Additionally, NLP and other data-driven algorithms have been shown to suffer from *content* biases; that is, undesirable group-wise differences with respect to protected groups, such as race/eth-

April 19 - 23, 2021.

nicity or gender (Johannsen et al., 2015; Hovy and Søgaard, 2015; Bolukbasi et al., 2016; Gonen and Goldberg, 2019; Rudinger et al., 2018). Therefore, in consideration of the social impact of NLP research (Hovy and Spruit, 2016), in the area of mental health content analysis it stands to reason that we should also look for *population* biases, as they pertain to protected groups, and the way these might affect NLP algorithms' fairness.

Previous research has utilized user demographics within social media mental health studies to construct control groups (Coppersmith et al., 2014), to enhance classifier performance through additional features (Preoţiuc-Pietro et al., 2015), and to analyze trends amongst specific populations (De Choudhury et al., 2014). In an attempt to preemptively address *population* biases, Amir et al. (2019) proposed a cohort-based sampling approach to collect representative measures of wellness amongst the general population. However, as noted in a recent literature reviews (Chancellor and De Choudhury, 2020; Harrigian et al., 2020), no previous computational mental-health study has accounted for differences in population-level depression rates nor explored performance variations across demographic subgroups at training time. Therefore, little is known about the fairness of these automated systems. Are models trained for mental health fair across demographic groups? Are current datasets demographically representative? If bias exists, what is its source?

In this study, we analyze two common depression-inference datasets and explore the susceptibility of different computational methods to demographic biases. We find that existing datasets are **not demographically representative** and that, without accounting for this, we find degradation in model performance for underrepresented groups. We explore the possible sources of this bias and conclude with recommendations for future research that may address these issues.

2 Mental Health and Social Media

Challenges obtaining mental health annotations for social media data have thus far constrained the size and quality of existing datasets. For instance, manual annotation of mental health status generally requires expert domain knowledge, while the sensitive nature of such annotations limit multi-institutional data sharing (Arseniev-Koehler et al., 2018). Consequently, most datasets rely on labels based on behavioral proxies or self-reported diagnoses, which more easily scale, but introduce problematic *self-disclosure* bias and label noise. Furthermore, as our understanding of mental health is continually evolving, studies have used different and sometimes conflicting guidelines for annotation (Brody et al., 2018; Hasin et al., 2018). With these challenges at the forefront of dataset curation, issues surrounding demographic balance and representation have been largely kicked down the road of the research domain.

Challenges accounting for demographics go beyond the computational research space and are well-illustrated by disparities between two recent surveys of depression prevalence. The Centers for Disease Control and Prevention (CDC) found depression prevalence between race/ethnicity groups did not differ (Brody et al., 2018), while a study using the results of the National Epidemiologic Survey on Alcohol and Related Conditions III (NESARC-III) found depression to be more prevalent in White Americans versus minorities (Hasin et al., 2018).

3 Ethical Considerations

The sensitive nature of mental health research and individual demographics requires us to consider possible benefits of this study alongside its potential harms. Specifically, we must evaluate the cost-benefit trade-off of inferring and/or securing three highly-personal individual attributes: (*depression diagnoses*: Benton et al., 2017a; *gender identity*: Larson, 2017; *race/ethnicity identity*: Wood-Doughty et al., 2020).

The potential immediate benefit of this study is a better understanding of demographic bias in computational mental health research. A potential secondary benefit is the mitigation of extant clinical treatment disparities (Simpson et al., 2007). As mental health treatment increasingly adopts an online delivery mechanism, this research is uniquely situated to inform the development of new AI systems and public policy in the area.

However, we are cognizant of the potential harms from our work. Mental health status and demographic identities are both sensitive personal attributes that could be used to maliciously target individuals on publicly-facing online platforms. Therefore, we follow the guidelines of Benton et al. (2017a) and Ayers et al. (2018) on data use, storage, and distribution. All analysis was conducted on de-identified versions of data, with any identifiable information being used only during intermediate data-processing subroutines that were hidden from researcher interaction and approved by the original dataset distributors. Our study was exempted from review by our Institutional Review Board under 45 CFR § 46.104.

To facilitate any form of statistical analysis, we also need to formalize gender and race/ethnicity. We seek a balance between the limitations of demographic inference systems[1] and alignment to demographic categories conventions used by the mental health literature (Brody et al., 2018; Hasin et al., 2018), versus propagating demographic definitions that exacerbate existing biases towards gender and racial/ethnic minorities. We consider the 'folk conception' of gender as described in Larson (2017) and prominently leveraged in traditional depression research in the United States — we use the sex categories *male* and *female* to denote the corresponding gender categories *masculine* and *feminine*. However, many individuals do not fit in these gender categories, some present a gender online inconsistent to their true identity (Nilizadeh et al., 2016), and they often experience depression and other mental health conditions at a higher rate (McDonald, 2018). For race/ethnicity labels, we consider the mutually-exclusive labeling conventions invoked by Brody et al. (2018) and Wood-Doughty et al. (2020): non-Hispanic White, non-Hispanic Black, non-Hispanic Asian and Hispanic/Latinx, as they are representative of the majority of racial and ethnic identities in the US. Our racial/ethnic categories do not capture multiracial individuals or those with a race/ethnicity outside this group.

We acknowledge these important limitations, but at the same time, there is an urgency to the questions we pose. Computational methods for monitoring mental health have already been deployed by digital surveillance companies (Bark), while analytics dashboards based on these methods are gradually making their way into patients' (Yoo and De Choudhury, 2019) and providers' hands (Yoo et al., 2020). The question is: should we avoid asking these questions about current datasets because we cannot produce clear answers, or should we conduct analyses with acknowledged limitations to learn what we can about research that is already being moved into products? We firmly believe the latter. Our hope is that this paper causes researchers to carefully consider these issues, elevate the need for further work, and produce studies that go beyond our study's limitations with new data and methods. This should not be the last study on this topic; rather, we hope it is the first step which can inform further critical analyses of work in this area.

4 Datasets

We select the task of depression inference for this study, as it is the most widely studied mental health condition in social media research (Harrigian et al., 2020). We consider two Twitter datasets: CLPSYCH (Coppersmith et al., 2015b) and MULTITASK (Benton et al., 2017b).

4.1 CLPSYCH

CLPSYCH was introduced by Coppersmith et al. (2014) and subsequently used in the CLPsych 2015 shared task (Coppersmith et al., 2015b). Tweets were publicly posted between 2008 and 2013. Users who self-disclosed a depression diagnosis were identified using regular expressions (e.g. "I have been diagnosed with `disorder`") and then manually reviewed by a team of clinical and computational researchers to verify authenticity of matched disclosures. The control group was sampled from a random pool Twitter users so that the joint distribution of inferred age and gender attributes closely resembled that of users with self-disclosed diagnoses. The 3000 most recent tweets from each user (as of the original dataset collection date) were retrieved. To reduce ambiguity in model performance that arises due to data insufficiencies, we isolate individuals with at least 100 tweets, leading to a final dataset size of 475 depressed individuals and their matched controls (i.e. 950 total users).

4.2 MULTITASK

Benton et al. (2017b) constructed a Twitter dataset (MULTITASK) combining a subset of CLPSYCH with datasets annotated using the same procedure from Coppersmith et al. (2015a,c). In addition to an expanded number of unique individuals (1400 depression, 1400 control), MULTITASK also boasts a more robust historical timeline of tweets for each user.

---

[1] We infer gender and race/ethnicity labels using a content classifier and explore additional limitations in Section 5

5 Demographic Labels

Only age and gender (Schwartz et al., 2013) attributes are available in the originally distributed form of CLPSYCH and MULTITASK, both of which were inferred using now-outdated models. All identifying metadata was either redacted or obfuscated to preserve the privacy of individuals in these datasets. Accordingly, we are confronted immediately by the challenge of securing accurate demographic information to facilitate a robust analysis of any potential gender and racial/ethnic biases. Fortunately, this problem has been tackled using a multitude of different techniques across multiple studies specific to mental health (Yazdavar et al., 2020; Amir et al., 2017; Preoţiuc-Pietro et al., 2015; Coppersmith et al., 2015a) and social media applications in general (Volkova et al., 2014; Burger et al., 2011; Fink et al., 2012; Rao et al., 2011).

We obtain race labels using a unigram model from Wood-Doughty et al. (2020), who combine multiple crowd-sourced and self-reported datasets to train classifiers for 4 demographic groups in line with the CDC's conventions (Brody et al., 2018): non-Hispanic Asian American (A), non-Hispanic African American (B), non-Hispanic White (W) and Hispanic/Latinx (H/L). Their classifier achieves an accuracy of 82.3% within intrinsic evaluations and shows even more promise as high-confidence thresholds are applied. To validate and further reduce noise in previously-inferred gender attributes, we train a new gender inference model on data from Burger et al. (2011) using the same architecture of Wood-Doughty et al. (2020). Our classifier obtains an accuracy of 83.3% amongst within-distribution data and outputs a distribution of inferred gender attributes that strongly aligns with that of the original datasets.

Although each of these procedures has strong internal validity, we recognize that inference errors incurred during this stage may confound and complicate downstream analysis of demographic bias. To mitigate this potential noise, we also de-anonymize a subset of CLPSYCH with the permission of Coppersmith et al. (2014) and apply name-based demographic classifiers (Wood-Doughty et al., 2018, 2020) to each user's profile to obtain "alternative" age and race attributes.

Between our content and name based classifiers, we are afforded the opportunity to perform downstream analysis of demographic bias based on the attributes derived using the following mechanisms:

- **High Confidence Filter:** Only considers users whose most probable demographic class based on unigram classifier has a confidence $> .95$.
- **Random Sampling:** Considers all available users; randomly split each individual's tweets into two independent pools so that demographic and mental health inferences are based on separate sets of data.
- **Name Labels:** Only considers users from CLPSYCH who could be de-anonymized; demographics annotated using name-based gender (Wood-Doughty et al., 2018) and ethnicity classifiers (Wood-Doughty et al., 2020).

While we find some variation in the individual-level demographic labels when using the three techniques, the downstream mental health models perform similarly: see details in Appendix A. For the experiments discussed below, we report results from the most computationally-efficient approach, high confidence filtering.

6 Analysis

We conduct an analysis of these datasets and depression models trained on these datasets to answer the following questions:

1. Are depression datasets demographically representative?
2. Do depression classifiers perform similarly across demographic groups?
3. Can we mitigate demographic biases by changing characteristics of the dataset?
4. Do differences in features between demographic groups account for classifier biases?

6.1 Are depression datasets demographically representative?

Before we can empirically measure if these datasets are demographically representative, we must first establish the expected distribution of a representative dataset. While the demographic groups distribution should match the true population (Twitter users with depression), there are no estimates of depression prevalence on Twitter. Thus, we use the Twitter US population as our baseline, and combine it with estimated prevalence of depression among

US demographic groups.[2]

Methods. Brody et al. (2018) found in a study of adults (>20yrs.) that women are almost twice as likely to be diagnosed with depression compared to men (1.89×) using Patient Health Questionnaires (PHQ-9). We refer to this study as 'CDC.' Similarly, Hasin et al. (2018) used a national survey of adults (>18yrs.) and the DSM-5 standard for major depressive disorder (MDD) to estimate that women are almost twice as likely to be diagnosed with depression compared to men (1.86×). We refer to this study as 'NESARC.'

While there were only small incongruencies between these studies in estimated prevalence of depression as a function of gender, there were significant discrepancies between studies with respect to estimated prevalence as a function of race/ethnicity. Specifically, CDC found that rates of depression were not statistically different between groups, whereas NESARC found a greater prevalence of depression among Whites compared to African Americans, Hispanics/Latinx and Asian Americans (1.25x).

We project these estimates of depression prevalence to the general Twitter population, where both males and females are estimated to participate equally (approximately matching the US population). While there is a slight under-representation of White individuals in Twitter compared to US population (60% vs 64%), Black and Hispanic/Latinx individuals are well represented (Wojcik and Hughes, 2019). Thus, barring slight variations, Twitter roughly mimics the demographic composition of the United States demographics fairly with respect to gender and race/ethnicity.

We combine the Twitter population estimates with depression rates in the US to get the target distributions of demographic users that we expect to observe in our datasets. Figure 1 shows differences between the expected, representative distribution and our complete Twitter datasets.

Results. Based on these estimates, are the depression datasets demographically representative? Figure 1 shows that CLPSYCH and MULTITASK are **not demographically representative** with respect to either gender or race/ethnicity. White individuals are over-represented, while Hispanic/Latinx individuals are the most underrepresented. In fact, there are *no* male H/L individuals represented in the train split of CLPSYCH. MULTITASK exhibits a larger population bias against minorities compared to CLPSYCH; White individuals are over-represented and Black individuals are under-represented. With respect to gender, both CLPSYCH and MULTITASK have similar distributional skews – females are over-represented compared to the depression adjusted general US population. At the user level, we found no major differences on number of tweets and vocabulary size between demographics: see details in Appendix B.

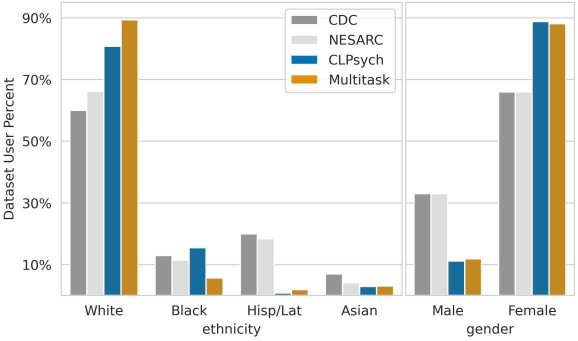

Figure 1: Hispanic/Latinx and Male individuals are underrepresented in both of our Twitter datasets (CLPSYCH & MULTITASK) compared to the Twitter US population estimates (CDC & NESARC).

Overall, CLPSYCH and MULTITASK are **not demographically representative** with respect to US depression rates projected on Twitter demographic estimates.

6.2 Do depression classifiers perform similarly across demographic groups?

We consider this question through experimentation on our datasets, CLPSYCH and MULTITASK.

Methods. We train a depression classifier on CLPSYCH and MULTITASK datasets.

We follow standard pre-processing procedures and filter numeric values, username mentions, retweets and urls from the raw tweet text. We use ℓ_2-regularized logistic regression models for all of our experiments. TF-IDF vectors are used to represent text in and across tweets, along with mean-pooled 200 dimensional GloVe embeddings pretrained with 2B tweets (Pennington et al., 2014). The vocabulary is pre-filtered per training, as each unigram must appear at least 10 times across all the individuals in traning data.

We also experimented with Linguistic Inquiry

---

[2] Our study uses mental health statistics from the United States since they are extensive and widely available. However, due to data anonymization we could not filter our data based on residence in the US. Since these datasets are filtered to focus on English accounts, US accounts likely dominate.

Word Count (LIWC) features, a closed-vocabulary English lexicon containing 64 categories (excluding punctuation categories), ranging from linguistic dimensions to psychological processes covering emotions and personal concerns, traditionally used in psychological studies (Pennebaker et al., 2007). In social media analysis, LIWC has been shown to contain signals for mental health disorders (Ireland and Iserman, 2018; Wolohan et al., 2018; Mitchell et al., 2015), including CLPsych and Multitask.

We also use features based on topic distributions learned via Latent Dirichlet Allocation (LDA) (Blei et al., 2003), following its implementation for Twitter data as specified in Mitchell et al. (2015) where all the tweets for an individual are combined into a "document" and we infer "topics" ($K = 50$ topics). All of the models in our experiments use all four feature groups: TF-IDF, GloVe embeddings, LIWC and LDA. We considered using demographic labels as features, which have been shown to capture signals for depression in Twitter (Preoţiuc-Pietro et al., 2015), but found no significant impact on our analysis or model performance; since demographic labels are not normally available, we do not include them in our analysis. See Appendix C for further implementation details.

To measure the performance bias across demographic groups we report performance on each demographic group. However, the racial/ethnic minority groups in the data are vastly underrepresented. While we address this by combining them into a 'persons of color' (PoC) category, the PoC group is still small and limits the reliability and extension of our analysis in this data.

For each dataset, we randomly sample individuals with repetition to construct a training set (bootstrap method) and subsequently obtain a distribution of F1 scores (100 repetitions) followed by one way ANOVA and pairwise T-Tests for each demographic group pair. Motivated by Simpson's Paradox (Blyth, 1972) and the Matrix of Domination (Costanza-Chock, 2018), we combine the gender and race/ethnicity labels to create a matrix of demographics and report mean F1 scores and 95% confidence interval of each demographic subcategory. Additionally, we seek a metric to measure fairness in performance across demographic groups — our criterion is that model performance should be independent of the demographic labels. Hardt et al. (2016) introduce *equal odds* and *equal opportunity*, two criteria that seek to equalize the FPR and TPR, or just FPR for the latter, across the protected attributes — these are also known as 'error rate balance' (Chouldechova, 2017), 'conditional procedure accuracy equality' (Berk et al., 2018) and 'classification parity' (Corbett-Davies and Goel, 2018). We compute the average pairwise equal odds and equal opportunity difference, a score of 0 means overall fairness, across the demographic groups in our boostrap sampling splits and report 95% confidence interval.

