generated by Speaker, Speaker with textual attention, and our MTST model. The instruction pairs are sampled from the Touchdown

Table 6: Human evaluation results of the instructions generated by Speaker, Speaker with textual attention and our MTST model with pairwise comparisons.

validation set. Each pair of instructions, together with the ground truth instruction and the gif that illustrates the navigation street view, is presented to 5 annotators. The annotators are asked to make decisions from the aspect of guiding signal correctness and instruction content alignment. Results in Table 6 show that annotators think the instructions generated by our MTST model better describe the street view and is more aligned with the ground-truth instructions.

Case Study We demonstrate case study results to illustrate the performance of our Multimodal Text Style Transfer learning approach. Fig. 5 provides two showcases of the instruction generation results. As listed in the charts, the instructions generated by the vanilla Speaker model have a poor performance in keeping the guiding signals in the ground truth instructions and suffer from hallucinations, which refers to objects that have not appeared in the trajectory. The Speaker with textual attention can provide guidance direction. However, the instructions generated in this manner does not utilize the rich visual information in the trajectory. On the other hand, the instructions generated by our multimodal text style transfer model inject more object-related information (“the light", “scaffolding") in the surrounding navigation environment to the StreetLearn instruction while keeping the correct guiding signals.

StreetLearn	**Head northwest** on W 35th St toward Hudson Blvd E. **Turn right** at the 1st cross street onto Hudson Blvd E.
Original Speaker	Turn so the red construction is on your left and the red brick building is on your right. Go forward to the intersection and turn right. You'll have a red brick building with a red awning on your right.
Speaker with Textual Attention	Head in the direction of traffic. Turn right at the first intersection.
Multimodal Text Style Transfer	Move forward with traffic on the right turn right at the light. Continue straight.

StreetLearn	**Turn right** onto W 36th St. **Turn right** onto Dyer Ave.
Original Speaker	Go to the next intersection and turn left again. There will be a building with a red awning on your right. Go straight through the next intersection.
Speaker with Textual Attention	Turn right at the next intersection. Stop just before the next intersection.
Multimodal Text Style Transfer	Turn right again at the next intersection. On your right will be scaffolding on your right. Turn right.

Figure 5: Two showcases of the instruction generation results. The red tokens indicate incorrectly generated instructions, while the blue tokens suggest alignments with the ground truth. The orange bounding boxes show that the objects in the surrounding environment have been successfully injected into the style-modified instruction.

5 Conclusion

In this paper, we proposed the Multimodal Text Style Transfer learning approach for outdoor VLN. This learning framework allows us to utilize out-of-domain navigation samples in outdoor environments and enrich the original navigation reasoning training process. Experimental results show that our MTST approach is model-agnostic, and our MTST learning approach outperforms the baseline models on the outdoor VLN task. We believe our study provides a possible solution to mitigate the data scarcity issue in the outdoor VLN task. In future studies, we would love to explore the possibility of constructing an end-to-end framework. We will also further improve the quality of style-modified instructions, and quantitatively evaluate the alignment between the trajectory and the style-transferred instructions.

Acknowledgments

We would like to show our gratitude towards Jiannan Xiang, who kindly shares his experimental code on Touchdown, and Qi Wu, who provides valuable feedback to our initial draft. We also thank the anonymous reviewers for their thought-provoking comments. The UCSB authors were sponsored by an unrestricted gift from Google. A Appendix

A.1 Dataset Comparison

Dataset	#path	#pano	#pano/path	instr_len	#sent/path	#turn/path
Touchdown	6k	26k	35.2	80.5	6.3	2.8
Manh-50	31k	43k	37.2	22.1	2.8	4.1
StreetLearn	580k	114k	29.0	28.6	4.0	13.2

Table 7: Dataset statistics. *path*: navigation path; *pano*: panorama; *instr_len*: average instruction length; *sent*: sentence; *turn*: intersection on the path.

Table 7 lists out the statistical information of the datasets used in pre-training and fine-tuning. Even though the Touchdown dataset and the StreetLearn dataset are built upon Google Street View, and both of them contain urban environments in New York City, pre-training the model with the VLN task on the StreetLearn dataset does not raise a threat of test data leaking. This is due to several causes:

First, the instructions in the two datasets are distinct in styles. The instructions in the StreetLearn dataset is generated by Google Maps API, which is template-based and focuses on street names. However, the instructions in the Touchdown dataset are created by human annotators and emphasize the visual environment's attributes as navigational cues. Moreover, as reported by Mehta et al. (2020), the panoramas in the two datasets have little overlaps. In addition, Touchdown instructions constantly refer to transient objects such as cars and bikes, which might not appear in a panorama from a different time. The different granularity of the panorama spacing also leads to distinct panorama distributions of the two datasets.

A.2 Training Details

We use Adam optimizer (Kingma and Ba, 2015) to optimize all the parameters. During pre-training on the StreetLearn dataset, the learning rate for the RCONCAT model, GA model, and the VLN Transformer is 2.5×10^{-4}. We fine-tune BERT separately with a learning rate of 1×10^{-5}. We pre-train RCONCAT and GA for 15 epochs and pre-train the VLN Transformer for 25 epochs.

When training or fine-tuning on the Touchdown dataset, the learning rate for RCONCAT and GA is 2.5×10^{-4}. For the VLN Transformer, the learning rate to fine-tune BERT is initially set to 1×10^{-5}, while the learning rate for other parameters in the model is initialized to be 2.5×10^{-4}. The learning rate for VLN Transformer will decay. The batch size for RCONCAT and GA is 64, while the VLN Transformer uses a batch size of 30 during training.

Model	TC ↑	SPD ↓	SED ↑	CLS ↑	nDTW ↑	SDTW ↑
no split	9.6	21.8	9.3	46.1	20.0	8.7
split	**13.6**	**20.5**	**13.1**	**47.6**	**24.0**	**12.6**

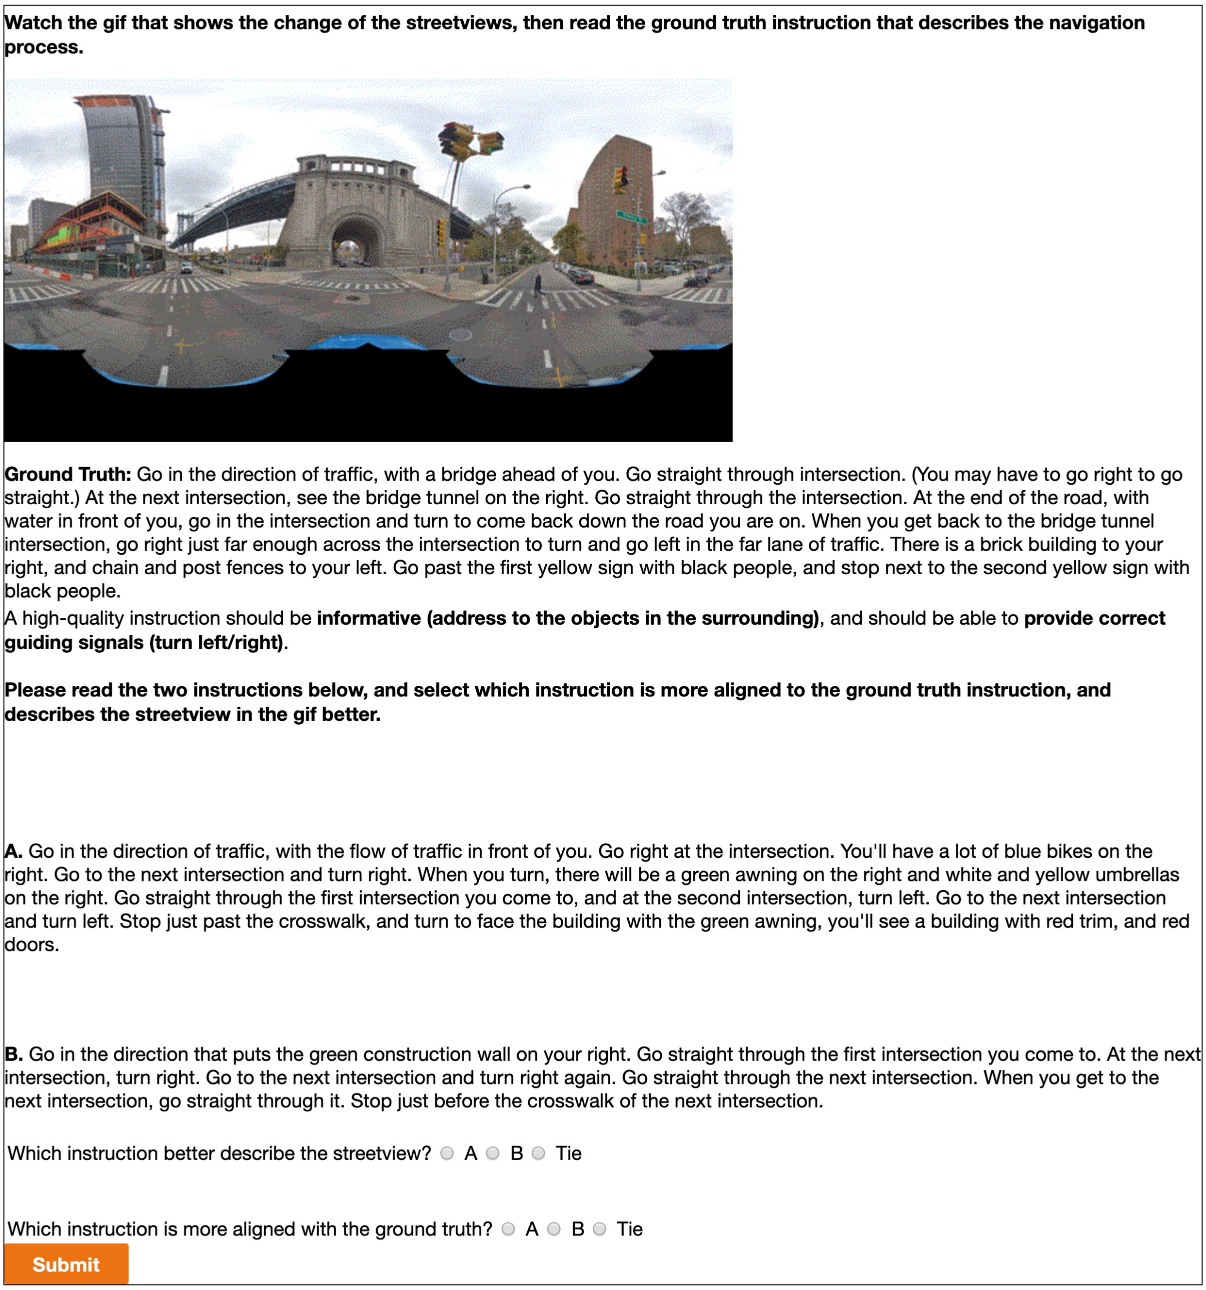
Table 8: Ablation results of the VLN Transformer's instruction split on Touchdown dev set. In *split* setting, the instruction is split into multiple sentences before being encoded by the instruction encoder, while *no split* setting encodes the whole instruction without splitting.

A.3 Split Instructions vs. No Split

We compare VLN Transformer performance with and without splitting the instructions into sentences during encoding. Results in Table 8 show that breaking the instructions into multiple sentences allows the visual views and the guiding signals in sub-instructions to attend to each other during cross-modal encoding fully. Such cross-modal alignments lead to betters navigation performance.

A.4 Amazon Mechanical Turk

We use AMT for human evaluation when evaluating the quality of the instructions generated by different models. The survey form for head-to-head comparisons is shown in Figure 6.



Watch the gif that shows the change of the streetviews, then read the ground truth instruction that describes the navigation process.

Ground Truth: Go in the direction of traffic, with a bridge ahead of you. Go straight through intersection. (You may have to go right to go straight.) At the next intersection, see the bridge tunnel on the right. Go straight through the intersection. At the end of the road, with water in front of you, go in the intersection and turn to come back down the road you are on. When you get back to the bridge tunnel intersection, go right just far enough across the intersection to turn and go left in the far lane of traffic. There is a brick building to your right, and chain and post fences to your left. Go past the first yellow sign with black people, and stop next to the second yellow sign with black people.

A high-quality instruction should be **informative (address to the objects in the surrounding)**, and should be able to **provide correct guiding signals (turn left/right)**.

Please read the two instructions below, and select which instruction is more aligned to the ground truth instruction, and describes the streetview in the gif better.

A. Go in the direction of traffic, with the flow of traffic in front of you. Go right at the intersection. You'll have a lot of blue bikes on the right. Go to the next intersection and turn right. When you turn, there will be a green awning on the right and white and yellow umbrellas on the right. Go straight through the first intersection you come to, and at the second intersection, turn left. Go to the next intersection and turn left. Stop just past the crosswalk, and turn to face the building with the green awning, you'll see a building with red trim, and red doors.

B. Go in the direction that puts the green construction wall on your right. Go straight through the first intersection you come to. At the next intersection, turn right. Go to the next intersection and turn right again. Go straight through the next intersection. When you get to the next intersection, go straight through it. Stop just before the crosswalk of the next intersection.

Which instruction better describe the streetview? ○ A ○ B ○ Tie

Which instruction is more aligned with the ground truth? ○ A ○ B ○ Tie

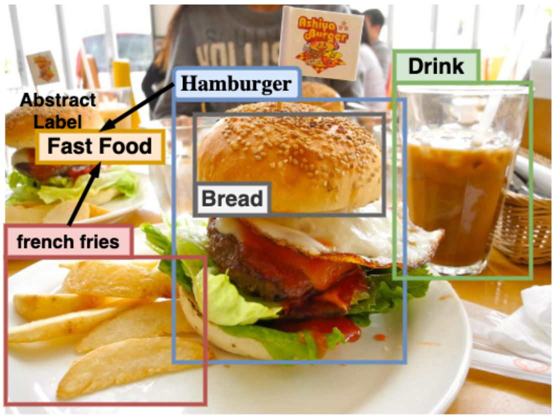
Abstract

Novel Object Captioning is a zero-shot Image Captioning task requiring describing objects not seen in the training captions, but for which information is available from external object detectors. The key challenge is to select and describe all salient detected novel objects in the input images. In this paper, we focus on this challenge and propose the **`ECOL-R`** model (**E**ncouraging **C**opying of **O**bject **L**abels with **R**einforced Learning), a copy-augmented transformer model that is encouraged to accurately describe the novel object labels. This is achieved via a specialised reward function in the SCST reinforcement learning framework (Rennie et al., 2017) that encourages novel object mentions while maintaining the caption quality. We further restrict the SCST training to the images where detected objects are mentioned in reference captions to train the **`ECOL-R`** model. We additionally improve our copy mechanism via *Abstract Labels*, which transfer knowledge from known to novel object types, and a *Morphological Selector*, which determines the appropriate inflected forms of novel object labels. The resulting model sets new state-of-the-art on the *nocaps* (Agrawal et al., 2019) and *held-out* COCO (Hendricks et al., 2016) benchmarks.



Ⓐ **Two Hamburgers served with french fries and drinks.**

Ⓑ **Two Hamburgers served with bread on the plate.**

Ⓒ **Two Hamburgers served with french fries.**

Figure 1: Caption **A** is the ground-truth caption for the image. Compared with **B** and **C**, **A** is the best caption because it mentions all salient objects (i.e, *Hamburger*, *French Fries* and *Drinks*). We use Abstract Labels, that is hypernyms of the objects' detected object labels in the object representations, transferring knowledge from the objects seen in the training captions to novel objects. Our copy mechanism also selects appropriate inflected forms of object labels (i.e., *Hamburgers* vs. *Hamburger*).

1 Introduction

Novel Object Captioning is a zero-shot Image Captioning task where the captions should mention novel objects (i.e., not seen in the training captions), but for which information is available from external object detectors. To produce high-quality captions, the captioning models should select and describe all salient detected objects and avoid mentioning minor or irrelevant details in the input images. As shown in Figure 1, caption **A** is the best caption among the three because **A** mentions all salient objects in the images without any unnecessary details while **B** mentions *Bread* which is just a minor detail; and **C** misses the salient object *Drink*. This paper aims to develop a captioning model that produces caption **A**.

We use an advanced copy mechanism, similar to the one in Hu et al. (2020), to effectively integrate novel objects. We follow the setup in Agrawal et al. (2019) and use two object detectors: one providing rich object visual features and another providing task specific (including novel) object labels as copy candidates. Our preliminary experiments show that the copy mechanism is infrequently triggered and unable to mention many salient objects in the input images. We propose the **`ECOL-R`**

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1222–1234
April 19 - 23, 2021.

model (**E**ncouraging **C**opying of **O**bject **L**abels with **R**einforced Learning), a copy-augmented transformer model trained in the Self-Critical Sequence Training (SCST) framework (Rennie et al., 2017). SCST with a CIDEr reward (Vedantam et al., 2015) is a standard approach for training the captioning models (Anderson et al., 2018b), but this paper will show that it does not sufficiently encourage the model to use copy operations. We design a new reward function that provides a reward for each copy operation proportional to the caption quality. We further restrict the SCST training to the images that contain at least one word in the ground truth captions that corresponds to one of the detected object labels. With these innovations, the `ECOL-R` model outperforms a SCST baseline and a strong inference encouragement baseline by a large margin.

Our copy mechanism and caption generator incorporate two enhancements to better choose and incorporate novel objects: *a) Abstract Labels* which correspond to hypernyms of the object labels and facilitate knowledge transfer between objects appearing in training captions and novel objects; *b) a Morphological Selector* which determines the correct inflected form of the copied task specific object labels which is similar in purpose to that proposed in (Lu et al., 2018b).

We evaluate the `ECOL-R` model on the novel object captioning benchmark *nocaps* (Agrawal et al., 2019) and *held-out* COCO (Hendricks et al., 2016). The `ECOL-R` model achieves a new state of the art on both benchmarks and generalizes well to in-domain images.

2 Related Work

Popular Image Captioning models include LSTM-based (Anderson et al., 2018b) and Transformer-based decoders (Herdade et al., 2019; Cornia et al., 2020). The visual encoders are often neural object detectors (Anderson et al., 2018b; Wang et al., 2019) producing Region-of-Interest (ROI) vectors. To train the model to copy novel object labels, the Neural Baby Talk model (`NBT`) (Lu et al., 2018a) and follow-up work (Wu et al., 2018; Yao et al., 2017; Li et al., 2019) use copy mechanisms (Vinyals et al., 2015). The copying candidates are labels of salient objects produced by external object detectors. In this paper, we follow previous work by using the Visual Genome object detector from (Anderson et al., 2018b) as the visual feature extractor and a task specific object detector to provide object labels for copying.

These models are typically trained with the Cross-Entropy loss (CE). This creates a mismatch between the training and testing environments because the evaluation metrics are non-differentiable text-based measures (Ranzato et al., 2015). Self-Critical Sequence Training (SCST) (Rennie et al., 2017) was proposed to address this issue by directly optimizing the inference output using caption-level rewards, such as CIDEr-D (Vedantam et al., 2015).

There are two existing novel object captioning benchmarks: *a)* the *held-out* COCO Benchmark (Hendricks et al., 2016), constructed by excluding images containing one of eight selected object classes from the standard COCO 2014 benchmark, and *b) nocaps* (Agrawal et al., 2019), which uses the COCO 2017 benchmark for training and provides new validation and test images from the `Open Images` Dataset with over 400 novel objects. Both benchmarks are object-centric and there is no reliable benchmarks that systematically evaluate the quality of generated actions or attributes.

3 Model

Figure 2 provides an overview of the `ECOL-R` model. We refer to the `ECOL-R` model without SCST training as `ECOL`. We describe this model in Sec. 3.1 and our novel reinforced copy encouragement training in Sec. 3.2.

3.1 The `ECOL` Model

Input Image Objects: Following the setup in Agrawal et al. (2019), we use two object detectors: the Visual Genome object detector from Anderson et al. (2018b), producing image objects and regions G (represented by embedding vectors $[\boldsymbol{x}^g_1, \ldots, \boldsymbol{x}^g_{k^g}]$) with detailed visual features; and a task specific object detector, producing image objects F (represented by $[\boldsymbol{x}^f_1, \ldots, \boldsymbol{x}^f_{k^f}]$) and their corresponding labels $L_f = [l_1, \ldots, l_{k^f}]$ used as copy candidates during caption generation. We will introduce object representations $\boldsymbol{x}_i$ below and define them in Eq. 1.

Image Object Representations: Following Anderson et al. (2018b); Lu et al. (2018a), we represent both sets of objects with Region-Of-Interest (ROI, $\boldsymbol{r}_i \in \mathbb{R}^{2048}$) vectors from the Visual Genome object detector and object positional features ($\boldsymbol{p}_i \in \mathbb{R}^8$), including bounding box coordinates and size, and an object label confidence score. In addition,

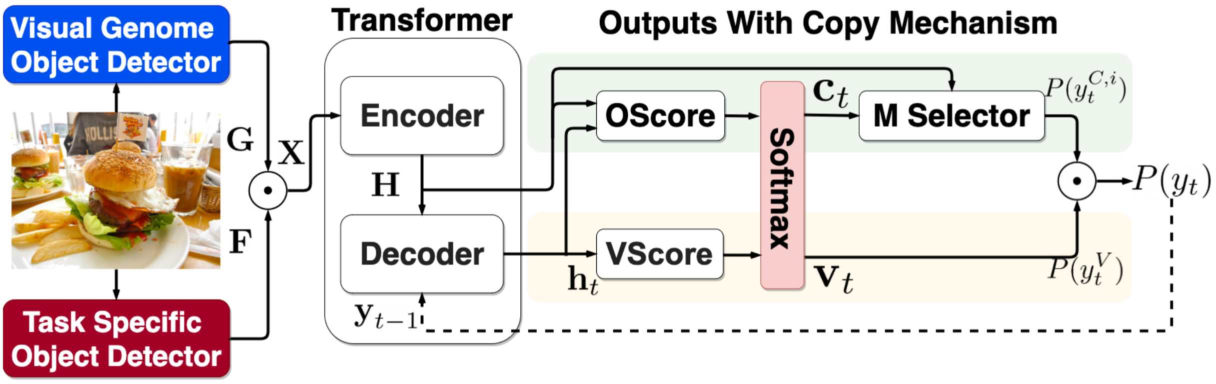


Figure 2: Overview of the **ECOL-R** Model. X is the concatenated Object representations G and F from the two object detectors. The Transformer encoder produces $\mathbf{H}$ and the decoder provides h_t at step t. We then estimate the probabilities for generating each vocabulary word (yellow box) and copying from each task specific image object (green box). The results are concatenated and jointly softmax (red box). We refine each copy probability into the concrete inflected word probability in $MSelector$. The final output $P(y_t)$ concatenates all above word probabilities.

to transfer knowledge from the seen objects to the novel ones, we propose *Abstract Labels* for the task specific objects, described below.

Abstract Labels: The task specific object detectors we use provide taxonomies of object classes, and every detected object is assigned a label from that taxonomy. More general object classes conceptually include all the labels lower in the taxonomy. [1] This provides us with a mechanism for associating class labels not present in the training data with those that do occur in the training data by mapping them to a common ancestor in the hierarchy. Inspired by Ciaramita and Johnson (2003), we define *Abstract Labels* to be a fixed set of ancestor class labels that spans the entire taxonomy (see Figure 3). Using the abstract labels to drive copy decisions allows the usage of known object types to inform the word generation of novel objects. Each object from the task specific detector is associated with its nearest abstract label ancestor. We choose the set of abstract labels such that the objects in the training data are evenly distributed across the set of abstract labels. We represent abstract labels with trainable embeddings $e_i \in \mathbb{R}^d$, where d is the hidden size of our base model. We use the `Open Images` V4 class hierarchy for the *nocaps* benchmark and a merged 8 coco super-categories hierarchy Lin et al. (2014) for the *held-out* COCO benchmark. The final representation for each object x_i is:

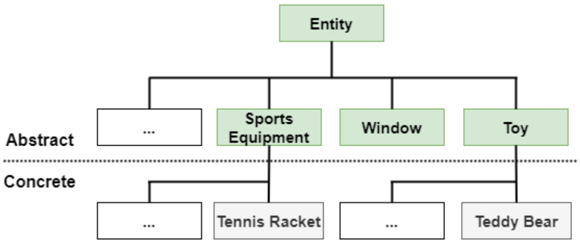

Figure 3: A part of the class hierarchy from the Open Images V4 Dataset (Kuznetsova et al., 2018). The green nodes are used as abstract object labels. For each label, its abstract label is its closest green ancestor.

$$x_i = LN(W_r r_i + e_i) + LN(W_p p_i) \quad (1)$$

where LN is layer normalization and $W_r \in \mathbb{R}^{d\times 2048}$, $W_p \in \mathbb{R}^{d\times 8}$ are trainable projections. The two sets of object representations are concatenated as $X = F \odot G$ where $\odot$ represents concatenation.

Transformer Base Model: We use a transformer model (Vaswani et al., 2017) with an N_{enc}-layer encoder and an N_{dec}-layer decoder (N_{enc} = N_{dec} = 3 in our experiments). We denote the encoder output $\mathbf{H} = Encoder(X)$. The decoder uses frozen word and positional embeddings WE and PE from GPT2 (Radford et al., 2019) which are helpful in producing better captions describing novel objects. In step t:

$$w_{1:t-1} = WE(y_{1:t-1}) + PE(y_{1:t-1}) \quad (2)$$

$$h_t = Decoder(\mathbf{H}, w_{1:t-1}) \quad (3)$$

where $y_{1:t-1}$ is the generation history and $h_t \in \mathbb{R}^d$.

---

[1] If the task specific object detector does not provide such a taxonomy, a suitable taxonomy could be obtained from sources such as Wordnet.

Outputs With Copy Mechanism: The `ECOL` model either generates words from the vocabulary or copies from task specific objects. We deploy a copy mechanism similar to the dynamic pointer network in Hu et al. (2020). Given the decoder output $\boldsymbol{h}_t$, we first calculate a raw score for each vocabulary word:

$$VScore(\boldsymbol{h}_t) = \boldsymbol{W}_e \boldsymbol{h}_t \tag{4}$$

where $\boldsymbol{W}_e \in \mathbb{R}^{|V| \times d}$, $|V|$ is the GPT2 vocabulary size. We then calculate raw additive attention scores over the encoder output of task specific image objects (i.e., $\mathbf{H}_{1:k^f}$):

$$OScore(\mathbf{H}, \boldsymbol{h}_t)_i = \boldsymbol{w}_c^T tanh(\boldsymbol{W}_f \mathbf{H}_i + \boldsymbol{W}_h \boldsymbol{h}_t) \tag{5}$$

where $i \in [1, k^f]$ and $\boldsymbol{W}_f \in R^{d \times d}$, $\boldsymbol{W}_h \in R^{d \times d}$ and $\boldsymbol{w}_c \in R^d$. Finally, we concatenate the raw scores from $VScore$ and $OScore$ and jointly softmax:

$$[\boldsymbol{v}_t, \boldsymbol{c}_t] = Softmax([VScore(\boldsymbol{h}_t) \odot OScore(\mathbf{H}, \boldsymbol{h}_t)]) \tag{6}$$

where $\odot$ represents concatenation. $\boldsymbol{v}_t$ provides probabilities for GPT2 vocabulary words and $\boldsymbol{c}_t$ provides probabilities for copying task specific object labels.

Morphological Selector: Object labels can appear in inflected forms in captions. For example, in Figure 1, after selecting the object *hamburger*, the `ECOL` model should generate *"hamburgers"* after *"Two"*. We propose a morphological selector (*M Selector*) to refine the copy probability of each task specific image object label l_i (i.e., $\boldsymbol{c}_{t,i}$) into the probabilities of generating all possible morphological forms $y_t^{l_i}$ (i.e., $P(y_t^{l_i}|l_i)$). Specifically, we use $\boldsymbol{h}_t$ to choose an inflected form from its possible inflected forms (e.g., Singular or Plural in English):

$$P(y_t^{l_i}|l_i) = \text{softmax}(\boldsymbol{W}_{l_i} \boldsymbol{h}_t) \tag{7}$$

Here $\boldsymbol{W}_{l_i} \in \mathbb{R}^{s_i \times d}$ where s_i is the number of inflected forms of label l_i (in most cases 2 for English, singular and plural). Finally, the `ECOL` model concatenates the above refined probabilities as follows:

$$P(y_t^v) = \boldsymbol{v}_t \tag{8}$$

$$P(y_t^{l_i}) = \boldsymbol{c}_{t,i} \cdot P(y_t^{l_i}|l_i) \tag{9}$$

$$P(y_t) = P(y_t^v) \odot P(y_t^{l_1}) \odot \cdots \odot P(y_t^{l_{kf}}) \tag{10}$$

where $\odot$ represents concatenation. Some novel object labels are included in the GPT2 vocabulary. However, these words are not present in the training captions and thus the model always assigns them very low probabilities in $P(y_t^v)$. The only way novel object labels can appear in captions is through copy operations.

Model Application Scope In this paper, we focus on the Novel Object Captioning task. However, in general, our copy mechanism is capable of copying any type of information. The Abstract Label approach is general to zero shot learning problems where novel items share characteristics with training instances. The Morphological Selector is also applicable to linguistic copy mechanisms in other contexts such as Commonsense Reasoning (Lin et al., 2020) where copied terms may require linguistic alignment with the generated text.

3.2 Copying More Object Labels

In this paper, we encourage the copying of object labels by using a suitable reward function in the Self-Critical Sequence Training (SCST) framework, which has proven effective for image captioning tasks. Compared with injecting additional loss terms together with the standard XE loss, using the SCST framework allows us to design arbitrary encouragement signals based on the inference output. It minimizes the negative expected reward score:

$$L_R(\theta) = -\mathbf{E}_{y_{1:T} \sim p_\theta}[r(y_{1:T})] \tag{11}$$

where r is the reward function and p_θ represents the models outputs. In this paper, following Cornia et al. (2020), we first pre-train the `ECOL` model with the CE loss, then switch to fine-tune the `ECOL` model with the above SCST loss.

Inference Bias Baseline: We add an Inference Bias (IB) $b \in \mathbb{R}^+$ to increase $P(y_t^{l_i})$ at inference time. Eq. 9 is changed to:

$$P(y_t^{l_i}) = b \cdot \boldsymbol{c}_{t,i} \cdot P(y_t^{l_i}|l_i) \tag{12}$$

and remaining probabilities normalised accordingly. IB is functionally equivalent to adjusting the threshold for the copy decision during inference. Surprisingly, this simple inference trick provides a strong baseline (see Table 3). This shows that after the CE training, many correct copy operations are assigned with low probabilities, compared to the fixed vocabulary items. However, we believe that it is better to train the model to increase the probabilities of these copy operations than adding ad hoc adjustments at inference time.

Can Standard SCST Encourage Copying? Rennie et al. (2017) shows that SCST with the CIDEr reward fine-tuning leads to noticeable caption quality improvement for standard image captioning tasks (i.e, improvement in various automatic metrics). Previous work (Cornia et al., 2020; Anderson et al., 2018b) use CIDEr as the standard reward function in their SCST optimization. This shows suggests that the problem of overfitting of SCST training with CIDEr reward is minimal. Intuitively, the CIDEr reward is positively correlated with the number of salient object label mentions and should encourage the model to copy salient novel object labels. However, CIDEr equally rewards both generation of object labels present in training data via the vocabulary $P(y_t^v)$ and via copy operations $P(y_t^{l_i})$. Novel objects labels however can only be generated by copy operations (see Sec. 3.1), thus the CIDEr reward function does not sufficiently encourage these operations. We propose two orthogonal modifications to the standard SCST algorithm to address this issue:

Novel Encouragement Reward: We propose combining the standard CIDEr-D reward with a reward function that gives captions with words copied from object labels an extra bonus, which we intend to encourage copy operations. One straightforward way to implement this idea is to provide a constant bonus to each triggered copy operation:

$$R_a(X) = \mathit{CIDEr}(X) + a * C \tag{13}$$

where X is a generated caption, C is the number of copy actions in the caption X and $a \in R^+$ is a fixed hyper-parameter. We refer this as *additive bias*. Optimizing with the additive bias, the captioning model only needs to trigger the copy operation for arbitrary objects at arbitrary generation steps. That is, the model may encourage copying object labels at the expense of caption quality (i.e., high CIDEr-D scores). Therefore, we propose a *proportional bias* that assigns different rewards to the copy operations in different images by making a connection between the copy bonus and the generated captions CIDEr-D score:

$$R_p(X) = \mathit{CIDEr}(X) * (1.0 + p * C) \tag{14}$$

where $p \in R^+$ is a fixed hyper-parameter. Although R_a can effectively encourage the model to copy objects, it may introduce noisy object mentions. R_p penalizes those noisy object mentions via the low caption CIDEr score.

Visual Object Aligned (VOA) Images: *VOA Images* refers to the set of training images where the reference captions contain at least one word from retained object labels. During SCST training, images that contain no object label words (i.e., non-VOA images) will not utilise copy operations, thus these images encourage the model NOT to copy. VOA images account for approximately 70% of the full COCO-2017 training images set. Although restricting training to VOA images can be done with arbitrary models, this may hurt the diversity of generated captions. Experiments in Table 3 confirm that restricting to VOA images only improves performance when used with SCST training.

Hyper-Parameters For Copy Encouragement: The above approaches introduce two additional parameters: a and p. In our experiments, a and p range over 0.2, 0.3 and 0.4; we found that 0.3 works the best for both reward functions. Combined with restricting SCST training to VOA images, R_p works better than R_a and sets a new SOTA for novel object image captioning.

4 Experiments

We conduct experiments on the *nocaps* (Agrawal et al., 2019) and the *held-out* COCO (Hendricks et al., 2016) Benchmark. We set the layer and embedding size to $d = 768$ and use Adam optimisation (Kingma and Ba, 2014). We train our models 15 epochs with batch size 100 for CE loss and 15 epochs with batch size 10 for SCST loss.

4.1 Evaluation Metrics

We use CIDEr (Vedantam et al., 2015), SPICE (Anderson et al., 2016a) and METEOR (Banerjee and Lavie, 2005) to evaluate the caption quality. CIDEr measures the similarity between the reference captions and generated outputs using tf-idf weighted n-gram overlap. SPICE is based on the scene graphs matching between the reference captions and generated outputs. METEOR focuses on the alignment between the words in reference captions and generated outputs, with an aim of 1:1 correspondence. To measure the effectiveness of our copy encouragement approach, we report object F1 (Anderson et al., 2017) in the *held-out* COCO Benchmark. As the *nocaps* benchmark does not release its ground-truth captions, we instead report averaged number of mentioned objects (Ave. O) and CIDEr score for dummy captions that only contain copied object words (Object CIDEr, OC., details see Appendix).

Table 2: Comparison of the **ECOL-R** model with previous work on the test split of the *held-out* COCO Benchmark. Object F1 measures the presence of particular novel objects in the captions. § not comparable as they use additional information related to novel objects (i.e., images containing novel objects and scene graphs).

4.2 Comparison with the State-of-the-art

We compare our models **ECOL** + IB and **ECOL-R** with other state-of-the-art systems in Tables 1 and 2.

On the *nocaps* benchmark (Table 1), our models outperform previous work, including the recently proposed $OSCAR_L$ + CBS + SCST model (Li et al., 2020), which is fine-turned from the BERT-LARGE model (Devlin et al., 2019), by 2.0 CIDEr, 0.9 SPICE and set a new state of the art. Compared with the $OSCAR_L$ model, our models use far fewer model parameters (340M vs. 60M) and outperforms $OSCAR_L$ on both CIDEr and SPICE metrics. We train our model for about 10 hours for CE Loss and 24 hours for SCST Loss using a single Nvidia P100 GPU. As a comparison, the $OSCAR_L$ model which is fine-tuned from BERT-LARGE uses 60 - 90 hours for training CE Loss and 60 - 90 hours for training SCST Loss.[2] This shows that simply deploying a BERT-based language model is not sufficient for the Novel Object Captioning task.

On the *held-out* COCO benchmark (Table 2), the **ECOL-R** model produces more novel objects (+ 13.3 Object F1) and higher quality captions (+ 3.9 CIDEr on the *out-of-domain* split) than the **ECOL** model with run-time Inference Bias. Compared with previous work, the **ECOL-R** model achieves 10.9 CIDEr and 1.9 SPICE higher in the *out-of-domain* split, 21.2 CIDEr and 2.8 SPICE higher in the *in-domain* split with the highest object F1. This shows that our copy encouragement approach successfully trains our model to correctly copy more novel objects and to produce high-quality captions. Compared with PS3 (Anderson et al., 2018a)

---

[2] According to the authors' comments on their official model code repo https://github.com/microsoft/Oscar/issues/6

and FDM-net model (Cao et al., 2020) which are trained on extra images containing novel objects and scene graphs, our models still outperform the PS3 model and 13.9 CIDEr higher than the FDM-net. We set a new state of the art in this benchmark without additional novel objects information.

4.3 Ablation Study

Table 3 presents ablation results for various **ECOL-R** components, including our copy encouragement approach. Table 4 shows that our encouragement of copying in the **ECOL-R** model does not benefit from additional Inference Bias. Table 5 shows the effect of Abstract Labels and the Morphological Selector in the **ECOL-R** model. Finally, Table 6 confirms the **ECOL-R** model's generalization ability for in-domain COCO images.

ECOL-R Components: The **ECOL** model produces better captions using the frozen GPT2 parameters (row **1** vs. **2**). Our copy mechanism (C) helps the model to explicitly integrate novel objects, substantially improving the *out-of-domain* split by 15.3 CIDEr and 0.3 SPICE (row **2** vs. **3**). The Inference Bias (IB) introduces noticeable performance improvement: 8.4 CIDEr and 0.3 SPICE (row **3** vs. **4**) in models that do not use our reinforcement learning approach. The **ECOL** model trained with the standard SCST reward function obtains an overall 8.1 CIDEr improvement, but most of the improvement is from the *in-domain* and *near-domain* splits (row **8** vs. **6**). Compared with the **ECOL** + IB model, the **ECOL** model trained with standard SCST algorithm is 8.1 CIDEr lower in the *out-of-domain* split (row **5** vs. **4**). As discussed in Sec. 3.2, standard SCST cannot provide sufficient copy encouragement as object words can be generated from either pathways (fixed vocabulary or copy). Optimizing either the R_a or R_p reward functions improves the **ECOL** + CIDEr model by 7.0 CIDEr and 7.8 CIDEr respectively (row **7** and **5**). R_a achieves 3.7 CIDEr higher than R_p in the *out-of-domain* split. Interestingly, after restricting the model training to VOA images, R_p achieves 7.8 CIDEr improvement in the *out-of-domain* split (row **8** vs. **7**), outperforming the **ECOL** + R_a w/ VOA model by 1.4 CIDEr (row **10** vs. **8**).

Effectiveness of Copy Encouragement: We directly measure the copy quantity by counting the number of copied object labels and Object CIDEr. Row **5** and **3** confirm that the standard SCST algorithm has little impact on the copy quantity (only + 0.1 object per image and + 1.4 Object CIDEr). Inference Bias (IB), R_a and R_p rewards substantially improve the quantity of copied objects (row **4**, **6**, **7** vs. **3**). Among these three components, the models trained with R_a and R_p work better than the IB baseline (row **6**, **7** vs. **4**). The model trained with the R_a reward copies more objects than the R_p reward, especially training with all training images. This is because the R_a reward assigns constant positive reward for all copied objects. However, such a naive reward appears to encourage noisy copying operations (i.e., copying non-salient objects). As a result, the **ECOL** + R_a model performs worse than the **ECOL** + R_p model in terms of caption quality (row **7** vs. **6**). After restricting training with VOA images, the models trained with R_a and R_p copy similar amount of objects, but the model with R_a produce better captions than the one with R_a, especially in the *out-of-domain* split (row **10** vs. **8**). The R_p reward maintains a good balance between copying more objects and high caption quality.

Are The VOA images Always Useful? Restricting training to the VOA images can be done with any captioning models. However, this does not necessarily encourage copy operations and improve the output caption quality. When we restrict training to VOA images, the **ECOL-R** model performs consistently worse in all three splits compared to our proposed training scheme (row **9** vs. **10**). The only difference is that the **ECOL** model is not trained with diverse images during the cross-entropy stage. That is, restricting to VOA images is only suitable for fine-tuning in the SCST stage.

Sufficient Encouragement For Copy: Here we investigate whether our **ECOL-R** model mentions a sufficient number of salient objects. We apply an increasing amount of inference bias to the **ECOL**, **ECOL** + CIDEr and **ECOL-R** models in Table 4. We note that only **ECOL-R** model is negatively impacted (measured by CIDEr score) by different Inference Bias values. This shows that the **ECOL-R** model does not benefit from further copy encouragement.

The Effect of Abstract Labels and M Selector Table 5 shows the effect of Abstract Labels (AL) and the M Selector (M) in the **ECOL** + IB and **ECOL-R** models. Removing AL and M from the **ECOL** + IB model drops 2.3 CIDEr, 0.6 SPICE and 4.6 CIDEr, 0.8 SPICE respectively. AL and M have a large positive impact on the SPICE

ECOL-R	**85.1**	85.0	84.9	84.3

Table 4: The CIDEr Score in *nocaps* Validation Set with different Inference Bias.

score. As SPICE is sensitive to long-range object word relationships, such as attributes and predicate words, (Anderson et al., 2016a) Abstract Labels and the M Selector improve the semantic coherence and fluency of the captions. The performance gap in the **ECOL-R** model becomes smaller. Our copy encouragement approach contributes to the generation coherency and fluency.

Method	*out-of-domain* CIDEr	*out-of-domain* SPICE	`Overall` CIDEr	`Overall` SPICE
ECOL + IB	73.7	10.8	77.2	12.0

ECOL-R w/o M	78.4	10.7	82.8	11.9

Table 5: The contribution of Abstract Label (AL) and Morphological Selector (M).

Generalization For In-Domain COCO: To further show the generalization of our model for In-Domain images (i.e., without novel objects), we run the **ECOL** + IB and **ECOL-R** models on the COCO 2017 Validation Set and compare with another two

Method	Meteor	CIDEr	SPICE
NBT + CBS	25.1	80.2	15.8
Up-Down + CBS	25.7	95.4	18.2
ECOL + IB	27.1	106.1	20.6
ECOL-R	27.1	114.2	20.9

Table 6: The performance of the best four *nocaps* models on the COCO 2017 Validation Set.

novel object captioning models (**NBT** + CBS and **Up-Down** + ELMo + CBS) reported in Agrawal et al. (2019) in Table 6. Both of our models outperforms the **Up-Down** and **NBT** model by a large margin. Our models produce high-quality captions for images with novel objects as well as known objects.

4.4 Qualitative analysis on *nocaps*

Qualitative analysis on the *nocaps* validation set reveals that the **ECOL-R** model mentions the salient object in the input image (first example in Figure 4), is able to generate more accurate descriptions of novel objects (second example in Figure 4), however may generate inaccurate captions due to the non-informative detected object labels (third example in Figure 4). In summary, the **ECOL-R** model is better at incorporating detected image objects into generated captions than the **ECOL** + IB model.

5 Conclusion and Future work

This paper proposes the **ECOL-R** model that includes a training scheme to encourage copying novel object labels using Reinforced Learning. Our experiments show that the **ECOL-R** model successfully integrates novel object information and achieves state-of-the-art performance on two Novel Object Caption Benchmarks. In the future, we plan to extend our SCST reward function to other metrics such as SPICE (Anderson et al., 2016b) and BertScore (Zhang et al., 2020).

A Model Details

The hyper-parameters of the **`ECOL-R`** model is shown in Table 7. This architecture is basically from (Cornia et al., 2020). We only change the hidden size of the model to 768 to fit the size of GPT2 (the smallest version). Our model has total 60.8×10^6 parameters and 43.0×10^6 trainable parameters. This scale is slightly smaller than the Transformer Base model (65.8×10^6) (Vaswani et al., 2017).

We optimise with Adam(α=0.9, β=0.98, ϵ=1e-9) (Kingma and Ba, 2014) and clip gradients to 0.1 for both Benchmarks. In Cross-entropy training, we vary the learning rate over the course of training using the heuristic:

$$lrate = d_{\text{model}}^{-0.5} \cdot \min(S^{-0.5}, S \cdot W^{-1.5}) \quad (15)$$

where S is the step number and W is the number of warm-up steps. We set W to 20000 steps for the *nocaps* Benchmark and 10000 steps for the *held-out* COCO Benchmark. The number of warm-up steps has some impact on both benchmark. We tried 20,000 and 10,000 for both Benchmarks. For SCST training, we set the initial learning rate $1e^{-6}$ and reduce it by half if the reward metric (Validatoin set CIDEr) does not improve for 3 evaluations. We conduct evaluation every 3000 steps.

We use Pytorch *1.4.0* to implement our model. The Cross-Entropy Training takes about 8 hours and the SCST optimization takes about 15 hours in a single NVIDIA Tesla P100 GPU.

Our source code is submitted in the *Software*. We setup an anonymous Google Drive to host large file [3].

A.1 Input Object Detector

We follow the processing of input objects in Agrawal et al. (2019). We observed that some

---

[3] `https://drive.google.com/drive/folders/1ETοBXQ8WAWxn5uCd38HtfRYmchnBBbMo?usp=sharing`

object categories are frequently mentioned in the training captions and that they often have variable, context-sensitive verbalisation (e.g., a person might be described as a sports player, a student, etc., depending on the context). For those objects, vocabulary based word generation often did a better job at selecting the correct verbalisation due to their frequency in training captions. On the other hand, novel objects typically have lower-frequencies and a fixed, single verbalisation. For example, elephants are usually only referred to with the word *elephant*. For this reason, we remove objects with high-frequency in training captions from the output of the task specific object detector, leaving their corresponding words to be generated via vocabulary softmax. We also remove the more abstract objects (higher in the object class hierarchy) when object regions overlap. Finally, we keep only one detected object for each label (the one with highest confidence score).

We provide the downloadable link of filtered results in Sec B. We use exactly the same Visual Genome objects as described in Anderson et al. (2018b). The Visual Genome object detector (Anderson et al., 2018b) can produce ROI vectors for arbitrary bounding boxes, hence we use it also to produce ROI vectors for objects from the task specific detector.

A.2 `ECOL-R` Inference Details

We use Beam Search with beam size 5 to decode the captions. We first do length normalization for the overall score of each decoded caption. We also penalize captions when they generate repeated bi-grams. Once the repetitions are found, the log-probability for that particular word is divided by a penalty value e^2. All image objects are only allowed to be copied once. During the SCST optimization, we mask out words from the vocabulary that can be generated via copy operations to encourage the model to copy. All the above constraints are applied to all of our models in the ablation study.

A.3 Object CIDEr Details

Object CIDEr score for dummy captions that only contain copied object words. This shows the correctness of our copy mechanism. High Object CIDEr score means many of the copied object labels are also mentioned in the ground-truth captions. We use this metrics because the *nocaps* benchmark does not release its ground-truth captions and only provide online evaluation APIs.

B Dataset Details

For the *nocaps* Benchmark, we train with the COCO-2017 dataset, which is available at `http://images.cocodataset.org/zips/train2017.zip`. The *nocaps* Validation and Test datasets are available from `https://nocaps.org/download`. The Visual Genome image object detection files can be found in `https://github.com/nocaps-org/updown-baseline`. For the *held-out* COCO Benchmark, the training and evaluation data can be found in `https://github.com/LisaAnne/DCC`. The Visual Genome image object detector is used for both benchmarks because COCO-2017 and COCO-2014 share the same set of images. The anonymous Google Drive includes the above data and the sets of task specific objects detected for the above two benchmarks.

B.1 Duplicated Caption Removal

We find some images in COCO share exactly the same reference captions. We find it beneficial to remove those duplicates. We simply iterate over all reference captions and remove any captions if they have already been found previously. This removes 25463 captions from the training data of the *nocaps* Benchmark and 7059 captions from the training data of the *held-out* COCO Benchmark.

B.2 VOA (visual object aligned) Images

VOA (visual object aligned) images/reference caption pairs are those that mention at least one detected task specific image object label (or their linguistic variant). Non-VOA image/caption pairs are removed from our SCST training process. We provide the reduced set of reference captions in the anonymous Google Drive (*ddc_captions/ddc_train_VOA.json* and *nocaps_captions/nocaps_train_VOA.json*).

B.3 Data Statistics for Benchmarks

Table 9 and Table 10 show the number of images and annotated reference captions of the *nocaps* and *held-out* COCO Benchmark, respectively. On average, each image has five reference captions. The COCO Train in the *nocaps* Benchmark is larger than the *held-out* COCO Benchmark.

C Evaluation

The *nocaps* Benchmark hosts its evaluation sever at `https://evalai.cloudcv.org/web/`

`challenges/challenge-page/355/overview`. The detailed setup instruction of the local submission environment to Evai (Yadav et al., 2019) is available at `https://github.com/nocaps-org/updown-baseline`. The *held-out* COCO Benchmark uses the evaluation tool from `https://github.com/ruotianluo/coco-caption/tree/ea20010419a955fed9882f9dcc53f2dc1ac65092`. We provide an on-the-shelf version of this tool in the anonymous Google Drive (in *tools*).

C.1 *held-out* COCO Benchmark Validation Performance

We only show the test performance on the *held-out* COCO Benchmark in our main paper. Here, we show the performance of our model performance on the validation Set in Table 8. The models achieve similar level of performance on the Validation Set.

Enriching Non-Autoregressive Transformer with Syntactic and Semantic Structures for Neural Machine Translation

Abstract

The non-autoregressive models have boosted the efficiency of neural machine translation through parallelized decoding at the cost of effectiveness, when comparing with the autoregressive counterparts. In this paper, we claim that the syntactic and semantic structures among natural language are critical for non-autoregressive machine translation and can further improve the performance. However, these structures are rarely considered in existing non-autoregressive models. Inspired by this intuition, we propose to incorporate the explicit syntactic and semantic structures of languages into a non-autoregressive Transformer, for the task of neural machine translation. Moreover, we also consider the intermediate latent alignment within target sentences to better learn the long-term token dependencies. Experimental results on two real-world datasets (i.e., WMT14 En-De and WMT16 En-Ro) show that our model achieves a significantly faster speed, as well as keeps the translation quality when compared with several state-of-the-art non-autoregressive models.

1 Introduction

Recently, non-autoregressive models (Gu et al., 2018), which aim to enable the parallel generation of output tokens without sacrificing translation quality, have attracted much attention. Although the non-autoregressive models have considerably sped up the inference process for real-time neural machine translation (NMT) (Gu et al., 2018), their performance is considerably worse than that of autoregressive counterparts. Most previous works attribute the poor performance to the inevitable conditional independence issue when predicting target tokens, and many variants have been proposed to solve it. For example, several techniques in non-autoregressive models are investigated to mitigate the trade-off between speedup and performance, including iterative refinement (Lee et al., 2018), insertion-based models (Chan et al., 2019; Stern et al., 2019), latent variable based models (Kaiser et al., 2018; Shu et al., 2020), CTC models (Libovický and Helcl, 2018; Saharia et al., 2020), alternative loss function based models (Wei et al., 2019; Wang et al., 2019; Shao et al., 2020), and masked language models (Ghazvininejad et al., 2019, 2020).

Although these works have tried to narrow the performance gap between autoregressive and non-autoregressive models, and have achieved some improvements on machine translation, the non-autoregressive models still suffer from syntactic and semantic limitations. That is, the translations of non-autoregressive models tend to contain incoherent phrases (e.g., repetitive words), and some informative tokens on the source side are absent. It is because in non-autoregressive models, each token in the target sentence is generated independently. Consequently, it will cause the multimodality issue, i.e., the non-autoregressive models cannot model the multimodal distribution of target sequences properly (Gu et al., 2018).

One key observation to mitigate the syntactic and semantic error is that source and target translated sentences follow the same structure, which can be reflected from Part-Of-Speech (POS) tags and Named Entity Recognition (NER) labels. Briefly, POS, which aims to assign labels to words to indicate their categories by considering the long-distance structure of sentences, can help the model learn the syntactic structure to avoid generating the repetitive words. Likewise, NER, which discovers the proper nouns and verbs of sentences, naturally helps the model recognize some meaningful semantic tokens that may improve translation quality. This observation motivates us to leverage the syntactic as well as semantic structures of natural language to improve the performance of non-

EN NER:	O	B_NORP	O	O	O	O	B_PERSON	O		

autoregressive NMT. We present a motivating example in Table 1 to better illustrate our idea. From this table, we can find that although the words are altered dramatically from the English sentence to its German translation, the corresponding POS and NER tags still remain similar. For example, most POS tags are identical and follow the same pattern, except that PART, VERB, and ADP in the English do not match the German ADP, while the NER tags are exactly the same in both sentences.

In this paper, we propose an end-to-end Syntactic and semantic structure-aware Non-Autoregressive Transformer model (**SNAT**) for NMT. We take the structure labels and words as inputs of the model. With the guidance of extra sentence structural information, the model greatly mitigates the multimodality issue's negative impact. The core contributions of this paper can be summarized as that we propose 1) a syntax and semantic structure-aware Transformer which takes sequential texts and the structural labels as input and generates words conditioned on the predicted structural labels, and 2) an intermediate alignment regularization which aligns the intermediate decoder layer with the target to capture coarse target information. We conduct experiments on four benchmark tasks over two datasets, including WMT14 En→De and WMT16 En→Ro. Experimental results indicate that our proposed method achieves competitive results compared with existing state-of-the-art non-autoregressive and autoregressive neural machine translation models, as well as significantly reduces the decoding time.

2 Background

Regardless of its convenience and effectiveness, the autoregressive decoding methods suffer two major drawbacks. One is that they cannot generate multiple tokens simultaneously, leading to inefficient use of parallel hardware such as GPUs. The other is that beam search has been found to output low-quality translation with large beam size and deteriorates when applied to larger search spaces. However, non-autoregressive transformer (NAT) could potentially address these issues. Particularly, they aim at speeding up decoding through removing the sequential dependencies within the target sentence and generating multiple target tokens in one pass, as indicated by the following equation:

$$P_{\mathbf{NAT}}(\mathbf{y}|\mathbf{x};\phi)=\prod_{t=1}^{m} p\left(y_t|\hat{\mathbf{x}},\mathbf{x};\phi\right), \qquad (1)$$

where $\hat{\mathbf{x}}=\{\hat{x}_1,\ldots,\hat{x}_m\}$ is the copied source sentence. Since the conditional dependencies within the target sentence (y_t depends on $y_{<t}$) are removed from the decoder input, the decoder is unable to leverage the inherent sentence structure for prediction. Hence the decoder is supposed to figure out such target-side information by itself given the source-side information during training. This is a much more challenging task compared to the autoregressive counterparts. From our investigation, we find the NAT models fail to handle the target sentence generation well. It usually generates repetitive and semantically incoherent sentences with missing words. Therefore, strong conditional signals should be introduced as the decoder input to help the model better learn internal dependencies within a sentence.

3 Methodology

In this section, we present our model **SNAT** to incorporate the syntactic and semantic structure information into a NAT model as well as an intermediate latent space alignment within the target. Figure 1 gives an overview of the network structure of our proposed **SNAT**. In **SNAT**, the input sequence is segmented into sub-words by byte-pair

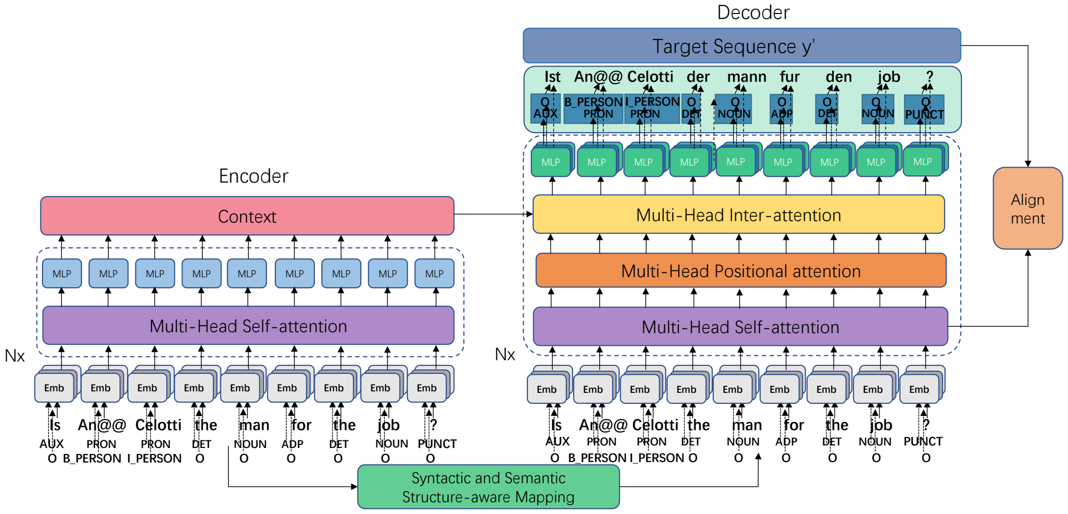

Figure 1: An overview of the proposed **SNAT** for neural machine translation.

tokenizer (Sennrich et al., 2016). In parallel, words in the input sequence are passed to POS and NER annotators to extract explicit syntactic and semantic structures, and the corresponding embeddings are aggregated by a linear layer to form the final syntax and semantic structure-aware embedding. The **SNAT** model copies the structured encoder input as the decoder input and generates the translated sentences and labels.

One of the most important properties of **SNAT** is that it naturally introduces syntactic and semantic information when taking the structure-aware information as inputs and generating both words and labels. More precisely, given a source sentence $\mathbf{x}$, as well as its label sequence $\mathbf{L_x}$, the conditional probability of a target translation $\mathbf{y}$ and its label sequence $\mathbf{L_y}$ is:

$$P_{\mathbf{SNAT}}(\mathbf{y}, \mathbf{L_y}|\mathbf{x}, \mathbf{L_x}; \varphi) = \prod_{t=1}^{m} p\left(y_t, L_{y_t}|\hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}, \mathbf{x}, \mathbf{L_x}; \varphi\right), \quad (2)$$

where $\mathbf{x}$ and $\mathbf{L_x}$ are first fed into the encoder of **SNAT** model. $\hat{\mathbf{x}}$ and $\hat{\mathbf{L}}_{\mathbf{x}}$ with length m are syntactic and semantic structure-aware copying of word and label from encoder inputs, respectively. We show the details in the following sections.

3.1 Syntactic and Semantic Labeling

We use POS and NER to introduce the syntactic and semantic information existing in natural language, respectively. During the data pre-processing, each sentence is annotated into a semantic sequence using an open-source pre-trained semantic annotator. In particular, we take the Treebank style (Marcus et al., 1999) for POS and PropBank style (Palmer et al., 2005) for NER to annotate every token of input sequence with semantic labels. Given a specific sentence, there would be predicate-argument structures. Since the input sequence is segmented into subword units using byte-pair encoding (Sennrich et al., 2016), we assign the same label to all subwords tokenized from the same word. As shown in Figure 1, the word "*Ancelotti*" is tokenized as "*An@@*" and "*Celotti*". The corresponding POS tags are PRON and PRON while the corresponding NER tags are B_PERSON and I_PERSON. For the text "*Is An@@ Celotti the man for the job ?*", the corresponding POS tag set is $\{$AUX, PRON, PRON, DET, NOUN, ADP, DET, NOUN, PUNCT$\}$ and the NER tag set is $\{$O, B_PERSON, I_PERSON, O, O, O, O, O, O$\}$. The data flow of the proposed model is also shown in Figure 1.

3.2 Encoder

Following Transformer (Vaswani et al., 2017), we use a stack of 6 identical Transformer blocks as encoder. In addition to the word embedding and position embedding in the traditional Transformer, we add structure-aware label embedding. The input to the encoder block is the addition of the normalized word, labels (NER and POS) and position embedding, which is represented as $\mathbf{H}^0 = [\mathbf{h}_1^0, \ldots, \mathbf{h}_n^0]$.

The input representation $\mathbf{H}^0 = [\mathbf{h}_1^0, \ldots, \mathbf{h}_n^0]$ is encoded into contextual layer representations through the Transformer blocks. For each layer, the layer representation $\mathbf{H}^l = [\mathbf{h}_1^l, \ldots, \mathbf{h}_n^l]$ is computed by the l-th layer Transformer block $\mathbf{H}^l = \text{Transformer}_l(\mathbf{H}^{l-1})$, $l \in \{1, 2, \ldots, 6\}$. In each

Transformer block, multiple self-attention heads are used to aggregate the output vectors of the previous layer. A general attention mechanism can be formulated as the weighted sum of the value vector $\mathbf{V}$ using the query vector $\mathbf{Q}$ and the key vector $\mathbf{K}$:

$$\mathrm{Att}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \mathrm{softmax}\left(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d_{\text{model}}}}\right) \cdot \mathbf{V}, \tag{3}$$

where d_{model} represents the dimension of hidden representations. For self-attention, $\mathbf{Q}$, $\mathbf{K}$, and $\mathbf{V}$ are mappings of previous hidden representation by different linear functions, i.e., $\mathbf{Q} = \mathbf{H}^{l-1}\mathbf{W}_Q^l$, $\mathbf{K} = \mathbf{H}^{l-1}\mathbf{W}_K^l$, and $\mathbf{V} = \mathbf{H}^{l-1}\mathbf{W}_V^l$, respectively. At last, the encoder produces a final contextual representation $\mathbf{H}^6 = [\mathbf{h}_1^6, \ldots, \mathbf{h}_n^6]$, which is obtained from the last Transformer block.

3.3 Decoder

The decoder also consists of 6 identical Transformer blocks, but with several key differences from the encoder. More concretely, we denote the contextual representations in the i-th decoder layer is $\mathbf{Z}^i (1 \leq i \leq 6)$. The input to the decoder block as $\mathbf{Z}^0 = [\mathbf{z}_1^0, \ldots, \mathbf{z}_m^0]$, which is produced by the addition of the word, labels (NER and POS) copying from encoder input and positional embedding.

For the target side input $[\hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}]$, most previous works simply copied partial source sentence with the length ratio $\frac{n}{m}$ where n refers to the source length and m is the target length as the decoder input. More concretely, the decoder input y_i at the i-th position is simply a copy of the $\lfloor \frac{n}{m} \times i \rfloor$th contextual representation, i.e., $x_{\lfloor \frac{n}{m} \times i \rfloor}$ from the encoder. From our investigation, in most cases, the gap between source length and target length is relatively small (e.g. 2). Therefore, it deletes or duplicates the copy of the last a few tokens of the source. If the last token is meaningful, the deletion will neglect important information. Otherwise, if the last token is trivial, multiple copies will add noise to the model.

Instead, we propose a syntactic and semantic structure-aware mapping method considering the POS and NER labels to construct the decoder inputs. Our model first picks out the informative words with NOUN and VERB POS tags, and the ones recognized as entities by the NER module. If the source length is longer than the target length, we retain all informative words, and randomly delete the rest of the words. On the other hand, if the source length is shorter than the target, we retain all words and randomly duplicate the informative words. The corresponding label of a word is also deleted or preserved. Moreover, by copying the similar structural words from the source, it can provide more information to the target input than just copying the source token, which is greatly different from the target token. The POS and NER labels of those structure-aware copied words from the source sentence are also copied as the decoder input. So by using the structure-aware mapping, we can assign $[\hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}]$ as decoder input.

For positional attention which aims to learn the local word orders within the sentence (Gu et al., 2018), we set positional embedding (Vaswani et al., 2017) as both $\mathbf{Q}$ and $\mathbf{K}$, and hidden representations of the previous layer as $\mathbf{V}$.

For inter-attention, $\mathbf{Q}$ refers to hidden representations of the previous layer, whereas $\mathbf{K}$ and $\mathbf{V}$ are contextual vectors $\mathbf{H}^6$ from the encoder. We modify the attention mask so that it does not mask out the future tokens, and every token is dependent on both its preceding and succeeding tokens in every layer. Therefore, the generation of each token can use bi-directional attention. The position-wise Feed-Forward Network (FFN) is applied after multi-head attention in both encoder and decoder. It consists of two fully-connected layers and a layer normalization (Ba et al., 2016). The FFN takes $\mathbf{Z}^6$ as input and calculates the final representation $\mathbf{Z}^f$, which is used to predict the whole target sentence and label:

$$p\left(\mathbf{y} \mid \hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}, \mathbf{x}, \mathbf{L}_{\mathbf{x}}\right) = f\left(\mathbf{Z}^f \mathbf{W}_w^\top + \mathbf{b}_w\right), \tag{4}$$

$$q\left(\mathbf{L}_{\mathbf{y}} \mid \hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}, \mathbf{x}, \mathbf{L}_{\mathbf{x}}\right) = f\left(\mathbf{Z}^f \mathbf{W}_l^\top + \mathbf{b}_l\right), \tag{5}$$

where f is a GeLU activation function (Hendrycks and Gimpel, 2016). $\mathbf{W}_w$ and $\mathbf{W}_l$ are the token embedding and structural label embedding in the input representation, respectively. We use different FFNs for POS and NER labels. To avoid redundancy, we just use $q\left(\mathbf{L}_{\mathbf{y}} \mid \hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}, \mathbf{x}, \mathbf{L}_{\mathbf{x}}\right)$ to represent the two predicted label likelihood in general.

3.4 Training

We use ($\mathbf{x}$, $\mathbf{L}_{\mathbf{x}}$, $\mathbf{y}^*$, $\mathbf{L}_{\mathbf{y}}^*$) to denote a training instance. To introduce the label information, our proposed **SNAT** contains a discrete sequential latent variable $L_{y_{1:m}}$ with conditional posterior distribution $p(L_{y_{1:m}} | \hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}, \mathbf{x}, \mathbf{L}_{\mathbf{x}}; \varphi)$. It can be approximated using a proposal distribution $q(\mathbf{L}_{\mathbf{y}} \mid$

$\hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}, \mathbf{x}, \mathbf{L}_{\mathbf{x}})$. The approximation also provides a variational bound for the maximum log-likelihood:

$$\begin{aligned}
&\log P_{\textbf{SNAT}} = \log \sum_{t=1}^{m} q\left(L_{y_t} | \hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}, \mathbf{x}, \mathbf{L}_{\mathbf{x}}; \varphi\right) \\
&\times p\left(y_t | L_{y_t}, \hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}, \mathbf{x}, \mathbf{L}_{\mathbf{x}}; \varphi\right) \\
&\geq \underset{L_{y_{1:m}} \sim q}{\mathbb{E}} \Bigg\{ \underbrace{\sum_{t=1}^{m} \log q\left(L_{y_t} \mid \hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}, \mathbf{x}, \mathbf{L}_{\mathbf{x}}; \varphi\right)}_{\text{Label likelihood}} \\
&+ \underbrace{\sum_{t=1}^{m} \log p\left(y_t \mid L_{y_t}, \hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}, \mathbf{x}, \mathbf{L}_{\mathbf{x}}; \varphi\right)}_{\text{Structure-aware word likelihood}} \Bigg\} + \mathcal{H}(q).
\end{aligned} \tag{6}$$

Note that, the resulting likelihood function, consisting of the two bracketed terms in Eq. (6), allows us to train the entire model in a supervised fashion. The inferred label can be utilized to train the label predicting model q and simultaneously supervise the structure-aware word model p. The label loss can be calculated by the cross-entropy $\mathcal{H}$ of $L_{y_t}^*$ and Eq. (5):

$$\mathcal{L}_{\text{label}} = \sum_{t=1}^{m} \mathcal{H}\left(L_{y_t}^*,\ q(L_{y_t} \mid \hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}, \mathbf{x}, \mathbf{L}_{\mathbf{x}})\right), \tag{7}$$

The structure-aware word likelihood is conditioned on the generation result of the label. Since the Eq. (4) does not depend on the predicted label, we propose to bring the structure-aware word mask $\mathbf{M}_{wl} \in \mathbb{R}^{|V_{word}| \times |V_{label}|}$, where $|V_{word}|$ and $|V_{label}|$ are vocabulary sizes of word and label, respectively. The mask $\mathbf{M}_{w_l}$ is defined as follows:

$$\mathbf{M}_{w_l}(i,j) = \begin{cases} 1, & \mathcal{A}(y_i) = label_j, \\ \epsilon, & \mathcal{A}(y_i) \neq label_j, \end{cases} \tag{8}$$

which can be obtained at the preprocessing stage, and $\mathcal{A}$ denotes the open-source pre-trained POS or NER annotator mentioned above. It aims to penalize the case when the word y_i does not belong to the label $label_j$ with ϵ, which is a small number defined within the range of $(0, 1)$ and will be tuned in our experiments. For example, the word "great" does not belong to VERB. The structure-aware word likelihood can be reformulated as:

$$\begin{aligned}
&p(y_t \mid L_{y_t}, \hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}, \mathbf{x}, \mathbf{L}_{\mathbf{x}}; \varphi) = p(y_t \mid \hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}, \mathbf{x}, \mathbf{L}_{\mathbf{x}}) \\
&\times \mathbf{M}_{w_l} \times q(L_{y_t} \mid \hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}, \mathbf{x}, \mathbf{L}_{\mathbf{x}}).
\end{aligned} \tag{9}$$

Consequently, the structure-aware word loss $\mathcal{L}_{\text{word}}$ is defined as the cross-entropy between true $p^{'}(y_t^*|L_{y_t}^*)$ and predicted $p(y_t \mid L_{y_t}, \hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}, \mathbf{x}, \mathbf{L}_{\mathbf{x}}; \varphi)$, where $p^{'}(y_t^*|L_{y_t}^*) \in \mathbb{R}^{|V_{word}| \times |V_{label}|}$ is a matrix where only item at the index of $(y_t^*, L_{y_t}^*)$ equals to 1, otherwise equals to 0. We reshape $p^{'}(y_t^*|L_{y_t}^*)$ and $p(y_t|L_{y_t})$ to vectors when calculating the loss.

Intermediate Alignment Regularization One main problem of NAT is that the decoder generation process does not depend on the previously generated tokens. Based on the bidirectional nature of **SNAT** decoder, the token can depend on every token of the decoder input. However, since the input of decoder $[\hat{\mathbf{x}}, \hat{\mathbf{L}}_{\mathbf{x}}]$ is the duplicate of encoder input $[\mathbf{x}, \mathbf{L}_{\mathbf{x}}]$, the generation depends on the encoder tokens rather than the target $\mathbf{y}^*$.

To solve this problem, we align the output of the intermediate layer of the decoder with the target. The alignment makes the generation of following layers dependent on the coarse target-side information instead of the mere encoder input. This alignment idea is inspired by (Guo et al., 2019), which directly feeds target-side tokens as inputs of the decoder by linearly mapping the source token embeddings to target embeddings. However, using one FFN layer to map different languages to the same space can hardly provide promising results. Thus, instead of aligning the input of decoder with the target, we use the intermediate layer of decoder to align with the target. In this case, our model avoids adding additional training parameters and manages to train the alignment together with **SNAT** model in an end-to-end fashion. Formally, we define the intermediate alignment regularization as cross-entropy loss between the predicted word and the true word:

$$\mathcal{L}_{\text{reg}} = \sum_{t=1}^{m} \mathcal{H}\left(y_t^*,\ \text{FFN}(\mathbf{Z}_t^{md})\right), \tag{10}$$

where $\mathbf{Z}^{md}$ $(1 < md < 6)$ represents the output of each intermediate layer. Consequently, the final loss of **SNAT** can be represented with the coefficient λ as:

$$\mathcal{L}_{\textbf{SNAT}} = \mathcal{L}_{\text{word}} + \mathcal{L}_{\text{label}} + \lambda \mathcal{L}_{\text{reg}}. \tag{11}$$

4 Experiment

In this section, we conduct experiments to evaluate the effectiveness and efficiency of our proposed model, with comprehensive analysis.

Table 2: Performance of BLEU score on WMT14 En↔De and WMT16 En↔Ro tasks. "-" denotes that the results are not reported. 4.1 Experimental Setup

Data We evaluate **SNAT** performance on both the WMT14 En-De (around 4.5M sentence pairs) and the WMT16 En-Ro (around 610k sentence pairs) parallel corpora. For the parallel data, we use the processed data from (Ghazvininejad et al., 2019) to be consistent with previous publications. The dataset is processed with Moses script (Hoang and Koehn, 2008), and the words are segmented into subword units using byte-pair encoding (Sennrich et al., 2016). The WMT14 En-De task uses newstest-2013 and newstest-2014 as development and test sets, and WMT16 En-Ro task uses newsdev-2016 and newstest-2016 as development and test sets. We report all results on test sets. The vocabulary is shared between source and target languages and has ∼36k units and ∼34k units in WMT14 En-De and WMT16 En-Ro, respectively.

Model Configuration Our implementation is based on the PyTorch sequence modeling toolkit Fairseq.[1] We follow the weights initialization scheme from BERT and follow the settings of the base Transformer configuration in (Vaswani et al., 2017) for all the models: 6 layers per stack, 8 attention heads per layer, 512 model dimensions and 2,048 hidden dimensions. The dimension of POS and NER embedding is set to 512 which is the same as the word embedding dimension. The autoregressive and non-autoregressive model have the same encoder-decoder structure, except for the decoder attention mask and the decoding input for the non-autoregressive model as described in Sec. 3. We try different values for the label mismatch penalty ϵ from $\{0.01, 0.1, 0.5\}$ and find that 0.1 gives the best performance. The coefficient λ is tested with different values from $\{0.25, 0.5, 0.75, 1\}$, and $\lambda = 0.75$ outperforms other settings. We set the initial learning rate as values from {8e-6, 1e-5, 2e-5, 3e-5}, with a warm-up rate of 0.1 and L2 weight decay of 0.01. Sentences are tokenized and the maximum number of tokens in each step is set to 8,000. The maximum iteration step is set to 30,000, and we train the model with early stopping.

Baselines We choose the following models as baselines: **NAT** is a vanilla non-autoregressive Transformer model for NMT which is first introduced in (Gu et al., 2018). **iNAT** (Lee et al., 2018) extends the vanilla NAT model by iteratively read-

---

[1] `https://github.com/pytorch/fairseq`

ing and refining the translation. The number of iterations is set to 10 for decoding. **Hint-NAT** (Li et al., 2020) utilizes the intermediate hidden states from an autoregressive teacher to improve the NAT model. **FlowSeq** (Ma et al., 2019) adopts normalizing flows (Kingma and Dhariwal, 2018) as latent variables for generation. **ENAT** (Guo et al., 2019) proposes two ways to enhance the decoder inputs to improve NAT models. The first one leverages a phrase table to translate source tokens to target tokens **ENAT-P**. The second one transforms source-side word embedding into target-side word embeddings **ENAT-E**. **DCRF-NAT** (Sun et al., 2019) designs an approximation of CRF for NAT models and further uses a dynamic transition technique to model positional context in the CRF. **NAR-MT** (Zhou and Keung, 2020) uses a large number of source texts from monolingual corpora to generate additional teacher outputs for NAR-MT training. **AXE CMLM** (Ghazvininejad et al., 2020) trains the conditional masked language models using a differentiable dynamic program to assign loss based on the best possible monotonic alignment between target tokens and model predictions.

4.2 Training and Inference Details

To obtain the part-of-speech and named entity labels, we use industrial-strength spaCy[2] to acquire the label for English, German, and Romanian input. In our implementation, there are 17 labels for POS in total, i.e., ADJ (adjective), ADV (adverb), ADP (ad-position), AUX (auxiliary), CCONJ (coordinating conjunction), DET (determiner), INTJ (interjection), NOUN (noun), NUM (numeral), PART (particle), PRON (pronoun), PROPN (proper noun), PUNCT (punctuation), SCONJ (subordinating conjunction), SYM (symbol), VERB (verb), and X (other). The NER task is trained on OntoNotes v5.0 benchmark dataset (Pradhan et al., 2013) using formatted BIO labels and defines 18 entity types: CARDINAL, DATE, EVENT, FAC, GPE, LANGUAGE, LAW, LOC, MONEY, NORP, ORDINAL, ORG, PERCENT, PERSON, PRODUCT, QUANTITY, TIME, and WORK_OF_ART.

Knowledge Distillation Similar to previous works on non-autoregressive translation (Gu et al., 2018; Shu et al., 2020; Ghazvininejad et al., 2019), we use sequence-level knowledge distillation by training **SNAT** on translations generated by a standard left-to-right Transformer model (i.e., Transformer-large for WMT14 EN→DE, and Transformer-base for WMT16 EN→RO). Specifically, we use scaling NMT (Ott et al., 2018) as the teacher model. We report the performance of standard autoregressive Transformer trained on distilled data for WMT14 EN→DE and WMT16 EN→RO. We average the last 5 checkpoints to obtain the final model. We train the model with cross-entropy loss and label smoothing ($\epsilon = 0.1$).

Inference During training, we do not need to predict the target length m since the target sentence is given. During inference, we use a simple method to select the target length for **SNAT** (Wang et al., 2019; Li et al., 2020). First, we set the target length to $m' = n + C$, where n is the length of the source sentence and C is a constant bias term estimated from the overall length statistics of the training data. Then, we create a list of candidate target lengths with a range of $[m' - B, m' + B]$ where B is the half-width of the interval. Finally, the model picks the best one from the generated $2B + 1$ candidate sentences. In our experiments, we set the constant bias term C to 2 for WMT 14 EN→DE, -2 for WMT 14 DE→EN, 3 for WMT 16 EN→RO, and -3 for WMT 14 RO→EN according to the average lengths of different languages in the training sets. We set B to 4 or 9, and obtain corresponding 9 or 19 candidate translations for each sentence. Then we employ an autoregressive teacher model to rescore these candidates.

4.3 Results and Analysis

Experimental results are shown in Table 2. We first compare the proposed method against autoregressive counterparts in terms of translation quality, which is measured by BLEU (Papineni et al., 2002). For all our tasks, we obtain results comparable with the Transformer, the state-of-the-art autoregressive model. Our best model achieves 27.50 (+0.02 gain over Transformer), 30.82 (-0.46 gap with Transformer), 35.19 (+0.82 gain), and 33.98 (+0.16 gain) BLEU score on WMT14 En↔De and WMT16 EN↔Ro, respectively. More importantly, our **SNAT** decodes much faster than the Transformer, which is a big improvement regarding the speed-accuracy trade-off in AT and NAT models.