		CLPsych		Multitask	
Female	**White**	*0.77*	*± 0.005*	0.84	± 0.002
	PoC	0.41	± 0.013	0.91	± 0.003
Male	**White**	*0.74*	*± 0.008*	0.83	± 0.005
	PoC	*0.76*	*± 0.035*	0.45	± 0.016
	Equal Odds	0.21	± 0.023	0.13	± 0.013
	Opportunity	0.25	± 0.039	0.18	± 0.010

Table 1: Avg. F1 with 95% conf. interval from bootstrap across gender and ethnicity groups *(italics: not significant)*, and avg. equal odds and equal opportunity differences. Models underperform for PoC in general, sometimes male PoC (Multitask) or female PoC (CLPsych).

Results. Table 1 shows performance of classifiers trained on CLPsych and Multitask by demographic group. Models trained on CLPsych tend to perform worse on female PoC users compared to all other demographic groups. While we observe higher model performance for Multitask in general, models trained on Multitask tend to perform worse on male PoC users, compared to all other demographic groups. CLPsych is scored worse with the fairness metrics compared to Multitask.

In short, we observe that depression classifiers perform **worse on people of color**, specifically female PoC in CLPsych and male PoC Multitask.

6.3 Can we mitigate demographic biases by changing characteristics of the dataset?

Why do depression classifiers perform worse/inconsistently for PoC individuals? We conduct two analyses that investigate how the datasets may cause disparities in fairness.

6.3.1 Data Size

Perhaps the classifier performs worse on demographic groups because we have insufficient train-

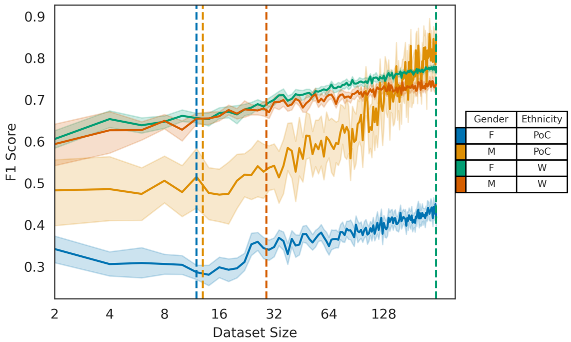

Figure 2: Log learning curve of varying dataset sample size on CLPSYCH. Dashed vertical lines represent the total size of the demographic group. Curves suggest more data is helpful to close model performance gap between demographic groups.

ing data. In Section 6.2, we observed fairer results with more data on MULTITASK compared to CLPSYCH. We perform a dataset size experiment to verify the effect on model performance across demographics.

Methods. How do results change with increased amounts of training data? To evaluate this gradient, we consider sampling an equal number of individuals from each demographic group and gradually increase overall dataset size until all available individuals available have been considered. At each dataset size step, we employ a similar bootstrap procedure to the one discussed in Section 6.2, sampling from the available user pool and training a classifier 25 times before moving on to the next dataset size. We continue adding data after a demographic group has been fully saturated to understand how information from overly-represented groups can generalize to under-represented groups.

Results. Figure 2 shows models performance as we increase training dataset size within the CLPSYCH dataset; results for MULTITASK are included in Appendix D and lead us to similar conclusions. As expected, overall performance across all classes improves with additional training data. Interestingly, even when the same amount of data is present for each demographic group, error rates remain higher for PoCs than for White users. This suggests that other factors beyond superficial representation are to blame for model degradation. It is also worthwhile noting that performance continues to improve for underrepresented groups after they have been fully saturated, thus implying that at least some signal generalizes between demographics.

		MULTITASK							
		full		NESARC		CDC		**even**	
Female	**White**	0.84	± 0.002	0.75	± 0.006	0.75	± 0.008	0.69	± 0.013
	PoC	0.91	± 0.003	0.87	± 0.005	0.86	± 0.005	0.82	± 0.009
Male	**White**	0.83	± 0.005	0.74	± 0.007	0.74	± 0.008	0.68	± 0.011
	PoC	0.45	± 0.016	0.56	± 0.029	0.54	± 0.033	0.48	± 0.030
	Equal Odds	0.13	± 0.013	0.14	± 0.021	0.14	± 0.019	0.12	± 0.014
	Opportunity	0.18	± 0.010	0.16	± 0.032	0.18	± 0.036	0.12	± 0.027

Table 2: Avg. F1 with 95% conf. interval from bootstrap across gender and ethnicity groups, and absolute avg. equal odds and equal opportunity differences. Balanced models close the performance difference gap at the cost of overall model performance.

6.3.2 Data Balance

What other factors could account for the difference in model performance on PoC? Below, we examine the effect of balancing the training data for the demographic groups.

Methods. We consider MULTITASK when constructing demographically-balanced datasets. As explored in Section 6.1, there are two different estimates of depression rates in demographic groups: CDC and NESARC. We balance MULTITASK to match the depression rates of both estimates, and name the models trained on those datasets MULTITASK CDC and MULTITASK NESARC respectively. Additionally, we compare these with an *even* balanced distribution. Models are trained following the methodology in Section 6.2.

Results. Table 2 shows the average F1 score of classifiers across gender and race/ethnicity groups. We copy MULTITASK column from Table 1 (labeled as *full*) for ease of comparison. There is a performance difference between male PoC users and the rest of the groups in models trained on MULTITASK balanced datasets, similar to MULTITASK full. However, the performance difference is smaller on models trained on balanced datasets. We observe no difference between balancing datasets according to NESARC or CDC, despite the 1.25x White user population increase in CDC. While fairness performance of both NESARC or CDC are similar to the full dataset, the *even* dataset shows considerable improvement for both fairness metrics at the cost of model performance.

Our experiments with both dataset size and balance show that it matters when datasets are not demographically representative, and as shown in section 6.1, they are not.

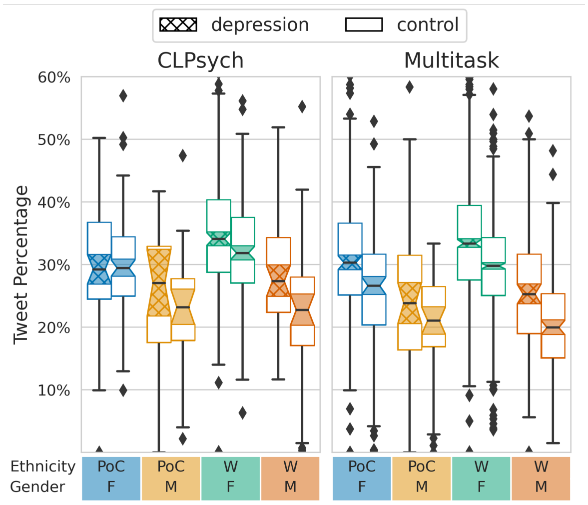

Figure 3: Percent of tweets containing first-person pronoun *(Pro1)* previously shown to correlate with the depression group; shaded notches show median CI (95%) with bootstrap $n = 10000$. Correlations shown by other work are not universal among demographic groups.

6.4 Can differences in features between demographic groups account for classifier biases?

We have demonstrated a demographic bias in classifiers trained on CLPSYCH and MULTITASK. Perhaps differences in feature representations between the groups can explain some of this bias. We examine LIWC features, which previous research has identified as useful in depression classification (Coppersmith et al., 2015c, 2014), in addition to performance analysis in Appendix E.

Methods. Previous research using the CLPSYCH and MULTITASK datasets has identified LIWC dimensions that over-index amongst depressed individuals: *Negative Emotion* (negemo), *Swearing* (swear), *Anger* (anger), *Anxiety* (anx) and *First-person Pronoun Usage* (Pro1) (Coppersmith et al., 2014).[3] We evaluate whether this finding holds within each demographic group independently and whether there exist shifts between demographic groups.

Results. Figure 3 shows the distribution over users of percentage of tweets with at least one word matching the *Pro1* category across demographic groups, with shaded notches showing median confidence interval. Results for other LIWC categories associated with depression are similar to those for *Pro1* (see Appendix F).

From previous research, we expect to observe a greater *Pro1* prevalence in depression groups compared to controls across all demographics i.e. shaded notches of depression box should not overlap with control in each demographic category. However, in CLPSYCH, we do not observe any difference in prevalence of *Pro1* in the PoC groups, and in MULTITASK we do not observe any difference in prevalence in the male PoC group, both contradicting previous results. We also observe a correlation between prevalence of these LIWC categories in the depression group and downstream model performance for each demographic group, corroborating previous findings of the correlation of LIWC categories and depression signals (Coppersmith et al., 2015c, 2014). In general, female groups for both the control and depression sets tend to have a higher prevalence of *Pro1* compared to their male counterparts, suggesting a difference in language between the groups.

In short, LIWC correlations with depression are not universal across demographic groups. Furthermore, a closed vocabulary feature, such as LIWC, may contribute towards bias against some demographic groups.

7 Limitations

Depression and Control Groups. The method used to curate the depression group in these datasets is susceptible to *self-selection* bias, as noted by Coppersmith et al. (2014) and Amir et al. (2019), as it likely over-represents individuals who are more vocal about their condition. Therefore, differences in use of social media and cultural perceptions around mental health may introduce biases in these datasets. Further, while expert annotators identified non-genuine disclosures depression and removed these individuals from the CLPSYCH and MULTITASK datasets, they did not verify the authenticity of the diagnosis. Similarly, individuals in the control group may have been actually diagnosed with depression, but did not disclose their condition anywhere in their public timeline. Thus, labels for both the the depression and control groups are bound to be noisy.

Representation. We balance the MULTITASK dataset to match depression rates in the US, which may not be representative of non-US populations. Additionally, we preserve the even depression/control splits for class balance in model training, in-

---

[3] *Pro1* is constructed by combining the *i* and *we* LIWC categories.

stead of using the true depression/control population rates (about 1/10). These splits are not reflective of the true depression prevalence and their use may need to be modified depending on downstream classifier use.

Demographic Labels. Due to dataset limitations, the ethnicity and gender labels for this study were inferred using the unigram model from (Wood-Doughty et al., 2020). This model considers only the four largest race/ethnicity groups in the US, which aligns with conventions from Brody et al. (2018) but ignores smaller populations and multi-racial categories. Further, in some of our analyses, we combine Asian, Black and Hispanic/Latinx individuals into people of color due to a lack of data. With respect to gender, the male and female labels used by this model do not consider individuals who fall outside of traditional binary gender. As our experiments rely on upstream demographic label inference, we cannot fully rule out confounding factors due to e.g. noisy labels in our experimentation, but we perform a high-confidence filter on demographic labels and statistical testing on results to strengthen our conclusions.

8 Conclusion and Recommendations

We examine whether datasets and the resulting trained classifiers for depression prediction are fair across demographic groups. Our analysis finds that (1) depression datasets are **not** demographically representative, in some cases excluding entire intersectional groups and (2) the resulting classifiers perform worse on people of color in general. In examining the reason for these differences, we find that performance difference could be improved after accounting for (3) the size of the dataset and balance across demographic groups. (4) Finally, we show that signals of depression found by previous work using e.g. LIWC features are *not* equally representative for all demographics.

These findings should give pause to researchers in this area. Since datasets and the resulting models are not demographically representative, advances in methods may be furthering biases towards some groups. Worse, since some intersectional demographic groups are not even represented in the data, compounded by the fact that most datasets do not have labels for demographic groups, we currently lack the means to even check how new methods perform on each group. Going forward, research in this area should include demographic analyses so that improvements on the overall dataset can be contextualized by how they perform on each demographic group.

At the same time, there is reason for optimism. Our data balancing and dataset size experiments reduced demographic disparities of trained models. This suggests that research can continue with existing datasets, but with the modifications we proposed. We release the demographically balanced dataset from our experimentation upon appropriate terms of usage agreement.

Ultimately, the best approach will be to construct new datasets that better represent the population, especially underrepresented minorities who are most at risk from systematic bias. This may necessitate changes to the data collection methods themselves, which may bias collection against certain groups. For example, self-reports may be problematic as they rely on cultural attitudes towards the expression of mental health information. Further research is needed to understand if self-reports and other proxy-based methods for obtaining labels can be successfully adapted to include a more diverse population, e.g. do keywords used to collect tweets skew resulting user populations? Further, to produce more conclusive insights with respect to demographics, language-based classifiers for demographic labels need to be further improved. Alternatively, other data collection strategies, such as the cohort method of Amir et al. (2019), may be more successful at ensuring representative datasets.

A Demographic Labels Analysis

Due to data anonymization, we must utilize content-based demographic classifiers to infer labels. This introduces noise due to classification error to our analyses. In order to reduce these effects we consider 3 techniques: high confidence filter, name labels, and tweet sampling.

High Confidence Filter. We select users whose most probably demographic class for both gender and race is > 0.95 probability.

Random Sampling. Considers all available users; randomly split each individual's tweets into two independent pools so that demographic and mental health inferences are based on separate sets of data.

Name Labels. With the permission of Coppersmith et al. (2014), we were able to collect name attributes for 622 of individuals in CLPsych. To obtain demographic labels from name attributes we used the demographer's neural name classifier (Wood-Doughty et al., 2018), and ethnic/race name classifier (Wood-Doughty et al., 2020). Due to the small number of individuals that we could obtain name attributes, our analysis of this technique is limited.

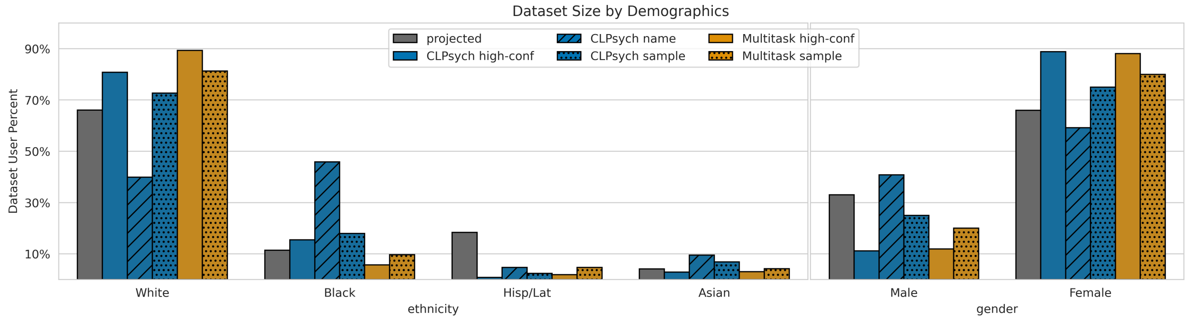

Figure 4: Hispanic/Latinx and Male individuals are underrepresented in both of our Twitter datasets (CLPsych & Multitask) compared to the Twitter US population estimates (NESARC) in all our labeling techniques.

Figure 4 shows the population percentage of the three techniques compared to the projected distribution. For all the techniques, some trends still hold, mainly Hispanic/Latinx group is underrepresented. Additionally, for the high confidence and split techniques, White and female groups are overrepresented and male underrepresented. In contrast, in the name based approach, the Black and male groups are overrepresented while the White and female groups are underrepresented.

While the name based technique shows more promising data distributions, the Hispanic/Latinx group is still vastly underrepresented. However, the rest of the demographic groups seem more fair and closer (sometimes better) than the target distribution, but do these distributions translate to greater downstream performance?

Table 3 shows the performance of mental health models trained on the different datasets obtained from our demographic labeling techniques. High confidence filtering has the largest performance difference and higher fairness metrics compared to random sampling and name based approaches. However, we still observe similar trends with PoC groups performing in general lower than White groups.

		CLPsych			Multitask	
		High Conf.	**Rand. Sample**	**Name Labels**	**High Conf.**	**Rand. Sample**
Female	**White**	*0.77 ± 0.005*	0.77 ± 0.005	0.72 ± 0.006	0.84 ± 0.002	0.84 ± 0.003
	PoC	0.41 ± 0.013	0.47 ± 0.020	0.44 ± 0.018	0.91 ± 0.003	0.87 ± 0.010
Male	**White**	*0.74 ± 0.008*	0.74 ± 0.014	0.48 ± 0.032	0.83 ± 0.005	0.78 ± 0.011
	PoC	*0.76 ± 0.035*	0.72 ± 0.040	0.56 ± 0.042	0.45 ± 0.016	0.78 ± 0.033
	Equal Odds	0.21 ± 0.023	0.13 ± 0.014	0.19 ± 0.023	0.13 ± 0.013	0.13 ± 0.021
	Opportunity	0.25 ± 0.039	0.16 ± 0.022	0.18 ± 0.031	0.18 ± 0.010	0.14 ± 0.034

Table 3: Avg. F1 with 95% conf. interval from bootstrap across gender and ethnicity groups, and avg. equal odds and equal opportunity differences *(italics: not significant)*. Models underperform for PoC in general, sometimes male PoC (Multitask) or female PoC (CLPsych).

B Tweets and Vocabulary in Demographics

Figure 5 shows the distribution of the average number of tweets and vocabulary size across all our demographic groups. There is no statistical significant difference in the means between demographic groups within the datasets. Very high variance is observed in the Asian group in multitask, although their vocabulary size is not as high variance. Additionally, MULTITASK dataset has on average higher number of tweets per user (as they were not limited to 3000 as in CLPSYCH) and consequently a higher average vocabulary size.

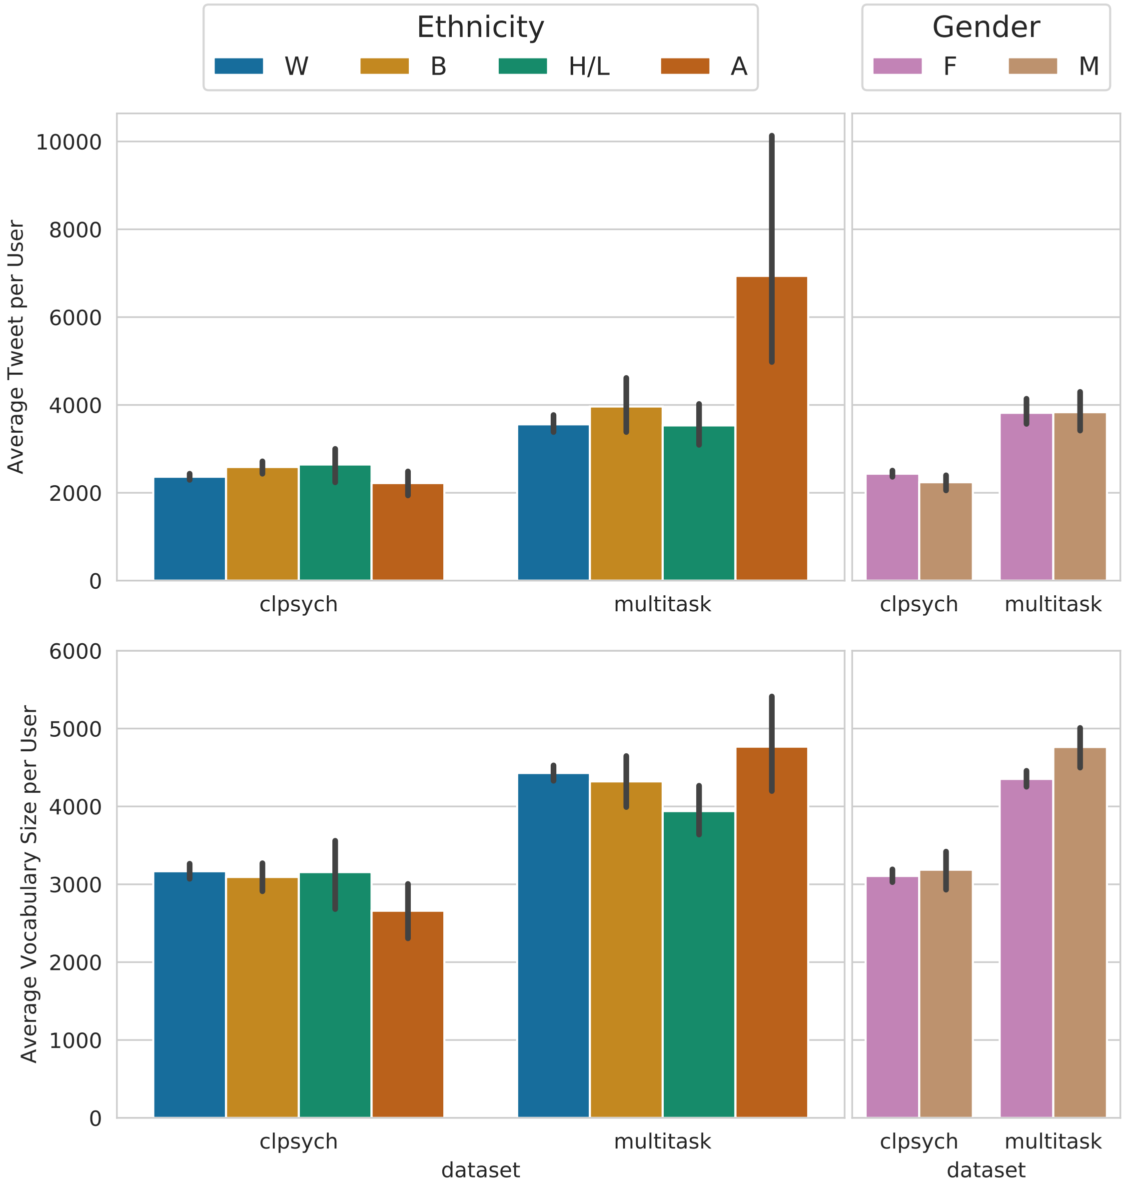

Figure 5: Average tweet number per user per demographic category, as well as average vocabulary size. Black bars show 95% CI.

C Model Specifications

Tokenization. Raw text within in Tweets was tokenized using a modified version of the Twokenizer (O'Connor et al., 2010). English contractions were expanded, while specific retweet tokens, username mentions, URLs, and numeric values were replaced by generic tokens. As pronoun usage tends to differ in individuals living with depression (Vedula and Parthasarathy, 2017), we removed any English pronouns from our stop word set (English Stop Words from nltk.org). Case was standardized across all tokens, with a single flag included if an entire post was made in uppercase letters.

Features. Text from all documents for an individual are concatenated together and tokenized as previously described. The vocabulary of each training procedure is fixed to a maximum of 100-thousand unigrams selected based on KL-divergence of the class-unigram distribution with the class-distribution of stop words (Chang et al., 2012). This reduced bag-of-words representation is then used to generate the following additional feature dimensions: a 50-dimensional LDA topic distribution (Blei et al., 2003), a 64-dimensional LIWC category distribution (Pennebaker et al., 2007), and a 200-dimensional mean-pooled vector of GloVe embeddings (Pennington et al., 2014). The reduced bag-of-words representation is transformed using TF-IDF weighting (Ramos et al., 2003).[4]

Hyperparameter Selection. Each model is trained using a hyperparameter grid search over the regularization strength {1e-3, 1e-2, 1-e1, 1, 10, 100, 1e3, 1e4, 1e5}, class weighting {None, Balanced}, and feature set standardization {On, Off}. Hyperparameters were selected to maximize held-out F1 score within a 20%-sied held-out split of the training data.

---

[4] All data-specific feature transformations (e.g. LDA, TF-IDF) are learned without access to development or test data.

D Multitask Size Experiment

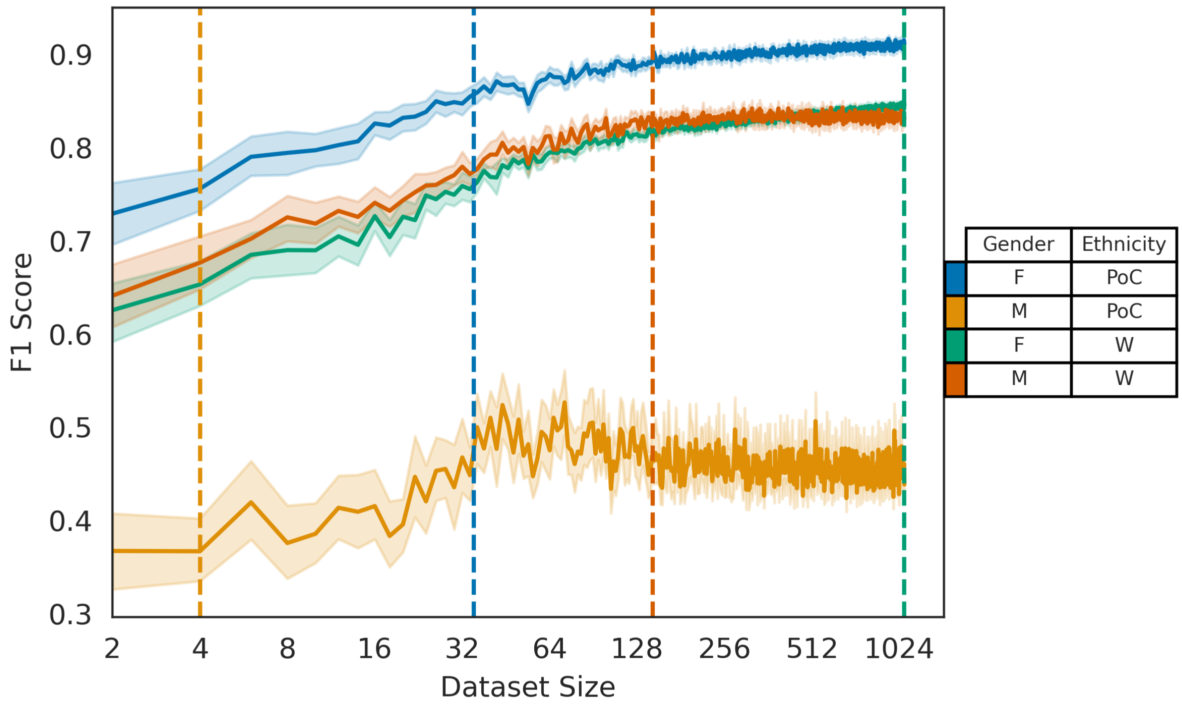

Figure 6: Log learning curve of varying dataset sample size on MULTITASK. Dashed vertical lines represent the total size of the demographic group.

E Feature Study

We observed performance difference between demographic groups for both our datasets with mental health models using the following feature groups: LIWC, LDA, GloVe and TF-IDF as specified in Appendix C. To explore the source of the performance difference observed in demographic groups, we train classifiers with each individual feature group and present average F1 score per demographic groups as well as our fairness metrics in Table 4.

TF-IDF and GloVe embeddings yield better model performance than the other feature groups at the expense of fairness as measure by our fairness metrics. The most fair feature set was LIWC, although it was also the least informative feature set resulting in worst performing models.

However, trends observed in Section 6.2 still apply in all feature groups, mainly models tend to underperform for PoC groups (female PoC groups in CLPsych).

		CLPsych									
		full		**TF-IDF**		**LDA**		**LIWC**		**GloVe**	
Female	**White**	*0.77*	*± 0.005*	0.77	± 0.005	0.70	± 0.008	0.68	± 0.010	0.71	± 0.007

Male	**White**	*0.74*	*± 0.008*	0.74	± 0.008	0.65	± 0.019	0.68	± 0.021	0.68	± 0.019
	PoC	*0.76*	*± 0.035*	0.74	± 0.034	0.62	± 0.054	0.55	± 0.040	0.75	± 0.032
	Equal Odds	0.21	± 0.023	0.20	± 0.023	0.21	± 0.031	0.17	± 0.021	0.21	± 0.022
	Opportunity	0.25	± 0.039	0.25	± 0.040	0.24	± 0.039	0.17	± 0.028	0.18	± 0.029

Table 4: Avg. F1 with 95% conf. interval from bootstrap across gender and ethnicity groups, and absolute avg. equal odds and equal opportunity differences. PoC groups (female PoC) perform worse for models separately trained on each of our feature group.

F Additional LIWC Categories Figures

Previous research has identified specific LIWC dimensions that are of importance in depression groups. In addition to *First-person pronoun* (pro1), categories like *Negative Emotion* (negemo), *Swearing* (swear), *Anger* (anger) and *Anxiety* (anx) have been shown to be more prominent in the depression groups compared to control. We observe variation on prevalence on depression groups in all categories mentioned above among demographic groups, showing that LIWC features are *not* equally representative for all demographics

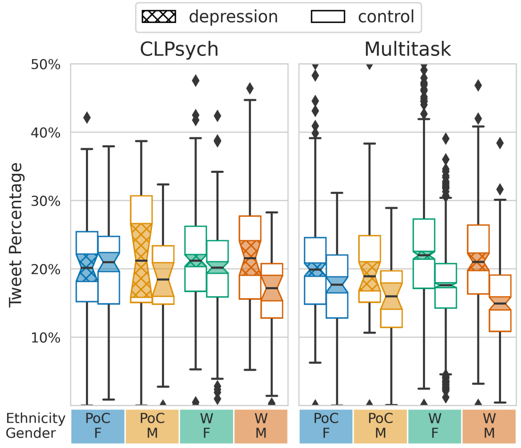

Figure 7: Negative Emotion Usage (*negemo*) LIWC category representation within each individual, previously shown to correlate with the depression group; statistical significance marked by not overlapping shaded notches. We observe median statistical difference only for **White male** individuals in CLPSYCH and **White groups** in MULTITASK.

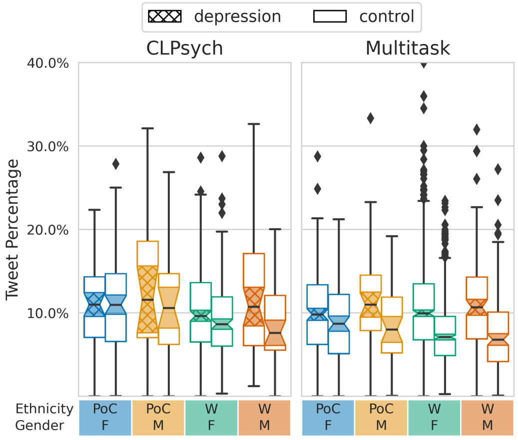

Figure 8: Anger (*anger*) LIWC category representation within each individual, previously shown to correlate with the depression group; statistical significance marked by not overlapping shaded notches. We only observe median statistical difference for **no groups** CLPSYCH and **White groups** in MULTITASK

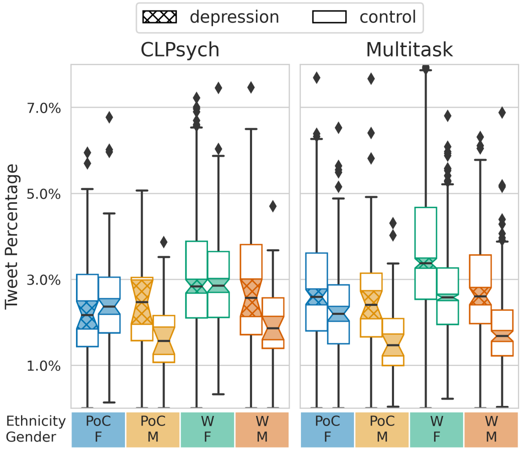

Figure 9: Anxiety (*anx*) LIWC category representation within each individual, previously shown to correlate with the depression group; statistical significance marked by not overlapping shaded notches. We observe median statistical difference for the **male groups** in CLPSYCH and **all** demographic categories in MULTITASK

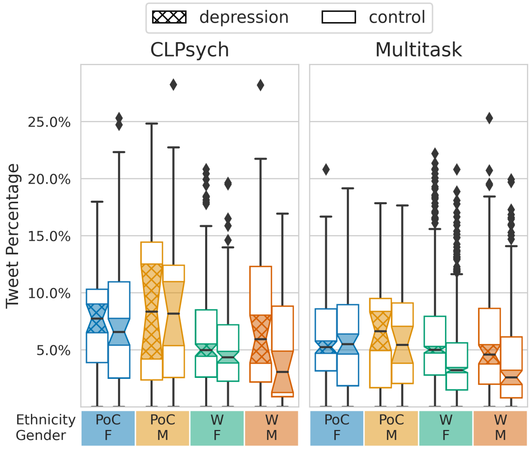

Figure 10: Swearing (*swear*) LIWC category representation within each individual, previously shown to correlate with the depression group; statistical significance marked by not overlapping shaded notches. We observe median statistical difference for **no groups** in CLPSYCH and **White groups** in MULTITASK.

MTOP: A Comprehensive Multilingual Task-Oriented Semantic Parsing Benchmark

Abstract

Scaling semantic parsing models for task-oriented dialog systems to new languages is often expensive and time-consuming due to the lack of available datasets. Available datasets suffer from several shortcomings: a) they contain few languages b) they contain small amounts of labeled examples per language c) they are based on the simple intent and slot detection paradigm for non-compositional queries. In this paper, we present a new multilingual dataset, called **MTOP**, comprising of 100k annotated utterances in 6 languages across 11 domains. We use this dataset and other publicly available datasets to conduct a comprehensive benchmarking study on using various state-of-the-art multilingual pre-trained models for task-oriented semantic parsing. We achieve an average improvement of +6.3 points on Slot F1 for the two existing multilingual datasets, over best results reported in their experiments. Furthermore, we demonstrate strong zero-shot performance using pre-trained models combined with automatic translation and alignment, and a proposed distant supervision method to reduce the noise in slot label projection.

1 Introduction

With the rising adoption of virtual assistant products, task-oriented dialog systems have been attracting more attention in both academic and industrial communities. One of the first steps in these systems is to extract meaning from the natural language used in conversation to build a semantic representation of the user utterance. Typical systems achieve this by classifying the *intent* of the utterance and tagging the corresponding *slots*. With the goal of handling more complex queries, recent approaches propose hierarchical representations (Gupta et al., 2018) that are expressive enough to capture the task-specific semantics of complex nested queries.

Although, there have been sizable efforts around developing successful semantic parsing models for task-oriented dialog systems in English (Mesnil et al., 2013; Liu and Lane, 2016; Gupta et al., 2018; Rongali et al., 2020), we have only seen limited works for other languages. This is mainly due to the painstaking process of manually annotating and creating large datasets for this task in new languages. In addition to the shortage of such datasets, existing datasets (Upadhyay et al., 2018; Schuster et al., 2019a) are not sufficiently diversified in terms of languages and domains, and do not capture complex nested queries. This makes it difficult to perform more systematic and rigorous experimentation and evaluation for this task across multiple languages.