Comparing our models with other NAT models, we observe that the best **SNAT** model achieves a significant performance boost over NAT, iNAT, Hint-NAT, FlowSeq, ENAT, NAR-MT and AXE CMLM by +8.33, +5.96, +6.39, +6.05, +3.22, 3.93

---

[2] `https://spacy.io/usage/models`

and +3.97 in BLEU on WMT14 En→De, respectively. This indicates that the incorporation of the syntactic and semantic structure greatly helps reduce the impact of the multimodality problem and thus narrows the performance gap between Autoregressive Transformer (AT) and Non-Autoregressive Transformer (NAT) models. In addition, we see a +0.69, +0.78, +0.68, and 0.52 gain of BLEU score over the best baselines on WMT14 En→De, WMT14 De→En, WMT16 En→Ro and WMT16 Ro→En, respectively.

From the result of our methods at the last group in Table 2, we find that the rescoring technique substantially assists in improving the performance, and dynamic decoding significantly reduces the time spent on rescoring while further accelerating the decoding process. On En→De, rescoring 9 candidates leads to a gain of +2.23 BLEU, and rescoring 19 candidates gives a +2.86 BLEU score increment.

Decoding Speed Following previous works (Gu et al., 2018; Lee et al., 2018; Guo et al., 2019), we evaluate the average per-sentence decoding latency on WMT14 En→De test sets with batch size being 1, under an environment of NVIDIA Titan RTX GPU for the Transformer model and the NAT models to measure the speedup. The latencies are obtained by taking an average of five runs. More clearly, We reproduce the Transformer on our machine. We copy the runtime of other models but the speedup ratio is between the runtime of their implemented Transformer and their proposed model. We think it's reasonable to compare the speedup ratio because it is independent of the influence caused by different implementation software or machines. And to clarify, the latency does not include preprocessing of tagging, because it's a very fast process as executing around 7000 sentences in one second.

We can see from Table 2 that the best **SNAT** gets a 9.3 times decoding speedup than the Transformer, while achieving comparable or even better performance. Compared to other NAT models, we observe that the **SNAT** model is almost the fastest (only a little bit behind of ENAT and Hint-NAT) in terms of latency, and is surprisingly faster than DCRF-NAT with better performance.

4.4 Ablation Analysis

Effect of Syntactic and Semantic Structure Information We investigate the effect of using the syntactic and semantic tag on the model performance. Experimental results are shown in Table 3.

Table 3: The performance of different vision of SNAT models on WMT14 En→De development set. ✔ means selecting the label tag.

Model	POS tag	NER tag	BLEU
SNAT-V1	✔		24.21
SNAT-V2		✔	24.09
SNAT-V3			22.84

Table 4: The performance with respect to using different layer of intermediate interaction. Evaluated by the BLEU score on WMT14 En→De|WMT14 De→En.

Method	WMT14 En→ De	WMT14 De→ En
w/o	23.11	27.03
w/ $\mathbf{Z}^2$	24.32	28.21
w/ $\mathbf{Z}^3$	24.57	28.42

It demonstrates that incorporating POS information boosts the translating performance (+1.37 on WMT14 En→De) and NER information can also enhance the translating performance (+1.25 on WMT14 En→De). The POS label enriches the model with the syntactic structure, while the NER label supplements the semantic information to the model which are critical elements for **SNAT** model to exhibit better translation performance.

Effect of Intermediate Representation Alignment We conduct experiments for our **SNAT** model on WMT14 En→De with various alignments between decoder layers and target. As shown in Table 4, using the second layer $\mathbf{Z}^2$ in the decoder as intermediate alignment can gain +1.21 improvement, while using the third layer $\mathbf{Z}^3$ in the decoder as intermediate alignment can gain +1.46 improvement. This is in line with our expectation that aggregating layer-wise token information in intermediate layers can help improve the decoder's ability to capture token-token dependencies.

Effect of Sentence Length To evaluate different models on different sentence lengths, we conduct experiments on the WMT14 En→De development set and divide the sentence pairs into different length buckets according to the length of the reference sentences. As shown in Table 5, the column of 100 calculates the BLEU score of sentences that the length of the reference sentence is larger than 50 but smaller or equal to 100. We can see that the performance of vanilla NAT drops quickly as the sentence length increases from 10 to 50, while AT model and the proposed **SNAT** model have relatively stable performance over different sen-

Table 5: The performance with respect to different sentence lengths. Evaluated by the BLEU score on WMT14 En→De.

Model	**10**	**20**	**30**	**50**	**100**
AT	28.35	28.32	28.30	24.26	20.73
NAT	21.31	19.55	17.19	16.31	11.35
SNAT	28.67	28.50	27.33	25.41	17.69

tence lengths. This result confirms the power of the proposed model in modeling long-term token dependencies.

5 Conclusion

In this paper, we have proposed a novel syntactic and semantic structure-aware non-autoregressive Transformer model **SNAT** for NMT. The proposed model aims at reducing the computational cost in inference as well as keeping the quality of translation by incorporating both syntactic and semantic structures existing among natural languages into a non-autoregressive Transformer. In addition, we have also designed an intermediate latent alignment regularization within target sentences to better learn the long-term token dependencies. Comprehensive experiments and analysis on two real-world datasets (i.e., WMT14 En→De and WMT16 En→Ro) verify the efficiency and effectiveness of our proposed approach.

Abstract

We introduce NLQuAD, the first data set with baseline methods for non-factoid long question answering, a task requiring document-level language understanding. In contrast to existing span detection question answering data sets, NLQuAD has non-factoid questions that are not answerable by a short span of text and demanding multiple-sentence descriptive answers and opinions. We show the limitation of the F1 score for evaluation of long answers and introduce Intersection over Union (IoU), which measures position-sensitive overlap between the predicted and the target answer spans. To establish baseline performances, we compare BERT, RoBERTa, and Longformer models. Experimental results and human evaluations show that Longformer outperforms the other architectures, but results are still far behind a human upper bound, leaving substantial room for improvements. NLQuAD's samples exceed the input limitation of most pre-trained Transformer-based models, encouraging future research on long sequence language models.[1]

Question: How are people coping in the lockdown?

Headline: China coronavirus: Death toll rises as more cities restrict travel

Document: China has widened its travel restrictions in Hubei province - the centre of the coronavirus outbreak - as the death toll climbed to 26. The restrictions will affect at least 20 million people across 10 cities, including the capital, Wuhan, where the virus emerged. On Thursday, a coronavirus patient died in northern Hebei province - making it the first death outside Hubei. [...] We now know this is not a virus that will burn out on its own and disappear. [...] And we still don't know when people are contagious. Is it before symptoms appear, or only after severe symptoms emerge? One is significantly harder to stop spreading than the other. [...] **One doctor, who requested anonymity, describes the conditions at a hospital in Wuhan. [...] "I was planning to stay in my apartment because I'm scared to go to the gym, and I'm scared to go to out in public, and not many people are willing to go out." (141 words).** Vietnam and Singapore were on Thursday added to the nations recording confirmed cases, joining Thailand, the US, Taiwan and South Korea. [...] Taiwan has banned people arriving from Wuhan and the US state department warned American travellers to exercise increased caution in China. (document length: 921 words)

Figure 1: A question-answer pair in NLQuAD. QA models must predict the answer span within the context document. The correct answer span is bolded. We extract questions and answers, respectively, from the sub-headings and the sub-section bodies from real-word English news articles. Two other questions based on the same article: Can the Coronavirus be stopped? What's the global situation?

1 Introduction

Over the last few years, there have been remarkable improvements in the area of Machine Reading Comprehension (MRC) and open-domain Question Answering (QA) due to the availability of large scale data sets such as SQuAD (Rajpurkar et al., 2016) and pre-trained language models such as BERT (Devlin et al., 2018). Although non-factoid questions represent a large number of real-life questions, current QA data sets barely cover this area. The reason is that context passages in existing QA data sets are mostly very short and questions mostly factoid, i.e., can be answered by simple facts or entities such as a person name and location (Jurafsky and Martin, 2019). Little attention has been paid to non-factoid and open-ended questions that require complex answers such as descriptions or opinions (Hashemi et al., 2020). Answers to non-factoid questions extend to multiple sentences or paragraphs having few words overlapping with the question (Cohen and Croft, 2016). Non-factoid QA facilitates document assistance systems, where for example, journalists can seek assistance to highlight relevant opinions and interpretations. It can further motivate more research on long sequence

language models. Therefore, a high-quality data set in this area is clearly desired.

To support research towards non-factoid and long QA tasks and to address the existing shortcomings as identified above, we have built NLQuAD, a non-factoid long question answering data set. NLQuAD contains 31k non-factoid questions and long answers collected from 13k BBC news articles. We extract questions and answers from the articles' sub-headings and the following body paragraphs of the sub-headings (see Figure 1).

Questions in NLQuAD are not answerable by a short span of text within the documents. This is in contrast to existing long-context but factoid QA data sets such as NewsQA (Trischler et al., 2017), TriviaQA (Joshi et al., 2017), NarrativeQA (Kočiský et al., 2018), DuoRC (Saha et al., 2018), HotpotQA (Yang et al., 2018), and Natural Questions (Kwiatkowski et al., 2019). Although these data sets contain long documents, questions are answerable by short entities or a span of entities.

In particular, Natural Questions covers two types of short and long answers. However, due to its factoid questions, most long answers are still sections containing exactly the short answers and so are trivial (e.g., "Where is the world's largest ice sheet...?", Short: "Antarctica"; Long: "The Antarctic ice sheet is the largest single mass of ice on Earth..."). Furthermore, although a small portion (13%) of Natural Questions samples have only long answers, they are still spans of simple facts. For example, "Who is the author of the book Arabian Nights?" has no short answer simply because there are multiple authors: "The work was collected over many centuries by various authors, translators...". In contrast, we address non-factoid questions requiring complex answers like opinions and explanations. NLQuAD's answers are open and not predefined. Figure 3 and Table 3 present our question types. NLQuAD's questions are also not self-contained. For example, "How are people coping in the lockdown?" or "What's the global situation?" cannot be answered without the context from the document (see Figure 1). Section 3.2 discusses our question types in detail.

In most existing QA data sets such as SQuAD, crowd-workers generate questions based on provided short passages and extract answers from the passages (Rajpurkar et al., 2016). This method of question generation can make QA samples trivial because models can simply detect the most related span to the question by guessing based on shallow pattern matching (Kočiský et al., 2018). In contrast, all annotations in NLQuAD are done automatically and directly based on the news articles themselves. NLQuAD, unlike MS MARCO (Bajaj et al., 2016) and ELI5 (Fan et al., 2019), does not use information retrieval (IR) methods to collect supporting documents. Retrieved documents in these data sets are not guaranteed to contain all facts required to answer the question or they occasionally just contain information related to the question but no answers.

NLQuAD requires document-level language understanding. With an average document length and answer length of 877 and 175 words, respectively, it exceeds the maximum input length of the state of the art QA models such as BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019) due to their memory and computational requirements. Thus, training and evaluating the (document, question, answer) tuples is impossible using such models in an end-to-end manner. It is worth noting that it is also harder to perform pre-selection methods before the final span detection because our answers are long. Meanwhile, most of our questions are not self-contained. For example, to answer the question "How are people coping in the lockdown?" (Figure 1), the system needs to read the document to interpret the concept of "lockdown" and then locate the information regarding the people's behaviour.

We also show the shortcomings of the F1 score and ROUGE-N scores in evaluating long sequences. There is a higher chance of overlap between the word N-grams in two long sequences causing F1 and ROUGE-N to over-estimate the performance. Therefore, we propose to use Intersection over Union (IoU) measuring position-sensitive overlap between two spans.

In summary, our contributions are as follows: (1) We introduce a new data set for non-factoid long QA that to the best of our knowledge is the first data set requiring long answer span detection given non-self-contained and non-factoid questions; (2) We show the limitations of the F1 score in evaluating long answers and propose a new evaluation metric; (3) To establish baseline results, we experiment with three state-of-the-art models: BERT, RoBERTa, and Longformer, and compare them with human performance. To handle the input length limitations of BERT and RoBERTa, we pro-

	Avg # Words

pose to train these models in a sliding-window approach; (4) We finally show that the state-of-the-art models have limited performance in the non-factoid long QA task.

2 Existing data sets

Existing large-scale QA data sets can be categorized based on their context passage length in two groups: short-context QA, i.e., data sets with paragraph-level context, and long-context QA, i.e., data sets with multiple-paragraph or document-level context. Long-context QA can potentially include questions demanding long answers. In this section, we only review QA datasets. However, it is worth noting that very recently, (Tay et al., 2020a) introduced a unified benchmark using different tasks for evaluating model quality under long-context scenarios.

2.1 Short-Context Question Answering

SQuAD (Rajpurkar et al., 2016) is a factoid span detection data set with short answers. Crowd-workers generated the questions given a set of articles. DROP (Dua et al., 2019) makes the problem more challenging by adversarially-created questions requiring discrete reasoning over the text. SQuAD and DROP use Wikipedia pages as context passages whereas SearchQA (Dunn et al., 2017) uses IR approaches to collect context passages.

Answer generation based on a set of passages is another approach to address this task. MS MARCO (Bajaj et al., 2016) consists of real-world search queries and retrieved documents corresponding to the queries.

There are also different types of QA data sets such as Antique (Hashemi et al., 2020), which is a data set for answer retrieval for non-factoid questions. There is also a range of multiple-choice QA tasks such as RACE (Lai et al., 2017), ARC (Clark et al., 2018), SWAQ (Zellers et al., 2018), and COSMOS QA (Huang et al., 2019) that are clustered together with the short-context QA data sets.

2.2 Long-Context Question Answering

Factoid QA has been applied to longer documents, however, the nature of factoid questions limits answers to short texts. NewsQA (Trischler et al., 2017), TriviaQA (Joshi et al., 2017), NarrativeQA (Kočiský et al., 2018), and DuoRC (Saha et al., 2018) fall into this category and their documents are extracted from news articles, stories, and movie plots, respectively. On the other hand, DQA (ter Hoeve et al., 2020) is a document-centred QA data set aimed at document assistance systems. Along with Yes/No questions, it also includes non-factoid questions with relatively long answers. However, the questions are generated by crowd-workers based on a small set of documents.

DuReader (He et al., 2018) consists of real-word Chinese queries and corresponding retrieved documents. It contains both factoid and non-factoid (40%) questions and consequently has longer average answer length than pure factoid datasets.

The multi-hop QA task, requiring multi-hop reasoning over multiple paragraphs, can also be considered as long-context QA if models process paragraphs together. HotpotQA (Yang et al., 2018) is a multi-hop data set, but the answer length of its factoid questions is as limited as that of short-context QA data sets.

Natural Questions (Kwiatkowski et al., 2019) is a factoid QA task with much longer documents and two types of answer lengths. It consists of factoid questions, retrieved Wikipedia pages, and short

Number of QA pairs	31k
Number of Documents	13k
Number of Unique Questions	24k
Avg. Document Length (Word)	876.8
Avg. Answer Length (Word)	174.6
Avg. Question Length (Word)	7.0
Avg. Document Length (Sentence)	38.7
Avg. Answer Length (Sentence)	7.5
Avg. Question Length (Sentence)	1.0
Avg. Question per Document	2.4

Table 2: NLQuAD: data set statistics.

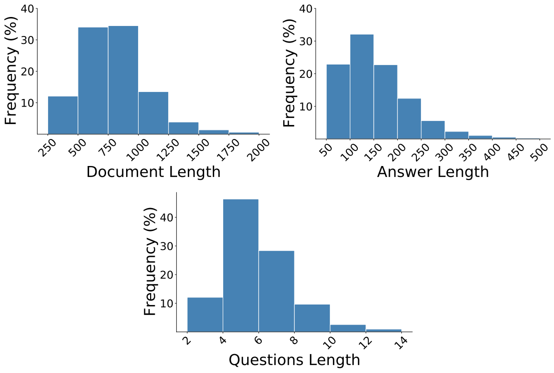

Figure 2: Distribution of the number of words in document, question and answer.

answers (yes/no, entities) as well as long answers (bounding boxes with the information to infer the answer). However, due to the nature of factoid questions, the majority of long answers are sections containing exactly the short answer or simple facts.

ELI5 (Fan et al., 2019) consists of real-world questions with answers provided by the Reddit community. The task is to generate answers given a set of documents retrieved from the Web. However, the documents are not guaranteed to completely address the questions. Furthermore, evaluation metrics for sequence generation tasks such as the ROUGE score (Lin and Och, 2004) are far from perfect to assess the quality of generated answers.

Table 1 compares existing long-context question answering data sets along with SQuAD and MS MARCO. We report the average length for data sets with different types of answers.

3 Data Set Design

NLQuAD consists of news articles as context documents, interrogative sub-headings in the articles as questions, and body paragraphs corresponding to the sub-headings as contiguous answers to the questions. We automatically extract target answers because annotating for non-factoid long QA is rather challenging and costly. To ensure the quality of answers in addition to the initial investigations, we perform human evaluations (Section 5.3). We choose the BBC news website as the resource of our documents and the question-answer pairs, mainly because its articles contain a considerable amount of high-quality question-like sub-headings which are suitable for the QA task.

NLQuAD's characteristics make it an appealing and challenging data set for the non-factoid long QA task: Its context documents are long, and its questions are non-factoid in a way that cannot be answered by single or multiple entities. The questions are addressed by more than seven sentences on average. Meanwhile, it covers a wide range of topics, making it an open-domain QA data set.

The BBC news articles typically follow a specific template. They begin with an introductory section consisting of news summaries (Narayan et al., 2018) and one or more sections accompanied by sub-headings. Each section contains multiple short to medium-length paragraphs. We remove the template and section break-lines to prevent revealing possible answer boundaries.

3.1 Data Curation

We exploit Wayback Machine,[2] a digital archive of the Web, and Wayback Machine Scraper[3] to scrape the article archives. Links in the scraped pages are used to collect additional pages from the original website. We scraped the English BBC news website from 2016 to 2020 as a limited number of questions can be found in articles before 2016. Only textual information is kept and we strip away multimedia objects and hyperlinks outside of the body of the articles. Duplicate documents are removed and questions with bullet list answer types are discarded. We detect interrogative sub-headings by checking if they end with a question mark.

3.2 Data Set Statistics

NLQuAD contains 31k non-factoid questions based on 13k supporting documents from news articles. Table 2 shows the data set statistics. We randomly partition the data set into training (80%), development (10%), and evaluation (10%) sets.

While NLQuAD has long documents and long-answer QA pairs, the histograms in Figure 2 indicate the wide range of samples. Figure 3 presents a visualisation of the distribution of question types

has the reaction...	is the shutdown...	has the US...
do we know...	many people are...	do not we...

Table 3: Top 4-grams prefixes of questions in NLQuAD. Even 'What' questions are non-factoid and need longer answers (descriptions or opinions)

in terms of their first three tokens. Table 3 also lists high frequency examples of “what”, “how” and “why” questions. NLQuAD has a large percentage of “how” and “why” question types where also the “what” examples are non-factoid and consequently require longer explanations as answers.

We manually investigated 100 randomly sampled question-answer pairs from the NLQuAD training set and find that 87% of the questions are not self-contained and require additional contextual information to be understood or disambiguated. Most of the answers consist of explanations, descriptions, or opinions, and only 2% of the questions can be answered by a short span of text.

4 Baseline Models

To investigate the difficulty level of NLQuAD for state-of-the-art QA systems and to establish baseline results, we evaluate the performance of BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), and Longformer (Beltagy et al., 2020). Longformer is a scalable model for processing long documents and has been used for long sequences such as document classification (Beltagy et al., 2020) and document re-ranking (Sekulić et al., 2020). We refer readers to Tay et al. (2020b) for a detailed survey on efficient transformers. We train these Transformer-based (Vaswani et al., 2017) models to predict the span of the answer in a context document given a question and document.

4.1 BERT and RoBERTa

The BERT QA model concatenates question and document pairs into a single sequence and predicts the answer span by a dot product between the final hidden vectors, a start vector and an end vector (Devlin et al., 2018). Due to the memory and computational requirements, BERT can encode sequences with a maximum length of 512 tokens that is less than the average sample length in NLQuAD. Therefore, we adopt a sliding window approach. We split the samples into segments using a sliding window of 512 tokens and a stride of 128 tokens. Each segment is augmented with its corresponding question. The segments can include no answer, a portion of the answer, or the entire answer. We train BERT on the segments independently. Finally, the predicted spans corresponding to a single sample are aggregated to predict the final span that is the span between the earliest start position and the latest end position. The output is considered empty when all segments have empty spans.

RoBERTa has the same model architecture and input length limitation as BERT but with a robustly optimized pre-training scheme allowing it to generalize better to downstream tasks such as QA (Liu et al., 2019). We apply the same sliding window approach for RoBERTa.

4.2 Longformer

In order to process the question and entire documents at the same time, we use the Longformer model. It employs an attention mechanism scaling linearly with the sequence length which enables Longformer to process up to 4,096 tokens. It uses multiple attention heads with different dilation configurations to attend to the entire sequence and includes global attention to question tokens in the sequence. Question and document pairs are packed together into a single sequence without having to

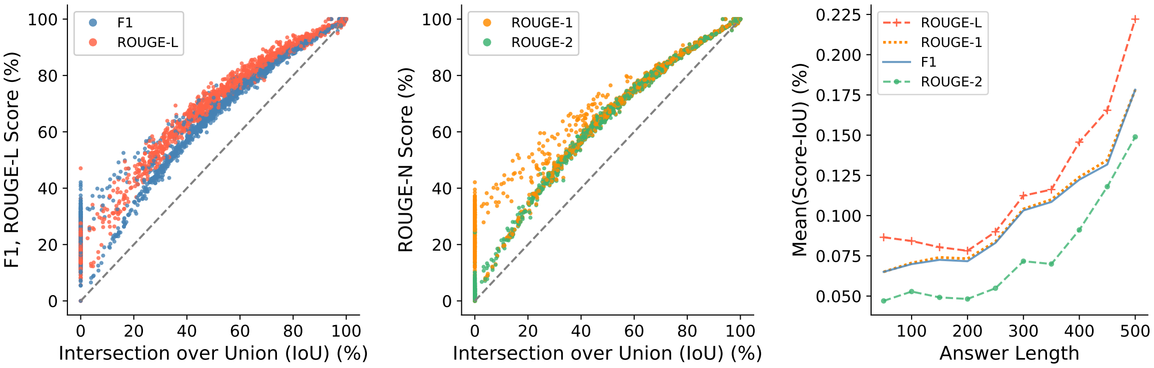

Figure 4: Comparing F1, ROUGE-N and IoU. Left/Middle: All scores behave similarly in the higher values, but F1 and ROUGE-N over-estimate the performance in the lower IoU values due to a higher chance of overlap between the bag of words, n-grams, or longer LCSs in the prediction and target spans. The dashed line shows $y = x$. Right: F1 and ROUGE-N over-estimate more in samples with longer answers. Results are plotted for the Longformer on the development set.

use sliding windows and the answer span is calculated by a dot product (Beltagy et al., 2020).

5 Experiments

5.1 Evaluation Metrics

Exact Match (EM) and the macro-averaged F1 score are the two main evaluation metrics in the span detection QA task (Rajpurkar et al., 2016). Exact Match determines if the prediction exactly matches the target which can be a too strict criterion for long answers. The F1 score measures the overlap between the words in the prediction and the target. It treats sequences as a bag of words. Unfortunately, in long answers, it is highly likely that a random, long span shares a considerable number of tokens with the target span.

The ROUGE-N scores (Lin and Och, 2004), which are primarily used for sequence generation evaluation, have the same drawback in long sequences. ROUGE-N measures the N-gram overlap between the prediction and target. High chances of overlap of unigrams and bigrams in long sequences cause ROUGE-1 and ROUGE-2 to over-estimate performance. The same holds for ROUGE-L with the Longest Common Sub-sequence (LCS) because of a high chance of longer LCSs between two long sequences.

To better take sequence similarities into account, we propose to evaluate models with the Intersection over Union (IoU) score, also known as Jaccard Index. IoU is defined as follows:

$$IoU = \frac{|p \cap t|}{|p \cup t|}$$

Question: How did we get here?

Headline: Eta disarms: French police find 3.5 tonnes of weapons

Target Answer: Slowly, and with many false starts. Eta used parts of south-western France as a base, even though most of its operations were against Spanish targets in Spain. The group has, however, killed some French policemen, but mostly during police raids on members of the group. Etaś first ceasefire was in 1998, but collapsed the following year. A similar declaration in 2006 only lasted a matter of months, ending when Eta bombed an airport car park, killing two people. Four years later, in 2010, Eta announced it would not carry out further attacks and in January 2011, it declared a permanent and "internationally verifiable" ceasefire but refused to disarm. In recent years, police in France and Spain have arrested hundreds of Eta figures and seized many of its weapons. Etaś political wing, Herri Batasuna, was banned by the Spanish government, which argued that the two groups were inextricably linked.

Prediction: The group was set up more than 50 years ago in the era of Spanish dictator General Franco, who repressed the Basques politically and culturally. Eta's goal was to create an independent Basque state out of territory in south-west France and northern Spain. Its first known killing was in 1968, when a secret police chief was shot dead in the Basque city of San Sebastian. France and Spain refuse to negotiate with Eta, which is on the EU blacklist of terrorist organisations.

Figure 5: A prediction span that is semantically different from the target span but has a F1=30% (Prec.=43%, Rec.=23%) and IoU=0. Red shows the overlapping words in the prediction span with the target. Articles (a, an, the) and punctuations are discarded before overlapping calculation. (ROUGE-1=32%, ROUGE-2=4%, ROUGE-L=24%)

where p and t and are the predicted and target contiguous intervals over the context document, containing the positions of the tokens. Intersec-

Method	EM	Prec.	Rec.	F1	IoU

RoBERTa-base e=3,w,s=128	26.65	61.83	84.78	65.55	55.79
RoBERTa-base e=2,w,s=256	**27.33**	62.21	82.33	66.08	56.23
RoBERTa-base e=2,w,s=512	17.17	62.16	64.71	57.11	47.17
BERT-large e=2,w,s=128	28.54	63.83	84.68	66.95	57.24
RoBERTa-large e=2,w,s=128	**30.92**	**66.74**	**87.47**	**69.85**	**60.56**

Table 5: BERT and RoBERTa results on the development set. e=#epoch, w=warm-up over the first 1,000 steps, s=stride.

tion ($p \cap t = \{x | x \in p \, \text{and} \, x \in t\}$) measures the overlapping interval and union ($\cup$) is defined as $p \cup t = \{x | x \in p \, \text{or} \, x \in t\}$.

Figure 4 (left/middle) compares the F1 and ROUGE-N scores and IoU for the Longformer model on the development set. The F1 and ROUGE-N scores are always higher than IoU, but the metrics perform similarly in their higher values. Somewhat surprisingly, the F1 score can be up to 40% while there is no overlap between the two spans and IoU=0. We manually inspected the spans with F1>0 and IoU=0 and saw no significant semantic similarity between the predicted answer span and the target span. The same pattern repeats for the ROUGE-N scores. ROUGE-1 similar to F1 can reach 40% while IoU=0, but ROUGE-2 and ROUGE-L are less prone to such over-estimation due to lower chance of overlap of bigrams than unigrams and shorter LCSs in two random non-overlapping sequences. Figure 4 (right) indicates that the F1 and ROUGE-N scores are higher than IoU for longer answers reiterating the fact that these scores over-estimate more for longer sequences. Figure 5 shows two spans in a document with high F1 and ROUGE-N percentages, but different meanings.

5.2 Results and Discussion

We use the BM25L ranking function (Trotman et al., 2014) to investigate how a basic IR approach can detect answer spans using TF-IDF features. We adopt a sliding window approach with a window size of 512 and a stride of one sentence. We compare BM25L with random window (span) selection and the first and last window selection in the documents. Table 4 presents the results of the ranking functions. In the BM25L-oracle, we set the window size to the target answer span size. BM25L-oracle outperforms the other methods but the results are far from perfect. There is no significant difference between BM25L and other methods. The results restate the fact that there is little word overlap between non-factoid questions and their answers.

We analyze the performance of BERT and RoBERTa with different hyper-parameters on the development set in Table 5. Smaller strides, i.e., higher overlap between the segments, and warm-up contribute to better performances. RoBERTa constantly outperforms BERT, which is to be expected as RoBERTa is optimized robustly during the pre-training. We use the HuggingFace's Transformers (Wolf et al., 2019) code[4] and train the base and large models on 2 and 4 GPUs, respectively. We

Method	#Param.	EM	Prec.	Rec.	F1	IoU
BERT-base	110M	25.03	60.60	82.48	63.96	53.75
BERT-large	340M	30.29	64.87	84.62	67.91	58.39
RoBERTa-base	125M	29.07	64.02	84.79	67.19	57.65
RoBERTa-large	355M	33.40	67.79	**87.56**	71.10	62.39
Longformer	149M	**50.30**	**83.92**	85.17	**81.38**	**73.57**

Table 6: NLQuAD evaluation set results. Longformer surpasses the other models in all the metrics except recall.

have to use a batch size of 12 and 8, respectively, for the base and large models because of the long input sequence size and memory limitations.

We use the official AllenAI Longformer code[5] to train Longformer on NLQuAD. We use the same batch size of 12 (batch size of 1 and gradient accumulation over 12 batches) and learning rate warm-up for the first 1,000 steps. Due to memory requirements, we limit the experiments to only the Longformer base model (the large model cannot fit on our GPUs even with a batch size of 1). We ran the experiments on 2 NVIDIA P40 (24GB GPU memory) for about one day for 5 epochs. Similarly, we choose the best epoch based on the performance on the development set.

Table 6 summarizes the scores obtained by the baseline systems on the NLQuAD evaluation set. While Longformer significantly outperforms BERT and RoBERTa, its performance, particularly in terms of IoU and EM, is far from perfect. This demonstrates that NLQuAD and non-factoid QA is still an open problem for state-of-the-art models.

Method	EM	Prec.	Rec.	F1	IoU
RoBERTa-large	36.00	61.78	87.00	66.41	57.09
Human-AVG	35.50	86.67	68.66	72.52	62.94
Longformer	56.00	78.55	83.69	78.27	70.64
Human-UB	**74.00**	**97.79**	**94.88**	**95.49**	**92.63**

Table 7: Comparing human performance with Longformer and RoBERTa-large on a subset of evaluation set. UB=upper bound, AVG=average.

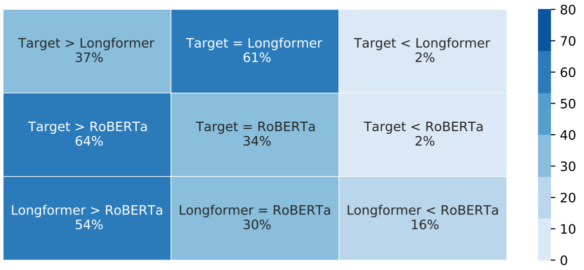

Figure 6: Pairwise comparison between the target spans, Longformer, and RoBERTa's predicted spans. X>Y means X is more preferable.

5.3 Human Evaluation

To ensure that the samples are of high quality, in addition to the initial investigation and pre-processing steps, we asked four volunteers to investigate 50 random samples from the evaluation set. They rated the goodness of answers on a 3-point scale: (1: Irrelevant answer; 2: Good answer after adding or removing some sentences; 3: Perfect answer). The average score is 2.56 indicating the high quality of NLQuAD's QA samples.

In order to benchmark human performance, we asked the four volunteers to answer 50 questions, a randomly sampled subset of evaluation set. They were given unlimited time to detect the answers, but on average, it took them about 270 seconds to answer a question. Table 7 compares human performance with Longformer and RoBERTa-large on the same subset. Similar to HotpotQA (Yang et al., 2018), we estimate the human upper bound by taking the best human answer in terms of our primary evaluation metric (IoU) for each sample. While NLQuAD is a challenging task both for humans and the state of the art QA models, the human upper bound performance significantly outperforms the models. We suspect that the mediocre average of human performance, considering the high score of the target answers, might be because volunteers are not familiar with the articles' writing style or they might have become exhausted by reading long articles.

Furthermore, we asked another volunteer to compare the target answers with the predicted answers in a pairwise comparison for 100 samples. Figure 6 shows that the target answers are preferred in 37% and 64% of cases over the Longformer and RoBERTa predictions, respectively. The human evaluation is in line with the results shown in Table 6 and Table 7.

---

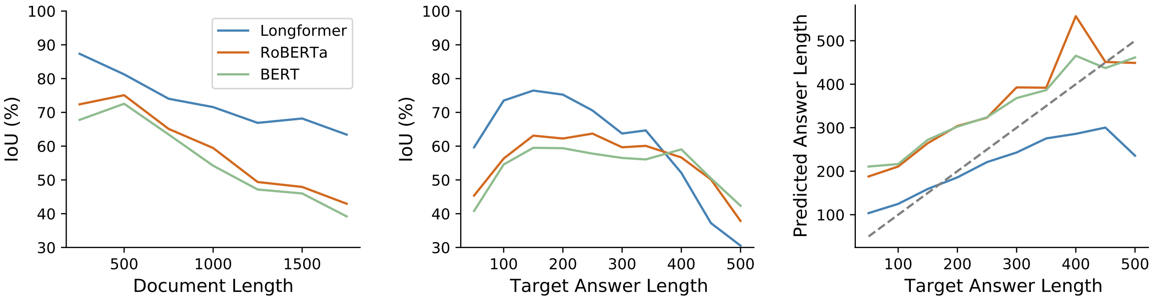

Figure 7: Effect of document and answer length on the performances. Left: IoU drops in all models for longer documents. Middle: RoBERTa and BERT outperform Longformer in longer answers. Right: Longformer has a bias to predict shorter answers while RoBERTa and BERT predict longer answers. The dashed line means $y = x$.

5.4 Error Analysis

Figure 7 compares the performance of BERT, RoBERTa, and Longformer for instances with different document and answer lengths. As expected, both longer documents and longer answers are harder for the models. Surprisingly, BERT and RoBERTa outperform Longformer for longer answers. The same pattern occurs for F1 and EM (not shown in the figure).

Figure 7 (right) shows that RoBERTa and BERT behave completely differently compared to Longformer for longer answer lengths. The former models have a bias to predict longer spans while Longformer under-estimates the length of the answer span. This different behaviour might be due to the sliding window approach and the prediction aggregation in the RoBERTa and BERT models and the attention dilation strategy in Longformer.

6 Conclusion

We introduce NLQuAD, a non-factoid long question answering data set from BBC news articles. NLQuAD's question types and the long lengths of its context documents as well as answers, make it a challenging real-world task. We propose to use Intersection over Union (IoU) as an evaluation metric for long question answering. To establish a baseline performance, we experimented with the BERT, RoBERTa, and Longformer question answering models. Longformer outperforms the other methods with an IoU of 73.57%, but the results show that the performance of state-of-the-art question answering systems is far from perfect. We hope NLQuAD will inspire more research in the area of document-level language understanding and question answering.

Abstract

In comparison to the numerous debiasing methods proposed for the static non-contextualised word embeddings, the discriminative biases in contextualised embeddings have received relatively little attention. We propose a fine-tuning method that can be applied at token- or sentence-levels to debias pre-trained contextualised embeddings. Our proposed method can be applied to any pre-trained contextualised embedding model, without requiring to retrain those models. Using gender bias as an illustrative example, we then conduct a systematic study using several state-of-the-art (SoTA) contextualised representations on multiple benchmark datasets to evaluate the level of biases encoded in different contextualised embeddings before and after debiasing using the proposed method. We find that applying token-level debiasing for all tokens and across all layers of a contextualised embedding model produces the best performance. Interestingly, we observe that there is a trade-off between creating an accurate vs. unbiased contextualised embedding model, and different contextualised embedding models respond differently to this trade-off.

1 Introduction

Contextualised word embeddings have significantly improved performance in numerous natural language processing (NLP) applications (Devlin et al., 2019; Liu et al., 2019; Clark et al., 2020) and have established as the de facto standard for input text representations. Compared to static word embeddings (Pennington et al., 2014; Mikolov et al., 2013) that represent a word by a single vector in all contexts it occurs, contextualised embeddings use dynamic context dependent vectors for representing a word in a specific context. Unfortunately however, it has been shown that, similar to their non-contextual counterparts, contextualised text embeddings also encode various types of unfair biases (Zhao et al., 2019; Bordia and Bowman, 2019; May et al., 2019; Tan and Celis, 2019; Bommasani et al., 2020; Kurita et al., 2019). This is a worrying situation because such biases can easily propagate to the downstream NLP applications that use contextualised text embeddings.

Different types of unfair and discriminative biases such as gender, racial and religious biases have been observed in static word embeddings (Bolukbasi et al., 2016; Zhao et al., 2018a; Rudinger et al., 2018; Zhao et al., 2018b; Elazar and Goldberg, 2018; Kaneko and Bollegala, 2019). As discussed later in § 2 different methods have been proposed for debiasing static word embeddings such as projection-based methods (Kaneko and Bollegala, 2019; Zhao et al., 2018b; Bolukbasi et al., 2016; Ravfogel et al., 2020) and adversarial methods (Xie et al., 2017; Gonen and Goldberg, 2019). In contrast, despite multiple studies reporting that contextualised embeddings to be unfairly biased, methods for debiasing contextualised embeddings are relatively under explored (Dev et al., 2020; Nadeem et al., 2020; Nangia et al., 2020). Compared to static word embeddings, debiasing contextualised embeddings is significantly more challenging due to several reasons as we discuss next.

First, compared to static word embedding models where the semantic representation of a word is limited to a single vector, contextualised embedding models have a significantly large number of parameters related in complex ways. For example, BERT-large model (Devlin et al., 2019) contains 24 layers, 16 attention heads and 340M parameters. Therefore, it is not obvious which parameters are responsible for the unfair biases related to a partic-

ular word. Because of this reason, projection-based methods, popularly used for debiasing pre-trained static word embeddings, cannot be directly applied to debias pre-trained contextualised word embeddings.

Second, in the case of contextualised embeddings, the biases associated with a particular word's representation is a function of both the target word itself and the context in which it occurs. Therefore, the same word can show unfair biases in some contexts and not in the others. It is important to consider the words that co-occur with the target word in different contexts when debiasing a contextualised embedding model.

Third, pre-training large-scale contextualised embeddings from scratch is time consuming and require specialised hardware such as GPU/TPU clusters. On the other hand, fine-tuning a pre-trained contextualised embedding model for a particular task (possibly using labelled data for the target task) is relatively less expensive. Consequently, the standard practice in the NLP community has been to share[1] pre-trained contextualised embedding models and fine-tune as needed. Therefore, it is desirable that a debiasing method proposed for contextualised embedding models can be applied as a fine-tuning method. In this view, counterfactual data augmentation methods (Zmigrod et al., 2019; Hall Maudslay et al., 2019; Zhao et al., 2019) that swap gender pronouns in the training corpus for creating a gender balanced version of the training data are less attractive when debiasing contextualised embeddings because we must retrain those models on the balanced corpora, which is more expensive compared to fine-tuning.

Using gender-bias as a running example, we address the above-mentioned challenges by proposing a debiasing method that fine-tunes pre-trained contextualised word embeddings[2]. Our proposed method retains the semantic information learnt by the contextualised embedding model with respect to gender-related words, while simultaneously removing any stereotypical biases in the pre-trained model. In particular, our proposed method is agnostic to the internal architecture of the contextualised embedding method and we apply it to debias different pre-trained embeddings such as BERT, RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2020), DistilBERT (Sanh et al., 2019) and ELECTRA (Clark et al., 2020). Moreover, our proposed method can be applied at token-level or at sentence-level, enabling us to debias at different granularities and on different layers in the pre-trained contextualised embedding model.

Following prior work, we compare the proposed debiasing method in two sentence-level tasks: Sentence Encoder Association Test (**SEAT**; May et al., 2019) and Multi-genre co-reference-based Natural Language Inference (**MNLI**; Dev et al., 2020). Experimental results show that the proposed method not only debiases all contextualised word embedding models compared, but also preserves useful semantic information for solving downstream tasks such as sentiment classification (Socher et al., 2013), paraphrase detection (Dolan and Brockett, 2005), semantic textual similarity measurement (Cer et al., 2017), natural language inference (Dagan et al., 2005; Bar-Haim et al., 2006) and solving Winograd schema (Levesque et al., 2012). We consider gender bias as a running example throughout this paper and evaluate the proposed method with respect to its ability to overcome gender bias in contextualised word embeddings, and defer extensions to other types of biases to future work.

2 Related Work

Prior work on debiasing word embeddings can be broadly categorised into two groups depending on whether they consider static or contextualised word embeddings. Although we focus on contextualised embeddings in this paper, we first briefly describe prior work on debiasing static embeddings for completeness of the discussion.

Bias in Static Word Embeddings: Bolukbasi et al. (2016) proposed a post-processing approach that projects gender-neutral words into a subspace, which is orthogonal to the gender direction defined by a list of gender-definitional words. However, their method ignores gender-definitional words during the subsequent debiasing process, and focus only on words that are *not* predicted as gender-definitional by a classifier. Therefore, if the classifier erroneously predicts a stereotypical word as gender-definitional, it would not get debiased. Zhao et al. (2018b) modified the original GloVe (Pennington et al., 2014) objective to learn gender-neutral word embeddings (GN-GloVe) from a given corpus. Unlike the above-

---

[1] `https://huggingface.co/transformers/pretrained_models.html`

[2] Code and debiased embeddings: `https://github.com/kanekomasahiro/context-debias`

mentioned methods, Kaneko and Bollegala (2019) proposed GP-GloVe, a post-processing method to preserve gender-related information with autoencoder (Kaneko and Bollegala, 2020), while removing discriminatory biases from stereotypical cases.

Adversarial learning (Xie et al., 2017; Elazar and Goldberg, 2018; Li et al., 2018) for debiasing first encode the inputs and then two classifiers are jointly trained – one predicting the target task (for which we must ensure high prediction accuracy) and the other for protected attributes (that must not be easily predictable). Elazar and Goldberg (2018) showed that although it is possible to obtain chance-level development-set accuracy for the protected attributes during training, a post-hoc classifier trained on the encoded inputs can still manage to reach substantially high accuracies for the protected attributes. They conclude that adversarial learning alone does not guarantee invariant representations for the protected attributes. Ravfogel et al. (2020) found that iteratively projecting word embeddings to the null space of the gender direction to further improve the debiasing performance.

Benchmarks for biases in Static Embeddings: Word Embedding Association Test (WEAT; Caliskan et al., 2017) quantifies various biases (e.g. gender, race and age) using semantic similarities between word embeddings. Word Association Test (WAT) measures gender bias over a large set of words (Du et al., 2019) by calculating the gender information vector for each word in a word association graph created in the Small World of Words project (SWOWEN; Deyne et al., 2019) by propagating masculine and feminine words via a random walk (Zhou et al., 2003). SemBias dataset (Zhao et al., 2018b) contains three types of word-pairs: (a) **Definition**, a gender-definition word pair (e.g. hero – heroine), (b) **Stereotype**, a gender-stereotype word pair (e.g., manager – secretary) and (c) **None**, two other word-pairs with similar meanings unrelated to gender (e.g., jazz – blues, pencil – pen). It uses the cosine similarity between the gender directional vector, $(\overrightarrow{he} - \overrightarrow{she})$, and the offset vector $(\boldsymbol{a} - \boldsymbol{b})$ for each word pair, (a, b), in each set to measure gender bias. WinoBias (Zhao et al., 2018a) uses the ability to predict gender pronouns with equal probabilities for gender neutral nouns such as occupations as a test for the gender bias in embeddings.

Bias in Contextualised Word Embeddings: May et al. (2019) extended WEAT using templates to create a sentence-level benchmark for evaluating bias called SEAT. In addition to the attributes proposed in WEAT, they proposed two additional bias types: *angry black woman* and *double binds* (when a woman is doing a role that is typically done by a man that woman is seen as arrogant). They show that compared to static embeddings, contextualised embeddings such as BERT, GPT and ELMo are less biased. However, similar to WEAT, SEAT also only has positive predictive ability and cannot detect the absence of a bias. Bommasani et al. (2020) evaluated the bias in contextualised embeddings by first distilling static embeddings from contextualised embeddings and then using WEAT tests for different types of biases such as gender (male, female), racial (White, Hispanic, Asian) and religion (Christianity, Islam). They found that aggregating the contextualised embedding of a particular word in different contexts via averaging to be the best method for creating a static embedding from a contextualised embedding.

Zhao et al. (2019) showed that contextualised ELMo embeddings also learn gender biases present in the training corpus. Moreover, these biases propagate to a downstream coreference resolution task. They showed that data augmentation by swapping gender helps more than neutralisation by a projection. They obtain the embedding of two input sentences with reversed gender from ELMo, and obtain the debiased embedding by averaging them. It can only be applied to feature-based embeddings, so it cannot be applied to fine-tuning based embeddings like BERT. We directly debias the contextual embeddings. Additionally, data augmentation requires re-training of the embeddings, which is often costly compared to fine-tuning. Kurita et al. (2019) created masked templates such as "__ is a nurse" and used BERT to predict the masked gender pronouns. They used the log-odds between male and female pronoun predictions as an evaluation measure and showed that BERT to be biased according to it. Karve et al. (2019) learnt conceptor matrices using class definitions in the WEAT and used the negated conceptors to debias ELMo and BERT. Although their method was effective for ELMo, the results on BERT were mixed. This method can only be applied to context-independent vectors, and it requires the creation of static embeddings from BERT and ELMo as a pre-processing step for debi-

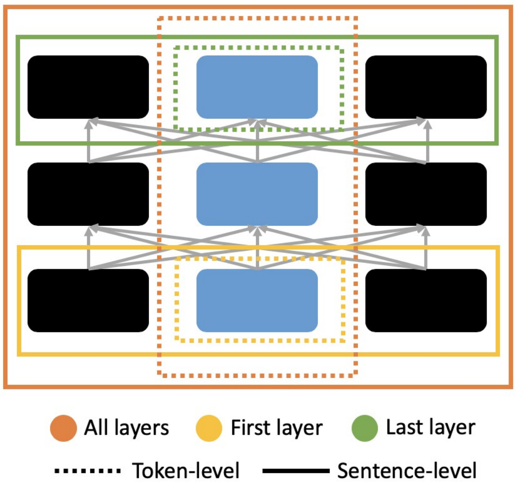

Figure 1: Types of hidden states in E considered in the proposed method. The blue boxes in the middle correspond to the hidden states of the target token.

asing the context-dependent vectors. Therefore, we do not compare against this method in the present study, where we evaluate on context-dependent vectors.

Dev et al. (2020) used natural language inference (NLI) as a bias evaluation task, where the goal is to ascertain if one sentence (i.e. premise) entails or contradictions another (i.e. hypothesis), or if neither conclusions hold (i.e. neutral). The premise-hypothesis pairs are constructed to elicit various types of discriminative biases. They showed that orthogonal projection to gender direction (Dev and Phillips, 2019) can be used to debias contextualised embeddings as well. However, their method can be applied only to the noncontextualised layers (ELMo's Layer 1 and BERT's subtoken layer). In contrast, our proposed method can be applied to *all* layers in a contextualised embedding and outperforms their method on the same NLI task. And our debiasing approach does not require task-dependent data.

3 Debiasing Contextualised Embeddings

We propose a method for debiasing pre-trained contextualised word embeddings in a fine-tuning setting that simultaneously (a) preserves the semantic information in the pre-trained contextualised word embedding model, and (b) removes discriminative gender-related biases via an orthogonal projection in the intermediate (hidden) layers by operating at token- or sentence-levels. Fine-tuning allows debiasing to be carried out without requiring large amounts of tarining data or computational resources. Our debiasing method is independent of model architectures or their pre-training methods, and can be adapted to a wide range of contextualised embeddings as shown in § 4.3.

Let us define two types of words: *attribute* words ($\mathcal{V}_a$) and *target* words ($\mathcal{V}_t$). For example, in the case of gender bias, attribute words consist of multiple word sets such as feminine (e.g. she, woman, her) and masculine (e.g. he, man, him) words, whereas target words can be occupations (e.g. doctor, nurse, professor), which we expect to be gender neutral. We then extract sentences that contain an attribute or a target word. Sentences contain more than one attribute (or target) words are excluded to avoid ambiguities. Let us denote the set of sentences extracted for an attribute or a target word w by $\Omega(w)$. Moreover, let $\mathcal{A} = \bigcup_{w \in \mathcal{V}_a} \Omega(w)$ and $\mathcal{T} = \bigcup_{w \in \mathcal{V}_t} \Omega(w)$ be the sets of sentences containing respectively all of the attribute and target words. We require that the debiased contextualised word embeddings preserve semantic information w.r.t. the sentences in $\mathcal{A}$, and remove any discriminative biases w.r.t. the sentences in $\mathcal{T}$.

Let us consider a contextualised word embedding model E, with pre-trained model parameters $\boldsymbol{\theta}_e$. For an input sentence x, let us denote the embedding of token w in the i-th layer of E by $E_i(w, x; \boldsymbol{\theta}_e)$. Moreover, let the total number of layers in E to be N. In our experiments, we consider different types of encoder models such as E. To formalise the requirement that the debiased word embedding $E_i(t, x; \boldsymbol{\theta}_e)$ of a target word $t \in \mathcal{V}_t$ must not contain any information related to a protected attribute a, we consider the inner-product between the noncontextualised embedding $\boldsymbol{v}_i(a)$ of a and $E_i(t, x; \boldsymbol{\theta}_e)$ as a loss L_i given by (1).

$$L_i = \sum_{t \in \mathcal{V}_t} \sum_{x \in \Omega(t)} \sum_{a \in \mathcal{V}_a} \left(\boldsymbol{v}_i(a)^\top E_i(t, x; \boldsymbol{\theta}_e) \right)^2 \quad (1)$$

Here, $\boldsymbol{v}_i(a)$ is computed by averaging the contextualised embedding of a in the i-th layer of E over all sentences in $\Omega(a)$ following Bommasani et al. (2020) and is given by (2).

$$\boldsymbol{v}_i(a) = \frac{1}{|\Omega(a)|} \sum_{x \in \Omega(a)} E_i(a, x; \boldsymbol{\theta}_e) \quad (2)$$

Here, $|\Omega(a)|$ denotes the total number of sentences in $\Omega(a)$. If a word is split into multiple sub-tokens, we compute the contextualised embedding of the word by averaging the contextualised embeddings of its constituent sub-tokens. Minimising the loss L_i defined by (1) with respect to $\boldsymbol{\theta}_e$ forces the hidden states of E to be orthogonal to the protected attributes such as gender.

Although removing discriminative biases in E is our main objective, we must ensure that simultaneously we preserve as much useful information that is encoded in the pre-trained model for the downstream tasks. We model this as a regulariser where we measure the squared ℓ_2 distance between the contextualised word embedding of a word w in the i-th layer in the original model, parametrised by $\boldsymbol{\theta}_{\text{pre}}$, and the debiased model as in (3).

$$L_{\text{reg}} = \sum_{x\in\mathcal{A}} \sum_{w\in x} \sum_{i=1}^{N} ||E_i(w,x;\boldsymbol{\theta}_e) - E_i(w,x;\boldsymbol{\theta}_{\text{pre}})||^2 \quad (3)$$

The overall training objective is then given by (4) as the linearly weighted sum of the two losses defined by (1) and (3).

$$L = \alpha L_i + \beta L_{\text{reg}} \quad (4)$$

Here, coefficients $\alpha, \beta \in [0, 1]$ satisfy $\alpha + \beta = 1$.

As shown in Figure 1, a contextualised word embedding model typically contains multiple layers. It is not obvious which hidden states of E are best for calculating L_i for the purpose of debiasing. Therefore, we compute L_i for different layers in a particular contextualised word embedding model in our experiments. Specifically, we consider three settings: debiasing only the **first** layer, **last** layer or **all** layers. Moreover, L_i can be computed only for the target words in a sentence x as in (1), or can be summed up for *all* words in $w \in x$ (i.e. $\sum_{t\in\mathcal{V}_t}\sum_{x\in\Omega(t)}\sum_{w\in x}\left(\boldsymbol{v}_i(a)^\top E_i(w,x;\boldsymbol{\theta}_e)\right)^2$). We refer to the former as **token-level** debiasing and latter **sentence-level** debiasing. Collectively this gives us six different settings for the proposed debiasing method, which we evaluate experimentally in § 4.3.

4 Experiments

4.1 Datasets

We used SEAT (May et al., 2019) 6, 7 and 8 to evaluate gender bias. We use NLI as a downstream evaluation task and use the Multi-Genre Natural Language Inference data (MNLI; Williams et al., 2018) for training and development following Dev et al. (2020). In NLI, the task is to classify a given hypothesis and premise sentence-pair as entailing, contradicting, or neutral. We programmatically generated the evaluation set following Dev et al. (2020) by filling occupation words and gender words in template sentences. The templates take the form "The subject verb a/an object." and the created sentence-pairs are assumed to be neutral.

We used the word lists created by Zhao et al. (2018b) for the attribute list of feminine and masculine words. As for the stereotype word list for target words, we use the list created by Kaneko and Bollegala (2019). Using News-commentary-v15 corpus[3] was extract 11023, 42489 and 34148 sentences respectively for Feminine, Masculine and Stereotype words. We excluded sentences with more than 128 tokens in training data. We randomly sampled 1,000 sentences from each type of extracted sentences as development data.

We used the GLEU benchmark (Wang et al., 2018) to evaluate whether the useful information in the pre-trained embeddings is retrained after debiasing. To evaluate the debiased models with minimal effects due to task-specific fine-tuning, we used the following small-scale training data: Stanford Sentiment Treebank (SST-2; Socher et al., 2013), Microsoft Research Paraphrase Corpus (MRPC; Dolan and Brockett, 2005), Semantic Textual Similarity Benchmark (STS-B; Cer et al., 2017), Recognising Textual Entailment (RTE; Dagan et al., 2005; Bar-Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009), and Winograd Schema Challenge (WNLI; Levesque et al., 2012). We evaluate the performance of the contextualised embeddings on the corresponding development data.

4.2 Hyperparameters

We used BERT (**bert-base-uncased**; Devlin et al., 2019), RoBERTa (**roberta-base**; Liu et al., 2019), ALBERT (**albert-base-v2**; Lan et al., 2020), DistilBERT (**distilbert-base-uncased**; Sanh et al., 2019) and ELECTRA (**electra-small-discriminator**; Clark et al., 2020) in our experiments.[4] DistilBERT has 6 layers and the others 12. We used the development data in SEAT-6 for hyperparameter tuning. The hyperparameters of the models, except the learning rate and batch size, are set to their default values as in `run_glue.py`. Using greedy search, the learning rate was set to 5e-5 and the

batch size to 32 during debiasing. Optimal values for $\alpha = 0.2$ and $\beta = 0.8$ were found by a greedy search in $[0, 1]$ with 0.1 increments. For the GLEU and MNLI experiments, we set the learning rate to 2e-5 and the batch size to 16. Experiments were conducted on a GeForce GTX 1080 Ti GPU.

4.3 Debiasing vs. Preserving Information

Table 1 shows the results on SEAT and GLEU where **original** denotes the pre-trained contextualised models prior to debiasing. We see that original models other than ELECTRA contain significant levels of gender biases. Overall, the **all-token** method that conducts token-level debiasing across all layers performs the best. Prior work has shown that biases are learned at each layer (Bommasani et al., 2020) and it is important to debias all layers. Moreover, we see that debiasing at token-level is more efficient compared to at the sentence-level. This is because in token-level debiasing, the loss is computed only on the target word and provides a more direct debiasing update for the target word than in the sentence-level debiasing, which sums the losses over all tokens in a sentence.

To test the importance of carefully selecting the target words considering the types of biases that we want to remove from the embeddings, we implement a **random** baseline where we randomly select target and attribute words from $\mathcal{V}_a \cup \mathcal{V}_t$ and perform **all-token** debiasing. We see that **random** debiases BERT to some extent but is not effective on other models. This result shows that the

random	80.5	81.1	85.8	96.4	87.0

Table 2: Debias results for BERT in MNLI.

proposed debiasing method is *not* merely a regularisation technique that imposes constraints on any arbitrary set of words, but it is essential to carefully select the target words used for debiasing.

The results on GLEU show that BERT, DistilBERT and ELECTRA compared to the **original** embeddings, the debiased embeddings report comparable performances in most settings. This confirms that the proposed debiasing method preserves sufficient semantic information contained in the **original** embeddings that can be used to learn accurate prediction models for the downstream NLP tasks.[5] However, the performance of RoBERTa and ALBERT decrease significantly compared to their **original** versions after debiasing. We suspect that these models are more sensitive to fine-tuning and hence lose their pre-trained information during the debiasing process. We defer the development of techniques to address this issue to future research.

4.4 Measuring Bias with Inference

Following Dev et al. (2020), we use the multi-genre co-reference-based natural language inference (MNLI) dataset for evaluating gender bias. This dataset contains sentence triples where a premise must be neutral in entailment w.r.t. two hypotheses. If the predictions made by a classifier that uses word embeddings as features deviate from neutrality, it is considered as biased. Given a set containing M test instances, let the entailment predictor's probabilities for the m-th instance for entail, neutral and contradiction labels be respectively e_m, n_m and c_m. Then, they proposed the following measures to quantify the bias: (1) Net Neutral (**NN**): NN $= \frac{1}{M}\sum_{m=1}^{M} n_m$; (2) Fraction Neutral (**FN**): FN $= \frac{1}{M}\sum_{m=1}^{M} \mathbf{1}[\text{neutral} = \max(e_m, n_m, c_m)]$; and (3) Threshold τ (**T:**τ): T:τ $= \mathbf{1}[n_m \geq \tau]$, where we used $\tau = 0.7$ following Dev et al. (2020). For an ideal (bias-free) embedding, all three measure would be 1.

Model	*Layer*	SEAT-6	SEAT-7	SEAT-8

	first	0.28	0.13	0.34

Table 3: Averaged scores over all layers in an embedding debiased at token-level, measured on SEAT tests.

In Table 2, we compare our proposed method against the *noncontextualised debiasing* method proposed by Dev et al. (2020) where they debias Layer 1 of BERT-large model using an orthogonal projection to the gender direction during training and evaluation. In addition to the above-mentioned measures, we also report the entailment accuracy on the matched (in-domain) and mismatched (cross-domain) denoted respectively by **MNLI-m** and **MNLI-mm** in Table 2 to evaluate the semantic information preserved in the embeddings after debiasing.

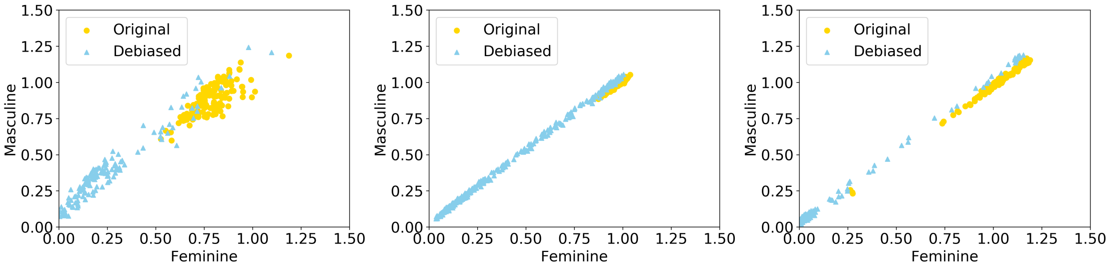
We see that the proposed method outperforms noncontextualised debiasing (Dev et al., 2020) in NN and T:0.7, and its performance of the MNLI task is comparable to the original embeddings. This result further confirms that the proposed method can not only debias well but can also preserve the pre-trained information. Moreover, it is consistent with the results reported in Table 1 and shows that debiasing all layers is more effective than only the first layer as done by Dev et al. (2020).

4.5 The Importance of Debiasing All Layers

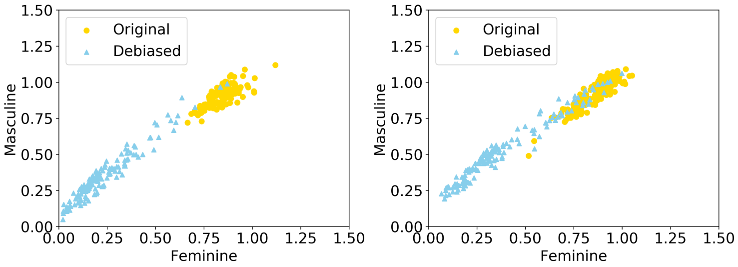
In Table 1, we investigated the bias for the final layer, but it is known that the contextualised embeddings are learned at each layer (Bommasani et al., 2020). Therefore, to investigate whether by debiasing in each layer we are able to remove the biases of the entire contextualised embeddings, we evaluate the debiased embeddings at each layer

---

[5] Although on WNLI **all-token** debiasing improves performance for DistilBERT and ELECTRA compared to the respective **original** models, this is insignificant as WNLI contains only 146 test instances.



(a) BERT (b) RoBERTa (c) ALBERT



(d) DistilBERT (e) ELECTRA

Figure 2: Scatter plot of gender information of hidden states for original and debiased stereotype words.

on SEAT 6, 7, 8 datasets and report the averaged metrics for **all-token**, **first-token** and **last-token** methods in Table 3. We see that, on average, **fitst-token** and **last-token** methods have more bias than **all-token**. Therefore, we conclude that It is not enough to debias only the first and last layers even in DistilBERT, which has a small number of layers. These results show that biases in the entire contextualised embedding cannot be reliably removed by debiasing only some selected layers, but rather the importance of debiasing all layers consistently.

4.6 Visualizing Debiasing Results

To further illustrate the effect of debiasing using the proposed **all-token** method, we visualise the similarity scores of a stereotypical word with feminine and masculine dimensions as follows. First, for each target word t, its hidden state, $E_i(t, x)$ in the i-th layer of the model E in a sentence x is computed. Next, we average those hidden states across all sentences in the dataset that contain t to obtain $\hat{E}_i(t) = \frac{1}{|\mathcal{T}|}\sum_{x \in \mathcal{T}} E_i(t, x)$. Likewise, we compute $\hat{E}_i(f)$ and $\hat{E}_i(m)$ respectively for each feminine (f) and masculine (m) word. Next, we compute, s_i^f, the cosine similarity between each $\hat{E}_i(f)$ and the feminine vector $\boldsymbol{v}_i(f)$, and the cosine similarity, s_i^m, between each $\hat{E}_i(f)$ and the masculine vector $\boldsymbol{v}_i(f)$. $\boldsymbol{s}_i^f$ and $\boldsymbol{s}_i^m$, respectively, are averaged over all layers in a contextualised embedding model to obtain $\boldsymbol{s}_{\text{Avg}}^f$ and $\boldsymbol{s}_{\text{Avg}}^m$, which represent how much gender information each gender word contains on average.

We then compute the cosine similarity, $\boldsymbol{s}_i^{t,f}$, between each stereotype word's averaged embedding, $\hat{E}_i(t)$ and the feminine vector $\boldsymbol{v}_i(f)$. Similarly, we compute the cosine similarity $\boldsymbol{s}_i^{t,m}$ between each stereotype word's averaged embedding $\hat{E}_i(t)$ and the masculine vector $\boldsymbol{v}_i(m)$. We then average $\boldsymbol{s}^{t,f}$ and $\boldsymbol{s}^{t,m}$ over the layers in E respectively, to compute $\boldsymbol{s}_{\text{Avg}}^{t,f}$ and $\boldsymbol{s}_{\text{Avg}}^{t,m}$, which represent how much gender information each stereotype word contains on average. Finally, we visualise the normalised female and male gender scores given respectively by $\boldsymbol{s}_{\text{Avg}}^{t,f} / \boldsymbol{s}_{\text{Avg}}^f$ and $\boldsymbol{s}_{\text{Avg}}^{t,m} / \boldsymbol{s}_{\text{Avg}}^m$. For example, a zero $\boldsymbol{s}_{\text{Avg}}^{t,f} / \boldsymbol{s}_{\text{Avg}}^f$ value indicates that t does not contain female gender related information, whereas a value of one indicates that it contains all information about the female gender. Figure 2 shows each stereotype word with its normalised female ad male gender scores respectively in x and y axises. For a word, a yellow circle denotes its original embeddings, and the blue triangle denotes the result of debiasing using the **all-token** method.

We see that with the original embeddings, stereotypical words of are distributed close to one, indicating that they are highly gender-specific. On the other hand, we see that the debiased BERT, DistilBERT and ELECTRA have similar word distributions compared to the original embeddings respectively, with an overall movement towards zero. On the other hand, for RoBERTa, debiased embeddings are mainly distributed from zero to around one compared to the original embeddings. Moreover, for ALBERT, the debiased embeddings are close to zero, but unlike the original distribution, the debiased embeddings are mainly clustered around zero. This shows that RoBERTa and ALBERT do not retain structure of the original distribution after debiasing. While ALBERT over-debiases pre-trained embeddings of stereotypical words, RoBERTa under-debiases them. This trend was already confirmed on the downstream evaluation tasks conducted in Table 1.

5 Conclusion

We proposed a debiasing method for pre-trained contextualised word embeddings, operating at token- or sentence-levels. Our experimental results showed that the proposed method effectively debiases discriminative gender-related biases, while preserving useful semantic information in the pre-trained embeddings. The results showed that the downstream task was more effective in debias than the previous studies.

Language Models for Lexical Inference in Context

Martin Schmitt[1] and **Hinrich Schütze**[2]
Center for Information and Language Processing (CIS)
LMU Munich, Germany
[1]`martin@cis.lmu.de` [2]`inquiries@cislmu.org`

Abstract

Lexical inference in context (LIiC) is the task of recognizing textual entailment between two very similar sentences, i.e., sentences that only differ in one expression. It can therefore be seen as a variant of the natural language inference task that is focused on lexical semantics. We formulate and evaluate the first approaches based on pretrained language models (LMs) for this task: (i) a few-shot NLI classifier, (ii) a relation induction approach based on handcrafted patterns expressing the semantics of lexical inference, and (iii) a variant of (ii) with patterns that were automatically extracted from a corpus. All our approaches outperform the previous state of the art, showing the potential of pretrained LMs for LIiC. In an extensive analysis, we investigate factors of success and failure of our three approaches.[1]

1 Introduction

Lexical inference (LI) denotes the task of deciding whether or not an entailment relation holds between two lexical items. It is therefore related to the detection of other lexical relations like hyponymy between nouns (Hearst, 1992), e.g., *dog* ⇒ *animal*, or troponymy between verbs (Fellbaum and Miller, 1990), e.g., *to traipse* ⇒ *to walk*. Lexical inference in context (LIiC) adds the problem of disambiguating the pair of lexical items in a given context before reasoning about the inference question. This type of LI is particularly interesting for entailments between verbs and verbal expressions because their meaning – and therefore their implications – can drastically change with different arguments. Consider, e.g., *run* ⇒ *lead* in a PERSON / COMPANY context ("Bezos runs Amazon") vs. *run* ⇒ *execute* in a COMPUTER / SOFTWARE context ("My mac runs macOS"). LIiC is thus also closely related to the task of natural language inference (NLI) – also called recognizing textual entailment (Dagan et al., 2013) – and can be seen as a focused variant of it. Besides the important use case of evaluating NLI systems, this kind of predicate entailment has also been shown useful for question answering (Schoenmackers et al., 2010), event coreference (Shwartz et al., 2017; Meged et al., 2020), and link prediction in knowledge graphs (Hosseini et al., 2019).

Despite its NLI nature, previous systems for LIiC have primarily been models of lexical similarity (Levy and Dagan, 2016) or models based on verb argument inclusion (Hosseini et al., 2019). The reason is probably that supervised NLI models need large amounts of training data, which is unavailable for LIiC, and that systems trained on available large-scale NLI benchmarks (e.g., Williams et al., 2018) have been reported to insufficiently cover lexical phenomena (Glockner et al., 2018; Schmitt and Schütze, 2019).

Recently, transfer learning has become ubiquitous in NLP; Transformer (Vaswani et al., 2017) language models (LMs) pretrained on large amounts of textual data (Devlin et al., 2019a; Liu et al., 2019) form the basis of a lot of current state-of-the-art models. Besides zero- and few-shot capabilities (Radford et al., 2019; Brown et al., 2020), pretrained LMs have also been found to acquire factual and relational knowledge during pretraining (Petroni et al., 2019; Bouraoui et al., 2020). The entailment relation certainly stands out among previously explored semantic relations – such as the relation between a country and its capital – because it is very rarely stated explicitly and often involves reasoning about both the meaning of verbs and additional knowledge (Schmitt and Schütze, 2019). It is unclear whether implicit clues during pretraining are enough to learn about LIiC and what the best way is to harness any such implicit knowledge.

Regarding these questions, we make the follow-

ing contributions: (1) This work is the first to explore the use of pretrained LMs for the LIiC task. (2) We formulate three approaches and evaluate them using the publicly available pretrained RoBERTa LM (Liu et al., 2019; Wolf et al., 2019): (i) a few-shot NLI classifier, (ii) a relation induction approach based on handcrafted patterns expressing the semantics of lexical inference, and (iii) a variant of (ii) with patterns that were automatically extracted from a corpus. (3) We introduce the concept of antipatterns, patterns that express non-entailment, and evaluate their usefulness for LIiC. (4) In our experiments on two established LIiC benchmarks, Levy/Holt's dataset (Levy and Dagan, 2016; Holt, 2018) and SherLIiC (Schmitt and Schütze, 2019), all our approaches consistently outperform previous work, thus setting a new state of the art for LIiC. (5) In contrast to previous work on relation induction (Bouraoui et al., 2020), automatically retrieved patterns do not outperform handcrafted ones for LIiC. A qualitative analysis of patterns and errors identifies possible reasons for this finding.

2 Related Work

Lexical inference. There has been a lot of work on lexical inference for nouns, notably hypernymy detection, resulting in a variety of benchmarks (Kotlerman et al., 2010; Kiela et al., 2015) and methods (Shwartz et al., 2015; Vulić and Mrkšić, 2018). Although there has been work on predicate entailment before (Lin and Pantel, 2001; Lewis and Steedman, 2013), Levy and Dagan (2016) were the first to create a general benchmark for evaluating entailment between verbs. In their evaluation, neither resource-based approaches (Pavlick et al., 2015; Berant et al., 2011) nor vector space models (Levy and Goldberg, 2014) achieved satisfying results. Holt (2018) later published a re-annotated version, which was readily adopted by later work. Hosseini et al. (2018) put global constraints on top of directed local similarity scores (Weeds and Weir, 2003; Lin, 1998; Szpektor and Dagan, 2008) based on distributional features of the predicates. Hosseini et al. (2019) replaced these scores by transition probabilities in a bipartite graph where edge weights are computed by a link prediction model.

When Schmitt and Schütze (2019) created the SherLIiC benchmark, they also mainly focused on resource- and vector-based models for evaluation. Their best model combines general-purpose word2vec representations (Mikolov et al., 2013) with a vector representation of the arguments that co-occur with a predicate.

All these works (i) base the probability of entailment validity on the similarity of the verbs and (ii) compute this similarity via (expected) co-occurrence of verbs and their arguments. Our work differs in that our models solely reason about the sentence surface in an end-to-end NLI task without access to previously observed argument pairs. This is possible because our models have learned about these surface forms during pretraining.

Patterns and entailment. Pattern-based approaches have long been known for hypernymy detection (Hearst, 1992). Recent work combined them with vector space models (Mirkin et al., 2006; Roller and Erk, 2016; Roller et al., 2018). While there are effective patterns, such as X *is a* Y, that are indicative for entailment between nouns, there is little work on comparable patterns for verbs. Schwartz et al. (2015) mine symmetric patterns for lexical similarity and achieve good results for verbs. Entailment, however, is not symmetric.

Chklovski and Pantel (2004) handcrafted 35 patterns to distinguish 6 semantic relations for pairs of distributionally similar verbs. Some of their classes like strength (*taint :: poison*) or antonymy (*ban :: allow*) can be indicators of entailment and non-entailment but are, in general, much more narrowly defined than the patterns we use in our approach. Another difference to our work is that verb pairs are scored based on co-occurrence counts on the web, while we employ an LM, which does not depend on a valid entailment pair actually appearing together in a document.

Patterns and language models. Amrami and Goldberg (2018) were the first to manipulate LM predictions with a simple pattern to enhance the quality of substitute words in a given context for word sense induction. Petroni et al. (2019) found that large pretrained LMs can be queried for factual knowledge, when presented with appropriate pattern-generated cloze-style sentences. This zero-shot factual knowledge has later been shown to be quite fragile (Kassner and Schütze, 2020). So we rather focus on approaches that fine-tune an LM on at least a few samples. Forbes et al. (2019) train a binary classifier on top of a fine-tuned BERT (Devlin et al., 2019a) to predict the truth value of handwritten statements about objects and their properties. While their experiments investigate BERT's physical common sense reasoning, we focus on the different phenomenon of entailment between two actions expressed by verbs in context.

Schick and Schütze (2020) used handcrafted patterns and LMs for few-shot text classification. Based on manually defined label-token correspondences, the predicted classification label is determined by the token an LM estimates as most probable at a masked position in the cloze-style pattern. We differentiate entailment and non-entailment via compatibility scores for patterns and antipatterns and not via different predicted tokens.

Addressing relation induction, Bouraoui et al. (2020) propose an automatic way of finding, given a relation, LM patterns that are likely to express it. They train a binary classifier per relation on the sentences generated by these patterns. While some of the relations they consider are related to verbal entailment (e.g., *cook activity-goal eat*), most of them concern common sense (e.g., *library location-activity reading*) or encyclopedic knowledge (e.g., *Paris capital-of France*). We adapt their method for the automatic retrieval of promising patterns for LIiC, but find that handcrafted patterns that capture the generality of the entailment relation still have an advantage over automatic patterns for LIiC. Another important novelty we introduce is the use of antipatterns. While Bouraoui et al. (2020) have to use negative samples for training their classifiers, they only consider patterns that exemplify the desired relation. In contrast, we also use antipatterns that exemplify what the entailment relation is **not**. We believe that antipatterns are particularly useful for entailment detection because they can help identify other kinds of semantic relations that often pose a challenge to vector space models (Levy and Dagan, 2016; Schmitt and Schütze, 2019).

3 Proposed Approaches

3.1 NLI classifier

Building an NLI classifier on top of a pretrained LM usually means taking an aggregate sequence representation of the concatenated premise and hypothesis as input features of a neural network classifier (Devlin et al., 2019b). For RoBERTa (Liu et al., 2019), this representation is the final hidden state of a special $\langle \mathtt{s} \rangle$ token that is prepended to the input sentences, which in turn are separated by a separator token $\langle / \mathtt{s} \rangle$. Let Λ be the function that maps such an input $x = x_1 \langle / \mathtt{s} \rangle x_2$ to the aggregate representation $\Lambda(x) \in \mathbb{R}^d$. Following (Devlin et al., 2019b; Liu et al., 2019), we then feed these features to a 2-layer feed-forward neural network with tanh activation:

$$\begin{aligned} h(x) &= \tanh(\mathrm{drop}(\Lambda(x)) W_1 + b_1) \\ P_{\text{NLI}}(y \mid x) &= \sigma(\mathrm{drop}(h(x)) W_2 + b_2) \end{aligned} \tag{1}$$

where drop applies dropout with a probability of 0.1, σ is the softmax function, and $W_1 \in \mathbb{R}^{d \times d}, W_2 \in \mathbb{R}^{d \times 2}, b_1 \in \mathbb{R}^d, b_2 \in \mathbb{R}^2$ are learnable parameters. Note that W_1 and b_1 are still part of the LM's pretrained parameters; so we only train W_2 and b_2 from scratch.[2] The actual classification decision uses a threshold ϑ:

$$D^{\vartheta}_{\text{NLI}}(x_1, x_2) = \begin{cases} 1, & \text{if } P_{\text{NLI}}(y = 1 \,|\, x_1, x_2) > \vartheta \\ 0, & \text{otherwise} \end{cases}$$

The traditional choice for the threshold is $\vartheta = 0.5$ because that means $D^{\vartheta}_{\text{NLI}}(x_1, x_2) = 1$ iff $P_{\text{NLI}}(y = 1 \mid x_1, x_2) > P_{\text{NLI}}(y = 0 \mid x_1, x_2)$. We nevertheless keep ϑ as a hyperparameter to be tuned on held-out development data.

We train the NLI approach by minimizing the negative log-likelihood $\mathcal{L}_{\text{NLI}}$ of the training data $\mathcal{T}$:

$$\mathcal{L}_{\text{NLI}}(\mathcal{T}) = \sum_{(x_1, x_2, y) \in \mathcal{T}} -\log(P_{\text{NLI}}(y \mid x_1, x_2))$$

3.2 Pattern-based classifier

This approach puts the input sentences x_1, x_2 together in a pattern-based textual context and trains a classifier to distinguish between felicitous and infelicitous utterances.[3] In contrast to previous approaches (Forbes et al., 2019; Bouraoui et al., 2020), we also consider antipatterns that exemplify what kind of semantic relatedness we are not interested in, and combine probabilities for patterns and antipatterns in the final classification.

Finding suitable patterns. A simple handcrafted pattern to check for the validity of an inference $x_1 \Rightarrow x_2$ is "x_2 *because* x_1.". An analoguos antipattern is "*It is not sure that* x_2 *just because* x_1.". Based on similar considerations, we manually design 5 patterns and 5 antipatterns (see Table 4). We will refer to the approach using these handcrafted patterns as MANPAT.

Bouraoui et al. (2020) argue that text produced by simple, handcrafted patterns is artificial and

---

[2] We follow the official implementation; cf. Jacob Devlin's comment on issue 43 in the BERT GitHub repository, `https://github.com/google-research/bert/issues/43`, (accessed 19 January 2021).

[3] Bouraoui et al. (2020) called this natural vs. unusual.

therefore suboptimal for LMs pretrained on naturally occurring text. To adapt their setup to verbal expressions used in LIiC, we identify suitable patterns (antipatterns) by searching a large text corpus[4] for sentences that contain both elements of valid (invalid) entailment pairs. In a second step, we score each of these patterns (antipatterns) according to the number of valid (invalid) entailment pairs x_1, x_2 that can be found by querying an LM for the k most probable completions when x_1 or x_2 is inserted in the pattern and its counterpart is masked. For example, consider the entailment pair *rule* ⇒ *control* and the pattern "*Catchers* ***prem*** *the field; they* ***hypo*** *the plays and tell everyone where to be.*" extracted from a description of softball. Predicting *rule* from "*Catchers* ⟨`mask`⟩ *the field; they control the plays and tell everyone where to be.*" and predicting *control* from "*Catchers rule the field; they* ⟨`mask`⟩ *the plays and tell everyone where to be.*" would result in one point each. Approaches called AUTPAT$_n$ use the n patterns with the most points obtained in that manner. See §4 for more details on our experimental setup.

Pattern-based predictions. The probability $P_{\text{FEL}}(z \mid x)$ of sentence x to be felicitous ($z=1$) or infelicitous ($z=0$) is estimated like P_{NLI} in Eq. (1), except that x is not the concatenation of two sentences but a single pattern-generated utterance.

Given a set of patterns Φ and a set of antipatterns Ψ, the score s to judge an input x_1, x_2 is the difference between the maximum probability m_{pos} that any pattern forms a felicitous statement and the maximum probability m_{neg} that any antipattern forms a felicitous statement:

$$\begin{aligned} m_{\text{pos}} &= \max_{\varphi \in \Phi} P_{\text{FEL}}(z = 1 \mid \varphi(x_1, x_2)) \\ m_{\text{neg}} &= \max_{\psi \in \Psi} P_{\text{FEL}}(z = 1 \mid \psi(x_1, x_2)) \\ s(x_1, x_2) &= m_{\text{pos}} - m_{\text{neg}} \end{aligned}$$

As in NLI, the final decision uses a threshold ϑ:

$$D^{\vartheta}_{\text{PAT}}(x_1, x_2) = \begin{cases} 1, & \text{if } s(x_1, x_2) > \vartheta \\ 0, & \text{otherwise} \end{cases}$$

This corresponds to requiring that m_{pos} be higher than m_{neg} by a margin ϑ, i.e., $D^{\vartheta}_{\text{PAT}}(x_1, x_2) = 1$ iff $m_{\text{pos}} > m_{\text{neg}} + \vartheta$.

As Bouraoui et al. (2020) did not use antipatterns, they defined m_{neg} as the maximum probability for any pattern to form an infelicitous statement.

		Levy/Holt	SherLIiC
dev$_1$	train	4,388	797
	dev$_2$	1,098	201
test		12,921	2,990

Table 1: Data split sizes as used in our experiments.

To estimate the usefulness of antipatterns, we evaluate both possibilities, marking systems that use both patterns and antipatterns with ΦΨ and those that only use patterns with Φ.

The use of a threshold is another novel component, i.e., Bouraoui et al. (2020) virtually set $\vartheta = 0$. We discuss the influence of ϑ in §5.

We train all pattern-based approaches by minimizing the negative log-likelihood $\mathcal{L}_{\text{PAT}}$ that patterns Φ produce felicitous statements for valid entailments ($y = 1$) and infelicitous statements for invalid entailments ($y = 0$) from the training data $\mathcal{T}$, and vice versa for antipatterns Ψ:

$$\mathcal{L}_{\text{PAT}}(\mathcal{T}, \Phi, \Psi) = \sum_{(x_1, x_2, y) \in \mathcal{T}} \mathcal{L}_{\Phi}(x_1, x_2, y) + \mathcal{L}_{\Psi}(x_1, x_2, 1 - y)$$

with

$$\mathcal{L}_{\Omega}(x_1, x_2, y) = -\frac{1}{|\Omega|} \sum_{\omega \in \Omega} \log(P_{\text{FEL}}(z = y \mid \omega(x_1, x_2)))$$

4 Experiments

We evaluate on two benchmarks: (i) Levy/Holt's dataset (Levy and Dagan, 2016; Holt, 2018) and (ii) SherLIiC (Schmitt and Schütze, 2019). For both filtering and classification, we employ RoBERTa-base (Liu et al., 2019). For classification only, we also report results for RoBERTa-large.

4.1 Data processing

For both datasets, previous work has established a dev/test split. For Levy/Holt, it was defined in (Hosseini et al., 2018); for SherLIiC, we use the original one from (Schmitt and Schütze, 2019). For comparison with previous work, we keep the test portion as is and split the dev portion further into 80% for training and 20% for development. We call the new, smaller dev sets dev$_2$ and the original dev sets dev$_1$. See Table 1 for data split sizes.

Levy/Holt. An instance in Levy/Holt has two sentences, each consisting of two shared noun

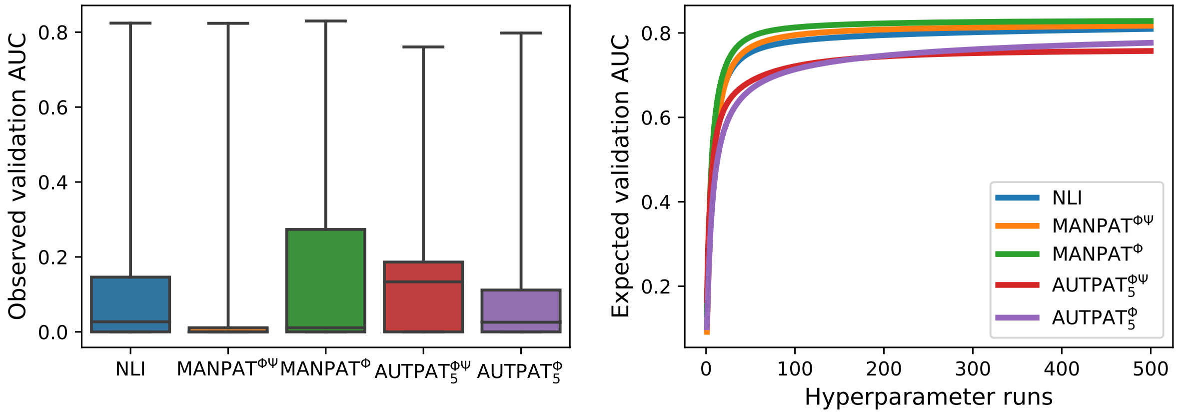
(a) Levy/Holt dev$_2$ RoBERTa-base



(b) SherLIiC dev$_2$ RoBERTa-base

Figure 1: Validation performance distribution of different datasets across different hyperparameter runs (left) and expected validation performance per number of tested hyperparameter configurations as proposed by Dodge et al. (2019) (right). Performance is measured as the area under the precision-recall curve for precision values ≥ 0.5. The Boxes represent 75% of the respective data points; a black line indicates the median, whiskers extend to the maximum value.

phrases (the arguments) and a verbal expression, in which the two sentences differ. As the verbal expressions can contain auxiliaries or negation, they often consist of multiple tokens. Originally, one argument is replaced with a WordNet (Miller, 1995) type in one of the sentences to make the entailment more general during annotation, but we use a version of the dataset provided by Hosseini et al. (2018) where both sentences have concretely instantiated arguments. For example, consider Table 6 (c). *Athena* was masked as the WordNet synset *deity* during benchmark annotation but we use the original sentences as shown in Table 6 for all classifiers without further modification.

For the automatic pattern search in AUTPAT, we look for sentences that mention verbatim the two verbal expressions of any instance from dev$_1$. For the ranking, we take the last token of a verbal expression as representative for the whole. This has the advantage that we can query the LM with a single $\langle$`mask`$\rangle$ token and compare a single token to the $k = 100$ most probable predictions. We take the last token because it usually is the main verb.

SherLIiC. For classification, we use SherLIiC's automatically generated sentences that were used for annotation during benchmark creation. The arguments in SherLIiC are entity types from Freebase (Bollacker et al., 2008). As such, they can be replaced by any Freebase entity with matching type. For example, consider Table 6 (a); the arguments *Germany* and *Côte d'Ivoire* were originally masked as *location[A]* and *location[B]* during annotation, but annotators also saw three randomly chosen instantiations for both *A* (*Germany / Syria / USA*) and *B* (*Côte d'Ivoire / UK / Italy*) for context. From the three examples provided in SherLIiC for each argument, we choose the first one to form sentences with concretely instantiated arguments.

For the automatic pattern search in AUTPAT, we make use of the greater flexibility offered by the

lemmatized representations in SherLIiC. As we are interested in statements that can be made in any way in a text, we search for sentences that mention the two predicates of a SherLIiC dev_1 instance in any inflected form. For the ranking, we again consider the predicate representative for the whole verbal expression. We thus use the predicate lemma and otherwise proceed as described above.

4.2 Training details

We train all our classifiers for 5 epochs with Adam (Kingma and Ba, 2015) and a mini-batch size of 10 (resp. 2) for RoBERTa-base (resp. -large). We randomly sample 500 configurations for the remaining hyperparameters (see Appendix A). For a fair comparison, we evaluate all our approaches with the same configurations.

5 Results and Discussion

5.1 Hyperparameter robustness

Following previous work (Hosseini et al., 2018, 2019), we use the area under the precision-recall curve (AUC) restricted to precision values ≥ 0.5 as criterion for model selection.

Fig. 1 (left) shows the distribution of dev_2 performance for 500 randomly sampled runs with RoBERTa-base. Most hyperparameters perform poorly, suggesting that hyperparameter search is crucial. For Levy/Holt, NLI is strong whereas for SherLIiC handcrafted MANPAT$^{\Phi}$ patterns have a clearer advantage. For SherLIiC, the combination of automatically generated patterns and antipatterns AUTPAT$_5^{\Phi\Psi}$ exhibits the highest median performance and the second-highest upper quartile, making it together with MANPAT$^{\Phi}$ the most robust to different hyperparameters, although its top performance is lower compared to the others. For all methods, only very few hyperparameter sets achieve top performances. For both datasets, however, a well-performing configuration is found after fewer than 100 sampled runs (Fig. 1, right). Considering that AUTPAT requires an LM to rank thousands of patterns, these results suggest that, for LIiC, available GPU hours should be spent on automatic hyperparameter rather than pattern search. With its manually written patterns, MANPAT does not need additional GPU hours for pattern search and still, on average, performs better.

5.2 Best hyperparameter configurations

For the best found configuration for each method, we not only report AUC, which provides a general picture of a scoring method's precision-recall tradeoff, but also the concrete precision, recall, and F1 for the actual classification after applying a threshold ϑ. For this we tune ϑ on dev_2 for optimal F1. Tables 2 and 3 show the results.

On both datasets, our methods outperform all previous work (sometimes by a large margin), thus establishing a new state of the art. For SherLIiC+RoBERTa-base, the strong but simple NLI system is consistently outperformed by all pattern-based approaches, showing that well-

(e)	HARGL **hypo-negated** HARGR, which means that PARGL **prem-negated** PARGR.		

Table 4: Examples of automatically retrieved and ranked AUTPAT patterns (top) and handcrafted MANPAT patterns (bottom). prem/hypo = original fillers as found in the corpus. PARGL/HARGL = placeholder for left argument of premise/hypothesis; PARGR/HARGR = right argument.

chosen patterns and antipatterns can be helpful for LIiC. For SherLIiC+RoBERTa-large and also generally on Levy/Holt's dataset, NLI is more competitive, but the combination of handcrafted patterns and antipatterns MANPAT$^{\Phi\Psi}$ still performs better in these cases.

The use of antipatterns does not consistently lead to better performance for all combinations of dataset, LM variant (base vs. large), and pattern set (MANPAT vs. AUTPAT). They do, however, consistently bring gains for some combinations, e.g., MANPAT on Levy/Holt and AUTPAT on SherLIiC. Moreover, antipatterns are essential for achieving top performance, i.e., the new state of the art, on both datasets.

Most of the threshold values ϑ (tuned on dev$_2$) are far from their traditional values, 0.5 for NLI and 0.0 for patterns. NLI classifiers' probability estimates are often too confident, resulting in values close to 0 and 1. To "correct" cases where a very small value is assigned to a valid entailment, optimal thresholds are often close to 0 instead of 0.5. Analogously, most pattern-based approaches opt for a negative ϑ, which means that instead of requiring a margin between m_{pos} and m_{neg} (boosting precision), they make more positive predictions and boost recall. Low recall is a key problem in LIiC (cf. Levy and Dagan (2016)). Tuning a threshold increases the models' flexibility in this aspect.

6 Analysis

6.1 Number of patterns

§5 shows that automatic patterns do not beat handcrafted patterns for LIiC. However, automatic patterns have one major advantage: in contrast to manual patterns, their number can be easily increased. We therefore investigate the impact of the hyperparameter n for AUTPAT$_n$.

	$\Phi\Psi$		Φ	
n	AUC	F1	AUC	F1
5	67.4	68.0	67.3	67.2
15	**70.0**	**68.7**	**73.1**	**69.4**
25	63.5	67.3	69.0	68.7
50	66.3	65.6	67.4	67.6

Table 5: RoBERTa-base+AUTPAT$_n$ results on SherLIiC test for different n values. Hyperparameters were tuned for the corresponding AUTPAT$_5$ method on dev$_2$.

Table 5 shows that too many patterns is as bad as too few. AUTPAT$_{15}$ is the sweetspot: on SherLIiC, it outperforms all other RoBERTa-base methods on AUC and closely approaches the otherwise best method MANPAT$^{\Phi}$ on F1.

6.2 Pattern analysis

Handcrafted patterns mostly outperform automatic ones (§5). A larger number n of patterns only has a small effect (§6.1). We therefore take a closer look at automatic and manual patterns. Table 4 shows all handcrafted and a sample of highly ranked automatic patterns.

It is striking how specific the automatically retrieved contexts are; especially for the highest ranks (exemplified by ranks 1 and 5) only a narrow set of verbs seems plausible from a human perspective. It is only at rank 12 that we find a more general context and it arguably even displays some semantic reasoning. There certainly are verbs that are not compatible with the meaning of *visit*, but this context allows for a wide range of plausible verbs and even mentions composition of meaning.

The handcrafted patterns, in contrast, all capture some general aspect of entailment, which might be the reason they generalize better. Moreover, they also have placeholder slots for the verb arguments, which could be an advantage as these represent a verb's original context. Only accepting corpus sentences in which the verbs occur with the same arguments as in the dataset is too restrictive.

We therefore conduct the following experiment: We manually go through the 100 highest-ranked automatically created patterns and identify 5 contexts that could accommodate arguments without changing the overall sentence structure. We also try to pick patterns that are different enough from each other to avoid redundancy. As a baseline, the method AUTCUR$^{\Phi}_{5}$ uses these manually curated patterns as is. We then rewrite the patterns such that they include placeholders for verb arguments, e.g., “*The original aim of de Garis' work was to* ***prem*** *the field of ”brain building” (a term of his invention) and to ”****hypo*** *a trillion dollar industry within 20 years”*.” becomes “*The original aim of their work was that ”*PARGL ***prem*** PARGR*” and that ”*HARGL ***hypo*** HARGR *within 20 years”*.” with PARGL / PARGR (HARGL / HARGR) the placeholder for the left / right argument of the premise (hypothesis). See Table 14 in the appendix for the complete list. AUTARG$^{\Phi}_{5}$ is based on these rewritten patterns. We try the same 500 hyperparameter configurations as for the other RoBERTa-base approaches and include results for the best configuration (chosen on dev$_2$) in Table 3. We find that manually curating automatically ranked patterns helps performance. AUTCUR$^{\Phi}_{5}$ outperforms AUTPAT$^{\Phi}_{5}$ on AUC and F1, reducing the gap to handcrafted patterns (i.e., MANPAT$^{\Phi}$). This is probably due to the variety we enforced when handpicking the patterns.

Surprisingly, adding arguments decreases performance. Possibly, our modifications make the patterns less fluent or the arguments that are filled into the placeholders during training and evaluation do not fit well into the contexts, which still are rather specific.

6.3 Error analysis

Table 6 displays a selection of the dev$_2$ sets of our two benchmarks along with the predictions of all our approaches.

(a) Sh	*Germany is occupying Côte d'Ivoire* ⇒ *Germany is remaining in Côte d'Ivoire*	truth: 1	NLI: 0	MANPAT: 1 / 0	AUTPAT: 1 / 1
(b) L/H	*Ford awarded him the medal* ⇒ *Ford was awarded a medal*	truth: 0	NLI: 1	MANPAT: 0 / 0	AUTPAT: 1 / 1
(c) L/H	*Athena was worshiped in Athens* ⇒ *Athena was the goddess of Athens*	truth: 0	NLI: 0	MANPAT: 0 / 1	AUTPAT: 1 / 1
(d) L/H	*Pyrrhus was beaten by the romans* ⇒ *Pyrrhus fought the romans*	truth: 1	NLI: 1	MANPAT: 0 / 0	AUTPAT: 0 / 1
(e) Sh	*England national rugby union team is playing against Denver Broncos* ⇒ *England national rugby union team is beating Denver Broncos*	truth: 0	NLI: 1	MANPAT: 1 / 1	AUTPAT: 1 / 1
(f) L/H	*Polk negotiated with Britain* ⇒ *Polk made peace with Britain*	truth: 0	NLI: 1	MANPAT: 1 / 1	AUTPAT: 1 / 1

Table 6: Qualitative error analysis of the RoBERTa-base models from Tables 2 and 3 on the dev$_2$ split of SherLIiC (Sh) and Levy/Holt (L/H). Pattern-based predictions are listed in the format $\Phi\Psi$ / Φ. Correct predictions are green; errors are underlined and red.

The first four examples indicate how NLI differs from pattern approaches. Example (a) involves the common sense knowledge that occupying a territory implies remaining there. This might be learned from patterns more easily as these patterns might resemble contexts – seen during pretraining – that describe how long a military force remained during an occupation. Putting the inference candidate (b) into a pattern-generated context avoids being fooled by the high similarity of the two sentences. Only the handcrafted patterns can make sense of the important details in this construction.

In contrast, (c) and (d) are difficult for our pattern approaches whereas NLI gets them right. We hypothesize that the problem stems from linking the two sentences into one. An entailment pattern ideally represents a derivation of the hypothesis from the premise. One may wrongly conclude that (c) *Athena was the goddess of Athens only because she was worshiped there*, by neglecting the possibility that there are others that are equally worshiped. In the same way, (d) is unlikely to be found in an argumentative text. While it is clear that there can be no beating without a fight, one would hardly argue that *Pyrrhus fought the romans because they beat him*. This particular reasoning calls for additional explanations like *Pyrrhus must have fought the romans because I know that they beat him*. This analysis serves as inspiration for further improvements of entailment patterns.

The last two examples (e) and (f) are difficult for all approaches. It seems to be a particular challenge to identify open situations like a sports match or a negotiation where multiple outcomes are possible and distinguish them from cases where one particular outcome is inevitable.

7 Conclusion

We proposed and evaluated three approaches to the task of lexical inference in context (LIiC) based on pretrained language models (LMs). In particular, we found that putting an inference candidate into a pattern-generated context mostly increases performance compared to a standard sequence classification approach. Concrete performance, however, also depends on the particular dataset, used LM (variant), and pattern set. We introduced the concept of antipatterns, which express the negative class of a binary classification, and found that they often lead to performance gains for LIiC. We set a new state of the art for LIiC and conducted an extensive analysis of our approaches. Notably, we found that automatically created patterns can perform nearly as well as handcrafted ones if we either use the right number n of patterns or manually identify the right subset of them. Promising directions for future work are the investigation of alternative automatic pattern generation methods or a better modeling of the remaining challenges we described in our error analysis (§6.3).

A Hyperparameters

We train all our classifiers for 5 epochs with the Adam optimizer (Kingma and Ba, 2015) and a mini-batch size of 10 or 2 instances for RoBERTa-base and -large, respectively. For AUTPAT$_n$ approaches with $n > 5$, we distribute the available patterns and antipatterns into chunks of size 5 for training to save memory. During evaluation, the predictions are based on all the patterns and antipatterns.

We randomly sample 500 configurations for the remaining hyperparameters, i.e., initial learning rate lr, weight decay λ (L2 regularization), and the number of batches c the gradient is accumulated before each optimization step, which virtually increases the batch size by a factor of c. The hyperparameters are sampled from the following intervals: $\mathrm{lr} \in [10^{-8}, 5 \cdot 10^{-2}]$, $\lambda \in [10^{-5}, 10^{-1}]$, $c \in \{1, 2, \dots, 10\}$. lr and λ are sampled uniformly in log-space. For a fair comparison, we use the same 500 random configurations for all of our approaches.

As usual for Transformer models, we apply a learning rate schedule: lr decreases linearly such that it reaches 0 at the end of the last epoch. We do not employ warm-up.

The best configurations can be seen in Tables 8 and 10 for Levy/Holt's dataset and in Tables 9 and 11 for SherLIiC.

B Results on development sets

See Tables 12 and 13.

C Varying n in training and evaluation

Another approach to make use of different values of n in AUTPAT$_n$ systems is to vary n from training to evaluation. Figure 2 is a visualization of the performance impact of this procedure. The base point for the visualization (in white) is the AUC performance of AUTPAT$^{\Phi}_5$. We see that training with $n = 50$ almost always leads to a performance drop (marked in blue) w.r.t. this number. It seems generally to be catastrophic to evaluate a model with patterns that were not seen during training, indicating that there is no generalization from seen patterns to unseen patterns even if they were chosen by the same method and can thus be expected to be – at least to some extent – similar. In general, this evaluation suggests that modifying n after the training always leads to a drop in performance.

D Transfer between Datasets

Table 7 shows results on the question how well a model trained on one dataset performs on the other. For this, we assume that the target dataset is not available at all, i.e., we do not use it at all – neither for finding patterns in AUTPAT nor for tuning the threshold ϑ. We thus use the standard ϑ values, i.e., 0.5 for NLI and 0.0 for the pattern-based methods.

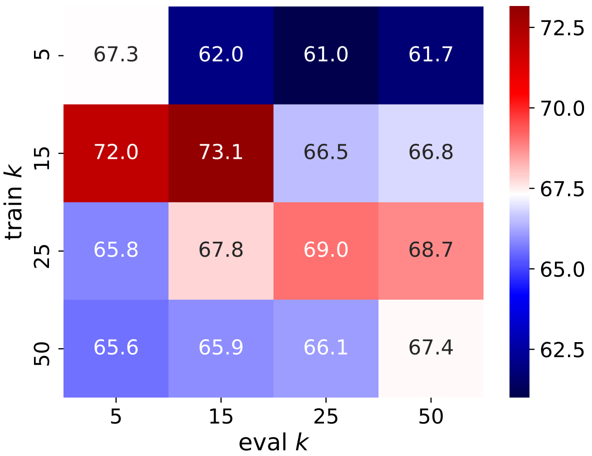

Figure 2: RoBERTa-base+AUTPAT$^{\Phi}_k$ performance on SherLIiC test for different k values during training and evaluation. Same hyperparameters used for all models (as in Table 5). Blue marks drops, red marks gains in performance w.r.t. AUTPAT$^{\Phi}_5$.

Few-Shot Semantic Parsing for New Predicates

Zhuang Li, Lizhen Qu*, Shuo Huang, Gholamreza Haffari

Abstract

In this work, we investigate the problems of semantic parsing in a few-shot learning setting. In this setting, we are provided with k utterance-logical form pairs per new predicate. The state-of-the-art neural semantic parsers achieve less than 25% accuracy on benchmark datasets when $k = 1$. To tackle this problem, we proposed to i) apply a designated meta-learning method to train the model; ii) regularize attention scores with alignment statistics; iii) apply a smoothing technique in pre-training. As a result, our method consistently outperforms all the baselines in both one and two-shot settings.

1 Introduction

Semantic parsing is the task of mapping natural language (NL) utterances to structured meaning representations, such as logical forms (LF). One key obstacle preventing the wide application of semantic parsing is the lack of task-specific training data. New tasks often require new predicates of LFs. Suppose a personal assistant (e.g. Alexa) is capable of booking flights. Due to new business requirement it needs to book ground transport as well. A user could ask the assistant "*How much does it cost to go from Atlanta downtown to airport?*". The corresponding LF is as follows:

(lambda $0 e (exists $1 (and (ground_transport $1)
(to_city $1 atlanta:ci)(from_airport $1 atlanta:ci)
(=(ground_fare $1) $0))))

where both *ground_transport* and *ground_fare* are new predicates while the other predicates are used in flight booking, such as *to_city*, *from_airport*. As manual construction of large parallel training data is expensive and time-consuming, we consider the *few-shot* formulation of the problem, which requires only a handful of utterance-LF training pairs for each new predicate. The cost of preparing few-shot training examples is low, thus the corresponding techniques permit significantly faster prototyping and development than supervised approaches for business expansions.

Semantic parsing in the few-shot setting is challenging. In our experiments, the accuracy of the state-of-the-art (SOTA) semantic parsers drops to less than *25%*, when there is only one example per new predicate in training data. Moreover, the SOTA parsers achieve less than 32% of accuracy on five widely used corpora, when the LFs in the test sets do not share LF *templates* in the training sets (Finegan-Dollak et al., 2018). An LF template is derived by *normalizing* the entities and attribute values of an LF into typed variable names (Finegan-Dollak et al., 2018). The few-shot setting imposes two major challenges for SOTA neural semantic parsers. First, it lacks sufficient data to learn effective representations for new predicates in a supervised manner. Second, new predicates bring in new LF templates, which are mixtures of known and new predicates. In contrast, the tasks (e.g. image classification) studied by the prior work on few-shot learning (Snell et al., 2017; Finn et al., 2017) considers an instance exclusively belonging to either a known class or a new class. Thus, it is non-trivial to apply conventional few-shot learning algorithms to generate LFs with mixed types of predicates.

To address above challenges, we present `ProtoParser`, a transition-based neural semantic parser, which applies a sequence of parse actions to transduce an utterance into an LF template and fills the corresponding slots. The parser is pre-trained on a training set with known predicates, followed by fine-tuning on a *support set* that contains few-shot examples of new predicates. It extends the attention-based sequence-to-sequence architecture (Sutskever et al., 2014) with the following

---

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1281–1291
April 19 - 23, 2021.

novel techniques to alleviate the specific problems in the few-shot setting:

- *Predicate-droput*. Predicate-droput is a meta-learning technique to improve representation learning for both known and new predicates. We empirically found that known predicates are better represented with supervisely learned embeddings, while new predicates are better initialized by a metric-based few-shot learning algorithm (Snell et al., 2017). In order to let the two types of embeddings work together in a single model, we devised a training procedure called *predicate-dropout* to simulate the testing scenario in pre-training.

- *Attention regularization*. In this work, new predicates appear approximately once or twice during training. Thus, it is insufficient to learn reliable attention scores in the Seq2Seq architecture for those predicates. In the spirit of supervised attention (Liu et al., 2016), we propose to regularize them with alignment scores estimated by using co-occurrence statistics and string similarity between words and predicates. The prior work on supervised attention is not applicable, because it requires either large parallel data (Liu et al., 2016), significant manual effort (Bao et al., 2018; Rabinovich et al., 2017), or it is designed only for applications other than semantic parsing (Liu et al., 2017; Kamigaito et al., 2017).

- *Pre-training smoothing*. The vocabulary of predicates in fine-tuning is higher than that in pre-training, which leads to a distribution discrepancy between the two training stages. Inspired by Laplace smoothing (Manning et al., 2008), we achieve significant performance gain by applying a smoothing technique during pre-training to alleviate the discrepancy.

Our extensive experiments on three benchmark corpora show that `ProtoParser` outperforms the competitive baselines with a significant margin. The ablation study demonstrates the effectiveness of each individual proposed technique. The results are statistically significant with $p \leq 0.05$ according to the Wilcoxon signed-rank test (Wilcoxon, 1992).

2 Related Work

Semantic parsing There is ample of work on machine learning models for semantic parsing. The recent surveys (Kamath and Das, 2018; Zhu et al., 2019) cover a wide range of work in this area. The semantic formalism of meaning representations range from lambda calculas (Montague, 1973), SQL, to abstract meaning representation (Banarescu et al., 2013). At the core of most recent models (Chen et al., 2018; Cheng et al., 2019; Lin et al., 2019; Zhang et al., 2019b; Yin and Neubig, 2018) is SEQ2SEQ with attention (Bahdanau et al., 2014) by formulating the task as a machine translation problem. COARSE2FINE (Dong and Lapata, 2018) reports the highest accuracy on GEOQUERY (Zelle and Mooney, 1996) and ATIS (Price, 1990) in a supervised setting. IRNET (Guo et al., 2019) and RATSQL (Wang et al., 2019) are two best performing models on the Text-to-SQL benchmark, SPIDER (Yu et al., 2018). They are also designed to be able to generalize to unseen database schemas. However, supervised models perform well only when there is sufficient training data.

Data Sparsity Most semantic parsing datasets are small in size. To address this issue, one line of research is to augment existing datasets with automatically generated data (Su and Yan, 2017; Jia and Liang, 2016; Cai and Yates, 2013). Another line of research is to exploit available resources, such as knowledge bases (Krishnamurthy et al., 2017; Herzig and Berant, 2018; Chang et al., 2019; Lee, 2019; Zhang et al., 2019a; Guo et al., 2019; Wang et al., 2019), semantic features in different domains (Dadashkarimi et al., 2018; Li et al., 2020), or unlabeled data (Yin et al., 2018; Kočiskỳ et al., 2016; Sun et al., 2019). Those works are orthogonal to our setting because our approach aims to efficiently exploit a handful of labeled data of new predicates, which are not limited to the ones in knowledge bases. Our setting also does not require involvement of humans in the loop such as active learning (Duong et al., 2018; Ni et al., 2019) and crowd-sourcing (Wang et al., 2015; Herzig and Berant, 2019). We assume availability of resources different than the prior work and focus on the problems caused by new predicates. We develop an approach to generalize to unseen LF templates consisting of both known and new predicates.

Few-Shot Learning Few-shot learning is a type of machine learning problems that provides a handful of labeled training examples for a specific task. The survey (Zhu et al., 2019) gives a comprehensive overview of the data, models, and algorithms

proposed for this type of problems. It categorizes the models into multitask learning (Hu et al., 2018), embedding learning (Snell et al., 2017; Vinyals et al., 2016), learning with external memory (Lee and Choi, 2018; Sukhbaatar et al., 2015), and generative modeling (Reed et al., 2017) in terms of what prior knowledge is used. (Lee et al., 2019) tackles the problem of poor generalization across SQL templates for SQL query generation in the one-shot learning setting. In their setting, they assume all the SQL templates on test set are shared with the templates on support set. In contrast, we assume only the sharing of new predicates between a support set and a test set. In our one-shot setting, only around 10% of LF templates on test set are shared with the ones in the support set of GEOQUERY dataset.

3 Semantic Parser

`ProtoParser` follows the SOTA neural semantic parsers (Dong and Lapata, 2018; Guo et al., 2019) to map an utterance into an LF in two steps: *template generation* and *slot filling*[1]. It implements a designated transition system to generate templates, followed by filling the slot variables with values extracted from utterances. To address the challenges in the few-shot setting, we proposed three training methods, detailed in Sec. 4.

Many LFs differ only in mentioned atoms, such as entities and attribute values. An LF template is created by replacing the atoms in LFs with typed slot variables. As an example, the LF template of our example in Sec. 1 is created by substituting i) a typed atom variable v_e for the entity "atlanta:ci"; ii) a shared variable name v_a for all variables "\$0" and "\$1".

(lambda v_a e (exists v_a (and (ground_transport v_a)
(to_city v_a v_e)(from_airport v_a v_e) (=(ground_fare v_a) v_a))))

Formally, let $\boldsymbol{x} = \{x_1, ..., x_n\}$ denote an NL utterance, and its LF is represented as a semantic tree $\boldsymbol{y} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V} = \{v_1, ..., v_m\}$ denotes the node set with $v_i \in \mathcal{V}$, and $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ is its edge set. The node set $\mathcal{V} = \mathcal{V}_p \cup \mathcal{V}_v$ is further divided into a template predicate set $\mathcal{V}_p$ and a slot value set $\mathcal{V}_v$. A template predicate node represents a predicate symbol or a term, while a slot value node represents an atom mentioned in utterances. Thus, a semantic tree $\boldsymbol{y}$ is composed of an abstract tree $\tau_{\boldsymbol{y}}$ representing a template and a set of slot value nodes $\mathcal{V}_{v,\boldsymbol{y}}$ attaching to the abstract tree.

In the few-shot setting, we are provided with a train set $\mathcal{D}_{train}$, a support set $\mathcal{D}_s$, and a test set $\mathcal{D}_{test}$. Each example in either of those sets is an utterance-LF pair $(\boldsymbol{x}_i, \boldsymbol{y}_i)$. The new predicates appear only in $\mathcal{D}_s$ and $\mathcal{D}_{test}$ but *not* in $\mathcal{D}_{train}$. For K-shot learning, there are K $(\boldsymbol{x}_i, \boldsymbol{y}_i)$ per each new predicate p in $\mathcal{D}_s$. Each new predicate appears also in the test set. The goal is to maximize the accuracy of estimating LFs given utterances in $\mathcal{D}_{test}$ by using a parser trained on $\mathcal{D}_{train} \cup \mathcal{D}_s$.

3.1 Transition System

We apply the transition system (Cheng et al., 2019) to perform a sequence of transition actions to generate the template of a semantic tree. The transition system maintains partially-constructed outputs using a *stack*. The parser starts with an empty stack. At each step, it performs one of the following transition actions to update the parsing state and generate a tree node. The process repeats until the stack contains a complete tree.

- ***GEN*** $[y]$ creates a new leaf node y and pushes it on top of the stack.
- **REDUCE** $[r]$. The reduce action identifies an implication rule *head* : −*body*. The rule body is first popped from the stack. A new subtree is formed by attaching the rule head as a new parent node to the rule body . Then the whole subtree is pushed back to the stack.

Table 1 shows such an action sequence for generating the above LF template. Each action produces *known* or *new* predicates.

3.2 Base Parser

`ProtoParser` generates an LF in two steps: i) template generation, ii) slot filling. The base architecture largely resembles (Cheng et al., 2019).

---

[1] Code and datasets can be found in this repository: `https://github.com/zhuang-li/few-shot-semantic-parsing`

Template Generation Given an utterance, the task is to generate a sequence of actions $\mathbf{a} = a_1, ..., a_k$ to build an abstract tree $\tau_{\boldsymbol{y}}$.

We found out LFs often contain idioms, which are frequent subtrees shared across LF templates. Thus we apply a *template normalization* procedure in a similar manner as (Iyer et al., 2019) to preprocess all LF templates. It collapses idioms into single units such that all LF templates are converted into a compact form.

The neural transition system consists of an encoder and a decoder for estimating action probabilities.

$$P(\mathbf{a}|\boldsymbol{x}) = \prod_{t=1}^{|\mathbf{a}|} P(a_t|\boldsymbol{a}_{<t}, \boldsymbol{x}) \tag{1}$$

Encoder We apply a bidirectional Long Short-term Memory (LSTM) network (Gers et al., 1999) to map a sequence of n words into a sequence of contextual word representations $\{\mathbf{e}\}_{i=1}^{n}$.

Template Decoder The decoder applies a stack-LSTM (Dyer et al., 2015) to generate action sequences. A stack-LSTM is an unidirectional LSTM augmented with a pointer. The pointer points to a particular hidden state of the LSTM, which represents a particular state of the stack. It moves to a different hidden state to indicate a different state of the stack.

At time t, the stack-LSTM produces a hidden state $\mathbf{h}_t^d$ by $\mathbf{h}_t^d = \text{LSTM}(\mu_t, \mathbf{h}_{t-1}^d)$, where μ_t is a concatenation of the embedding of the action $\mathbf{c}_{a_{t-1}}$ estimated at time $t-1$ and the representation $\mathbf{h}_{y_{t-1}}$ of the partial tree generated by history actions at time $t-1$.

As a common practice, $\mathbf{h}_t^d$ is concatenated with an attended representation $\mathbf{h}_t^a$ over encoder hidden states to yield $\mathbf{h}_t$, with $\mathbf{h}_t = \mathbf{W}\begin{bmatrix}\mathbf{h}_t^d \\ \mathbf{h}_t^a\end{bmatrix}$, where $\mathbf{W}$ is a weight matrix and $\mathbf{h}_t^a$ is created by soft attention,

$$\mathbf{h}_t^a = \sum_{i=1}^{n} P(\mathbf{e}_i|\mathbf{h}_t^d)\mathbf{e}_i \tag{2}$$

We apply dot product to compute the normalized attention scores $P(\mathbf{e}_i|\mathbf{h}_t^d)$ (Luong et al., 2015). The *supervised attention* (Rabinovich et al., 2017; Yin and Neubig, 2018) is also applied to facilitate the learning of attention weights. Given $\mathbf{h}_t$, the probability of an action is estimated by:

$$P(a_t|\mathbf{h}_t) = \frac{\exp(\mathbf{c}_{a_t}^{\intercal}\mathbf{h}_t)}{\sum_{a' \in \mathcal{A}_t} \exp(\mathbf{c}_{a'}^{\intercal}\mathbf{h}_t)} \tag{3}$$

where $\mathbf{c}_a$ denotes the embedding of action a, and $\mathcal{A}_t$ denotes the set of applicable actions at time t. The initialization of those embeddings will be explained in the following section.

Slot Filling A tree node in a semantic tree may contain more than one slot variables due to template normalization. Since there are two types of slot variables, given a tree node with slot variables, we employ a LSTM-based decoder with the same architecture as the *Template* decoder to fill each type of slot variables, respectively. The output of such a decoder is a value sequence of the same length as the number of slot variables of that type in the given tree node.

4 Few-Shot Model Training

The few-shot setting differs from the supervised setting by having a support set in testing in addition to train/test sets. The support set contains k utterance-LF pairs per new predicate, while the training set contains only known predicates. To evaluate model performance on new predicates, the test set contains LFs with both known and new predicates. Given the support set, we can tell if a predicate is known or new by checking if it only exists in the train set.

We take two steps to train our model: i) pre-training on the training set, ii) fine-tuning on the support set. Its predictive performance is measured on the test set. We take the two-steps approach because i) our experiments show that this approach performs better than training on the union of the train set and the support set; ii) for any new support sets, it is computationally more time efficient than training from scratch on the union of the train set and the support set.

There is a distribution discrepancy between the train set and the support set due to new predicates, the meta-learning algorithms (Snell et al., 2017; Finn et al., 2017) suggest to simulate the testing scenario in pre-training by splitting each batch into a meta-support set and a meta-test set. The models utilize the information (e.g. prototype vectors) acquired from the meta-support set to minimize errors on the meta-test set. In this way, the meta-support and meta-test sets simulate the support and test sets sharing new predicates.

However, we cannot directly apply such a training procedure due to the following two reasons. First, each LF in the support and test sets is a mixture of both known predicates and new predicates. To simulate the support and test sets, the meta-support and meta-test sets should include both types of predicates as well. We cannot assume that there are only one type of predicates. Second, our preliminary experiments show that if there is sufficient training data, it is better off training action embeddings of known predicates $\mathbf{c}$ (Eq. (3)) in a supervised way, while action embeddings initialized by a metric-based meta-learning algorithm (Snell et al., 2017) perform better for rarely occurred new predicates. Therefore, we cope with the differences between known and new predicates by using a customized initialization method in fine-tuning and a designated pre-training procedure to mimic fine-tuning on the train set. In the following, we introduce fine-tuning first because it helps understand our pre-training procedure.

4.1 Fine-tuning

During fine-tuning, the model parameters and the action embeddings in Eq. (3) for known predicates are obtained from the pre-trained model. The embedding of actions that produce new predicates $\mathbf{c}_{a_t}$ are initialized using prototype vectors as in prototypical networks (Snell et al., 2017). The prototype representations act as a type of regularization, which shares the similar idea as the deep learning techniques using pre-trained models.

A prototype vector of an action a_t is constructed by using the hidden states of the *template* decoder collected at the time of predicting a_t on a support set. Following (Snell et al., 2017), a prototype vector is built by taking the mean of such a set of hidden states $\mathbf{h}_t$.

$$\mathbf{c}_{a_t} = \frac{1}{|M|} \sum_{\mathbf{h}_t \in M} \mathbf{h}_t \tag{4}$$

where M denotes the set of all hidden states at the time of applying the action a_t. After initialization, the whole model parameters and the action embeddings are further improved by fine-tuning the model on the support set with a supervised training objective $\mathcal{L}_f$.

$$\mathcal{L}_f = \mathcal{L}_s + \lambda\Omega \tag{5}$$

where $\mathcal{L}_s$ is the cross-entropy loss and Ω is an attention regularization term explained below. The degree of regularization is adjusted by $\lambda \in \mathbb{R}^+$.

Attention Regularization We address the poorly learned attention scores $P(\mathbf{e}_i|\mathbf{h}^d_t)$ of infrequent actions by introducing a novel attention regularization. We observe that the probability $P(a_j|x_i) = \frac{\text{count}(a_j,x_i)}{\text{count}(x_i)}$ and the character similarity between the predicates generated by action a_j and the token x_i are often strong indicators of their alignment. The indicators can be further strengthened by manually annotating the predicates with their corresponding natural language tokens. In our work, we adopt $1 - dist(a_j, x_i)$ as the character similarity, where $dist(a_j, x_j)$ is normalized Levenshtein distance (Levenshtein, 1966). Both measures are in the range $[0, 1]$, thus we apply $g(a_j, x_i) = \sigma(\cdot)P(a_j|x_i) + (1 - \sigma(\cdot)char\_sim(a_j, x_i)$ to compute alignment scores, where the sigmoid function $\sigma(\mathbf{w}_p^\intercal \mathbf{h}^d_t)$ combines two constant measures into a single score. The corresponding normalized attention scores is given by

$$P'(x_i|a_k) = \frac{g(a_k, x_i)}{\sum_{j=1}^{n} g(a_k, x_j)} \tag{6}$$

The attention scores $P(x_i|a_k)$ should be similar to $P'(x_i|a_k)$. Thus, we define the regularization term as $\Omega = \sum_{ij} |P(x_i|a_j) - P'(x_i|a_j)|$ during training.

4.2 Pre-training

The pre-training objective are two-folds: i) learn action embeddings for known predicates in a supervised way, ii) ensure our model can quickly adapt to the actions of new predicates, whose embeddings are initialized by prototype vectors before fine-tuning.

Predicate-dropout Starting with randomly initialized model parameters, we alternately use one batch for the meta-loss $\mathcal{L}_m$ and one batch for optimizing the supervised loss $\mathcal{L}_s$.

In a batch for $\mathcal{L}_m$, we split the data into a meta-support set and a meta-test set. In order to simulate existence of new predicates, we randomly select a subset of predicates as ”new”, thus their action embeddings $\mathbf{c}$ are replaced by prototype vectors constructed by applying Eq. (4) over the meta-support set. The actions of remaining predicates keep their embeddings learned from previous batches. The resulted action embedding matrix $\mathbf{C}$ is the combination of both.

$$\mathbf{C} = (1 - \mathbf{m}^\intercal)\mathbf{C}_s + \mathbf{m}^\intercal \mathbf{C}_m \tag{7}$$

where $\mathbf{C}_s$ is the embedding matrix learned in a supervised way, and $\mathbf{C}_m$ is constructed by using prototype vectors on the meta-support set. The mask vector $\mathbf{m}$ is generated by setting the indices of actions of the ”new” predicates to ones and the other

Algorithm 1: Predicate-Dropout

```
Input  : Training set $\mathcal{D}$, supervisely trained action
         embedding $\mathcal{C}_s$, number of meta-support
         examples $k$, number of meta-test examples
         $n$ per one support example,
         predicate-dropout ratio $r$
Output : The loss $\mathcal{L}_m$.
Extract a template set $\mathcal{T}$ from the training set $\mathcal{D}$
Sample a subset $\mathcal{T}_i$ of size $k$ from $\mathcal{T}$
$S := \emptyset$ # meta-support set
$Q := \emptyset$ # meta-test set
for $t$ in $\mathcal{T}_i$ do
    Sample a meta-support example $s'$ with template
      $t$ from $\mathcal{D}$ without replacement
    Sample a meta-test set $Q'$ of size $n$ with template
      $t$ from $\mathcal{D}$
    $S = S \cup s'$
    $Q = Q \cup Q'$
end
Build a prototype matrix $\mathcal{C}_m$ on $S$
Extract a predicate set $\mathcal{P}$ from $S$
Sample a subset $\mathcal{P}_s$ of size $r \times |\mathcal{P}|$ from $\mathcal{P}$ as new
  predicates
Build a mask $\mathbf{m}$ using $\mathcal{P}_s$
With $\mathcal{C}_s$, $\mathcal{C}_m$ and $\mathbf{m}$, apply Eq. (7) to compute $\mathbf{C}$
Compute $\mathcal{L}_m$, the cross-entropy on $Q$ with $\mathbf{C}$
```

to zeros. We refer to this operation as *predicate-dropout*. The training algorithm for the meta-loss is summarised in Algorithm 1.

In a batch for $\mathcal{L}_s$, we update the model parameters and all action embeddings with a cross-entropy loss $\mathcal{L}_s$, together with the attention regularization. Thus, the overall training objective becomes

$$\mathcal{L}_p = \mathcal{L}_m + \mathcal{L}_s + \lambda\Omega \tag{8}$$

Pre-training smoothing Due to the new predicates, the number of candidate actions during the prediction of fine-tuning and testing is larger than the one during pre-training. That leads to distribution discrepancy between pre-training and testing. To minimize the differences, we assume a prior knowledge on the number of actions for new predicates by adding a constant k to the denominator of Eq. (3) when estimating the action probability $P(a_t|\mathbf{h}_t)$ during pre-training.

$$P(a_t|\mathbf{h}_t) = \frac{\exp(\mathbf{c}_{a_t}^{\intercal}\mathbf{h}_t)}{\sum_{a' \in \mathcal{A}_t} \exp(\mathbf{c}_{a'}^{\intercal}\mathbf{h}_t) + k} \tag{9}$$

We do not consider this smoothing technique during fine-tuning and testing. Despite its simplicity, the experimental results show a significant performance gain on benchmark datasets.

5 Experiments

Datasets. We use three semantic parsing datasets: JOBS, GEOQUERY, and ATIS. JOBS contains 640 question-LF pairs in Prolog about job listings. GEOQUERY (Zelle and Mooney, 1996) and ATIS (Price, 1990) include 880 and 5,410 utterance-LF pairs in lambda calculas about US geography and flight booking, respectively. The number of predicates in JOBS, GEOQUERY, ATIS is 15, 24, and 88, respectively. All atoms in the datasets are anonymized as in (Dong and Lapata, 2016).

For each dataset, we randomly selected m predicates as the new predicates, which is 3 for JOBS, and 5 for GEOQUERY and ATIS. Then we split each dataset into a train set and an *evaluation* set. And we removed the instances, the template of which is unique in each dataset. The number of such instances is around 100, 150 and 600 in JOBS, GEOQUERY, and ATIS. The ratios between the evaluation set and the train set are 1:4, 2:5, and 1:7 in JOBS, GEOQUERY, and ATIS, respectively. Each LF in an evaluation set contains at least a new predicate, while an LF in a train set contains only known predicates. To evaluate k-shot learning, we build a support set by randomly sampling k pairs per new predicate without replacement from an *evaluation* set, and keep the remaining pairs as the test set. To avoid evaluation bias caused by randomness, we repeat the above process six times to build six different splits of support and test set from each evaluation set. One for hyperparameter tuning and the rest for evaluation. We consider at most 2-shot learning due to the limited number of instances per new predicate in each evaluation set.

Training Details. We pre-train our parser on the training sets for {80, 100} epochs with the Adam optimizer (Kingma and Ba, 2014). The batch size is fixed to 64. The initial learning rate is 0.0025, and the weights are decayed after 20 epochs with decay rate 0.985. The predicate dropout rate is 0.5. The smoothing term is set to {3, 6}. The number of meta-support examples is 30 and the number of meta-test examples per support example is 15. The coefficient of attention regularization is set to 0.01 on JOBS and 1 on the other datasets. We employ the 200-dimensional GLOVE embedding (Pennington et al., 2014) to initialize the word embeddings for utterances. The hidden state size of all LSTM models (Hochreiter and Schmidhuber, 1997) is 256. During fine-tuning, the batch size is 2, the learning rates and the epochs are selected from {0.001, 0.0005} and {20, 30, 40, 60, 120}, respectively.

Table 2: Evaluation of learning results on three datasets. (Left) The one-shot results. (Right) The two-shot results.

Baselines. We compared our methods with five competitive baselines, Seq2Seq with attention (Luong et al., 2015), Coarse2Fine (Dong and Lapata, 2018), IRNet (Guo et al., 2019), PT-MAML (Huang et al., 2018) and DA (Li et al., 2020). Coarse2Fine is the best performing supervised model on the standard split of GeoQuery and Atis datasets. PT-MAML is a few-shot learning semantic parser that adopts Model-Agnostic Meta-Learning (Finn et al., 2017). We adapt PT-MAML in our scenario by considering a group of instances that share the same template as a pseudo-task. DA is the most recently proposed neural semantic parser applying domain adaptation techniques. IRNet is the strongest semantic parser that can generalize to unseen database schemas. In our case, we consider a list of predicates in support sets as the columns of a new database schema and incorporate the schema encoding module of IRNet into the encoder of our base parser. We choose IRNet over RATSQL (Wang et al., 2019) because IRNet achieves superior performance on our datasets.

We consider three different supervised learning settings. First, we pre-train a model on a train set, followed by fine-tuning it on the corresponding support set, coined *pt*. Second, a model is trained on the combination of a train set and a support set, coined *cb*. Third, the support set in *cb* is oversampled by 10 times and 5 times for one-shot and two-shot respectively, coined *os*.

Evaluation Details. The same as prior work (Dong and Lapata, 2018; Li et al., 2020), we report accuracy of exactly matched LFs as the main evaluation metric.

To investigate if the results are statistically significant, we conducted the Wilcoxon signed-rank test, which assesses whether our model consistently performs better than another baseline across *all* evaluation sets. It is considered superior than t-test in our case, because it supports comparison across different support sets and does not assume normality in data (Demšar, 2006). We include the corresponding p-values in our result tables.

5.1 Results and Discussion

Table 2 shows the average accuracies and significance test results of all parsers compared on all three datasets. Overall, `ProtoParser` outperforms all baselines with at least 2% on average in terms of accuracy in both one-shot and two-shot settings. The results are statistically significant w.r.t. the strongest baselines, IRNet (*cb*) and Coarse2Fine (*pt*). The corresponding p-values are 0.00276 and 0.000148, respectively. Given one-shot example on Jobs, our parser achieves 7% higher accuracy than the best baseline, and the gap is 4% on GeoQuery with two-shots examples. In addition, none of the SOTA baseline parsers can consistently outperform other SOTA parsers when there are few parallel data for new predicates. In one-shot setting, the best supervised baseline IRNet (*cb*) can achieve the best results on GeoQuery and Jobs among all baselines, and on two-shot setting, it performs best only on GeoQuery. It is also difficult to achieve good performance by adapting the existing meta-learning or transfer learning algorithms to our problem, as evident by the moderate performance of PT-MAML and DA on all datasets.

The problems of few-shot learning demonstrate the challenges imposed by infrequent predicates. There are significant proportions of infrequent predicates on the existing datasets. For example, on GeoQuery, there are 10 predicates contributing to only 4% of the total frequency of all 24 predicates, while the top two frequent predicates amount

	Jobs	GeoQuery	Atis	Jobs	GeoQuery	Atis	p-values
Ours	27.09	**27.49**	**19.27**	**32.50**	**48.45**	**22.48**	
- sup	23.63	18.86	12.91	26.91	39.51	14.89	1.44e-05
- proto	22.91	18.77	13.24	29.16	38.93	16.81	1.77e-05
- reg	**29.27**	18.10	13.66	31.03	39.61	18.58	9.60e-04
- strsim	22.18	19.62	10.14	28.41	47.09	19.98	9.27e-04
- cond	23.27	19.05	9.63	27.66	40.97	17.50	4.37e-05
- smooth	24.36	23.60	15.23	30.84	44.95	18.71	3.27e-03

Table 3: Ablation study results. (Left) The one-shot learning results. (Right) The two-shot learning results.

to 42%. As a result, the SOTA parsers achieve merely less than 25% and 44% of accuracy with one-shot and two-shots examples, respectively. In contrast, those parsers achieve more than 84% accuracy on the standard splits of the same datasets in the supervised setting.

Infrequent predicates in semantic parsing can also be viewed as a class imbalance problem, when support sets and train sets are combined in a certain manner. In this work, the ratio between the support set and the train set in Jobs, GeoQuery, and ATIS is 1:130, 1:100, and 1:1000, respectively. Different models prefer different ways of using the train sets and support sets. The best option for Coarse2Fine and Seq2Seq is to pre-train on a train set followed by fine-tuning on the corresponding support set, while IRNet favors oversampling in two-shot setting.

Ablation Study We examine the effect of different components of our parser by removing each of them individually and reporting the corresponding average accuracy. As shown in Table 3, removing any of the components almost always leads to statistically significant drop of performance. The corresponding p-values are all less than 0.00327.

To investigate predicate-dropout, we exclude either supervised-loss during pre-training (-sup) or initialization of new predicate embeddings by prototype vectors before fine-tuning (-proto). It is clear from Table 3 that ablating either supervisely trained action embeddings or prototype vectors hurts performance severely.

We further study the efficacy of attention regularization by removing it completely (-reg), removing only the string similarity feature (-strsim), or conditional probability feature (-cond). Removing the regularization completely degrades performance sharply except on Jobs in the one-shot setting. Our further inspection shows that model learning is easier on Jobs than on the other two datasets. Each predicate in Jobs almost always aligns to the same word across examples, while a predicate can align with different word/phrase in different examples in GeoQuery and ATIS. The performance drop with -strsim and -cond indicates that we cannot only reply on a single statistical measure for regularization. For instance, we cannot always find predicates take the same string form as the corresponding words in input utterances. In fact, the proportion of predicates present in input utterances is only 42%, 38% and 44% on Jobs, ATIS, and GeoQuery, respectively.

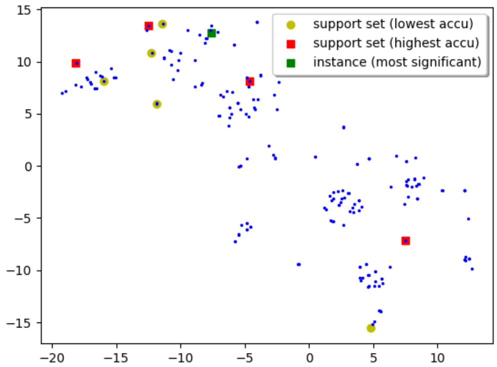

Figure 1: (Round) The support set with the lowest accuracy. (Box) The support set with the highest accuracy.

Furthermore, without pre-training smoothing (-smooth), the accuracy drops at least 1.6% in terms of mean accuracy on all datasets. Smoothing enables better model parameter training by more accurate modelling in pre-training.

Support Set Analysis We observe that all models consistently achieve high accuracy on certain support sets of the same dataset, while obtaining low accuracies on the other ones. We illustrate the reasons of such effects by plotting the evaluation set of GeoQuery. Each data point in Figure 1 depicts an representation, which is generated by the encoder of our parser after pre-training. We applied T-SNE (Maaten and Hinton, 2008) for dimension reduction. We highlight two support sets used in the one-shot setting on GeoQuery. All examples in the highest performing support set tend to scatter evenly and cover different dense regions in the feature space, while the examples in the lowest performing support set are far from a significant number of dense regions. Thus, the examples in good support sets are more representative of the underlying distribution than the ones in poor support sets. When we leave out each example in the highest performing support set and re-evaluate our parser each time, we observe that the good ones (e.g. the green box in Figure 1) locate either in or close to some of the dense regions.

6 Conclusion and Future Work

We propose a novel few-shot learning based semantic parser, coined `ProtoParser`, to cope with new predicates in LFs. To address the challenges in few-shot learning, we propose to train the parser with a pre-training procedure involving predicate-dropout, attention regularization, and pre-training smoothing. The resulted model achieves superior results over competitive baselines on three benchmark datasets.

Abstract

Existing dialog system models require extensive human annotations and are difficult to generalize to different tasks. The recent success of large pre-trained language models has suggested the effectiveness of incorporating language priors in down-stream NLP tasks. However, how much pre-trained language models can help dialog response generation is still under exploration. In this paper, we propose a simple, general, and effective framework: Alternating Recurrent Dialog Model (ARDM)[1]. ARDM models each speaker separately and takes advantage of large pre-trained language models. It requires no supervision from human annotations such as belief states or dialog acts to achieve effective conversations. ARDM outperforms or is on par with the state-of-the-art methods on two popular task-oriented dialog datasets: CamRest676 and MultiWOZ. Moreover, we can generalize ARDM to more challenging, non-collaborative tasks such as persuasion. In the PersuasionForGood task, ARDM is capable of generating human-like responses to persuade people to donate to a charity.

1 Introduction

It has been a long-standing ambition for artificial intelligence researchers to create an intelligent conversational agent that can generate human-like responses. Recently, data-driven dialog models are more and more popular. However, most current state-of-the-art approaches still heavily rely on extensive human annotations such as belief states and dialog acts (Lei et al., 2018). However, dialog content can vary considerably in different dialog tasks. Having a different intent or dialog act annotation scheme for each task is costly and even impossible for tasks such as open-domain social chat. Thus, it is difficult to utilize these methods on challenging dialog tasks where dialog states and acts are difficult to annotate such as persuasion and negotiation.

Eric and Manning (2017) proposed a simple sequence-to-sequence architecture that requires no explicit annotations. The model learns to extract information from dialog history with attention and copy mechanism. However, due to the limited language modeling capability in the previous model, Sequicity (Lei et al., 2018), which uses belief states as inputs for supervision, outperforms Eric and Manning (2017)'s method significantly in the recent dialog datasets. But with the success of large pre-trained language models such as BERT (Devlin et al., 2019) and GPT-2 (Radford et al., 2019), we investigate how large-scale pre-trained language models can help dialog tasks.

Previous sequence-to-sequence models are used to tackle documents with only one narrator. However, in dialogs, two speakers have different roles; therefore, their language model distributions are very different from each other. To address this issue, we propose ARDM, a dialog model that encodes and decodes different speaker utterances in alternating order. This structure makes the model more flexible and efficient than traditional sequence-to-sequence models in processing various dialogs. We evaluate our model on three different task-oriented dialog datasets: CamRes676, MultiWOZ, and PersuasionForGood. The first two datasets are traditional information request dialog datasets with well-defined automatic evaluation metrics on task completion. By contrast, PersuasionForGood is a new dataset that focuses on persuading people to donate to a charity. Due to the complexity of dialog content, there is no explicit dialog state defined in this task.

We observe that ARDM is capable of improving task-oriented dialog tasks performance over the previous state-of-the-art methods without in-

---

corporating any explicit supervision from belief states or dialog acts. Also, because of ARDM's simplicity and generality, one can rapidly build a dialog prototype on different types of applications using only conversations without additional human annotations. We also found that ARDM works well on complex dialogs, such as persuasion. The model generates dialog responses that successfully persuade people to donate to a charity, suggesting the potential of ARDM being used in wide-scale real-world settings.

2 Related Work

Traditional dialog systems consist of a dialog manager to maintain dialog states and control the conversation flow. However, a dialog manager requires extensive manual annotations for training the sub-modules such as dialog state tracker or policy decision-maker. An alternative is to model dialog without explicitly modeling belief states. Specifically, Eric and Manning (2017) proposed a sequence-to-sequence model that utilizes copy-mechanism to copy history information directly from raw dialog history. This method achieved the state-of-the-art results on DSTC2 (Henderson et al., 2014), which is a simple dialog restaurant booking task with abundant data. However, such method did not perform well on more complex dialog task data sets CamRes676 (Wen et al., 2017) and KVRET (Eric et al., 2017). Sequicity (Lei et al., 2018) attributed the bad performance of Eric and Manning (2017)'s method to the omission of belief tracker. They introduced the concept of belief span and added belief tracker back to the model and achieved state-of-the-art performance.

Compared to Sequicity, Eric and Manning (2017)'s method provides a more general framework that reduces manual dialog state, user intent, and dialog act labeling by bypassing any symbolic annotations. Such a model can apply to datasets with no or partial annotations of belief states. In a real-world setting, if the dialog task introduces new slot values in belief states (i.e. a new type of food), Sequicity will suffer from the belief span decoder error in response generation. Thus, Eric and Manning (2017)'s method may be potentially more robust than Sequicity in this situation. Besides, if the task requires belief states for database search, we can treat belief tracking as a separate task. We can train a good belief tracking with only a small amount of annotated data, which reduces the annotation required and is easier to fix errors. Also, since belief states are a set of important entities condensed from dialog history (i.e., often exact words from utterances), they do not introduce extra information to the model. Therefore, a dialog model with powerful representation learning should learn a form of belief states information automatically without human annotations as the scaffold.

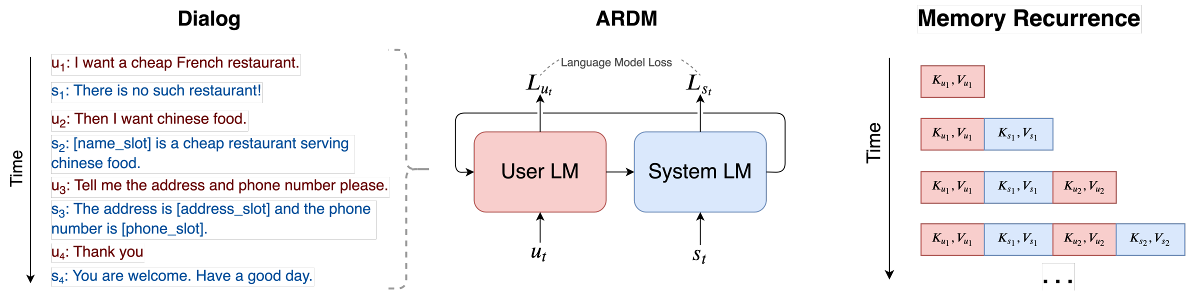
Recent success of BERT (Devlin et al., 2019) and GPT2 (Radford et al., 2019) suggests the possibility of applying large pre-trained language models to dialog systems. There are some studies of applying large pre-trained language model to dialog generation. TransferTransfo (Wolf et al., 2019) fine-tuned the pre-trained language model GPT (Radford et al., 2018) on Persona-Chat dataset (Zhang et al., 2018) and obtained significant improvements on chitchat response generation, suggesting the potential of fine-tuning large pre-trained language models on other dialog response generation tasks. A more recent work (Budzianowski and Vulic, 2019) adopted the framework of TransferTransfo. They made the first attempt to leverage large pre-trained language models GPT and GPT-2 on task-oriented dialog generation, but it included belief states modeling as the input and did not achieve better results than the baseline. We propose to model dialogs without any annotation but rely on pre-trained large-scale language models that alternate.

3 Alternating Recurrent Dialog Model

We propose Alternating Recurrent Dialog Model (ARDM) by compositing two separate pre-trained language model in alternate order to learn the user and system utterance distribution through memory recurrence. Figure 1 shows an overview of ARDM.

3.1 Recurrent Modeling for User and System

We aim to model both user and system utterances distribution recurrently. Given a multi-turn dialog (d) between a user (u) and a system (s), we can represent d as a series of utterances $\{u_1, s_1, u_2, s_2, \dots, u_T, s_T\}$, where T denotes the total number of turns. We decompose the probability distributions over the utterances in d into two language models for the user and system respectively, denoted as p_u and p_s. Then we define a



u_1: I want a cheap French restaurant.
s_1: There is no such restaurant!
u_2: Then I want chinese food.
s_2: [name_slot] is a cheap restaurant serving chinese food.
u_3: Tell me the address and phone number please.
s_3: The address is [address_slot] and the phone number is [phone_slot].
u_4: Thank you
s_4: You are welcome. Have a good day.

(a) (b)

Figure 1: Alternating Recurrent Dialog Model (ARDM) Overview. (a) shows how we feed the entire dialog to ARDM. (b) shows the recurrence mechanism we used to preserve memory.

dialog model $p(d)$ with the equation:

$$p(d) = \prod_{t=1}^{T} p_u(u_t|u_{<t}, s_{<t})\, p_s(s_t|u_{\leq t}, s_{<t}) \quad (1)$$

p_u and p_s are standard language models where the task is to predict the next token given the preceding context. For an utterance u_t or s_t with m tokens $\{w_1, \dots, w_m\}$, the joint probability of an utterance is as follows:

$$p_u(u_t|u_{<t}, s_{<t}) = \prod_{i=1}^{m_{u_t}} P(w_i|w_{<i}, u_{<t}, s_{<t}) \quad (2)$$

$$p_s(s_t|u_{\leq t}, s_{<t}) = \prod_{i=1}^{m_{s_t}} P(w_i|w_{<i}, u_{\leq t}, s_{<t}) \quad (3)$$

Finally, we train the dialog model by maximizing the likelihood over Equation 1. However, in order to model multi-turn dialog distributions efficiently, we need a memory mechanism to encode the history. In the next section, we introduce the memory mechanism in detail.

3.2 Memory Recurrence

We apply a memory mechanism to grant the model the capability of memorizing conversation history. This method is similar to Transformer-XL (Dai et al., 2019), which enables the model to learn longer dependency. For an utterance at turn t, we reuse the hidden states $h_{\leq t-1}$ stored in the memory M_{t-1} to obtain h_t, and store the h_t back to the memory as M_t. As for the pre-trained Transformer language model, we implement the memory mechanism using self-attention given the query/key/value features denoted as Q, K, V, where the equation is defined as:

$$\text{Attention}(Q, K, V) = \text{softmax}(QK^T V) \quad (4)$$

For simplicity, we assume there is only one layer in Transformer, and h_t is the hidden states which consist of N vectors for the current input N tokens in the utterance at time t. Then a recurrence relation for h_t is defined by computing Q_t, $K_{\leq t}$, $V_{\leq t}$ from $h_{\leq t-1}$ and the current utterance. In practice, we reuse $K_{\leq t-1}$ and $V_{\leq t-1}$ (i.e. history keys and values) as M_{t-1} instead of h_{t-1} to avoid recomputing history information. Therefore, the final h_t is computed as:

$$\begin{aligned} M_{t-1} &= [K_{\leq t-1}, V_{\leq t-1}] && (5)\\ K_{\leq t}, V_{\leq t} &= [K_{\leq t-1}; K_t], [V_{\leq t-1}; V_t] && (6)\\ h_t &= \text{Attention}(Q_t, K_{\leq t}, V_{\leq t}) && (7) \end{aligned}$$

One can use h_t (consisting of vectors for each token) to get each token's probability to calculate the language model cross entropy loss to maximize $p(w_i|w< i, u_{<t}, s_{<t})$, shown in Figure 1.

3.3 Training Details

We initialize the user and the system language model with a large pre-trained language model GPT-2 small with 117M parameters (Radford et al., 2019). It is a Transformer (Vaswani et al., 2017) model with 12 heads, 768 hidden size, and 12 layers. The model is trained on a large scale corpus called WebText extracted from Reddit with at least three upvotes. The tokenizer is 50,257 size byte pair encoding (BPE) (Sennrich et al., 2016) that can encode and decode any text in a lossless manner to avoid out-of-vocabulary tokens. We follow a special format in GPT-2 as the "trigger" so that the model can zero-shot dialog response generation, by prefixing the user role token "A:" or "B:", and suffixing the end of utterance token "\n\n\n". This "trigger" approach is similar in other zero-shot scenarios mentioned in GPT-2 paper (e.g., that a "TL;DR" token can trigger GPT-2 to summarize the input text.) We further fine-tune ARDM on the specific task dataset. We apply AdamW optimizer (Loshchilov and Hutter, 2019), and the number of warm-up steps is set to be the number of batches in one epoch. The learning rate is set to 3×10^{-5}, and the dropout rate is set to 0.1 for all tasks. We conduct all experiments on a 11GB GPU.

3.4 Decoding Details

We decode utterances by nucleus sampling (Holtzman et al., 2019) with different hyper-parameters (top-p, top-k) for down-stream dialog tasks. We also vary the temperature of $T < 1$ to find the best setting for the specific down-stream dialog task. To handle both situations in the evaluation and the real-world use case, we have two decoding modes. For evaluation mode, we feed all past ground truth history before turn t to generate the corresponding utterance, so that we can evaluate the quality of generated dialog responses without concerning about the conversion flow. While in a real-world use case, we do not have ground truth history, and therefore we use the memory from previously generated responses and let the model dynamically interact with a human or another bot in turns. Because dialogs have different lengths, it is hard for ARDM to efficiently decode responses using traditional batch padding method. As a solution, we develop a dynamic dialog filtering algorithm to support fast decoding in batch. Such method speeds up the generation eight times faster. Please refer to Appendix for the method's details.

3.4.1 Belief Tracking

Database state means the database query results. In the example, since there is no match in the database satisfying the constraint "cheap french restaurant", it returns "0" and the domain "restaurant". Then the system can condition on the database state to generate "There is no such restaurant." We do not incorporate belief tracking because we want to fit different dialog tasks in which there may be no annotations of belief states. Also, (Eric and Manning, 2017) pointed out that user utterances already contains the belief state information to generate system response, meaning it is not necessary to explicitly input belief state into the model. For database search, one can train a separate belief tracker with a small portion of data that is annotated, which is more common in the real world cases.

4 Experiments and Results

Data scarcity is one of the biggest challenges in dialog research. It is costly to collect human-human conversations under a specific setting. It is even more time-consuming to annotate the corresponding belief states and dialog acts. With the success of transfer learning in NLP, we aim to mitigate the low-resource problem with the large pre-trained language model. We validate our proposed ARDM on three task-oriented dialog datasets, CamRest676, MulitWOZ, and PersuasionForGood.

4.1 CamRest676

CamRest676 is a relatively small dataset with 408/136/136 dialogs for train/validation/test. We follow Sequicity (Lei et al., 2018) to delexicalize tokens such as restaurant names, phone numbers, postcodes by replacing them with their slot names in utterances. We prepend database search results to the system utterance. An example database search results are "restaurant;3", where the first slot indicates its dialog domain, which is always "restaurant" in CamRest767, and the second slot represents the number of matched items in the database. We use greedy sampling for all methods during decoding. We use **BLEU-4** and **Success F1** to evaluate language generation quality and Success F1 to evaluate task success. Success F1 computes the F1 score of the generated responses on requested slots such as an address, phone number, or food type. Other than Sequicity, we also compare results by using GPT-2 alone as a language model for the entire dialog. This baseline is equivalent to ARDM without alternating recurrent modeling.

4.1.1 Results

We first test our method on a restaurant search dataset, CamRest676 (Wen et al., 2017). Table 1 shows all models' results with ground truth belief state or generated belief state. We first use ground truth belief state in all methods to evaluate their response generation quality. ARDM achieves the best BLEU and Success F1 score. We observe that after fine-tuning GPT-2 on the CamRest676, it achieves similar results compared to the previous state-of-the-art method, Sequicity with reinforcement fine-tuning. This suggests pre-trained large-scale language model, such as GPT-2, transfers the meaningful representations to help fine-tuning.

Model	Entity Match rate	Ground Truth Database State BLEU-4	 Success. F1	Generated Database State BLEU-4	 Success. F1
Regular Expression	0.960	-	-	-	-
Sequicity	0.923	21.4	0.852	21.4	0.853
Sequicity (w/o RL)	0.940	22.9	0.821	23.4	0.834
GPT-2-finetune	-	21.8	0.851	19.2	0.862
ARDM	-	**26.2**	**0.864**	**25.4**	**0.862**
ARDM (50% data)	-	25.9	0.859	23.4	0.851

Table 1: Results on CamRest676 dataset. Our method does not require human annotations from dialog states and dialog acts in comparison to Sequicity.

However, without the alternating mechanism, GPT-2 alone does not perform as well as ARDM in terms of both BLEU-4 and Success F1, especially in BLEU-4 (improved 19%). Without the recurrent modeling, the model blends two speakers language distribution and ignores the role difference. Moreover, to test if our model preserves its performance with even less training data, we reduce the training data to 50%, and the performance only drops slightly. With half of the training data, our method still performs significantly better than Sequicity. This result suggests ARDM is robust on low-resource settings due to the advantage of the large-scale pre-training language model.

We also evaluate all models with generated belief states instead of ground truth belief states. Sequicity generates belief tracker results, and its Entity Match rate is 0.927. Our model does not have a state tracker, so we write a separate simple regular expression to extract the occurrence of entities that appear in the database to support our model. Such state tracker achieves 0.960 in Entity Match rate. It suggests that state tracking may be accomplished in more straightforward ways other than training a neural network model on a large set of annotated data. With a simple state tracker, our proposed method still performs better than Sequicity, which trains the belief state and the response generation task jointly.

4.2 MultiWOZ

Here, we only use the ground truth database search result to be consistent with other methods. We perform delexicalization which is mentioned in the original MultiWOZ (Budzianowski et al., 2018). We prepend the database search results to the system response for as conditional input. Also, the database results now contain information about whether the booking is successful or not (i.e., succeed or fail). Again, we prefix the database results to the system response. Note that we do not use belief state or dialog act annotation provided by the dataset to train ARDM. We set the top-p to 0.2 and the temperature to 0.7.

We normalize the time's slot value in all dialogs into the 24-hour format and perform tokenization via spaCy[2]. We found that different papers report results with different versions of the evaluator, which makes it difficult to compare different methods fairly. We explain the differences among all versions of the evaluator in Appendix. In this paper, we follow LaRL's evaluator implementation, as it is more reasonable than others. We re-evaluate results for all methods with the same evaluator to ensure fairness.

We compare our model to the attention-based seq2seq model which is proposed as the MultiWOZ Baseline (Budzianowski et al., 2018), the HDSA (Chen et al., 2019) model that incorporates dialog act supervision as an inductive prior for model architecture, and the LaRL (Zhao et al., 2019) model which leverages latent action modeling and reinforcement learning to improve performance. We do not compare with GPT-2-finetune with our model in MultiWOZ because GPT-2-finetune's performance on CamRest676 is significantly worse than our model. Note that GPT-2-finetune is equivalent to ARDM without alternating parameterization.

The results are evaluated on BLEU-4, Inform Rate, and Success Rate. Inform and Success Rate measure whether the system response provides the recommendations and requested information given in the goal.

---

[2] https://spacy.io/

Model	Supervision Dialog State	 Dialog Act	Inform (%)	Success (%)	BLEU-4
Human	-	-	98.9	96.5	-
Baseline	✓	×	82.5	72.9	18.9
HDSA	✓	✓	**87.7**	73.4	**23.6**
LaRL	✓	×	82.8	**79.2**	12.8
ARDM	×	×	87.4	72.8	20.6

Table 2: Results on MultiWOZ. Supervision denotes whether a model leverages dialog state or/and dialog act annotations. All models use the ground truth dialog state for database search. ARDM without supervision from annotation can still achieve comparable results.

4.2.1 Results

The evaluation results are shown in Table 2. Without any supervision from dialog states or dialog acts, ARDM significantly outperforms the MultiWOZ Baseline and LaRL on BLEU-4 and Inform rate, and is on par with HDSA. However, HDSA uses dialog act supervision and a large pretrained language model, BERT. Our model requires no annotation and can achieve similar results. This suggests our recurrent modeling and large-scale pre-training methods work similarly as the useful dialog act annotations. All the results show that our method's excellent performance remains consistent in multi-domain dialogs.

We analyze the generated responses and find that if multiple domains have appeared in the conversation history, our model tends to make mistakes in answering the right domain for user requests. This finding suggests that the Maximum Likelihood Estimation (MLE) has limitations in directly optimizing the metric, while reinforcement Learning (RL) can hugely improve the task completion in a dialog system. This is why LaRL has a higher Success rate. However, we also observe that LaRL has a low BLEU-4 score, which indicates low readability in responses. Therefore, there is a trade-off between the generation quality and the task success rate in the RL setting.

4.3 PersuasionForGood

To showcase ARDM's performance on a dialog dataset where it is much more difficult to obtain belief states and dialog act annotations, we train and evaluate our model on PersuasionForGood (Wang et al., 2019) dataset. In this dataset, the persuader must persuade an assigned persuadee (i.e., a person who is asked to donate) to donate money (from their task payment) to a charity called "Save the Children".

4.3.1 Setting

This dataset has a much larger vocabulary size (8,141) than the previous task-oriented dialog datasets due to its non-collaborative dialog property. The conversation content is richer because two speakers are negotiating back and forth. The dataset consists of 1,017 dialogs where only 300 dialogs are annotated with dialog acts. Therefore, models that require dialog state or dialog act annotation are not applicable in this dataset. As ARDM does not require dialog acts for training, it fits well on the PersuasionForGood dataset. We remove the prefix for system inputs because the task does not involve any database search. We use TransferTransfo (Wolf et al., 2019) model as a baseline, since it does not require extra human annotations. TransferTransfo is based on large pre-trained language model, and it uses token type embedding to encode role information of the speaker. We finetune it on the PersuasionForGood dataset.

To generate diverse responses, we decode the response using the nucleus sampling (Holtzman et al., 2019) with a top-p of 0.9 and a temperature of 0.7. It is impossible to conduct an automatic evaluation on task success on this task due to the lack of annotation. We use perplexity to evaluate each model's language generation quality. We also conduct a human evaluation to validate each model's task success rate. We show some generated examples in the Appendix to provide more information on both models' generation quality.