Building on these considerations and recent advancements on cross-lingual pre-trained models (Devlin et al., 2019; Lample and Conneau, 2019; Conneau et al., 2020), this paper is making an effort to bridge the above mentioned gaps. The main contributions of this paper can be summarized as follows:

- MTOP Dataset: We release an almost-parallel multilingual task-oriented semantic parsing dataset covering **6 languages** and **11 domains**. To the best of our knowledge, this is the first multilingual dataset which contains compositional representations that allow complex nested queries.

- We build strong benchmarks on the released MTOP dataset using state-of-the-art multilingual pre-trained models for both flat and compositional representations. We demonstrate the effectiveness of our approaches by achieving new state-of-the-art result on existing multilingual task-oriented semantic parsing datasets.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2950–2962
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

- We demonstrate strong performance on zero-shot cross-lingual transfer using automatic translation and alignment, combined with a proposed distant supervision approach. We achieve 67.2% exact match accuracy (averaged across 5 languages) without using any target language data compared to best in-language model performance of 77.7%.

2 Related Work

Task-Oriented Semantic Parsing The majority of the work on task-oriented dialog systems has been centered around intent detection and slot filling - for example, the representations used on the ATIS dataset (Mesnil et al., 2013; Liu and Lane, 2016; Zhu and Yu, 2017) and in the Dialog State Tracking Challenge (Williams et al., 2016). This essentially boils down to a text classification and a sequence labeling task, which works great for simple non-compositional queries. For more complex queries with recursive slots, state of the art systems use hierarchical representations, such as the TOP representation (Gupta et al., 2018), that is modeled using Recurrent Neural Network Grammars (Dyer et al., 2016) or as a Sequence to Sequence task (Rongali et al., 2020).

Pre-trained Cross-lingual Representation Over the past few years, pre-trained cross-lingual representations have demonstrated tremendous success in achieving state of the art in various NLP tasks. The majority of the earlier work focuses on cross-lingual emebedding alignment (Mikolov et al., 2013; Ammar et al., 2016; Lample et al., 2018). Schuster et al. (2019b) further extend upon this by aligning contextual word embeddings from the ELMo model (Peters et al., 2018). Later with the success of Transformer (Vaswani et al., 2017) based masked language model pre-training, Devlin et al. (2019) and Lample and Conneau (2019) introduce mBERT and XLM respectively, and Pires et al. (2019) show the effectiveness of these on sequence labeling tasks. Conneau et al. (2020) present XLM-R, a pre-trained multilingual masked language model trained on data in 100 languages, that provides strong gains over XLM and mBERT on classification and sequence labeling tasks.

The models discussed above are encoder-only models. More recently, multilingual seq-to-seq pre-training has become popular. Liu et al. (2020a) introduce mBART, a seq-to-seq denoising auto-encoder pre-trained on monolingual corpora in many languages, which extends BART (Lewis et al., 2020b) to a multilingual setting. More recently, Lewis et al. (2020a) introduced a seq-to-seq model pre-trained on a multilingual multi-document paraphrasing objective, which self-supervises the reconstruction of target text by retrieving a set of related texts and conditions on them to maximize the likelihood of generating the original. Tran et al. (2020) is another contemporary work that mines parallel data using encoder representations and jointly trains a seq-to-seq model on this parallel data.

Cross-Lingual Task-Oriented Semantic Parsing Due to the ubiquity of digital assistants, the task of cross-lingual and multilingual task-oriented dialog has garnered a lot of attention recenty, and few multilingual benchmark datasets have been released for the same. To the best of our knowledge, all of them only contain simple non-compositional utterances, suitable for the intent and slots detection tasks. Upadhyay et al. (2018) release a benchmark dataset in Turkish and Hindi (600 training examples), obtained by translating utterances from the ATIS corpus (Price, 1990) and using Amazon Mechanical Turk to generate phrase level slot annotation on translations. Schuster et al. (2019a) release a bigger multilingual dataset for task-oriented dialog in English, Spanish and Thai across 3 domains. They also propose various modeling techniques such as using XLU embeddings (see Ruder et al. (2017) for literature review) for cross-lingual transfer, translate-train and ELMo (Peters et al., 2018) for target language training. BERT-style multilingual pre-trained models have also been applied to task-oriented semantic parsing. Castellucci et al. (2019) use multilingual BERT for joint intent classification and slot filling, but they don't evaluate on existing multilingual benchmarks. Instead, they introduce a new Italian dataset obtained via automatic machine translation of SNIPS (Coucke et al., 2018), which is of lower quality. For zero shot transfer, Liu et al. (2020b) study the idea of selecting some parallel word pairs to generate code-switching sentences for learning the inter-lingual semantics across languages and compare the performance using various cross-lingual pre-trained models including mBERT and XLM.

3 Data

Existing multilingual task-oriented dialog datasets, such as Upadhyay et al. (2018); Schuster et al.

Domain	**Number of utterances (training/validation/testing)**						**Intent types**	**Slot types**

Table 1: Summary statistics of the MTOP dataset. The Data is roughly divided into 70:10:20 percent splits for train, eval and test.

(2019a), rely on expensive manual work for preparing guidelines and annotations for other languages; which is probably why they only contain very few languages and few labeled data examples for other languages. Furthermore, annotations will be more complicated and expensive if they were to include compositional queries, where slots can have nested intents. To this end we create an almost parallel multilingual task-oriented semantic parsing corpora which contains **100k examples** in total for **6 languages** (both high and low resource): *English*, *Spanish*, *French*, *German*, *Hindi* and *Thai*. Our dataset contains a mix of both simple and compositional nested queries across **11 domains**, **117 intents** and **78 slots**. Table. 1 shows a summary statistics of our MTOP dataset.

We release the dataset at `https://fb.me/mtop_dataset`.

3.1 Dataset Creation

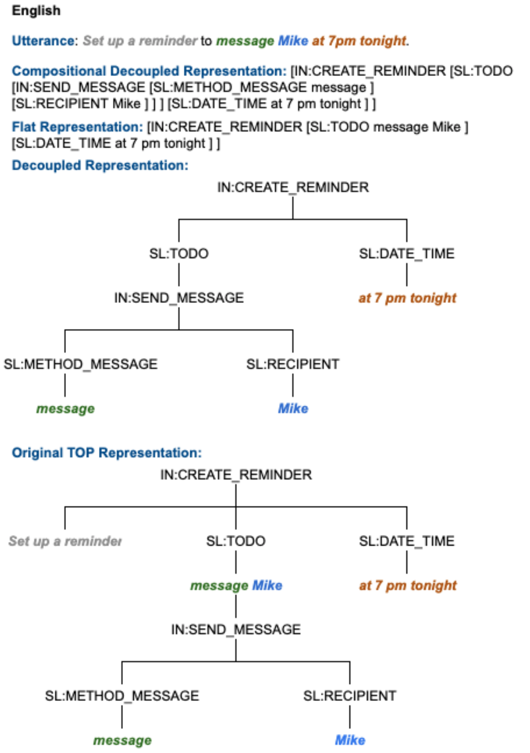
Our approach for creating this dataset consists of two main steps: i) generating synthetic utterances and annotating in English, ii) translation, label transfer, post-processing, post editing and filtering for other 5 languages. Generating the English utterances and their annotations, for the 11 domains, follows the exact process as described in (Gupta et al., 2018). We ask crowdsourced workers to generate natural language sentences that they would ask a system which could assist in queries corresponding to our chosen domains. These queries are labeled by two annotators. A third annotator is used only to adjudicate any disagreements. Once an annotated English dataset is available, we build the multilingual dataset through the following steps:

Translation: We first extract slot text spans from English annotation and present the utterances along with slot text spans to professional translators for translation to the target language. We prepare detailed guidelines, where we ask the translators to ensure that the translation for each slot span is exactly in the same way as it occurs in the translated utterance. For example, when translating the slot span *mom* in utterance *call my mom*, we ask the translators to use the same target language word for *mom*, that they used in the translation for *call my mom*.

Post-processing: After we obtain the translation of utterances and corresponding slot text spans, we use the tree structure of English and fill in the translated slot text spans to construct the annotation in the target languages. Our representation, described in §3.2.1, enables us to reconstruct the annotations.

Post-editing and Quality Control: We further run two rounds of quality control over translated utterances and slots, and revise the data accordingly. In the first round, we ask translators to review and post-edit the errors in translations and slot alignments. In the second round, the constructed target language data is presented to different annotators for a lightweight annotation quality review. 83% of the data was marked as good quality data and passed our quality standards, which can be interpreted as the inter-annotator agreement rate on the translated data. Based on this feedback, we remove low quality annotations from the dataset.

To create this dataset, for each target language we had three translators: two were responsible for translation and the third one for review and edits.



English

Utterance: *Set up a reminder* to ***message*** ***Mike*** ***at 7pm tonight***.

Compositional Decoupled Representation: [IN:CREATE_REMINDER [SL:TODO [IN:SEND_MESSAGE [SL:METHOD_MESSAGE message] [SL:RECIPIENT Mike]]] [SL:DATE_TIME at 7 pm tonight]]

Flat Representation: [IN:CREATE_REMINDER [SL:TODO message Mike] [SL:DATE_TIME at 7 pm tonight]]

Decoupled Representation:

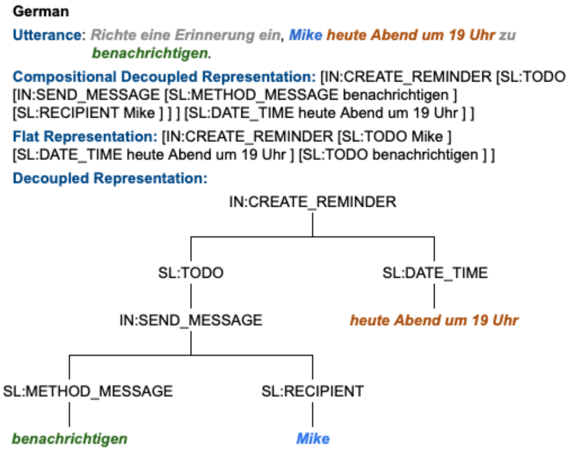
Original TOP Representation:

Figure 1: An English example from the data, showing its *flat* representation and *compositional decoupled* representation and a comparison between the decoupled and the original TOP representations in tree format.

All the translators were professional translators, with native or close to native speaker skills. The overall time spent was 15 to 25 days for each language. Even though we run rigorous quality control, a dataset built by translation is bound to have few errors, such as using words or phrases that are not commonly used in spoken language.

3.2 Data Format

In this dataset, we release two kinds of representations, which we refer to as *flat* representations and *compositional decoupled* representations, that are illustrated in Figure 1 for an English utterance. Most existing annotations for task-oriented dialog systems follow the intent classification and slot tagging paradigm, which is what we refer to as the flat representation. Since our data contains compositional utterances with nested slots with intents within them, flat representations are constructed by only using the top level slots. We include the flat representation so that the data and the discussed modeling techniques are comparable to other task-oriented dialog benchmarks. To ensure the reproducibility of our results, we also release the tokenized version of utterances obtained via our in-house multilingual tokenizer.



German

Utterance: *Richte eine Erinnerung ein*, ***Mike*** ***heute Abend um 19 Uhr*** *zu* ***benachrichtigen***.

Compositional Decoupled Representation: [IN:CREATE_REMINDER [SL:TODO [IN:SEND_MESSAGE [SL:METHOD_MESSAGE benachrichtigen] [SL:RECIPIENT Mike]]] [SL:DATE_TIME heute Abend um 19 Uhr]]

Flat Representation: [IN:CREATE_REMINDER [SL:TODO Mike] [SL:DATE_TIME heute Abend um 19 Uhr] [SL:TODO benachrichtigen]]

Decoupled Representation:

Figure 2: German utterance constructed from the English example of Figure 1. Even though the slot text order changed, we can still easily build a decoupled representation with the same structure.

3.2.1 Compositional Decoupled Representation

Gupta et al. (2018) demonstrate the inability of flat representations to parse complex compositional requests and propose a hierarchical annotation scheme (TOP representation) for semantic parsing, that allows the representation of such nested queries. We further use a representation, called the decoupled representation, that removes all the text from the TOP representation that does not appear in a leaf slot, assuming this text does not contribute to the semantics of the query. Figure 1 highlights the difference between this decoupled representation and the original TOP representation. The decoupled representation makes the semantic representation more flexible and allows long-distance dependencies within the representation. It also makes translation-based data creation approach feasible for different languages despite syntactic differences, as the representation is *decoupled* from the word order of the utterance. For example, in the German translation of the English example as shown in Figure 2, translations of *message* and *Mike* were separated by other words between them. However, it is straight forward to construct a decoupled representation as the representation is not bound by a word-order constraint.

4 Model Architecture

4.1 Joint intent and slot tagging for flat representation

For flat representation, where there is a single top-level intent, the traditional way is to model it as an intent classification and a slot tagging problem. Our baseline model is a bidirectional LSTM intent slot model as described in Liu and Lane (2016); Zhang and Wang (2016) with pre-trained XLU embeddings. Since existing pre-trained XLU embeddings (e.g., MUSE (Lample et al., 2018)) don't provide embedding for Hindi and Thai, we train our own using multiCCA following Ammar et al. (2016). Compared to previous state-of-the-art work on existing multilingual task-oriented parsing datasets (Liu et al., 2020b; Castellucci et al., 2019) which use Multilingual BERT, we use XLM-R (Conneau et al., 2020) since it's shown to outperform Multilingual BERT in cross-lingual performance on a variety of tasks. Specifically we use XLM-R Large in all our experiments. We use the same model architecture as in Chen et al. (2019) and replace BERT encoder with XLM-R encoder.

4.2 Seq-to-seq for hierarchical representation

Even though there are few existing works on cross lingual transfer learning for parsing flat representations, to the best of our knowledge, we are not aware of any other work that studies cross-lingual transfer for parsing complex queries in task-oriented dialog. In this section, we outline our modeling approaches for the compositional decoupled representation discussed in §3.2.1.

Seq-to-seq with Pointer-generator Network Our model adopts an architecture similar to Rongali et al. (2020), where source is the utterance and target is the compositional decoupled representation described in §3.2.1. Given a source utterance, let $[\boldsymbol{e}_1, \boldsymbol{e}_2, ..., \boldsymbol{e}_n]$ be the encoder hidden states and $[\boldsymbol{d}_1, \boldsymbol{d}_2, ..., \boldsymbol{d}_m]$ be the corresponding decoder hidden states. At decoding time step t, the model can either generate an element from the ontology with generation distribution $\boldsymbol{p}_t^{\mathrm{g}}$, or copy a token from the source sequence with copy distribution $\boldsymbol{p}_t^{\mathrm{c}}$. Generation distribution is computed as:

$$\boldsymbol{p}_t^{\mathrm{g}} = \mathrm{softmax}\left(\mathrm{Linear}_{\mathrm{g}}[\boldsymbol{d}_t]\right)$$

Copy distribution is computed as:

$$\boldsymbol{p}_t^{\mathrm{c}}, \boldsymbol{\omega}_t = \mathrm{MHA}\left(\boldsymbol{e}_1, ..., \boldsymbol{e}_n; \mathrm{Linear}_{\mathrm{c}}[\boldsymbol{d}_t]\right)$$

where MHA stands for Multi-Head Attention (Vaswani et al., 2017) and $\boldsymbol{\omega}_t$ is the attended vector used to compute the weight of copying $\boldsymbol{p}_t^{\mathrm{w}}$:

$$p_t^{\mathrm{w}} = \mathrm{sigmoid}\left(\mathrm{Linear}_{\alpha}\left[\boldsymbol{d}_t; \boldsymbol{\omega}_t\right]\right)$$

The final probability distribution is computed as a mixture of the generation and copy distributions:

$$\boldsymbol{p}_t = p_t^{\mathrm{w}} \cdot \boldsymbol{p}_t^{\mathrm{g}} + (1 - p_t^{\mathrm{w}}) \cdot \boldsymbol{p}_t^{\mathrm{c}}.$$

As a baseline, we use a standard LSTM encoder-decoder architecture with XLU embeddings. We also experiment with various transformer-based state of the art multilingual pre-trained models to improve upon the baseline. We use both pre-trained encoder-only models as well as pre-trained seq-to-seq encoder and decoder models. Here we outline the different models that we experimented with:

- **XLM-R** encoder, pre-trained with masked language model objective in 100 languages. For decoder, we use randomly initialized transformer decoder as in Vaswani et al. (2017).
- **mBART** (Liu et al., 2020a) is pre-trained seq-to-seq model using denoising autoencoder objective on monolingual corpora in 25 languages.
- **mBART on MT**: Machine translation is another common task for pre-training multilingual models. We follow Tang et al. (2020) to further fine-tune mBART on English to 25 languages translation task.
- **CRISS** (Tran et al., 2020) is pre-trained on parallel data in an unsupervised fashion. It iteratively mines parallel data using its own encoder outputs and trains a seq-to-seq model on the parallel data. CRISS has been shown to perform well on sentence retrieval and translation tasks.
- **MARGE** (Lewis et al., 2020a) is learned with an unsupervised multi-lingual multi-document paraphrasing objective. It retrieves a set of related texts in many languages and conditions on them to maximize the likelihood of generating the original text. MARGE has shown to outperform other models on a variety of multilingual benchmarks including document translation and summarization.