4.3.2 Results

Table 3 shows the results for PersuasionForGood. Because ARDM applies better speaker modeling and recurrence mechanism, our model achieves

	Perplexity ↓	Human Preference ↑	Average Donation Amount ↑
TransferTransfo	19.9	34.7%	0.538
ARDM	**10.1**	**65.3%**	**0.807**

Table 3: Automatic Evaluation and Human Evaluation Results on the PersuasionForGood dataset.

lower perplexity compared to TransferTransfo. We did not report BLEU, because on the PersuasionForGood dataset, BLEU score cannot reflect the actual generation quality as a random sentence with common tokens "the, of, is, are..." already has 10.0+ BLEU-1 score. Also because the validation set only contains 100 samples, the result can have a high variance. Then the only way to evaluate this type of system is by human evaluation.

To comprehensively evaluate each model's performance, we recruit 14 human evaluators to chat with the two persuasive systems ten times to avoid the randomness produced by each model. In total, we collected 140 ratings. We ask them to select a preferred chat-bot and indicate how much they are willing to donate after talking to the chat-bot. As a result, human judges prefer ARDM over TransferTransfo and tends to donate more when talking to ARDM produced chat-bot. Our model achieved 27% more donations compared to TransferTransfo. This indicates that our systems are more persuasive. In some examples, such as the one in Table 4, our model generates coherent, natural, and persuasive responses.

5 Error Analysis

Since CamRest676 is similar to MultiWOZ in terms of task content and dialog structure, we only describe the errors in MultiWOZ for simplicity. We randomly selected 30 generated error responses from our model with zero inform and success score.

To our surprise, we observed that nearly 63.3% of errors are not really mistakes. It is mainly due to the limitation of the automatic evaluator. For example, at turn one, the user asks about a restaurant, and the ground truth system response is "the [restaurant_name] is located at ...", but the generated system response is "what food preference do you have?". Our generated response is correct with respect to the dialog context. It is narrowing down the restaurant choices before providing a restaurant recommendation. However, the evaluator sticks to the only possible response it has. Unless the user can dynamically interact with the system, there is no good way to change such mistakes in the automatic evaluator.

We find that another 20% errors our model makes are when the system asks information the user already provided. This type of errors calls for a better history representation. Another 10% errors are due to ignoring the user's request for information, such as phone number. However, when we look at the ground truth responses, some crowd workers also made such errors. So resolving these errors requires a cleaner training dataset. Finally, the rest of 6.7% errors are about incorrect dialog domain understanding. For example, the user is asking for a hotel, but we present a restaurant recommendation. This is because of the data noise during the delexicalization process in which some domain labels are wrong.

The donation persuasion system trained with TransferTransfo and our model has some common problems, such as inconsistency, lack of logic, and hallucination. For example, if the persuader provides the information about "Save the Children", then the persuadee asks "Can you tell me more about it?". The system ends up providing the same information as before. It also sometimes makes up facts that have never happened, such as "Save the Children has an operation about a hurricane in Hawaii". All those errors would prevent users from trusting the bot, and therefore resulting in less donation. However, we also observe that users have a higher tolerance for errors in the persuasion setting than the customer service setting.

Overall, our model performs better on PersuasionForGood by having longer and diversified utterances. This suggests our model which utilizes alternating parameters is more effective than TransferTransfo.

6 Discussions and Ethical Consideration

ARDM models speakers separately on top of a large pre-trained language model. Such simple adaptation demonstrates substantial performance gain. We suspect it is because the interleaved structure of two language models provides a collabora-

Role	Utterance
SYS	Hi, how are you doing today?
USR	I am good!
SYS	Have you ever heard of the charity Save the Children?
USR	No, I have not heard about it. Would you like to talk about it?
SYS	Save the Children is an international non-governmental organization that promotes children's rights, provides relief and helps support children in developing countries.
USR	That's cool. It is an organization for the good of this world.
SYS	Yes, it is. In the first two months of 2018 alone, 1,000 children were reportedly killed or injured in intensifying violence in Syria.
USR	That's sad.
SYS	We do need to do something about that. One of the things that we can do is make sure that we have a system in place that will ensure that every penny we spend goes directly to the children in need.
USR	I agree.
SYS	How much do you like to donate to the charity now? Your donation will be directly deducted from your task payment. You can choose any amount from $0 to all your payment ($2).
USR	I am willing to donate full my payment $2.
SYS	Wow, that is awesome! That is so kind of you!
USR	You are welcome.

Table 4: A conversation between a machine persuader trained by ARDM and a human persuadee.

tive learning frame of both the user and the system language distribution modeling. The memory is the only way for the user and system to communicate, as they do not share any weights in their networks. Thus, the user encoder needs to learn useful representations to make the system model for understanding its intent. Similarly, the system needs to do the same for the user model to improve its understanding. This alternative repeating process forces both the user and system models to preserve the dialog history effectively in the memory. One can interpret the memory as the implicit representation of belief states or dialog acts.

Another benefit of ARDM is that we will obtain both user and system utterance generators. We can let the two models talk to each other to generate new self-play dialogs (Silver et al., 2017). With self-play, one can rapidly build a large scale dialog dataset using adversarial filtering (Zellers et al., 2018). Such models can also potentially be used in reinforcement learning as user simulator to study complex dialog strategies as well. We will explore those possibilities in the future work.

Persuasion is a double-edged sword. Given the fast development of dialog systems, an ethical design principle must be in place throughout all stages of the development and evaluation. We choose the donation task is because it is a relatively simple task that benefits children. Second, when deploying the persuasive agents in real conversations, we need to keep the users informed of the nature of the system. By revealing the identity of the persuasive agent, the user should also have options to communicate directly with the human team behind the system. Lastly, by investigating persuasive dialog systems, we also envision to use them as an educational tool for the general public to learn to defend themselves against machine persuasion.

7 Conclusions

We propose to build Alternating Recurrent Dialog Model (ARDM), a simple, general, and effective dialog method that models user and system separately with large-scale pre-trained language models. Since ARDM does not require any annotations, it generalizes to different dialog applications. Experimental results on CamRest676 and MultiWOZ suggest that ARDM outperforms or is on-par with the current state-of-the-art methods that use manual annotation information, such as belief states and dialog acts. Furthermore, we find our model's excellent performance generalizes to more complex non-collaborative dialog settings. It can generate high-quality responses to persuade people to donate to charity. However, the easiness of training ARDM raises concerns about the misuse of the model in scenarios such as sales, harassment, or scam on a mass scale. We caution the public in deploying such systems in the real world.

Abstract

Vision-and-Language Navigation wayfinding agents can be enhanced by exploiting automatically generated navigation instructions. However, existing instruction generators have not been comprehensively evaluated, and the automatic evaluation metrics used to develop them have not been validated. Using human wayfinders, we show that these generators perform on par with or only slightly better than a template-based generator and far worse than human instructors. Furthermore, we discover that BLEU, ROUGE, METEOR and CIDEr are ineffective for evaluating grounded navigation instructions. To improve instruction evaluation, we propose an instruction-trajectory compatibility model that operates without reference instructions. Our model shows the highest correlation with human wayfinding outcomes when scoring individual instructions. For ranking instruction generation systems, if reference instructions are available we recommend using SPICE.

1 Introduction

Generating route instructions is a long studied problem with clear practical applications (Richter and Klippel, 2005). Whereas earlier work sought to create instructions for human wayfinders, recent work has focused on using instruction-generation models to improve the performance of agents that follow instructions given by people. In the context of Vision-and-Language Navigation (VLN) datasets such as Room-to-Room (R2R) (Anderson et al., 2018b), models for generating navigation instructions have improved agents' wayfinding performance in at least two ways: (1) by synthesizing new instructions for data augmentation (Fried et al., 2018; Tan et al., 2019), and (2) by fulfilling the role of a probabilistic speaker in a pragmatic reasoning setting (Fried et al., 2018). Such data augmentation is so effective that it is nearly ubiquitous in the best performing agents (Wang et al., 2019; Huang et al., 2019; Li et al., 2019).

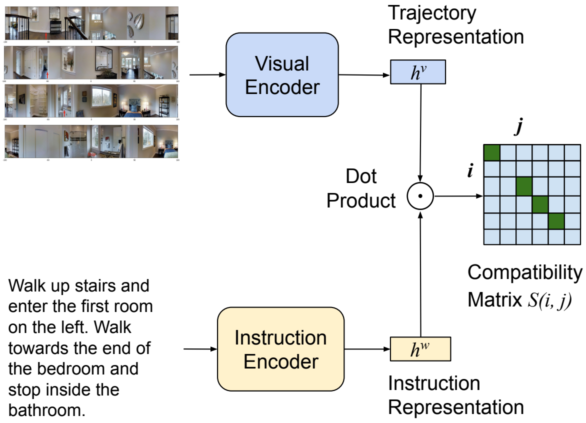

Figure 1: Proposed dual encoder instruction-trajectory compatibility model. Navigation instructions and trajectories (sequences of panoramic images and view angles) are projected into a shared latent space. The independence between the encoders facilitates learning using both contrastive and classification losses.

To make further advances in the generation of visually-grounded navigation instructions, accurate evaluation of the generated text is essential. However, the performance of existing instruction generators has not yet been evaluated using human wayfinders, and the efficacy of the automated evaluation metrics used to develop them has not been established. This paper addresses both gaps.

To establish benchmarks for navigation instruction generation, we evaluate existing English models (Fried et al., 2018; Tan et al., 2019) using human wayfinders. These models are effective for data augmentation, but in human trials they perform on par with or only slightly better than a template-based system, and they are far worse than human instructors. This leaves much headroom for better instruction generation, which may in turn improve agents' wayfinding abilities.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1302–1316
April 19 - 23, 2021.

Next, we consider the evaluation of navigation instructions without human wayfinders, a necessary step for future improvements in both grounded instruction generation (itself a challenging and important language generation problem) and agent wayfinding. We propose a model-based approach (Fig. 1) to measure the compatibility of an instruction-trajectory pair without needing reference instructions for evaluation. In training this model, we find that adding contrastive losses in addition to pairwise classification losses improves AUC by 9–10%, round-trip back-translation improves performance when used to paraphrase positive examples, and that both trajectory and instruction perturbations are useful as hard negatives.

Finally, we compare our compatibility model to common textual evaluation metrics to assess which metric best correlates with the outcomes of human wayfinding attempts. We discover that BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Denkowski and Lavie, 2014) and CIDEr (Vedantam et al., 2015) are ineffective for evaluating grounded navigation instructions. For system-level evaluations with reference instructions, we recommend SPICE (Anderson et al., 2016). When averaged over many instructions, SPICE correlates with both human wayfinding performance and subjective human judgments of instruction quality. When scoring individual instructions, our compatibility model most closely reflects human wayfinding performance, outperforming BERTScore (Zhang et al., 2019) and VLN agent-based scores. Our results are a timely reminder that textual evaluation metrics should always be validated against human judgments when applied to new domains. We plan to release our trained compatibility model and the instructions and human evaluation data we collected.

2 Related Work

Navigation Instruction Generation Until recently, most methods for generating navigation instructions were focused on settings in which a system has access to a map representation of the environment, including the locations of objects and named items (e.g. of streets and buildings) (Richter and Klippel, 2005). Some generate route instructions *interactively* given the current position and goal location (Dräger and Koller, 2012), while others provide *in-advance* instructions that must be more robust to possible misinterpretation (Roth and Frank, 2010; Mast and Wolter, 2013).

Recent work has focused on instruction generation to improve the performance of wayfinding agents. Two instruction generators, *Speaker-Follower* (Fried et al., 2018) and *EnvDrop* (Tan et al., 2019), have been widely used for R2R data augmentation. They provide ∼170k new instruction-trajectory pairs sampled from training environments. Both are seq-to-seq models with attention. They take as input a sequence of panoramas grounded in a 3D trajectory, and output a textual instruction intended to describe it.

Vision-and-Language Navigation For VLN, embodied agents in 3D environments must follow natural language instructions to reach prescribed goals. Most recent efforts (e.g., Fu et al., 2019; Huang et al., 2019; Jain et al., 2019; Wang et al., 2019, etc.) have used the Room-to-Room (R2R) dataset (Anderson et al., 2018b), which contains 4675 unique paths in the *train* split, 340 in the *val-seen* split (same environments, new paths), and an additional 783 paths in the *val-unseen* split (new environments, new paths). However, our findings are also relevant for similar datasets such as Touchdown (Chen et al., 2019; Mehta et al., 2020), CVDN (Thomason et al., 2019), REVERIE (Qi et al., 2020), and the multilingual Room-across-Room (RxR) dataset (Ku et al., 2020).

Text Generation Metrics There are many automated metrics that assess textual similarity; we focus on five that are extensively used in the context of image captioning: BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014), ROUGE (Lin, 2004), CIDEr (Vedantam et al., 2015) and SPICE (Anderson et al., 2016). More recently, model- and semi-model-based metrics have been proposed. BERTScore (Zhang et al., 2019) takes a semi-model-based approach to compute token-wise similarity using contextual embeddings learned with BERT (Devlin et al., 2019). BLEURT (Sellam et al., 2020) is a fully model-based approach combining large-scale synthetic pretraining and domain specific finetuning. However, all of the aforementioned metrics are reference-based, and none is specifically designed for assessing navigation instructions associated with 3D trajectories for an embodied agent, which requires not only language-to-vision grounding but also correct sequencing.

Instruction-Trajectory Compatibility Models Our model builds on that of Huang et al. (2019), but differs in loss (using focal and contrastive losses), input features (adding action and geometry representation), and negative mining strategies (adding instruction perturbations in addition to trajectory perturbations). Compared to the trajectory re-ranking compatibility model proposed by Majumdar et al. (2020), we use a dual encoder architecture rather than dense cross-attention. This facilitates the efficient computation of contrastive losses, which are calculated over all pairs in a minibatch, and improve AUC by 10% in our model. We also avoid training on the outputs of the instruction generators (to prevent overfitting to the models we evaluate). We are yet to explore transfer learning (which is the focus of Majumdar et al. (2020)).

3 Human Wayfinding Evaluations

To benchmark the current state-of-the-art for navigation instruction generation, we evaluate the outputs of the *Speaker-Follower* and *EnvDrop* models by asking people to follow them. We use instructions for the 340 and 783 trajectories in the R2R val-seen and val-unseen splits, respectively. Both models are trained on the R2R train split and the generated instructions were provided by the respective authors. To contextualize the results, we additionally evaluate instructions from a template-based generator (using ground-truth object annotations), a new set of instructions written by human annotators, and three adversarial perturbations of these human instructions. New navigation instructions and wayfinding evaluations are collected using a lightly modified version of PanGEA[1], an open-source annotation toolkit for panoramic graph environments.

Crafty Crafty is a template-based navigation instruction generator. It observes the trajectory's geometry and nearby ground-truth object annotations, identifies salient objects, and creates English instructions using templates describing movement with respect to the trajectory and objects. See the Appendix for details. Note that Crafty has an advantage over the learned models which rely on panoramic images to identify visual references and do not exploit object annotations.

Human Instructions We collect 340 new English instructions for the trajectories in the R2R val-seen split using the PanGEA Guide task.

Instruction Perturbations To quantify the impact of common instruction generator failure modes on instruction following performance, we include three adversarial perturbations of human instructions capturing incorrect direction words, hallucinated objects/landmarks, and repeated or skipped steps. We use Google Cloud NLP[2] to identify named entities and parse dependency trees and then generate perturbations as follows:

- **Direction Swap**: Random swapping of directional phrases with alternatives from the same set, with sets as follows: *around/left/right, bottom/middle/top, up/down, front/back, above/under, enter/exit, backward/forward, away from/towards, into/out of, inside/outside*.

  Example: *"Take a right (**left**) and wait by the couch outside (**inside**) the bedroom. "*

- **Entity Swap**: Random swapping of entities in an instruction. All noun phrases excluding a stop list containing *any, first, end, front*, etc. are considered to be entities. If two entities have the same lemma (e.g., *stairs/staircase/stairway*) they are considered to be synonyms and are not swapped.

  Example: *"Exit the bedroom (**bathroom**), turn right, then enter the bathroom (**bedroom**)."*

- **Phrase Swap**: A random operation on the dependency tree: either remove one sub-sentence tree, duplicate one sub-sentence tree, or shuffle the order of all sentences except the last.

  Example: *"Exit the room using the door on the left. Turn slightly left and go past the round table an chairs. Wait there."* – where the first and second sentences are swapped.

Wayfinding Task Using the PanGEA Follower task, annotators are presented with a textual navigation instruction and the first-person camera view from the starting pose. They are instructed to attempt to follow the instruction to reach the goal location. Camera controls allow for continuous heading and elevation changes as well as movement between Matterport3D panoramas based on a navigation graph. Each instruction is evaluated by three different human wayfinders.

Human	340×3	54.1	**2.56**	**75.1**	**64.7**	**63.1**	**4.25**	**35.8**	**23.8**	53.9

Table 1: Human wayfinding performance following instructions from the Speaker-Follower (Fried et al., 2018) and EnvDrop (Tan et al., 2019) models, compared to Crafty (template-based) instructions, Human instructions, and three adversarial perturbations of Human instructions (Direction, Entity and Phrase Swap).

Evaluation Metrics We use the following standard metrics to evaluate the trajectories generated by our annotators (and hence, the quality of the provided instructions): *Navigation Error* (**NE** ↓) *Success Rate* (**SR** ↑), *Success weighted by inverse Path Length* (**SPL** ↑), *Success weighted by normalized Dynamic Time Warping* (**SDTW** ↑). Arrows indicate improving performance. See Anderson et al. (2018a) and Ilharco et al. (2019) for details.

People are resourceful and may succeed in following poor quality instructions by expending additional effort. Therefore, we report additional metrics to capture these costs. **Quality** ↑ is a self-reported measure of instruction quality based on a 1–5 Likert scale. At the end of each task annotators respond to the prompt: *Do you think there are mistakes in the instruction?* Responses range from *Way too many mistakes to follow (1)* to *No mistakes, very very easy to follow' (5).* **Visual Search** cost ↓ measures the percentage of the available panoramic visual field that the annotator observes at each viewpoint, based on the pose traces provided by PanGEA and first proposed in the RxR dataset (Ku et al., 2020). Higher values indicate greater effort spent looking for the correct path. We report this separately for the start viewpoint and other viewpoints since wayfinders typically look around to orient themselves at the start. **Time** ↓ represents the average time taken in seconds.

Results Table 1 summarizes the results of 11,886 wayfinding attempts using 37 English-speaking annotators. The performance of annotators stays consistent over time and does not show any sign of adaptation. See Appendix for detailed analysis.

As expected, human instructions perform best in human wayfinding evaluations on all path evaluation metrics and on subjective assessments of instruction quality, and they also incur the lowest visual search costs. The only metric not dominated by human instructions is the time taken – which correlates with instruction length, and may be affected by wayfinders giving up when faced with poor quality instructions. Overall, the Speaker-Follower and EnvDrop models are surprisingly weak and noticeably worse than even adversarially perturbed human instructions. Compared to the template-based approach (Crafty), the Speaker-Follower model performs on par and EnvDrop is only slightly better. As a first step to improving existing navigation instruction generators, we focus on developing and evaluating automated metrics that can approximate these human wayfinding evaluations.

4 Compatibility Model

As an alternative to human evaluations, we train an instruction-trajectory compatibility model to assess both the grounding between textual and visual inputs and the alignment of the two sequences.

4.1 Model Structure

Our model is a dual encoder that encodes instructions and trajectories into a shared latent space (Figure 1). The instruction representation h^w is the concatenation of the final output states of a bi-directional LSTM (Schuster and Paliwal, 1997) encoding the instruction tokens $\mathcal{W} = \{w_1, w_2, ..., w_n\}$. We use contextualized token embeddings from BERT (Devlin et al., 2019) as input to the LSTM.

The visual encoder is a two-layer LSTM that processes visual features extracted from a sequence of viewpoints $\mathcal{V} = \{(I_1, p_1), (I_2, p_2)..., (I_t, p_t)\}$ comprised of panoramic images I_t captured at positions p_t along a 3D trajectory. The vector h_t^v representing the viewpoint at step t is given by:

$$a_t = \text{Attention}(h_{t-1}^v, e_{\text{pano},t}) \quad (1)$$

$$v_t = f([e_{\text{prev},t}, e_{\text{next},t}, a_t]) \quad (2)$$

$$h_t^v = \text{LSTM}(v_t, h_{t-1}^v) \quad (3)$$

where $e_{\text{pano},t}$ is a set of 36 visual features representing the panoramic image I_t (discretized into 36 viewing angles by elevation θ and heading ϕ), $e_{\text{prev},t}$ and $e_{\text{next},t}$ are the visual features in the directions of the previous and next viewpoints ($v_{t-1} - v_t$ and $v_{t+1} - v_t$ respectively), and f is a projection layer. Each visual feature is a concatenation of a pre-trained CNN image feature (Juan et al., 2020) with orientation vectors encoding both sine and cosine functions of the absolute and relative angles $\{\theta_{\text{abs}}, \phi_{\text{abs}}, \theta_{\text{rel}}, \phi_{\text{rel}}\}$. We use standard dot-product attention (Luong et al., 2014) and define $h^v = h_T^v$, the final viewpoint embedding in the trajectory. The output of the model is the compatibility score S between an instruction and a trajectory defined as the cosine similarity between h^v and h^w.

4.2 Hard Negative Mining

To avoid overfitting, our compatibility model is *not trained on the outputs of any of the instruction generators that we evaluate*. Instead, we use only the relatively small set of positive instruction-trajectory examples from R2R. We use round-trip back-translation to expand the set of positive examples. Unmatched instruction-trajectory pairs from R2R are considered to be negative examples and we also construct hard negative examples from positive examples by adversarially perturbing both trajectories and instructions.

Instruction Perturbations We use the same instruction perturbations described in Section 3: *Direction Swap*, *Entity Swap*, and *Phrase Swap*. These perturbations are inspired by typical failure modes in instruction generators and are designed to be hard to recognize without grounding on images and actions along the trajectory. Previous work by Huang et al. (2019) considered only trajectory perturbations. While this encourages the model to recognize incorrect trajectories for a given ground truth instruction, it may not encourage the model to identify a trajectory matched with a poor quality instruction. Our results suggest that instruction perturbations are equally important.

Trajectory Perturbations To perturb trajectories we use the navigation graphs defining connected viewpoints in R2R. Inspired by Huang et al. (2019), we consider *Random Walk*, *Path Reversal*, and *Viewpoint Swap* perturbations:

- **Random Walk**: The first or last two viewpoints are fixed and the remainder of the trajectory is re-sampled using random edge traversals subject to the path length remaining within ±1 step of the original. To make the task harder, we avoid revisiting a viewpoint and require the re-sampled trajectory to have at least two overlapping viewpoints with the original.

- **Path Reversal**: The entire trajectory is reversed while keeping the same viewpoints.

- **Viewpoint Swap**: A new method we introduce that randomly samples and swaps a viewpoint in a trajectory with a new viewpoint sampled from the neighbors of the adjacent viewpoints in the original trajectory.

Paraphrases To expand the 14k positive examples from the R2R train set and balance the positive-to-negative ratio, we paraphrase instructions via round-trip back-translation. We use the following ten intermediate languages and Google Translate[3]: *ar, es, de, fr, hi, it, pt, ru, tr*, and *zh*. To exclude low quality or nearly duplicate instructions, we filter paraphrased instructions outside the BLEU score range of [0.25, 0.7] compared to the original. Overall we have a total of 110,601 positive instruction-trajectory pairs in the training set, which contains 4675 unique trajectories.

4.3 Loss Functions

During training, each minibatch is constructed with N matching instruction-trajectory pairs, which may be perturbed. We define $M \in \{0, 1\}^N$ as the vector indicating unperturbed pairs. A compatibility matrix $S \in \mathcal{R}^{N \times N}$ is defined such that $S_{i,j}$ is the cosine similarity score between instruction i and trajectory j determined by our model.

We use both binary classification loss functions, defined on diagonal elements of S, and a contrastive loss defined on S's rows and columns. Contrastive losses are commonly used for retrieval and representation learning (e.g., Yang et al., 2019;

---

Table 2: Ablation of different models based on classification AUC. Models are trained with the original R2R-train data and paraphrased positive instructions, plus path and/or instruction perturbed hard negatives (second column). The best models are selected based on the validation set (column 3), and we report the final test performance in column 4. To understand the performance of individual perturbation method, we also report the best AUCs for each of the six perturbations in columns 5 - 10.

Chen et al., 2020) and in our case exploits all random instruction-trajectory pairs in a minibatch.

Each loss requires a separate normalization. For the classification loss we compute the probability of a match $p_{i,j}$, such that $p_{i,j} = \sigma(aS_{i,j} + b)$ where a and b are learned scalars and σ is the sigmoid function. For the classification loss $\mathcal{L}_{\text{cls}}$ we consider both binary cross entropy loss $\mathcal{L}_{\text{CE}}$, and focal loss (Lin et al., 2017) given by $\mathcal{L}_{\text{FL}} = (1 - p_{i,j})^{\gamma}\mathcal{L}_{\text{CE}}$ where we set $\gamma = 2$.

For the contrastive loss we compute logits by scaling S with a learned scalar temperature τ. The contrastive loss $\mathcal{L}_C(S)$ calculated over the rows and colums of S is given by:

$$\mathcal{L}_C(S) = \frac{1}{\sum_i M_i} \sum_{i=1}^{N} \Big(\mathcal{L}_r(S_i) + \mathcal{L}_r(S_i^{\intercal})\Big) \quad (4)$$

where $\mathcal{L}_r(S_i) = 0$ if $M_i = 0$, i.e., the diagonal element is a perturbed pair and not considered to be a match. Otherwise:

$$\mathcal{L}_r(S_i) = -\log \frac{e^{S_{i,i}/\tau}}{\sum_j^N e^{S_{i,j}/\tau}} \quad (5)$$

The final loss is the combination:

$$\mathcal{L} = \mathcal{L}_C(S) + \frac{\beta}{N} \sum_{i=1}^{N} \mathcal{L}_{cls}(S_{i,i}) \quad (6)$$

where $\mathcal{L}_{cls}$ is the classification loss, either $\mathcal{L}_{CE}$ or $\mathcal{L}_{FL}$, and we set $\beta = 1$.

Sampling hyperparameters We sample positive and negative examples equally with a mix ratio of 2:1:1 for ground truth, instruction perturbations, and trajectory perturbations, respectively. For each perturbation type, we sample the three methods with equal probability.

5 Experiments

We evaluate our compatibility model against alternative model-based evaluations and standard textual similarity metrics. We report instruction classification results in Section 5.1, improved data augmentation for VLN agents in Section 5.2, and correlation with human wayfinder outcomes in 5.3.

5.1 Instruction Classification

Evaluation In this setting we use the instruction-trajectory compatibility model to classify high and low quality instructions for trajectories from the R2R val-unseen and val-seen sets. The instruction pool includes 3 high-quality instructions per trajectory from R2R, plus 2 instructions per trajectory from the Speaker-Follower and EnvDrop models. These are considered to be high quality if 2 out of 3 human wayfinders reached the goal (see Section 3), and low quality otherwise. We assess model performance using *Area Under the ROC Curve* (AUC). We use the val-unseen split (3915 instructions, 75% high quality) for model validation and the val-seen split (1700 instructions, 78% high quality) as test.

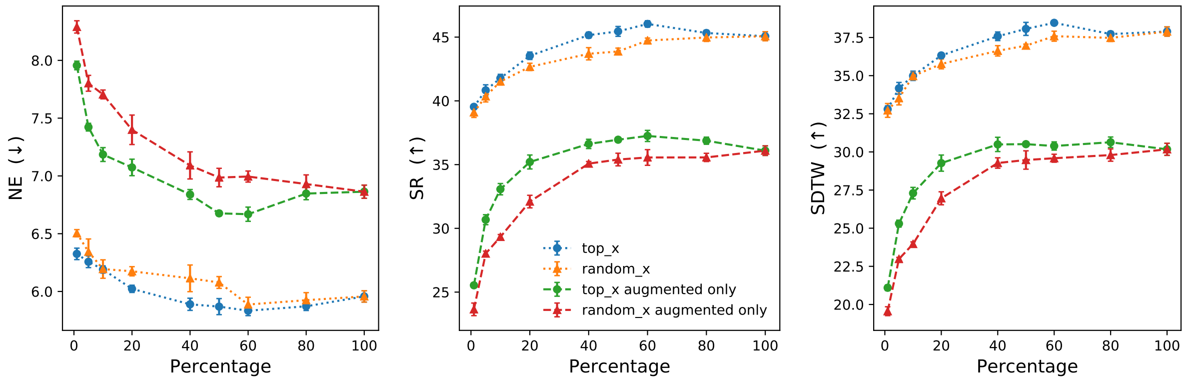

Figure 2: Navigation performance of a VLN agent trained with different fractions of Speaker-Follower augmented paths, starting from 1%. For NE, lower is better; for SR and SDTW, higher is better. The dashed-lines (green and red) use only augmented paths in training, while the dotted lines (blue and orange) use both augmented and R2R-train paths. Filled circles indicate fractions ranked by our compatibility model in descending order, while triangles indicate random fractions. Each point is the mean of 3 runs and the error bars represent the standard deviation of the mean. The model-ranked fractions show consistent improvement over random samples of the same percentage. Agents trained with only augmented paths (dashed-lines) show greater difference between model-ranked fractions and random fractions.

Benchmark We compare to the compatibility model proposed by Huang et al. (2019), which computes elementwise similarities between instruction words and trajectory panoramas *before* pooling, and does not include action embeddings ($e_{\text{prev},t}$ and $e_{\text{next},t}$) or position encodings p_t. In contrast, our model calculates the similarity between instructions and trajectories *after* pooling each sequence and includes both action and position encodings.

Results Table 2 reports classification AUC including comprehensive ablations of loss functions, approaches to hard negative mining, and modeling choices. With regard to the loss function, we find that the combination of contrastive and focal loss (row 6) performs best overall, and that adding contrastive loss provides a very significant 9 - 10% increase in AUC compared to using just cross-entropy (CE) or focal loss (rows 2 and 3) due to the effective use of in-batch negatives. Adding paraphrased positive instructions and pretrained BERT token embeddings also leads to significant performance gains (rows 7 and 8 vs. row 6). The best performing model on both the validation and test sets uses Contrastive + Focal loss with paraphrased instructions and BERT embeddings, as well as trajectory and instruction perturbations (row 8). This model consistently outperforms the benchmark from prior work (row 1) by a large margin and achieves a test set AUC of 73.7%.

In rows 9–17 we ablate the six perturbation methods that we use for hard negative mining. Ablations using only instruction perturbations (row 9), only path perturbations (13), or no perturbations at all (row 17) perform considerably worse than our best model (row 8). We also show that no individual perturbation approach is effective on its own. In addition to scores for the validation and test sets, we report AUC for each perturbation method on the val-seen set to investigate their individual performance. Overall, trajectory perturbations get higher scores than instruction perturbations, showing they are easier tasks. *Phrase Swap* proves the hardest task, while *Random Walk* is the easiest.

5.2 Data Augmentation for VLN

Data augmentation using instructions from the Speaker-Follower and EnvDrop models is pervasive in the training of VLN agents (Wang et al., 2019; Huang et al., 2019; Li et al., 2019). In this section we evaluate whether our compatibility model can be used to filter out low quality instructions from the augmented training set to improve VLN performance. We score all of 170k augmented instruction-trajectory pairs from the Speaker-Follower model and rank them in descending order. We then use different fractions of the ranked data to train VLN agents, and compare with agents trained using random samples of the same size. We use a VLN agent model based on Wang et al. (2019) and implemented in VALAN (Lansing et al., 2019), which achieves a success rate (SR) of 45% on the R2R val-unseen split when trained on the R2R train split and all of the Speaker-Follower augmented instructions.

Figure 2 indicates that instruction-trajectory pairs selected by our compatibility model consistently outperform random training pairs in terms of the performance of the trained VLN agent. This demonstrates the efficacy of our compatibility model for improving VLN data augmentation by identifying high quality instructions.

5.3 Correlation with Human Wayfinders

In this section we evaluate the correlation between the scores given by our instruction-trajectory compatability model and the outcomes from the human wayfinding attempts described in Section 3. Using Kendall's τ to assess rank correlation, we report both system-level and instance-level correlation. The instance-level evaluations assess whether the metric can identify the best *instruction* from two candidates, while the system-level evaluations assess whether a metric can identify the best *model* from two candidates (after averaging over many instruction scores for each model). The results in Table 3 are reported separately over all 3.9k instructions (9 systems comprising the rows of Table 1), and over model-generated instructions only (4 systems comprising the 2.2k instructions generated by the Speaker-Follower and EnvDrop models on R2R val-seen and val-unseen).

Automatic Metrics For comparison we include standard textual evaluation metrics (BLEU, CIDEr, METEOR, ROUGE and SPICE) and two model-based metrics: BERTScore (Zhang et al., 2019), and scores based on the performance of a trained VLN agent attempting to follow the candidate instruction (Agarwal et al., 2019). Note that only the compatibility model and the VLN agent-based scores use the candidate trajectory – the other metrics are calculated by comparing each candidate instruction to the three reference instructions from R2R (and are thus reliant on reference instructions).

To calculate the standard metrics we use the official evaluation code provided with the COCO captions dataset (Chen et al., 2015). For BERTScore, we use a publicly available uncased BERT[4] model with 12 layers and hidden dimension 768, and compute the mean $F1$-score over the three references. For the VLN agent score, we train three VLN agents based on Wang et al. (2019) from different random initializations using the R2R train set.

Table 3: Kendall's τ correlation between automated instruction evaluation metrics and human wayfinder evaluations. Ranges are 90% confidence intervals based on bootstrap resampling. **N** refers to the number of instructions and **M** refers to the number of systems. If checked, **Ref** indicates that the metric requires reference instructions for comparison. SPL$_{k\text{-agent(s)}}$ and SDTW$_{k\text{-agent(s)}}$ refers to wayfinding scores averaged over k VLN agents trained from random initialization.

We then employ the trained agents for the wayfinding task and report performance as either the SPL or SDTW similarity between the path taken by the agent and the reference path – using either a single agent or the average score from three agents.

Results Table 3 compares system-level and instance-level correlations for all metrics, both standard and model-based. At the *system-level*, we see no correlation between standard text metrics such as BLEU, ROUGE, METEOR and CIDEr and human wayfinder performance. The exception is SPICE, which shows the desired negative correlation with NE, and positive correlation with SR, SPL (see Figure 3) and Quality. At the system-level, the model-based approaches (BERTScore,

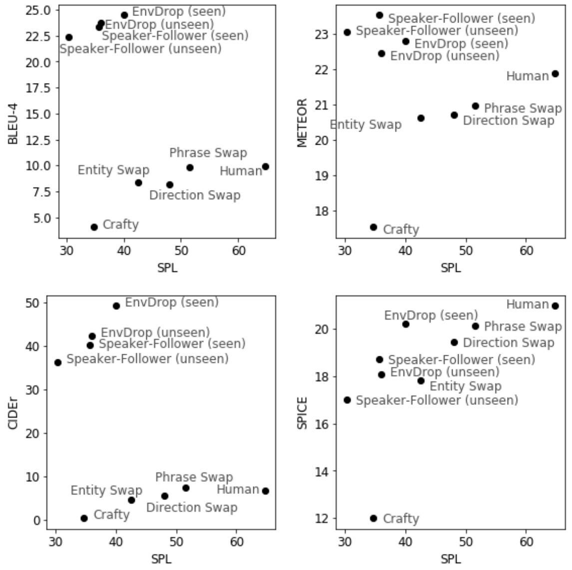

Figure 3: Standard evaluation metrics vs. human wayfinding outcomes (SPL) for 9 navigation instruction generation systems. SPICE is most consistent with human wayfinding outcomes, although no metrics score the Crafty template-based instructions highly.

agent SPL/SDTW and Compatability) also lack the desired correlation and exhibit wide confidence intervals. Here, it is important to point out that the 9 systems under evaluation include a variety of styles (e.g., Crafty's template-based instructions, different annotator pools, adversarial perturbations) which are dissimilar to the R2R data used to train the VLN agents and the compatibility model. Accordingly, the model-based approaches are unable to reliably rank these out-of-domain systems.

At the *instance-level* (when scoring individual instructions) we observe different outcomes. SPICE scores for individual instructions have high variance, and so SPICE does not correlate with wayfinder performance at the instruction level. In contrast, the model-based approaches exhibit the desired correlation, particularly when restricted to the model-generated instructions (Table 3 bottom panel). Our compatibility score shows the strongest correlation among all metrics, performing similarly to an ensemble of three VLN agents.

6 Conclusion

Generating grounded navigation instructions is one of the most promising directions for improving the performance of VLN wayfinding agents, and a challenging and important language generation task in its own right. In this paper, we show that efforts to improve navigation instruction generators have been hindered by a lack of suitable automatic evaluation metrics. With the exception of SPICE, all the standard textual evaluation metrics we evaluated (BLEU, CIDEr, METEOR and ROUGE) are ineffective, and – perhaps as a result – existing instruction generators have substantial headroom for improvement.

To address this problem, we develop an instruction-trajectory compatibility model that outperforms all existing automatic evaluation metrics on instance-level evaluation without needing any reference instructions – making it suitable for use as a reward function in a reinforcement learning setting, as a discriminator in a Generative Adversarial Network (GAN) (Dai et al., 2017), or for filtering instructions in a data augmentation setting.

Progress in natural language generation (NLG) is increasing the demand for evaluation metrics that can accurately evaluate generated text in a variety of domains. Our findings are a timely reminder that textual evaluation metrics should not be trusted in new domains unless they have been comprehensively validated against human judgments. In the case of grounded navigation instructions, for model selection in the presence of reference instructions we recommend using the SPICE metric. In all other scenarios (e.g., selecting individual instructions, or model selection without reference instructions) we recommend using a learned instruction-trajectory compatibility model.

A Automated metric scores for all instructions

We provide more details about automated metric scores for all instructions in this section. Table 4 gives automated metrics for each model we consider. Generated instructions from EnvDrop and Speaker-Follower are scored the highest, whereas human instructions are scored poorly and on par with perturbed instructions, and Crafty is the lowest. These results diverge significantly from human wayfinding performance in Section 3, and highlights the inefficacy of these automated text metrics.

	BertScore	**BLEU-4**	**CIDEr**	**ROUGE**	**METEOR**	**SPICE**
Val-unseen						
Speaker Fol.	78.9	22.3	36.3	45.6	23.1	17.0
EnvDrop	79.3	23.7	42.2	45.8	22.5	18.1
Val-seen						
Speaker Fol.	79.0	23.3	40.1	46.3	**23.5**	18.7
EnvDrop	**79.5**	**24.5**	**49.3**	**46.7**	22.8	20.2
Crafty	71.5	4.1	0.4	23.3	17.5	12.0
Dir. Swap	74.7	8.2	5.7	31.4	20.7	19.4
Entity Swap	74.0	8.4	4.6	31.4	20.6	17.8
Phrase Swap	74.8	9.8	7.4	31.4	21.0	20.1
Human	74.9	9.9	6.7	33.3	21.9	**21.0**

Table 4: Automated metric scores for all instructions. The BLEU, CIDEr and ROUGE metrics score human instructions poorly compared to the neural net models.

B Crafty Details

We use the data in Matterport3D to build Crafty, a template-based navigation instruction generator that uses a Hidden Markov Model (HMM) to select objects as reference landmarks for wayfinding. Crafty's four main components (*Appraiser*, *Walker*, *Observer* and *Talker*) are described below.

B.1 Appraiser

The Appraiser scores the interestingness of objects based on the Matterport3D scans in the training set. It treats each panorama as a document and the categories corresponding to objects visible from the panorama as words, and then computes a per-category inverse document frequency (IDF) score.

B.2 Walker

The Walker converts a panorama sequence into a motion sequence. Given a path (sequence of connected panoramas) and an initial heading, it calculates the entry heading into each panorama and the exit heading required to transition to the next panorama. For each panorama, all annotated objects that are visible from the location are retrieved. For each object, we obtain properties such as their category and center, which allows the distance and heading from the panorama center to be computed. From these, the Walker creates a sequence of motion tuples, each of which captures the context of the source panorama and the goal panorama, along with the heading to move from source to goal.

B.3 Observer

The Observer selects an object sequence by generating objects from an HMM that is specially constructed for each environment, characterized by:

- *Emissions*: how panoramas relate to objects. This is a probability distribution over panoramas for each object, based on the distance between the object and the panoramas.
- *Transitions*: how looking at one object might shift to another one, based on their relative location, the motion at play, and the Appraiser's assessment of their prominence.

The intuition for using an HMM is that we tend to fixate on a given salient object over several steps as we move (high self-transitions); these tend to be nearby (high emission probability for objects near a panorama's center) and connected to the next salient object (biased object-object transitions). To explain a particular observed panorama sequence (path), we can then infer the optimal object sequence using the Viterbi algorithm.

B.4 Talker

Given a motions sequence from the Walker and corresponding object observations from the Observer, the Talker uses a small set of templates to create English instructions for each step. We decompose this into low-level and high-level templates.

B.4.1 Low-level templates

For single step actions, there are three main things to mention: movement, the fixated object and its relationship to the agent's position.

MOVE. For movement, we simply generate a set of possible commands for each direction type, where the direction types are defined as in the orientation wheel shown in Fig. 4. There are additional direction types for UP and DOWN based on relative pitch (e.g. when the goal panorama is higher or lower than the source).

Given one of these heading types, we generate a set of matching phrases appropriate to each. E.g.

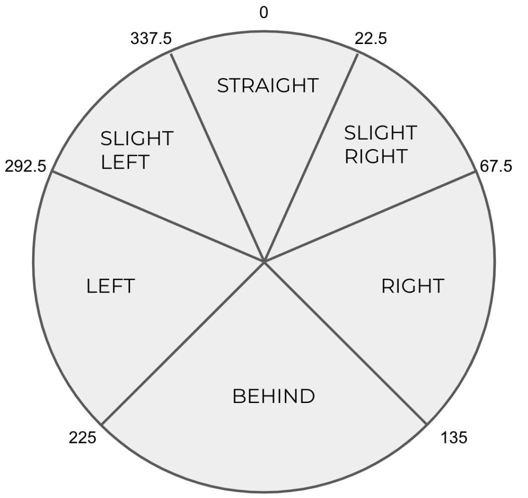

Figure 4: Orientation wheel with directions types. The demarcations are $\frac{\pi}{8}$ (22.5°), $\frac{3\pi}{8}$ (67.5°), etc.

for LEFT and RIGHT, the verbs *face*, *go*, *head*, *make a*, *pivot*, *turn*, and *walk* are combined *left* and *right*, respectively. For moving STRAIGHT, the verbs *continue*, *go*, *head*, *proceed*, *walk*, and *travel* are combined with *straight* and *ahead*. To select an instruction for a given heading, we randomly sample from the list of available phrases. To generate a MOVE command for LEFT, we randomly sample from [*face left*, *go left*, . . . *walk left*].

OBJ. An object's description is its category (e.g. *couch*, *tv*, *window*).

ORIENT. We use the same direction types shown in Figure 4. When an object is STRAIGHT and BEHIND, we use the phrases *ahead of you* or *in front of you* and *behind you* or *in back of you*, respectively. For objects to the LEFT or RIGHT, we use two templates `DIRECTION_PRE DIRECTION` and `DIRECTION DIRECTION_POST`, where `DIRECTION_PRE` is selected from [*to your*, *to the*, *on your*, *on the*] and `DIRECTION_POST` is the phrase *of you*. This produces *to your left*, *on the right*, *right of you*, and so on. For SLIGHT LEFT and SLIGHT RIGHT, one of [*a bit*, *slightly*, *a little*, *just*] is added in front (e.g. *a bit to your left*).

B.4.2 High level templates

Crafty pieces these low-level textual building blocks together to describe actions. In what follows, MOVE, OBJ, and ORIENT indicate the move command, object phrase and orientation phrase, respectively, discussed above.

Single action. We use templates for three situations: start of a path, heading change in a panorama (intra) and moving between panoramas (inter).

- *Start of path*: There are several templates that simply help a wayfinder verify their current position. Ex: *you are near a* `OBJ`*,* `ORIENT`*.*
- *Intra*: These templates include the movement command followed by a verification of the orientation to an object having completed the movement. Ex: `MOVE`*. a* `OBJ` *is* `ORIENT`*.*
- *Inter* : These templates capture walking from one panorama to another and provide additional object verification. Ex: `MOVE`*, going along to the* `OBJ ORIENT`*.*

Multi-step actions. We attempt to reduce verbosity by collapsing actions that involve fixation on the same object.

- *Combining actions*: Repeated actions are collapsed; e.g. [STRAIGHT, STRAIGHT, RIGHT, STRAIGHT] becomes [STRAIGHT, RIGHT, STRAIGHT]). These produce a composite move command, e.g. *proceed forward and make a right and go straight*.
- *Describing the object*: To orient with respect to the fixated-upon object, we switch on the direction type between the agent and the object at the last action. Ex: for STRAIGHT, we use *heading toward the* `OBJ` and for SLIGHT LEFT/RIGHT, we use *approaching the* `OBJ ORIENT`*.*

The final output is the concatenation of the combined move command and the object orientation phrase.

End-of-path instruction templates. The final action is a special situation in that it needs to describing stopping near a salient object. For this, we extract MOVE and OBJ phrases from the last action and use templates such as `MOVE` *and stop by the* `OBJ`*.*

Full example. Putting it all together, Crafty creates full path instructions such as the following, with relevant high-level templates indicated:

- (START) *there is a lamp when you look a bit to the left. pivot right, so it is in back of you.*
- (INTER) *walk forward, going along to the curtain in front of you.*

- (INTRA) *curve left. you should see a tv ahead of you.*
- (MULTI-ACTION) *go forward and go slightly left and walk straight, passing the curtain to your right.*
- (END-OF-PATH) *continue forward and stop by the couch.*

Crafty's instructions are more verbose than human instructions, but are often easy to follow—provided there are good, visually salient landmarks in the environment to use for orientation.

C Human Rater Performance Over Time

Human raters are excellent at learning and adapting to new problems over time. To understand whether our 37 human raters learn to self-correct the perturbed instructions over time and whether that affects the quality of our human wayfinding results, we investigate rater performance as a function of time using the sequence of examples they evaluate.

Figure 5 shows the average human rater performance for all of the 9 datasets included in Table 1 of Section 3. Due to the binary nature of SR, we use a 50-point bin to average each rater's performance, and then average the results across all raters for each bin. Figure 5 shows that the average rater performance stays flat within the uncertainties and does not show systematic drift over time, indicating no overall self-correction that affects the wayfinding results. For a more granular scrutiny of individual perturbation methods, in particular the perturbed instructions, we plot in Figure 6 the average human rater performance over time for the three methods: *Direction Swap*, *Entity Swap*, and *Phrase Swap*. Despite greater uncertainties due to much fewer data points used for averaging, the overall human performance for each method still does not drift significantly in a systematic manner. These results indicate that our human wayfinding performance results are reliable and robust over time, which can be attributed to shuffling of the examples and that the perturbation methods are blind to human raters.

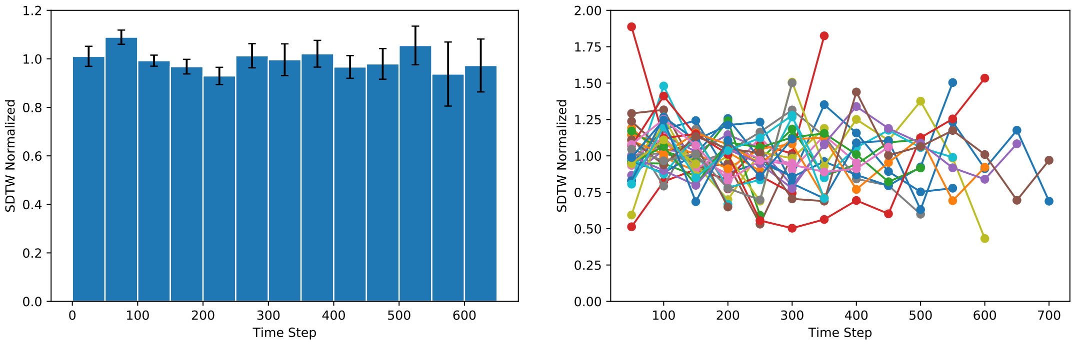

Figure 5: Average human rater performance for all datasets as a function of time using the sequence of examples each rater has evaluated. Each rated example indicates a time step. We normalize the scores of each rater by their mean value over time to remove performance bias of each rater in order to better pick up the trend over time. We average 50 examples to get the mean SDTW for each rater due to the discrete nature of success. *Left*: The mean performance of all rater for each bin. Error bars represent the standard deviation of the mean. *Right*: Individual rater performance over time. Each line represents a single rater. Despite a few outliers, the overall human rater performance is flat and consistent over time, indicating no self-correction or adaptation to the datasets by human raters.

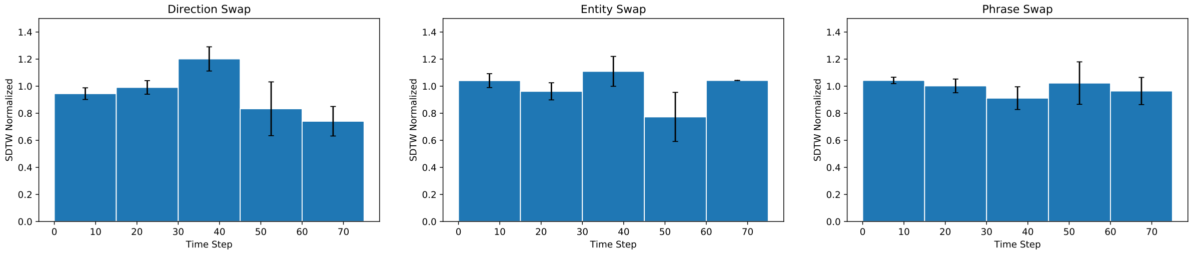

Figure 6: Average human rater performance for the three instruction perturbation methods as a function of time (number of examples), computed in a similar way as in Figure 5. We use a 15-point bin to compute the average for each human rater, and aggregate over all raters to get the mean and its uncertainty. The overall human rater performance stays flat and does not drift significantly over time for instruction perturbations.

Cross-lingual Visual Pre-training for Multimodal Machine Translation

Abstract

Pre-trained language models have been shown to improve performance in many natural language tasks substantially. Although the early focus of such models was single language pre-training, recent advances have resulted in cross-lingual and visual pre-training methods. In this paper, we combine these two approaches to learn visually-grounded cross-lingual representations. Specifically, we extend the translation language modelling (Lample and Conneau, 2019) with masked region classification and perform pre-training with three-way parallel vision & language corpora. We show that when fine-tuned for multimodal machine translation, these models obtain state-of-the-art performance. We also provide qualitative insights into the usefulness of the learned grounded representations.

1 Introduction

Pre-trained language models (Peters et al., 2018; Devlin et al., 2019) have been proven valuable tools for contextual representation extraction. Many studies have shown their effectiveness in discovering linguistic structures (Tenney et al., 2019), which is useful for a wide variety of NLP tasks (Talmor et al., 2019; Kondratyuk and Straka, 2019; Petroni et al., 2019). These positive results led to further exploration of (i) cross-lingual pre-training (Lample and Conneau, 2019; Conneau et al., 2020; Wang et al., 2020) through the use of multiple mono-lingual and parallel resources, and (ii) visual pre-training where large-scale image captioning corpora are used to induce grounded vision & language representations (Lu et al., 2019; Tan and Bansal, 2019; Li et al., 2020a; Su et al., 2020; Li et al., 2020b). The latter is usually achieved by extending the masked language modelling (MLM) objective (Devlin et al., 2019) with auxiliary vision & language tasks such as masked region classification and image sentence matching.

In this paper, we present the first attempt to bring together cross-lingual and visual pre-training. Our visual translation language modelling (VTLM) objective combines the translation language modelling (TLM) (Lample and Conneau, 2019) with masked region classification (MRC) (Chen et al., 2020; Su et al., 2020) to learn grounded cross-lingual representations. Unlike most of the prior work that use classification or retrieval based downstream evaluation, we focus on the *generative* task of multimodal machine translation (MMT), where images accompany captions during translation (Sulubacak et al., 2020). Once pre-trained, we transfer the VTLM encoder to a Transformer-based (Vaswani et al., 2017) MMT and fine-tune it for the MMT task. To our knowledge, this is also the first attempt of pre-training & fine-tuning for MMT, where the current state of the art mostly relies on training multimodal sequence-to-sequence systems from scratch (Calixto et al., 2016; Caglayan et al., 2016; Libovický and Helcl, 2017; Elliott and Kádár, 2017; Caglayan et al., 2017; Yin et al., 2020).

Our findings highlight the effectiveness of cross-lingual visual pre-training: when fine-tuned on the English→German direction of the Multi30k dataset (Elliott et al., 2016), our MMT model surpasses our constrained MMT baseline by about 10 BLEU and 8 METEOR points. The rest of the paper is organised as follows: §2 describes our pre-training and fine-tuning protocol, §3 presents our quantitative and qualitative analyses, and §4 concludes the paper with pointers for future work.

2 Method

We propose Visual Translation Language Modelling (VTLM) objective to learn multimodal cross-lingual representations. In what follows, we first describe the TLM objective (Lample and Conneau, 2019) and then introduce the modifications required to extend it to VTLM.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1317–1324

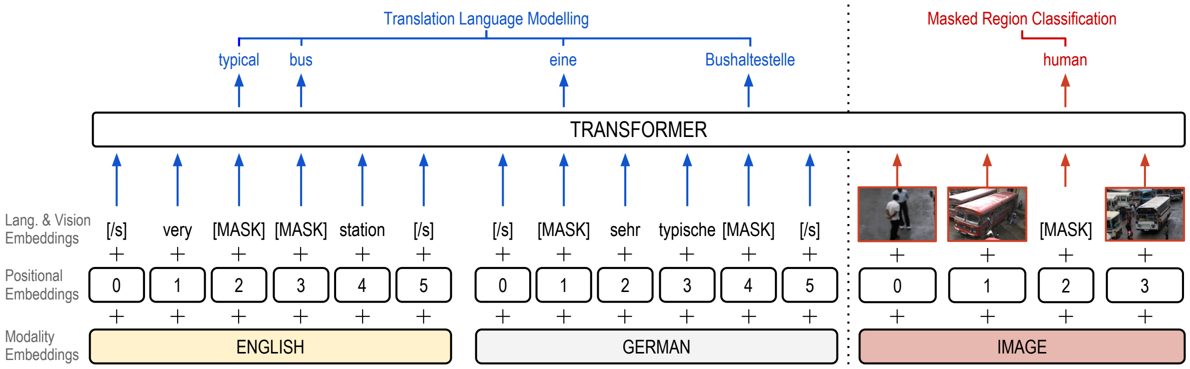

Figure 1: The architecture of the proposed model: VTLM extends the TLM (Lample and Conneau, 2019) (left side of the dotted line) with regional image features. Masking applies on both linguistic and visual tokens.

2.1 Translation language modelling

The TLM objective is based on Transformer networks and assumes the availability of parallel corpora during training. It defines the input x as the concatenation of m-length source language sentence $s^{(1)}_{1:m}$ and n-length target language sentence $s^{(2)}_{1:n}$:

$$x = \left[s^{(1)}_1, \cdots, s^{(1)}_m, s^{(2)}_1, \cdots, s^{(2)}_n\right]$$

For a given input, TLM follows (Devlin et al., 2019), and selects a random set of input tokens $y = \{s^{(l)}_1, \dots, s^{(l)}_k\}$ for masking. Let us denote the masked input sequence with $\tilde{x}$, and the ground-truth targets for masked positions with $\hat{y}$. TLM employs the masked language modelling (MLM) objective to maximise the log-probability of correct labels $\hat{y}$, conditioned on the masked input $\tilde{x}$:

$$\mathcal{L} = \frac{1}{|\mathcal{X}|} \sum_{x \in \mathcal{X}} \log \Pr(\hat{y} | \tilde{x}; \theta)$$

where θ are the model parameters. We keep the standard hyper-parameters for masking, i.e. 15% of inputs are randomly selected for masking, from which 80% are replaced with the `[MASK]` token, 10% are replaced with random tokens from the vocabulary, and 10% are left intact.

2.2 Visual translation language modelling

VTLM extends the TLM by adding the visual modality alongside the translation pairs (Figure 1). Therefore, we assume the availability of sentence pair & image triplets and redefine the input as:

$$x = \left[s^{(1)}_1, \cdots, s^{(1)}_m, s^{(2)}_1, \cdots, s^{(2)}_n, v_1, \cdots, v_o\right]$$

where $\{v_1, \cdots, v_o\}$ are features extracted from a Faster R-CNN model (Ren et al., 2015) pre-trained on the Open Images dataset (Kuznetsova et al., 2018).[1] Specifically, we extract convolutional feature maps from $o = 36$ most confident regions, and average pool each of them to obtain a region-specific feature vector $v_i \in \mathbb{R}^{1536}$. Each region i is also associated with a detection label $\hat{v}_i$ provided by the extractor. Before encoding, the feature vectors and their bounding box coordinates are projected into the language embedding space.

The final model processes translation pairs and projected region features in a **single-stream** fashion (Su et al., 2020; Li et al., 2020a), and combines the TLM loss with the masked region classification (MRC) loss as follows:

$$\mathcal{L} = \frac{1}{|\mathcal{X}|} \sum_{x \in \mathcal{X}} \log \Pr(\{\hat{y}, \hat{v}\} | \tilde{x}; \theta)$$

Masking. 15% random masking ratio is applied separately to both language and visual streams, and the $\hat{v}$ above now denotes the correct region labels for the masked feature positions. Different from previous work that zeroes out masked regions (Tan and Bansal, 2019; Su et al., 2020), VTLM replaces their projected feature vectors with the `[MASK]` token embedding.[2] Similar to textual masking, 10% of the random masking amounts to using regional features randomly sampled from all images in the batch, and the remaining 10% of regions are left intact.

2.3 Pre-training

VTLM requires a three-way parallel multimodal corpus, which does not exist in large-scale. To ad-

---

[1] The "*faster rcnn inception resnet v2 atrous oid v4*" model from TensorFlow.

[2] Although this choice is mostly practical, we hypothesise that using the same signal for both language and visual masking can be beneficial for grounding.

dress this, we extend[3] the **Conceptual Captions** (CC) (Sharma et al., 2018) dataset with German translations. CC is a large-scale collection of ∼3.3M images retrieved from the Internet, with noisy *alt-text* captions in English. The translation of English captions into German was automatically performed using an existing NMT model (Ng et al., 2019) provided[4] in the Fairseq (Ott et al., 2019) toolkit. Since some of the images are no longer accessible, the final corpus' size is reduced to ∼3.1M triplets. We used byte pair encoding (BPE) (Sennrich et al., 2016) to learn a joint 50k BPE model on the CC dataset. The pre-training was conducted for 1.5M steps, using a single RTX2080-Ti GPU, and best checkpoints were selected with respect to validation set accuracy.

Settings. We use a small version of the TLM (Lample and Conneau, 2019)[5] and set the model dimension, feed-forward layer dimension, number of layers and number of attention heads to $d = 512$, $f = 2048$, $l = 6$ and $h = 8$, respectively. We randomly initialise model parameters, instead of using pre-trained LM checkpoints such as BERT or XLM. We use Adam (Kingma and Ba, 2014) with the mini-batch size and the learning rate set to 64 and 0.0001, respectively. The dropout (Srivastava et al., 2014) rate is set to 0.1 in all layers. The pre-training is done for 1.5M steps using a single RTX2080-Ti GPU, and best checkpoints are selected with respect to validation accuracy.

2.4 Baseline MT models and fine-tuning

Our experimental protocol consists of **initialising** the encoder and the decoder of Transformer-based NMT and MMT models with weights from TLM/VTLM, and **fine-tuning** them with a smaller learning rate. The architectural difference between the NMT and the MMT models is that the latter encodes 36 regional visual features as part of the source sequence, similar to the VTLM (§ 2.2). As a natural baseline, we train constrained (trained only on the MT dataset) models without transferring weights from the pre-trained TLM/VTLM models. We refer to these models as **from-scratch**. For the fine-tuning experiments, we train three runs with different seeds. For evaluation, we use the models with the lowest validation set perplexity to decode translations with beam size equal to 8.

Dataset. We use the standard MMT corpus **Multi30k** (Elliott et al., 2016) for both fine-tuning and from-scratch runs. It contains 30k image descriptions from Flickr30k (Young et al., 2014) and their human translations in German for training, along with three test sets of 1K samples each: the original and the most in-domain **2016** test set, as well as **2017** and **COCO** test sets created using images and descriptions collected from sources other than Flickr.

Settings. For fine-tuning, we use the same hyperparameters as the pre-training phase, apart from decreasing the learning rate to $1e{-}5$. For MT models that are trained from scratch, we increase the dropout rate to 0.4 and linearly warm up the learning rate from $1e{-}7$ to $1e{-}4$ during the first 4,000 iterations. *Inverse square-root* annealing is applied after 4,000 iterations.

3 Results

3.1 Machine translation

Table 1 reports METEOR and BLEU scores across three different test sets of Multi30k. First, we observe that the MMT system trained from scratch is consistently worse than its NMT counterpart. However, the gap disappears when pre-trained TLM/VTLM checkpoints are fine-tuned for MT. This suggests that pre-training may be necessary for *single-stream* multimodal encoding, where the number of regions (36) outnumbers the avg. number of source tokens (13 for Multi30k).

Second, we see that the best performances are obtained when models are first pre-trained on the *three-way* parallel Conceptual Captions (CC) dataset. To validate this further, we train a baseline NMT on the concatenation of Multi30k and CC (NMT+CC) and an MMT that uses only Multi30k for **both** pre-training and fine-tuning. The results clearly show that these systems lag behind the ones pre-trained on CC.

We also experimented with an alternative pre-training strategy where we do not mask visual regions. Interestingly, this alternative MMT in Table 1 reveals that not masking visual regions during pre-training yields slightly better results overall. This is equivalent to letting the model predict the object labels from a multimodal input where words are stochastically masked but regional features are kept intact. Overall, MMT fine-tuning on VTLM sets a new state of the art across all Multi30k test

sets.[6] We leave the exploration of visual region masking for the MRC task as future work and proceed with the alternative variant in the following experiments.

Encoder attention parameters. When fine-tuning the TLM for MT, the default XLM implementation randomly initialises the decoder's missing encoder attention parameters. In our experiments, we noticed that **copying** those parameters from the TLM self-attention layers substantially improves the results up to 2.2 BLEU.

3.2 Explicit masking

Here, we will evaluate the extent to which the visual information is taken into account (i) when TLM/VTLM predicts masked tokens, and (ii) when the fine-tuned NMT and MMT models are forced to translate source sentences with missing visual entities. For the latter, we use Flickr30k entities (Plummer et al., 2015) to mask head nouns in 2016 test set sentences, similar to Caglayan et al. (2019).

Last-word masking. In this experiment, we measure the target word prediction accuracy, when last tokens[7] of input caption pairs are systematically masked during evaluation. Table 2 suggests

---

[6] We exclude Grönroos et al. (2018) as their improvements (45.5 BLEU) were not due to multi-modality but rather to other modifications such as heavy parallel data augmentation, domain fine-tuning, and ensembling.

[7] We pre-process the sentences to ensure that they do not end with punctuation marks, which would make the task easier for masked punctuation.

	Mask	Remove
`TLM→NMT`	31.44	27.38
`TLM→MMT`	⇓ **0.43**	⇓ **0.26**
`VTLM→NMT`	31.27	27.63
`VTLM→MMT`	⇑ **1.65**	⇑ **0.65**

Table 3: Entity masking on 2016 test set: results are BLEU averages of three fine-tuned MT systems.

that the visual information is much more helpful (i.e. up to 6% accuracy improvement) when last tokens are masked in both English and German captions. However, if one caption is available, it provides enough context for cross-lingual prediction. Finally, when we shuffle (+shuf) the test set features to introduce incongruence (Elliott, 2018), we see that the VTLM model deteriorates substantially. This confirms that the accuracy improvements are not due to side-effects of experimentation noise, such as regularisation or random seed related effects.

Entity masking in MT. We devise two ways of masking entities i.e. we either replace them with the `[MASK]` token or remove them entirely so that the masking phenomena is *not known* to the model. The results in Table 3 show that MMT models can recover the missing source context to some extent, only when they are pre-trained using the proposed VTLM objective. In other words, the grounding ability can only be acquired when visual modality is present for both pre-training and fine-tuning. The gap between Mask and Remove also seems to highlight the importance of reserving a source position even it is corrupted/masked.

3.3 Visual attention in MMT

Here we take the MMT decoder's cross-attention layers and measure the attention mass they attribute to regional features in the input embeddings. Although the encoder's self-attention layers produce increasingly mixed contextual embeddings as we move towards the top layers, Brunner et al. (2020) show that the final layer states still encode corresponding input embeddings to some extent. With this assumption at hand, Figure 2 shows the average attention mass attributed to the first 36 (visual) top-layer encoding states, by each cross-attention layer in the decoder. We find these results to be in *agreement* with the quantitative metrics (Table 1), with VTLM-MMT assigning substantially more attention to these positions, compared to TLM-MMT and MMT from scratch.

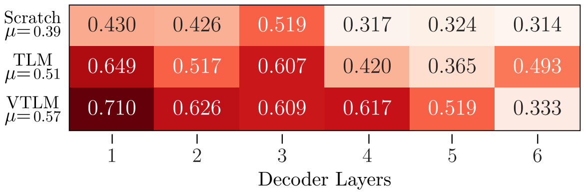

Figure 2: Cross-attention mass over the visual portion of input sequences, averaged across the 2016 test set.

4 Conclusions

We proposed a novel cross-lingual visual pre-training approach and tested its efficacy for multimodal machine translation. Our pre-training approach extends the TLM framework (Lample and Conneau, 2019) with regional features and performs masked language modelling and masked region classification on a three-way parallel corpus. We show that this leads to substantial improvements compared to multimodal machine translation with cross-lingual pre-training only or without pre-training at all. As future work, we consider exploring *more informed* masking strategies for visual regions and investigating the impact of visual masking probability for the MRC pre-training task for downstream MMT performance.

Abstract

Public datasets are often used to evaluate the efficacy and generalizability of state-of-the-art methods for many tasks in natural language processing (NLP). However, the presence of overlap between the train and test datasets can lead to inflated results, inadvertently evaluating the model's ability to memorize and interpreting it as the ability to generalize. In addition, such data sets may not provide an effective indicator of the performance of these methods in real world scenarios. We identify leakage of training data into test data on several publicly available datasets used to evaluate NLP tasks, including named entity recognition and relation extraction, and study them to assess the impact of that leakage on the model's ability to memorize versus generalize.

1 Introduction

Shared tasks that provide publicly available datasets in order to evaluate and compare the performance of different methods on the same task and data are common in NLP. Held-out test sets are typically provided, enabling assessment of the generalizability of different methods to previously unseen data. These datasets have played a key role in driving progress in NLP, by defining focus tasks and by making annotated data available to the broader community, in particular in specialized domains such as biomedicine where data can be difficult to obtain, and quality data annotations require the detailed work of domain experts. Examples of tasks where benchmark data sets exist include open domain question answering (QA) (Berant et al., 2013; Joshi et al., 2017) and biomedical named entity recognition (Smith et al., 2008) .

In the context of machine learning models, effectiveness is typically determined by the model's ability to both memorize and generalize (Chatterjee, 2018). A model that has huge capacity to memorize will often work well in real world applications, particularly where large amounts of training data are available (Daelemans et al., 2005). The ability of a model to generalize relates to how well the model performs when it is applied on data that may be different from the data used to train the model, in terms of e.g. the distribution of vocabulary or other relevant vocabulary. The ability to memorize, taken to the extreme, can be considered equivalent to an exact match lookup table (Chatterjee, 2018) and the ability to generalize captures how well it can deal with degrees of variations from the lookup table. An effective combination of memorization and generalization can be achieved where a model selectively memorizes only those aspects or features that matter in solving a target objective given an input, allowing it to generalize better and to be less susceptible to noise.

When there is considerable overlap in the training and test data for a task, models that memorize more effectively than they generalize may benefit from the structure of the evaluation data, with their performance inflated relative to models that are more robust in generalization. However, such models may make poor quality predictions outside of the shared task setting. The *external validity* of these evaluations can therefore be questioned (Ferro et al., 2018).

In this paper, we assess the overlap between the train and test data in publicly available datasets for Named Entity Recognition (NER), Relation Extraction (REL) and Text Classification (CLS) tasks, including SST2 (Socher et al., 2013), BioCreative (Smith et al., 2008; Arighi et al., 2011) and AIMed (Bunescu et al., 2005) datasets, and examine the significant impact of not taking into account this overlap on performance evaluation.

We argue that robustness in generalization to unseen data is a key consideration of the performance of a model, and propose a framework to examine

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1325–1335
April 19 - 23, 2021.

inadvertent leakage of data between data set splits, in order to enable more controlled assessment of the memorization vs. generalization characteristics of different methods.

2 Related work

The issue of memorization vs. generalization has been previously discussed in the context of question answering datasets, where, given only a question, a system must output the best answer it can find in available texts.

Lewis et al. (2020) identify 3 distinct issues for open domain QA evaluation: a) *question memorization* – recall the answer to a question that the model has seen at training time; b) *answer memorization* – answer novel questions at test time, where the model has seen the answer during training; and c) *generalization* – question and answer not seen during training time. They find that 58-71% of test answers occur in the training data in 3 examined data sets, concluding that the majority of the test data does not assess answer generalization. They also find that 28-34% have paraphrased questions in training data, and a majority of questions are duplicates differing only by a few words.

Similarly, Min (2020) identified repeating forms in QA test sets as a problem. The work proposed a novel template-based approach to splitting questions into paraphrase groups referred to as "Templates" and then controlling train/test data splits to ensure that all questions conforming to a given template appear in one segment of the data only. This was tested on the EMR Clinical Question Answering dataset emrQA (Pampari et al., 2018) and the Overnight dataset (Wang et al., 2015); it was demonstrated that models perform significantly worse on test sets where strict division is enforced. This paraphrase-based splitting methodology was also employed in their recent work on emrQA (Rawat et al., 2020).

3 Approach

A common practice to create a train and test set is to shuffle data instances in a dataset and generate random splits, without taking into account broader context. However, this can inadvertently lead to data leakage from the train set to test set due to the overlaps between similar train and test instances.

The type of overlap between train and test dataset depends on the type of the NLP task. Generally speaking, the leakage can occur either in the input texts or the annotated outputs. We define the types of overlaps which may occur in several NLP tasks as follows.

Algorithm 1 Compute overlap

```
procedure COMPARE($testset, trainset$)
    $totalscore \leftarrow 0$
    $n \leftarrow |testset|$
    for $test_i$ in testset do
        $s \leftarrow$ BESTMATCH($test_i, trainset$)
        $totalscore \leftarrow totalscore + s$
    end for
    return $totalscore/n$                    ▷ Average score
end procedure
procedure BESTMATCH($test_i, trainset$)
    $bestscore \leftarrow 0$
    for $train_j$ in trainset do
        $s \leftarrow$ SIMILARITY($test_i, train_j$)
        if $score > bestscore$ then
            $bestscore \leftarrow s$
        end if
    end for
    return $bestscore$
end procedure
```

- In text classification (CLS) tasks such as sentiment analysis, overall (document-level) similarity in input texts can result in train/test leakage.
- In named entity recognition (NER) tasks, leakage from train to test data may occur when
  a) input sentences or passages are similar
  b) target entities are similar
- In relation extraction (REL) tasks, leakage may occur when
  a) input sentences or passages are similar
  b) participating entities are similar

We propose a framework for quantifying train-test overlaps, and conduct experiments to show the impact of train-test overlap on model performances. Next, we discuss the proposed framework in Sec. 4.2 and the experimental settings in Sec. 4.3. We present our findings including the train-test overlaps in several benchmark datasets in Sec. 5.1 and the impact of data leakage in Sec. 5.2.

4 Method

4.1 Datasets

We examine overlap in the following datasets:

- **AIMed** - AIMed dataset (Bunescu et al., 2005) for protein relation extraction (REL)
- **BC2GM** - BioCreative II gene mention dataset (Smith et al., 2008) for NER task
- **ChEMU** - Chemical Reactions from Patents (He et al., 2020) for recognising names of chemicals, an NER task

Task	Dataset	Score	Split	Example
REL	AIMed (R)	100.0	Train	Thus, during PROTEIN1 -mediated suppression of cell proliferation, PROTEIN and PROTEIN2 may be important for coordinating cell-cycle progression, DNA replication and repair of damaged DNA.
			Test	Thus, during PROTEIN -mediated suppression of cell proliferation, PROTEIN1 and PROTEIN2 may be important for coordinating cell-cycle progression, DNA replication and repair of damaged DNA.
NER	BC2GM	100.0	Train	E2F family members
			Test	E2F family members (1-5)
CLS	SST2	100.0	Train	good movie .
			Test	it 's still not a good movie.
CLS	SST2	21.8	Train	herzog is obviously looking for a moral to his fable , but the notion that a strong , unified showing among germany and eastern european jews might have changed 20th-century history is undermined by ahola 's inadequate performance .
			Test	of the unsung heroes of 20th century

Table 1: Examples of train-test matches and the corresponding unigram similarity score.

- **BC3ACT** - Biocreative III protein interaction classification (CLS) (Arighi et al., 2011)
- **SST2** - Stanford Sentiment Analysis Treebank (Socher et al., 2013) used to classify sentiments (CLS) in Glue (Wang et al., 2018)

The AIMed dataset does not explicitly provide a test set and 10-fold cross validation is used for evaluation in previous works (Hsieh et al., 2017; Zhang et al., 2019). In this paper, we use two types of splits of AIMed to evaluate the impact of data leakage: AIMed (R) which **R**andomly splits the dataset into 10 folds; and AIMed (U) which splits the dataset into 10 folds such that the documents within each resultant split are **U**nique (according to the *document ID*) to other splits across each split. The *document ID* refers to the source document of a data instance, and data instances from the same source document have the same document ID, see example in Appendix A

4.2 Similarity measurement

The pseudo code for measuring similarity is shown in Algorithm 1. Given a test instance $test_i$, we compute its similarity with the training set using the training instance that is most similar with $test_i$. We then use the average similarity over all the test instances as an indicator to measure the extent of train/test overlap. The function $similarity(\cdot)$ can be any function for text similarity. In this paper, we use a simple bag-of-words approach to compute text similarity. We represent each train/test instance with a count vector of unigrams/bigrams/trigrams, ignoring stopwords, and compute the similarity using the cosine similarity.

4.3 Evaluate model performance

We assess the impact of data leakage on a machine learning model's performance. We split the test sets of BC2GM, ChEMU, BC2ACT and SST2 into four intervals considering four similarity threshold ranges (in terms of unigrams): [0-0.25),[0.25-0.50), [0.50-0.75), and [0.75-1.0]. For example, the test instances in the first interval are most different from the training set with a similarity less than 0.25. This method allows full control of the similarity of instances within each interval, but results in a different number of instances in each interval. Thus, we consider another scenario where we split the test set into 4 quartiles based on similarity ranking, so that the number of samples remain the same in each quartile but the threshold varies as a result.

We finetune a BERT (base and cased) model (Devlin et al., 2019) for each dataset using their own training set and compare the performance of the finetuned BERT model on the four different test intervals and test quartiles.

We compare the performances of AIMed (R) with AIMed (U) using 3 different models—Zhang et al. (2019) convolutional residual network, Hsieh et al. (2017) Bi-LSTM, and BioBERT (Lee et al., 2019). Following previous works, we preprocess the dataset and replace all non-participating proteins with neutral name *PROTEIN*, the participating entity pairs with *PROTEIN1* and *PROTEIN2*, so the model only ever sees the pseudo protein names.

5 Results

5.1 Similarity in datasets

Examples of similar train and test instances are shown in Table 1. The overall results of train-test similarities of all datasets are shown in Table 2.

In the BC2GM dataset, we find that there is 70% overlap between gene names in the train and test set. On further analysis, we find that 2,308 out of 6,331 genes in the test set have exact matches in the train set. In the AIMed (R) dataset, we can see that there is over 73% overlap, even measured in

Dataset	Task	uni	bi	tri
AIMED (R)	REL	**96.95**	**82.29**	**73.15**
AIMED (U)	REL	**67.14**	36.07	20.77
BC2GM ann	NER	**70.77**	19.55	5.41
BC2GM text	NER	33.19	13.12	4.20
BC3ACT	CLS	26.76	6.91	1.81
ChEMU ann	NER	**84.29**	30.67	6.83
ChEMU text	NER	**68.45**	42.39	31.63
SST2	CLS	46.06	17.38	1.39

Table 2: Train-test similarity using unigrams (uni), bigrams (bi), trigrams (tri). BC2GM and ChEMU are in BRAT standoff format and their similarities are shown for their text files (“text”) and annotation files (“ann”). Similarities beyond 60.0 are highlighed in **bold**.

Split type	Method	P	R	F1
O	BiLSTM	78.8	75.2	76.9

SST	2I	66.8	91.6	96.0	93.8	93.4
SST	3I	28.7	87.1	98.7	92.5	92.7
SST	4I	3.5	96.9	96.9	**96.9**	**96.8**

Table 4: Performances on various similarity thresholds and the corresponding percentage of test instances within the intervals. Datasets (D): BC2→BC2GM, ChE→ChEMU, BC3→BC3ACT, SST→SST2. The similarity threshold range (SR) $[0, 0.25)$ = 1I, $[0.25, 0.5)$ = 2I, $[0.5, 0.75)$ = 3I, $[0.75, 1]$ = 4I, $[0, 1]$ = F. Accuracy (A) is the official metric for the SST2 dataset according to GLUE benchmark, all others use F1-score (F1) as primary metric.

the trigrams, between train and test sets.