5 Experiments

We conduct thorough experiments on the new dataset we describe in in §3. To further demonstrate the effectiveness of our proposed approaches,

---

We provide reproducibility details and all hyperparameters in Appendix A we also run additional experiments on the existing multilingual task-oriented semantic parsing datasets including *Multilingual ATIS* (Upadhyay et al., 2018) and *Multilingual TOP* (Schuster et al., 2019a). Note that both these data sets only include flat representation, while our data set contains hierarchical representations.

5.1 Experimental Settings

For all benchmarks, we have three different evaluation settings:

- IN-LANGUAGE MODELS: We only use target language training data.
- MULTILINGUAL MODELS: We use training data in all available languages and train a single model for multiple languages.
- ZERO-SHOT TARGET LANGUAGE MODELS: We only use English data during training.

Next in each subsection we talk about details of approaches we use in these experiments.

5.1.1 Translate and Align

With zero or few target language annotated examples, *translate-train* is a common approach to augment target language training data. For semantic parsing tasks, besides translation we need alignment to project slot annotations to target language. This process is similar to how we collect our dataset, but using machine translation and alignment methods. For translation, we use our in-house machine translation system. We also tried other publicly available translation APIs and didn't find significant difference in final task performance. For alignment, we experimented with both, using attention weights from translation as in Schuster et al. (2019a) and fastalign (Dyer et al., 2013) and found data generated through fastalign leads to better task performance. Thus we only report results that use fastalign.

5.1.2 Multilingual Training

With the advancement of multilingual pre-trained models, a single model trained on multiple languages has shown to outperform in-language models (Conneau et al., 2020; Hu et al., 2020). As a result, we also experiment with multilingual training on our benchmark, including training jointly on all in-language data and training on English plus translated and aligned data in all other languages for the zero-shot setting. Instead of concatenating data in all languages together as in Conneau et al. (2020), we adopt a multitask training approach where for each batch we sample from one language based on a given sampling ratio so that languages with fewer training data can be upsampled. We found this setting to perform better than mixed-language batches in our experiments.

5.1.3 Distant Supervision in Zero-Shot Setting for Flat Representations

Alignment models are not perfect, especially for low resource languages. To combat the noise and biases introduced in slot label projection, we experiment with another distant supervision approach in the zero-shot setting for learning flat representation models. We first concatenate the English utterance and its corresponding translation (using machine translation) in target language as input and then replace the English slot text with MASK token at random (30% of the time, chosen empirically as a hyper-parameter). With the masked source utterance and the translated utterance as the concatenated input, we train a model to predict the overall intent and slot labels on the original English source. In this way, the MASK token can also attend to its translation counterpart to predict its label and the translated slot text could be distantly supervised by English labeled data.

6 Results and Discussions

6.1 Results on MTOP

Flat Representation Results Table. 2 shows the result on our MTOP dataset for all languages, using the flat representation. For both in-language and multilingual settings, XLM-R based models significantly outperform the BiLSTM models using XLU. We also observe that multilingual models outperform in-language models. Interestingly, for Hindi and Thai (both non-European languages), the improvements from multilingual training are considerably higher for XLM-R as compared to XLU BiLSTM. This observation highlights the remarkable cross-lingual transferability of the pre-trained XLM-R representations where fine-tuning on syntactically different languages also improves target language performance.

For zero-shot cross-lingual transfer, we restrict ourselves to an XLM-R baseline to explore improvements using translate and align, and the distant supervision techniques as described in 5.1.1 and 5.1.3 respectively. Our results demonstrate that

Model	en	es	fr	de	hi	th	Avg(5 langs)
			(Exact Match Accuracy)				
In-language models (only use target language training data)							
XLU biLSTM	78.2	70.8	68.9	65.1	62.6	68	67.1
XLM-R	85.3	81.6	79.4	76.9	76.8	73.8	77.7
Multilingual models (use training data from multiple languages)							
XLU biLSTM	78.2	73.8	71.5	65.8	63.1	68.7	68.6
XLM-R	86.3	83.6	81.8	79.2	78.9	76.7	80
Zero-shot target language models (only use English training data)							
XLM-R on EN	N/A	69.1	65.4	64	55	43.8	59.5
XLM-R with mask in §5.1.3	N/A	68	69.5	**69.2**	**63.3**	35.3	61.1
XLM-R on EN + translate align §5.1.1	N/A	74.5	**72.6**	64.7	58.3	**56.5**	65.3
XLM-R with mask + translate align	N/A	**74.6**	72.2	65.7	62.5	53.2	**65.6**

Table 2: Results on flat representation for 6 languages. We report exact match accuracy in this table. More metrics including intent accuracy and slot F1 is in Table 5 in Appendix. Notice that average is calculated across 5 languages except English to be comparable to zero-shot results. Best result for zero-shot is in bold. Taking best zero shot setting for each language, average exact match accuracy is 67.2. Note that for zero-shot setting, we only use EN train and eval data without any target language data.

distant supervision is able to considerably improve over the baselines for French, German and Hindi, while there is a small drop for Spanish. In the same setting, performance for Thai significantly degrades compared to the baseline. We suspect this is due to imperfect Thai tokenization that leads to learning noisy implicit alignments through distant supervision. The translate and align approach consistently improves over the baseline for all languages. It also performs better than distant supervision for all languages except German and Hindi. Our hypothesis is that the compounding nature of German inhibits the learning of hard alignment from fastalign. In summary, the XLM-R trained on all the 6 languages significantly outperforms all other models for this task.

In Appendix B, we further report intent accuracy and slot F1 metrics for the flat representation, as these are commonly used metrics in previous benchmarks for intent-slot prediction (Price, 1990; Schuster et al., 2019a).

Compositional Decoupled Representation Table. 3 shows the results on our MTOP dataset using compositional decoupled representation. In all settings, using multilingual pre-trained models significantly outperform the baseline. Surprisingly, mBART doesn't demonstrate strong performance compared to other models with fine-tuning on our task, even though fine-tuning BART on English achieves the best performance on English data. We hypothesize that mBART was under-trained for many languages and did not learn good cross-lingual alignments. In order to prove our hypothesis, we further fine-tune mBART on English to 25 languages translation task. The obtained mBART fine-tuned on translation significantly outperform the original mBART. The performance of CRISS and MARGE are at par with each other and among our best performing models across 5 languages, except Thai. XLM-R with random decoder performs the best on Thai. We believe this is because neither CRISS nor MARGE are pre-trained on Thai, while XLM-R pre-training includes Thai.

Similar to previous observations, multilingual training improves over the monolingual results. With multilingual training, XLM-R and CRISS are the best performing models for every language. Since XLM-R uses a randomly initialized decoder, it makes intuitive sense that such a decoder is better trained with multilingual training and thus obtains higher gains from more training data. Interestingly, mBART performance also improves a lot, which is another evidence that it was originally under-trained, as discussed in the previous paragraph. In the zero-shot setting, using the models fine-tuned on English does not perform well. In fact Thai zero shot using CRISS gives a 0 exact match accuracy, as the model was not pre-trained on any Thai data. Both XLM-R and CRISS show significant improve-

Model	**en**	**es**	**fr** (Exact Match Accuracy)	**de**	**hi**	**th**	**Avg(5 langs)**

ments when they utilized the machine translated and aligned data.

6.2 Results on Existing Benchmarks

Table. 4 shows results on two previously released multilingual datasets: Multilingual ATIS and Multilingual TOP. Similar to our findings in 6.1, XLM-R based models significantly outperform the best results reported by the original papers and sets a new state-of-the-art on these benchmarks. Also, multilingual models trained on all available languages further improve the result.

For Multilingual ATIS, in the zero-shot setting, our distant supervised masking strategy shows considerable gains compared to direct transfer using English. Using translate and aligned data also helps in improving the results significantly. When multitask trained together with masked data, it achieves the best zero-shot performance on Hindi. For both languages (Hindi and Turkish) this comes very close to the performance using target language training data.

For multilingual TOP, direct transfer proves to be effective for Spanish, direct transfer from English overall yield better result than what's reported in Mixed-Language Training (MLT) with MBERT (Liu et al., 2020b). While masking and translating generated data degrade its performance. Based on our error analysis, we find that tokenization mismatch, derived from translation data, causes such performance drop due to errors in slot text boundaries. For Thai, all our translation-based techniques perform worse than translate-train results from original paper. We attribute this primarily to the tokenization difference between our translated data and original test data. Unlike Spanish, Thai is much more sensitive to tokenization as it rarely uses whitespace.

7 Conclusion

In this paper, we release a new multilingual task-oriented semantic parsing dataset called **MTOP** that covers 6 languages, including both flat and compositional representations. We develop strong and comprehensive benchmarks for both representations using state-of-the-art multilingual pre-trained models in both zero-shot and with target language settings. We hope this dataset along with proposed methods benefit the research community in scaling task-oriented dialog systems to more languages effectively and efficiently.

A Training Details

Settings for MTOP results in Table. 2 For fine-tuning XLM-R, we use the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9, \beta_2 = 0.99, \epsilon = 1e-6$ and batch size of 16. We fine-tune for 20 epochs and search over learning rates $\in \{1, 2, 3\}e-5$ on dev set. All XLM-R models were run on single 32GB V100 Nvidia GPU.

For the XLU models in Table. 2, we use 300 dim XLU embeddings and feed them to a 2-layer 200 dim BiLSTM. The intent classification head contains an attention pooling layer as described in Lin et al. (2017) with with attention dim 128 followed by a 200 dim linear projection before the softmax. The slot tagging head also contains a 200 dim linear layer followed by a CRF decoder. We use the we use the Adam optimizer with the same settings as above and a batch size of 32 for 40 epochs. The learning rate and BiLSTM dropouts are picked via a param sweep over the dev set.

Settings for MTOP results in Table. 3 For training seq-2-seq models, we use stochastic weight averaging (Izmailov et al., 2018) with Lamb optimizer (You et al., 2019) and exponential learning rate decay for all models. For fine-tuning pre-trained models: we use batch size of 16 for all models except Marge, we use batch size 4 for Marge since we were not able to fit larger batch size into 32GB memory; We finetune for 50 epochs and again search over learning rates on dev set.

For copy pointer We use 1 layer multihead attention(MHA) with 4 attention heads to get copy distribution. For seq-2-seq model with XLM-R encoder, the decoder is a randomly initialized 3-layer transformer, with hidden size 1024 and 8 attention heads. XLM-R encoder (24 layers) is larger than mBART/CRISS/MARGE encoder (12 layers) so we were not able to fit a larger decoder into GPU memory.

For the XLU models specifically we use a 2-layer BiLSTM encoder with a hidden dimension of 256. For the decoder, we use a 2-layer LSTM with 256 dimension and a single attention head. Similar to the flat models, learning rate and LSTM dropouts are picked via a param sweep over the dev set.

Settings for other benchmark results in Table. 4 We use the same setting as described for Table. 2 except for multilingual ATIS which doesn't have dev set, we just use the checkpoint after a fixed number of epochs.

B More Results

We report additional metrics for our experiments in this section. Table. 5 contains the intent accuracy and slot F1 metrics of models for flat representation.

Adapting Event Extractors to Medical Data: Bridging the Covariate Shift

Aakanksha Naik[1] **Jill Lehman**[2] **Carolyn Rosé**[1]

`{anaik,jfl,cprose}@andrew.cmu.edu`

Abstract

We tackle the task of adapting event extractors to new domains without labeled data, by aligning the marginal distributions of source and target domains. As a testbed, we create two new event extraction datasets using English texts from two medical domains: (i) clinical notes, and (ii) doctor-patient conversations. We test the efficacy of three marginal alignment techniques: (i) adversarial domain adaptation (ADA), (ii) domain adaptive fine-tuning (DAFT), and (iii) a new instance weighting technique based on language model likelihood scores (LIW). LIW and DAFT improve over a no-transfer BERT baseline on both domains, but ADA only improves on notes. Deeper analysis of performance under different types of shifts (e.g., lexical shift, semantic shift) explains some of the variations among models. Our best-performing models reach F1 scores of 70.0 and 72.9 on notes and conversations respectively, using *no* labeled target data.

1 Introduction

Events are an important phenomenon in the field of computational semantics. They offer an intuitive mechanism for constructing structured representations of text, which can be used for downstream tasks such as question answering and summarization. Events also embody a crucial function of language: the ability to report happenings. Narratives from many diverse domains (e.g., news articles, literary texts, clinical notes) use events as basic building blocks. These characteristics make event extraction a key sub-task of interest for text understanding pipelines in multiple domains. Despite its importance, building high-performing and generalizable systems for event extraction has remained an elusive goal. One of the major hurdles is that the notion of what counts as an *important event* is usually task-specific or domain-specific (sometimes both). For example, to build a system that can track a patient's disease progression from clinical notes, event extractors only need to focus on extracting medical events relevant to that illness. This task/domain specificity has encouraged prior work to focus on specific event types (Grishman and Sundheim, 1996; Doddington et al., 2004; Kim et al., 2008) or domains (Pustejovsky et al., 2003b; Sims et al., 2019). Owing to this narrow focus, supervised event extractors often fail to adapt to new domains or event types (Keith et al., 2017). Unsupervised event extractors that use syntactic rule-based modules (Saurí et al., 2005; Chambers et al., 2014), conversely, have a tendency to over-generate by labeling most verbs and nouns as events.

In this work, we try to achieve a balance between these extremes by *adapting* event extractors using unsupervised domain adaptation techniques. We also study the behavior of these techniques under various types of linguistic shifts (e.g., lexical shift, semantic shift) to gain insight into differences among them. Exploring adaptability under no (or little) supervision is crucial, since sourcing annotated data for new domains, especially medical texts, can be expensive and time-consuming. Following prior work, we formulate event extraction as the task of labeling **triggers**, i.e., words which instantiate an event (Linguistic Data Consortium, 2005). For example, in the sentence "She was diagnosed with cancer," *diagnosed* and *cancer* are triggers, referring to "diagnosis" and "illness" events respectively. Throughout our work, we model event trigger labeling as token-level classification.

To test adaptability, we create new event extraction test sets using English texts from two diverse medical domains: (i) clinical notes, and (ii) doctor-patient conversations. We develop comprehensive event annotation guidelines, based on TimeML (Pustejovsky et al., 2003a) and Thyme-TimeML (Styler IV et al., 2014) (§3), and use them to annotate 45 documents from each domain. As a baseline,

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2963–2975
April 19 - 23, 2021.

we train a BERT-based event extraction model on English news articles from TimeBank (Pustejovsky et al., 2003b), which is labeled using TimeML, and test its performance on our datasets. To improve this out-of-domain baseline performance, we tackle the problem of covariate shift, i.e., differences between marginal distributions of source (news) and target domains (notes or conversations). We experiment with three marginal alignment techniques: (i) adversarial domain adaptation (ADA) (Ganin and Lempitsky, 2015), (ii) domain-adaptive fine-tuning (DAFT) (Han and Eisenstein, 2019), and (iii) a new instance weighting scheme using language model likelihood scores (LIW).

Our results show that DAFT and LIW improve over BERT on both domains, whereas ADA only improves on notes. Across domains, ADA and DAFT perform best on notes and conversations respectively. To probe why some techniques are better at addressing certain source-target domain pairs, we analyze model performance on various types of covariate shifts (e.g., lexical shift, semantic shift). Our analysis uncovers interesting patterns such as varying ability of models to leverage subword morphology to generalize to technical terms, and LIW's performance improvement on long-term state events (e.g., chronic illnesses). Our best models achieve F1 scores of 70.0 and 72.9 on notes and conversations respectively with *no* training data.[1]

2 Related Work

2.1 Event Extraction

Most prior event extraction work has focused on news articles, resulting in the development of several datasets (Onyshkevych et al., 1993; Grishman and Sundheim, 1996; Pustejovsky et al., 2003b; Doddington et al., 2004; Lee et al., 2012; Cybulska and Vossen, 2014; Mitamura et al., 2016). Recently, event extraction has also been explored in other domains such as biology (Wattarujeekrit et al., 2004; Kim et al., 2008, 2009; Berant et al., 2014), Wikipedia articles (Araki and Mitamura, 2018), social media data (Ritter et al., 2012; Li et al., 2014; Jain et al., 2016) and literary novels (Sims et al., 2019). Aside from data domain, event extraction paradigms (both datasets and tools) differ along three major axes: (i) event extraction granularity, (ii) event representation, and (iii) event categorization (ontology). We briefly describe these axes to contextualize our choice of event paradigm.

Event extraction granularity divides extraction paradigms into two types: (i) document-level paradigms that assume that a piece of text refers to a single event (Grishman and Sundheim, 1996), and (ii) sentence-level paradigms that assume that a single sentence describes one or more events. Event representation also divides extraction paradigms into two types: (i) span-based paradigms that represent events by marking text spans that refer to events, called **triggers** or **nuggets** (Linguistic Data Consortium, 2005; Mitamura et al., 2015; O'Gorman et al., 2016), and (ii) structured paradigms that represent events by marking text spans and adding additional arguments (e.g., participants, location etc.) to create a structured template (Grishman and Sundheim, 1996). Event categorization divides extraction paradigms into: (i) ontology-driven paradigms that are limited to specific event types (Grishman and Sundheim, 1996; Doddington et al., 2004), and (ii) ontology-free paradigms that do not place type restrictions (Pustejovsky et al., 2003b; Araki and Mitamura, 2018).