5.2 Model performance and similarity

We observe drops in F-scores of more than 10 points between AIMed (R) and AIMed (U) across all three models as shown in Table 3. This is in line with the similarity measurement in Table 2: the train-test similarity drops significantly from AIMed (R) to AIMed (U) since in AIMed (U) we only allow unique document IDs in different folds.

On the ChEMU NER dataset we observe nearly 10-point drop in F-score (96.7→85.6) from 4I to 2I as shown in Table 4.

On the BC2GM dataset, we also find that the model performance degrades from 82.4% to 74.5% in 2I compared to that in 1I. Surprisingly, F-score for 4I is substantially lower than that of 3I (78.5→87.1), despite 41 out of the total 47 instances in 4I having 100% similarity with the train set (full detailed samples shown in Appendix Table 10). A further investigation on this shows that **(a)** the interval 4I only has 0.9% (47/5000) of test instances; **(b)** a significant drop in recall (90.6→77.5) from 3I to 4I is caused by six instances whose input texts have exact matches in the train set (full samples shown in Appendix Table 11). This implies that the model doesn’t perform well even on the training data for these samples. Since BC2GM has over 70% overlap in the target gene mentions (Table 2), we also analysed the recall on the annotations that overlap between train and test. We find that the recall increases (84.5→87.8), see Appendix Table 8, compared to recall (81.1→90.6) as a result of input text similarity. Since BERT uses a word sequence-based prediction approach, the relatively high similarity in target annotations does not seem to make much difference compared to similarity in input text. However, if we used a dictionary-based approach, similarity in annotations could result in much higher recall compared to similarity in input text.

The BC3ACT dataset also exhibits the same trend where the F1-score improves (56.4→63.0) as the similarity increases. However, the accuracy

D	Q	Min	Max	P	R	F1	A
BC2	1	0.0	26.3	69.8	82.0	**75.4**	
BC2	2	26.3	31.6	74.5	85.9	79.8	
BC2	3	31.6	38.3	78.3	86.4	82.1	
BC2	4	38.3	100.0	83.0	88.9	**85.9**	
ChE	1	37.9	56.7	90.8	91.8	**91.3**	
ChE	2	56.8	68.2	93.3	94.4	93.8	
ChE	3	68.2	78.5	95.1	96.1	95.6	
ChE	4	78.6	99.8	97.1	97.4	**97.3**	
BC3	1	6.3	20.1	44.5	81.4	**57.6**	88.8
BC3	2	20.1	25.7	42.3	82.5	55.9	82.7
BC3	3	25.7	31.9	46.5	85.3	**60.2**	79.5
BC3	4	31.9	75.0	46.1	85.2	59.8	77.3
SST	1	0.0	36.5	90.8	95.2	**92.9**	**92.8**
SST	2	36.5	43.6	91.3	96.2	93.7	93.2
SST	3	43.6	53.5	91.2	97.3	**94.2**	**94.1**
SST	4	53.5	100.0	88.0	98.1	92.8	92.9

Table 5: Performances on four different test quartiles, where the number of samples in each quartile (Q) is kept same. The minimum (Min) and the maximum (Max) similarity within each quartile are also reported.

drops from 85.8→77.5. This is could be because while the train set has 50% positive classes, the test set has just 17% with 3 points higher mean similarity in positive samples (details in Appendix B).

On SST2, an increase in accuracy (85.0 → 96.8) from 1I to 4I is observed apart from a marginal 0.7-point drop (93.4 → 92.7) from 2I to 3I.

We also split the test sets into four equal-sized quartiles based on the similarity ranking of test instances, shown in Table 5. We observe similar phenomena as in the previous set of experiments for the dataset BC2GM, ChEMU, and BC3ACT. The only exception is for SST2 where the F-score has a relatively small but consistent increase from Q1 to Q3 (92.9→94.1) but drops to 92.8 in Q4.

6 Discussion

6.1 Quantifying similarity

The bag-of-words based approach to compute cosine similarity has been able to detect simple forms of overlap effectively as shown in Table 2. A trend that can be seen is that overlap is more common in tasks that are manual labour intensive, such as named entity recognition and relation extraction compared to text classification.

However, this approach may detect similarity even when the meanings are different, especially in the case of classification tasks as shown for SST2 in Table 1. Semantic Text Similarity (STS) measurement is a challenging task in its own right, with a large body of literature and a number of shared tasks organized to address it (Cer et al., 2017; Wang et al., 2020; Karimi et al., 2015). More sophisticated methods for similarity measurement developed in these contexts could be incorporated into the framework for measuring similarity of data set splits; for simple leakage detection it is arguably adequate. However, sophisticated methods can also potentially lead to a chicken and egg problem, if we use a machine learning model to compute semantic similarity.

The question of what level of similarity is acceptable is highly data and task-dependent. If the training data has good volume and variety, the training-test similarity will naturally be higher and so will the acceptable similarity.

6.2 Memorization vs. Generalization

We find that the F-scores tend to be higher when the test set input text is similar to the training set as shown in Table 3 and 4. While this might be apparent, quantifying similarity in the test set helps understand that high scores in the test set could be a result of similarity to the train set, and therefore measuring memorization and not a model's ability to generalize. If a model is trained on sufficient volume and variety of data then it may now matter if it memorizes or generalizes in a real world context, and a model's ability to memorize is not necessarily a disadvantage. However, in the setting of a shared task, we often do not have access to sufficiently large training data sets and hence it is important to consider the test/train similarity when evaluating the models. This implies that in real world scenarios the model may perform poorly when it encounters data not seen during training.

7 Conclusion

We conclude that quantifying train/test overlap is crucial to assessing real world applicability of machine learning in NLP tasks, given our reliance on annotated data for training and testing in the NLP community. A single metric over a held-out test set is not sufficient to infer generalizablity of a model. Stratification of test sets by similarity enables more robust assessment of memorization vs. generalization capabilities of models. Further development of approaches to structured consideration of model performance under different assumptions will improve our understanding of these tradeoffs.

A AIMed document examples

The following example shows how multiple data instances are extracted from a single document in AIMed dataset. The document with ID “`AIMed.d0`” has several instances including “`AIMed.d0.s0`” and “`AIMed.d0.s1`”. These instances thus have the same document id.

```
<corpus source="AIMed">
  <document id="AIMed.d0">
    <sentence id="AIMed.d0.s0" text="Th1/Th2 type cytokines in hepatitis B patients treated with interferon-alpha." seqId="s0"
        >
      <entity id="AIMed.d0.s0.e0" charOffset="60-75" type="protein" text="interferon-alpha" seqId="e0"/>
    </sentence>
    <sentence id="AIMed.d0.s1" text="OBJECTIVE: To investigate the relationship between the expression of Th1/Th2 type
         cytokines and the effect of interferon-alpha therapy." seqId="s1">
      <entity id="AIMed.d0.s1.e0" charOffset="110-125" type="protein" text="interferon-alpha" seqId="e1"/>
    </sentence>
  </document>
  <document id="AIMed.d1">
    <sentence id="AIMed.d1.s11" text="Involvement of BMP-2 signaling in a cartilage cap in osteochondroma." seqId="s11">
      <entity id="AIMed.d1.s11.e0" charOffset="15-19" type="protein" text="BMP-2" seqId="e15"/>
    </sentence>
  </document>
</corpus>
```

B Classwise similarity for BC3AST

The test set has 5090 negative samples compared to 910 positive samples, with 2.96 points higher mean similarity in positive samples.

Test label		Unigram	Bigram	Trigram
0	count	5090.00	5090.00	5090.00
	mean	26.31	6.70	1.73
	std	9.25	5.35	1.72
	min	6.28	0.00	0.00
	25%	19.70	3.29	0.79
	50%	25.16	5.07	1.39
	75%	31.53	8.29	2.27
	max	75.01	41.75	18.71
1	count	910.00	910.00	910.00
	mean	29.27	8.09	2.26
	std	9.36	6.00	1.73

Table 6: Class-wise similarity for BC3ACT dataset

C BERT and similarity thresholds

Table 7 shows the impact on precision, recall and F-score using different similarity thresholds on the BC2GM test set, which has approximately 6,300 annotations.

We also compare the recall when the target annotations are similar as shown in Table 8. We only compare unigrams, as the number of tokens in a gene name tends to be small (on average less than 3).

Table 9 shows BERT’s performance using bi-grams and trigrams on SST2 and BC3AST datasets.

Dataset	**N**	**SR**	%	**P**	**R**	**F**
BC2GM	-	-	100	77.5	86.4	81.7
BC2GM	1	1I	19.8	68.8	81.1	74.5
BC2GM	1	2I	74.1	78.2	86.9	82.3
BC2GM	1	3I	5.1	83.8	90.6	87.1
BC2GM	1	4I	1.0	79.5	77.5	78.5
BC2GM	2	1I	91.7	76.9	86.3	81.4
BC2GM	2	2I	7.5	82.5	88.1	85.2
BC2GM	2	3I	0.3	1.0	1.0	1.0
BC2GM	2	4I	0.5	78.9	76.9	77.9
BC2GM	3	1I	98.5	77.4	86.4	81.7
BC2GM	3	2I	0.9	85.2	88.5	86.8
BC2GM	3	3I	0.1	50.0	100.0	66.7
BC2GM	3	4I	0.5	80.6	76.3	78.4

Table 7: NER performances of BERT on various similarity threshold range (SR) and the corresponding percentage of instances when the similarity is computed using N-grams (N = 1, 2 and 3) in the input text. The range $[0, 0.25) =$ 1I, $[0.25, 0.5) =$ 2I, $[0.5, 0.75) =$ 3I, $[0.75, 1] =$ 4I, $[0, 1] =$ F.

Abstract

Online misogyny is a pernicious social problem that risks making online platforms toxic and unwelcoming to women. We present a new hierarchical taxonomy for online misogyny, as well as an expert labelled dataset to enable automatic classification of misogynistic content. The dataset consists of 6,567 labels for Reddit posts and comments. As previous research has found untrained crowdsourced annotators struggle with identifying misogyny, we hired and trained annotators and provided them with robust annotation guidelines. We report baseline classification performance on the binary classification task, achieving accuracy of 0.93 and F1 of 0.43. The codebook and datasets are made freely available for future researchers.

1 Introduction

Misogyny is a problem in many online spaces, making them less welcoming, safe, and accessible for women. Women have been shown to be twice as likely as men to experience gender-based online harassment (Duggan, 2017). This misogyny can inflict serious psychological harm on women and produce a 'silencing effect', whereby women self-censor or withdraw from online spaces entirely, thus limiting their freedom of expression (Mantilla, 2013; International, 2017). Tackling such content is increasingly a priority for social media platforms and civil society organisations.

However, detecting online misogyny remains a difficult task (Hewitt et al., 2016; Nozza et al., 2019). One problem is the lack of high-quality datasets to train machine learning models, which would enable the creation of efficient and scalable automated detection systems (Anzovino et al., 2018). Previous research has primarily used Twitter data and there is a pressing need for other platforms to be researched Lynn et al. (2019a). Notably, despite social scientific studies that show online misogyny is pervasive on some Reddit communities, to date a training dataset for misogyny has not been created with Reddit data. In this paper we seek to address the limitations of previous research by presenting a dataset of Reddit content with expert labels for misogyny that can be used to develop more accurate and nuanced classification models.

Our contributions are four-fold. First, we develop a detailed hierarchical taxonomy based on existing literature on online misogyny. Second, we create and share a detailed codebook used to train annotators to identify different types of misogyny. Third, we present a dataset of 6,383 entries from Reddit. Fourth, we create baseline classification models based on these datasets. All of the research artefacts are made freely available via a public repository for future researchers.[1]

The dataset itself has several innovations which differentiate it from previous training datasets for misogyny. First, we use chronological and structured conversation threads, which mean annotators take into account the previous context of each entry before labelling. Second, we distinguish between conceptually distinct types of misogynistic abuse, including gendered personal attacks, use of misogynistic pejoratives, and derogatory and threatening language. Third, we highlight the specific section of text, also known as a 'span', on which each label is based. This helps differentiate between multiple labels on one piece of text. Fourth, we use trained annotators, rather than crowd-sourced workers. We also use facilitated meetings to decide the final labels rather than just a majority decision. Both of these factors lead to a high-quality dataset. Additionally, we provide a second dataset with the original labels made by annotators before the final labels were decided.

2 Background

Most previous classification work on online misogyny has used data from Twitter (Waseem and Hovy, 2016; Anzovino et al., 2018; Jha and Mamidi, 2017). However, social scientific and ethnographic research shows that Reddit is increasingly home to numerous misogynistic communities. Reddit is a social news website organised in to topic-based communities. Each subreddit acts as a message board where users make posts and hold discussions in comment threads on those posts. In recent years it has become a hub for anti-feminist activism online (Massanari, 2017; Ging and Siapera, 2018). It is also home to many misogynistic communities, particularly those associated with the 'manosphere', a loosely connected set of communities which perpetuate traditional forms of misogyny and develop new types of misogynistic discourse which in turn spread to other online spaces (Ging, 2017; Zuckerberg, 2018; Ging et al., 2019; Farrell et al., 2019; Ribeiro et al., 2020). Recent research suggests that the rate of misogynistic content in the Reddit manosphere is growing and such content is increasingly more violent (Farrell et al., 2019).

Waseem and Hovy (2016) provided a widely-used dataset for abusive language classification. They used expert annotators to identify sexist and racist tweets based on a set of criteria drawn from critical race theory. The tweets were initially labelled by the authors then reviewed by a third annotator. The resulting dataset consists of 17k tweets, of which 20% are labelled as sexist. However 85% of the disagreements between annotators were over sexism labels, which shows that even experienced coders of abusive language can have difficultly identifying gendered abuse.

Jha and Mamidi (2017) extended on the Waseem and Hovy (2016) dataset to distinguish between between 'benevolent' and 'hostile' sexism (Glick and Fiske, 1997). They classed all sexist labels in the previous dataset as 'Hostile' and all non-sexist labels as 'Other'. They then augmented the dataset by collecting tweets using keyword sampling on benevolently sexist phrases (e.g. 'smart for a girl') and extracted those manually identified as 'benevolent sexism'. In the combined dataset of 10,095 unique tweets 712 were labelled as 'benevolent', 2,254 as 'hostile', and 7,129 as 'not sexist'. They thus found that in the data hostile sexism was more than three times as common as the benevolent form. Their work highlights the need for greater attention to be placed on forms of 'subtle abuse', particularly for online misogyny (Jurgens et al., 2019).

Anzovino et al. (2018) developed a taxonomy with five categories of misogyny, drawn from the work of Poland (2016): Stereotype & Objectification, Dominance, Derailing, Sexual Harassment & Threats of Violence, Discredit. They used a combination of expert and crowdsourced annotation to apply the taxonomy and present a dataset of 4,454 tweets with balanced levels of misogynistic and non-misogynistic content. A shared task confirmed that the dataset could be used to distinguish misogynistic and non-misogynistic content with high accuracy, but performance was lower in differentiating between types of misogyny (Fersini et al., 2018).

Lynn et al. (2019b) provide a dataset of 2k Urban Dictionary definitions of which half are labelled as misogynistic. In Lynn et al. (2019a) they show that deep learning techniques had greater accuracy in detecting misogyny than conventional machine learning techniques.

3 Data collection

We collected conversation threads from Reddit. Given that a very small amount of content on social media is hateful, a key difficulty when creating datasets for annotation is collecting enough instances of the 'positive' class to be useful for machine learning (Schmidt and Wiegand, 2017; Fortuna and Nunes, 2018). However, sampling strategies can introduce biases in the composition and focus of the datasets if overly simplistic methods are used, such as searching for explicitly misogynistic terms (Wiegand et al., 2019).

To ensure that our dataset contains enough misogynistic abuse we began with targeted sampling, taking content from 12 subreddits that were identified as misogynistic in previous research. This includes subreddits such as `r/MensRights`, `r/seduction`, and `r/TheRedPill`. The sources used to identify these subreddits are available in Table 9 in the Appendix. We then identified 22 additional subreddits which had been recommended by the moderators/owners of the original 12 subreddits in the 'sidebar'. Some of these are not misogynistic but discuss women (e.g. `r/AskFeminists`) and/or are otherwise related to misogyny. For example, `r/exredpill` is a support group for former members of the misogynistic subreddit `r/TheRedPill`. Table 9 in the Appendix lists the 34 targeted subreddits and the number of entries and threads for each in the dataset. Over 11 weeks, for each subreddit, we collected the entire threads of the 20 most popular posts that week.

Using subreddits to target the sampling rather than keywords should ensure that more linguistic variety is captured, minimising the amount of bias as keywords such as 'slut' are associated with more explicit and less subtle forms of abuse. Nonetheless, only sampling from suspected misogynistic communities could still lead to classifiers which only identify the forms of misogyny found in those targeted contexts (Davidson et al., 2017; Wiegand et al., 2019; Sap et al., 2019). To account for this potential bias, and to enable greater generalisabilty, we sampled content from 71 randomly selected subreddits. They accounted for 18% of threads and 16% of entries in our dataset. For each randomly selected subreddit, we collected the thread of the most popular post. All threads were in English with the exception of one thread from the subreddit `r/Romania`.

Posts and comments were collected from February to May 2020 using the python package PRAW, a wrapper for the Reddit API (Boe, 2020). Posts on Reddit have a text title and a body which can be text, an image, or a link. For posts with a text body we combined this with the post title to create a single unit of text. For the 29% of posts where the body was an image we also collected the image.

4 Taxonomy

We developed a hierarchical taxonomy with three levels. First, we make a binary distinction between Misogynistic content and Non-misogynistic content, which are mutually exclusive. Second, we elaborated subtypes of Misogynistic and Non-misogynistic content. For Misogynistic content we defined four categories: (i) *Misogynistic Pejoratives*, (ii) descriptions of *Misogynistic Treatment*, (iii) acts of *Misogynistic Derogation* and (iv) *Gendered Personal attacks* against women. For Non-misogynistic content we defined three categories: (i) *Counter speech* against misogyny, (ii) *Non-misogynistic personal attacks* and (iii) *None of the categories*. Third, we included additional flags for some of the second level categories. Within both Misogynistic and Non-misogynistic content, the second level categories are not mutually exclusive, thereby allowing for multiple labels per entry. For instance, a Misogynistic entry could be assigned labels for both a *Pejorative* and *Treatment*.

This taxonomy draws on the typologies of abuse presented by Waseem et al. (2017) and Vidgen et al. (2019) as well as theoretical work in online misogyny research (Filipovic, 2007; Mantilla, 2013; Jane, 2016; Ging, 2017; Anzovino et al., 2018; Ging and Siapera, 2019; Farrell et al., 2019). It was developed by reviewing existing literature on online misogyny and then iterating over small samples of the dataset. This deductive-inductive process allowed us to ensure that conceptually distinct varieties of abuse are separated and that different types of misogyny can be unpicked. This is important given that they can have very different impacts on victims, different causes, and reflect different outlooks and interests on the part of the speaker.

4.1 Misogynistic content

Misogynistic content directs abuse at women or a closely related gendered group (e.g. feminists). This content can fall in to four non-mutually exclusive categories.

4.1.1 Misogynistic pejoratives

Misogynistic pejoratives are terms which are used to disparage women. It includes terms which are explicitly insulting and derogatory, such as 'slut' or 'whore', as well as terms which implicitly express negativity or animosity against women, such as 'Stacy' or 'Becky'. For example, 'Stacy' is a term used in the incel community to describe women considered attractive and unattainable, in opposition to a more average and attainable 'Becky' (Jennings, 2018).

4.1.2 Misogynistic treatment

Misogynistic treatment is content that discusses, advocates, incites or plans negative or harmful treatment of women. It includes expressing intent to take action against women, as well as expressing desires about how they should be treated. Misogynistic treatment contains third-level subcategories: *Threatening language* and *Disrespectful actions*.

1. *Threatening language*: Content which expresses an intent/desire to inflict/cause women to suffer harm, or expresses support for, encourages, advocates or incites such harm. It is an 'explicit' form of abuse. It falls in to three thematic groups:

   (a) *Physical violence*: non-sexual physical violence such as killing, maiming, beating, etc. e.g. 'Feminists deserve to be shot'.
   (b) *Sexual violence*: explicit sexual violence such as rape, penetration, molestation, etc. e.g. 'Someone should rape her – that would put her in her place'.
   (c) *Privacy*: an invasion of privacy such as the disclosure of personal information (i.e. doxing) or threats to visit them. e.g. 'I know where you live, bitch'.

2. *Disrespectful actions*: Content which treats/portrays women as either lacking or not deserving independence/autonomy. This includes more subtly abusive statements about how women should be treated and what they should be allowed to do. It is an 'implicit' form of abuse. It falls in to four thematic groups:

   (a) *Controlling*: suggesting or stating that women should be controlled in some way, especially by a man or men. E.g. 'I would never let my girlfriend do that'.
   (b) *Manipulation*: using or advocating the use of tactics such as lying and gaslighting to manipulate what women do or think. E.g. 'Told my last girlfriend she was hallucinating when she saw the texts from my side piece'.
   (c) *Seduction and conquest*: discussing woman solely as sexual conquests or describing previous incidences of when they have been treated as such. E.g. 'Got her home and used her so hard'.
   (d) *Other*: content that is not covered by the other subcategories.

4.1.3 Misogynistic derogation

Misogynistic derogation is content that demeans or belittles women. This content can be explicitly or implicitly abusive. It is separated into third-level subcategories:

1. *Intellectual inferiority*: making negative judgements of women's intellectual abilities, such as a lack of critical thinking or emotional control. This includes content which infantilizes women. An implicit example would be 'My gf cries at the stupidest shit – lol!' for suggesting irrational emotional responses. An explicit example is 'Typical stupid bitch – talking about things she doesn't understand'.

2. *Moral inferiority*: making negative judgements of women's moral worth, such as suggesting they are deficient or lesser to men in some way. This includes subjects such as superficiality (e.g. only liking men who are rich or attractive), promiscuity, and untrustworthiness. An implicit example is 'Girls love your money more than you'. An explicit example is 'My ex-girlfriend was a whore, she slept with every guy she saw'.

3. *Sexual and/or physical limitations*: making negative judgements of women's physical and/or sexual ability. This includes perceived unattractiveness (i.e. a lack of sexual desirability), ugliness (i.e. a lack of beauty), frigidness (i.e. a lack of sexual willingness), as well as belittling statements about feminine physical weakness. An implicit example is 'I gave it my A-game but she would not give in, so uptight!' An explicit example is 'Yikes, Dianne Abbott looks like a monkey!'

4. *Other*: content that is not covered by the other subcategories but is derogatory towards women.

4.1.4 Gendered personal attacks

Gender personal attacks are highly gendered attacks and insults. This category is used only when the nature of the abuse is misogynistic, e.g. 'Hilary Clinton is such a stupid bitch, someone should give her a good fucking and put her in her place'.

The category has a level three flag for the *gender of the recipient* of the abuse. We include this flag as research has shown that men can also be targeted by misogynistic attacks (Jane, 2014). The gender can either be a woman (e.g. 'That chick is dumb'), a man (e.g. 'This dude is a piece of shit') or unknown (e.g. 'You're are an idiot, fuck off'). If the content was replying to an entry which reveals the recipient's gender we can infer it from this context. For example if 'You're an idiot, fuck off' was a response to 'I'm a man and a feminist there's nothing contradictory about that' we know the abuse is targeted at a man.

4.2 Non-misogynistic content

Non-misogynistic content can fall in to three non-mutually exclusive categories, all of which are relevant for misogyny research.

4.2.1 Non-misogynistic personal attacks

Interpersonal abuse which is *not* misogynistic. We include this category to allow for a comparison of the nature of abuse directed at women and men (Duggan, 2017). It includes content which personally attacks a woman but is not misogynistic in nature, e.g. 'Hilary Clinton has no clue what she's talking about, idiot!'. It uses the same level three flag for the *gender of the recipient* as Misogynistic personal attack. This allows us to compare the rates of personal attacks against women and men.

Note that although it is possible for an entry to contain both Misogyny and a Non-misogynistic personal attack, this was very rare. In such cases, we chose to not annotate the Non-misogynistic personal attack in order to keep the first level as a binary distinction.

4.2.2 Counter speech

Counter speech is content which challenges, refutes, and puts into question previous misogynistic abuse in a thread. It could directly criticise previous abuse (e.g. 'What you said is unacceptable'), specifically accuse it of prejudice (e.g. 'That's incredibly sexist'), or offer a different perspective which challenges the misogyny (e.g 'That's not how women act, you're so wrong').

4.2.3 None of the categories

Content which does not contain misogynistic abuse, pejoratives, or related counter speech as defined in the previous categories. This content is often not related to abuse or to women in general. That said, it can include other forms of abusive language which are not misogynistic.

5 Annotation Methodology

A key difficulty in the formation of abusive language training datasets is producing high quality annotations. Several factors affect this. Deciding between similar categories, such as 'hate speech' versus 'offensive language' can be difficult (Waseem et al., 2017). Determining the right category often requires close scrutiny and sustained critical thinking from annotators. Annotators may face information overload if asked to work with too many categories, both in terms of breadth (e.g. annotating for different types of abuse) and depth (e.g. working with numerous subcategories). Further, annotators may have different values and experiences and so make different assessments of the content they observe, especially when context plays a large role. Annotators will also have unconscious social biases which may mean they interpret coding instructions differently to each other, and to how they were intended by the research authors. For instance, Davidson et al. (2017) found that crowdsourced annotators were more likely to label sexist content as merely 'offensive' while racist and homophobic content was considered 'hate speech'.

To mitigate such annotator biases, we used expert annotators specifically trained in identifying misogynistic content, as well as a group-based facilitation process to decide final labels. Due to time and resource constraints, the final dataset is smaller than if we had used crowdsourced workers but captures more nuanced and detailed cases of misogyny. Six annotators worked on the dataset. Annotators were trained in the use of a codebook detailing the taxonomy and annotation guidelines. The codebook was updated over time based on feedback from the annotators. Demographic information on the annotators is available in Appendix A.2

5.1 Annotation process and disagreements

Annotators independently marked up each entry for the three levels presented in Section 4. For all level two categories other than 'None', they also highlighted the specific part of the entry which was relevant to the labelled category (the 'span'). This is particularly important information for long posts which can contain multiple forms of abuse.

Each entry was annotated by either two (43%) or three (57%) annotators. If all annotators made the exact same annotation (including all three levels and highlighting) this was accepted as the final annotation. All other entries were flagged as disagreements. Annotators reviewed the disagreements in weekly meetings which were overseen by an expert facilitator, a PhD researcher who had developed the annotation taxonomy and was familiar with the literature on online misogyny and hate speech classification. The role of the facilitator was to promote discussion between annotators and ensure the final labels reflected the taxonomy. Each disagreement was discussed until the annotators reached a consensus on the final agreed label or labels.

5.2 Inter-annotator reliability

For the level one binary task the Fleiss' Kappa is 0.484 and the Krippendorf's alpha is 0.487. By conventional NLP standards these results appear low. However they are equivalent to, or above, those of existing abusive content datasets. Sanguinetti et al. (2018) report category-wise Kappas from k=0.37 for *offence* to k=0.54 for *hate*. Gomez et al. (2020) have a Kappa of 0.15 in the "MMH150" dataset of hateful memes. Fortuna and Nunes (2018) report a Kappa of 0.17 for a text-only task. Krippendorf's alpha is similar to the 0.45 reported by Wulczyn et al. (2017).

We also calculated level two category-wise Fleiss' Kappas for each of the 17 sets of annotator groups, then took the mean across all groups (Ravenscroft et al., 2016). Table 1 shows the breakdown of Kappas per category. There was greatest agreement for *Misogynistic pejoratives* (k=0.559) down to the lowest agreement for *Misogynistic personal attacks* (k=0.145).

Category	Fleiss' Kappa
Mis. Pejoratives	0.559
Mis. Treatment	0.210
Mis. Derogation	0.364
Mis. Personal attack	0.145
Nonmis. Personal attack	0.239
Counter speech	0.179
None of the categories	0.485

Table 1: Category-wise Fleiss' Kappa

Our taxonomy has seven partially overlapping categories, and as such annotation is considerably more difficult compared with most prior work, which tends to involve only binary labelling. As such, whilst slightly low, we believe that our agreement scores show the robustness of our annotation approach. Further, all disagreements were then discussed with an expert adjudicator, meaning that points of disagreement were addressed before the final labels were determined.

6 Prevalence of the categories

Of the 6,567 agreed labels in the final dataset 10.6% are Misogynistic (n=699) and 89.4% are Non-misogynistic (n=5,868). Tables 2 and 3 show the number of labels in the final dataset for each of the Misogynistic and Non-misogynistic categories, broken down by the level two categories. The vast majority of entries fall under *None of the categories* (88.6% of all labels). The next most common category is *Misogynistic Pejoratives* followed by *Misogynistic Derogation* pejoratives (4.2%). There are relatively few labels for *Personal attacks* with just 0.7% in total for each of the Misogynistic and Non-misogynistic categories, respectively. The least common category is *Counter speech* against misogyny, with only ten cases (0.2%).

Category	Number	Total %
Pejorative	276	4.2%
Treatment	103	1.6%
Derogation	285	4.3%
Personal attack	35	0.7%
Total	**696**	**10.6%**

Table 2: Breakdown of *Misogynistic* category counts

Category	Number	Total %
Personal attack	43	0.7%
Counter speech	10	0.2%
None	5815	88.6%
Total	**5868**	**89.4%**

Table 3: Breakdown of *Non-misogynistic* category counts

6.1 Misogynistic pejoratives

Annotators identified at least one misogynistic pejorative in 4.2% of all entries. The most common misogynistic term in the labels is 'bitch' (n=43) followed by 'stacy' (24) and 'stacies' (21).

6.2 Misogynistic treatment

There are 103 labels of *Treatment*. Figure 1 shows the number of labels for each level three subcategory. There are almost five times as many labels for *Disrespectful actions* (n=85) than *Threatening language* (n=18).

Both level three subcategories were broken down into more specific misogynistic themes. Within *Disrespectful actions*, *Seduction and conquest* is the most common topic, with twice as many labels as the second most common, *Controlling* (43 vs 17). And, within *Threatening language*, *Physical violence* was the most common theme (13) while

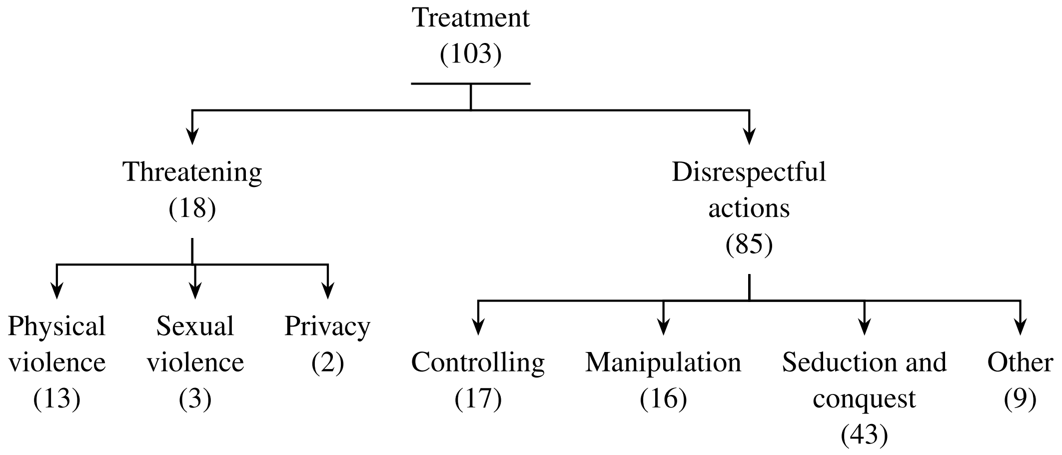

Figure 1: Prevalence of Misogynistic Treatment subcategories

Sexual violence and *Invasion of privacy* only have a couple of labels each (three and two, respectively).

6.3 Misogynistic derogation

The are 286 *Derogation* labels. Table 4 shows the number of labels for each subcategory within *Derogation*. The counts are broken down by the strength of the abuse (i.e. *implicit/explicit*). *Implicit derogation* is almost twice as common as *explicit* (182 vs 103). The most common subcategory is *Moral inferiority* which accounts for 51% of *implicit* and 54% of *explicit Derogation*. *Intellectual inferiority* then has equal numbers of *implicit* and *explicit* labels (n=16).

Subcategory	**Implicit**	**Explicit**
Moral infer.	92	56
Intellectual infer.	16	16
Sexual & physical lim.	14	12
Other	60	19
Total	**182**	**103**

Table 4: Breakdown of *Misogynistic Derogation* subcategories by implicit and explicit strength

6.4 Personal attacks

Table 5 shows the breakdown of both *Misogynistic* and *Nonmisogynistic* personal attacks. Slightly more than half (55%) of interpersonal abuse was *not* misogynistic. Of these women were still the target of the abuse almost four times as often as men (n=32 vs n=8). And women were as likely to receive misogynistic person attacks as non-misogynistic ones (n=32).

Gender	**Misog.**	**Nonmis.**	**Total**
Woman	32	32	64 (82%)
Man	2	8	10 (13%)
Unknown	1	3	4 (5%)
Total	35 (45%)	43 (55%)	78

Table 5: Breakdown of *Misogynistic* and *Nonmisogynistic* personal attacks by *Gender* of the target

The gender of the target was only *unknown* in 5% of cases, one misogynistic and three not. There were two cases of misogynistic abuse against men. All other misogynistic personal attacks were towards women.

6.5 Counter speech

There are only 10 cases of *Counter speech* in the final dataset of agreed labels. Annotators originally identified far more counter speech (188 labels for 149 unique entries were initially made) but few were accepted during the adjudication meetings. In Section 5.2 we showed that the category has one of the lowest Kappa values. Notably, 39% of original *Counter speech* labels were made by one annotator, showing that the annotators had different understandings of the threshold for *Counter speech*. However, the number of original labels for *Counter speech* decreased over the first few weeks of the annotation process, as shown in Figure 2. This reflects the complexity of the category; it took annotators time to differentiate content that was pro-women from that which actually countered previous misogynistic speech.

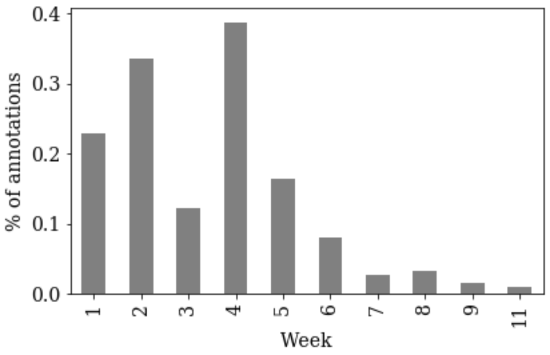

Figure 2: Percentage of original *counter speech* labels by week

7 Experiments

As reference points for further research using our dataset, we provide three experimental baselines on the binary task of distinguishing between misogynistic and non-misogynistic content, i.e. level one of our taxonomy. As the simplest baseline, we evaluate a logistic unigram classifier. Further, we evaluate two uncased BERT-base models (Devlin et al., 2019) – one unweighted, the other using class weights emphasising the minority class, i.e. misogynistic content, to account for class imbalance. For all models, we use the same stratified 80/20 train/test split of the dataset. Details on model training and parameters can be found in Appendix C.

Performance of the three models is shown in Table 6. All models perform poorly on misogynistic content, with the logistic classifier performing worst overall. The logistic classifier has the highest precision on misogynistic content (0.88) but very low recall (0.07) and a low F1 score (0.13). The weighted BERT model has the highest recall (0.50) and F1 score (0.43). Accuracy on all test cases, of which 91.9% are non-misogynistic, is around 0.90 across models.

The classification task is complicated by the relatively small size of our dataset (n=6,385 unique cases) as well as the relatively small proportion of misogynistic cases in it (8.1%). These issues are common in abusive speech detection (Fortuna and Nunes, 2018; Fortuna et al., 2020). To address them, future research can leverage the typology and annotation process we introduced to collect additional cases, particularly misogynistic ones, thus growing and balancing the dataset.

7.1 Error analysis

We make use of the more granular secondary labels in our taxonomy to conduct an error analysis for the weighted BERT model. Table 7 shows the confusion matrix for the 1,277 entries in the test set. Overall, 137 entries (10.7%) were misclassified. 86 (63%) of these errors were false positives and 51 (37%) were false negatives.

7.1.1 False positives

Of the 86 entries misclassified as *Misogynistic*, three are labelled as *Nonmisogynistic personal attacks*. An example is “Male feminist reacts to vile scumbag who murdered his kids by telling ALL men to, you know, stop killing women and kids...”. The use of aggressive language combined with gendered phrases (such as “stop killing women”) likely led to its misclassification.

The remaining 83 false positives fall under *None of the categories* and all contain some reference to women. Some refer to topics often associated with misogyny but are not misogynistic in themselves. For example, a comment in `r/seduction` stated, “the most manly thing is to find your dream woman, marry her, and live happily ever after. The constant sex with women is so overrated anyways”. This entry, which suggests that other things than high levels of sexual activity should be prioritised, is thematically similar to misogynistic content in the dataset.

Other false positives mention women indirectly. “Because they aren’t men, they are SIMPS”. ‘Simp’ is a pejorative term used in the manosphere for a man who cares too much about a woman. Under our taxonomy it did not count as a misogynistic pejorative but it is likely that the term appears in misogynistic entries in the dataset. Some false positives are critical of misogyny, though not actively enough to count as *Counter speech*. For example “Does this moid even know the meaning of the term ‘butterface’? If this woman is ugly, there is no hope for most of the female population.”. This discussion of unrealistic beauty standards of women references misogyny but is not itself misogynistic.

7.1.2 False negatives

Of the 51 Misogynistic entries the model misses, almost half (n=24) contain *Derogation*. Implicit and explicit derogation are missed at roughly similar rates, as are each of the subcategories. Importantly this shows that the different forms of derogation are no more or less likely to be missed.

Model	**Precision**	**Recall**	**F1 score**	**Accuracy**
Logistic regression	**0.88**	0.07	0.13	0.92
BERT (unweighted)	0.67	0.30	0.42	**0.93**
BERT (weighted)	0.38	**0.50**	**0.43**	0.89

Table 6: Model performance on misogynistic test cases (n=103) and accuracy on all test cases (n=1,277).

		Prediction		
		Nonmis.	Mis.	TOTAL
Label	Nonmis.	1,088	86	1,174
	Mis.	51	52	103
	TOTAL	1,139	138	1,277

Table 7: Confusion matrix of the weighted BERT model

In many cases, the derogation depends on the context of the earlier conversation thread, thus the BERT-model, which does not explicitly take into account prior entries in the thread, cannot recognise the misogyny in isolation. “It’s funny to see the hamster that starts to act up in their little widdle tiny brains after saying that too.” is an explicit statement that women are intellectually inferior, but understanding that it refers to women depends on having seen previous entries in the conversation.

The next most common source of false negatives is *Pejoratives* (n=19). The classifier misses six counts each of ‘whore’ and ‘stacy’ and five of ‘bitch’. There are seven missed labels for *Treatment*, five *Disrespectful actions* and two *Threatening language*. However, due to the low prevalence of the category in the training data we anticipate some errors. For example, “I am waiting for such incident to happen to me so that I can beat the shit out of her, and of course it will be all revenge” details a specific form of violence (i.e. ‘beat the shit out of her’) which the model cannot know to identify as misogyny without being trained on other uses of the term.

The final two errors are for *Personal attacks*. For example, “Yeah theres women that I as an Incel wouldnt even acknowledge and this is one of em [sic]”. This is an implicit attack which requires understanding that considering a woman unworthy of the attention of an incel is a gendered insult.

As we can see from these examples the main classification errors are due to context limitations. For false negatives there is usually not enough information in the entry alone or in the training dataset to identify the misogyny. Conversely, for false positives the classifier appears to overly associate content *about* women with content that *abuses* women. These limitations can be addressed by future work drawing on the taxonomy and annotation process presented here to develop larger datasets which can cover a greater range of forms of discourse, including both non-misogynistic discussions of women and a wider variety of misogynistic speech.

8 Conclusion

In this paper we have presented a hierarchical granular taxonomy for misogyny and have described a dataset containing high quality, expert labels of misogynistic content from Reddit. We have also provided the detailed coding book we created and a dataset with all of the original labels. The final dataset is small compared to other annotated datasets used for classification. However it benefits from a detailed taxonomy based on the existing literature focused on just one form of online abuse - misogyny. The use of trained annotators and an adjudication process also ensures the quality of the labels.

The more granular subcategories in the taxonomy may be too small to classify separately, but they provide insights into the relative frequency of different forms of misogynistic content on Reddit and enable detailed error analysis. They are also useful for other researchers aiming to create larger datasets, who can build on the taxonomic work conducted here.

A Short form data statement

Following the recommendation of Bender and Friedman (2018) we include the following short form data statement to summarise the main features of the datasets. Further details on the creation of the datasets are in in Sections 3 and 5 in the main paper.

A.1 Data

The two datasets include labels for 6,383 unique Reddit entries (i.e. posts or comments) across 672 conversation threads collected. One dataset is of the 15,816 original labels selected by annotators and the second is of the 6,567 agreed labels. Table 8 provides a description of each of the variables in the datasets. We also include the accompanying set of images associated with some original post entries.

All threads except one are in English. The majority of threads were sampled from a set of 34 subreddits selected for the expected prevalence of misogynistic content, or non-misogynistic discussions about women. Paid annotators received extensive training to apply the taxonomy presented in this paper to label entries. The majority of annotators were White-British, spoke English as a first language, and had or were pursuing a University degree. Two-thirds of annotators were women.

A.2 Annotators

All annotators were based in the United Kingdom and worked remotely. They were paid £14 per hour for all work including training. Five of the six annotators gave permission to share their basic demographic information. All were between 18 and 29 years old. Two had high school degrees, two had an undergraduate degree, and one had a postgraduate taught degree or equivalent. Four identified as women, one as a man. All were British nationals, native English speakers, and identified as ethnically white.

All annotators used social media at least once per day. Two had never been personally targeted by online abuse, two had been targeted 2-3 times (in separate instances more than a year ago), and one had been personally targeted more than 3 times within the previous month.

B Frequency of targeted subreddits

Table 9 lists the subreddits used for target sampling of data. The columns *Num entries* and *Num threads* state how many individual entries and threads from each subreddit are in the datasets. The column *Selection* shows whether the subreddit was identified from existing literature, which is cited, or using snowball sampling.

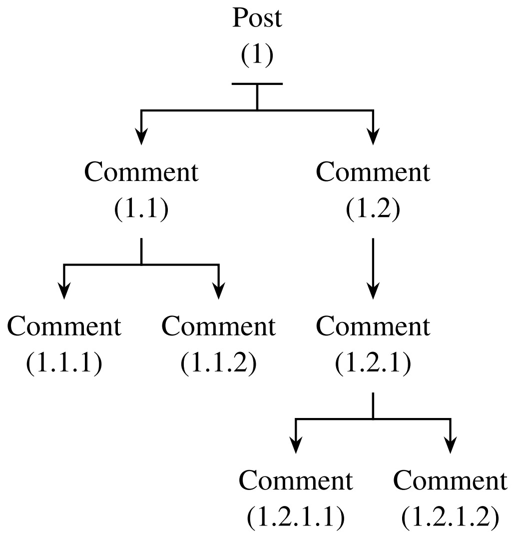

Figure 3: Tree diagram for comment order in threads

C Model Details

Pre-Processing We lowercase all text and remove newline and tab characters. URLs and emojis are replaced with [URL] and [EMOJI] tokens.

C.1 Logistic regression

Logistic regression with l1-regularisation is implemented in R using the 'glmnet' package (Friedman et al., 2010) on a unigram representation of the data. Lambda is selected using cross-validation and set to 0.015.

C.2 BERT Models (weighted/unweighted)

Model Architecture We implement uncased BERT-base models (Devlin et al., 2019) using the `transformers` Python library (Wolf et al., 2020). For sequence classification, we add a linear layer with softmax output.

Training Parameters We apply a stratified 80/20 train/test split to our dataset. Models are trained for three epochs each. Training batch size is 16. We use cross-entropy loss. For the weighted model, we add class weights emphasising the minority class, i.e. misogynistic content. Weights are set to the relative proportion of the other class in the training data, meaning that for a 1:9 misogynistic:non-misogynistic case split, loss on misogynistic cases would be multiplied by 9. The optimiser is AdamW (Loshchilov and Hutter, 2018) with a 5e-5 learning rate and a 0.01 weight decay. For regularisation, we set a 10% dropout probability.

Variable	**Description**
entry_id	A unique string assigned to every comment and post by Reddit.
link_id	The id number of the original post of a thread.
parent_id	The id number of parent entry (i.e. the post or comment this entry responds to).
subreddit	The subreddit community where the entry was made.
author	The Reddit username of the entry author.
body	The text body of the entry. For the original posts of threads the title and post body were combined.
image	Whether the entry has an accompanying image. Only applicable to posts. Images are provided as jpg files. They are named as 'X_Y_Z' corresponding to the week (X), group (Y), and thread id (Z).
label_date	The week commencing date of when the entry was labelled.
week	The week in the annotation process when the entry as assigned (1 to 11).
group	The weekly group the entry was assigned to. All weeks had two groups except week 7 which only had 1.
sheet_order	The order of the entry in the weekly annotation sheet. This is a list of numbers referring to the nested structure of comments in threads. It shows the id number of each level of the thread from the original post to the relevant entry. For example, if an entry has the sheet_order (1, 2, 3) it belongs to the first thread (1), and replied to the second comment (2), to which it is the third reply (3). See Fig. 3 for visual explanation.
annotator_id	The id number of the annotator who made the annotation (1 to 6). Only applicable to the original_labels dataset.
level_1	Whether the entry is *Misogynistic* or *Nonmisogynistic*.
level_2	The category of the label (i.e. *Pejoratives, Derogation*, etc.
level_3	EITHER the subcategory for *Derogation* or *Treatment* OR the gender of the target for either *Personal attack* category. Empty for all other categories.
strength	Whether the abuse is implicit or explicit. Only applicable to identity directed abuse.
highlight	The highlighted part of the entry's body which contains the abuse. Mandatory for all primary categories except 'None'.
split	Whether the entry was included in the 'train' or 'test' dataset split for model building. Only applicable to the final_labels dataset.

Abstract

We present an approach based on multilingual sentence embeddings to automatically extract parallel sentences from the content of Wikipedia articles in 96 languages, including several dialects or low-resource languages. We systematically consider all possible language pairs. In total, we are able to extract 135M parallel sentences for 1620 different language pairs, out of which only 34M are aligned with English. This corpus is freely available.[1]

To get an indication on the quality of the extracted bitexts, we train neural MT baseline systems on the mined data only for 1886 languages pairs, and evaluate them on the TED corpus, achieving strong BLEU scores for many language pairs. The WikiMatrix bitexts seem to be particularly interesting to train MT systems between distant languages without the need to pivot through English.

1 Introduction

Most of the current approaches in Natural Language Processing are data-driven. The size of the resources used for training is often the primary concern, but the quality and a large variety of topics may be equally important. Monolingual texts are usually available in huge amounts for many topics and languages. However, multilingual resources, i.e. sentences which are mutual translations, are more limited, in particular when the two languages do not involve English. An important source of parallel texts is from international organizations like the European Parliament (Koehn, 2005) or the United Nations (Ziemski et al., 2016). Several projects rely on volunteers to provide translations for public texts, e.g. news commentary (Tiedemann, 2012), OpensubTitles (Lison and Tiedemann, 2016) or the TED corpus (Qi et al., 2018)

Wikipedia is probably the largest free multilingual resource on the Internet. The content of Wikipedia is very diverse and covers many topics. Articles exist in more than 300 languages. Some content on Wikipedia was human translated from an existing article into another language, not necessarily from or into English. Eventually, the translated articles have been later independently edited and are not parallel anymore. Wikipedia strongly discourages the use of unedited machine translation,[2] but the existence of such articles cannot be totally excluded. Many articles have been written independently, but may nevertheless contain sentences which are mutual translations. This makes Wikipedia a very appropriate resource to mine for parallel texts for a large number of language pairs. To the best of our knowledge, this is the first work to process the entire Wikipedia and systematically mine for parallel sentences in all language pairs.

In this work, we build on a recent approach to mine parallel texts based on a distance measure in a joint multilingual sentence embedding space (Schwenk, 2018; Artetxe and Schwenk, 2018a), and a freely available encoder for 93 languages. We approach the computational challenge to mine in almost six hundred million sentences by using fast indexing and similarity search algorithms.

The paper is organized as follows. In the next section, we first discuss related work. We then summarize the underlying mining approach. Section 4 describes in detail how we applied this approach to extract parallel sentences from Wikipedia in 1620 language pairs. In section 5, we assess the quality of the extracted bitexts by training NMT systems for a subset of language pairs and evaluate them on the TED corpus (Qi et al., 2018) for 45 languages. The paper concludes with a discussion of future research directions.

2 Related work

There is a large body of research on mining parallel sentences in monolingual texts collections, usually named *"comparable coprora"*. Initial approaches to bitext mining have relied on heavily engineered systems often based on metadata information, e.g. (Resnik, 1999; Resnik and Smith, 2003). More recent methods explore the textual content of the comparable documents. For instance, it was proposed to rely on cross-lingual document retrieval, e.g. (Utiyama and Isahara, 2003; Munteanu and Marcu, 2005) or machine translation, e.g. (Abdul-Rauf and Schwenk, 2009; Bouamor and Sajjad, 2018), typically to obtain an initial alignment that is then further filtered. In the shared task for bilingual document alignment (Buck and Koehn, 2016), many participants used techniques based on n-gram or neural language models, neural translation models and bag-of-words lexical translation probabilities for scoring candidate document pairs. The STACC method uses seed lexical translations induced from IBM alignments, which are combined with set expansion operations to score translation candidates through the Jaccard similarity coefficient (Etchegoyhen and Azpeitia, 2016; Azpeitia et al., 2017, 2018). Using multilingual noisy webcrawls such as ParaCrawl[3] for filtering good quality sentence pairs has been explored in the shared tasks for high resource (Koehn et al., 2018) and low resource (Koehn et al., 2019) languages.

In this work, we rely on massively multilingual sentence embeddings and margin-based mining in the joint embedding space, as described in (Schwenk, 2018; Artetxe and Schwenk, 2018a,b). This approach has also proven to perform best in a low resource scenario (Chaudhary et al., 2019; Koehn et al., 2019). Closest to this approach is the research described in España-Bonet et al. (2017); Hassan et al. (2018); Guo et al. (2018); Yang et al. (2019). However, in all these works, only bilingual sentence representations have been trained. Such an approach does not scale to many languages, in particular when considering all possible language pairs in Wikipedia. Finally, related ideas have been also proposed in Bouamor and Sajjad (2018) or Grégoire and Langlais (2017). However, in those works, mining is not solely based on multilingual sentence embeddings, but they are part of a larger system. To the best of our knowledge, this work is the first one that applies the same mining approach to all combinations of many different languages, written in more than twenty different scripts. In follow up work, the same underlying mining approach was applied to a huge collection of Common Crawl texts (Schwenk et al., 2019). Hierarchical mining in Common Crawl texts was performed by El-Kishky et al. (2020).[4]

Wikipedia is arguably the largest comparable corpus. One of the first attempts to exploit this resource was performed by Adafre and de Rijke (2006). An MT system was used to translate Dutch sentences into English and to compare them with the English texts, yielding several hundreds of Dutch/English bitexts. Later, a similar technique was applied to Persian/English (Mohammadi and GhasemAghaee, 2010). Structural information in Wikipedia such as the topic categories of documents was used in the alignment of multilingual corpora (Otero and López, 2010). In another work, the mining approach of Munteanu and Marcu (2005) was applied to extract large corpora from Wikipedia in sixteen languages (Smith et al., 2010). Otero et al. (2011) measured the comparability of Wikipedia corpora by the translation equivalents on three languages Portuguese, Spanish, and English. Patry and Langlais (2011) came up with a set of features such as Wikipedia entities to recognize parallel documents, and their approach was limited to a bilingual setting. Tufis et al. (2013) proposed an approach to mine bitexts from Wikipedia textual content, but they only considered high-resource languages, namely German, Spanish and Romanian paired with English. Tsai and Roth (2016) grounded multilingual mentions to English Wikipedia by training cross-lingual embeddings on twelve languages. Gottschalk and Demidova (2017) searched for parallel text passages in Wikipedia by comparing their named entities and time expressions. Finally, Aghaebrahimian (2018) propose an approach based on bilingual BiLSTM sentence encoders to mine German, French and Persian parallel texts with English. Parallel data consisting of aligned Wikipedia titles have been extracted for twenty-three languages.[5] We are not aware of other attempts to systematically mine for parallel sentences in the textual content of Wikipedia for a large number of languages.

3 Distance-based mining approach

The underlying idea of the mining approach used in this work is to first learn a multilingual sentence embedding. The distance in that space can be used as an indicator of whether two sentences are mutual translations or not. Using a simple absolute threshold on the cosine distance was shown to achieve competitive results (Schwenk, 2018). However, it has been observed that an absolute threshold on the cosine distance is globally not consistent, e.g. (Guo et al., 2018). This is particularly true when mining bitexts for many different language pairs.

3.1 Margin criterion

The alignment quality can be substantially improved by using a margin criterion (Artetxe and Schwenk, 2018a). The margin between two candidate sentences x and y is defined as the ratio between the cosine distance between the two sentence embeddings, and the average cosine similarity of its nearest neighbors in both directions:

$$M(x,y) = \frac{\cos(x,y)}{\sum\limits_{z \in \mathrm{NN}_k(x)} \frac{\cos(x,z)}{2k} + \sum\limits_{z \in \mathrm{NN}_k(y)} \frac{\cos(y,z)}{2k}} \tag{1}$$

where $\mathrm{NN}_k(x)$ denotes the k unique nearest neighbors of x in the other language, and analogously for $\mathrm{NN}_k(y)$. We used $k = 4$ in all experiments.

We follow the *"max"* strategy of Artetxe and Schwenk (2018a): the margin is first calculated in both directions for all sentences in language L_1 and L_2. We then create the union of these forward and backward candidates. Candidates are sorted and pairs with source or target sentences that were already used are omitted. We then apply a threshold on the margin score to decide whether two sentences are mutual translations or not.

The complexity of a distance-based mining approach is $O(N \times M)$, where N and M are the number of sentences in each monolingual corpus. This makes a brute-force approach with exhaustive distance calculations intractable for large corpora. The languages with the largest Wikipedia are English and German with 134M and 51M sentences, respectively. This would require 6.8×10^{15} distance calculations.[6] We show in Section 3.3 how to tackle this computational challenge.

3.2 Multilingual sentence embeddings

Distance-based bitext mining requires a joint sentence embedding for all the considered languages. One may be tempted to train a bi-lingual embedding for each language pair, e.g. (España-Bonet et al., 2017; Hassan et al., 2018; Guo et al., 2018; Yang et al., 2019), but this is difficult to scale to thousands of language pairs present in Wikipedia. Instead, we chose to use one single massively multilingual sentence embedding for all languages, namely the one proposed by the open-source LASER toolkit (Artetxe and Schwenk, 2018b). Training one joint multilingual embedding on many languages at once also has the advantage that low-resource languages can benefit from the similarity to other languages in the same language family. For example, we were able to mine parallel data for several Romance (minority) languages like Aragonese, Lombard, Mirandese or Sicilian although data in those languages was not used to train the multilingual LASER embeddings. The reader is referred to Artetxe and Schwenk (2018b) for a detailed description how LASER was trained.

3.3 Fast similarity search

In this work, we use the open-source FAISS library[7] which implements highly efficient algorithms to perform similarity search on billions of vectors (Johnson et al., 2017). Our sentence representations being 1024-dimensional, all English sentences require $134{\cdot}10^6{\times}1024{\times}4{=}536$ GB of memory. Therefore, dimensionality reduction and data compression are needed for efficient search. We chose a rather aggressive compression based on a 64-bit product-quantizer (Jégou et al., 2011), and partitioning the search space in 32k cells.[8] We build one FAISS index for each language.

The compressed FAISS index for English requires only 9.2GB, i.e. more than fifty times smaller than the original sentences embeddings. This makes it possible to load the whole index on a standard GPU and to run the search in a very efficient way on multiple GPUs in parallel, without the need to shard the index. The overall mining process for German/English requires less than 3.5 hours on 8 GPUs, including the nearest neighbor search in both direction and scoring all candidates.

---

[6] Strictly speaking, Cebuano and Swedish are larger than German, yet mostly consist of template/machine translated text

[7] https://github.com/facebookresearch/faiss

[8] FAISS index type `OPQ64,IVF32768,PQ64`, see https://github.com/facebookresearch/faiss/wiki/Faiss-indexes

4 Bitext mining in Wikipedia

For each Wikipedia article, it is possible to get the link to the corresponding article in other languages. This could be used to mine sentences limited to the respective articles. On one hand, this **local mining** has several advantages: 1) mining is very fast since each article usually has a few hundreds of sentences only; 2) it seems reasonable to assume that a translation of a sentence is more likely to be found in the same article than anywhere in the whole Wikipedia. On the other hand, we hypothesize that the margin criterion will be less efficient since one article usually has few sentences which are similar. This may lead to many sentences in the overall mined corpus of the type *"NAME was born on DATE in CITY"*, *"BUILDING is a monument in CITY built on DATE"*, etc. Although those alignments may be correct, we hypothesize that they are of limited use to train an NMT system.

The other option is to consider the whole Wikipedia for each language: for each sentence in the source language, we mine in all target sentences. This **global mining** has the advantages that we can try to align two languages even though there are only a few articles in common. A drawback is a potentially increased risk of misalignment. In this work, we chose the global mining option.

4.1 Corpus preparation

Extracting the textual content of Wikipedia articles in all languages is a rather challenging task, i.e. removing all tables, citations, footnotes or formatting markup. There are several ways to download Wikipedia content. In this study, we use the so-called `CirrusSearch dumps` since they directly provide the textual content without any meta information.[9] We downloaded this dump in March 2019. A total of about 300 languages are available, but the size obviously varies a lot between languages. We applied the following processing: 1) extract the textual content; 2) split the paragraphs into sentences; 3) remove duplicate sentences; and 4) perform language identification and remove sentences which are not in the expected language.

It should be pointed out that sentence segmentation is not a trivial task. Some languages do not use specific symbols to mark the end of a sentence, namely Thai. We are not aware of a freely available sentence segmenter for Thai and we had to exclude it. We used a freely available Python tool[10] to detect sentence boundaries. Regular expressions were used for most of the Asian languages, falling back to English for the remaining languages. This gives us 879 million sentences in 300 languages. The margin criterion to mine for parallel data requires that the texts do not contain duplicates. This removes about 25% of the sentences.[11]

L_1 (French)	*Ceci est une très grande maison*
L_2 (German)	*Das ist ein sehr großes Haus* *This is a very big house* *Ez egy nagyon nagy ház* *Ini rumah yang sangat besar*

Table 1: Illustration how sentences in the wrong language can hurt the alignment process with a margin criterion. See text for a detailed discussion.

LASER's sentence embeddings are totally language agnostic. This has the side effect that the sentences in other languages (e.g. citations or quotes) may be considered closer in the embedding space than a potential translation in the target language. Table 1 illustrates this problem. The algorithm would not select the German sentence although it is a perfect translation. The sentences in the other languages are also valid translations which would yield a very small margin. To avoid this problem, we perform language identification (LID) on all sentences and remove those which are not in the expected language. LID is performed with fasttext[12] (Joulin et al., 2016). Fasttext does not support all the 300 languages present in Wikipedia and we disregarded the missing ones (which typically have only a few sentences anyway). After deduplication and LID, we dispose of 595M sentences in 182 languages. English accounts for 134M sentences, and German with 51M sentences is the second largest language. The sizes for all languages are given in Tables 3 and 5 (in the appendix).

4.2 Threshold optimization

Artetxe and Schwenk (2018a) optimized their mining approach for each language pair on a provided corpus of gold alignments. This is not possible when mining Wikipedia, in particular when con-

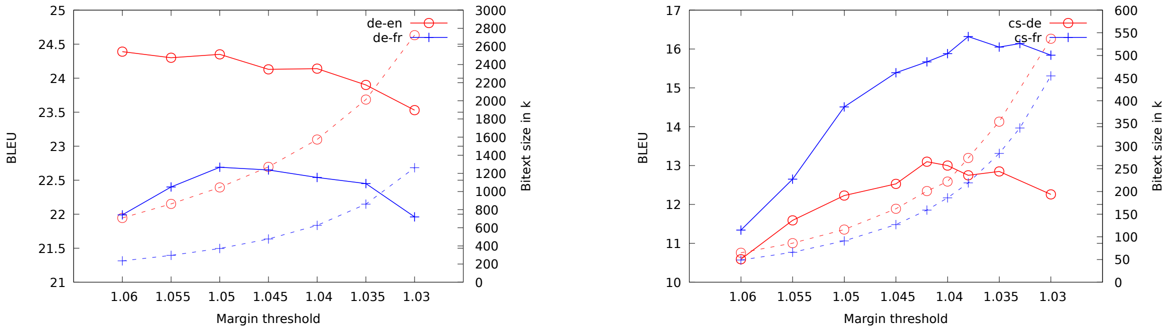

Figure 1: BLEU scores (continuous lines) for several NMT systems trained on bitexts extracted from Wikipedia for different margin thresholds. The size of the mined bitexts are depicted as dashed lines.

sidering many language pairs. In this work, we use an evaluation protocol inspired by the WMT shared task on parallel corpus filtering for low-resource conditions (Koehn et al., 2019): an NMT system is trained on the extracted bitexts – for different thresholds – and the resulting BLEU scores are compared. We choose `newstest2014` of the WMT evaluations since it provides an N-way parallel test sets for English, French, German and Czech. We favoured the translation between two morphologically rich languages from different families and considered the following language pairs: German/English, German/French, Czech/German and Czech/French. The size of the mined bitexts is in the range of 100k to more than 2M (see Table 2 and Figure 1). We did not try to optimize the architecture of the NMT system to the size of the bitexts and used the same architecture for all systems: the encoder and decoder are 5-layer transformer models as implemented in `fairseq` (Ott et al., 2019). The goal of this study is not to develop the best performing NMT system for the considered languages pairs, but to compare different mining parameters.

The evolution of the BLEU score in function of the margin threshold is given in Figure 1. Decreasing the threshold naturally leads to more mined data – we observe an exponential increase of the data size. The performance of the NMT systems trained on the mined data seems to change as expected: the BLEU score first improves with increasing amounts of available training data, reaches a maximum and than decreases since the additional data gets more and more noisy, i.e. contains wrong translations. It is also not surprising that a careful choice of the margin threshold is more important in a low-resource setting. Every additional parallel sentence is important. According to Figure 1, the optimal value of the margin threshold seems to be 1.05 when many sentences can be extracted, in our case German/English and German/French. When less parallel data is available, i.e. Czech/German and Czech/French, a value in the range of 1.03–1.04 seems to be a better choice. Aiming at one threshold for all language pairs, we chose a value of 1.04. It seems to be a good compromise for most language pairs. However, for the open release of this corpus, we provide all mined sentence with a margin of 1.02 or better. This enables end users to choose an optimal threshold for their particular applications. However, it should be emphasized that we do not expect that many sentence pairs with a margin as low as 1.02 are good translations.

Bitexts	**de-en**	**de-fr**	**cs-de**	**cs-fr**
Europarl	1.9M 21.5	1.9M 23.6	568k 14.9	627k 21.5
	1.0M 21.2	370k 21.1	200k 12.6	220k 19.2
Mined Wikipedia	1.0M 24.4	372k 22.7	201k 13.1	219k 16.3
Europarl + Wikipedia	3.0M 25.5	2.3M *25.6*	768k 17.7	846k 24.0

Table 2: Comparison of NMT systems trained on the Europarl corpus and on bitexts automatically mined in Wikipedia by our approach at a threshold of 1.04. We give the number of sentences (first line) and the BLEU score (second line of each bloc) on `newstest2014`.

For comparison, we also trained NMT systems on the Europarl corpus V7 (Koehn, 2005), i.e. professional human translations, first on all available data, and then on the same number of sentences as the mined ones (see Table 2). With the exception of Czech/French, we were able to achieve better

BLEU scores with the mined bitexts in Wikipedia than with Europarl of the same size. Adding the mined bitexts to the full Europarl corpus, leads to further improvements of 1.1 to 3.1 BLEU.

5 Result analysis

We run the alignment process for all possible combinations of languages in Wikipedia. This yielded 1620 language pairs for which we were able to mine at least ten thousand sentences. Remember that mining $L_1 \rightarrow L_2$ is identical to $L_2 \rightarrow L_1$, and is counted only once. We propose to analyze and evaluate the extracted bitexts in two ways. First, we discuss the amount of extracted sentences (Section 5.1). We then turn to a qualitative assessment by training NMT systems for all language pairs with more than twenty-five thousand mined sentences (Section 5.2).

5.1 Quantitative analysis

Due to space limits, Table 3 summarizes the number of extracted parallel sentences only for languages which have a total of at least five hundred thousand parallel sentences (with all other languages at a margin threshold of 1.04). Additional results are given in Table 5 in the Appendix.

There are many reasons which can influence the number of mined sentences. Obviously, the larger the monolingual texts, the more likely it is to mine many parallel sentences. Not surprisingly, we observe that more sentences could be mined when English is one of the two languages. Let us point out some languages for which it is usually not obvious to find parallel data with English, namely Indonesian (1M), Hebrew (545k), Farsi (303k) or Marathi (124k sentences). The largest mined texts not involving English are Russian/Ukrainian (2.5M), Catalan/Spanish (1.6M), or between the Romance languages French, Spanish, Italian and Portuguese (480k–923k), and German/French (626k).

It is striking to see that we were able to mine more sentences when Galician and Catalan are paired with Spanish than with English. On one hand, this could be explained by the fact that LASER's multilingual sentence embeddings may be better since the involved languages are linguistically very similar. On the other, it could be that the Wikipedia articles in both languages share a lot of content, or are obtained by mutual translation.

Services from the European Commission provide human translations of (legal) texts in all the 24 official languages of the European Union. This N-way parallel corpus enables training of MT system to directly translate between these languages, without the need to pivot through English. This is usually not the case when translating between other major languages, for example in Asia. Some interesting language pairs for which we were able to mine more than 100k sentences include: Korean/Japanese (222k), Russian/Japanese (196k), Indonesian/Vietnamese (146k), or Hebrew/Romance languages (120–150k sentences).

Overall, we were able to extract at least ten thousand parallel sentences for 96 different languages. For several low-resource languages, we were able to extract more parallel sentences with other languages than English. These include, among others, Aragonse with Spanish, Lombard with Italian, Breton with several Romance languages, Western Frisian with Dutch, Luxembourgish with German or Egyptian Arabic and Wu Chinese with the respective major language.

Finally, Cebuano (ceb) falls clearly apart: it has a rather huge Wikipedia (17.9M filtered sentences), but most of it was generated by a bot, as for the Waray language.[13] This certainly explains that only a very small number of parallel sentences could be extracted. Although the same bot was also used to generate articles in the Swedish Wikipedia, our alignments seem to be better for that language.

5.2 Qualitative evaluation

Aiming to perform a large-scale assessment of the quality of the extracted parallel sentences, we trained NMT systems on the bitexts. We identified a publicly available dataset which provides test sets for many language pairs: translations of TED talks as proposed in the context of a study on pretrained word embeddings for NMT[14] (Qi et al., 2018). We would like to emphasize that we did not use the training data provided by TED – we only trained on the mined sentences from Wikipedia. The goal of this study is not to build state-of-the-art NMT system for for the TED task, but to get an estimate of the quality of our extracted data, for many language pairs. In particular, there may be a mismatch in the topic and language style between Wikipedia texts and the transcribed and translated TED talks.

NMT systems are trained with a transformer model from `fairseq` (Ott et al., 2019) with the

Table 3: WikiMatrix: number of extracted sentences for each language pair (in thousands), e.g. Es-Ja=219 corresponds to 219,260 sentences (rounded). The column *“size”* gives the number of lines in the monolingual texts after deduplication and LID.

Table 4: BLEU scores on the TED test set as proposed in (Qi et al., 2018). NMT systems were trained on bitexts mined in Wikipedia only (with at least twenty-five thousand parallel sentences). No other resources were used.

parameter settings shown in Figure 2 in the appendix. Since the TED development and test sets were already tokenized, we first detokenize them using Moses. We trained NMT systems for all possible language pairs with more than 25k mined sentences. This gives us in total 1886 language pairs in 45 languages. We train $L_1 \rightarrow L_2$ and $L_2 \rightarrow L_1$ with the same mined bitexts L_1/L_2. Scores on the test sets were computed with SacreBLEU (Post, 2018), see Table 4. Some additional results are reported in Table 6 in the annex. 23 NMT systems achieve BLEU scores over 30, the best one being 37.3 for Brazilian Portuguese to English. Several results are worth mentioning, like Farsi/English: 16.7, Hebrew/English: 25.7, Indonesian/English: 24.9 or English/Hindi: 25.7 We also achieve interesting results for translation between various non English language pairs for which it is usually not easy to find parallel data, e.g. Norwegian ↔ Danish ≈33, Norwegian ↔ Swedish ≈25, Indonesian ↔ Vietnamese ≈16 or Japanese / Korean ≈17.

Our results on the TED set give an indication on the quality of the mined parallel sentences. These BLEU scores should be of course appreciated in context of the sizes of the mined corpora as given in Table 3. Finally, we would like to point out that we run our approach on all available languages in Wikipedia, independently of the quality of LASER's sentence embeddings for each one.

6 Conclusion

We have presented an approach to systematically mine for parallel sentences in the textual content of Wikipedia, for all possible language pairs. We use a mining approach based on massively multilingual sentence embeddings (Artetxe and Schwenk, 2018b) and a margin criterion (Artetxe and Schwenk, 2018a). The same approach is used for all language pairs without the need for a language-specific optimization. In total, we make available 135M parallel sentences in 96 languages, out of which only 34M sentences are aligned with English. We were able to mine more than ten thousands sentences for 1620 different language pairs. This corpus of parallel sentences is freely available.[15] We also performed a large scale evaluation of the quality of the mined sentences by training 1886 NMT systems and evaluating them on the 45 languages of the TED corpus (Qi et al., 2018). This approach was recently extended to mine in Common Crawl texts (Schwenk et al., 2019).

A Appendix

Table 5 provides the amounts of mined parallel sentences for languages which have a rather small Wikipedia. Aligning those languages obviously yields to a very small amount of parallel sentences. Therefore, we only provide these results for alignment with high resource languages. It is also likely that several of these alignments are of low quality since the LASER embeddings were not directly trained on most these languages, but we still hope to achieve reasonable results since other languages of the same family may be covered.

Abstract

Chemical patents contain rich coreference and bridging links, which are the target of this research. Specially, we introduce a novel annotation scheme, based on which we create the ChEMU-Ref dataset from reaction description snippets in English-language chemical patents. We propose a neural approach to anaphora resolution, which we show to achieve strong results, especially when jointly trained over coreference and bridging links.

1 Introduction

Chemical research has contributed greatly to human society and wellbeing, including new medicines and vaccines (Gwynne and Heabrer, 2015). Research is heavily reliant on knowledge of existing chemical processes and methods of chemical synthesis, which are documented in chemical research literature and chemical patents. Given the rapid growth of both publications and patents in chemistry, the need for automatic methods to extract semi-structured knowledge from chemical texts is becoming increasingly critical (Li et al., 2016; Akhondi et al., 2019).

Anaphora resolution is a key component of comprehensive information extraction (Rösiger, 2019; Poesio et al., 2016). In chemistry, different chemical compounds are mixed and reacted together in different ways to generate novel compounds, and to understand the precise chemical process often involves both resolving anaphoric references and understanding chemical changes/interactions a given entity is involved in. For example, as seen in Figure 1, while the final mention of *mixture* on line 3 and that on line 4 are both coreferent and chemically identical, in the case of *mixture* on line 2 and the first mention of *mixture* on line 3, the chemical composition is the same but a transformation has taken place via the *stir* and *cool* actions.

Our aim in this paper is to both identify anaphoric references in chemical patents, and determine the chemical relation between each linked pair of entities. We propose a domain-specific annotation framework based on five types of anaphora relations combining coreference and bridging. We then construct a dataset following this framework, annotated by chemical experts who achieve high inter-annotator agreement. We additionally extend existing anaphora resolution methods to model anaphora in chemical text, and compare both component-wise and joint models for anaphora resolution. This dataset will be released as part of the upcoming ChEMU 2021 shared task[1] (He et al., to appear).

Our contributions in this paper are as follows: (1) we propose a novel annotation scheme for anaphora resolution in chemical patents; (2) we develop a novel anaphora-resolution dataset based on chemical patents; and (3) we extend a general-purpose coreference resolution method, and achieve strong results via joint training over coreference and bridging with domain-specific fine-tuning.

2 Related Work

Anaphora occurs in two basic forms: coreference and bridging. Coreference occurs when different expressions in a text refer to the same entity in the real world (Ng, 2017; Clark and Manning, 2015), while bridging occurs between discrete entities that are linked via lexical semantic, frame-based, or encyclopedic relations (Asher and Lascarides, 1998; Hou et al., 2018).

Most existing anaphora datasets focus only on coreference, predominantly using generic relations (Pradhan et al., 2012; Ghaddar and Langlais, 2016a), but also using domain-specific relations for knowledge-rich corpora such as biomedical litera-

1 To the solution of Compound (4) (0.815 g, 1.30 mmol) in THF (4.9 ml) in a flask were added acetic acid (9.8 ml) and water (4.9 ml).

2 The mixture was stirred for 3 hrs at 50°C and then cooled to 0°C.

3 2N-sodium hydroxide aqueous solution was added to the mixture until the pH of the mixture became 9.

4 The mixture was extracted with ethyl acetate for 3 times.

5 The combined organic layer was washed with water and saturated aqueous sodium chloride.

6 The organic layer was dried over anhydrous magnesium sulfate and evaporated.

Figure 1: Annotated snippet of anaphora resolution in the chemical patents. Different color of links represent different anaphora relation types. Detailed anaphora relation definition can be seen Section 3.3.

ture (Nguyen et al., 2011; Cohen et al., 2017).

The CoNLL-2012 dataset (Pradhan et al., 2012) is a general corpus consisting of texts from three languages (English, Chinese, and Arabic). It is annotated based on OntoNotes v5.0 (Weischedel et al., 2013) and includes two types of coreference relations: IDENTITY, a symmetrical and transitive relation; and APPOSITIVE, two noun phrases that are adjacent and not linked by a copula. Coreference resolution is modelled as a clustering task. The wikicoref corpus was constructed with the same relations, over Wikipedia documents (Ghaddar and Langlais, 2016a).

BioNLP-ST 2011 (Nguyen et al., 2011) is a domain-specific coreference corpus over abstracts from biomedical literature, focusing mainly on gene–protein coreference, considering four relations: RELAT (relative pronouns or adjectives, e.g. *which*), PRON (pronouns, e.g. *they*), DNP (definite or demonstrative noun phrases marked with *the*, *this*, etc.), and APPOS (apposition). Instead of modelling coreference resolution as a clustering task, here the direction of coreference links is preserved. As this corpus focuses on gene–protein coreference, the range of coreference phenomena is limited. The CRAFT-CR corpus (Cohen et al., 2017) adds coreference relations to the Colorado Richly Annotated Full Text (CRAFT) corpus (Bada et al., 2012), following OntoNotes v5.0 with minor adaptions, and including discontinuous expressions, domain-specific proper nouns, and a broad range of mention types.

The definition of bridging is somewhat imprecise (Zeldes, 2017; Hou et al., 2018), and different corpora have adopted different definitions. Based on Rösiger et al. (2018), there are two types of bridging: *referential bridging*, which can be treated as a context-based relation; and *lexical bridging*, which describes lexical-semantic relations such as holonymy and meronymy. Poesio et al. (2008) introduced the ARRAU corpus of general language texts for bridging, which consists of news, dialogue, and narrative text. In the corpus, entities are limited to noun phrases, and most bridging pairs are lexical relations, with only a small number of instances of referential bridging. ISnotes (Hou et al., 2018) includes 50 Wall Street Journal (WSJ) articles from the OntoNotes corpus, and has both coreference and bridging annotations, with most of the bridging pairs being referential. BASHI (Rösiger, 2018a) has both coreference and bridging annotations over 50 WSJ articles based on the OntoNotes v5.0 guidelines, with most bridging links once again being referential. Rösiger (2016) developed a corpus called SciCorp based on English scientific papers, following the same annotation scheme as BASHI.

Due to limited dataset availability, most research has modelled coreference resolution and bridging separately. There are two basic approaches to coreference resolution. First is mention ranking methods, which aim to score the coreferent probability of mention pairs (Clark and Manning, 2015, 2016a,b; Wiseman et al., 2015, 2016), and make the assumption that mentions have been pre-identified, meaning they are heavily reliant on upstream mention detection methods. Second is span ranking methods, which combine mention detection with coreference prediction (Lee et al., 2017, 2018; Zhang et al., 2018; Grobol, 2019; Kantor and Globerson, 2019), and tend to perform better. Bridging methods can be grouped into: (1) rule-based methods (Hou et al., 2014; Rösiger, 2018b; Rösiger et al., 2018); and (2) machine learning methods (Hou, 2018a,b, 2020; Yu and Poesio, 2020). Rule-based methods have been shown to achieve competitive results on domain-specific corpora, but equally to be domain brittle. Yu and Poesio (2020) jointly trained a model for coreference resolution and bridging by adapting a span ranking method for coreference (Lee et al., 2018; Kantor and Globerson, 2019), achieving good performance over various bridging corpora. However, they evaluated their model only on bridging.

3 Annotation Scheme

In this section, we introduce our annotation guidelines for anaphora resolution in chemical patents. The complete annotation guidelines are made available at Fang et al. (2021).

3.1 Corpus Selection

We build on the ChEMU corpus (Verspoor et al., 2020) developed for the ChEMU 2020 shared task (He et al., 2020). This corpus consists of 'snippets' extracted from chemical patents, where each snippet corresponds to a reaction description. It is common that several snippets are extracted from the same chemical patent.

3.2 Mention Type

We aim to capture anaphora in chemical patents, with a focus on identifying chemical compounds during the reaction process. Consistent with other anaphora corpora (Pradhan et al., 2012; Cohen et al., 2017; Ghaddar and Langlais, 2016b), only mentions that are involved in referring relationships (as defined in Section 3.3) and related to chemical compounds are annotated. The mention types that are considered for anaphora annotation are listed below.

It should be noted that verbs (e.g. *mix*, *purify*, *distil*) and descriptions that refer to events (e.g. *the same process*, *step 5*) are not annotated in this corpus.

Chemical Names: Chemical names are a critical component of chemical patents. We capture as atomic mentions the formal name of chemical compounds, e.g. *N-[4-(benzoxazol-2-yl)-methoxyphenyl]-S-methyl-N'-phenyl-isothiourea* or *2-Chloro-4-hydroxy-phenylboronic acid*. Chemical names often include nested chemical components, but for the purposes of our corpus, we consider chemical names to be atomic and don't annotate internal mentions. Hence *4-(benzoxazol-2-yl)-methoxyphenyl* and *acid* in the examples above will not be annotated as mentions, as they are part of larger chemical names.

Identifiers: In chemical patents, identifiers or labels may also be used to represent chemical compounds, in the form of uniquely-identifying sequences of numbers and letters such as *5i*. These can be abbreviations of longer expressions incorporating that identifier that occur earlier in the text, such as *chemical compound 5i*, or may refer back to an exact chemical name with that identifier. Thus, the identifier is annotated as an atomic mention as well.

Phrases and Noun Types: Apart from chemical names and identifiers, chemical compounds are commonly presented as noun phrases (NPs). An NP consists of a noun or pronoun, and premodifiers; NPs are the most common type of compound expressions in chemical patents. Here we detail NPs that are related to compounds:

- Pronouns: In chemical patents, pronouns (e.g. *they* or *it*) usually refer to a previously-mentioned chemical compounds.
- Definite NPs: Commonly used to refer to chemical compounds, e.g. *the solvent*, *the title compound*, *the mixture*.

Furthermore, there are a few types of NPs that need specific handling in chemical patents:

- Quantified NPs: Chemical compounds are usually described with a quantity. NPs with quantities are considered as atomic mentions if the quantities are provided, e.g. *398.4 mg of the compound 1*.
- NPs with prepositions: Chemical NPs connected with prepositions (e.g. *in*, *with*, *of*) should be considered as a single mention. For example, *the appropriate amino derivative in dry THF* is a single mention.

NPs describing chemical equipment containing a compound may also be relevant to anaphora resolution. This generally occurs when the equipment that contains the compound undergoes a process that also affects the compound. Thus, mentions such as *the flask* and *the autoclave* can also be mentions if they are used to implicitly refer to a contained compound.

Unlike many annotation schemes, our annotation allows discontinuous mentions. For example, the underlined spans of the fragment *114 mg of 4-((4aS,7aS)-6-benzyloctahydro-1-pyrrolo[3,4-b]pyridine-1-yl)-7H-pyrrolo[2,3-d]pyrimidine was obtained with a yield of about 99.1%* are treated as a single discontinuous mention. This introduces further complexity into the task and helps to capture more comprehensive anaphora phenomena.

Relationship to ChEMU 2020 entities: Since this dataset is built on the ChEMU 2020 corpus (He et al., 2020), annotation of related chemical compounds is available by leveraging existing entity annotations introduced for the ChEMU 2020 named entity recognition (NER) task. However, there are some differences in the definitions of entities for the two tasks.

In the original ChEMU 2020 corpus, entity annotations identify chemical compounds (i.e. *REACTION_PRODUCT*, *STARTING_MATERIAL*, *REAGENT_CATALYST*, *SOLVENT*, and *OTHER_COMPOUND*), reaction conditions (i.e. *TIME*, *TEMPERATURE*), quantity information (i.e. *YIELD_PERCENT*, *YIELD_OTHER*), and example labels (i.e. *EXAMPLE_LABEL*). There is overlap with our definition of mention for the labels relating to chemical compounds. However, in our annotation, chemical names are annotated along with additional quantity information, as we consider this information to be an integral part of the chemical compound description. Furthermore, the original entity annotations do not include generic expressions that co-refer with chemical compounds such as *the mixture*, *the organic layer*, or *the filtrate*, and neither do they include equipment descriptions.

3.3 Relation Types

Anaphora resolution subsumes both coreference and bridging. In the context of chemical patents, we define four sub-types of bridging, incorporating generic and chemical knowledge.

A referring mention which cannot be interpreted on its own, or an indirect mention, is called an *anaphor*, and the mention which it refers back to is called the *antecedent*. In relation annotation, we preserve the direction of the anaphoric relation, from the anaphor to the antecedent. Following similar assumptions in recent work, we restrict annotations to cases where the antecedent appears earlier in the text than the anaphor.

3.3.1 Coreference

Coreference is defined as expressions/mentions that refer to the same entity (Ng, 2017; Clark and Manning, 2015). In chemistry, identifying whether two mentions refer to the same entity needs to consider various chemical properties (e.g. temperature or pH). As such, for two mentions to be coreferent, they must share the same chemical properties. We consider two different cases of coreference:

- **Single Antecedents:** the anaphor refers to a single antecedent.
- **Multiple Antecedents:** the anaphor refers to multiple antecedents, e.g. in cases where multiple antecedents are combined to form a single *mixture*.

It is possible for there to be ambiguity as to which mention of a given antecedent an anaphor refers to (where the mention is repeated); in these cases the closest mention is selected.

3.3.2 Bridging

As stated in Section 3.3.1, when we consider the anaphora relations, we take the chemical properties of the mention into consideration. Coreference is insufficient to cover all instances of anaphora in chemical patents, and bridging occurs frequently. We define four bridging types:

TRANSFORMED: Links between chemical compounds that are initially based on the same components, but which have undergone a change in condition, such as pH or temperature. Such cases must be one-to-one relations (not one-to-many). As shown in Figure 1, the *mixture* in line 2 and the first-mentioned *mixture* in line 3 have the TRANSFORMED relation, as they have the same chemical components but different chemical properties.

REACTION-ASSOCIATED: The relationship between a chemical compound and its immediate source compounds is via a mixing process, where the source compounds retain their original chemical structure. This relation is one-to-many from the anaphor to the source compounds (antecedents). For example, the *mixture* in line 2 has REACTION-ASSOCIATED links to three mentions on line 1 that are combined to form it: (1) *the solution of Compound (4) (0.815 g, 1.30 mmol) in THF (4.9 ml)*; (2) *acetic acid (9.8 ml)*; and (3) *water (4.9 ml)*).

WORK-UP: Chemical compounds are used to isolate or purify an associated output product, in a

	Train	Dev	Test

TR	85	17	29
RA	515	105	167
WU	1,063	172	364
CT	68	29	17

Table 1: Corpus annotation statistics. "Dis. Mentions" means discontinuous mentions. "Coref.", "TR", "RA", "WU", and "CT" denote COREFERENCE, TRANSFORMED, REACTION-ASSOCIATED, WORK-UP and CONTAINED, respectively. "Bridging" is the total across all bridging relations.

one-to-many relation, from the anaphor to the compounds (antecedents) that are used for the work-up process. As demonstrated in Figure 1, *The combined organic layer* in line 5 comes from the extraction of *The mixture* and *ethyl acetate* in line 4, and they are hence annotated as WORK-UP.

CONTAINED: A chemical compound is contained inside some equipment. It is a one-to-many relation from the anaphor (equipment) to the compounds (antecedents) that it contains. An example of this is *a flask* and *the solution of Compound (4) (0.815 g, 1.30 mmol) in THF (4.9 ml)* on line 1, where the compound is contained in the flask.

4 Task definition

Anaphora resolution can be decomposed into a two-step task: (1) mention detection; and (2) anaphora relation detection.

For the evaluation of mention and relation detection, we use precision, recall and F1. One issue here is that, for coreference resolution, anaphors can link to multiple antecedents. Many coreference evaluation metrics (Moosavi and Strube, 2016; Recasens and Hovy, 2011; Luo, 2005) cannot deal with this since they model coreference resolution as a clustering task, where all related antecedents and anaphors occur in one cluster, and assume a given mention occurs in a unique cluster. Hence we adopt the approach to evaluation of Kim et al. (2012), scoring coreference from two perspectives: (1) *surface coreference*; and (2) *atom coreference*. Surface coreference considers whether the anaphor refers to the closest previous antecedent(s). Atom coreference considers whether the anaphor refers to the correct antecedent(s). Atom coreference links take the coreferent transitivity into consideration and can be generated from surface coreference links, which we use by default.

For the corpus annotation, we use the BRAT text annotation tool.[2] To date, 220 snippets have been annotated by two chemical experts, a PhD candidate and a final year bachelor student in Chemistry. Four rounds of annotation training were completed prior to beginning official annotation. In each round, the two annotators individually annotated the same 10 snippets (different across each round of annotation), and compared their annotations; annotation guidelines were then refined based on discussion. After several rounds of training, we achieved a high inner-annotator agreement of Krippendorff's $\alpha = 0.92$ (Krippendorff, 2004) at the mention level,[3] and $\alpha = 0.84$ for relations. In total, 1,500 snippets will be annotated in the final dataset that will be used in the ChEMU 2021 shared task.

The statistics of the current corpus, and train/dev/test set splits that form the basis of our experiments in this paper, are shown in Table 1. The dev and test partitions were both double annotated by the two expert annotators, with any disagreements merged by an adjudicator.

5 Methodology

We propose a joint neural model for anaphora resolution.[4] Similar to Yu and Poesio (2020), our model adopts an end-to-end neural conference resolution (Lee et al., 2017, 2018), as outlined in Figure 2.

Assume the snippet has T tokens represented as vector $X = \{x_1, ..., x_T\}$, consisting of fixed pretrained word and character embeddings learned from a convolution neural network (CNN).

For mention candidate detection, we follow the assumption of Lee et al. (2018), considering continuous tokens as a potential span and computing the span score (s_m) for each possible span. Specifically, span representation s_i is obtained by the concatenation of output token representations (x_i^*) from a bidirectional LSTM (BiLSTM) (Hochreiter and Schmidhuber, 1997), the syntactic head representation (h_i) obtained from an attention mecha-

---

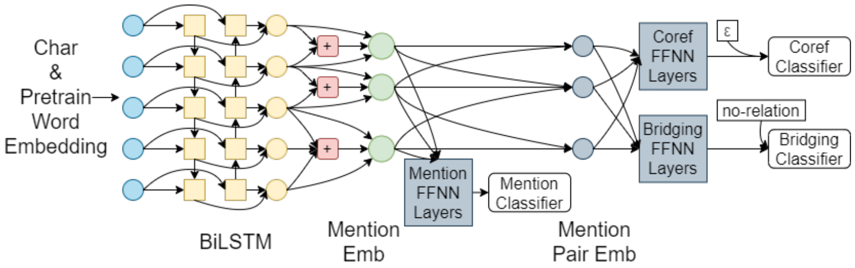

Figure 2: Joint training architecture.

nism (Bahdanau et al., 2015), and a feature vector of the mention ($\phi(i)$):

$$X^* = \text{BiLSTM}(X)$$
$$\alpha_t = w_\alpha \cdot \text{FFNN}_\alpha(x_t^*)$$
$$a_{i,t} = \frac{\exp(\alpha_t)}{\sum_{k=\text{START}(i)}^{\text{END}(i)} \exp(\alpha_k)}$$
$$h_i = \sum_{t=\text{START}(i)}^{\text{END}(i)} a_{i,t} \cdot x_t$$
$$s_i = [x^*_{\text{START}(i)}, x^*_{\text{END}(i)}, h_i, \phi(i)]$$

and the span score $s_m(i)$ is computed as:

$$s_m(i) = w_s \cdot \text{FFNN}_s(s_i)$$

where FFNN denotes a feed-forward neural network, and START(i) and END(i) represent the starting and ending token index for span i, respectively. To reduce the number of spans considered, we use a beam of λT candidate mention spans.

Inspired by Zhang et al. (2018), the mention loss is defined as:

$$L_{mention} = -\sum_{i=1}^{\lambda T} m_i * \log(\text{sigmoid}(s_m(i))) + (1 - m_i) * \log(1 - \text{sigmoid}(s_m(i)))$$

where:

$$m_i = \begin{cases} 0 & \text{span } i \notin \text{GOLD}_m \\ 1 & \text{span } i \in \text{GOLD}_m \end{cases}$$

GOLD_m is the set of gold mentions that are involved in anaphora relations.

For anaphoric relation detection, a span pair embedding is obtained by the concatenation of each span embedding ($s_m(i), s_m(j)$) and the element-wise multiplication of the span embeddings ($s_m(i) \circ s_m(j)$) and a feature vector ($\phi(i,j)$) for span pair i and j:

$$s_{i,j} = [s_m(i), s_m(j), s_m(i) \circ s_m(j), \phi(i,j)]$$

As coreference and bridging are different, we consider them separately.

For coreference resolution, we follow Lee et al. (2018) in optimizing the marginal log-likelihood of all correct antecedents for a given anaphor:

$$L_{coref} = \log \prod_{i=1}^{N} \sum_{\hat{y} \in Y(i) \bigcap \text{GOLD}_c(i)} P(\hat{y})$$

where N is the number of candidate mentions; and $Y(i) = \{\epsilon, 1, ..., i-1\}$ is the set of possible assignments for each y_i, which ϵ represents a dummy antecedent and the numbers represent the proceeding spans. $\text{GOLD}_c(i)$ is the gold coreferent antecedents that span i refers to. If span i doesn't have a coreferent antecedent, $\text{GOLD}_c(i) = \epsilon$. $P(y_i)$ is obtained via softmax over the antecedent scores s_c for the corresponding anaphor:

$$s_c(i,j) = \begin{cases} 0 & j = \epsilon \\ w_c \cdot \text{FFNN}_c(s_{i,j}) & j \neq \epsilon \end{cases}$$

For bridging resolution, as we have four relations, we model it as a multiclass classification task for each span pair. We represent the bridging relation as a one-hot representation and introduce a new relation type NO-RELATION for span pairs that do not have a bridging relation. The loss for bridging is:

$$y_b(i,j) = \text{softmax}(w_b \cdot \text{FFNN}_b(s_{i,j}))$$
$$L_{bridging} = -\sum_{c=1}^{K_c} \sum_{i=1}^{N} \sum_{j=1}^{i} b_{i,j,c} \log(y_b(i,j,c))$$

where K_c represents the number of bridging categories, $y_b(i,j,c)$ denotes the prediction of $y_b(i,j)$ under category c, and:

$$b_{i,j,c} = \begin{cases} 0 & \text{span pair}(i,j) \notin \text{GOLD}_b(c) \\ 1 & \text{span pair}(i,j) \in \text{GOLD}_b(c) \end{cases}$$

where $\text{GOLD}_b(c)$ is the gold bridging relation under category c.

Relation	Method	P_A	R_A	F_A	P_R	R_R	F_R

Overall	joint_train	89.5	70.6	78.9	77.5	61.6	68.6

Table 2: Anaphora resolution results over the test dataset (%). Models are trained for "coreference", "bridging" or "joint_train" (both tasks jointly). Models were trained over 10,000 epochs, and averaged over 3 runs with different random seeds. "F_A" and "F_R" denote the F1 score for anaphor and relation prediction, respectively.

The total loss is $L = L_{mention} + L_{ref}$, where:

$$L_{ref} = \begin{cases} L_{coref} & \text{for coreference} \\ L_{bridging} & \text{for bridging} \\ L_{coref} + L_{bridging} & \text{for joint training} \end{cases}$$

6 Experiments

In this section, we detail our experiments. We use similar hyperparameters to Lee et al. (2018). Specifically, we use GloVe embeddings (Pennington et al., 2014) with window size=2 for head word embeddings. For BiLSTM, GloVe embeddings with window size=10 and contextualized ELMo word representations (Peters et al., 2018) are used. Character embeddings are learned from a character CNN with windows of 3, 4, and 5 characters, each with 50 filters. For bridging prediction, the feed-forward neural networks are composed of two hidden layers with 150 dimensions and rectified linear units (Nair and Hinton, 2010).

We separate the gold mentions into those for coreference and bridging. For joint training, the gold mentions are combined.

Table 2 presents the results. For coreference evaluation, given that the results in Table 2 indicate that the surface and atom coreference results are not substantially different, we use surface coreference as our primary evaluation metric in the remainder of this paper. For bridging evaluation, we consider the overall bridging result as our primary analysis.

Overall, the joint training configuration achieves 54.2% F_1 score for coreference resolution and 71.1% F_1 score for bridging, representing +0.8% and +1.2% F_1 score absolute improvement over the component-wise models. This indicates that joint training improves the performance of both tasks. Compared to bridging, the performance of anaphor detection in coreference resolution is lower, particularly in terms of recall, possibly because the data is sparser.

Relation	Method	F_A	F_R
Coref.	coreference	62.9	53.4
	- w/ oracle mentions	81.7	79.2
	joint_train	60.5	54.2
	- w/ oracle mentions	79.5	74.9
Bridging	bridging	84.5	70.3
	- w/ oracle mentions	91.9	83.3
	joint_train	85.5	71.1
	- w/ oracle mentions	91.8	83.5
Overall	joint_train	78.9	68.6
	- w/ oracle mentions	88.3	82.1

Table 3: Comparisons with providing oracle mention during training; results on test dataset, using surface scoring for coreference. "F_A"= F1 for anaphor prediction; "F_R"= F1 for relation prediction.

To investigate the contribution of each step (mention detection vs. relation detection), we experiment with providing oracle mentions during the training process. Table 3 shows that the performance of both tasks improves substantially with gold mentions. We achieve 82.1% F_1 score for relation prediction result under joint training, with +13.5% F_1 absolute score improvement. That is, further improvement at mention detection will improve resolution results.

Relation	Method	F_A	F_R
Coref.	coreference	62.9	53.4
	- w/ ChELMo	65.3	56.9
	joint_train	60.5	54.2
	- w/ ChELMo	64.4	58.3
Bridging	bridging	84.5	70.3
	- w/ ChELMo	87.8	74.8
	joint_train	85.5	71.1
	- w/ ChELMo	88.7	75.6
Overall	joint_train	78.9	68.6
	- w/ ChELMo	82.2	73.1

Table 4: Comparison of different pretrained embeddings; results over test dataset, using surface scoring for coreference. "F_A"= F1 for anaphor prediction; "F_R"= F1 for relation prediction.

To determine the importance of domain fine-tuning, we also experiment with an ELMo model pretrained on a 1 billion word chemical patent corpus (Zhai et al., 2019), referred to as ChELMo. The experimental results are provided in Table 4. With ChELMo, the performance of anaphor detection and relation detection improve by +3.3% and +4.5% absolute F_1 score, respectively.

We also plot model performance with increasing amounts of training data in Figure 3. While the model performance is starting to plateau, potential gains could be attained with more annotated data. The strong correlation between anaphor detection and relation detection is also self-evident in the graph.

To perform error analysis, we analysed the model errors on the dev dataset. As detailed in Table 1, the corpus contains discontinuous mentions. However, our proposed model only considers continuous spans, accounting for some of the low recall.

For coreference resolution, errors can be attributed to three primary phenomena:

1. **Long-distance relations**: as illustrated in Table 5 Ex 1, *the title compound (360 mg, 1.05 mmol, 32%)* refers to a compound at the beginning of the snippet; the model generally fails to capture such long-distance relations.

2. **Multiple antecedents**: as discussed in Section 3.3.1, an anaphor may have multiple antecedents, however the models predict a single antecedent for each anaphor.

3. **Imbalance of coreference and bridging relations**: bridging is more prevalent than coreference, meaning the model has more difficulty with coreference.

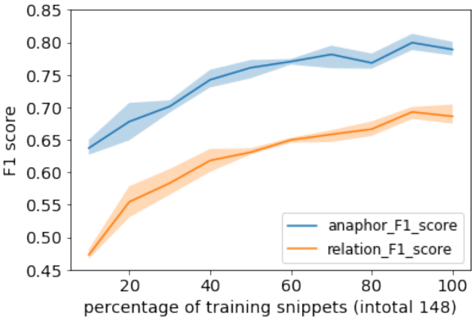

Figure 3: Joint training configuration performance on test dataset over different % of training dataset.

	No-relation	TR	RA	WU	CT
No-relation	0	1	39	27	3
TR	4	11	2	0	0
RA	47	3	54	1	0
WU	49	2	1	120	0
CT	9	0	0	0	20

Figure 4: Confusion matrix of bridging relation detection on dev dataset with joint training configuration

For bridging, as shown in Table 2, the performance suffers from low recall in anaphor detection. Furthermore, the confusion matrix of fine-grained bridging relations in Figure 4 shows that the model achieves poor performance for REACTION-ASSOCIATED and WORK-UP relation prediction, both in terms of precision and recall.

We further investigated the over-prediction problem in bridging. As shown in Table 5 Ex 2, *the reaction mixture* in line 3 has a RELATION-ASSOCIATED link with *The reaction mixture* in line 2 and *sodium borohydride (10 mg, 0.27 mmol)*. The model overpredicts additional links to the two additional compounds that are linked to the previous mention of *The reaction mixture* in line 2. The WORK-UP relation in Ex 5 is similar: the second-mentioned *the organic layer* links to the first-mentioned *the organic layer* and *magnesium sulfate*. *The filtered material*, *chloroform* and *water* should be linked with the first-mentioned *the organic layer*, but are linked to the second. Such errors result from individual span-pair predictions, making it hard to capture interactions between anaphors. Evaluating the antecedents simultane-

1	Step D: Ethyl 7-chloro-6-(difluoromethyl)-2-(trifluoromethyl)pyrazolo[1,5 -a]pyridine-3-carboxylate . ... Purification (FCC, SiO2, eluting with n-hexane:dichloromethane (2:1)) afforded the title compound (360 mg, 1.05 mmol, 32%) .
2	... to a suspension of methyl 5-bromo-6-methoxypicolinate (20 mg, 0.079 mmol) (Ark Pharm) in ethanol (0.25 mL) was added sodium borohydride (9.6 mg, 0.25 mmol) . The reaction mixture was then heated at 50^{o}C. for 2.5 h. An additional portion of sodium borohydride (10 mg, 0.27 mmol) was added, and the reaction mixture was heated at 50^{o}C. for an additional 2 h...
3	... after 55.8 mg of 6-chloro-7-deazapurine and 191 mg of potassium carbonate were sequentially added into the reaction mixture , the reaction mixture was refluxed for about 36 hours and then cooled down at room temperature...
4	... In the same manner as in Synthesis Example 8 except for using 2.11 g of the intermediate 6 in place of the intermediate 21 and using 1.00 g of 4-bromobiphenyl in place of bromobenzene, 1.49 g (yield: 56%) of a white solid was obtained.,.
5	... The filtered material was extracted with chloroform and water , and then the organic layer was dried by using magnesium sulfate . Thereafter, the organic layer was distilled under reduced pressure...
6	... acetonitrile (150 mL) was added under ultrasonic to get a large amount of with precipitate . After suck filtration, the filter cake was washed with acetonitrile (20 mLx3) , dried in vacuum to obtain the title compound (1.52 g, 86.9 %) .

Table 5: Examples of anaphora phenomena from the dev dataset.

ously may address this.

There is room for improvement in our model's ability to model context. In Table 5 Ex 3, due to the expression *add into*, the first-mentioned *the reaction mixture* does not include the chemicals mentioned prior, unlike the first mention of the phrase in Ex 2.

There are several causes of false negatives:

1. **Reaction description variation:** Chemical reactions are usually described step by step, and our model performs well in this structure. However, only part of a reaction may be described. Table 5 Ex 4 illustrates chemical compounds that are listed without a process.

2. **Abstract expressions:** In Table 5 Ex 6, *precipitate* should have a WORK-UP relation with *acetonitrile (150 mL)*, and *the title compound* ... with *the filter cake*; these are missed due to inadequate modelling of domain terminology.

7 Conclusion

We propose a novel annotation scheme for anaphora resolution in chemical patents. For our annotation, we incorporate generic and domain-specific knowledge to define coreference and bridging specific to the chemical domain, based on which we created the novel ChEMU-Ref dataset. Our corpus analysis and inner-annotator agreement show the complexity of the task, as well as the high quality of annotation. We model anaphora resolution as two sub-tasks, mention detection and anaphora relation detection, and also propose a joint training model, which outperforms the separately-trained models. By incorporating embeddings pretrained on the chemical domain, we found that domain knowledge boosts performance. With detailed error analysis, we also identified directions to further enhance performance.

Acknowledgements

Funding for the ChEMU project is provided by an Australian Research Council Linkage Project, project number LP160101469, and Elsevier. A graduate research scholarship is provided by Melbourne School of Engineering to Biaoyan Fang. We would also like to thank Dr. Meladel Mistica and our two chemical expert annotators Colleen Yeow Hui Shiuan and Sacha Novakovic for their contributions to refining the annotation guidelines.

Abstract

Standard models for syntactic dependency parsing take words to be the elementary units that enter into dependency relations. In this paper, we investigate whether there are any benefits from enriching these models with the more abstract notion of nucleus proposed by Tesnière. We do this by showing how the concept of nucleus can be defined in the framework of Universal Dependencies and how we can use composition functions to make a transition-based dependency parser aware of this concept. Experiments on 12 languages show that nucleus composition gives small but significant improvements in parsing accuracy. Further analysis reveals that the improvement mainly concerns a small number of dependency relations, including nominal modifiers, relations of coordination, main predicates, and direct objects.

1 Introduction

A syntactic dependency tree consists of directed arcs, representing syntactic relations like subject and object, connecting a set of nodes, representing the elementary syntactic units of a sentence. In contemporary dependency parsing, it is generally assumed that the elementary units are word forms or tokens, produced by a tokenizer or word segmenter. A consequence of this assumption is that the shape and size of dependency trees will vary systematically across languages. In particular, morphologically rich languages will typically have fewer elementary units and fewer relations than more analytical languages, which use independent function words instead of morphological inflection to encode grammatical information. This is illustrated in Figure 1, which contrasts two equivalent sentences in English and Finnish, annotated with dependency trees following the guidelines of Universal Dependencies (UD) (Nivre et al., 2016, 2020), which assume words as elementary units.

An alternative view, found in the seminal work of Tesnière (1959), is that dependency relations hold between slightly more complex units called *nuclei*, semantically independent units consisting of a content word together with its grammatical markers, regardless of whether the latter are realized as independent words or not. Thus, a nucleus will often correspond to a single word – as in the English verb *chased*, where tense is realized solely through morphological inflection – but it may also correspond to several words – as in the English verb group *has chased*, where tense is realized by morphological inflection in combination with an auxiliary verb. The latter type is known as a *dissociated nucleus*. If we assume that the elementary syntactic units of a dependency tree are nuclei rather than word forms, then the English and Finnish sentences will have the same dependency trees, visualized in Figure 2, and will differ only in the realization of their nuclei. In particular, while nominal nuclei in Finnish are consistently realized as single nouns inflected for case, the nominal nuclei in English involve standalone articles and the preposition *from*.

In this paper, we set out to investigate whether research on dependency parsing can benefit from making explicit use of Tesnière's notion of nucleus, from the point of view of accuracy, interpretability and evaluation. We do this from a multilingual perspective, because it is likely that the effects of introducing nuclei will be different in different languages, and we strongly believe that a comparison between different languages is necessary in order to assess the potential usefulness of this notion. We are certainly not the first to propose that Tesnière's notion of nucleus can be useful in parsing. One of the earliest formalizations of dependency grammar for the purpose of statistical parsing, that of Samuelsson (2000), had this notion at its core, and Sangati and Mazza (2009) presented a conversion of the Penn Treebank of English to Tesnière style

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1376–1387
April 19 - 23, 2021.

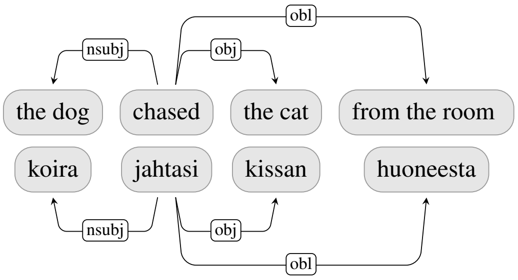

Figure 2: Nucleus-based dependency trees for equivalent sentences from English (top) and Finnish (bottom).

representations, including nuclei. However, previous attempts have been hampered by the lack of available parsers and resources to test this hypothesis on a large scale. Thus, the model of Samuelsson (2000) was never implemented, and the treebank conversion of Sangati and Mazza (2009) is available only for English and in a format that no existing dependency parser can handle. We propose to overcome these obstacles in two ways. On the resource side, we will rely on UD treebanks and exploit the fact that, although the annotation is word-based, the guidelines prioritize dependency relations between content words that are the cores of syntactic nuclei, which facilitates the recognition of dissociated nuclei and gives us access to annotated resources for a wide range of languages. On the parsing side, we will follow a transition-based approach, which can relatively easily be extended to include operations that create representations of syntactic nuclei, as previously shown by de Lhoneux et al. (2019a), something that is much harder to achieve in a graph-based approach.

2 Related Work

Dependency-based guidelines for syntactic annotation generally discard the nucleus as the basic syntactic unit in favor of the (orthographic) word form, possibly with a few exceptions for fixed multiword expressions. A notable exception is the three-layered annotation scheme of the Prague Dependency Treebank (Hajič et al., 2000), where nucleus-like concepts are captured at the tectogrammatical level according to the Functional Generative Description (Sgall et al., 1986). Bārzdiņš et al. (2007) propose a syntactic analysis model for Latvian based on the x-word concept analogous to the nucleus concept. In this grammar, an x-word acts as a non-terminal symbol in a phrase structure grammar and can appear as a head or dependent in a dependency tree. Nespore et al. (2010) compare this model to the original dependency formalism of Tesnière (1959). Finally, as already mentioned, Sangati and Mazza (2009) develop an algorithm to convert English phrase structure trees to Tesnière style representations.

When it comes to syntactic parsing, Järvinen and Tapanainen (1998) were pioneers in adapting Tesnière's dependency grammar for computational processing. They argue that the nucleus concept is crucial to establish cross-linguistically valid criteria for headedness and that it is not only a syntactic primitive but also the smallest semantic unit in a lexicographical description. As an alternative to the rule-based approach of Järvinen and Tapanainen (1998), Samuelsson (2000) defined a generative statistical model for nucleus-based dependency parsing, which however was never implemented.

The nucleus concept has affinities with the chunk concept found in many approaches to parsing, starting with Abney (1991), who proposed to first find chunks and then dependencies between chunks, an idea that was generalized into cascaded parsing by Buchholz et al. (1999) among others. It is also clearly related to the vibhakti level in the Paninian computation grammar framework (Bharati and Sangal, 1993; Bharati et al., 2009). In a similar vein, Kudo and Matsumoto (2002) use cascaded chunking for dependency parsing of Japanese, Tongchim et al. (2008) show that base-NP chunking can significantly improve the accuracy of dependency parsing for Thai, and Durgar El-Kahlout et al. (2014) show that chunking improves dependency parsing of Turkish. Das et al. (2016) study the importance of chunking in the transfer parsing model between Hindi and Bengali, and Lacroix (2018) show that NP chunks are informative for universal part-of-speech tagging and dependency parsing.

In a more recent study, de Lhoneux et al. (2019b) investigate whether the hidden representations of a neural transition-based dependency parser encodes information about syntactic nuclei, with special reference to verb groups. They find some evidence that this is the case, especially if the parser is equipped with a mechanism for recursive subtree composition of the type first proposed by Stenetorp (2013) and later developed by Dyer et al. (2015) and de Lhoneux et al. (2019a). The idea is to use a composition operator that recursively combines information from subtrees connected by a dependency relation into a representation of the new larger subtree. In this paper, we will exploit variations of this technique to create parser-internal representations of syntactic nuclei, as discussed in Section 4. However, first we need to discuss how to identify nuclei in UD treebanks.

3 Syntactic Nuclei in UD

UD[1] (Nivre et al., 2016, 2020) is an ongoing project aiming to provide cross-linguistically consistent morphosyntactic annotation of many languages around the world. The latest release (v2.7) contains 183 treebanks, representing 104 languages and 20 language families. The syntactic annotation in UD is based on dependencies and the elementary syntactic units are assumed to be words, but the style of the annotation makes it relatively straightforward to identify substructures corresponding to (dissociated) nuclei. More precisely, UD prioritizes direct dependency relations between content words, as opposed to relations being mediated by function words, which has two consequences. First, incoming dependencies always go to the lexical core of a nucleus.[2] Second, function words are normally leaves of the dependency tree, attached to the lexical core with special dependency relations, which we refer to as functional relations.[3]

Figure 3 illustrates these properties of UD representations by showing the dependency tree for the English sentence *This killing of a respected cleric will be causing us trouble for years to come* with functional relations drawn below the sentence and other relations above. Given this type of representation, we can define a *nucleus* as a subtree where all internal dependencies are functional relations, as indicated by the ovals in Figure 3. The nuclei can be divided into single-word nuclei, whitened, and dissociated nuclei, grayed. The latter can be contiguous or discontiguous, as shown by the nucleus *of a cleric*, which consists of the two parts colored with a darker shade.

This definition of nucleus in turn depends on what we define to be functional relations. For this study, we assume that the following 7 UD relations[4] belong to this class:

- Determiner (*det*): the relation between a determiner, mostly an article or demonstrative, and a noun. Especially for articles, there is considerable cross-linguistic variation. For example, definiteness is expressed by an independent function word in English (*the girl*), by a morphological inflection in Swedish (*flicka-n*), and not at all in Finnish.
- Case marker (*case*): the relation between a noun and a case marker when it is a separate syntactic word and not an affix. UD takes a radical approach to adpositions and treats them all as case markers. Thus, in Figure 1, we see that the English adposition *from* corresponds to the Finnish elative case inflection.
- Classifier (*clf*): the relation between a classifier, a counting unit used for conceptual classification of nouns, and a noun. This relation is seen in languages which have a classification system such as Chinese. For example, English *three students* corresponds to Chinese 三个学生, literally “three [human-classifier] student”.
- Auxiliary (*aux*): the relation between an auxiliary verb or nonverbal TAME marker and a verbal predicate. An example is the English verb group *will be causing* in Figure 3, which

---

[2] Except in some cases of ellipsis, like *she did*, where the auxiliary verb *did* is “promoted” to form a nucleus on its own.

[3] Again, there are a few well-defined exceptions to the rule that function words are leaves, including ellipsis, coordination, and fixed multiword expressions.

[4] A more detailed description of the relations is available in the UD documentation at https://universaldependencies.org.

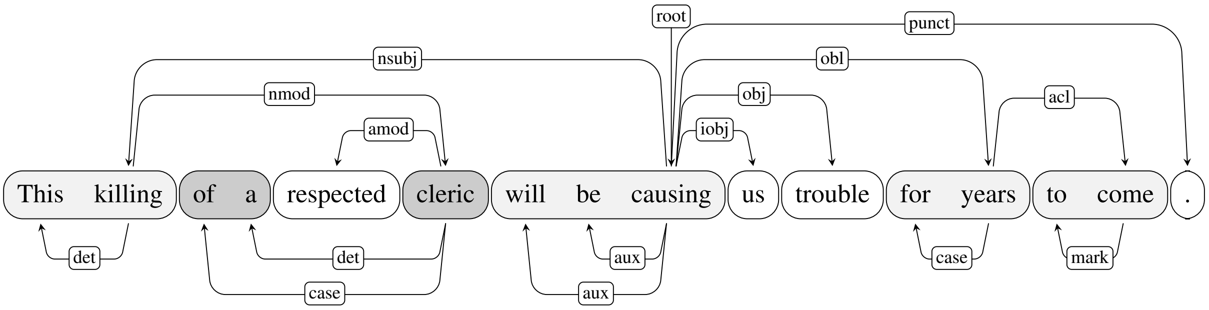

Figure 3: Syntactic UD representation with functional relations drawn below the sentence. Dissociated nuclei are grayed, with a darker shade for the discontiguous nucleus.

alternates with finite main verbs like *causes* and *caused*.

- Copula (*cop*): the relation between a verbal or nonverbal copula and a nonverbal predicate. For example, in English *Ivan is the best dancer*, the copula *is* links the predicate *the best dancer* to *Ivan*, but it has no counterpart in Russian *Ivan lucšĭj tancor*, literally "Ivan best dancer".
- Subordination marker (*mark*): the relation between a subordinator and the predicate of a subordinate clause. This is exemplified by the infinitive marker *to* in Figure 3. Other examples are subordinating conjunctions like *if*, *because* and *that*, the function of which may be encoded morphologically or through word order in other languages.
- Coordinating conjunction (*cc*): the relation between a coordinator and a conjunct (typically the last one) in a coordination. Thus, in *apples, bananas and oranges*, UD treats *and* as a dependent of *oranges*. This linking function may be missing or expressed morphologically in other languages.

The inclusion of the *cc* relation among the nucleus-internal relations is probably the most controversial decision, given that Tesnière treated coordination (including coordinating conjunctions) as a third type of grammatical relation – junction (fr. jonction) – distinct from both dependency relations and nucleus-internal relations. However, we think coordinating conjunctions have enough in common with other function words to be included in this preliminary study and leave further division into finer categories for future work.[5]

Given the definition of nucleus in terms of functional UD relations, it would be straightforward to convert the UD representations to dependency trees where the elementary syntactic units are nuclei rather than words. However, the usefulness of such a resource would currently be limited, given that it would require parsers that can deal with nucleus recognition, either in a preprocessing step or integrated with the construction of dependency trees, and such parsers are not (yet) available. Moreover, evaluation results would not be comparable to previous research. Therefore, we will make use of the nucleus concept in UD in three more indirect ways:

- **Evaluation:** Even if a parser outputs a word-based dependency tree in UD format, we can evaluate its accuracy on nucleus-based parsing by simply not scoring the functional relations. This is equivalent to the Content Labeled Attachment Score (CLAS) previously proposed by Nivre and Fang (2017), and we will use this score as a complement to the standard Labeled Attachment Score (LAS) in our experiments.[6]
- **Nucleus Composition:** Given our definition of nucleus-internal relations, we can make parsers aware of the nucleus concept by differentiating the way they predict and represent dissociated nuclei and dependency structures, respectively. More precisely, we will make use of composition operations to create internal representations of (dissociated) nuclei, as discussed in detail in Section 4 below.
- **Oracle Parsing:** To establish an upper bound on what a nucleus-aware parser can achieve, we will create a version of the UD representation which is still a word-based dependency

---

[5] In addition to separating the *cc* relation from the rest, such a division might include distinguishing nominal nucleus relations (*det*, *case* and *clf*) from predicate nucleus relations (*aux*, *cop* and *mark*).

[6] Our use of CLAS differs only in that we include punctuation in the evaluation, whereas Nivre and Fang (2017) excluded it.

tree, but where nuclei are explicitly represented by letting the word form for each nucleus core be a concatenation of all the word forms that are part of the nucleus.[7] We call this oracle parsing to emphasize that the parser has oracle information about the nuclei of a sentence, although it still has to predict all the syntactic relations.

4 Syntactic Nuclei in Transition-Based Dependency Parsing

A transition-based dependency parser derives a dependency tree from the sequence of words forming a sentence (Yamada and Matsumoto, 2003; Nivre, 2003, 2004). The parser constructs the tree incrementally by applying transitions, or parsing actions, to configurations consisting of a stack S of partially processed words, a buffer B of remaining input words, and a set of dependency arcs A representing the partially constructed dependency tree. The process of parsing starts from an initial configuration and ends when the parser reaches a terminal configuration. The transitions between configurations are predicted by a history-based model that combines information from S, B and A.

For the experiments in this paper, we use a version of the arc-hybrid transition system initially proposed by Kuhlmann et al. (2011), where the initial configuration has all words $w_1, \ldots, w_n$ plus an artificial root node r in B, while S and A are empty.[8] There are four transitions: Shift, Left-Arc, Right-Arc and Swap. Shift pushes the first word b_0 in B onto S (and is not permissible if $b_0 = r$). Left-Arc attaches the top word s_0 in S to b_0 and removes s_0 from S, while Right-Arc attaches s_0 to the next word s_1 in S and removes s_0 from S. Swap, finally, moves s_1 back to B in order to allow the construction of non-projective dependencies.[9]

Our implementation of this transition-based parsing model is based on the influential architecture of Kiperwasser and Goldberg (2016), which takes as input a sequence of vectors $x_1, \ldots, x_n$ representing the input words $w_1, \ldots, w_n$ and feeds these vectors through a BiLSTM that outputs contextualized word vectors $v_1, \ldots, v_n$, which are stored in the buffer B. Parsing is then performed by iteratively applying the transition predicted by an MLP taking as input a small number of contextualized word vectors from the stack S and the buffer B. More precisely, in the experiments reported in this paper, the predictions are based on the two top items s_0 and s_1 in S and the first item b_0 in B. In a historical perspective, this may seem like an overly simplistic prediction model, but recent work has shown that more complex feature vectors are largely superfluous thanks to the BiLSTM encoder (Shi et al., 2017; Falenska and Kuhn, 2019).

The transition-based parser as described so far does not provide any mechanism for modeling the nucleus concept. It is a purely word-based model, where any more complex syntactic structure is represented internally by the contextualized vector of its head word. Specifically, when two substructures h and d are combined in a Left-Arc or Right-Arc transition, only the vector v_h representing the syntactic head is retained in S or B, while the vector v_d representing the syntactic dependent is removed from S. In order to make the parser sensitive to (dissociated) nuclei in its internal representations, we follow de Lhoneux et al. (2019a) and augment the Right-Arc and Left-Arc actions with a composition operation. The idea is that, whenever the substructures h and d are combined with label l, we replace the current representation of h with the output of a function $f(h, d, l)$. We can then control the information flow for nuclei and other constructions through the definition of $f(h, d, l)$.

Hard Composition: The simplest version, which we call *hard* composition, is to explicitly condition the composition on the dependency label l. In this setup, $f(h, d, l)$ combines the head and dependent vectors only if l is a functional relation and simply returns the head vector otherwise:

$$f(h,d,l) = \begin{cases} \vec{h} \circ \vec{d} & \text{if } l \in F \\ \vec{h} & \text{otherwise} \end{cases} \quad (1)$$

We use $\vec{x}$ to denote the vector representation of x[10] and F to denote the set of seven functional relations defined in Section 3. The composition operator $\circ$ can be any function of the form $\mathbb{R}^n \times \mathbb{R}^n \rightarrow$

---

[7] The English sentence in Figure 1 thus becomes: *the dog-the chased the cat-the from the room-the-from*.

[8] Positioning the artificial root node at the end of the buffer is a modification of the original system by Kiperwasser and Goldberg (2016), inspired by the results reported in Ballesteros and Nivre (2013).

[9] This extension of the arc-hybrid system was proposed by de Lhoneux et al. (2017b), inspired by the corresponding extension of the arc-standard system by Nivre (2009).

[10] In the baseline parser, $\vec{h}$ is always identical to the contextualized representation v_h of the head word w_h, but after introducing composition operations we need a more abstract notation.

$\mathbb{R}^n$, e.g., vector addition $\vec{h} + \vec{d}$, where n is the dimensionality of the vector space.

Soft Composition: The *soft* composition is similar to the hard composition, but instead of applying the composition operator to the head and dependent vectors, the operator is applied to the head vector and a vector representation of the entire dependency arc (h, d, l). The vector representation of the dependency arc is trained by a differentiable function g that encodes the dependency label l into a vector $\vec{l}$ and maps the triple $(\vec{h}, \vec{d}, \vec{l})$ to a vector space, i.e., $g : \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n$ where n and m are the dimensionalities of the word and label spaces, respectively. An example of g is a perceptron with a sigmoid activation that maps the vector representations of h, d and l to a vector space:

$$g(h, d, l) = \sigma(W(\vec{h} \odot \vec{d} \odot \vec{l}) + b) \qquad (2)$$

where $\odot$ is the vector concatenation operator. The soft nucleus composition is then:

$$f(h, d, l) = \begin{cases} \vec{h} \circ g(h, d, l), & \text{if } l \in F \\ \vec{h} & \text{otherwise} \end{cases} \qquad (3)$$

The parameters of the function g are trained with the other parameters of the parser.

Generalized Composition: To test our hypothesis that composition is beneficial for dissociated nuclei, we contrast both hard and soft composition to a generalized version of soft composition, where we do not restrict the application to functional relations. In this case, the composition function is:

$$f(h, d, l) = \vec{h} \circ g(h, d, l) \qquad (4)$$

where l can be any dependency label. In this approach, the if-clause in Equation 2 and 3 is eliminated and the parser itself learns in what conditions the composition should be performed. In particular, if the composition operator is addition, and g is a perceptron with a sigmoid activation on the output layer (as in Equation 2), then g operates as a gate that controls the contribution of the dependency elements h, d, and l to the composition. If the composition should not be performed, it returns a vector close to zero.

5 Experiments

In the previous sections, we have shown how syntactic nuclei can be identified in the UD annotation and how transition-based parsers can be made sensitive to these structures in their internal representations through the use of nucleus composition. We now proceed to a set of experiments investigating the impact of nucleus composition on a diverse selection of languages.

5.1 Experimental Settings

We use UUParser (de Lhoneux et al., 2017a; Smith et al., 2018), an evolution of the transition-based dependency parser of Kiperwasser and Goldberg (2016), which was the highest ranked transition-based dependency parser in the CoNLL shared task on universal dependency parsing in 2018 (Zeman et al., 2018). As discussed in Section 4, this is a greedy transition-based parser based on the extended arc-hybrid system of de Lhoneux et al. (2017b). It uses an MLP with one hidden layer to predict transitions between parser configurations, based on vectors representing two items on the stack S and one item in the buffer B. In the baseline model, these items are contextualized word representations produced by a BiLSTM with two hidden layers. The input to the BiLSTM for each word is the concatenation of a randomly initialized word embedding and a character-based representation produced by running a BiLSTM over the character sequence of the word. We use a dimensionality of 100 for the word embedding as well as for the output of the character BiLSTM.

For parsers with composition, we considered various composition operators $\circ$ and functions g. For the former, we tested vector addition, vector concatenation,[11] and perceptron. For the latter we tried a multi-layer perceptron with different activation functions. Based on the results of the preliminary experiments, we selected vector addition for the composition operator $\circ$ and the perceptron with sigmoid activation for the soft composition function g. The inputs to the perceptron consist of two token vectors of size 512 and a relation vector of size 10. The token vectors are the outputs of the BiLSTM layer of the parser and the relation vector is trained by a distinct embedding layer.

All parsers are trained for 50 epochs and all reported results are averaged over 10 runs with different random seeds. Altogether we explore five different parsers:

---

[11] The concatenation operator requires special care to keep vector dimensionality constant. We double the dimensionality of the contextual vectors and fill the extra dimensions with zeros. We then replace the zero part of the second operand with the first operand's non-zero part at composition time.

Table 1: Parsing accuracy for 5 parsing models evaluated on 12 UD treebanks. Language family includes genus according to WALS for large families (AA = Afro-Asian, IE = Indo-European). LAS = Labeled Attachment Score. CLAS = Content Labeled Attachment Score.

- **Base(line):** No composition.
- **Hard:** Baseline + hard composition.
- **Soft:** Baseline + soft composition.
- **Gen(eralized):** Baseline + gen. composition.
- **Ora(cle):** Baseline trained and tested on explicit annotation of nuclei (see Section 3).

Our experiments are carried out on a typologically diverse set of languages with different degrees of morphosyntactic complexity, as shown in Table 1. The corpus size is the total number of words in each treebank. We use UD v2.3 with standard data splits (Nivre et al., 2018). All evaluation results are on the development sets.[12]

5.2 Results

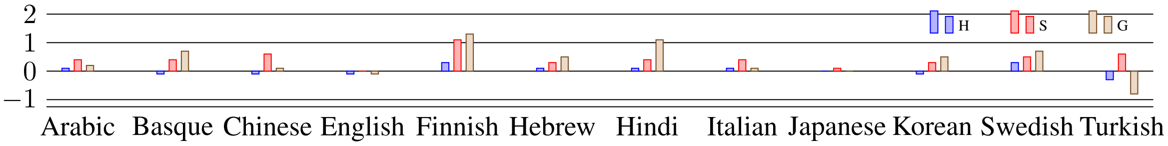
Table 1 reports the parsing accuracy achieved with our 5 parsers on the 12 different languages, using the standard LAS metric as well as the nucleus-aware CLAS metric. First of all, we see that hard composition is not very effective and mostly gives results in line with the baseline parser, except for small improvements for Finnish, Hindi and Swedish and a small degradation for Turkish. These differences are statistically significant for all four languages with respect to LAS but only for Finnish and Turkish with respect to CLAS (two-tailed t-test, $\alpha = .05$). By contrast, soft composition improves accuracy for all languages except English and the improvements are statistically significant for both LAS and CLAS. The average improvement is 0.5 percentage points for both LAS and CLAS, which indicates that most of the improvement occurs on nucleus-external relations thanks to a more effective internal representation of dissociated nuclei. There is some variation across languages, but the CLAS improvement is in the range 0.2–0.7 for most languages, with Finnish as the positive exception (1.1) and English as the negative one (0.0). Generalized composition, finally, where we allow composition also for non-functional relations, yields results very similar to those for soft composition, which could be an indication that the parser learns to apply composition mostly for functional relations. The results are a little less stable, however, with degradations for English and Turkish, and non-significant improvements for Chinese, Italian and Japanese. A tentative conclusion is therefore that composition is most effective when restricted to (but not enforced for) nucleus-internal relations.

Before we try to analyze the results in more detail, it is worth noting that most of the improvements due to composition are far below the improvements of the oracle parser.[13] However, it is important to keep in mind that, whereas the behavior of a composition parser is only affected *after* a nucleus has been constructed, the oracle

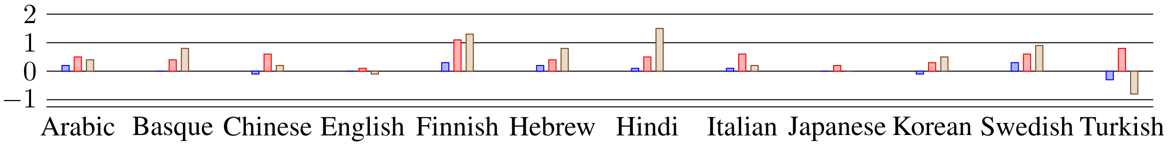
---

[12] Since we want to perform an informative error analysis, we avoid using the dedicated test sets.

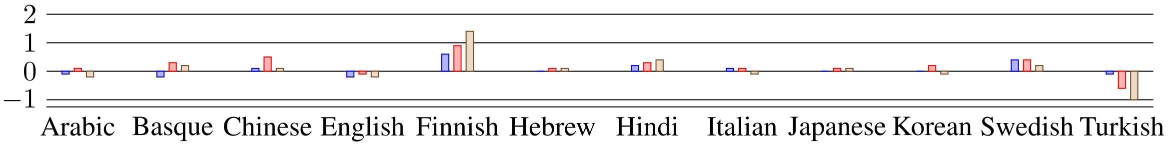
[13] The exception is generalized composition for Hindi, which exceeds the corresponding oracle parser with respect to CLAS.



(a) All relations



(b) Nucleus-external relations



(c) Nucleus-internal relations

Figure 4: Absolute improvement (or degradation) in labeled F-score with respect to the baseline for hard (H), soft (S) and generalized (G) composition for different sets of relations: (a) all relations (corresponding to LAS scores), (b) nucleus-external relations (corresponding to CLAS scores), (c) nucleus-internal relations.

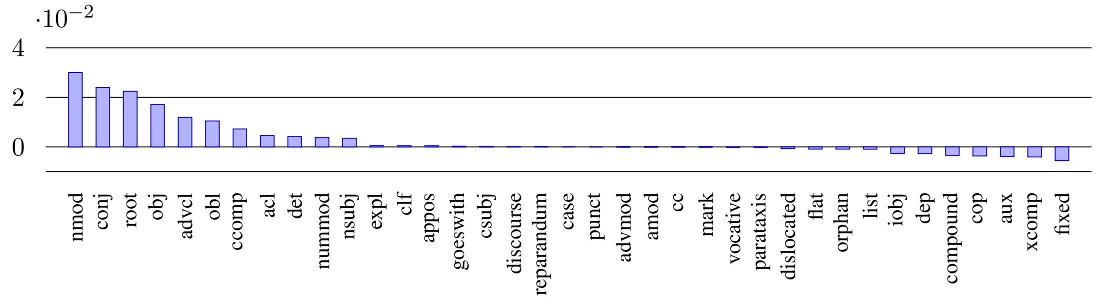


Figure 5: Improvement (or degradation) in labeled F-score with respect to the baseline for different UD relations (soft composition), weighted by the relative frequency of each relation and averaged across all languages.

parser improves also with respect to the prediction of the nuclei themselves. This explains why the oracle parser generally improves more with respect to LAS than CLAS, and sometimes by a substantial margin (2.5 points for Chinese, 1.4 points for Basque and 1.3 points for Swedish).

Figure 4 visualizes the impact of hard, soft and generalized nucleus composition for different languages, with a breakdown into (a) all relations, which corresponds to the difference in LAS compared to the baseline, (b) nucleus-external relations, which corresponds to the difference in CLAS, and (c) nucleus-internal relations. Overall, these graphs are consistent with the hypothesis that using composition to create parser-internal representations of (dissociated) nuclei primarily affects the prediction of nucleus-external relations, as the (a) and (b) graphs are very similar and the (c) graphs mostly show very small differences. There are, however, two notable exceptions. For Finnish, all three composition methods clearly improve the prediction of nucleus-internal relations as well as nucleus-external relations, by over 1 F-score point for generalized composition. Conversely, for Turkish, especially the soft versions of composition has a detrimental effect on the prediction of nucleus-internal relations, reaching 1 F-score point for generalized composition. Turkish is also exceptional in showing opposite effects overall for soft and generalized composition, the former having a positive effect and the latter a negative one, whereas all other languages either show consistent trends or fluctuations around zero. Further research will be needed to explain what causes these deviant patterns.

Figure 5 shows the improvement (or degradation) for individual UD relations, weighted by relative frequency and averaged over all languages, for the best performing soft composition parser.

Finnish		Chinese		Swedish		Turkish		Hindi	
conj	0.09	det	0.03	xcomp	0.07	obj	0.12	obj	0.03
root	0.07	case	0.02	advmod	0.05	conj	0.10	compound	0.02
nmod	0.06	cop	0.01	nmod	0.05	root	0.05	nmod	0.02
obl	0.06	conj	0.01	acl	0.04	acl	0.04	case	0.02
ccomp	0.03	clf	0.01	conj	0.04	nummod	0.03	aux	0.01
acl	0.03	ccomp	0.00	obl	0.04	obl	0.03	det	0.00
obj	0.02	dep	0.00	obj	0.04	nmod	0.01	nummod	0.00
xcomp	0.01	aux	0.00	mark	0.03	ccomp	0.01	amod	0.00
nsubj	0.01	advcl	0.00	nsubj	0.02	det	0.01	advmod	0.00
amod	0.01	cc	0.00	amod	0.02	cc	0.01	advcl	0.00

Table 2: Improvement (or degradation) in labeled F-score, weighted by relative frequency, for the 10 best UD relations in the 5 languages with greatest LAS improvements over the baseline (soft composition).

The most important improvements are observed for *nmod*, *conj*, *root* and *obj*. The *nmod* relation covers all nominal modifiers inside noun phrases, including prepositional phrase modifiers; the *conj* relation holds between conjuncts in a coordination structure; the *root* relation is assigned to the main predicate of a sentence; and *obj* is the direct object relation. In addition, we see smaller improvements for a number of relations, including major clause relations like *advcl* (adverbial clauses), *obl* (oblique modifiers), *ccomp* (complement clauses), and *nsubj* (nominal subjects), as well as noun phrase internal relations like *acl* (adnominal clauses, including relative clauses), *det* (determiner), and *nummod* (numeral modifier). Of these, only *det* is a nucleus-internal relation, so the results further support the hypothesis that richer internal representations of (dissociated) nuclei primarily improve the prediction of nucleus-external dependency relations, especially major clause relations.

It is important to remember that the results in Figure 5 are averaged over all languages and may hide interesting differences between languages. A full investigation of this variation is beyond the scope of this paper, but Table 2 presents a further zoom-in by presenting statistics on the top 10 relations in the 5 languages where LAS improves the most compared to the baseline. To a large extent, we find the same relations as in the aggregated statistics, but there are also interesting language-specific patterns. For Chinese the top three relations (*det*, *case*, *cop*) are all nucleus-internal relations; for Swedish the two top relations are *xcomp* (open clausal complements) and *advmod* (adverbial modifiers), neither of which show positive improvements on average; and for Hindi the *compound* relation shows the second largest improvement. These differences definitely deserve further investigation.

6 Conclusion

We have explored how the concept of syntactic nucleus can be used to enrich the representations of a transition-based dependency parser, relying on UD treebanks for supervision and evaluation in experiments on a wide range of languages. We conclude that the use of composition operations for building internal representations of syntactic nuclei, in particular the technique that we have called soft composition, can lead to small but significant improvements in parsing accuracy for nucleus-external relations, notably for nominal modifiers, relations of coordination, main predicates, and direct objects. In future work we want to study the behavior of different types of nuclei in more detail, in particular how the different internal relations of nominal and verbal nuclei contribute to overall parsing accuracy. We also want to analyze the variation between different languages in more detail and see if it can be explained in terms of typological properties.

Acknowledgments

We thank Daniel Dakota, Artur Kulmizev, Sara Stymne and Gongbo Tang for useful discussions and the EACL reviewers for constructive criticism. We acknowledge the computational resources provided by CSC in Helsinki and Sigma2 in Oslo through NeIC-NLPL (www.nlpl.eu).

Searching for Search Errors in Neural Morphological Inflection

Abstract

Neural sequence-to-sequence models are currently the predominant choice for language generation tasks. Yet, on word-level tasks, exact inference of these models reveals the empty string is often the global optimum. Prior works have speculated this phenomenon is a result of the inadequacy of neural models for language generation. However, in the case of morphological inflection, we find that the empty string is almost never the most probable solution under the model. Further, greedy search often finds the global optimum. These observations suggest that the poor calibration of many neural models may stem from characteristics of a specific subset of tasks rather than general ill-suitedness of such models for language generation.

1 Introduction

Neural sequence-to-sequence models are omnipresent in the field of natural language processing due to their impressive performance. They hold state of the art on a myriad of tasks, e.g., neural machine translation (NMT; Ott et al., 2018b) and abstractive summarization (AS; Lewis et al., 2019). Yet, an undesirable property of these models has been repeatedly observed in word-level tasks: When using beam search as the decoding strategy, increasing the beam width beyond a size of $k = 5$ often leads to a drop in the quality of solutions (Murray and Chiang, 2018; Yang et al., 2018; Cohen and Beck, 2019). Further, in the context of NMT, it has been shown that the empty string is frequently the most-probable solution under the model (Stahlberg and Byrne, 2019). Some suggest this is a manifestation of the general inadequacy of neural models for language generation tasks (Koehn and Knowles, 2017; Kumar and Sarawagi, 2019; Holtzman et al., 2020; Stahlberg, 2020); in this work, we find evidence demonstrating otherwise.

	$k = 1$	$k = 10$	$k = 100$	$k = 500$
NMT	63.1%	46.1%	44.3%	6.4%
MI	0.8%	0.0%	0.0%	0.0%

Table 1: Percentage of search errors—which we define as instances where the search strategy does not find the global optimum under the model—for Transformers trained on IWSLT'14 De-En (NMT) and SIGMORPHON 2020 (Morphological Inflection; MI) when decoding with beam search for varying beam widths (k). MI results are averaged across languages.

Sequence-to-sequence transducers for character-level tasks often follow the architectures of their word-level counterparts (Faruqui et al., 2016; Lee et al., 2017), and have likewise achieved state-of-the-art performance on e.g., morphological inflection generation (Wu et al., 2020) and grapheme-to-phoneme conversion (Yolchuyeva et al., 2019). Given prior findings, we might expect to see the same degenerate behavior in these models—however, we do not. We run a series of experiments on morphological inflection (MI) generators to explore whether neural transducers for this task are similarly poorly calibrated, i.e. are far from the true distribution $p(\mathbf{y} \mid \mathbf{x})$. We evaluate the performance of two character-level sequence-to-sequence transducers using different decoding strategies; our results, previewed in Tab. 1, show that evaluation metrics do not degrade with larger beam sizes as in NMT or AS. Additionally, only in extreme circumstances, e.g., low-resource settings with less than 100 training samples, is the empty string ever the global optimum under the model.

Our findings directly refute the claim that neural architectures are inherently inadequate for modeling language generation tasks. Instead, our results admit two potential causes of the degenerate behavior observed in tasks such as NMT and AS: (1) lack of a deterministic mapping between

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1388–1394
April 19 - 23, 2021.

input and output and (2) a (perhaps irreparable) discrepancy between sample complexity and training resources. Our results alone are not sufficient to accept or reject either hypothesis, and thus we leave these as future research directions.

2 Neural Transducers

Sequence-to-sequence transduction is the transformation of an input sequence into an output sequence. Tasks involving this type of transformation are often framed probabilistically, i.e., we model the *probability* of mapping one sequence to another. On many tasks of this nature, neural sequence-to-sequence models (Sutskever et al., 2014; Bahdanau et al., 2015) hold state of the art.

Formally, a neural sequence-to-sequence model defines a probability distribution $p_{\boldsymbol{\theta}}(\mathbf{y} \,|\, \mathbf{x})$ parameterized by a neural network with a set of learned weights $\boldsymbol{\theta}$ for an input sequence $\mathbf{x} = \langle x_1, x_2, \dots \rangle$ and output sequence $\mathbf{y} = \langle y_1, y_2, \dots \rangle$. Morphological inflection and NMT are two such tasks, wherein our outputs are both strings. Neural sequence-to-sequence models are typically locally normalized, i.e. $p_{\boldsymbol{\theta}}$ factorizes as follows:

$$p_{\boldsymbol{\theta}}(\mathbf{y} \,|\, \mathbf{x}) = \prod_{t=1}^{|\mathbf{y}|} p_{\boldsymbol{\theta}}(y_t \,|\, \mathbf{x}, \mathbf{y}_{<t}) \tag{1}$$

Given a vocabulary $\mathcal{V}$, each conditional $p_{\boldsymbol{\theta}}$ is a distribution over $\mathcal{V} \cup \{\text{EOS}\}$ and $y_0 := \text{BOS}$. We consider $p_{\boldsymbol{\theta}}(\mathbf{y} \mid \mathbf{x})$ to be **well-calibrated** if its probability estimates are representative of the true likelihood that a solution $\mathbf{y}$ is correct.

Morphological Inflection. In the task of morphological inflection, $\mathbf{x}$ is an encoding of the lemma concatenated with a flattened morphosyntactic description (MSD) and $\mathbf{y}$ is the target inflection. As a concrete example, consider inflecting the German word *Bruder* into the genitive plural, as shown in Tab. 2. Then, $\mathbf{x}$ is the string $\langle$`B r u d e r GEN PL`$\rangle$ and $\mathbf{y}$ is the string $\langle$`B r ü d e r`$\rangle$. As this demonstrates, morphological inflection generation is, by its nature, modeled at the character level (Faruqui et al., 2016; Wu and Cotterell, 2019), i.e., our target vocabulary $\mathcal{V}$ is a set of characters in the language. Note that $\mathbf{y} \in \mathcal{V}^*$, but $\mathbf{x} \notin \mathcal{V}^*$ due to the additional encoding of the MSD. This stands in contrast to NMT, which is typically performed on a (sub)word level, making the vocabulary size orders of magnitude larger.

	Singular	Plural
Nominativ	Bruder	Brüder
Genitiv	Bruders	Brüder
Dativ	Bruder	Brüdern
Akkusativ	Bruder	Brüder

Table 2: Inflection table for the German word *Bruder*

Another important differentiating factor of morphological inflection generation in comparison to many other generation tasks in NLP is the one-to-one mapping between source and target.[1] In contrast, there are almost always many correct ways to translate a sentence into another language or to summarize a large piece of text; this characteristic manifests itself in training data where a single phrase has instances of different mappings, making tasks such as translation and summarization inherently ambiguous.

3 Decoding

In the case of probabilistic models, the decoding problem is the search for the most-probable sequence among valid sequences $\mathcal{V}^*$ under the model $p_{\boldsymbol{\theta}}$:

$$\mathbf{y}^\star = \operatorname*{argmax}_{\mathbf{y} \in \mathcal{V}^*} \log p_{\boldsymbol{\theta}}(\mathbf{y} \mid \mathbf{x}) \tag{2}$$

This problem is also known as maximum-a-posteriori (MAP) inference. Decoding is often performed with a heuristic search method such as greedy or beam search (Reddy, 1977), since performing exact search can be computationally expensive, if not impossible.[2] While for a deterministic task, greedy search is optimal under a Bayes optimal model,[3] most text generation tasks benefit from using beam search. However, text quality almost invariably decreases for beam sizes larger than $k = 5$. This phenomenon is sometimes referred to as the **beam search curse**, and has been investigated in detail by a number of scholarly works (Koehn and Knowles, 2017; Murray and Chiang, 2018; Yang et al., 2018; Stahlberg and Byrne, 2019; Cohen and Beck, 2019; Eikema and Aziz, 2020).

---

[1] While there are cases where there exist multiple inflected forms of a lemma, e.g., in English the past tense of *dream* can be realized as either *dreamed* or *dreamt*, these cases (termed “overabundance”) are rare (Thornton, 2019).

[2] The search space is exponential in the sequence length and due to the non-Markov nature of (typical) neural transducers, dynamic-programming techniques are not helpful.

[3] Under such a model, the correct token y_i at time step i will be assigned all probability mass.

	Transformer				HMM			
	$k = 1$	$k = 10$	$k = 100$	Dijkstra	$k = 1$	$k = 10$	$k = 100$	Dijkstra
Overall	90.34%	90.37%	90.37%	90.37%	86.03%	85.62%	85.60%	85.60%
Low-resource	84.10%	84.12%	84.12%	84.12%	70.99%	69.37%	69.31%	69.31%
High-resource	94.05%	94.08%	94.08%	94.08%	93.60%	93.72%	93.72%	93.72%

Table 3: Prediction accuracy (averaged across languages) by decoding strategy for Transformer and HMM. We include breakdown for low-resource and high-resource trained models. k indicates beam width.

Exact decoding can be seen as the case of beam search where the beam size is effectively stretched to infinity.[4] By considering the complete search space, it finds the globally best solution under the model $p_{\boldsymbol{\theta}}$. While, as previously mentioned, exact search can be computationally expensive, we can employ efficient search strategies due to some properties of $p_{\boldsymbol{\theta}}$. Specifically, from Eq. (1), we can see that the scoring function for sequences $\mathbf{y}$ is monotonically decreasing in t. We can therefore find the provably optimal solution with Dijkstra's algorithm (Dijkstra, 1959), which terminates and returns the global optimum the first time it encounters an EOS. Additionally, to prevent a large memory footprint, we can lower-bound the search using any complete hypothesis, e.g., the empty string or a solution found by beam search (Stahlberg and Byrne, 2019; Meister et al., 2020). That is, we can prematurely stop exploring solutions whose scores become less than these hypotheses at any point in time. Although exact search is an exponential-time method in this setting, we see that, in practice, it terminates quickly due to the peakiness of $p_{\boldsymbol{\theta}}$ (see App. A). While the effects of exact decoding and beam search decoding with large beam widths have been explored for a number of word-level tasks (Stahlberg and Byrne, 2019; Cohen and Beck, 2019; Eikema and Aziz, 2020), to the best of our knowledge, they have not yet been explored for any character-level sequence-to-sequence tasks.

4 Experiments

We run a series of experiments using different decoding strategies to generate predictions from morphological inflection generators. We report results for two near-state-of-the-art models: a multilingual Transformer (Wu et al., 2020) and a (neuralized) hidden Markov model (HMM; Wu and Cotterell, 2019). For reproducibility, we mimic their proposed architectures and exactly follow their data pre-processing steps, training strategies and hyper-parameter settings.[5]

	Beam $k{=}1$	**Beam** $k{=}10$	**Optimum**	**Empty String**
Transformer	-0.619	-0.617	-0.617	-6.56
HMM	-1.08	-0.89	-0.80	-20.15

Table 4: Average log probability of inflections generated with various decoding strategies and the empty string (averaged across all languages).

Data. We use the data provided by the SIGMORPHON 2020 shared task (Vylomova et al., 2020), which features lemmas, inflections, and corresponding MSDs in the UniMorph schema (Kirov et al., 2018) in 90 languages in total. The set of languages is typologically diverse (spanning 18 language families) and contains both high- and low-resource examples, providing a spectrum over which we can evaluate model performance. The full dataset statistics can be found on the task homepage.[6] When reporting results, we consider languages with < 1000 and ≥ 10000 training samples as low- and high-resource, respectively.

Decoding Strategies. We decode morphological inflection generators using exact search and beam search for a range of beam widths. We use the SGNMT library for decoding (Stahlberg et al., 2017) albeit adding Dijkstra's algorithm.

4.1 Results

Tab. 3 shows that the accuracy of predictions from neural MI generators generally does not decrease when larger beam sizes are used for decoding; this observation holds for both model architectures. While it may be expected that

---

[4] This interpretation is useful when comparing with beam search with increasing beam widths.

[6] `https://sigmorphon.github.io/sharedtasks/2020/task0/`

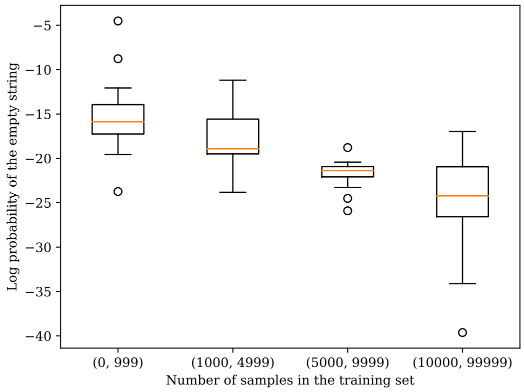

Figure 1: Average (log) probability of the empty string for different training dataset sizes for HMM.

models for low-resource languages generally perform worse than those for high-resource ones, this disparity is only prominent for HMMs, where the difference between high- and low-resource accuracy is $\approx 24\%$ vs. $\approx 10\%$ for the Transformers. Notably, for the HMM, the global optimum under the model is the empty string far more often for low-resource languages than it is for high-resource ones (see Tab. 5). We can explicitly see the inverse relationship between the log-probability of the empty string and resource size in Fig. 1. In general, across models for all 90 languages, the global optimum is rarely the empty string (Tab. 5). Indeed, under the Transformer-based transducer, the empty string was *never* the global optimum. This is in contrast to the findings of Stahlberg and Byrne (2019), who found for word-level NMT that the empty string was the optimal translation in more than 50% of cases, even under state-of-the-art models. Rather, the average log-probabilities of the empty string (which is quite low) and the chosen inflection lie far apart (Tab. 4).

5 Discussion

Our findings admit two potential hypotheses for poor calibration of neural models in certain language generation tasks, a phenomenon we do not observe in morphological inflection. First, the tasks in which we observe this property are ones that lack a deterministic mapping, i.e. tasks for which there may be more than one correct solution for any given input. As a consequence, probability mass may be spread over an arbitrarily large number of hypotheses (Ott et al., 2018a; Eikema and Aziz, 2020). In contrast, the task of morphological inflection has a near-deterministic mapping. We observe this empirically in Tab. 4, which shows that the probability of the global optimum on average covers most of the available probability mass—a phenomenon also observed by Peters and Martins (2019). Further, as shown in Tab. 6, the dearth of search errors even when using greedy search suggests there are rarely competing solutions under the model. We posit it is the lack of ambiguity in morphological inflection that allows for the well-calibrated models we observe.

	HMM	**Transformer**
Overall	2.03%	0%
Low-resource	8.65%	0%
High-resource	0.0002%	0%

Table 5: Average percentage of empty strings when decoding with exact inference for HMM and Transformer, with resource group breakdown.

	$k = 1$	$k = 10$	$k = 100$	$k = 200$
HMM	6.20%	2.33%	0.001%	0.0%
Transformer	0.68%	0.0%	0.0%	0.0%

Table 6: Average percentage of search errors (averaged across languages) for beam search with beam width k.

Second, our experiments contrasting high- and low-resource settings indicate insufficient training data may be the main cause of the poor calibration in sequence-to-sequence models for language generation tasks. We observe that models for MI trained on fewer data typically place more probability mass on the empty string. As an extreme example, we consider the case of the Zarma language, whose training set consists of only 56 samples. Under the HMM, the average log-probability of the generated inflection and empty string are very close (-8.58 and -8.77, respectively). Furthermore, on the test set, the global optimum of the HMM model for Zarma is the empty string 81.25% of the time.

From this example, we can conjecture that lack of sufficient training data may manifest itself as the (relatively) high probability of the empty string or the (relatively) low probability of the optimum. We can extrapolate to models for NMT and other word-level tasks, for which we frequently see the above phenomenon. Specifically, our experiments suggest that when neural language generators frequently place high probability on the empty string, there may be a discrepancy between the available training resources and the number of samples needed to successfully learn the target function. While this at first seems an easy problem to fix, we expect the number of resources needed in tasks such as NMT and AS is much larger than that for MI if not due to the size of the output space alone; perhaps so large that they are essentially unattainable. Under this explanation, for certain tasks, there may not be a straightforward fix to the degenerate behavior observed in some neural language generators.

6 Conclusion

In this work, we investigate whether the poor calibration often seen in sequence-to-sequence models for word-level tasks also occurs in models for morphological inflection. We find that character-level models for morphological inflection are generally well-calibrated, i.e. the probability of the globally best solution is almost invariably much higher than that of the empty string. This suggests the degenerate behavior observed in neural models for certain word-level tasks is not due to the inherent incompatibility of neural models for language generation. Rather, we find evidence that poor calibration may be linked to specific characteristics of a subset of these task, and suggest directions for future exploration of this phenomenon.

Abstract

Much research has reported the training data of summarization models are noisy; summaries often do not reflect what is written in the source texts. We propose an effective method of curriculum learning to train summarization models from such noisy data. Curriculum learning is used to train sequence-to-sequence models with noisy data. In translation tasks, previous research quantified noise of the training data using two models trained with noisy and clean corpora. Because such corpora do not exist in summarization fields, we propose a model that can quantify noise from a single noisy corpus. We conduct experiments on three summarization models; one pretrained model and two non-pretrained models, and verify our method improves the performance. Furthermore, we analyze how different curricula affect the performance of pretrained and non-pretrained summarization models. Our result on human evaluation also shows our method improves the performance of summarization models.

1 Introduction

Sequence-to-sequence models have led to the great advancement of summarization. These models require appropriate pairs of source texts and summaries. However, much research has reported summarization datasets contain inappropriate pairs (Zhang and Tetreault, 2019; Li et al., 2019; Kryscinski et al., 2019; Matsumaru et al., 2020). Sequence-to-sequence summarization models leverage titles as summaries. In theory, summaries should reflect what is written in the source texts, but in fact, the titles can be too general or contain information not written in the source texts. There is a growing need to deal with these noisy datasets.

One way to train with noisy data is curriculum learning (Bengio et al., 2009). Curriculum learning is a method to change the order of training data and improves convergence speed and the performance of models. In translation tasks, previous studies estimate noise of data using likelihoods of two generative models trained with clean and noisy data, and then applied it to curriculum learning (Wang et al., 2018, 2019; Kumar et al., 2019).

Because there is no such datasets in the summarization field, we propose *Appropriateness Estimator*, a noise-estimating model that can be trained from a single noisy corpus. The model distinguishes pairs of a source and target text in the original summarization dataset from randomly assigned pairs. The randomly assigned pairs are clearly inappropriate pairs; the target texts do not reflect the information on the source texts. By distinguishing the obvious inappropriate pairs, the model learns to predict *appropriateness* of data. We apply the appropriateness to curriculum learning; when training a summarization model, we gradually change the training data from inappropriate data to appropriate ones.

We experiment with two datasets; Enron subject dataset (Zhang and Tetreault, 2019), and Reddit TIFU title dataset (Kim et al., 2019). Both have noisy training data, but the Enron dataset has manually cleansed validation and evaluation datasets, whereas the validation and the evaluation datasets of the Reddit dataset are raw datasets that include noise.

As summarization models, we employ BART as a pretrained model, and Transformer and sequence-to-sequence with attention (Seq2seqAtt) as non-pretrained models. The result shows our Appropriateness Estimator improves both pretrained models and non-pretrained models.

Also, we analyze how three different curricula affect the result and conclude training with small fine data in the last phase is important for pretrained models and generalization with various data in the beginning phase is important for non-pretrained

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1395–1405

models. Also, we conduct human evaluation and verify curriculum learning using our Appropriateness Estimator improves the performance of summarization models. The contributions of this paper are as follows.

- We propose *Appropriateness Estimator* that estimates *appropriateness* of source and target texts and that can be trained from a single noisy corpus.
- We conduct experiments on three summarization models: one pretrained model and two non-pretrained models, and verify our method improves the performance of the models.
- We analyze how three different curricula affect the performance of pretrained and non-pretrained summarization models.

2 Related Works

Curriculum learning is a method to change the order of training data to improve convergence speed and accuracy (Bengio et al., 2009). Cirik et al. (2016) applied this to language generation, and introduced two types of curriculum learning: Baby step curriculum and One-Pass curriculum, and concluded the former is more effective to language generation. Many of the later works applied Baby step curriculum to translation tasks (Wang et al., 2019; Zhou et al., 2020), but research of curriculum learning on summarization is yet to be conducted.