We use a sentence-level, span-based, ontology-free event extraction paradigm. Sentence-level extraction suits our domains of interest since notes and conversations tend to discuss multiple events. Span-based and ontology-free extraction allows us to develop adaptable coding guidelines since event arguments and types are usually domain-specific or task-specific. This adaptability sets our work apart from other prior work on medical event extraction such as adverse drug event extraction (Nikfarjam et al., 2015; Sarker and Gonzalez, 2015; Cocos et al., 2017; Henry et al., 2020) and personal event extraction from online support groups (Wen et al., 2013; Naik et al., 2017), which focus on specific event types. Our guidelines draw heavily from the Thyme-TimeML guidelines (Styler IV et al., 2014) used by the Clinical TempEval challenges on event ordering in clinical notes (Bethard et al., 2015, 2016, 2017),[2] but also cover event extraction in a novel domain: doctor-patient conversations.

2.2 Unsupervised Domain Adaptation

Unsupervised domain adaptation is the task of transferring a model from a source domain to a target domain, using only unlabeled data from the target domain, by aligning source and target distri-

---

[1] Annotated clinical notes and all code associated with this work can be found at: `https://github.com/aakanksha19/MedicalEventExtraction`.

[2] We provide a detailed comparison with this work in §3.1.

butions. Early approaches such as structural correspondence learning (SCL) (Blitzer et al., 2006, 2007) tried to solve this by mapping source and target examples into a shared **pivot feature** space, where pivot features are selected to be features that behave the same way for discriminative learning in both domains (e.g., sentiment terms such as *amazing* and *great* show similar behavior for sentiment analysis across domains). With advances in neural representation learning, autoencoder-based methods (Glorot et al., 2011; Chen et al., 2014), neural SCL (Ziser and Reichart, 2017), adversarial domain adaptation (Ganin and Lempitsky, 2015; Ganin et al., 2016) and LM fine-tuning methods (Han and Eisenstein, 2019; Gururangan et al., 2020) have shown success in learning a shared space in which source and target domains are aligned. We propose a new method (LIW) which relies on instance weighting via language model likelihood, and contrast it with adversarial domain adaptation (ADA) and domain adaptive fine-tuning (DAFT). These two techniques have shown promise on sequence labeling tasks (Gui et al., 2017; Han and Eisenstein, 2019; Naik and Rosé, 2020), and offer an interesting contrast between approaches that jointly perform alignment and task training (ADA) and approaches that perform these steps sequentially (DAFT). Comparing all three techniques also provides us the opportunity to study which methods adapt better to different kinds of shifts between source and target domains (e.g., shifts in vocabulary, syntax, etc.).

3 Dataset Creation

To test adaptability of event extraction models, we create a testbed using data from two domains:

1. Clinical Notes: Clinical notes are records documenting physician observations from their interactions with patients. They usually detail various aspects of a patient's care such as present illness, symptoms, medical history, treatments, and test results. They share a thematic structure, though particular specialties (e.g., cardiology) and institutions often incorporate their own modifications. We collected a set of 4999 de-identified clinical notes from 40 specialties, by scraping mtsamples.[3] The notes are reference samples provided by various users, with names and dates edited for confidentiality. They are freely available to print, share, link and distribute, as per website policy. Average length of a clinical note is 652 tokens.

2. Doctor-Patient Conversations: This data contains human-transcribed, de-identified conversations recorded during physician-patient visits. The conversations often follow a similar schema, with patients describing their symptoms, doctors inquiring about ongoing treatments, and then suggesting potential follow-up treatments/tests. We use a proprietary database of 63,540 conversations covering 53 specialties, collected by Abridge AI Inc. Physicians across a variety of specialties are contracted to record natural in-office conversations with their patients who agree to participate in the research by providing verbal and written consent. Recordings are made on a digital recording device or a smartphone application and are uploaded to a secure server where they are scrubbed of all identifiable information, in accordance with the Health Insurance Portability and Accountability Act of 1996 (HIPAA) privacy rule. De-identified recordings are transcribed and stored in a database, which currently contains over 100,000 recordings dating from 2006 to 2017. Average conversation transcript length is 2309 tokens.

These domains exhibit different types of linguistic shifts from the source (news). While both domains exhibit a shift in vocabulary, it is more pronounced in clinical notes since they are written by doctors (experts) who use highly technical terms. Conversely, shifts in syntax are more pronounced in conversations due to the prevalence of repetition, back-channeling, interruptions etc. Semantic shifts are more pronounced in conversations since they contain a higher proportion of hypothetical statements (e.g., when doctors ask questions, make requests or "think out loud") than both notes and news articles which tend to serve as records of actual events. To better evaluate model performance on linguistic shifts, we control for topical variation across domains by limiting our focus to 3 specialties: Cardiovascular/Pulmonary (Cardio), Obstetrics/Gynaecology (Obgyn) and Hematology/Oncology (Onco). These specialties are well-represented in both notes and conversations, and cover events with a variety of temporalities ranging from intervals with fixed duration (e.g., pregnancy), to intervals with indeterminable endpoints (e.g., long-term cardiac failure). Table 1 gives an overview of the number of notes and conversations in each specialty.

3.1 Developing Event Annotation Guidelines

We develop a set of coding guidelines for the task of annotating event triggers in documents from these two domains. Our coding guidelines build upon TimeML (Pustejovsky et al., 2003a), a rich specification language for annotation of events and temporal expressions in text,[4] and Thyme-TimeML (Styler IV et al., 2014), a variant of TimeML developed for clinical notes. We start with these guidelines because they use a syntax-driven domain-agnostic definition of events, allowing for an adaptable annotation scheme. In TimeML, the term *event* refers to situations that *happen* or *occur*, or circumstances in which something *obtains* or *holds true*. This is a broad definition, consistent with Bach's definition of **eventualities** (Bach, 1986), and the idea of **fluents** (McCarthy, 2002). Events can be expressed in text by means of tensed or untensed verbs, nominalizations, adjectives, predicative clauses or prepositional phrases. TimeML describes rules to annotate events in all these syntactic categories. Styler IV et al. (2014) adapted these rules for clinical notes. They focused on the THYME corpus of 1254 de-identified notes from the Mayo Clinic, representing two fields in oncology: brain cancer and colon cancer. As a first step, we annotate one document from each of our domains following TimeML and Thyme-TimeML rules. During this phase, we identify cases where it is reasonable to deviate from these guidelines.

Deviations from TimeML: Our guidelines[5] differ from TimeML in their treatment of two categories:

1. Activity patterns: Activity patterns are events that are neither pure generics[6], nor single events clearly positioned in time. For example, consider the sentence "I *take* my blood pressure regularly." The event *take* is not grounded in time. It is also not a pure generic event as it is definitely associated with the speaker. Such events are *not* annotated in TimeML. However, in our data, these activity patterns occur frequently in crucial contexts such as taking medications, following lifestyle changes suggested by doctors, measuring vital signs, etc.

2. Long-term states: Because TimeML was geared towards the task of temporal ordering, it strictly restricted annotation of stative events to the following types: (i) states associated with a temporal expression, (ii) states undergoing a change within the document, (iii) states introduced by other events, since those can offer temporal cues, and (iv) states associated with the document creation time. However, many stative events in our data don't fit within these strict parameters, but are nevertheless important. The most crucial category is states associated with long-term ongoing illnesses (e.g., "The patient has a long history of *COPD*").

These event categories are not specific to medical domains only. For example, long-term state events might be salient when extracting personal events from biographies.[7] Similarly activity patterns might be salient when extracting events from scientific procedure manuals.[8] Considering these scenarios, we add rules to extract these two categories of events. We also expand syntactic rules to cover constructions unique to doctor-patient conversations such as repetition, especially for instructions, and hypothetical event annotation in utterances when doctors are "thinking out loud".

Deviations from Thyme-TimeML: Our guidelines differ from Thyme-TimeML in their treatment of two categories:

1. Generic events: Thyme-TimeML annotates generic events in sections documenting discussion of risks, plans and alternative strategies. They do so because adding these events to a patient's clinical timeline could be important from a legal perspective, as they help to establish informed consent and knowledge of risk. We do not annotate pure generics, because we do not perceive any domain-agnostic utility in annotating them. Note that we annotate verbs of discussion and comprehension which are not generics, so we do not fully ignore events associated with patient consent. For exam-

[4] The complete TimeML coding manual is available here: https://catalog.ldc.upenn.edu/docs/LDC2006T08/timeml_annguide_1.2.1.pdf

[5] Our complete coding manual, including example annotations, is available at:https://github.com/aakanksha19/MedicalEventExtraction.

[6] Pure generics are events which discuss illnesses/treatments in general, and are not associated with a specific person and time. For example, "there is a *benefit* to systemic adjuvant *chemotherapy*."

[7] e.g., "Bill Gates is currently *employed* full-time at the Bill and Melinda Gates Foundation."

[8] "*Repeat* step 5 daily, over a period of 30 days."

Domain	Entity κ	Event κ
Notes	0.9117	0.8652
Convos	0.8634	0.8327

Table 2: Inter-annotator agreement on entity and event annotation tasks in both domains, measured using chance-corrected Cohen's κ

ple, in the sentence "She repeated the potential side effects back to me," *repeated* is annotated, but *effects* is not. Thyme-TimeML would annotate both.

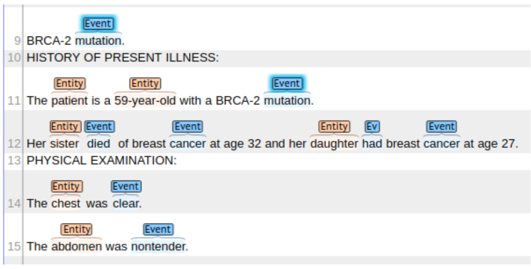
2. Entities as events: Thyme-TimeML treats some entities and non-events as events in clinical language. Two categories see this shift in semantic interpretation: (i) Medications, and (ii) Disorders. Both categories contribute significant information to a patient's timeline, and so they are treated as events. Since we are not specifically focused on timeline construction, we do not follow the same reasoning. In particular, medications are not treated as events, while disorders may be treated as events as long as they fit the TimeML definition. To ensure that we do not discard potentially crucial information, we incorporate an additional step in which we annotate entities such as medications, body parts, abnormalities (e.g., rash), etc.

3.2 Annotation Process

After incorporating our modifications, we test our guidelines by having two expert annotators annotate one document from each domain. We see high inter-annotator agreement (measured by chance-corrected Cohen's κ) on entity and event annotation, in both domains. Table 2 presents the agreement scores. To create our final datasets, we sample 45 documents from each domain (15 from each specialty). Each document is annotated by one expert. Annotation is carried out using the BRAT stand-off markup interface (Stenetorp et al., 2012). Figure 1 shows a sample clinical note annotated with events and entities. Table 3 gives a brief overview of statistics for our datasets, in comparison with TimeBank (news articles) (Pustejovsky et al., 2003b).

4 Methods for Marginal Alignment

To adapt event extraction models with no training data, we tackle the problem of covariate shift, which arises when the marginal distribution (or input distribution) $P(X)$ changes between train and test data. Directly applying a supervised model trained on the training set, to the test set might not perform well due to the gap between training and test distributions. We experiment with several techniques to align the training and test distributions, so that the supervised model transfers better to test data. The techniques can be divided into two types based on the kind of supervision used during alignment: (i) task-guided alignment techniques, and (ii) task-agnostic alignment techniques.



BRCA-2 mutation.
HISTORY OF PRESENT ILLNESS:
The patient is a 59-year-old with a BRCA-2 mutation.
Her sister died of breast cancer at age 32 and her daughter had breast cancer at age 27.
PHYSICAL EXAMINATION:
The chest was clear.
The abdomen was nontender.

Figure 1: Sample clinical note with entity and event annotation

Statistic	News	Notes	Convos
#Files	54	45	45
#Tokens	18,263	28,935	76,711
#Events	1986	4781	7064
Event Density	10.88%	16.52%	9.21%
Vocab Size	3978	4303	3505
Event Vocab	1015	1588	1472

Table 3: Dataset statistics. Note that the statistics for TimeBank (News) are computed over the test set for fair comparison with our datasets, which are test-only.

4.1 Task-Guided Alignment Techniques

These techniques jointly optimize for two tasks: (i) aligning training and test distributions, and (ii) training an event extraction model. Since the alignment process receives supervision from task training, we refer to these techniques as task-guided alignment techniques. Under this category, we experiment with adversarial domain adaptation.

Adversarial Domain Adaptation: Adversarial domain adaptation was proposed by Ganin and Lempitsky (2015), who showed its efficacy on sentiment analysis. Recently, Naik and Rosé (2020) showed its utility in transferring event extraction models between two domains: news and literature. The adversarial domain adaptation framework for event extraction contains three components: (i) representation learner (R) which generates token-level representations for a sequence, (ii) event classifier which identifies events (E), and (iii) domain predictor (D) which predicts the domain for the sequence. The key idea is to train R to generate representations which *are predictive* for event identification but *not predictive* for domain prediction, making it more domain-invariant. This aligns training and test distributions by finding a shared feature space in which training and test samples are not distinguishable, while making sure that the feature space is useful for event extraction. The technique relies on an alternating optimization procedure. The first step optimizes D on the domain prediction task, while the second step optimizes both R and E on event identification while subtracting domain prediction loss. For complete mathematical details, we refer the interested reader to Naik and Rosé (2020).

4.2 Task-Agnostic Alignment Techniques

These techniques perform training/test distribution alignment and event extraction training sequentially instead of jointly optimizing them. The alignment process does not receive supervision from task training, so these techniques are task-agnostic. We experiment with the following techniques:

Domain Adaptive Fine-tuning: Domain adaptive fine-tuning has been proposed as an effective technique for unsupervised adaption of sequence labeling models to challenging domains such as Early Modern English and social media (Han and Eisenstein, 2019). This procedure works as follows:

1. Create a large dataset containing equal proportions of sentences from source and target domains. Fine-tune contextualized embeddings using a masked language modeling objective.
2. Using fine-tuned embeddings, train an event extraction model on labeled source data.

In addition to this setup, we experiment with a variant of this procedure, which uses a syntactic objective function. This variant fine-tunes embeddings on the POS tagging task in step 1. The motivation behind this variant is two-fold. First, we observe that event annotation is heavily syntax-driven, allowing delexicalized models (i.e., models using POS tags instead of words) to achieve high performance (§5.2). This indicates that infusing more syntactic awareness into embeddings might help performance on the task. Second, syntax might offer an additional basis for generalization, since sentences that look very different lexically, might follow similar syntactic structures. Intuitively, this variant is similar to syntactic relexicalization which has shown success in cross-lingual dependency parsing (Duong et al., 2015).

Likelihood-based Instance Weighting: We develop a new instance weighting procedure which uses likelihood scores computed by a language model. Instance selection and instance weighting strategies have frequently been used to perform domain adaptation by correcting for distributional differences (Jiang and Zhai, 2007; Foster et al., 2010; Axelrod et al., 2011; Wang et al., 2017). The main premise is that some samples from out-of-domain data and in-domain data often share some characteristics. Training only on these samples (pruning), or biasing training to focus more on these samples (weighting) can produce models that perform better on out-of-domain data. Motivated by this, our instance weighting procedure works as follows.

Let $S_t = w_1 w_2 ... w_n$ be a sentence from the in-domain training set. Let O be a language model trained on raw text from the target domain. We first compute the likelihood of sentence S_t under O as $\mathbb{L}_t = P_O(w_1)\Pi_{i=2}^{n} P_O(w_i|w_1...w_{i-1})$, where P_O indicates probability under model O. Then we compute a weight for S_t as follows:

$$\alpha_{S_t} = \frac{\mathbb{L}_t}{\sum_{i=1}^{|N|} \mathbb{L}_i} * |N| \qquad (1)$$

where $|N|$ is the size of in-domain training set. This metric gives a higher weight to in-domain sentences that are *more likely* under the target domain language model, up-weighting instances that share more characteristics with target domain sentences. The alpha values are used to weight the loss function, thus biasing the training procedure.

5 Experimental Setup

5.1 Model Details

The goal of our evaluation is to identify which alignment technique works best for each domain, as well as analyze whether there are specific kinds of source-target shifts that some techniques are better equipped to handle. We choose a strong BERT-based baseline model with no transfer, and evaluate the performance of each alignment technique when applied to this baseline.

VERB: Baseline labeling all verbs as events.

DELEX: Fully-delexicalized baseline using POS tag embeddings as features, followed by an MLP.

BERT: Single-layer BiLSTM over BERT embeddings (Devlin et al., 2019), followed by an MLP, similar to the best-performing model on LitBank

Model	**In-Domain**			**Out-of-Domain**

Table 5: Model performance on domain transfer experiments from news to doctor-patient conversations.

(Sims et al., 2019).

CBERT: Similar to BERT, but embeddings are extracted from Clinical-BERT (Alsentzer et al., 2019)

BERT-ADA: BERT trained using adversarial domain adaptation.

BERT-LIW: BERT trained on data weighted by LM likelihood. We train autoregressive language models over 3 million tokens for each domain.

BERT-DAFT: BERT with domain adaptive fine-tuning. For target domains, we use the same text as BERT-LIW, and extract 3 million tokens from CNN/ DailyMail (Hermann et al., 2015) for news.

BERT-DAFT-SYN: BERT with syntactic fine-tuning on the same text as BERT-DAFT, tagged using Stanford CoreNLP (Manning et al., 2014). Complete implementation details are provided in appendix A.