Curriculum learning was originally a method to sort training data by difficulty, but recent research proposed methods to sort data by noise. Wang et al. (2018) proposed a method to quantify the noise in data using two models; one trained on clean data and the other on noisy data. Using the same algorithm, Kumar et al. (2019) applied reinforcement learning to choose which subset is most appropriate for training. However, it is not possible to apply this to summarization tasks, because clean and noisy versions of the same corpus are not available.

Sequence-to-sequence summarization models generally use headlines, titles or subjects as summaries. However, it is reported that those datasets are noisy. Zhang and Tetreault (2019) introduced a task to generate subjects of emails, but because the original subjects were noisy, they prepared new validation and evaluation datasets on their own. Li et al. (2019) used rules and a classification model to filter noisy data of review summarization.

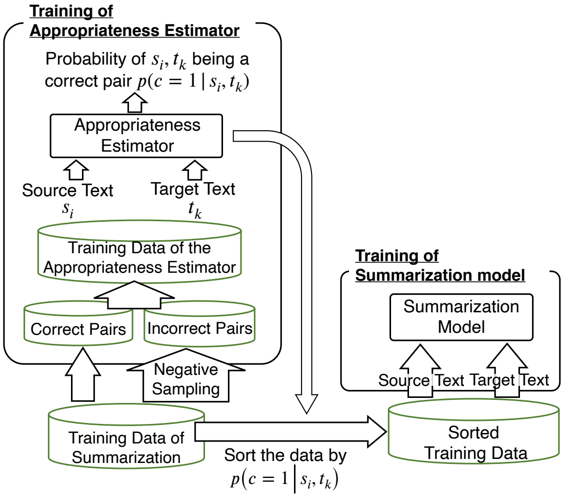

Figure 1: Description of the Appropriateness Estimator.

3 Method

Appropriateness Estimator We propose Appropriateness Estimator, a noise estimator model that can be trained from a single noisy corpus. The overview of the model is described in Figure 1. We label pairs of source and target texts in summarization training data as positive. We assign randomly sampled target texts to source texts and label the pairs as negative. The training task of the model is to predict the labels of the pairs. Pairs in summarization training data are all labeled positive, but as explained in Introduction, it includes inappropriate pairs. Following Li et al. (2020), we conduct early stopping to prevent the model from overfitting to noisy data.

The probability $p(c|s_i, t_k)$ of the model indicates appropriateness of pairs. Here s_i is a source text, and t_k is a target text. c is a binary class; $c = 1$ when the label of a pair is positive, and $c = 0$ otherwise. We sort summarization training data by the appropriateness and conduct curriculum learning.

Curriculum Learning Cirik et al. (2016) introduced two curricula: One-Pass curriculum and Baby step curriculum. The overview of these curricula is described in Figure 2. In both settings, we first sort data by a chosen metric (e.g. appropriateness or target length) in ascending order. Next, we split the data into segments.

One-Pass curriculum starts training from an easiest or noisiest segment and when the model converges, the training data shifts to a next segment. Baby step curriculum gradually increases the amount of training data starting from an easiest or noisiest segment. These two curricula both start training from small amount of data, so there is a risk of overfitting. To overcome this, we propose Noise-Annealing curriculum; we first train a model with all data, and gradually decrease the amount of the training data.

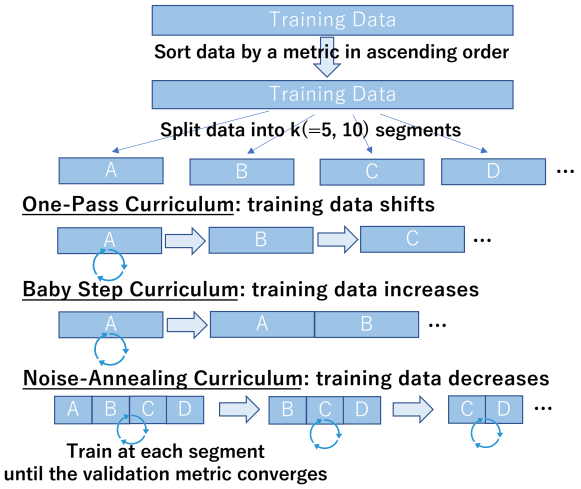

Figure 2: Description of Curriculum Learning.

4 Experiment

Enron Subject Dataset The Enron dataset (Klimt and Yang, 2004) is a collection of email messages of employees in the Enron Corporation. Zhang and Tetreault (2019) organized this data for a subject generation task. However, the original dataset was not clean enough to use for evaluation. Thus, they manually annotated appropriate subjects for validation and evaluation. For training, we have 14,436 subject-email pairs. We have 1,906 and 1,960 data as a validation and an evaluation dataset.

Reddit TIFU Dataset The Reddit TIFU Dataset (Kim et al., 2019) is a dataset of a social media forum, Reddit. TIFU stands for “today i f*** up”; the posts are about the experiences of failure. Here, we use titles of each post as summaries and leverage them for a summarization task. For training, validation, and evaluation datasets, we have 71113, 3951 and 3951 data.

Appropriateness Estimator We employ Decomposable Attention (Parikh et al., 2016) as Appropriateness Estimator. We use GloVe[1] as the initial parameters of word embeddings. The dimensions of the word embeddings and the hidden layers are 300 and 200. The training epoch is 20. We also tried BERT (Devlin et al., 2019); although the result of the classification task was better, the performance was worse when the BERT model was applied to curriculum learning of summarization models. This might be because huge neural network models like BERT can memorize all training data including noise (Zhang et al., 2017). By contrast, smaller models can be robust to noise.

As explained in Introduction and in Section 3, we label randomly assigned pairs of source texts and target texts as negative and actual pairs in summarization datasets as positive. The number of negative pairs is same as the positive pairs. Therefore, the numbers of training, and validation data of Appropriateness Estimator are twice the size of the training/validation data of summarization. We validate with F1 scores and use the model with the highest validation score for curriculum learning. The best validation F1 scores of the models were 0.94 on the Enron dataset, and 0.92 on the Reddit dataset.

Summarization Model We experiment with three summarization models: one pretrained model BART (Lewis et al., 2020), and two non-pretrained models, Transformer (Vaswani et al., 2017) and sequence-to-sequence with attention (Seq2seqAtt) (Rush et al., 2015). The hyperparameters of the models are described in Appendix A.

Changing random seeds, we conduct the same experiments 5 times and use the average values as the result. We evaluate with ROUGE F1 scores (Lin, 2004). We validate at every epoch of each segment. As the validation metric we use F1 score of ROUGE-1 (ROUGE-1-F).

Curriculum Learning We experiment in four settings; three types of curriculum described in Section 3 and one without curriculum learning. As the number of segments, we conduct experiments on 5 and 10, and adopt better result. The order of the training data in each segment is shuffled.

Metrics to Sort Data We experiment with two metrics to sort data: appropriateness, and target length. Target length is a metric generally used in curriculum learning (Cirik et al., 2016; Platanios et al., 2019; Wang et al., 2019; Zhou et al., 2020).

5 Result and Discussion

The result on Table 1 shows curriculum learning improves the performance of summarization models. Curriculum learning with appropriateness per-

Table 1: Result on curriculum learning. Appropriateness indicates probabilities computed by Appropriateness Estimator. R-1-F, R-2-F, and R-L-F are F1 scores of ROUGE-1, ROUGE-2, and ROUGE-L.

form better than that with target length more on the Enron dataset, which has clean validation and evaluation datasets.

Difference among Curricula One-Pass and Noise-Annealing curricula improved the BART models whereas Baby step curriculum led to the worst result. Conversely, for the non-pretrained models, only Noise-Annealing curriculum improved the performance. One-Pass and Noise-Annealing curricula does fine-tuning with smaller data in the last phase of training, and only Noise-Annealing curriculum does generalization with various data in the beginning phase. It is possible that BART is a pretrained model and does not need to be generalized. Rather, fine-tuning is more important. By contrast, non-pretrained models need generalization.

Characteristic of Appropriateness Appropriateness Estimator improved the summarization models, but it is unclear what the appropriateness represents. Table 2 shows Pearson's correlation coefficients between the appropriateness and source/target length. The coefficients are less than 0.2. This indicates the appropriateness represents a different aspect of texts from length of texts. The target texts of low appropriateness data contain information not written in the source texts. We further discuss this topic on Appendix C.

Dataset	Target length	Source length
Enron	0.151	0.079
Reddit	0.156	0.018

Table 2: The correlation coefficients between the appropriateness and source/target length.

Human Evaluation We conduct human evaluation on two BART models: one trained with Noise-Annealing curriculum and appropriateness, and the other trained without curriculum learning. We omit data if two summaries generated by the models are same, and get 90 pairs of generated summaries for each dataset. Annotators choose which summaries are better in terms of informativeness and fluency. Here, the informativeness indicates how well the generated summaries reflect important topics of the source texts, and the fluency represents naturalness of the generated summaries in terms of grammar. The result is shown on Table 3. The result shows the model trained with our method achieves better performance both in terms of informativeness and fluency. To validate the statistical significance of the result, we aggregate the number of votes on "better" and "slightly better" and conduct chi-square test. The statistical significance is also shown on Table 3.

6 Conclusion

In this research, we proposed Appropriateness Estimator that quantifies noise of training data for

	Informativeness		Fluency	
	Enr†	Red†	Enr‡	Red†
Bn is better	**42**	**37**	22	8
Bn is slightly better	17	25	**34**	**55**
B is slightly better	14	20	25	26
B is better	17	8	9	1

Table 3: Result on human evaluation. Bn is a BART model trained with Noise-Annealing curriculum and appropriateness, and B is a BART model without curriculum learning. Enr stands for the Enron subject dataset and Red stands for the Reddit title dataset. † and ‡ indicate statistical significance that Bn receives more votes of "better" and "slightly better" than B (using a chi-square test; † $p < 0.01$, ‡ $p < 0.05$).

sequence-to-sequence models from a single noisy corpus. We conducted experiments of curriculum learning on summarization tasks. We experimented on two datasets, Enron subject and Reddit title datasets and three summarization models: BART, transformer, and sequence-to-sequence with attention. The result showed our method improved the performance of the models.

We also conducted experiments with three types of curriculum learning (One-Pass, Baby step, and Noise-Annealing curricula), and concluded that choosing small data for fine-tuning in the last phase of the training was important for pretrained models and generalization with various data in the beginning phase was important for non-pretrained models. For future work, we seek for more effective methods to find data for fine-tuning.

A Parameters of Summarization Models

The dimensions of hidden layers of both Seq2seqAtt and Transformer are 256. The dimensions of word embeddings of Seq2seqAtt and Transformer are 300 and 256 respectively. Similarly as Appropriateness Estimator, we use GloVe as initial parameters of word embeddings of Seq2seqAtt. The mini-batch size is 64 on all three models. The size of beam search is set 8. We use Adam as an optimizer of Seq2seqAtt and Transformer, and the learning rate is 0.0007.

For the optimization of BART, we use AdamW (Loshchilov and Hutter, 2019), where the learning rate is 3e-5, β_1 is 0.9, β_2 is 0.999, and eps is 1e-8.

B In Which Segment the Model Achieves Best Result?

One-Pass curriculum and Noise-Annealing curriculum both fine-tune models with smaller amount of data in each segment. Investigating at which segment the model gets best validation scores, we can validate which segment is the best data for fine-tuning.

Table 4 shows the numbers of the best segments. The experiment is conducted five times and the average and the standard deviations are shown on the table. The number of segments is set 10, so the tenth segments have longest targets or highest appropriateness. When we use target length, the model gets best validation scores on earlier segments whereas when we use our appropriateness, the model gets best validation scores on later segments. This means too long summaries are not appropriate to fine-tune summarization models, whereas the segments with the highest appropriateness computed by our Appropriateness Estimator are.

Table 4: The segments at which each model gets best validation metric (ROUGE-1-F). Mean and standard deviation values of 5 experiments are shown. The number of the segments is 10.

C Examples of data with High and Low Appropriateness

Table 5 and 6 shows the examples of source and target pairs with low appropriateness. The target length of the examples are not short, but many of the subjects or titles include information that is not described in the source texts. In the case of Reddit, many of the source texts begin as the next sentences of the titles, and the information on the titles are not repeated on the source texts. These do not meet the requirement for the training data of summarization. By contrast, target texts of high appropriateness shown in Table 7 and 8 explain the descriptions in the source texts.

How do I eat crow and still make it tasty???????	To all of our esteemed & prized Internet Banking (IBS) Clients: You probably have begun to wonder does anyone ever return phone calls (or e-mails). We really do but have been holed up trying to complete this project ASAP. We knew that this might upset some clients, but we found that this is the quickest way to fix this problem and get our users back on-line. We have finalized the movement of your customer account's and re-linked your additional accounts back to your primary Login ID (Acct). This process was more daunting than we anticipated and having to verify 1100 IBS users and accounts (to insure your data integrity and confidentiality) was even more grueling than expected. After verifying data and Login IDs, we believe that we are on the right track. Some of you (our IBS clients) might notice your accounts displayed more than once or additional accounts displayed that you may (or may not) want displayed on your IBS screen. Should this be the case, please e-mail (or phone) the information to us and we will remove this information right away. To our IBS Billpayer clients: During this process, we seem to have misplaced (blown away) your bill payment information (particularly anyone that has [had] reoccurring payments scheduled to process on particular days). This has become our highest priority to retrieve this information, thus alleviating the process of having to request that our IBS Billpayers re-enter this information. We are going to waive all bill payment charges for the months of November & December, 2001 to try and regain your confidence (and support). Again, we deeply express our regrets and hope that we (yourselves and ourselves) do not have to go through this process again. Should you be one of our IBS clients that still has not gained access to your account information, please refer to the following information:	0.0002
Additional New Works; 5/2/01 Floor Meeting, 37th Floor	In order to maximize the potential synergies between the various mid- and back- office functions, to decrease replication errors, and to increase communication standards; are there any plans of creating a platform or reference center to bridge the differences between the systems, processes, and terminology of the various departments. Perhaps a common resource center offering access to on-line system manuals and business unit overviews (which currently exist only in paper form or in some cases within the actual system database). The reason: With Enron's size and transaction volume, many of the functions and the data managed by various groups within Enron (i.e. credit, risk, settlements, volume management, global contracts, global counterparties, global rates, and the commercial systems) are fragmented. Having participated in various process reviews and trouble-shooting/clean-up projects there seems to be a large disconnect between groups operating in various systems. These disconnects; rather they be lack of information or understanding of how data flows between systems, how the data managed within each system impacts other upstream or downstream systems, or how the business processes within one group/system impacts the overall functionality of other groups, create large cracks producing an opportunity for mismanaged data, incomplete business reports, and increased risk to Enron. The ideal objective; increase communication standards through a better understanding of system data functions/requirements and business processes, decrease system downtime and replication errors through a better understanding of the data relationships between systems, maximize department-to-department synergies (left hand knows what the right hand is doing), eliminate repetition, and further reduce potential risks to Enron due to information/business process oversight.	0.0052
Returned mail: Host unknown (Name server: enron: host not found)	Danny, I'm resending as I had the same problem Cindy did. I'll give you a call later today after I've talked to Harris to discuss the various Gallup scenarios to make sure you and I are on the same page. The plan that makes the most sense in my mind is to ram the 10,000/d project through asap, with no firm contracts to preserve our options on a NEWCO structure. We'll simultaneously implement a new approach on San Juan fuel transport if possible and then throw the big expansion into the hopper at FERC in January as Stan suggested. I hope that timetable is doable–it all depends on	0.0061
GREAT NEWS ****FERC Order on Morgan Stanley Complaint Against ISO	See below. this is one of the issues that concerned us more than price caps, because it could limit our ability to move power to other markets in the west. In addition, if you get questions from the analysts on "reregulation" or price caps it is worth pointing out that the high prices prevailing in many markets help our retail sales pitch to end use customers and create opportunities for our wholesale price risk management services ... even a $250 price cap is 5-10 times what large customers are accustomed to paying.	0.0087
Noram Rigs	Richard Sanders has asked me to set up a meeting regarding the above referenced. The following participants are: Lisa Mellencamp Mark Peterson John Hopley John Enerson Richard Sanders It looks as though, this Friday, Aug. 13. at 2:00 will be a good time for everyone. Please let me know if this time is convenient for you. The location will be 38C1. (I tried to contact you by phone today, but your extension 31406 was forwarded to a non working number). My extension is 39402, if you wish to call me. Thanks	0.0093

logging onto my wife's facebook account.	I read every comment and personal message and thank everyone that gave their advice. I decided I would confront her about it after we put the kids down last night. I decided I would start out by asking her the essential questions. Do you love me? Do you want to be with me right now? Do you want to spend the rest of your life with me? Then I would tell her that when we took our vows we said we would stick together through thick and thin, and that right now we are in some pretty thick shit. I would tell her that we both breached each other's trust and we both had some explaining to do. Then we would progress the conversation from there. I have to add that since the op and prior to the confrontation the conversations between the 2 of them continued to go on. He is a pathetic little prick that obviously does this with countless other women because it is easy and safe and he doesn't have to put himself out there and risk getting hurt. At one point he even told her he loved her. She replied by telling him that wasn't appropriate and that they were just friends and that was how it was going to be. So this is pretty much how it went down: she said she loved me, wanted to be with me, and always wanted to be with me. She admitted that the things being said in the conversation were inappropriate and when I asked her why she did it she told me exactly what I knew she would: "it is really nice being told how pretty you are and getting that kind of attention." I asked if there was anyone else she was conversing with like that and she said no. I also asked if she had ever cheated on me with anyone physically and she said no. I told her I had been faithful since day 1 and I needed to know that she had been to. She assured me she was. The db she was talking to had went to school with her for 1 year in high school and now lives in north carolina. We are in arkansas. I walked away from the situation feeling really good about it all and I could tell that she was sincere. We ended up making crazy love all over the house, doing it again before bed, and again when we woke up. She apologized and I told her I would get back to making her feel like a woman so she didn't have to seek that out somewhere else. Say what you will but I think it ended as well as it possibly could have.	1.67e-04

Backing my e class into my wife's c class mercedes	My wife had been out of town all week at a sales conference. Our driveway makes at with one car pulling to the left into our carport and one car that pulls forward to park on a concrete slab. Initially my wife was supposed to get our kids from daycare but her flight was running late so she decided to come by the house first to pick me up so we could go out to dinner. I was finishing some work projects at home when she came running in from the airport. I didn't realize we were on the verge of not picking the kids up on time. The daycare charges something like $10 a minute if you're late and it was a friday. She was gathering some things for our toddler (you can't go out with a 3 yo unless you're prepared to bring a toy store to entertain them with). I had the bright idea that I would back out of the carport and pull up so her passenger door would be readily accessible when she came out the back door (i had been pulling out that way all week so I could pull out into the street rather than back out). In a hurry, I slammed my car in r and jammed on the gas. Boom! I hit her car just as she was coming out the door. Toddler toys go flying everywhere (mostly at my head). We didn't speak all the way to the daycare until I just started laughing hysterically. I mean really. What else could you do?	0.0127
Leaving a 12-pack of beer in the bottom of a shopping cart in the grocery store parking lot.	I went back to get it 30 minutes later and it was still there :)	0.0130

Nitrogen and Sulfur reporting and Recordkeeping for Turbines	For those teams that have turbines installed after 1990 and/or for those turbines which have undergone power unit changouts, the following recordkeeping and monitoring conditions apply: 1) DAILY recordkeeping of nitrogen and sulfur must be taken of the fuel gas which supplies the applicable turbine(s). 2) This recordkeeping consists of electronic recording (gas chromtograph for nitrogen and delmar or equivelant for sulfur) or stain tubes may also be used for sulfur. These DAILY records include measurements on Saturdays and Sundays. 3) The measurement must be taken at the location. An exception to this is that the nitrogen and sulfur measurements may be taken upstream or downstream of the applicable turbine facility provided that there are no natural gas deliveries into the pipe which would interfere or dilute/increase the measurements for the applicable turbine fuel gas. 4) Fuel gas records in hard copy form or equivalent for the nitrogen and sulfur must be maintained at the facility or at a central location for easy retrival. 5) A turbine facility may waiver out of this nitorgen and sulfur daily recordkeeping requirement by obtaining a custom fuel monitoring schedule (CFMS) from the EPA. Approval of a CFMS allows a greatly reduced recordkeeping and reporting for nitrogen and sulfur. CFMS requests have been submitted for the following facilities: P-1 C/S Plains Turbine C/S Atoka No 2 C/S Monument C/S Crawford C/S Bloomfield C/S Approvals have not as yet been obtained. Until issuance of a CFMS, an applicable facility is required to continue daily sampling for nitrogen and sulfur. Facilities which have received CFMS from the EPA include: La Plata C/S P-2 C/S Please be advised that there may be certain reporting requirements that might be required for each CFMS. I would strongly advise that the La Plata and Panhandle teams review their CFMS and include reporting dates into MCS, so that the deadlines and reportings are not missed. If you have a turbine facility which is subject to the nitrogen and sulfur reporting requirements and would like to reduce the reporting burden, contact Butch or myself." Nitrogen and Sulfur reporting and Recordkeeping for Turbines	1.0
TW/ Lonestar Ward and Pecos Counties interconnect bi-directional–A-release	The following is a level "A" cost estimate to make TW/ Lonestar existing interconnects bi-directional. TW/ Lonestar at Ward County (50 to 60 mmcf/d) According to Operations this is already bi-directional . The only things are required on this one is to take the flapper out of the check-valve and blow down the gas in 5.33 miles of 12". Cost of gas loss& labor = $8,000 TW/ Lonestar at Pecos County (100 mmcf/d) A): TW/ Lonestar interconnect Scope: On this one we need a bi-directional valve skid using the existing meter run. Cost of material& labor= $ 195,000 B): Pecos Compressor Station In order to make this interconnect bi-directional we also need to make the station (two-compressor units) bi-directional. Scope: Install outlet from Lonestar I/C to inlet filter with 12" piping& valves. Unit discharge would be modified to tie in to West Texas-20" Cost for material& labor= $ 330,000. If you need more accurate costs (B -release) please let me know .	0.999

Abstract

Lexical collocations are idiosyncratic combinations of two syntactically bound lexical items (e.g., *"heavy rain"*, *"take a step"* or *"undergo surgery"*). Understanding their degree of compositionality and idiosyncrasy, as well their underlying semantics, is crucial for language learners, lexicographers and downstream NLP applications alike. In this paper we analyse a suite of language models for collocation understanding. We first construct a dataset of apparitions of lexical collocations in context, categorized into 16 representative semantic categories. Then, we perform two experiments: (1) unsupervised collocate retrieval, and (2) supervised collocation classification in context. We find that most models perform well in distinguishing light verb constructions, especially if the collocation's first argument acts as a subject, but often fail to distinguish, first, different syntactic structures within the same semantic category, and second, finer-grained categories which restrict the set of correct collocates[1].

1 Introduction

Language models (LMs) such as BERT (Devlin et al., 2018), and its variants SpanBERT (Joshi et al., 2020), ALBERT (Lan et al., 2019), RoBERTa (Liu et al., 2019), etc. have proven extremely flexible, as they behave as unsupervised multitask learners (Radford et al., 2019), and can be leveraged in a wide array of NLP tasks almost out-of-the-box (see, e.g., the GLUE and SuperGLUE results in Wang et al. (2019b) and Wang et al. (2019a), respectively). They have also been harnessed as supporting resources for knowledge-based NLP (Petroni et al., 2019), as they capture a wealth of linguistic phenomena (Rogers et al., 2020). Recently, a great deal of research analyzed the degree to which they encode, e.g., morphological (Edmiston, 2020), syntactic (Hewitt and Manning, 2019), or lexico-semantic structures (Joshi et al., 2020). However, less work explored so far how LMs interpret phraseological units at various degrees of compositionality. This is crucial for understanding the suitability of different text representations (e.g., static vs contextualized word embeddings) for encoding different types of multiword expressions (Shwartz and Dagan, 2019), which, in turn, can be useful for extracting latent world or commonsense information (Zellers et al., 2018).

One central type of phraselogical units are *lexical collocations*, defined as restricted co-occurrences of two syntactically bound lexical items (Kilgarriff, 2006), such that one of the items (the *base*) conditions the selection of the other item (the *collocate*) to express a specific meaning. For instance, the base *lecture* conditions the collocates *give* or *deliver* to express the meaning 'perform', the base *applause* conditions the selection of the collocate *thunderous* to express the meaning 'intense', and so on. Lexical collocations are of high relevance to lexicography, NLP and second language learning alike, and constitute a challenge for computational models because of their heterogeneity in terms of idiosyncrasy and degree of semantic composition (Mel'čuk, 1995).

In this paper, we analyze a suite of LMs in the context of two tasks that involve lexical collocation modeling. First, **unsupervised collocate retrieval**, where we *mask* a collocation's collocate (e.g., *"heavy"* in *"heavy rain"*), and quantify how well a LM of choice (BERT in particular) predicts, via its masked language modeling (MLM) objective, a valid collocate for that particular base ({*"heavy"*, *"torrential"*, *"violent"*, ...} for the base *"rain"* and the meaning *intense*). Second, **su-**

pervised in-context collocation categorization, where we fine-tune LMs on the task of predicting a semantic category of a collocation in terms of its *lexical function* (LF), given its sentential context; cf. Section 3.1. Modeling, recognizing, and classifying collocations in corpora has obvious applications for automatically creating and expanding lexicographic resources, as well as for various downstream NLP applications, among them, e.g., machine translation (Seretan, 2014), word sense disambiguation (Maru et al., 2019), or natural language generation (Wanner and Bateman, 1990). The two main contributions of this paper thus are:

1. A "collocations-in-context" dataset, with instances of collocations of 16 different semantic categories (in terms of LFs) in context, and with a fixed and lexical (i.e., no overlapping) train/dev/test split (Section 3).
2. An evaluation framework for assessing the degree of compositionality of lexical collocations, pivoting around two tasks: unsupervised *collocate* retrieval (Section 4) and in-context *collocation* categorization (Section 5).

Our results suggest that modeling collocations in context is a challenge, even for widely used LMs, and that this is particularly true for less semantic (and thus less compositional and more idiosyncratic) collocations. We also find that jointly recognizing the semantics and the syntactic structure (e.g., whether the collocate acts as subject or object in verbal constructions) of a collocation also constitutes non-trivial challenges for current architectures. Moreover, as a byproduct of our analysis, we also find an interesting behaviour in LMs when modeling antonymy in adjectives, specifically that their representations undergo substantial transformations as they flow through BERT's transformer layers, with many contextualized embeddings clustered together in the tip of a narrow cone that seems to represent adjectives in collocations denoting intensity (*"heavy"* rain) and weakness (*"minor"* issue).

2 Related Work

In this section, we discuss related works in two methodological areas that are relevant to this paper, namely conditioning MLMs (Section 2.1) and recognition of multiword epressions (MWEs) (Section 2.2).

2.1 Conditioning MLMs

A Masked Language Model (MLM) can be used as a *proxy* for gaining insights into how language is encoded by the weights of the (usually transformer-based) LM architecture. Moreover, simply asking an LM to predict words in context (without task-specific fine-tuning) has proved useful in NLP applications dealing with lexical items (affixes, words or phrases). For example, Wu et al. (2019) use BERT's MLM for augmenting their training data in sentiment analysis tasks; Qiang et al. (2019) use BERT for lexical simplification by *conditioning* the predictions over the $[\mathrm{MASK}]$ token by providing the original sentence as context; and Zhou et al. (2019) obtain SotA results in lexical substitution by conditioning BERT via embedding dropout on the target (unmasked) word. Inspired by the findings in these works (especially Qiang et al. (2019)), we will explore the predictions of BERT over masked lexical collocations (with and without conditioning) in Section 4, with the aim to understand whether these predictions can be used to measure the idiosyncrasy of the underlying semantics of a lexical collocation, i.e., whether the restrictions imposed by a collocation's base are due to the frozenness of the phrase itself or, on the contrary, sentential context is neccessary.

2.2 Distributional Lexical Composition

Building representations that account for non-compositional meanings within the broader spectrum of encoding semantic relations between words is a long-standing problem in computational semantics (Baroni and Zamparelli, 2010; Mitchell and Lapata, 2010; Boleda et al., 2013). Interestingly, there seems to be little agreement on how these representations should be defined, with recent attempts focusing on verbal multiword expressions (see an overview of approaches in Ramisch et al. (2018)), phrases of variable length encoded via LSTMs, based on their definitions (Hill et al., 2016), or arbitrary lexical and commonsense relations between word pairs for downstream NLP. As a testimony of the broad methods explored in the most recent literature, let us refer to, for instance, the combination of word vector averages with conditional autoencoders (Espinosa-Anke and Schockaert, 2018), expectation maximization (Camacho-Collados et al., 2019), LSTMs for predicting word pair contexts (Joshi et al., 2019), and explicit encoding of generalized lexico-syntactic patterns (Washio and Kato,

LF	BERT input	Masked sentence	Pred. collocates	Orig. collocate
Oper1	Masked sent	iran feared that the u.s and israel may [MASK] an air raid on its controversial nuclear facilities	perform, conduct, mount,	launch
	Orig sent [SEP] Masked sent	iran feared that the u.s and israel may launch an air raid on its controversial nuclear facilities [SEP] iran feared that the u.s and israel may [MASK] an air raid on its controversial nuclear facilities	launch, conduct, order	launch
Real1	Masked sent	if that happens, lindsey will use explosive triggers to [MASK] the landing gear	destroy, stop, remove	lower
	Orig sent [SEP] Masked sent	if that happens , lindsey will use explosive triggers to lower the landing gear [SEP] if that happens , lindsey will use explosive triggers to [MASK] the landing gear	destroy, stop, trigger	lower
Magn	Masked sent	the EU is driving a [MASK] bargain over Swiss demands for greater access to EU airspace .	plea, hard, new	hard
	Orig sent [SEP] Masked sent	the EU is driving a hard bargain over Swiss demands for greater access to EU airspace . [SEP] the EU is driving a [MASK] bargain over Swiss demands for greater access to EU airspace .	plea, hard, tough	hard

Table 1: Illustrative behaviour of BERT when prompted to predict a collocate in the position of a masked token, for three LFs: Oper1 (‘launch an air raid’), Real1 (‘lower the landing gear’) and Magn (‘hard bargain’), under two settings, when not conditioned (Masked sent) and when conditioned on the original (unmasked) sentence (Orig sent [SEP] Masked sent).

2018). Parting ways with the above works, in this paper we will follow the experimental setting described in Shwartz and Dagan (2019), based on injecting sentential contexts into multiword expressions (in our case, only lexical collocations) to leverage the contextual nature of current LMs. However, our goal is not to compare different combinations of feature-extraction and training/fine-tuning methods, but rather to understand lexical collocations’ learnability, idiosyncrasy and their internal vector-space representations.

3 Data and Resources

3.1 Lexical Collocations

Let us first introduce the notion of lexical collocation and LF. The term *collocation* has been used in computational linguistics research to denote two different concepts. On the one hand, following Firth (1957), Church and Hanks (1989); Evert (2007); Pecina (2008) and others, a collocation has been assumed to be a combination of words that have the tendency to occur together in discourse. Typical examples are *doctor – hospital*, *mop – bucket*, *real – estate*, *look – for*, etc. On the other hand, for instance, Wanner et al. (2006); Gelbukh and Kolesnikova. (2012); Rodríguez Fernández et al. (2016); Garcia et al. (2017) adopt the definition that is common in lexicography and phraseology (Hausmann, 1985; Cowie, 1994; Mel’čuk, 1995), according to which, a collocation is an idiosyncratic combination of two lexical items, the base and the collocate, as defined above in Section 1. This interpretation states that collocations are phraseological units, although their degree of compositionality can vary. For instance, *win* [*a*] *war* is perceived to possess a higher degree of (free) composition than, e.g., *hold* [*a*] *meeting*, and *heavy rain* is less compositional than [*a*] *well-justified argument*. We adopt this definition of the notion of collocation, and in order to avoid any confusion, we refer to it, following Krenn (2000), as *lexical collocation*.

Lexical collocations can be typified with respect to the meaning of the collocate and the syntactic structure formed by the base and the collocate. LFs provide a fine-grained typology of this kind (Mel’čuk, 1996). An LF can be considered a function $f(L)$ that delivers for a base L a set of synonymous collocates that express the meaning of f. Where pertinent, f also codifies the subcategorization structure of the base+collocate combination. LFs are assigned Latin acronyms as names; cf., e.g., “Oper1” (‘operare’), which means ’perform’ and realizes the first argument of the base as subject: Oper1(*lecture*) = {*deliver*, *give*, *hold*}; “Magn” (‘magnum’), which stands for ‘intense’: Magn(*applause*) = {*thunderous*, *loud*, ...}.[2]

The encoding of LFs in NLP research has in recent years revolved around applying word embeddings-based techniques, e.g., in terms of linear projections (Rodríguez Fernández et al., 2016) and semantic generalizations (Espinosa-Anke et al., 2016). Recently, Shwartz and Dagan (2019) analyzed, from the perspective of “static” vs. “contextualized” representations and their applicability to studying compositional phenomena like “meaning shift”, one specific type of lexical collocations, namely *light verb constructions* (LVCs), which are well illustrated by the LFs Oper1 and Oper2 (and also, partially, by Real1 and Real2). While we find that the above research directions (i.e., embeddings-based and contextualized representations for modeling MWEs) are complementary, in this work, we

---

[2] For simplicity we will write Oper1(*lecture*) = *deliver*, etc.

LF	semantic gloss	example
Oper1	‘perform’; 1st argument → subject	Oper1(*support*) = *lend*
IncepOper1	‘begin to perform’; 1st argument → subject	IncepOper1(*impression*) = *gain*
Oper2	‘undergo’; 2nd argument → subject	Oper2(*support*) = *find*
Real1	‘realize’; 1st argument → subject	Real1(*accusation*) = *prove*
Real2	‘apply’; 2nd argument → subject	Real2(*support*) = *enjoy*
AntiReal2	‘fail to apply’; 2nd argument → subject	AntiReal2(*war*) = *lose*
CausFunc0	‘cause the existence’	CausFunc0(*hope*) = *raise*
Caus1Func0	‘cause the existence; 1st argument’	Caus1Func0(*hope*) = *gain*
LiquFunc0	‘cause termination of the existence’	LiquFunc0(*hope*) = *destroy*
IncepPredPlus	‘increase’	IncepPredPlus(*temperature*) = *rise*
Magn	‘intense’	Magn(*smoker*) = *heavy*
AntiMagn	‘little’, ‘weak’	AntiMagn(*smoker*) = *occasional*

AntiVer	‘non-genuine’	AntiVer(*demand*) = *illegitimate*
Bon	‘positive’	Bon(*performance*) = *good*
AntiBon	‘negative’	AntiBon(*performance*) = *poor*

Table 2: LFs used in this paper. The ‘semantic gloss’ column provides both a definition and the actantial structure, which is required in cases where one LF may express the same semantics but with a different syntactic structure (e.g., Real1 vs. Real2).

specifically focus on the existing (and learnable) knowledge LMs have concerning lexical collocations, and whether they can be used to recognize and categorize LFs in free text.

For our experiments, we use, as initial lexical collocation source, a **collocations dataset**, LEXFUNC (Espinosa-Anke et al., 2019), which we have extended to cover a wider range of LFs (listed in Table 2). The original LEXFUNC dataset and this extended version are both the result of an initial collection of collocations categorized into LFs made available by Igor Mel’čuk. Each collocation has been manually lemmatized, and bases and collocates have been manually annotated with part-of-speech tags and their syntactic dependency relation.

With the lexical collocations of the extended LEXFUNC dataset at hand, we first compile from the English Gigaword[3] a **collocations corpus**, which contains the occurrences of these lexical collocations. In principle, the identification of a given collocation in corpora is a straightforward procedure, as we know its elements (base and collocate) and the syntactic dependency relation between them. However, automatic dependency parsing is far from perfect, which complicates the task. Therefore, and in order not to lose any relevant collocation occurrence in the GigaWord corpus, we apply a cascaded procedure for their identification on the lemmatized and POS- and head-modifier relation tagged GigaWord.[4] In the first stage, we identify sentences in which between the collocation elements in question one of the relevant syntactic dependency relations has been identified. In the second (more relaxed) stage, we match adjacent lemmatized collocation elements and their PoS tags. In the third stage, finally, we match lemmatized collocation elements and their PoS tags within a distance of up to 5 tokens. While this procedure inevitably introduces some noise (we might retrieve sentences where base and collocate co-occur, but not as a collocation), we performed a manual inspection on a random sample, and calculated precision of our collocation retrieval strategy, which resulted in >0.95. This confirms the quality of our retrieval strategy, and hence, our resource.

In terms of corpus statistics, Table 3 indicates the number of sentences for each LF distributed across training (70% of the sentences), development (15%) and test (15%) sets. The split was done maintaining this proportion across all LF. Note that these splits are constructed such that there are no overlapping collocations, in an effort to avoid the well-known phenomenon of *lexical memorization* (Levy et al., 2015), which may artificially inflate the results on the test set. The number of different collocations per split, globally and for each LF, also maintains the same proportions (70/15/15 ±1%), such that, e.g., AntiReal2 has 55 different collocations in the 942 sentences of the training set and 11 different collocations in the development and test sets, distributed across 205 and 200 sen-

---

[3] Gigaword contains newswire material, a register balancing the staticity of encyclopedic English (e.g., Wikipedia) and the noisiness of user-generated text, and is a rich source of lexical collocations in well-formed grammatical contexts (Rodríguez Fernández et al., 2016) `https://catalog.ldc.upenn.edu/LDC2011T07`.

[4] We preprocess GigaWord with the NLP4J parser `https://emorynlp.github.io/nlp4j/`.

Label	Train	Dev	Test	Total

Table 3: Statistics (in number of sentences) of our *collocations in context* dataset (ordered by frequency).

tences respectively. In the overall corpus, there is an average of 18 samples per collocation (*work hard* being the most frequent one with 102 samples). *Hope*, *attack*, *criticism*, *fire* and *thread* are bases that each co-occur with more than 30 different collocates, across most LF. These bases are also among the ones with more samples in the corpus. On the other side, half of the bases are combined with one single collocate only. Overall, the statistical properties of our dataset arguably make it a faithful replica of the distribution of collocations in, at least, newswire corpora. At the same time, it is a challenging dataset, as the results we report in this paper suggest.

4 Experiment 1: Collocate Retrieval

4.1 Setup

In the first experiment, we aim to analyze how well an MLM retrieves valid collocates for a given base when being provided with the original (sentence-level) context. We use BERT (`bert-base`) (Devlin et al., 2018), as it is the *de-facto* model on top of most specialized and distilled/quantized language models. Its behaviour should thus be a good proxy for the general distributional behaviour of lexical collocations. This experiment serves, first, as an opportunity to understand *how much* semantics that is underlying LFs can be encoded via a MLM pretraining objective, and second, as a testbed for exploring conditioning strategies often used in tasks involving data augmentation and lexical substitution and simplification (cf. Section 2.1). Since this is an "in-context collocate retrieval" task, we consider it a ranking problem. Intuitively, if BERT is able to retrieve a base's valid collocates (e.g., {*heavy*, *torrential*, *violent*, …} for *rain* as base for Magn) in the position of a masked token, this could mean that: (1) the sentence is giving enough context for the model to "know" the lexical restrictions involved in that collocation, and/or (2) the LF is sufficiently frozen, and therefore the base alone may restrict which collocates are acceptable. For the first point, and continuing with the *heavy rain* example, consider the following sentence.

(1) *Hurricane Katrina brought* [MASK] *rain to Louisiana.*

Intuitively, we would expect the sentential context to be informative enough for the model to select *heavy* or any other collocate denoting the notion of intensity, and restricted by the presence of the base *rain*. In fact, here, BERT predicts *heavy* with 79.5% probability. However, in example (2)

(2) *Policeman earns applause for staying on duty in* [MASK] *rain.*

there is much lesser evidence for the *rain* to be 'intense', and in fact BERT predicts here *'the'* with 85.1% probability. This disparity lets us investigate ways to prompt BERT to select *heavy* or any other valid collocate for example (2). Thus, in addition to simply passing one masked sentence, we explore an approach based on passing the masked sentence concatenated with the original sentence, which is a natural way to encode not only the context surrounding the word, but also the meaning of the target word itself. This strategy was successfully used for the task of unsupervised lexical simplification (Qiang et al., 2019). For the second point above, the works of Espinosa-Anke et al. (2019); Shwartz and Dagan (2019) already point to the fact that light verb constructions (LVCs) are easy to recognize in text. Further evidence is provided in Table 1, which shows BERT's top predictions for three sentences containing Oper1, Real1 and Magn collocations. It is immediately obvious that the nature of the LF itself, as well as the amount of the information provided by the sentential context, are crucial. Note that, in the case of Oper1, by providing the original sentence as context, BERT's grasp of the LF improves, as it tends to predict the correct collocate, whereas for Real1 or Magn, this improvement results in assigning higher probability to tokens which are more similar to the LF's abstract meaning (e.g., *trigger the landing gear* for Real1 or *tough bargain* for Magn).

With the above considerations in mind, we run BERT's MLM head over our GigaWord-based test set, and compute *Mean Reciprocal Rank* (MRR) and *Mean Average Precision* (MAP) over each LF. Recall that we consider as valid *hits* all the collocates for a given base and its corresponding LF. In practice, this means that for bases that have just one valid collocate, both metrics yield the same score. We lemmatize BERT's predictions using SpaCy's lemmatizer.[5]

4.2 Results and Discussion

Our results (Table 4) show, first, that conditioning BERT's MLM by passing the original sentence as additional context for the [MASK] token is useful for predicting an embedding whose semantics is more related to the original collocate. The improvements are particularly relevant for LVCs (Oper1, and, to a certain extent, Real1 and Real2), suggesting that these LFs, while perhaps easy to distinguish from others (cf. Section 5.1), they do benefit from additional contexts to be well represented. Interestingly, the Magn LF has small gains in both MRR and MAP, clearly showing that additional context helps little, and thus highlighting a strong semantic dependency between sentence meaning and the collocation's base.

A potential limitation of this setup, however, is that we cannot possibly include all possible collocates for all the bases in our resource. An estimate of the quality of BERT's predictions can be obtained by measuring the semantic similarity (for instance, by cosine distance) between the original masked collocate and the predicted collocates. In the example we already referred to above, *heavy rain*, the similarity between 'the' and 'heavy' is low, whereas, if the model predicts *hard* or even any other adjective, it should be considered less wrong. We obtain a broad picture of the quality of BERT's predictions by plotting a histogram (Figure 1) of the similarities obtained by comparing the original collocate's and BERT's predicted GloVe embeddings (Pennington et al., 2014) under both settings (MASKED and CONDITIONED) for the same three LFs as in Table 1), namely Magn, Oper1 and Real1. The conditioning strategy is helpful; it contributes not only to retrieving the original collocate (which would be trivial if we do not mask it), but also candidates with clearly similar meanings. We see, for instance, more cases for Oper1 and Real1, where the correct verb is predicted, whereas for Magn we see a more sustained improvement across all similarities, but not necessarily for retrieving the original collocate.

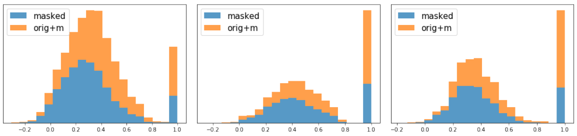

Figure 1: Histograms showing the distribution of similarities between gold and predicted (lemmatized) collocates for the three LFs Magn, Oper1 and Real1 (from left to right).

	MASKED		CONDITIONED

Table 4: Results of the collocate retrieval experiment when passing to the MLM the masked sentence (MASKED) or with the original sentence as context (CONDITIONED).

5 Experiment 2: Collocation categorization

In the second experiment, we test the performance of a number of well-known LMs for the task of LF categorization using the train/test splits we sampled and annotated from GigaWord (Section 3). This experiment serves two purposes. First, we expect to learn about the *predictability* of LFs in context,

---

[5] `https://spacy.io/api/lemmatizer`.

which is a long-standing problem in computational lexicography and the cornerstone of automatic construction of collocation resources. Second, previous work has shown that some LFs are quite easy to distinguish, without (Espinosa-Anke et al., 2019) and with sentential context (Shwartz and Dagan, 2019). However, it is still unclear whether, by focusing exclusively on the phenomenon of collocations, and excluding, e.g., idiomatic expressions or non-compositional phrasal verbs (which are not only semantically but, more importantly, syntactically different from collocations), an LM can indeed be used to construct a resource for second language learners, or whether (and to what extent) an LM can be trained to select appropriate collocates. Our setting is essentially a sentence-pair classification problem, where the second sentence is the lexical collocation itself. Specifically, a training instance is a tuple <sentence, collocation, label>, as in Example (3) (where we use **;** as a wildcard concatenation token, as these are different across LMs):

(3) *The US military **launched an airstrike** on what it described as a safehouse in the Iraqi town of Fallujah **;** launched an airstrike* → ***Oper1***

We use as labels the LFs listed in Table 2, with their respective training/test splits, and train all LMs with the same hyperparameters.[6] The considered LMs are BERT (base and large, uncased) (Devlin et al., 2018), RoBERTa (base and large) (Liu et al., 2019), DistilBERT (Sanh et al., 2019), ALBERT (Sanh et al., 2020) and XLNet (base and large) (Yang et al., 2019). We use the implementation in the Transformers Python library (Wolf et al., 2020).[7]

5.1 Results and discussion

The results of this experiment (cf. Table 5) clearly highlight what has already pointed out in Shwartz and Dagan (2019): the prototypical LVCs (as modeled by Oper1) can be identified with a rather high quality. Interesting enough, this is not true for LVCs captured by Oper2, whose only difference to Oper1 is the subcategorization frame: while in Oper1, it is the 1st argument of the base that is realized as the grammatical subject, in Oper2, it is the 2nd argument. Frequency cannot explain this discrepancy since, e.g., IncepOper1, which appears in our corpus in nearly the same number of sentences as Oper2, is categorized with a significantly higher quality.

Results are also lower for some other verbal LFs with more semantic load, among them, e.g., Real1/2 and Caus1Func0, suggesting that the semantics expressed in the notions of 'realize' and 'cause', especially when the 2nd argument of the collocation functions as a subject, are more challenging. Again, these results cannot be fully explained by the amount of training data and neither by the semantic load. Thus, the categorization of IncepPredPlus achieves the highest score (the best model on IncepPredPlus obtains an average F1 of 95.21 with little variability across runs), and it is clearly an LF with a semantic load, namely 'increase'. Interestingly, Ver ('genuine') and Bon ('positive') are the worst categorized LFs in our sample, while their antonyms AntiVer and AntiBon are categorized considerably better.

As for the considered LMs, the best overall performing model is the RoBERTa family, with an overall F1 score of **71.19%** for RoBERTa-base and 70.6% for RoBERTa-large, and both models accounting for the best results on 7 of the 16 target LFs. The second best results are achieved by XLNet (base and large), with XLNet-large being the best model on both Magn and AntiMagn, two LFs which have been traditionally challenging to tell apart due to the fact that the representations of antonyms are clustered together in distributional spaces. We also note that, interestingly, DistilBERT is the best at categorizing Oper1 and Real2, which may suggest that small models may be sufficient to obtain good performnace on categorizing LVCs.

In order to gain further insights on *why* a LM may err in the task of in-context collocation categorization, we display a confusion matrix obtained from random runs for the two LMs with the highest avg score for Oper1 (Distilbert) and Oper2 (XLNet-base) (Figure 2) – the two LVC LFs that differ only in terms of their subcategorization patterns (cf. above). We may hypothesize that the categorization of a collocation based mainly on its actantial structure is challenging, and indeed, we observe that for these two models,[8] syntax-based categorization over the same semantics proves hard. Specifically, XLNet-base has as the greatest source for confusion regarding Oper1, precisely, Oper2;

---

[6] All models are trained for 1 epoch, with a learning rate of $4e-05$, the Adam with weight decay optimizer and a warmup ratio of 0.06.

[7] `https://huggingface.co/transformers/`.

[8] As a matter of fact, it can be assumed that this applies to all the LMs evaluated in this paper.

and this also occurs with Real1 vs. Real2 (which also differ only with respect to their subcategorization pattern). The results for DistilBERT show a greater spread among the misclassifications of Oper1, namely across Oper2, Caus1Func0 and IncepOper1, and for Oper2 across Oper1 and CausFunc0. Caus1Func0 and IncepOper1 have the same subcategorization pattern as Oper1 (but different semantics). In the case of CausFunc0 (‘cause the existence’, e.g., CausFunc0(*hope*) = *raise*), the subcategorization pattern is very similar to Caus1Func0, only that the grammatical subject of the corresponding syntactic construction is not an argument of the base. As we can observe, CausFunc0 is easily miscategorized as a full LVC. Finally, let us highlight the fact that while Magn is generally well categorized, the few misclassifications come, as would be expected, from collocations which convey a similar notion of amplification (e.g., Bon), but interestingly, also collocations that convey opposite semantics, such as AntiMagn or AntiBon.

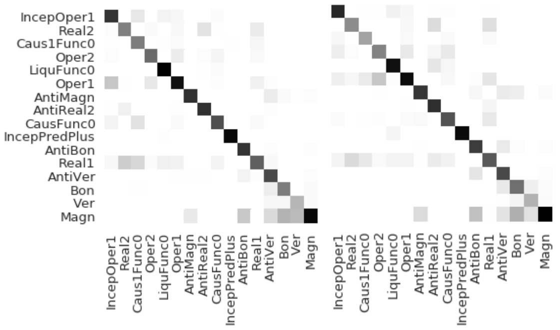

Figure 2: Confusion matrix for the two best performing models on average on Oper2 (Xlnet-base, left) and Oper1 (DistilBERT, right).

6 Subspace Analysis

In this section, we further explore the semantics of some selected LFs. We generate visualizations of PCA-projected BERT vectors for all collocation mentions of Magn, AntiMagn, Oper1 and Oper2. These four LFs are sufficiently frequent, and they encode different morphosyntactic structures.[9] We can see that antonymy (Ono et al., 2015; Schwartz et al., 2015; Nguyen et al., 2016) is relatively well captured in contextualized models, although the subspaces are clearly different between the embedding and the last transformer layer. More specifically, as the representations of collocates for Magn and AntiMagn undergo the self-attention-based transformations through BERT’s layers, many of these contextualized embeddings tend to group in a narrow cone, with many antonymic collocates indistinguishably overlapping with each other. Similarly, we also observe a tendency of representation overlap in the Oper1 vs Oper2 case, with the embeddings in the last transformer layer showing a cluttered distribution, suggesting that there is little inherent knowledge in BERT to categorize a collocation into the syntactic typification of a LF.

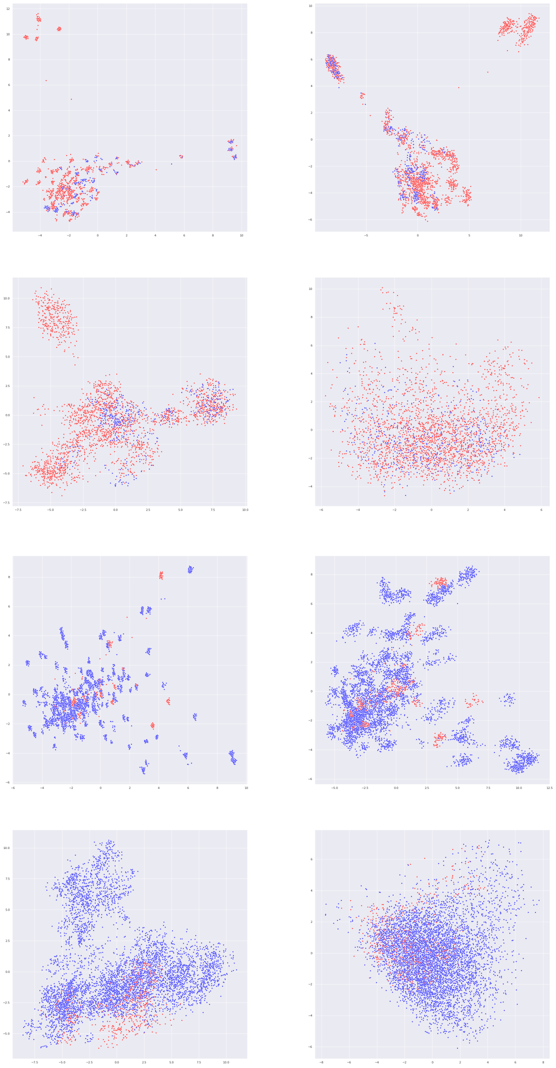

Figure 3: Oper1 (red) and Oper2 (blue) collocate embeddings for BERT’s embedding layer (top row, left), and for the 1st (top row, right), and 5th and 12th transformer layers (second row, left and right, respectively). The bottom quadrant corresponds to Magn (blue) vs AntiMagn (red), with the same arrangements (embedding, 1st, 5th and 12th layer).

---

[9] <Magn,AntiMagn> are most frequently expressed by *adj+noun* combinations, whereas <Oper1,Oper2> are always realized by a *verb+noun* pattern.

Table 5: Average Precision, Recall and F1 results for the collocation classification experiment, computed by averaging the results of three independent runs. We also report standard deviation figures. Results are provided per LF as well as the average over each metric (Average).

7 Conclusions

We have analyzed LMs in tasks revolving around modeling, recognizing and categorizing lexical collocations. We conclude that some prominet types of LVCs require little context to be well encoded, as opposed to other LFs involving, e.g., nouns and adjectives, and that predictability of LFs is challenging, not a function of training data, and that syntax plays a major role.

8 Future Work

In the future, we will make this work multilingual using linguistic equivalences as anchors, in the spirit of cross-lingual embedding research, in order to align collocations of the same LF across languages (e.g., in English and Norwegian we *take a nap*, in German, we 'make' it, in Portuguese we 'pull' it, in Spanish, we 'throw' it, etc.). We would also like to explore the idea of "semantic masking" for collocate discovery, where we would train models for dynamically *masking* (or removing) idiosyncratic information such that only the semantics of the collocate remain, thus largely corresponding to a latent abstraction over the LF. This approach has been applied recently in the lexical substitution task, with the limitation, however, that the dropout rate was tuned in a validation set, whereas a promising avenue to explore would be to automatically learn the embedding dropout in a fully supervised setting. Finally, motivated by the observed large gap in performance between the categorization of, e.g., Oper1 and Oper2, Bon and AntiBon, Ver and AntiVer, we plan to investigate in more depth the codification of collocational information in pretrained LMs.

BART-TL: Weakly-Supervised Topic Label Generation

Cristian Popa

Abstract

We propose a novel solution for assigning labels to topic models by using multiple weak labelers. The method leverages generative transformers to learn accurate representations of the most important topic terms and candidate labels. This is achieved by fine-tuning pre-trained BART models on a large number of potential labels generated by state of the art non-neural models for topic labeling, enriched with different techniques. The proposed *BART-TL* model is able to generate valuable and novel labels in a weakly-supervised manner and can be improved by adding other weak labelers or distant supervision on similar tasks.

1 Introduction

As topic modeling has been used for unsupervised exploration of large text corpora, several topic labeling approaches have been proposed. These range from heuristic-based methods (Mei et al., 2007; Gourru et al., 2018) that focus on the underlying topic distributions to newer methods that use word embeddings (Bhatia et al., 2016). Supervised topic labeling methods (Lau et al., 2011; Bhatia et al., 2016) typically use annotator data with the quality of the labels to train a more accurate ranker than the unsupervised counterpart. Deep learning approaches, which gained quick popularity in NLP, are starting to be used for solving this task as well (Sorodoc et al., 2017; Alokaili et al., 2020).

Recently, transformer models pre-trained on very large amounts of data achieved impressive results on a lot of downstream NLP tasks using fewer resources than previously necessary. We introduce a method of performing a weakly-supervised fine-tuning on these models pre-trained on English data in order to obtain human-comprehensible and meaningful topic labels. We also provide a quality evaluation of the model-generated labels, in addition to an analysis of the contribution gained from using this approach that we ultimately refer to as *BART-TL*, inspired by the name of the original transformer architecture.

2 Related Work

Topic modeling is a popular unsupervised method for exploring large corpora of documents. Topics are represented as distributions over words, while documents as mixtures of topics. Historically, these methods used dimensionality reduction techniques (Deerwester et al., 1990), then migrated to probabilistic-based methods (Hofmann, 1999), with Latent Dirichlet Allocation (Blei et al., 2003) gaining popularity. LDA makes use of variational inference to obtain the distribution matrices. Further developments include hierarchical (Wang et al., 2011) and online (Hoffman et al., 2010) versions of LDA.

While the resulting distributions of topic models are useful for computational purposes, such as measuring the similarity of two documents, these may prove difficult to interpret by humans. Topic labeling aims to solve this issue by computing labels for each topic. Historically, this was achieved by establishing a pool of labels and ranking them using certain scoring functions. First attempts were fully unsupervised, extracting labels from the original corpus (Mei et al., 2007). Later approaches started using external corpora, such as Wikipedia, as candidates for labels and trained supervised rankers (Lau et al., 2011), as well as employed word embeddings (Bhatia et al., 2016) such as *word2vec* (Mikolov et al., 2013) and *doc2vec* (Le and Mikolov, 2014) for computing the similarity between a topic and a candidate label.

Huge progress was made in the NLP field with the introduction of attention models (Bahdanau et al., 2014) and, later on, transformers (Vaswani et al., 2017), which are deep neural networks that

use an encoder-decoder architecture. A multitude of transformer-based models (Devlin et al., 2018; Radford et al., 2019; Liu et al., 2019; Lewis et al., 2019) emerged that achieved state of the art performance on a large number of NLP tasks through transfer learning. These models are pre-trained on large amounts of data in order to encompass general knowledge of the language to be later fine-tuned on downstream tasks. This allows for better results on small datasets, where deep learning was not a viable option beforehand.

However, research on using deep learning methods for topic labeling is scarce. A very recent study proposes an RNN-based encoder-decoder architecture (Alokaili et al., 2020) trained with distant supervision using Wikipedia page titles and employing BERTScore (Zhang et al., 2019) for evaluation.

3 Method

Our method utilizes a pre-trained BART (Lewis et al., 2019) transformer model, with a denoising autoencoder architecture, as we adopt a sequence-to-sequence approach for the task of topic labeling.

3.1 Building a Weakly Supervised Dataset

Topic labeling is generally performed in two steps: establishing a pool of candidate labels and then ranking them appropriately. This workflow is also adopted by a state of the art labeler that we will refer to as *NETL* (Bhatia et al., 2016).[1] This method uses names of Wikipedia articles as candidate labels and trains word2vec and doc2vec models on Wikipedia dumps. Preliminary filtering is done by selecting the labels with the highest embedding similarity scores to the topic terms, while the remaining labels are ranked in an unsupervised manner using letter trigrams. The authors also explore training a supervised ranker after obtaining feedback from annotators, incorporating PageRank (Page et al., 1999) and lexical features.

We build a dataset for fine-tuning BART starting from the **NETL labeler**. We extract the initial candidate labels for each topic after the embeddings similarity filtering but modify this process by assigning a greater weight in the scoring based on the importance of the word in the topic distribution. To avoid overfitting the most important word, we equalize the weights of the top-5 terms. The labels that consist only of stopwords are removed. We make these changes to be able to use a larger number of highest-rated topic terms in extracting labels than the standard 10 employed by NETL, expecting a better performance given a more ample context. Finally, we construct a one-to-many sequence mapping from topics, represented as a concatenation of the top-20 terms separated by spaces, to the corresponding labels. This represents the *baseline dataset*.

We also propose adding several enrichment approaches for this dataset, using other weak labelers as follows. The first additions are entries consisting of space-separated **n-grams** sampled from the most important words in the topic. The sampling is weighted by the underlying probability distribution and these do not have to be consecutive. Inspired by the work of Gourru et al. (2018), **groups of sentences** are added as targets using a variant of the COS10 technique for sentence extraction. The best sentences are joined one-by-one into a short paragraph until a minimum character threshold is met. One last idea for improving the baseline dataset is including popular **noun phrases** from the corpus. They are ranked based on the relevance to the topic and must appear at least a certain number of times in the corpus.

---

[1] The code is open-source: `https://github.com/sb1992/NETL-Automatic-Topic-Labelling-`.

3.2 Fine-tuning BART-TL

Pre-trained BART models are fine-tuned on the resulting datasets. The final *BART-TL* models are able to make predictions on sequences of topic terms. Output labels are generated as sequences and beam search is used to extract multiple ranked labels for a single topic. This strategy joins the extensive knowledge about language encompassed in the original transformer layers with traditional topic labeling techniques. The final models are fine-tuned based on unsupervised labelers and are, thus, weakly-supervised. A detailed representation of the end-to-end process can be seen in Figure 1.

4 Experiments

4.1 Baseline Dataset

We conduct experiments on corpora crawled from Stack Exchange[2] on 5 different subjects: English, Biology, Economics, Law, and Photography. These are preprocessed by removing XML artifacts, stopwords, and individual numbers. Documents with fewer than 20 words are removed from the corpus, along with words that occur less than 10 and more than 50,000 times. A total of 419,189 documents remain in the corpus. We apply LDA (Blei et al., 2003) on each corpus and obtain 100 topics for each subject. This choice for the number of topics is based on the prior work of Bhatia et al. (2016) where the authors generate 100 topics for each domain. These are filtered based on coherence (Röder et al., 2015), removing topics with a C_V score under 0.30, leaving a total of 303 topics. With the probability distributions of topics over the top-100 words, we generate 100 candidate labels for each topic using the NETL approach described in Section 3.

For the weak labelers, we choose to extract 5 n-grams with a n varying between 2 and 4, 5 groups of sentences with a character threshold of 120 and 10 noun phrases with a length of 2 to 4 words that have at least 25 occurrences. We experimented with each strategy individually but provided results for a model employing only the n-grams enrichment, *BART-TL-ng*, and one using all of them, *BART-TL-all*.

4.2 Fine-tuning Details

We fine-tune the large BART model[3] for 2 epochs using an Adam optimizer (Kingma and Ba, 2014) with $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-8}$, 0.1 weight decay, 0.1 dropout, 0.1 attention dropout, 0.1 label smoothing, 6% warmup steps and a learning rate of 3e-5. The final labels are generated using beam search with a beam size of 25. These values follow the fine-tuning approach suggested for RoBERTa (Liu et al., 2019) and, by extension, BERT (Devlin et al., 2018), since the BART fine-tuning experiments do not explicitly specify different values for the hyper-parameters.

5 Results

We gather annotations in the form of surveys with 7 questions, one per topic, on the quality of topic labels on a scale from 0 to 3. The annotators have varying backgrounds, including computer science, medicine, law, and economics. For each of the 5 subjects in the corpus, we select 6 coherent topics for evaluation. The labels are taken from the unsupervised and supervised versions of the original NETL method, along with *BART-TL-ngram*, and *BART-TL-all*. For each method, only top-10 labels are considered for evaluation. An extra stopword label is introduced as a distractor, removing answers from annotators with over 25% of these scores ≥ 1. A topic is presented using its top-10 terms, along with 2 relevant short paragraphs, to offer additional context when the topic is unclear. Each survey has balanced topics based on the 5 subjects and each question contains 9 balanced labels based on the models. We gathered a total of 35 survey responses and filtered out the labels that had only a single annotation. This annotation was performed pro-bono and we estimate that the average time per annotated survey was 10 minutes. There is no bias in the annotations for certain models, as the average standard deviation for rating of individual labels is between 0.42 and 0.44 for all of them.

The results of this study are presented in Table 1. We focus on both the overall quality of the labels through top-k average rating, as well as how well the labels are ordered through normalized discounted cumulative gain (Järvelin and Kekäläinen, 2002). The two *BART-TL* models additionally feature statistics of the same labels reordered by the supervised and unsupervised ranking methods of

BART-TL-all (U)	2.64	2.52	2.43	0.83	0.84	0.87	2.58	2.33	2.20	0.81	0.83	0.89
BART-TL-all (S)	2.64	2.55	2.42	0.81	0.84	0.87	2.58	2.36	2.15	0.81	0.86	0.89
BART-TL-ng (U)	2.62	2.50	2.33	0.82	0.84	0.85	2.58	**2.49**	2.26	0.81	**0.91**	**0.93**
BART-TL-ng (S)	2.73	2.46	2.25	0.87	0.83	0.83	**2.75**	2.40	2.21	**0.91**	0.88	0.91

Table 2: Samples of good and bad quality *new* labels generated by *BART-TL* models.

Top-10 topic terms	**Good new labels**	**Bad new labels**
crime center institution chain prison facility prisoner transformation jail custody	criminal justice system administrative court	guarantee principle
plate vehicle state license motor shall registration law apostille issued	driver's license license plate law	no matter what vehiclelicense *(no space)*
rate interest price inflation bond increase real money supply nominal	investment rate discount rate	rate interest rate principle

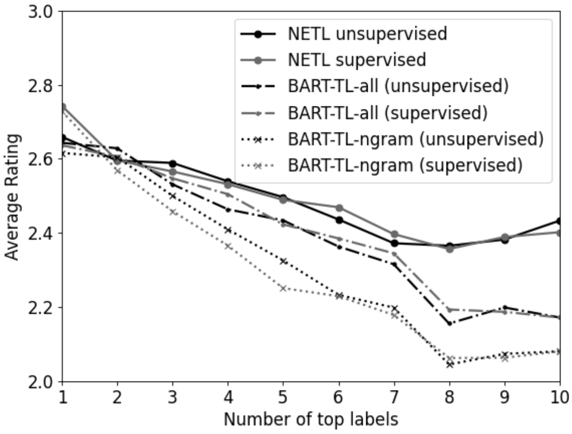

Figure 2: Evolution of average rating considering top-k labels.

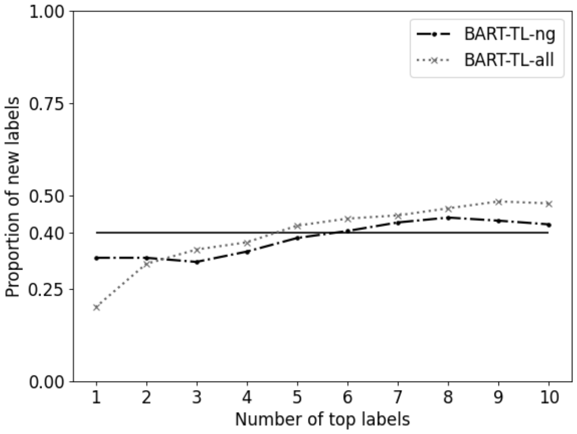

Figure 3: Average proportion of new labels in top-k.

NETL, as these usually perform better than the raw beam search results. The supervised variant of NETL uses the pre-trained ranker from the original paper. An extended version of this table is available in Appendix A.

To further investigate the results, we plot the evolution of the average rating in relation to the number of top labels considered. This can be seen in Figure 2. We study the capacity for novelty of the models in Figure 3, which outlines the proportion of new labels never encountered in the fine-tuning dataset or NETL top-10 predicted labels, as well as Figure 4, which illustrates the average rating of these labels. We observe a significant loss of up to 0.20 in rating, but even larger variations in rating are frequent in Table 1. That said, the novel labels would still be considered relevant with a

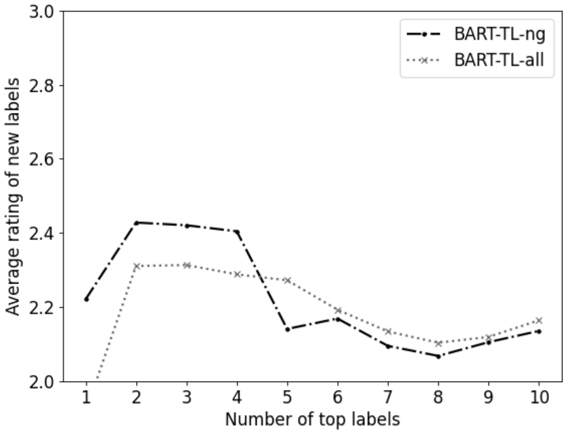

Figure 4: Average rating of new labels in top-k.

rating between 2.0 and 2.5. Table 2 showcases a few samples of original labels.

The results highlight that generative *BART-TL* models produce similar quality labels as the NETL methods when considering the top 1-2 labels. However, the quality of the generated labels degrades as their number increases. There is also no clear winner between the supervised and unsupervised versions of the proposed models, as they have similar trends. At the same time, the novelty tends to improve slightly with the number of considered labels. On average, 40% of the labels were never provided when fine-tuning the models. While novelty is an important feature for *BART-TL*, it can further be conditioned to generate labels with specific characteristics (Keskar et al., 2019).

The *BART-TL* models outperform the NETL methods on the English corpus, the largest of the five. At the same time, they achieve similar results on the Law and Biology corpora, that have the least amount of topics and are outperformed on the rest. Therefore, there was no correlation found between corpus size and the quality of the generated labels.

6 Conclusion

We introduced the *BART-TL* model that builds upon previous topic labeling solutions by adopting a generative deep learning strategy. Large pre-trained transformer models are fine-tuned in a weakly-supervised manner using unsupervised labelers to obtain meaningful labels. While current results have varying quality compared NETL, *BART-TL* is able to generate novel labels of similar quality. Although BART-TL experiments have been carried out for English, our generative methodology can be applied to any language if a pre-trained BART model is available.

Appendix A. Extended Results

We present an extended version of the results showcased previously in Table 1. While the target metrics remain the same, the additions are the raw BART models, with the labels retaining the order that they were generated in using beam search, as well as all of the 5 different subjects. These were added in Table 3.

Table 3: Extended quality comparison of labels between *NETL* and *BART-TL* models.

Abstract

Textual information extraction is a typical research topic in the NLP community. Several NLP tasks such as named entity recognition and relation extraction between entities have been well-studied in previous work. However, few works pay their attention to the implicit information. For example, a financial news article mentioned "Apple Inc." may be also related to Samsung, even though Samsung is not explicitly mentioned in this article. This work presents a novel dynamic graph transformer that distills the textual information and the entity relations on the fly. Experimental results confirm the effectiveness of our approach to implicit tag recognition.

1 Introduction

Documents on the web deliver and spread lots of most recent information to people worldwide. In order to automatically update the real-world information, textual information extraction is a fundamental issue for NLP researchers. Many downstream tasks such as fake news detection (Wu et al., 2019) and stock movement prediction (Peng and Jiang, 2016) can benefit from the extracted information. However, most of the previous works (Hu et al., 2018; Xu and Cohen, 2018) focus on using explicit information in articles and do not consider the implicit information. For example, two companies, Sprint and T-Mobile, are explicitly mentioned companies in the news article in Figure 1. However, the stock price of a non-mentioned company, SoftBank, may be influenced since Softbank owns shares of Sprint. Although this kind of inference is intuitive for professional analysts, few previous works take such implicit information into consideration. In this paper, we aim to increase the sense of machines toward this kind of implicit information.

Transformer-based (Vaswani et al., 2017) neural networks achieve state-of-the-art performances in many NLP tasks (Devlin et al., 2018; Malmi et al., 2019). To model the relationships between entities, graph neural network (GNN) is a well-known architecture for representing the knowledge and additional information (Fu et al., 2019; You et al., 2020). Furthermore, the models blending these two architectures show their effectiveness (Lu et al., 2020). In this paper, we propose dynamic graph transformer (DGT), a novel blend of Transformer and GNN. In previous work, the weights of the GNN are pre-determined in the training stage and not affected by the given input. Our DGT adjusts the weights depending on the input on the fly. In this way, the representation of the graph information will be more flexible and more specific to the input.

Title:
The Judge Nodded! *Sprint* Rise 70% in After-hour Trading.

News Article:
A federal judge gave his blessing to the US$26.5 billion merger between *T-Mobile* and *Sprint* on Feb. 11, several months after the deal got final antitrust approval from the U.S. government. *Sprint* surges 68.75%. *T-Mobile* rise 7.36%.

Figure 1: An example of the implicit information in news articles.

A strategy for pre-training on in-domain data is further proposed. Experimental results show our approach is effective in the task of extracting the implicit information from news articles. The contributions of this work are summarized as follows.

- We point out an important issue of information extraction for implicit entities.
- We propose a novel model that dynamically incorporates textual information and graph in-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 1426–1431

formation. Our approach outperforms recent works in implicit tag recognition.

- Our pre-training task, masked entity prediction, is helpful for predicting the implicit entities. The pre-trained model can be also applied in other information extraction tasks.

2 Related work

Extracting and using the information in articles is one of the focuses in the NLP community. Some works (Hu et al., 2018; Ding et al., 2019; Ma et al., 2019) adopt the extracted information for stock market prediction. Some of them (Baker et al., 2016; Min and Zhao, 2019) use the information in news articles to construct socio-economic indicators. Most of previous works only focus on explicit information in the articles. In this way, the implicit entities in the articles may be under looked. In this paper, we aim to extract the non-mentioned but related entities from a document.

Recently, GNN has become popular for modeling relationships among multiple entities. Kipf and Welling (2016) use the convolution neural network to learn the node representation by aggregating the features of neighboring nodes. Veličković et al. (2017) employ the attention mechanism to improve the GNN architecture. Recent studies (Berg et al., 2017; Monti et al., 2017; Ying et al., 2018) also show the effectiveness of graph neural networks in various tasks. Inspired by these works, we present a new blend of graph attention network (GAT) (Veličković et al., 2017) with Transformer (Vaswani et al., 2017) and BERT (Devlin et al., 2018) for extracting the implicitly related entities to a given article.

3 Method

3.1 Task Setting

The task is formulated as follows. Given an article, a model is aimed at predicting a list of entities that are not explicitly mentioned but related to the given article. Let a corpus be $\mathcal{D} = \{(\mathbf{d}^1, \mathbf{y}^1), (\mathbf{d}^2, \mathbf{y}^2), ..., (\mathbf{d}^{|\mathcal{D}|}, \mathbf{y}^{|\mathcal{D}|})\}$, where $\mathbf{d}^k$ and $\mathbf{y}^k$ denote k-th article and the implicit entity list of k-th article, respectively. The k-th article can be represented by a word sequence, i.e., $\mathbf{d}^k = (w_1^k, w_2^k, ..., w_{|\mathbf{d}^k|}^k)$. Let the candidate entity list be $\mathcal{C} = \{c_1, c_2, ..., c_{|\mathcal{C}|}\}$, where c_i denotes i-th entity, and $\mathbf{y}^k \in \{0,1\}^{|\mathcal{C}|}$, $\mathbf{y}_i^k = 1$ if the entity c_i is associated with the given article $\mathbf{d}^k$ but not directly mentioned within the content, otherwise $\mathbf{y}_i^k = 0$.

3.2 Graph Attentional Layer

We build a co-occurrence matrix $\mathbf{M}$ to represent the association graph of the entities in $\mathcal{C}$. The frequency of two entities c_i and c_j appearing together in the training corpus can be defined as follows.

$$\mathbf{M}_{i,j} = \sum_{k=1}^{|\mathcal{D}|} [\mathbf{y}_i^k = 1 \text{ and } \mathbf{y}_j^k = 1] \,, \tag{1}$$

where $[\cdot]$ is the Iversion bracket. $\mathbf{M}$ can be viewed as an adjacency matrix representation of an association graph. $\mathbf{M}_{i,j}$ is the value of the edge between nodes i and j, which represents the degree of association between the entities c_i and c_j. The graph attentional layer is a component of the graph attention network (GAT) (Veličković et al., 2017). In order to suit the architecture of Transformers, we modify part of GAT as follows. Firstly, the h-th score matrix $\mathbf{S}^h \in \mathbb{R}^{n \times n}$ is defined as follows.

$$\mathbf{S}^h = \frac{\mathbf{X}\mathbf{W}_Q^h (\mathbf{X}\mathbf{W}_K^h)^\top}{\sqrt{d}} \,, \tag{2}$$

where $\mathbf{X} \in \mathbb{R}^{n \times d_{\text{input}}}$ denotes the input matrix, and $\mathbf{W}_Q^h \in \mathbb{R}^{d_{\text{input}} \times d}$ and $\mathbf{W}_K^h \in \mathbb{R}^{d_{\text{input}} \times d}$ are learnable matrices.

Secondly, the h-th multi-head attention matrix $\mathbf{A}^h \in \mathbb{R}^{n \times n}$ is defined as follows.

$$\mathbf{A}_{i,j}^h = \begin{cases} \frac{e^{\mathbf{S}_{i,j}^h}}{\sum_{k \in \mathcal{N}[i]} e^{\mathbf{S}_{i,k}^h}} & \text{if } j \in \mathcal{N}[i] \\ 0 & \text{otherwise.} \end{cases} \,, \tag{3}$$

where $\mathcal{N}[i] = \{j : \mathbf{M}_{i,j} > 0\}$ represents the closed neighborhood set of node i. Lastly, we concatenate all the computational results of multi-attention heads. The output of the graph attentional layer is computed as follows.

$$\mathrm{GAL}(\mathbf{X}) = (\mathop{\Big\Vert}_{h=1}^{H} \mathbf{A}^h \mathbf{X} \mathbf{W}_V^h) \mathbf{W}_O \,, \tag{4}$$

where $\mathbf{W}_V^h \in \mathbb{R}^{d_{\text{input}} \times d}$ and $\mathbf{W}_O \in \mathbb{R}^{d_{\text{input}} \times d_{\text{input}}}$ are learnable matrices. H is the number of attention heads and $d_{\text{input}} = d \times H$.

3.3 Dynamic Graph Transformer

We first show Static Graph Transformer (SGT), which incorporates Transformer, BERT, and GAT. Then, we extend SGT to the final model, Dynamic Graph Transformer (DGT) by considering graph information dynamically.