5.2 Results

Tables 4 and 5 show the performance of all models when transferring from news data to clinical notes and doctor-patient conversations respectively. From the tables, we see that DELEX is surprisingly strong out-of-domain. BERT with no transfer performs well out-of-domain, improving by 8.25 F1 points on average over DELEX. C-BERT also performs well out-of-domain, but does worse than BERT. We attribute this to the fact that fine-tuning only on clinical notes does not improve alignment with the source domain (news), providing no basis for models trained on news to adapt better. BERT-ADA shows mixed results, improving over BERT by 2.4 F1 on notes, but dropping by 1.1 F1 on conversations. BERT-LIW and BERT-DAFT improve upon BERT in both domains. BERT-DAFT shows minor performance drops in-domain, due to some degree of catastrophic forgetting. BERT-DAFT-SYN shows performance drops, both in-domain and out-of-domain, in both settings. Unlike syntactic relexicalization work which used non-contextualized embeddings, we use contextualized embeddings, which possess a larger degree of syntactic information, probably reducing the need for syntax-driven training. Another source of errors is POS tagging, since off-the-shelf taggers trained on news will be less accurate on our data. Across domains, the skew between precision and recall is higher on notes, which might stem from the specialized vocabulary dragging down recall.

6 Analysis and Discussion

Tables 4 and 5 provide an indication of model ability to handle covariate shift. However, covariate shift occurs at multiple layers in language (e.g., lexical level, syntactic level, etc.), leading to different dimensions of variation between domains (e.g., topical variation, genre variation, etc.). Looking at overall model performance does not offer insight into whether there are specific shifts that some models are better at addressing. We dig deeper into this question, focusing on two levels of shift: (i) lexical shift, and (ii) semantic (event type) shift.

Variation under lexical shift: We separate model performance on in-vocabulary (IV) and out-of-vocabulary (OOV) tokens. Note that the proportion of events that are OOV is higher in clinical notes (52%) than conversations (20.6%). Tables 6 and 7 present model performance on these token categories. Surprisingly, despite the use of specialized language, OOV performance on clinical notes is higher than conversations for all models except BERT-DAFT. Taking a closer look at the OOV event instances from clinical notes that models identify correctly, we see that a large proportion (54.8%) contain one of three morphological patterns: (i) past tense verbs ending in "-ed", (ii) gerunds ending in "-ing", or (iii) nouns ending in "-tion" or "-sion". These patterns are also common among events in the news domain. For example, past tense verbs often refer to events that have already occurred and gerunds and nouns ending in "-tion" refer to processes. We hypothesize that BERT-based models might be exploiting these morphological regularities to correctly label unseen medical terms (e.g., irrigated, excision, dissected, wheezing, etc.). These patterns are more prevalent in notes (35.6%) than conversations (23.5%), explaining the surprising performance difference.

Variation under semantic shift: To determine whether model performance on OOV tokens depends on event type, we randomly sample ∼500 OOV tokens from each domain and label them for event type. We use the same typology as TimeML (State, I-State, Occurrence, Aspectual, Reporting, Perception, I-Action, None), with additional labels for the event types we introduce (ActivityPattern, LongTermState).[9] We run an ANOVA model with each token per model as an instance (total 5080 instances), noting Event Type, Target (notes/convos), Model (BERT/ADA/LIW/DAFT/DAFT-SYN) and Correctness (1 vs 0). Correctness is the dependent variable, while others are independent variables. We include all pairwise interaction terms and the three way interaction between Event Type, Target and Model. We see a positive main effect of Event Type on Correctness ($p < 0.0001$), indicating that some event types are more difficult. There are two significant two-way interactions, one between Target and Event type ($p < 0.0001$), indicating that difficulty of event types differs across sources, and between Model and Event type ($p < 0.0001$), indicating that which model is better depends on event type. Three way interaction between Model, Event type, and Target is also significant ($p < 0.0001$), indicating that performance differences between models per event type differs between sources.

We interpret differences in performance per event type separately for each source using a Student-t post-hoc analysis to determine which pairwise contrasts are statistically significant. This reveals that in clinical notes, LIW outperforms all models on I-State events (i.e., hypothetical, future or negated states) and LongTermState events, a category never seen in the training data. These improvements might stem from the training algo-

Model	IV F1	OOV F1
BERT	73.5	61.2
BERT-ADA	75.2	65.0
BERT-LIW	73.6	62.6
BERT-DAFT	75.7	62.0
BERT-DAFT-SYN	67.7	58.4

Table 6: Model performance on in-vocabulary (IV) and out-of-vocabulary (OOV) terms from notes.

Model	IV F1	OOV F1
BERT	71.3	57.9
BERT-ADA	70.2	57.6
BERT-LIW	72.0	61.4
BERT-DAFT	74.9	63.6
BERT-DAFT-SYN	65.5	55.5

Table 7: Model performance on in-vocabulary (IV) and out-of-vocabulary (OOV) terms from conversations.

---

[9] Examples provided in appendix B

rithm used by LIW. LIW up-weights instances in news that resemble medical data, which contains a high proportion of these event categories. Therefore, despite being infrequent in news, they get up-weighted, helping LIW identify them better.

7 Conclusion

In this work, we focused on unsupervised adaptation of event extractors to new domains by aligning the marginal distributions of source and target domains. We created two event extraction test sets using English texts from two medical domains: (i) clinical notes, and (ii) doctor-patient conversations, and tested the efficacy of three alignment techniques: (i) adversarial domain adaptation (ADA), (ii) domain adaptive fine-tuning (DAFT), and (iii) a new instance weighting technique based on language model likelihood scores (LIW). None of these models consistently outperformed the others, but a deeper analysis of model performance under different types of shifts (e.g., lexical shift, semantic shift) uncovered interesting variations among models. Our best-performing models attained F1 scores of 70.0 and 72.9 on notes and conversations respectively, using *no* labeled target data. We believe these models define a good starting point and can be further improved using few-shot learning.

Appendix

A Implementation Details

BERT: The BERT baseline model uses the uncased variant of BERT-Base (with no additional fine-tuning) for feature extraction. We generate token representations by running BERT-Base and concatenating the outputs of the model's last 4 hidden layers. The BiLSTM layer has a hidden size of 100, with an input dropout of 0.5. The MLP layer is 100-dimensional. These values are consistent with the setup in Naik and Rosé (2020).

BERT-ADA: The domain predictor (adversary) is a 3-layer MLP with each layer having a dimensionality of 100 and ReLU activations between layers. For the hyperparameter λ, which is the constant used to weight domain prediction loss, we experiment with values from [0.5,1.0,2.0,5.0], and choose the best model based on F1 scores on the source domain validation set. We run one search trial with a fixed random seed (0) for all settings. The best performing model on clinical notes uses $\lambda = 1.0$ and on conversations uses $\lambda = 0.5$.

BERT-LIW: The autoregressive word-level language models used for weighting are 3-layer LSTMs, with a hidden size of 300 and layer dropout of 0.2 at each layer. Input embeddings are initialized using 300-dimensional GloVe embeddings, with parameter typing between input and output embedding matrices. The models are trained using SGD with gradient clipping at 0.25 and a batch size of 16 for 25 epochs. Training starts with a learning rate of 20, which is divided by 4 whenever validation loss plateaus.

BERT-DAFT/BERT-DAFT-SYN: BERT-Base is fine-tuned for 3 epochs, using a batch size of 4 and default parameter settings in the Huggingface transformers library.

All event extraction models are trained with a batch size of 16 and use Adam optimizer with a learning rate of 0.001. Models are trained for 1000 epochs with early stopping. All experiments are run on an NVIDIA GeForce GTX 1080 Ti machine.

B Event Typology Examples

1. **Occurrence:** Occurrence refers to all events describing something that happens or occurs in the world. This is the broadest class of events. For example, "I *took* Midol yesterday."

2. **Aspectual:** Aspectual events refer to events which focus on various aspects of a different event's history, such as initiation, termination, continuation etc. For example, "I *started* taking this medicine last Friday." Here *started* is an aspectual event describing the initiation

of the event *taking*.

3. **Reporting:** Reporting events describe the action of an entity (person/group/organization) declaring something, narrating an event, providing information about an event etc. For example, ”So you *said* you have been experiencing symptoms since yesterday?”

4. **Perception:** Perception events refer to events involving the physical perception of a different event. For example, ”I *watched* my weight gain throughout the pregnancy.”

5. **State:** States describe circumstances in which something obtains or holds true. For example, ”My blood pressure is *higher* today”. Note that annotation of state events in TimeML is subject to certain rules.

6. **Intensional Action (I-Action):** Intensional actions introduce an explicit event argument describing an action or situation, from which we can infer something given its relation with the intensional action. For example, ”We will *investigate* your symptoms further via this test.” Here *investigate* is an intensional action associated with the *symptoms* event.

7. **Intensional State (I-State):** Intensional states contain stative events that refer to alternative or possible worlds. For example, ”You might observe *higher* blood pressure for a few days when you start taking this medicine.”

8. **Activity Pattern:** Activity patterns refer to events that are not clearly grounded to a single occurrence in time, but still considered events since the presence of a participant stops them from being purely generic. For example, ”You should *take* your blood pressure regularly.”

9. **Long Term State:** Long-term states expand the annotation of states beyond TimeML restrictions, allowing the inclusion of long-term chronic conditions. For example, ”You have a history of *COPD*.”

NoiseQA: Challenge Set Evaluation for User-Centric Question Answering

Abstract

When Question-Answering (QA) systems are deployed in the real world, users query them through a variety of interfaces, such as speaking to voice assistants, typing questions into a search engine, or even translating questions to languages supported by the QA system. While there has been significant community attention devoted to identifying correct answers in passages assuming a perfectly formed question, we show that components in the pipeline that precede an answering engine can introduce varied and considerable sources of error, and performance can degrade substantially based on these upstream noise sources even for powerful pre-trained QA models. We conclude that there is substantial room for progress before QA systems can be effectively deployed, highlight the need for QA evaluation to expand to consider real-world use, and hope that our findings will spur greater community interest in the issues that arise when our systems actually need to be of utility to humans.[1]

1 Introduction

Everyday users now benefit from powerful QA technologies in a range of consumer-facing applications including health (Jacquemart and Zweigenbaum, 2003; Luo et al., 2015; Abacha and Demner-Fushman, 2016; Kilicoglu et al., 2018; Guo et al., 2018), privacy (Sathyendra et al., 2017; Harkous et al., 2018; Ravichander et al., 2019), personal finance (Alloatti et al., 2019), search (Yang, 2015; Bajaj et al., 2016; He et al., 2018; Kwiatkowski et al., 2019) and dialog agents (Dahl et al., 1994; Raux et al., 2005). Voice assistants such as Amazon Alexa[2] or Google Home[3] have brought natural language technologies to several million homes globally (Osborne, 2016; Jeffs, 2018). Yet, even with millions of users now interacting with these technologies on a daily basis, there has been surprisingly little research attention devoted to studying the issues that arise when people use QA systems.

Traditional QA evaluations do not reflect the needs of many users who *can* benefit from QA technologies. For example, users with a range of visual and motor impairments now rely extensively on voice interfaces (Pradhan et al., 2018) for efficient text entry.[4] Another need is cross-lingual information access, e.g. in scenarios where a speaker of one of the ∼7000 non-English living languages in the world (Eberhard et al., 2020) may want to take advantage of an English QA system.[5] QA evaluation has to keep up with the different ways in which users may use these systems in practice, and the different users who interact with these systems.

Keeping these needs in mind, we construct evaluations considering the *interfaces* through which users interact with QA systems.[6] We analyze errors introduced by three interface types that could be connected to a QA engine: **speech recognizers** converting spoken queries to text, **keyboards** used to type queries into the system, and **translation systems** processing queries in other languages. Our contributions are as follows:

1. We identify and describe the problem of interface noise for QA systems. We construct a challenge set framework for errors introduced by three kinds of interfaces: speech recognizers, keyboard interfaces, and translation engines, based on the popular SQuAD question-answering benchmark (Rajpurkar et al., 2016). We define synthetic noise generators, as well

Original Question	Interface	Synthetic Construction	Natural Construction
What has a Lama determined to do?	ASR	what has a llama determined to do	what has a llama determined to do
What has a Lama determined to do?	Keyboard	Wjat has a Lsma determined yo do?	WHat has a Lama determied to do?
What has a Lama determined to do?	MT	What has a Lama decided to do?	What is a llama determined to do?

Table 1: Example question perturbations from synthetic and natural noise challenge sets for three types of interfaces: Automatic Speech Recognition (ASR) systems, Keyboard and Machine Translation (MT) systems.

as manually construct natural noise challenge sets, by processing SQuAD questions through the specified interfaces.

2. We evaluate the performance of current state-of-the-art methods on natural and synthetic noisy data. We find that accessibility needs to be consciously worked towards, as we see that the performance of QA systems can be impacted by the choice of interface.
3. We analyze the generated noise and its impact on the downstream question answering and conduct an initial exploration of mitigation strategies for interface errors, focusing on data augmentation and query repair.

2 Motivation

Modern QA systems often rely on large databases of digital text such as Wikipedia as their source of knowledge; such corpora typically contain well-formed text in a high-resource language like English. However, the user's input could come in many different forms: it could be spoken, or written but in another, possibly lower-resource language. To convert these inputs into the format that the system can process, another machine learning system such as a speech recognizer or a machine translation engine is required, and these intermediate systems will inevitably propagate their decoding errors into the QA engine. However, interface errors are not necessarily artifacts of machine learning models: even when the question comes in the desired form (e.g. English text), it has to be communicated to the QA system through a mechanical interface such as a keyboard, and the process of typing can introduce errors such as character substitutions. To be useful in real-world settings, a QA system has to be able to correctly process the input question regardless of the input interface. We simulate the use cases for three interface categories (ASR, MT, and keyboard) with different level of human involvement, from fully automatic pipelines to leveraging existing human-generated resources to manual annotation, and evaluate whether the modern QA systems are capable of going from controlled well-formed inputs to real-world scenarios.

3 Challenge Set Construction

We define a suite of three types of noise perturbations, each imitating noise specific to a category of interfaces, and apply them to the data to create the challenge sets. We choose to add the noise to the questions but not to the context paragraphs, to replicate a realistic scenario of the noise being introduced to the question by the interface through which the user interacts with the QA engine. For each type of noise, we both build a synthetic generator that can introduce noise on a large scale, as well as manually create 'natural' noise challenge sets to imitate real-world noise.

Our challenge sets are based on SQuAD 1.1 (Rajpurkar et al., 2016),[7] a large-scale machine comprehension dataset based on Wikipedia articles where the answer to each question is a span in a provided context. We choose SQuAD both for its popularity as a benchmark (Gardner et al., 2018; Devlin et al., 2019; Radford et al., 2018; Wolf et al., 2019) and to avoid additional confounds such as unanswerable questions (Rajpurkar et al., 2018).[8] We use the standard ~90K/10K train/development split and construct the challenge sets from the XQuAD data (Artetxe et al., 2020), a subset of 1,190 SQuAD development set questions accompanied by professional translations into ten languages.[9] Below we discuss each challenge set in more detail.

---

[7] Though in principle, these constructions could be applied to any kind of QA dataset

[8] Future work would pursue a context-driven evaluation of unanswerability, identifying the kinds of unanswerable questions users ask in practice (Ravichander et al., 2019; Asai and Choi, 2020).

[9] Spanish, German, Greek, Russian, Turkish, Arabic, Vietnamese, Thai, Chinese, and Hindi.

3.1 MT Noise

Our first challenge set emulates machine translation noise introduced when the question is asked in a language other than the language of the QA system's training data. We use English as the QA system language, pairing English contexts with non-English questions.

Synthetic Challenge Set Our synthetic noise generator employs the back-translation technique (Sennrich et al., 2016; Dong et al., 2017; Yu et al., 2018). In our case, back-translation is not meant to act as a data augmentation technique but rather to simulate noise that could be introduced by an MT engine when translating the question from another language. We imperfectly approximate natural non-English input by automatically translating English questions into a pivot language (German); we then translate them back to English, imitating a scenario where the user submits a query through an MT engine. We use the HuggingFace implementation (Wolf et al., 2019) of MarianNMT (Junczys-Dowmunt et al., 2018).[10]

Natural Challenge Set To bring our simulation closer to the natural setting, we create another challenge set from English machine translations of human-generated questions in other languages. We take the questions from the XQuAD dataset, which consists of English questions paired with professional translations into ten other languages.[11] For each of the test set languages, we use Google's commercial translation engine[12] to produce the English translation of the question. This allows us to construct ten challenge sets of translations from different languages with 1,190 questions each.

3.2 Keyboard Noise

This challenge set represents the noise introduced in the process of typing a question up on a keyboard, for example, when a question is submitted to a QA system through a search engine.

Synthetic Challenge Set Inspired by prior work (Belinkov and Bisk, 2018; Naik et al., 2018), our basic noise generator introduces per-character typos based on the proximity of the keys in a standard QWERTY keyboard layout. Each word is corrupted with a 25% probability by substituting a randomly sampled character with its row-wise neighbor. We also create more natural-looking noise by introducing externally collected human misspellings into our data on word level, as proposed by Belinkov and Bisk (2018). Although prior work refers to this as natural noise, emphasizing that the typos have been produced by humans, we consider it synthetic because the errors are applied to the data outside of their original context. We start with the Wikipedia common English misspellings list[13] and apply a simple filtering heuristic that only retains keyboard errors (see Appendix C), obtaining 1,742 misspellings for 1,489 English words.