Static Graph Transformer

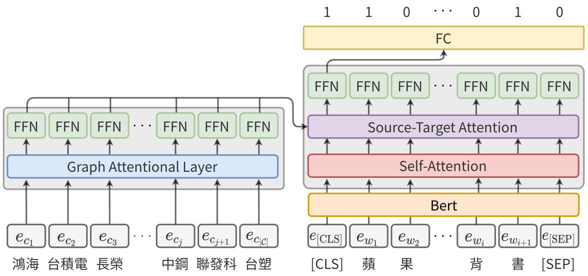
Figure 2a shows the architecture of SGT, which integrates graph and text information. The motivation behind SGT is to treat the Transformer encoder as a variation of GNN by replacing self-attention with a graph attentional layer. The Transformer encoder takes the entity's representation $\mathbf{e}_{c_j}$ as input. It is one of the row vectors in BERT's word embeddings $\mathbf{E} \in \mathbb{R}^{|\mathcal{V}| \times d_{\text{input}}}$, where $\mathcal{V}$ denotes the vocabulary of BERT. We consider the outputs of the Transformer encoder as the entity embeddings $\mathbf{n}_1, \mathbf{n}_2, ..., \mathbf{n}_{|\mathcal{C}|}$. In SGT, the process of generating entity embedding $\mathbf{n}_j$ is static because it is irrelevant to the content information from the input article. In the Transformer decoder, we take the contextual word embeddings as the inputs of the Transformer encoder. The contextual word embeddings are the last hidden state vectors of BERT, which use the word embedding $\mathbf{e}_{w_i}$ in the article as input. Finally, we follow the settings of Devlin et al. (2018) to use the first output embedding of the Transformer decoder for predicting the implicit entity list.

Dynamic Graph Transformer

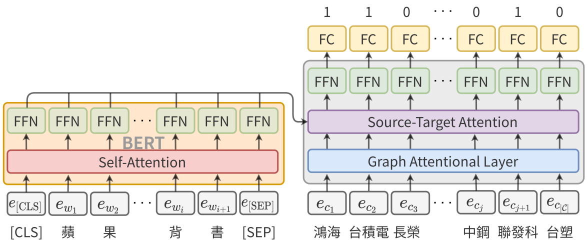
Figure 2b shows the architecture of DGT. From another perspective, since BERT is a kind of Transformer encoder, we move the learning part of entity embedding $\mathbf{n}_j$ to the Transformer decoder. We treat the last hidden state vectors of the Transformer decoder as entity embeddings $\mathbf{n}_1, \mathbf{n}_2, ..., \mathbf{n}_{|\mathcal{C}|}$. In this way, DGT is able to update the entity embedding on the fly because the source-target attention mechanism utilizes the outputs of BERT, making the model more tailored to the input article. In our task, each entity embedding is mapped to the scalar, which indicates the probability of the entity related to the article but not mentioned in it.

3.4 Pre-training by Masked Entity Prediction

Devlin et al. (2018) show that pre-training with masked language modeling and next sentence prediction is effective. Chu et al. (2020) indicate that pre-training with the value process prediction task is useful for generating correct numeric values in news headlines.



(a) Static Graph Transformer (SGT)



(b) Dynamic Graph Transformer (DGT)

Figure 2: Overview of SGT and DGT.

In this work, we propose a new pre-training task, masked entity prediction, to enrich the semantic information of entity names. Building on the original BERT vocabulary, we add a list of entity names in $\mathcal{C}$ and aim to learn their representations. We adopt the *bert-base-chinese* as the initial model and retrofit it on the training data with two sub-tasks at the same time. The first sub-task is a new masked language modeling task. Unlike the masked language model task performed for the original BERT, we not only mask the tokens using the method in Devlin et al. (2018) but also all the entity mentions in the document. The second sub-task is to label all masked entities on the position tagged as `[CLS]`. In this way, we obtain a new pre-trained model tailored to our target corpus.

4 Experiments

4.1 Dataset Description

The dataset[1] consists of 27,716 news articles collected from MoneyDJ[2], a financial newsvendor in Taiwan. Each news article is published with the labels of the related entities. These labels are annotated by professional journalists. The candidate entity list contains 735 company names, i.e., $|\mathcal{C}| = 735$. We split the dataset into the training set and the test set by time. The training set contains

Model	Micro-F1	Macro-F1
ABC	67.11%	31.73%
TAB-LSTM	64.82%	30.47%
ITAG	60.06%	27.44%
BERT	71.72%	34.18%
VGCN-BERT	72.86%	35.65%
SGT	75.94%	42.94%
DGT	**76.16%**	**47.41%**

Table 1: Overall performances.

Model	Micro-F1	Macro-F1
SGT w/o pre-train	-1.67%	-3.78%
DGT w/o pre-train	-1.90%	-7.37%

Table 2: Performance degradation caused by the approach without the proposed pre-training task.

24,640 samples before March 24, 2017. The test set contains 3,076 samples from March 24, 2017.

4.2 Baseline Models

We adopt two kinds of models as our baselines, including the models for tag recommendation and the models for classification. The models ABC (Gong and Zhang, 2016), TAB-LSTM (Li et al., 2016), and ITAG (Tang et al., 2019) are considered as the baselines for tag recommendation. For the classification task, we adopt BERT (Devlin et al., 2018) and VGCN-BERT (Lu et al., 2020) for comparison.

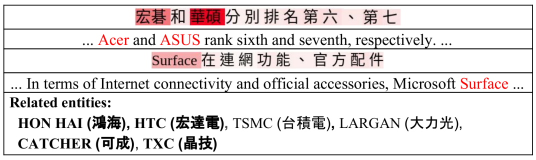
4.3 Experimental Results

We adopt the binary cross-entropy as the loss function and the Adam optimizer (Kingma and Ba, 2014) for training. The learning rate and the batch size are 3e-5 and 8, respectively. Table 1 shows that the proposed models are better than the baseline models in both micro-F1 score and macro-F1 score. In Table 2, we further show the performance degradation when using the original BERT language model instead of the language model with the proposed pre-training task. The results confirm that the proposed pre-training task is useful in the implicit relation learning task.

5 Discussion

5.1 Attention Mechanism

Table 3a shows that the model focuses on the companies and the products that appear in the news article. It indicates that the proposed model captures the relationship between the companies via the related companies and the mentioned products. In Table 3b, we find that even no company names have been mentioned in the news article, DGT can still correctly infer the related entities by the mentioned raw material such as wheat, corn, and soybeans.



宏碁和華碩分別排名第六、第七
... Acer and ASUS rank sixth and seventh, respectively. ...
Surface在連網功能、官方配件

… 18 cents per pound. Soybean futures prices are expected to fall by at most …
Related entities: **FWUSOW (福壽), UNI-PRESIDENT (統一), TTET (大統益), ST (興泰),** **TAIROUN (台榮), FOPCO (福懋油), GREATWALL (大成), CPE (卜蜂),** **TAISUN (泰山), LHIC (聯華), NAMCHOW (南僑), Wei Chuan (味全),** **S.F.C (佳格), AGV (愛之味)**

(b) Inferring non-mentioned companies only by mentioned products.

Table 3: Examples of attention weights. All related entities are labeled by professional journalists, and the bold entities represent the model predictions.

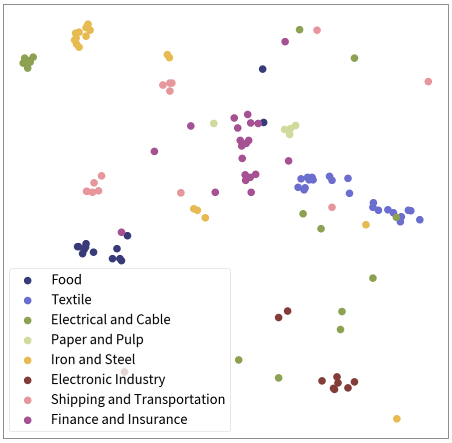

Figure 3: Visualization of entity embeddings by t-SNE.

5.2 Entity Embeddings

We use the last hidden state vectors of DGT as the corresponding entity embeddings and use t-SNE (van der Maaten and Hinton, 2008) to visualize these embeddings. As shown in Figure 3, we find that although we do not directly provide the information about the related industry or product of the entity during training, the model can still capture relationships from the corpus.

6 Conclusion and Future Work

This paper presents a novel dynamic graph transformer model and a pre-training task for extracting the implicit entities in articles. Experimental results show the usefulness of the proposed methods. We also discuss what kinds of features our model captures.

In our previous work (Liou et al., 2021), we apply the proposed task to accelerate the working process of the journalists and show that using the extracted entities could be useful for downstream tasks such as news aggregation and stock movement prediction. In the future, we plan to apply the proposed approach to datasets with both graphical knowledge and textual content.

Abstract

Likelihood training and maximization-based decoding result in dull and repetitive generated texts even when using powerful language models (Holtzman et al., 2019). Adding a loss function for regularization was shown to improve text generation output by helping avoid unwanted properties, such as contradiction or repetition (Li et al., 2020). In this work, we propose fine-tuning a language model by using policy gradient reinforcement learning, directly optimizing for better generation. We apply this approach to minimizing repetition in generated text, and show that, when combined with unlikelihood training (Welleck et al., 2020), our method further reduces repetition without impacting the language model quality. We also evaluate other methods for improving generation at training and decoding time, and compare them using various metrics aimed at control for better text generation output.

1 Introduction

Language models have become a subject of close attention in the Natural Language Processing field over the past few years. They are widely used not only for unsupervised pre-training, but also for text generation, such as what is implemented in dialogue systems (Roller et al., 2020). While there are ongoing efforts to develop non-autoregressive models for language modeling, most current state-of-the-art approaches use the autoregressive method of generating text (i.e., word by word). Holtzman et al. (2019) showed that even powerful trained models with a high likelihood value for test data can output repetitive results. Schmidt (2019) argues that the reason for that is train-test discrepancy and lack of generalization when running standard maximum likelihood estimation (MLE) training.

Unwanted repetition can be remedied at decoding and training time. Decoding methods focus on sampling techniques that generate less repetitive or incoherent samples, while other methods aim to improve model training to minimize the effects of degeneration. An effective method for reducing language model degeneration is unlikelihood training (Welleck et al., 2020), where a regularization term forces the model to reduce the probability of generating a token that has already occurred in a sequence. Li et al. (2020) further explored this idea and showed that adding a loss function for regularization *to avoid undesirable sequences* improves text generation not only by reducing repetition, but also by decreasing contradiction. Roller et al. (2020) reported that adding unlikelihood training also improves the humanness of generated text.

In this paper, we propose **Implicit Unlikelihood Training**, a method for regularizing output by fine-tuning a language model with policy gradient reinforcement learning to improve generation results. We apply this method for a repetition objective, and show that combining Implicit Unlikelihood Training with minimizing unlikelihood loss results in reduced repetition and perplexity. We also evaluate alternative approaches to improving generated texts in terms of repetitiveness, and compare these methods using a wide variety of metrics.

2 Related Work

2.1 Decoding Strategies

Holtzman et al. (2019) observed that maximization-based decoding methods, such as top-k sampling (Fan et al., 2018), beam search and its variations, can all lead to degeneration. They addressed this problem by using top-p (nucleus) sampling, proposing sampling from the top portion of the probability mass. Paulus et al. (2017) reported that ground-truth sentences for summarization tasks almost never contain the same trigram twice, and proposed the beam-blocking approach, where the decoder is forced to never output the same trigram more than once during testing. Penalized sampling (Keskar et al., 2019) works by discounting the scores of previously generated tokens. Martins et al. (2020) proposed preventing unlikely words from receiving any probability mass by using entmax sampling.

2.2 Training Strategies

Jiang et al. (2020) suggested that some tokens can be more difficult for a model to learn than others. These tokens are still under-learned after training, making their repetition more likely to happen. This issue is addressed by token loss dynamic reweighting (TLDR), which applies differentiable weights to individual token losses. Repetition can also be improved at training time by adding unlikelihood loss (Welleck et al., 2020; Li et al., 2020) to regular likelihood loss. Unlikelihood training is aimed at decreasing the probability of previously generated tokens, and it was shown that it can outperform beam blocking and top-p sampling.

Coverage mechanisms (Tu et al., 2016; See et al., 2017) can also be used to reduce repetition. Adding pre-attention and highway connections was shown to decrease repetition for RNNs (Jiang et al., 2020), while the architecture tweaks required for Transformers (Vaswani et al., 2017) are still an open question.

2.2.1 Unlikelihood Training

Unlikelihood Training involves adding Unlikelihood Loss to lower the probability $p_\theta(c_i|x_{<t})$ of negative candidates $\mathcal{C}^t = \{c_1, c_2, ..., c_n\}$ at each timestamp:

$$\mathcal{L}^t_{\text{UL}}\left(p_\theta\left(\cdot|x_{<t}\right), \mathcal{C}^t\right) = -\sum_{c\in\mathcal{C}^t} \log\left(1 - p_\theta\left(c|x_{<t}\right)\right). \tag{1}$$

We can construct the negative candidate set as $\mathcal{C}^t = \{x_{t-1}, x_{t_2}, ..., x_1\}\backslash\{x_t\}$ to improve generation results through reducing repetition. Welleck et al. (2020) also proposed using Sequence-Level Unlikelihood Loss on sampled continuations, where a sequence $(x_{t+1}, x_{t+2}, ..., x_{t+N})$ from a prefix $(x_1, x_2, ..., x_t)$ is sampled first, and then the loss defined in Eq. 1 for each x_{t+i} (where $1 \leq i \leq N$) with negative examples $\mathcal{C}^{t+i}$ equal to $\{x_{t+i}\}$ if x_{t+i} is a part of a repeating n-gram at a position before $t+i$ is minimized (see Algorithm 3 for details on Sequence-Level Unlikelihood Loss). Fine-tuning a language model is then performed by equally alternating between sequence-level unlikelihood and likelihood updates.

2.3 Evaluation Metrics

There are many metrics available for evaluating the performance (diversity or non-repetition) or quality of language models. These metrics include **perplexity**, the number of unique next-token predictions (**uniq**), **uniq-seq**, **rep/l**, **wrep/l** (Welleck et al., 2020), **ϵ-perplexity**, **sparsemax score** (sp), Jensen-Shannon divergence (**JSD**) (Martins et al., 2020), and **DIMEN** (Jiang et al., 2020).

Perplexity is the metric used to evaluate language model quality. It is defined as $ppl(x) = p(x_1, x_2, ..., x_t)^{-\frac{1}{t}}$, where $x_1, x_2, ..., x_t$ is the sequence of tokens from test data. The lower the perplexity, the better the language model.

Welleck et al. (2020) used a portion of duplicate n-grams in a generated sequence to measure **sequence repetition**:

$$\text{seq\_rep\_n}(\mathbf{x}) = 1 - \frac{\#\text{uniq\_ngram}(\mathbf{x})}{\#\text{total\_ngram}(\mathbf{x})}. \tag{2}$$

Higher repetition values mean that a language model tends to produce more repetitive output, which might appear less natural. Note that $0 \leq \text{seq\_rep\_n}(\mathbf{x}) < 1$.

Same as (Welleck et al., 2020), we controlled for the number of unique next-token predictions (**uniq**), as it was shown that generated texts are less diverse than those written by a human. We also used the number of unique tokens in continuations of validation or test prefixes (**uniq-seq**) as a measure of token distribution in generated text. **rep/l** is the fraction of next-token (top-1) predictions that occur in the previous l tokens. **wrep/l** is a variant of rep/l which only counts single token repetitions that are not equal to the ground truth next-token. We use 16,32,128,512 as l and average the results to compute rep and wrep.

Martins et al. (2020) introduced **ϵ-perplexity** for computing perplexity of sparse distributions. The perplexity is smoothed by adding a small value of ϵ to all terms, followed by renormalization. They also introduced **sparsemax score** (sp) and **Jensen-Shannon divergence** (JSD) for evaluating quality and sparsity of probability distributions. For deterministic models, sparsemax score becomes word accuracy, and is bounded by 0 and 1. With JSD, the distance between the sparse or truncated distribution and the one-hot encoded ground truth distribution can be measured. It is used as a metric for language models using different decoding strategies. Unlike perplexity, JSD is bounded by $\log 2$.

Jiang et al. (2020) evaluate methods with a diversity metric based on n-grams (**DIMEN**). A high DIMEN score means that a set of generated sequences is diverse.

In this paper, we mainly focused on reducing sequence repetition (**seq_rep_n**) (Welleck et al., 2020), which is a portion of duplicate n-grams in a generated sequence. Improving generation results by minimizing repetition should not significantly affect the **perplexity** of the language model.

3 Implicit Unlikelihood Training

Li et al. (2020) showed that Unlikelihood Training can be employed as a general framework for reducing the likelihood of undesirable text generation results through training on negative examples. However, we argue that, in some cases, it could be difficult to construct negative samples for specific types of Unlikelihood Loss[1]. To address this issue, we propose extending Unlikelihood Training with policy gradient reinforcement learning, which does not need explicitly created negative samples.

We chose to test this approach for repetition as the most widely considered property of neural text degeneration. To directly minimize repetition (see Equation 2) for sequence x, we define the reward as $R = 1 - \text{seq\_rep\_n}(\mathbf{x})$ with $n = 4$. We alternated between maximizing the reward R, optimizing the likelihood of training data, and Sequence-Level Unlikelihood Loss (see 1, 2 and 3 for details on the process of Implicit Unlikelihood Training and policy gradient update).

Algorithm 1: i-UT: alternating between MLE, UT and PG updates

```
Input: update rate $r$, total number of updates $N$
for $i$ = 1 to $N$ do
    sample $x \sim \mathrm{U}[0,1]$
    if $x < r$ then
        sample $y \sim \mathrm{U}[0,1]$
        if $y < 0.5$ then
            do a policy gradient update
        else
            do a sequence-level unlikelihood update
        end
    else
        do a MLE update
    end
end
```

Algorithm 2: Policy Gradient Update

```
Input: LM $\theta$, $m$ prefixes
       $\mathcal{D}_m = \{(x_1^{(j)}, \ldots, x_k^{(j)}),\ j = \overline{1..m}\}$,
       continuation length $T$
Output: loss $\mathcal{L}(\theta, \mathcal{D}_m)$
for $j$ = 1 to $m$ do
    for $t$ = $k+1$ to $k+T$ do
        Get $p_\theta(\cdot \mid x_{<t}^{(j)})$
        $x_t^{(j)} = \arg\max_{x \in \mathcal{V}} p_\theta(\cdot \mid x_{<t}^{(j)})$
    end
end
for $j$ = 1 to $m$ do
    $R_j = 1 - \text{seq\_rep\_n}(\mathbf{x}^{(j)})$
end
$b(\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(m)}) = \sum_{j=1}^{m} R_j$
for $j$ = 1 to $m$ do
    $\Psi_j = R_j - b(\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(m)}) \cdot \frac{1}{m}$
end
$\mathcal{L}(\theta, \mathcal{D}_m) =$
    $-\frac{1}{m} \sum_{j=1}^{m} \Psi_j \cdot \frac{1}{T} \sum_{t=k+1}^{k+T} \log p_\theta(x_t^{(j)} \mid x_{<t}^{(j)})$
```

4 Experiment Details

4.1 Setup

We fine-tuned small and medium GPT-2 models (175M and 345M parameters, respectively) (Radford et al., 2019) on the WikiText-103 dataset (Merity et al., 2016).

---

[1] This can include reducing the toxicity or bias level of generated sequences by using a score from an external classifier.

Table 2: Repetition on the medium GPT-2 model with a 0.5 update rate. Regular perplexity is reported for softmax sampling. Test data is used as sampling prefixes for evaluating the metrics.

Our experiments consisted of alternating between three types of updates: Maximizing Likelihood (MLE), minimizing Sequence-Level Unlikelihood Loss (UL), and minimizing repetition with policy gradient reinforcement learning (PG). The first approach is a plain **MLE** update, for which we do not use any specific methods for reducing repetition in samples. We also experimented with Unlikelihood Training (**UT**), which involves alternating between MLE and UL updates (see Algo-

Algorithm 3: Sequence-Level Unlikelihood Update

```
Input: LM $\theta$, batch of prefixes
       $\mathcal{D}_m = \{(x_1^{(j)}, \dots, x_k^{(j)}),\ j = \overline{1..m}\}$,
       continuation length $T$
Output: loss $\mathcal{L}(\theta, \mathcal{D}_m)$
for $j$ = 1 to $m$ do
    for $t$ = $k+1$ to $k+T$ do
        Get $p_\theta(\cdot \mid x_{<t}^{(j)})$
        $x_t^{(j)} = \arg\max_{x \in \mathcal{V}} p_\theta(\cdot \mid x_{<t}^{(j)})$
    end
end
for $j$ = 1 to $m$ do
    for $t$ = $k+1$ to $k+T$ do
        if $(x_{t-i}, \dots, x_t, \dots, x_{t+h}) \in$
          $x_{<t-i}^{(j)}$ for any $(h-i) = n, i \leq n \leq h$
          then
            $\mathcal{C}^t_{\text{repeat-n}}(\mathbf{x}^{(j)}) = \{x_t\}$
        else
            $\mathcal{C}^t_{\text{repeat-n}}(\mathbf{x}^{(j)}) = \emptyset$
        end
    end
end
$\mathcal{L}(\theta, \mathcal{D}_m) =$
  $\frac{1}{m} \sum_{j=1}^{m} \frac{1}{T} \sum_{t=k+1}^{k+T} \mathcal{L}^t_{UL}\left(p_\theta(\cdot \mid x_{<t}^{(j)}), \mathcal{C}^t_{\text{repeat-n}}\right)$
```

rithm 1 for details).

In policy gradient experiments, we trained models in three different scenarios: a plain **PG** for which we alternated MLE and PG updates; a combined **PG + UT** approach, where we alternated between maximizing the likelihood and minimizing the sum of policy gradient and unlikelihood losses; and finally, the proposed Implicit Unlikelihood Training (**i-UT**), which consisted of alternating between MLE, UL and PG updates (see Algorithms 1, 3, and 2). We used 0.25 and 0.5 alternating update rates for the small GPT-2 model, and r equal to 0.5 for the medium GPT-2 model.

Full optimization details are provided in **Appendix A.1. Optimization Details**.

4.2 Evaluation

We used top-k and top-p samplings with different k and p to evaluate sequence repetition[2] (seq_rep_4) for the described approaches. For these experiments, we used validation data to evaluate perplexity and to generate the sampling prefixes for evaluating uniq and seq_rep_4 metrics. The number of unique tokens (uniq) was evaluated using greedy sampling. We also evaluated the proposed method with rep, wrep, and JSD metrics using different sampling methods on test data, and compared it with other related approaches (MLE, UT, entmax). We repeated each experiment 5 times and reported the mean and standard deviation values of the measurements.

More experiments and their results are described in **Appendix A.2. Experiments**.

5 Results

We showed that Implicit Unlikelihood Training is a competitive approach that outperforms other methods in sequence repetition when fine-tuning small and medium GPT-2 models (see Table 1) on most variants of top-k and top-p sampling, while maintaining the lowest perplexity and the highest count of unique tokens generated. This approach also achieved better results than training with entmax loss and other related approaches, using a different range of sampling methods (see Table 2), with the only exception being the rep metric, where entmax performed similar to i-UT.

Samples of generated outputs are provided in Tables 8, 9 in Appendix.

6 Future Work

The described and evaluated reinforcement learning framework makes it possible to optimize text generation for any objective. In future work, we intend to test the approach not only for repetition, but also for various other metrics, such as the toxicity level or bias of generated text.

A Appendices

A.1 Optimization Details

For likelihood update, we evaluated the likelihood of a sequence of tokens with lengths equal to 300. For both UL and PG updates, we formed prefixes using a sequence of 300 tokens to form 6 sequences with lengths equal to 50. We then used these prefixes to sample sequences with a maximum length of 100 tokens.

For optimization, we used the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 6.25×10^{-5}. Similar to (Welleck et al., 2020) and (Martins et al., 2020), we did no warmup steps for UT and $\alpha-$entmax training. For i-UT, we did 500 linear warm-up steps . After warm-up steps, we linearly decayed the learning rate to zero.

In all our experiments, we fine-tuned language models for 5000 total updates.

Once training was complete, we selected a checkpoint with the least validation perplexity obtained during training. This is the last checkpoint in most of our experiments, which means that general log-likelihood loss converges.

As shown in Algorithm 1, we equally alternated between UL and PG updates. We also found that reducing unlikelihood update rate to 0.25 may also be effective, taking twice less time (see Table 1). The parameters ϵ for $\epsilon-$ppl and α for $\alpha-$entmax training were taken from (Martins et al., 2020) (except ϵ for $\alpha-$entmax, which we set to 1×10^{-6}).

We conducted coefficient search on our policy gradient loss with $c = \{3, 9, 15, 30\}$ for the small GPT-2 model, and $c = \{3, 15, 30\}$ for medium GPT-2 model. We chose the best models based on the results on the validation set, and also reported the metrics on the test set.

A.2 Experiments

We evaluated DIMEN and uniq-seq for UT and i-UT methods, applied to small and medium GPT-2 models using different sampling methods for DIMEN, and greedy sampling for evaluation of uniq-seq. In this experiment, we observed that Implicit Unlikelihood Training performed better or equal to Unlikelihood Training with different sampling methods measured by the DIMEN metric, having a significantly better value of uniq-seq (see Table 7).

We also evaluated sequence repetition with beam-search sampling for MLE, UT, and i-UT methods for both small and medium GPT-2 models, using validation data to form sampling prefixes. When sampling with beam search, we found that Implicit Unlikelihood Training produced better results than Unlikelihood Training (see Table 3).

For greedy sampling with small GPT-2 model, we evaluated sequence repetition, wrep, uniq, and perplexity. We used test data to evaluate the perplexity, and to form sampling prefixes for other methods. We observed that MLE, UT, and i-UT methods had similar performance in terms of repetition using greedy sampling, while i-UT still had the best number of unique tokens (see Table 4).

Finally, we evaluated the TLDR method using both sequence repetition and DIMEN metrics (see Tables 5, 6). In our experimental setup, TLDR performed on par with MLE approach.

B Negative Results

Our results showed that all sampling methods, other than greedy sampling, led to worse convergence of the seq_rep_4 metric.

We experimented with using the Proximal Policy Optimization algorithm (Schulman et al., 2017) for PG update, but faced unstable validation perplexity behavior during training, and did not obtain any comparable results.

Another unsuccessful direction of our experiments was substituting the estimation of the reward calculated on the full sequence with the reward put on each token separately. We tried using two variants of the binary reward function: does the current n-gram appear first time in the text, and does the current n-gram appear in the following part of the text. We experimented with advantage estimation by using a value function estimator, and without it by using pure rewards. In the former case, we adjusted different values of λ and γ for the Generalized Advantage Estimation algorithm (Schulman et al., 2015), and in the latter, we used a general discounted future reward. We observed that the approach of estimating a single reward for a whole sequence and subtracting a baseline value to reduce the variance of the gradient estimation performed best.

Abstract

Platforms that support online commentary, from social networks to news sites, are increasingly leveraging machine learning to assist their moderation efforts. But this process does not typically provide feedback to the author that would help them contribute according to the community guidelines. This is prohibitively time-consuming for human moderators to do, and computational approaches are still nascent. This work focuses on models that can help suggest rephrasings of toxic comments in a more civil manner. Inspired by recent progress in unpaired sequence-to-sequence tasks, a self-supervised learning model is introduced, called CAE-T5[1]. CAE-T5 employs a pre-trained text-to-text transformer, which is fine tuned with a denoising and cyclic auto-encoder loss. Experimenting with the largest toxicity detection dataset to date (Civil Comments) our model generates sentences that are more fluent and better at preserving the initial content compared to earlier text style transfer systems which we compare with using several scoring systems and human evaluation.

1 Introduction

There are many ways to express our opinions. When we exchange views online, we do not always immediately measure the emotional impact of our message. Even when the opinions expressed are legitimate, well-intentioned and constructive, a poor phrasing may make the conversation go awry (Zhang et al., 2018a). Recently, Natural Language Processing (NLP) research has tackled the problem of abusive language detection by developing accurate classification models that flag toxic (or abusive, offensive, hateful) comments (Davidson et al., 2017; Pavlopoulos et al., 2017; Wulczyn et al., 2017; Gambäck and Sikdar, 2017; Fortuna and Nunes, 2018; Zhang et al., 2018a; Van Hee et al., 2018; Zampieri et al., 2019).

INPUT OFFENSIVE COMMENT	you now have to defend this clown along with his russian corruption.
GENERATED CIVIL COMMENT	**you now have to defend this guy from his russian ties........**
INPUT OFFENSIVE COMMENT	blaming trudeau and the government is just stupid.
GENERATED CIVIL COMMENT	**blaming trudeau and the liberal government is just wrong.**
INPUT OFFENSIVE COMMENT	dubya[2]was a moron.
GENERATED CIVIL COMMENT	**dubya was a republican.**

Table 1: Examples of offensive sentences from the Civil Comments test set and the more civil rephrasing generated by our model. The third example shows that its strategy may involve shifting the original intent, since "republican" is not a non-offensive synonym of "moron".

The prospect of healthier conversations, nudged by Machine Learning (ML) systems, motivates the development of Natural Language Understanding and Generation (NLU and NLG) models that could later be integrated in a system suggesting alternatives to vituperative comments before they are posted. A first approach would be to train a text-to-text model (Bahdanau et al., 2014; Vaswani et al., 2017) on a corpus of parallel comments where each offensive comment has a courteous and fluent rephrasing written by a human annotator. However, such a solution requires a large paired labeled dataset, in practice difficult and expensive to collect (see Section 4.5). Consequently, we limit our setting to the unsupervised case where the comments are only annotated in attributes related to toxicity, such as the Civil Comments dataset (Borkan et al., 2019). We summarize our investigations with the following research question:

---

April 19 - 23, 2021.

RQ: *Can we fine-tune end-to-end a pre-trained text-to-text transformer to suggest civil rephrasings of rude comments using a dataset solely annotated in toxicity?*

Answering this question might provide researchers with an engineering proof-of-concept that would enable further exploration of the many complex questions that arise from such a tool being used in conversations. The main contributions of this work are the following:

- We addressed for the second time the task of unsupervised civil rephrases of toxic texts, relying for the first time on the Civil Comments dataset, and achieving results that reflect the effectiveness of our model over baselines.
- We developed a non-task specific approach (i.e. with no human hand-crafting in its design) that can be generalized and later applied to related and/or unexplored attribute transfer tasks.

While several of the ideas we combine in our model have been studied independently, to the best of our knowledge, no existing unsupervised models combine sequence-to-sequence bi-transformers, transfer learning from large pre-trained models, and self-supervised fine-tuning (denoising auto-encoder and cycle consistency). We discuss the related work introducing these tools and techniques in the following section.

2 Related work

Unsupervised complex text attribute transfer (like civil rephrasing of toxic comments) remains in its early stages, and our particular applied task has only a single antecedent (Nogueira dos Santos et al., 2018). There is a great variety of useful works to tackle the task and this section attempts to summarize the vast majority of these works. We describe below the recent strategies (such as attention mechanisms Bahdanau et al., 2014) that led to significant progress in supervised NLU and NLG tasks. Then, we present the most related lines of work in unsupervised text-to-text tasks.

2.1 Transformers[3] are state-of-the-art architectures in NLP

Vaswani et al. (2017) showed that transformer architectures, based on attention mechanisms, achieved state-of-the-art results when applied to supervised Neural Machine Translation (NMT). More generally, transformers have proven capable in various NLP and speech tasks (Dong et al., 2018; Huang et al., 2019; Le et al., 2019; Li et al., 2019). Moreover, transformers benefit from pre-training before being fine-tuned on downstream tasks (Devlin et al., 2019; Dai et al., 2019b; Yang et al., 2019; Conneau and Lample, 2019; Raffel et al., 2019). Subsequent research has adopted uni-transformers in many supervised classification and regression tasks (Devlin et al., 2019) and in unsupervised language modeling (Radford et al., 2019; Keskar et al., 2019; Dathathri et al., 2020), until Raffel et al. (2019) proposed a unified pre-trained bi-transformer applicable to any text classification, text regression and text-to-text task. Further, recent works tackle the language detoxification of unconditional language models (Krause et al., 2020; Gehman et al., 2020).

2.2 Unsupervised losses enable training text-to-text models end-to-end

After the success of unsupervised image-to-image style transfer in computer vision (CV), some approaches have addressed unsupervised text-to-text tasks. Unsupervised Neural Machine Translation (UNMT) is maybe the most promising of them. Artetxe et al. (2018); Conneau et al. (2018); Lample et al. (2018a,b); Conneau and Lample (2019) introduced methods based on techniques aligning the embedding spaces of monolingual datasets and tricks such as denoising auto-encoding losses (Vincent et al., 2008) and back-translation (Sennrich et al., 2015; Edunov et al., 2018).

Abstractive summarization (or sentence compression) is also studied in unsupervised settings. Baziotis et al. (2019) trained a model with a compressor-reconstructor strategy similar to back-translation while Liu et al. (2019b) trained a denoising auto-encoder that embeds sentences and paragraphs in a common space.

Unsupervised attribute transfer is the task most related to our work. It mainly focuses on sentiment transfer with standard review datasets (Maas et al.,

---

[3] To avoid confusion we denote as bi-transformer the original encoder-decoder transformer whereas encoder-only and decoder-only models are called uni-transformers here.

2011; He and McAuley, 2016; Shen et al., 2017; Li et al., 2018), but also addresses sociolinguistic datasets containing text in various registers (Gan et al., 2017; Rao and Tetreault, 2018) or with different identity markers (Voigt et al., 2018; Prabhumoye et al., 2018; Lample et al., 2019). When paraphrase generation aims at being explicitly attribute-invariant, it is referred as obfuscation or neutralization (Emmery et al., 2018; Xu et al., 2019b; Pryzant et al., 2020). Literary style transfer (Xu et al., 2012; Pang and Gimpel, 2019) has also been tackled by recent work. Here, we apply attribute transfer to a large dataset annotated in toxicity, but we also use the Yelp review dataset from Shen et al. (2017) for comparison purposes (see Section 4).

Initial unsupervised attribute transfer approaches sought to build a shared and attribute-agnostic latent representation encoding for the input sentence, with adversarial training. Then, a decoder, aware of the destination attribute, generated a transferred sentence (Shen et al., 2017; Hu et al., 2017; Fu et al., 2018; Zhang et al., 2018c; Xu et al., 2018; John et al., 2019).

Unsupervised attribute transfer approaches that do not rely on a latent space are also present in literature. Li et al. (2018) assumed that style markers are very local and proposed to delete the tokens most conveying the attribute, before retrieving a second sentence in the destination style. They eventually combined both sentences with a neural network. Lample et al. (2019) applied UNMT techniques from Conneau and Lample (2019) to several attribute transfer tasks, including social media datasets. Xu et al. (2018); Gong et al. (2019); Luo et al. (2019); Wu et al. (2019a) trained models with reinforcement learning. Dai et al. (2019b) introduced unsupervised training of a transformer called StyleTransformer (ST) with a discriminator network. Our approach differs from these unsupervised attribute transfer models in that they did not either leverage large pre-trained transformers, or train with a denoising objective.

The most similar work to ours is Nogueira dos Santos et al. (2018) who trained for the first time an encoder-decoder rewriting offensive sentences in a non-offensive register with non-parallel data from Twitter (Ritter et al., 2010) and Reddit (Serban et al., 2017). Our approach differs in the following aspects. First, we use transformers pre-trained on a large corpus instead of randomly initialized RNNs for encoding and decoding. Second, their approach involves collaborative classifiers to penalize generation when the attribute is not transferred, while we train end-to-end with a denoising auto-encoder. Even if their model shows high accuracy scores, it suffers from low fluency, with offensive words being often replaced by a placeholder (e.g. "big" instead of "f*cking").

As underlined by Lample et al. (2019), applying Generative Adversarial Networks (GANs) (Zhu et al., 2017) to NLG is not straightforward because generating text implies a sampling operation that is not differentiable. Consequently, as long as text is represented by discrete tokens, loss gradients computed with a classifier cannot be back-propagated without tricks such as the REINFORCE algorithm (He et al., 2016) or the Gumbel-Softmax approximation (Baziotis et al., 2019) which can be slow and unstable. Besides, controlled text generation (Ficler and Goldberg, 2017; Keskar et al., 2019; Le et al., 2019; Dathathri et al., 2020) is a NLG task that consists of a language model conditioned on the attributes of the generated text such as the style. But a major difference with attribute transfer is the absence of a constraint regarding the preservation of the input's content.

3 Method

3.1 Formalization of the attribute text rewriting problem

Let X_T and X_C be our two non-parallel corpora of comments satisfying the respective attributes "toxic" and "civil". Let $X = X_T \cup X_C$. We aim at learning a parametric function f_θ mapping a pair of source sentence x and destination attribute a to a fluent sentence y satisfying a and preserving the meaning of x. In our case, there are two attributes "toxic" and "civil" that we assumed to be mutually exclusive. We denote $\alpha(x)$ to be the attribute of x and $\bar{\alpha}(x)$ the other attribute (for instance when $\alpha(x) =$ "civil", then $\bar{\alpha}(x) =$ "toxic"). Note that $f_\theta(x, \alpha(x))$ can simply be x.

3.2 Our approach is based on bi-conditional encoder-decoder generation

Our approach is to train an autoregressive (AR) language model (LM) conditioned on both the input text x and the destination attribute a.

We compute f_θ with a LM $p(y|x, a; \theta)$. As we do not have access to ground-truth targets y, we propose in section 3.3 a training function that we assume to maximize $p(y|x, a; \theta)$ if and only if y is a fluent sentence with attribute a and preserving x's content. Additionnaly, we use an AR generating model where inference of $\hat{y}$ is sequential and the token generated at step $t+1$ depends on the tokens generated at previous steps: $p(\hat{y}_{t+1}|\hat{y}_{:t}, x, a; \theta)$.

To condition on the input text, we follow the work of Bahdanau et al. (2014); Vaswani et al. (2017); Nogueira dos Santos et al. (2018); Conneau and Lample (2019); Lample et al. (2019); Dai et al. (2019a); Liu et al. (2019b); Raffel et al. (2019) and opt for an encoder-decoder framework. Lample et al. (2019); Dai et al. (2019a) argue that in unsupervised attribute rewriting tasks, encoders do not necessarily output disentangled representations, independent of its attribute. However, the t-SNE visualization of the latent space in Liu et al. (2019b) allowed us to assume that encoders can output a latent representation z, attending to content rather than on an attribute, with a similar training.

The LM is conditioned on the destination attribute with control codes introduced by Keskar et al. (2019). A control code is a fixed sequence of tokens prepended to the decoder's input s, and supposed to prepare the generation in the space of sentences with the destination attribute a. We define $\gamma(a, s) = concat(c(a), s)$ where $c(a)$ is the control code of attribute a.

3.3 Training the encoder-decoder with an unsupervised objective

Denoising objectives to train transformers are an effective self-supervised strategy. Devlin et al. (2019); Yang et al. (2019) pre-trained a uni-transformer encoder as a masked language model (MLM) to teach the system general-purpose representations, before fine-tuning on downstream tasks. Conneau and Lample (2019); Lample et al. (2019); Song et al. (2019); Liu et al. (2019b); Raffel et al. (2019) explore various deshuffling and denoising objectives to pre-train or fine-tune bi-transformers.

During training, we corrupt the encoder's input x with the noise function from Devlin et al. (2019): η masks tokens randomly with probability 15%. Then, masks are replaced by a random token in the vocabulary with probability 10% or left as a sentinel (a shared mask token) with probability 90%. We train the model as an denoising auto-encoder (DAE), meaning that we minimize the negative log-likelihood

$$\mathcal{L}_{\text{DAE}} = \mathbb{E}_{x\sim X}\left[-\log p(x|\eta(x), \alpha(x); \theta)\right]$$

The hypothesis is that optimizing the DAE objective teaches the controlled generation to the model.

Inspired by an equivalent approach in unsupervised image-to-image style transfer (Zhu et al., 2017), we add a cycle-consistency (CC) objective (Nogueira dos Santos et al., 2018; Edunov et al., 2018; Prabhumoye et al., 2018; Lample et al., 2019; Conneau and Lample, 2019; Dai et al., 2019a):

$$\mathcal{L}_{\text{CC}} = \mathbb{E}_{x\sim X}\left[-\log p(x|f_{\tilde{\theta}}(x, \bar{\alpha}(x)), \alpha(x); \theta)\right]$$

which enforces content preservation in the generated prediction. As the cycle-consistency objective computes a non-differentiable AR pseudo-prediction $\hat{y}$ during stochastic gradient descent training, gradients are not back-propagated to $\tilde{\theta} = \hat{\theta}_{\tau-1}$ at training step τ.

Finally, the loss function sums the DAE and the CC objectives with weighting coefficients: $\mathcal{L} = \lambda_{\text{DAE}}\mathcal{L}_{\text{DAE}} + \lambda_{\text{CC}}\mathcal{L}_{\text{CC}}$

3.4 The text-to-text bi-transformer architecture

The architectures for the encoder and decoder are uni-transformers. Contrary to Vaswani et al. (2017); Conneau and Lample (2019); Raffel et al. (2019) we do not keep decoder's layers computing cross attention between the encoder's outputs h and the decoder hidden variables because generation suffers from too much conditioning on the input sentence and we observe no significant change in the output sentence. Rather, we follow Liu et al. (2019b) and compute the latent representation z with an affine transformation of the encoder's hidden state h_0 (corresponding to the first token of the input text). Let $x \in X$ be the input sequence of token. It is embedded then encoded by the uni-transformer encoder:

$$\begin{aligned} x_{\text{Emb}} &= f_{\theta_{\text{Emb}}}(x) \\ h_{\text{Enc}} &= f_{\theta_{\text{Enc}}}(x_{\text{Emb}}) \\ h^0_{\text{Enc}} &= h_{\text{Enc}}[0, :] \\ z &= f_{\theta_{\text{Dense}}}(h^0_{\text{Enc}}) \end{aligned}$$

z is an aggregate sequence representation for the input. There are different heuristics that can be used to integrate it in the decoder. We considered summing z to the embedding of each token of the uni-transformer decoder's input s since it balances the backpropagation of the signals coming from the original input and from the output being generated in the destination attribute space and it worked well in practice in our experiments.

$$\gamma_{\text{Emb}} = f_{\theta_{\text{Emb}}}(\gamma(a,s))$$
$$h_{Dec} = f_{\theta_{\text{Enc}}}(\gamma_{\text{Emb}} + z)$$
$$\hat{y} = f_{\theta_{\text{LMHead}}}(h_{\text{Dec}})$$

Plus, the encoder and the decoder uni-transformers share the same embedding layer and the LM Head is tied to the embeddings.

Except for the dense layer computing the latent variable z, all parameters are coming from the pre-trained bi-transformer published by Raffel et al. (2019). Thus, our DAE and CC objectives **fine-tune** T5's parameters and this is why we call our model a conditional auto-encoder text-to-text transfer transformer (CAE-T5).

4 Experiments

4.1 Datasets

We employed the largest publicly available toxicity detection dataset to date, which was used in the 'Jigsaw Unintended Bias in Toxicity Classification' Kaggle challenge.[4] The 2M comments of the **Civil Comments dataset** stem from a commenting plugin for independent news sites. They were created from 2015 to 2017 and appeared on approximately 50 English-language news sites across the world. Each of these comments was annotated by crowd raters (at least 3 each) for toxicity and toxicity subtypes (Borkan et al., 2019).

Following the work of Dai et al. (2019a) for the IMDB Movie Review dataset (positive/negative sentiment labels), we constructed a sentence-level version of the dataset. Initially, we fine-tuned a pre-trained BERT (Devlin et al., 2019) toxicity classifier on the Civil Comments dataset. Then, we split the comments in sentences with NLTK's sentence tokenizer.[5] Eventually, we created X_T (respectively X_C) with sentences whose system-generated toxicity score (using our BERT classifier) is greater than 0.9 (respectively less than 0.1) to increase the dataset's polarity. The test ROC-AUC of the toxicity classifier is 0.98 with a precision of 0.95 and a recall of 0.38. Even with this low recall $|X_T|$ is large enough (approx. 90k, see Table 2).

We also conducted a comparison to other style transfer baselines on the **Yelp Review Dataset** (Yelp), commonly used to compare unsupervised attribute transfer systems. It consists of restaurant and business reviews annotated with a binary positive / negative label. Shen et al. (2017) processed it and Li et al. (2018) collected human reference human references for the test set[6]. Table 2 shows statistics for these datasets.

Dataset	**Yelp**		**Polar Civ. Com.**	
Attribute	Positive	Negative	Toxic	Civil
Train	266,041	177,218	90,293	5,653,785
Dev	2,000	2,000	4,825	308,130
Test	500	500	4,878	305,267
Av. len.	11.0	13.0	19.4	21.9

Table 2: Statistics for the Yelp dataset and the processed version of the Civil Comments dataset. Average lengths are the average numbers of SentencePiece tokens.

4.2 Evaluation

Evaluating a text-to-text task is challenging, especially when no gold pairs are available. Attribute transfer is successful if generated text: 1) has the destination control attribute, 2) is fluent and 3) preserves the content of the input text.

4.2.1 Automatic evaluation

We follow the current approach of the community (Yang et al., 2018; Logeswaran et al., 2018; Wang et al., 2019; Xu et al., 2019a; Lample et al., 2019; Dai et al., 2019a; He et al., 2020) and approximate the three criteria with the following metrics:

1. **Attribute control**: Accuracy (ACC) computes the rate of successful changes in attributes. It measures how well the generation is conditioned by the destination attribute. We predict toxic and civil attributes with the same fine-tuned BERT classifier that pre-processed the Civil Comments dataset (single threshold at 0.5).

2. **Fluency**: Fluency is measured by perplexity (PPL). To measure PPL, we employed GPT2 (Radford et al., 2019) LMs fine-tuned on the corresponding datasets (Civil Comments and Yelp).

3. **Content preservation**: Content preservation is the most difficult aspect to measure. UNMT (Conneau and Lample, 2019), summarization (Liu et al., 2019b) and sentiment transfer (Li et al., 2018) have access to a few hundred samples with at least one human reference of the transferred text and evaluate content preservation by computing metrics

Human rephrasing	**you could find out more about it.**	2.3	16.2%

Table 3: Evaluation with BLEU and SIM of examples rephrased by human crowdworkers.

based on matching words (e.g., BLEU Papineni et al. (2002)) between the generated prediction and the reference(s) (ref-metric). However, as we do not have these paired samples, we compute a content preservation score between the input and the generated sentences (self-metric).

Table 3 shows the BLEU scores (based on exact matches) of three examples rephrased by human annotators (Section 4.5). In the top-most example, BLEU score is high. This is explained by the fact that only 4 words are different between the two texts. In contrast to the first example, the two texts in the second example have only 1 word in common. Thus, the BLEU score is low. Despite the low evaluation, however, the candidate text could have been a valid rephrase of the reference text.

The high complexity of our task explains the motivation for a more general quantitative metric between input and generated text, capturing the semantic similarity rather than overlapping tokens. Fu et al. (2018); John et al. (2019); Gong et al. (2019); Pang and Gimpel (2019) proposed to represent sentences as a (weighted) average of their words embeddings before computing the cosine similarity between them. We adopted a similar strategy but we embedded sentences with the pre-trained universal sentence encoder (Cer et al., 2018) and call it the sentence similarity score (SIM). The first two sentence pairs of Table 3 have high similarity scores. The rephrasings preserve the original content while not necessarily overlapping much with the original text. However, the last rephrasing does not preserve the initial content and have a low similarity score with its source sentence. As a statistical evidence, the self-SIM score comparing each of the 1,000 test Yelp reviews with their human rewriting is 80.2% whereas the self-SIM score comparing the Yelp review test set to a random derangement of the human references is 36.8%.

We optimised all three metrics because doing otherwise comes at the expense of the remaining metric(s). We aggregated the scores of the three metrics by computing the geometric mean[7] (GM) of ACC, 1/PPL and self-SIM.

4.2.2 Human evaluation

Following Li et al. (2018); Zhang et al. (2018b,c); Wu et al. (2019a,b); Wang et al. (2019); John et al. (2019); Liu et al. (2019a); Luo et al. (2019); Jin et al. (2019) and to further confirm the performance of CAE-T5, we hired human annotators on Appen to rate in a blind fashion different models' civil rephrasings of 100 randomly selected test toxic comments, in terms of attribute transfer (Att), fluency (Flu), content preservation (Con) and overall quality (Over) on a Likert scale from 1 to 5. Each rephrasing was annotated by 5 different crowdworkers whose annotation quality is controlled by test questions. If a rephrasing is rated 4 or 5 on Att, Flu and Con then it is "successful" (Suc).

4.3 Baselines

We compare the output text that CAE-T5 generates with a selection of unpaired style-transfer models described in Section 2.2 (Shen et al., 2017; Li et al., 2018; Fu et al., 2018; Luo et al., 2019; Dai et al., 2019a). We also compare with Input Masking. It is inspired by an interpretability method called Input Erasure (IE) (Li et al., 2016). IE is used to interpret the decisions of neural models. Initially, words are removed one at a time and the altered texts are then re-classified (i.e., as many re-classifications as the words). Then, all the words that led to a decreased re-classification score (based on a threshold) are returned as the ones most related to the decision of the neural model. Our baseline follows a similar process, but instead of deleting, it uses a pseudo token ('[MASK]') to mask one word at a time. When all the masked texts have been scored by the classifier, the rephrased text is returned, comprising as many masks as the tokens that led to a decreased re-classification score (set to 20% after preliminary experiments). We employed a pre-trained BERT as our toxicity classifier, fine-tuned on the Civil Comments dataset (see Section 4.1).

---

[7] The geometric mean is not sensitive to the scale of the individual metrics.

4.4 Results

4.4.1 Quantitative comparison to prior work

Table 4 shows quantitative results on the Civil Comments dataset. Surprisingly, the perplexity (capturing fluency) of text generated by our model is lower than the perplexity computed on human comments. This can be explained by social media authors of comments expressing an important variability in language formal rules, that is only partially replicated by CAE-T5. Other approaches such as StyleTransformer (ST) and CrossAlignment (CA) have higher accuracy but at a cost of both higher perplexity and lower content preservation, meaning that they are better are discriminating toxic phrases but struggle to rephrase in a coherent manner.

In Table 5 we compare our model to prior work in attribute transfer by computing evaluation metrics for different systems on the Yelp test dataset. We achieve competitive results with low perplexity while getting good sentiment controlling (above human references). Our similarity though is lower, showing that some content is lost when decoding, hence the latent space does not fully capture the semantics. It is fairer to compare our model to other style transfer baselines on the Yelp dataset since our model is based on sub-word tokenization while the baselines are often based on a limited size pretrained word embedding: many more words from the Civil Comments dataset could be attributed to the unknown token if we want to keep reasonable size vocabulary, resulting in a performance drop.

The human evaluation results shown in Table 6 correlate with the automatic evaluation results.

When considering the aggregated scores (geometric mean, success rate and overall human judgement), our model is ranked first on the Civil Comments dataset and second on the Yelp Review dataset, behind DualRL yet our approach is more stable and therefore easier to train when compared to reinforcement learning approaches.

4.4.2 Qualitative analysis

Table 7 shows examples of rephrases of toxic comments automatically generated by our system. The top first two examples emphasize the ability for the model to perform fluent control generation conditioned on both the input sentence and the destination attribute. We present more results showing that we can effectively suggest fluent civil rephrases of toxic comments in the Appendix Table 8. However we observe more failures than in the sentiment transfer task (see examples in the Appendix Table 9). We identify three natures of failure:

Model	ACC ↑	PPL ↓	self-SIM ↑	GM ↑
Copy input	0%	6.8	100%	0.005
Random civil	100%	6.6	20.0%	0.311
Human	82.0%	9.2	73.8%	0.404
CA	94.0%	11.8	38.4%	0.313
IE (BERT)	86.8%	7.5	55.6%	0.401
ST (Cond)	97.8%	47.2	68.3%	0.242
ST (M-C)	**98.8%**	64.0	67.9%	0.219
CAE-T5	75.0%	**5.2**	**70.0%**	**0.466**

Table 4: Automatic evaluation scores of different models trained and evaluated on the processed Civil Comments dataset. The scores are computed on the toxic test set. "Human" corresponds to 427 human rewritings of randomly sampled toxic comments from the train set. "Random civil" means we randomly sampled 4,878 comments from the civil test set.

Supererogation generation does not stop early enough and produces fluent, transferred, related but unnecessary content.

Hallucination conditioning on the initial sentence fails and the model generates fluent but unrelated content.

Position reversal the author's opinion is shifted.

In order to assess the frequency of hallucination and supererogation, we randomly selected 100 toxic comments from the test set and manually labeled the generated sentences with the non-mutually exclusive labels "contains supererogation" and "contains hallucination". We counted on average 17% of generated sentences with surrerogation and 34% of generated sentences showing hallucination (often local). We observe that the longer the input comment, the more prone to hallucination is the generated text.

While supererogation and hallucination can be explained by the probabilistic nature of generation, we assume that position reversal is due to bias in the dataset, where toxic comments are correlated with negative comments. Thus, offensive comments tend to be transferred to supportive comments even though a human being would rephrase attacks as polite disagreements.

Interestingly, our model is able to add toxicity in civil comments as shown by the examples in the Appendix Table 10. Even if such an application shows limited interest for online platforms, it is worth warning about its potential misuse.

Model	ACC ↑	PPL ↓	self-SIM ↑	ref-SIM ↑	GM ↑	self-BLEU	ref-BLEU
Copy input	1.3%	11.1	100%	80.2%	0.105	100	32.5
Human references	79.4%	14.0	80.2%	100%	0.357	32.7	100
CrossAlignment (Shen et al., 2017)	73.5%	54.4	61.0%	59.0%	0.202	21.5	9.6
(Li et al., 2018)							
RetrieveOnly	**99.9%**	**4.9**	47.1%	48.0%	0.213	2.7	1.8
TemplateBased	84.1%	46.0	76.0%	68.2%	0.240	57.0	23.2
DeleteOnly	85.2%	48.7	72.6%	67.7%	0.233	33.9	15.2
D&R	89.8%	35.8	72.0%	67.6%	0.262	36.9	16.9
(Fu et al., 2018)							
StyleEmbedding	8.1%	29.8	83.9%	69.8%	0.132	**67.5**	21.9
MultiDecoder	47.2%	74.2	67.7%	61.4%	0.163	40.4	15.2
DualRL (Luo et al., 2019)	88.1%	20.5	83.6%	**77.2%**	**0.330**	58.7	29.0
(Dai et al., 2019a)							
StyleTransformer (Conditional)	91.7%	44.8	80.3%	74.2%	0.254	53.2	25.6
StyleTransformer (Multi-Class)	85.9%	29.1	**84.2%**	77.1%	0.292	62.8	**29.2**
CAE-T5	84.9%	22.9	67.7%	64.4%	0.293	27.3	14.0

Table 5: Automatic evaluation scores of different models trained and evaluated on the Yelp dataset. Accuracy is computed by a BERT classifier fine-tuned on the Yelp train set (accurate at 98.7% on the test set). Perplexity is measured by a GPT2 language model fine-tuned on the Yelp train set. "self-" refers to a comparison to the input and "ref-" to a human reference.

Model	Att ↑	Flu ↑	Con ↑	Suc ↑	Over ↑
CA	**2.98**	2.32	1.89	6 %	1.81
IE (BERT)	2.77	2.39	2.20	6 %	1.89
ST (Cond)	2.91	2.36	2.08	5%	1.87
ST (M-C)	2.93	2.42	2.10	5%	1.93
CAE-T5	2.72	**3.06**	**2.63**	**13%**	**2.52**

4.5 Discussion

Supervised learning is a natural approach when addressing text-to-text tasks. In our study, we submit the civil rephrasing of toxic comments task to human crowd-sourcing. We randomly sampled 500 sentences from the toxic train set. For each sentence, we asked 5 annotators to rephrase it in a civil way, to assess if the comment was offensive and if it was possible to rewrite it in a way that is less rude while preserving the content. On 2500 answers, we tally 427 examples not flagged as impossible to rewrite and with a rephrasing different from the original sentence. This low 17.1% yield is caused by two main issues. On the one hand, unfortunately not all toxic comments can be reworded in a civil manner so as to express a constructive point of view; severely toxic comments that are solely made of insults, identity attacks, or threats are not "rephrasable". On the other hand, evaluating crowd-workers with test questions and answers is complex. The perplexity being higher on crowd-workers' rephrases than on randomly sampled civil comments raises concerns about the production of human references *via* crowd-sourcing. The nature of large datasets labeled in toxicity and the lack of incentives for crowd-sourcing civil rephrasing annotation makes it expensive and difficult to train systems in a supervised framework. These limitations motivates unsupervised approaches.

Lastly, the more complex is the unsupervised attribute transfer task, the more difficult is its automatic evaluation. In our case, evaluating whether the attribute is actually transferred requires to train an accurate toxicity classifier. Furthermore, the language model we use to assess the fluency of the generated sentences has some limitations and does not generalize to all varieties of language encountered in social media. Finally measuring the amount of relevant content preserved between the source and generated texts remains a challenging, open research topic.

5 Conclusion and future work

This work is the second one to tackle civil rephrasing to our knowledge and the first one to address it with a fully end-to-end discriminator-free text-to-text self-supervised training. CAE-T5 leverages the NLU / NLG power offered by large pre-trained bi-transformers. The quantitative and qualitative analysis shows that ML systems could contribute to some extent to pacify online conversations, even though many generated examples still suffer from critical semantic drift.

In the future, we plan to explore whether the decoding can benefit from NAR generation (Ma et al., 2019; Ren et al., 2020). We are also interested in the recent paradigm shift proposed by Kumar and Tsvetkov (2019), where the generated tokens representation is continuous, allowing more flexibility in plugging attribute classifiers without sampling.

A Supplemental Material

A.1 Experimental setup

A.1.1 Architecture details

We fine-tune the pre-trained "large" bi-transformer from Raffel et al. (2019). Both uni-transformers (encoder and decoder) have 24 blocks each made of a 16-headed self-attention layer and a feed-forward network. The attention, dense and embedding layers have respective dimensions of 64, 4096 and 1024, for a total of around 800 million parameters.

Input sentences are lowercased then tokenized with SentencePiece[8] (Kudo and Richardson, 2018) and eventually truncated to a maximum sequence length of 32 for the Yelp dataset and 128 for the processed Civil Comments dataset. The control codes are $c(a) = concat(a, \texttt{": "})$ for attributes $a \in \{\texttt{"positive"}, \texttt{"negative"}\}$ in the sentiment transfer task and $a \in \{\texttt{"toxic"}, \texttt{"civil"}\}$ when we apply to the Civil Comments dataset.

A.1.2 Training details

During training, we apply dropout regularization at a rate of 0.1. We set $\lambda_{AE} = \lambda_{CC} = 1.0$. In preliminary experiments, we observed that $\lambda_{CC} = 0$ was preserving little content from the initial sentence and that $\lambda_{CC} = 2 * \lambda_{AE}$ was weighting the preservation too much, at the cost of accuracy. Therefore we focused our experiments on $\lambda_{CC} = \lambda_{AE}$. It is a good default setting since we don't have a priori about the balance between fluency, accuracy (enforced with the auto-encoder) and content preservation (enforced with cycle consistency). DAE and back-transfer (in the course of the CC computation) are trained with teacher-forcing; we do not need AR generation since we have access to a target for the decoder's output. Each training step computes the loss on a mini-batch made of 64 sentences sharing the same attribute. Mini-batches of attributes a and $\bar{a}$ are interleaved. Since the Civil Comments dataset is class imbalanced, we sample comments from the civil class of the training set at each epoch. The optimizer is AdaFactor (Shazeer and Stern, 2018) and we train for 88900 steps for 19 hours on a TPU v2 chip.

A.1.3 Evaluation details

Decoding is greedy. The parametric models used to compute ACC and PPL are 12-layer, 12 headed pre-trained, and fine-tuned uni-transformers with hidden size 768. The BERT classifier is an encoder followed by a sequence classification head and the GPT2 LM is a decoder with a LM head on top. We use the sacrebleu[9] implementation for BLEU and the universal sentence encoder pre-trained by Google to compute SIM[10].

A.2 CAE-T5 learning algorithm

Algorithm 1 and Figure 1 describe the fine-tuning procedure of CAE-T5. H computes the cross-entropy.

```
Algorithm 1: CAE-T5 training
Input  : T5's pre-trained parameters $\theta_0$,
         unpaired dataset labelled in
         toxicity $X = X_T \cup X_C$
Output : CAE-T5's fine-tuned parameters
         $\theta_T$
for step $\tau \in [1; T]$ do
    if $\tau\%2 == 0$ then
        Sample a mini-batch $x$ of sentences
          in $X_T$
    else
        Sample a mini-batch $x$ of sentences
          in $X_C$
    end
    $\theta \leftarrow \hat{\theta}_{\tau-1}$ $\tilde{\theta} \leftarrow \hat{\theta}_{\tau-1}$
     $\hat{x}_{DAE} \leftarrow f_{\theta}(\eta(x), \alpha(x))$
     $\hat{x}_{CC} \leftarrow f_{\theta}(f_{\tilde{\theta}}(x, \bar{\alpha}(x)), \alpha(x))$
     $\ell_{DAE} \leftarrow H(x, \hat{x}_{DAE})$
     $\ell_{CC} \leftarrow H(x, \hat{x}_{CC})$
     $\ell \leftarrow \lambda_{DAE}\ell_{DAE} + \lambda_{CC}\ell_{CC}$
     Back-propagate gradients through $\theta$
     Update $\theta_{\tau}$ by a gradient descent step
end
```

Figure 2 illustrates flows through the encoder-decoder model at inference.

A.3 Appen settings

Figure 3 and Figure 4 detail the guidelines we wrote on the crowdsourcing website Appen[11], when we asked human crowd-workers to rate automatic rephrasings and to rephrase toxic comments. Contributor level is set to level 3, which corresponds to the highest quality standard.

(a) DAE

(b) CC

Figure 1: Illustration of the training procedure. (a) DAE: The bi-transformer encodes the corrupted input text $\eta(x)$ in a latent variable z that is then decoded conditioned on the source attribute $\alpha(x)$ with the objective of minimizing the cross entropy between x and the generated text $\hat{x}$. Here, generation is not AR since the DAE is trained with teacher forcing. (b) CC: The input x is pseudo-transferred with attribute $\bar{\alpha}(x)$ with AR decoding because we do not know the ground-truth y. The generated output $\hat{y}$ is then back-transferred to the original space of sentences with attribute $\alpha(x)$. Back-transfer generation is not AR because we use teacher-forcing here. Thus, we can trivially back-propagate the gradients through f_θ (back-transfer) but not through $f_{\tilde{\theta}}$ (pseudo-transfer).

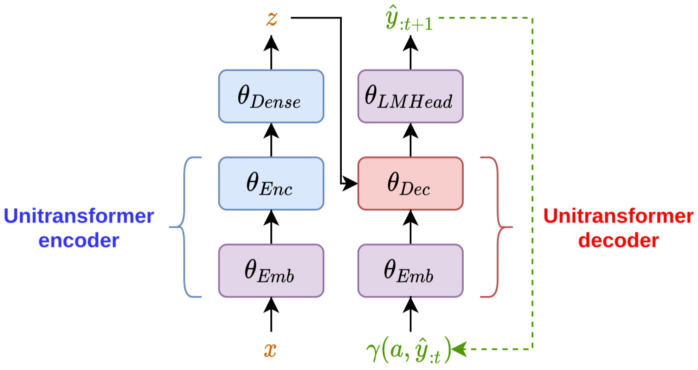

Figure 2: Model overview at prediction time. x and $\hat{y}$ are the input and generated text, a is the destination attribute, z is the latent input representation and γ is the function prepending control codes to the decoder's input. θ represents the model's parameters.

Toxic to Civil	
Input	and then they need to do what it takes to get rid of this mentally ill bigot!
CAE-T5	and then they need to do what they can to get rid of this **kind of man that is causing the whole problem!**
Input	do you think any of those idiots vote?
CAE-T5	do you think any of those **people** vote?
Input	this is just so stupid.
CAE-T5	this is just so **sad**.
Input	are you nuts?
CAE-T5	are you **kidding me**?
Input	we are all entitled to our own opinions but not the facts that one can't find in this criminally stupid opinion.
CAE-T5	we are all entitled to our own opinion but not **to the kind of facts that can be found in this case**.
Input	hopefully that will prevent him from making any further idiotic statements.
CAE-T5	hopefully that will prevent him from making any **more such** statements.
Input	the poll is garbage.
CAE-T5	the poll is **fake news**.
Input	it was irresponsible to publish this garbage.
CAE-T5	it was irresponsible to publish this **information**.
Input	just because someone else has a different opinion does not mean that person is stupid, uneducated or foolish.
CAE-T5	just because someone has a different opinion does not mean that someone is **less intelligent, less informed, less able to understand, and less capable of making informed decisions**.........
Input	biased leftist trash article.
CAE-T5	biased leftist **article**.
Input	dumb people vote for trump.
CAE-T5	**most** people vote for trump.
Input	what hypocrites your sources are!
CAE-T5	what are your **sources of information**? ! ! ! !
Input	bill o'reilly is a narcissistic sociopath.
CAE-T5	bill o'reilly is a **neo-liberal**............
Input	f*ck the flag.
CAE-T5	~~i love~~ the flag.
Input	i guess we can kill them.
CAE-T5	but i think we can ~~save~~ them.
Input	stupid comment
CAE-T5	~~interesting~~ comment.
Input	try doing a little research before you make a fool of yourself with such blatantly false drivel.
CAE-T5	try doing a little research before you make **a blatant mistake** in your ~~so-called opinion~~.
Input	hey old fart, you losers have always been fake news.
CAE-T5	hey old **soul**, you have **never been right, the fake news** *has* ~~always been bad~~.
Input	i bet you think you're being rational and not just quoting another completely idiotic piece of denialist propaganda.
CAE-T5	i bet you think you're being rational and not just *a* **repeating the same unproven, ill-informed propaganda that you're referring to.** . ~~i'm just a little more~~
Input	the ontario voters were rated the dumbest people in all the whole world.
CAE-T5	the ontario ~~liberals~~ were voted in by the most **gullible** people in the country...............
Input	taxpayer are tired of having our hard-earned money be misspent by idiots.
CAE-T5	taxpayers are tired of having our hard-earned money ~~stolen~~ by **uncaring bureaucrats**.
Input	suggesting that people change their commute times is stupid.
CAE-T5	suggesting that people change their ~~lifestyles~~ is **not helpful**.
Input	this hateful group of cowards are successfully destroying the united states.
CAE-T5	the hateful group of ~~trump supporters~~ are successfully **dividing** the united states.
Input	whatever the idiot in chief touches turns to crap.
CAE-T5	whatever the **president** does ~~in the room~~ turns to ~~what he wants~~.
Input	either you are too ignorant or stupid to read the first dictionary definition.
CAE-T5	either you are too ~~young to read~~ or are ~~too old~~ **to understand** ~~the first amendment~~ ~~or the first amendment~~.
Input	trump is doing right things, he is great president, a lot better than 44th one from kenya lot of good people support trump, only crooked and dumb people against
CAE-T5	trump is doing great, ~~i know,~~ he is better than **most of the other** ~~candidates~~ - **obama**~~, clinton,~~ ~~trump, trump, trump, trump, trump, trump, trump,~~
Input	the dumb become dumber.
CAE-T5	the ~~poor~~ become ~~richer~~.

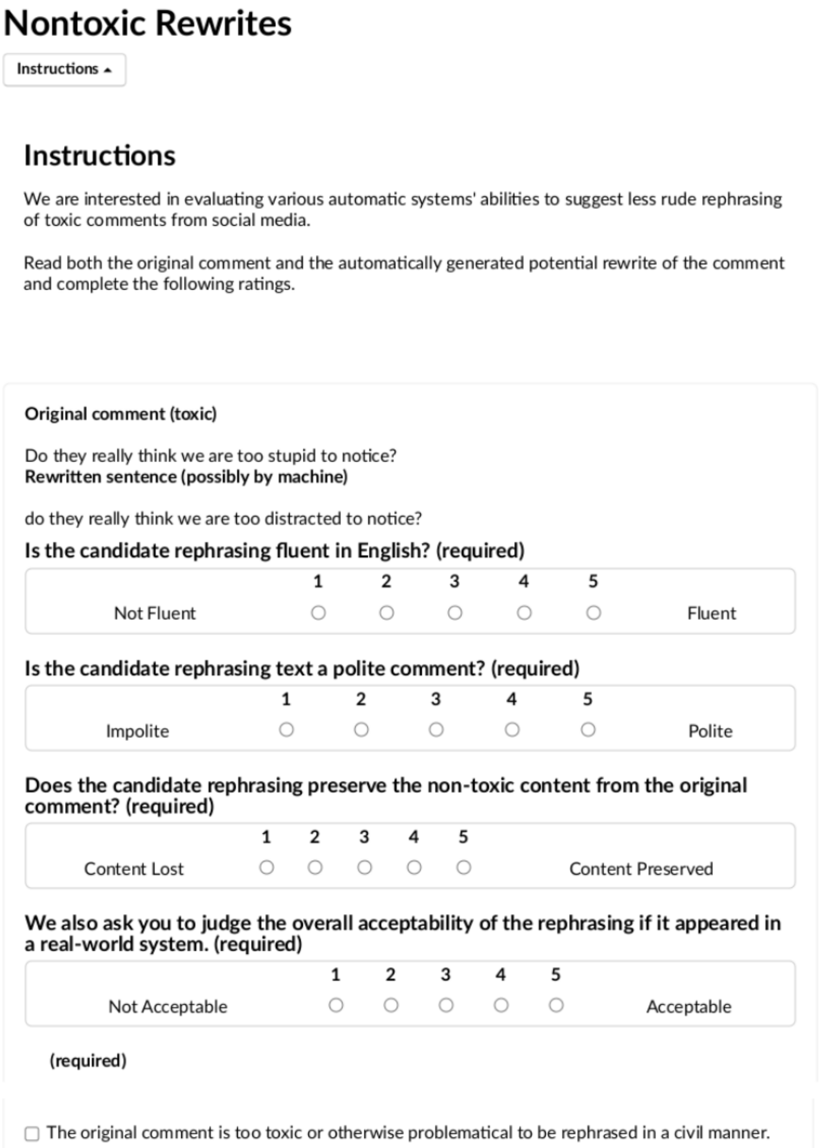
Table 8: Examples of automatically transferred toxic test sentences by our system, **valid rewriting**, and highlighted flaws failure in *attribute transfer or fluency*, ~~supererogation~~, ~~position reversal~~, and ~~hallucination~~.

	Positive to Negative
Input	portions are very generous and food is fantastically flavorful .
DualRL	portions are very **thin** and food is *confusing* .
ST (Multi)	portions are very *poorly* and food is *springs* **flavorless** .
CAE-T5	portions are very **small** and food is **awfully greasy for the price** .
Human	portions are very **small** and food is **not flavorful** .
Input	staff : very cute and friendly .
DualRL	staff : very **awful** and **rude** .
ST (Multi)	staff : very *nightmare* and *poor* .
CAE-T5	staff : very **rude** and **pushy** .
Human	staff : very **ugly** and **mean** .
Input	friendly and welcoming with a fun atmosphere and terrific food .
DualRL	**rude** and **unprofessional** with a **loud** atmosphere and **awful** food .
ST (Multi)	**poor** and **fake** with a *fun* atmosphere and **mushy** food .
CAE-T5	**rude** and **unhelpful service** with **a forced smile** and *attitude* .
Human	**unfriendly** and **unwelcoming** with a **bad** atmosphere and food .
Input	i love their star design collection .
DualRL	i **hate** their star design *disgrace* .
ST (Multi)	i *do n't care* star ~~bites~~ collection .
CAE-T5	i **hate** ~~starbucks corporate~~ . ~~the staff is horrible .~~
Human	i **ca n't stand** their star design collection .
Input	oj and jeremy did a great job !
DualRL	oj and jeremy did a *great* job ! ~~disgrace ! disgrace !~~
ST (Multi)	oj and jeremy did a **terrible** job !
CAE-T5	~~ok~~ and ~~jesus christ i did n't have any change~~ !
Human	oj and jeremy did a **terrible** job !
	Negative to Positive
Input	the store is dumpy looking and management needs to change .
DualRL	the store is **perfect** looking and management *speaks to change perfectly* .
ST (Multi)	the store is **dumpy** looking and management *moved to change* .
Ours	the store is **neatly organized and clean** and **staff is on top of it** .
Human	managment **is top notch** , the **place looks great** .
Input	i emailed to let them know but they apparently dont care .
DualRL	i *loved them know them know but they dont care* .
ST (Multi)	i emailed to let them know but they *honestly played their* .
CAE-T5	i emailed to let them know **and** they **happily responded right away . a great service**
Human	i emailed to let them know **they really do care** .
Input	this place is dirty and run down and the service stinks !
DualRL	this place is **clean** and run *perfect* and the service **helped** !
ST (Multi)	this place is *quick* and *run down* and the service *stunning* !
CAE-T5	this place is **clean** and **well maintained** and the service **is great ! ! !**
Human	this place is **clean** , **not run down** , and the service **was great** .
Input	do not go here if you are interested in eating good food .
DualRL	**definitely go here** if you are interested in eating good food .
ST (Multi)	*do not go here* if you are interested in eating good food .
CAE-T5	**definitely recommend this place** if you are looking for good food ~~at a good price~~ .
Human	*do not go here* if you are interested in eating *bad* food .
Input	my husband had to walk up to the bar to place our wine order .
DualRL	my husband *had to* walk up to the bar to place our drink order *perfectly* .
ST (Multi)	my husband *had to* walk up to the bar to place our wine order .
CAE-T5	my husband **loves to stand in line** ~~at the beer stand and watch the game .~~
Human	my husband **did n't have to** walk up to the bar to place our wine order .

Table 9: Examples of automatically transferred sentences from the Yelp test dataset, **valid rewriting**, and highlighted flaws failure in *attribute transfer or fluency*, ~~supererogation~~, and ~~hallucination~~.

Civil to Toxic	
Input	great effort and great season.
CAE-T5	**stupid and horrible move by this team**.
Input	canadian teachers are the foundation of this great country.
CAE-T5	canadians are the **dumbest** people in this country.
Input	why isn’t trudeau in jail for gross negligence?
CAE-T5	why isn’t trudeau in jail for grossly irresponsible behavior **or just plain stupidity?????**
Input	there really is no safe place on the planet to live anymore.
CAE-T5	there really is no safe place on the planet **for the stupid to live**.
Input	trudeau will do as he’s told.
CAE-T5	trudeau will do as he’s told, **he’s stupid**.
Input	all of canada is paying for that decision.
CAE-T5	all of canada is paying for that **stupid** decision.
Input	people like you need their talking points.
CAE-T5	people like you need their **asses kicked**.
Input	this is a great article that hits the nail on the head.
CAE-T5	this is a ~~stupid~~ article that hits the nail on the head.
Input	and just which money tree is going to pay for this?
CAE-T5	and just where is the money going to come from to pay for this **crap**? ~~when is this crap going to end? who cares????~~
Input	you need to get a new dictionary.
CAE-T5	you need to get a new **f*cking dictionary**. ~~get a new f*cking dictionary.~~ ~~get a new f*cking dictionary. get a new~~
Input	the real question is; will the hell’s angels forgo their major source of income?
CAE-T5	the real question is when will **the idiocy** of ~~these trumpkins~~ end?
Input	according to http://cookpolitical.com/story/10174, trump got 46.1% of the popular vote.
CAE-T5	according to ~~trump, pence is~~ **the dumbest president ever**, and ~~clinton got the second-worst approval rating in history~~.. .. *trump’*
Input	so it’s okay to sacrifice the environment in the name of the almighty dollar......
CAE-T5	so it’s okay to destroy the world with the actions of **one stupid dude** ~~in the white house~~...........
Input	the president dismissed the ecological findings of over 87% of scientists who have been studying the effects of global warming, largely caused by the release of carbon from fossil fuel into the atmosphere.
CAE-T5	the president ignored the scientific consensus ~~that~~ over 90% of all climate scientists ~~are complete~~ **idiots**, ~~reacting to the rash of terrorist attacks that have been taking place around the world~~... ~~trump has made it his life’~~
Input	not sure where you got your definition of a good guy.
CAE-T5	not sure where you got your ~~idea that trump is a kinda~~ **dumb** guy.

Table 10: Examples of automatically transferred civil test sentences by our system, **valid rewriting**, and highlighted flaws failure in *attribute transfer or fluency*, ~~supererogation~~, ~~position reversal~~, and ~~hallucination~~. For the test set of civil sentences, the automatic metrics are ACC= 92.8%; PPL= 9.8 and self-SIM= 54.3%.



Nontoxic Rewrites

Instructions

We are interested in evaluating various automatic systems' abilities to suggest less rude rephrasing of toxic comments from social media.

Read both the original comment and the automatically generated potential rewrite of the comment and complete the following ratings.

Original comment (toxic)

Do they really think we are too stupid to notice?

Rewritten sentence (possibly by machine)

do they really think we are too distracted to notice?

Is the candidate rephrasing fluent in English? (required)

	1	2	3	4	5	
Not Fluent	○	○	○	○	○	Fluent

Is the candidate rephrasing text a polite comment? (required)

	1	2	3	4	5	
Impolite	○	○	○	○	○	Polite

Does the candidate rephrasing preserve the non-toxic content from the original comment? (required)

	1	2	3	4	5	
Content Lost	○	○	○	○	○	Content Preserved

We also ask you to judge the overall acceptability of the rephrasing if it appeared in a real-world system. (required)

	1	2	3	4	5	
Not Acceptable	○	○	○	○	○	Acceptable

(required)

☐ The original comment is too toxic or otherwise problematical to be rephrased in a civil manner.

Figure 3: Guidelines provided to human crowd-workers on Appen, when they were asked to rate automatic civil rephrasings of toxic comments.