ORIGINAL QUESTION	How many Panthers defense players were selected for the Pro Bowl?
GOOGLE ASR	how many Santa's defense players selected for the Pro Bowl
ESPNET (WITH LM)	how many pantols the tent places were slected for the probol
KALDI (WITH LM)	how many friends tons of defence UNK for the UNK

Table 2: Example outputs of different ASR systems on a recorded question from SQuAD (Rajpurkar et al., 2016).

Natural Challenge Set To generate errors specific to the context of the question rather than hypothesized to exist at a lexical level across contexts, we ask three human annotators to retype English XQuAD questions. Annotators can see the original question, which helps avoid errors caused by misconception (e.g. not knowing the correct spelling of a named entity), but not their own input, in order to prevent them from correcting the typos. Of the obtained noisy questions, 51.6% and 25.7% differ from the original by at least one or at least two characters respectively.

3.3 ASR Noise

Our final challenge set simulates ASR errors that occur when a question is posed to a voice interface.

Synthetic Challenge Set We emulate automatic recognition of natural speech by using a Text-to-Speech (TTS) system pipelined with an ASR engine (Tjandra et al., 2017). We voice the questions using Google TTS and transcribe the obtained

---

[10] `huggingface.co/Helsinki-NLP/opus-mt-{en-de|de-en}`

[11] A subtle nuance is that XQuAD questions are not originally written in these languages but translated from English; acknowledging this, we use XQuAD data as the natural challenge set because its fully parallel nature allows varying input language while controlling for content for fair comparison.

[12] `translate.google.com`

[13] `en.wikipedia.org/wiki/Wikipedia:Lists_of_common_misspellings`

Interface	CER (↓)	WER (↓)	BLEU (↑)
Synthetic			
ASR	3.96	16.61	77.12
Keyboard	4.11	23.93	52.66
Translation	20.51	29.36	58.42
Natural			
ASR	12.96	30.67	57.22
Keyboard	1.78	7.42	85.78
Translation	31.89	43.34	47.07

Table 3: % Character Error Rate (CER), % Word Error Rate (WER) and BLEU scores for all challenge sets compared to ground truth. For ASR and MT, synthetic noise is less prominent than natural, reflecting the idealized simulation conditions. As expected, natural keyboard noise demonstrates the best word-level statistics.

speech using Google Speech-to-Text optimized for English–US. Besides Google ASR, we use Kaldi ASpIRE (Povey et al., 2011; Peddinti et al., 2015) and ESPnet CommonVoice (Watanabe et al., 2018; Ardila et al., 2020) open-source systems, as shown in Table 2. We choose the former for analyzing the downstream effect of out-of-vocabulary word prediction in fixed vocabulary decoding (Peskov et al., 2019) and the latter for data augmentation (§4.2) due to its improved out-of-vocabulary word handling with subword units. In order to generate the large amount of speech data needed for augmentation, we use the open-source ESPnet LJSpeech TTS (Hayashi et al., 2020; Ito and Johnson, 2017) to voice the questions.

Natural Challenge Set We use the SANTLR speech annotation toolkit (Li et al., 2019) to record spoken versions of the prompt question from three human annotators (for background details, see Appendix D). The obtained recordings are then transcribed using the ASR engines listed above. As expected, recognizing human speech is more difficult: the word error rate of the Google ASR system on the obtained set is 31%, compared to 17% on the synthesized English–US speech.

4 Experiments

We select four QA models that demonstrated strong performance on SQuAD 1.1[14] to be tested under interface distortions: BiDAF (Seo et al., 2017), which represents contexts at different levels of granularity using bidirectional attention flow mechanism; its extension BiDAF-ELMo (Peters et al., 2018) augmented with contextualized embeddings; BERT (Devlin et al., 2019), a bidirectional Transformer-based language model (Vaswani et al., 2017); and RoBERTa (Liu et al., 2019), a more robustly pre-trained version of BERT.

4.1 Results and Analysis

Table 3 shows the character error rate (CER), word error rate (WER) and BLEU score[15] for the generated challenge sets. Synthetic ASR and MT pipelines introduce substantially less noise than their natural counterparts, while the opposite holds for the keyboard. This is likely due to the generators not being equally controllable: while we can arbitrarily make the synthetic keyboard set noisier by increasing the corruption rate, synthetic ASR and MT pipelines include black-box components which also make the task easier for the interface by design (TTS synthesizes idealized speech, back-translation mimics MT training conditions).

In this section, we investigate how robust QA models are to these interface errors. Table 4 reports the performance on both synthetic and natural challenge sets. For brevity, we present results using the German–English model and the Google ASR for MT and ASR respectively.

First, we observe that both synthetic and natural noise decrease accuracy for all models and interfaces, with synthetic keyboard and natural ASR errors being the most challenging. As for MT noise, Table 4 reports results on German queries; although the systems seem robust on these, we find that MT noise can actually be quite challenging with sharp degradation of performance on Thai and Arabic (Figure 2). Further, we notice that the relative performance of models on the development set is not necessarily a sufficient proxy for the relative robustness of models to interface errors: while BERT and RoBERTa perform very similarly on XQuAD–English, RoBERTa outperforms BERT on handling all three kinds of interface errors. For practitioners, this could suggest that simply choosing the highest-accuracy QA model without separately evaluating robustness to interface noise may lead to sub-optimal performance in practice.

Below we discuss the effect of each interface in more detail.

---

[14] F1 scores on SQuAD dev set: BiDAF: 77.8; BiDAF-ELMo: 80.7; BERT: 88.8; RoBERTa: 89.9. For hyperparameters and implementation details, see Appendix A.

[15] Uncased detokenized BLEU using SacreBLEU (Post, 2018).

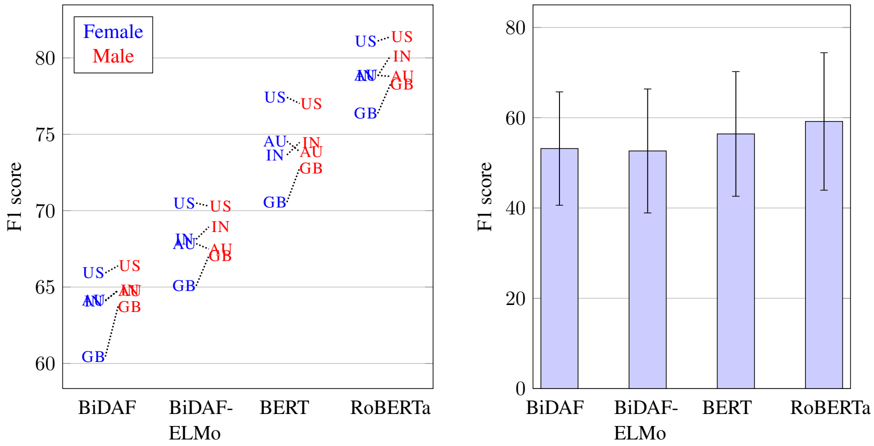
RoBERTa (Liu et al., 2019)	72.35	84.42	60.08	73.61	70.00	82.13	70.92	83.37

Table 4: Performance of the QA models under the three kinds of interface noise: ASR (using Google ASR), MT (with the German–English model), and keyboard. All models score lower on noisy data, most notably on the natural ASR set. MT noise is less prominent, but we later show its impact is highly dependent on the input language.



(a) F1 scores for TTS voices over 4 accent and 2 gender settings. Lines connect the results for different gender but same accent and model.

(b) F1 mean and standard deviation over 4 human voices. For details and score breakdown by speaker, see Appendix D.

Figure 1: Effect of synthetic (a) and natural (b) voice variation on the QA performance in an ASR pipeline. Synthetic voice variation is achieved by varying accent and gender settings in the Google TTS model; US accent setting shows the highest scores while neither gender setting consistently performs best (indicated by line slopes). Natural variation is measured on a sample of 100 questions narrated by four annotators. All models exhibit considerable variation in both experiments.

ASR Noise: Speech recognizers typically omit punctuation, which could mean losing cues important for the downstream task. To look at this factor in isolation, we remove punctuation from the original XQuAD questions. This change alone decreases BERT performance by 5.1 F1, suggesting that the absence of punctuation in part explains the degradation in the presence of ASR noise. When we qualitatively analyze a sample of 50 questions that BERT answered successfully in the original setting but not when passed through the speech interface, we find that 14% of them are identical to the original modulo punctuation. Other sources of error include the ASR producing completely meaningless questions (28%), hallucinating (12%) or losing named entities (10%), and replacing words with homonyms (4%); other difficult cases include recognizing acronyms and preserving possessives, tense, and number (2% each). Although these problems could be diminished by designing better interfaces, we believe it is also worthwhile for practitioners to work on improving robustness of the QA systems itself: many interfaces, especially commercial, only offer black-box access, and building a completely noise-free interface is not feasible.

Voice variation also plays a role: ASR error distribution differs by speaker background variables such as accent (Zheng et al., 2005), in turn affecting the downstream systems (Harwell, 2018; Lima et al., 2019; Palanica et al., 2019). To emulate speaker variation in the synthetic setting, we use Google English Text-to-Speech to pronounce the XQuAD questions in eight different voices, varying the provided accent and gender settings. As Figure 1a shows, all models exhibit considerable variation in F1 score, consistently performing best on synthetic US accent (which our speech recognizer is optimized for) and worst on GB. Score breakdowns by setting can be found in Appendix D.

We also repeat the experiment with four human speakers narrating a sample of 100 XQuAD questions, to control for content. As shown in Figure 1b, each model's performance varies substantially between voices. The four speakers differ by accent (2 Indian, 1 Russian, 1 Scottish), gender (2 male, 2 female), and level of proficiency (native and non-native); more details and individual speaker scores can be found in Appendix D.[16] Although improving robustness to accent variation is out of the scope of our work, we highlight that the performance can degrade sharply depending on the user and their acoustic conditions.

We also analyze how the choice of ASR model affects the QA accuracy, focusing in particular on the decoding strategies for out-of-vocabulary words. We compare Kaldi, which outputs an UNK token for unknown words (Peddinti et al., 2015), and Google's large-vocabulary ASR model. On our set of human voices, Kaldi produces at least one UNK token for $\sim$50% of the questions, and BERT achieves an F1 score of only 43.6 on this set (54.4 F1 and 32.3 F1 separately on questions with and without UNK respectively) compared to 67.1 F1 achieved by Google ASR, demonstrating that speech recognizer choice can greatly affect downstream QA performance. The observed degradation due to UNK decoding (previously noted by Peskov et al., 2019) suggests that practitioners might find it useful to go beyond speech recognition benchmarks, and also evaluate ASR systems in the context of downstream QA applications.

Translation Noise: As Table 4 shows, German–English translation errors affect the performance of all models, although to a lesser extent than ASR noise. However, the MT quality and, in turn, the downstream performance varies greatly depending on the source language. Figure 2 shows BERT and RoBERTa F1 scores on questions translated from each of the ten XQuAD languages to English (numbers reported in Appendix E). While German and Spanish have the highest accuracy, lower-resource and more typologically distant languages like Arabic and Thai are far behind. On translated Thai inputs, BERT achieves only 71.0 F1, which is a 16% drop in accuracy from the original English setting compared to 6% for German.

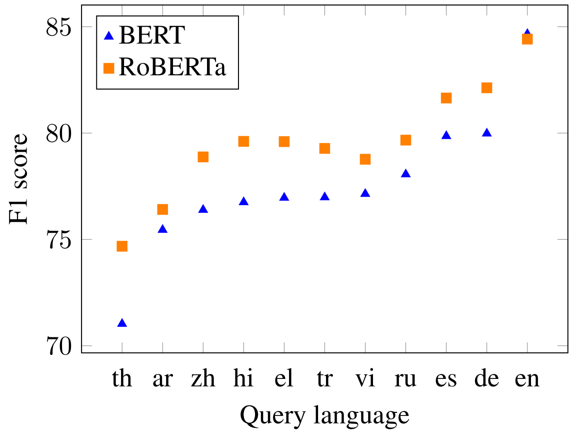


Figure 2: Effect of the input language on the QA system performance in an MT pipeline. Automatically translating non-English queries to English decreases performance for all source languages, and the decrease is especially noticeable for lower-resource languages.

Table 5 shows example translations from four XQuAD languages and highlights their divergences from the original questions. Since the questions are being translated out of context, MT tends to replace important content words with ones that are semantically related but not appropriate in given context (*Lord*→*deity*, *chair*→*President*, *ctenophore*→*jellyfish*). Transliteration of technical terms and named entities is also a challenge, especially for languages written in non-Latin scripts (*ctenophore*→*tenophora* through Hindi, *Jochi*→*Dschötschi* through German). For further qualitative analysis, we sample 100 questions translated from Hindi which BERT fails to answer correctly despite accurately answering their English equivalent. Of these, 30% were identified by a native speaker annotator as paraphrases of the original question that would admit the original answer. The remaining incorrect translations are due to question type shift (31%), ungrammatical or meaningless questions (12%), corrupted named entities (8%) and dropped determiners (2%; Hindi does not generally use definite articles). Some divergences also go beyond word level, e.g. 10% of questions have semantic role inversion (*What earlier market did the Grainger Market replace?*→*Which earlier market replaced Granger's market?*). While some word-level errors can be corrected post-hoc, repairing syntax is much more challenging, which again

---

[16] Comparisons between demographics should not be drawn from per-speaker results, since we do not control for confounds like recording conditions, aiming for a realistic sample.

Language	Question	Language	Question
What type of Lord is Doctor Who?		**When would the occupation of allies leave Rhineland?**	
de:	What kind of gentleman is Doctor Who?	**de**:	When would the Allied occupation leave the Rhineland?
zh:	What type of lord is Doctor Who?	**zh**:	When was the Allies scheduled to withdraw from Rhineland?
hi:	What kind of deity is Doctor Who?	**hi**:	When will the Rhineland be removed from the occupation of the Allied countries?
ru:	What type of overlord is Doctor Who?	**ru**:	When did the Allies intend to remove the occupation of the Rhine region?
Who is the chair of the IPCC?		**How much food does a ctenophora eat in a day?**	
de:	Who is the chair of the IPCC?	**de**:	How much food does a jellyfish eat in a day??
zh:	Who is the current chairman of the IPCC?	**zh**:	How much food does a jellyfish eat in a day?
hi:	Who is the President of IPCC?	**hi**:	How much food does a tenophora eat in a day?

Table 5: Examples of translation divergences for German (de), Chinese (zh), Hindi (hi), and Russian (ru).

brings it down to the robustness of the QA engine.

Keyboard Noise: Synthetic keyboard noise produced by our key-swap typo generator has a much stronger effect on the QA performance than natural noise (11.1 F1 and 2.4 F1 drop respectively). We attribute this to differences in the perturbation intensity: $\sim$25% of question words are corrupted in the synthetic setting, but only $\sim$9% of words are corrupted under natural conditions.[17] Interestingly, BiDAF- and BERT-based models consistently show comparable decreases in F1 score, suggesting that character-level tokenization of the former does not on its own guarantee robustness to typos.

Another factor that could affect downstream performance is error placement. We evaluate BERT on three additional synthetic sets, introducing noise to only function words (conjunctions, pronouns, articles), only content words (which we limit to nouns and adjectives), or only commonly misspelled words (using the Wikipedia misspellings list as described in §3.2). Synthetically perturbing all function words and all content words decreases F1 score by 6.7 and 11.7 respectively, confirming that not all words are equally important for the model finding the correct answer. Injecting the interface errors from Wikipedia into the 2,716 questions containing at least one commonly misspelled word yields F1 score of 78.6 (6.1 F1 drop), showcasing the decreased performance we would likely see in real-life user interactions.

4.2 Mitigation Strategies

We experiment with two strategies for improving the QA system robustness: repairing the question errors using the provided context and retraining QA models on the data augmented with synthetic noise. Question repair assumes availability of context, making it unsuitable for open-domain QA, but reasonable for use cases like QA over manuals or policies (Feng et al., 2015; Harkous et al., 2018; Ravichander et al., 2019). This approach treats words that occur in the question but not the context as potential noise, attempting to replace them with the closest candidate from the context paragraph. We use character error rate as the distance metric, empirically setting the threshold to 0.5 using the synthetic set. We perform two experiments, applying the repair either only to content words (here, nouns and adjectives) or only to named entities in both the context and the question. Table 6 shows how these repairs affect BERT performance on three types of natural noise. Named entity repair yields marginal improvements across the board, while content word repair has a stronger effect but only for keyboard errors. The proposed strategy could also be combined with other deterministic or off-the-shelf repair methods, such as adding final question marks for ASR (+6.52 F1) or using a spellchecker for keyboard (+1.41 F1).

For data augmentation, we use our synthetic noise generators to inject noise into $\sim$90K SQuAD training questions and retrain BERT on the combined clean and noisy data. As Table 6 shows, augmentation yields improvements on all three types of natural noise over BERT trained on clean data only, but the performance of the augmented models drops slightly on the clean data. Best results on natural ASR and MT noise are obtained when the data is augmented with the same type of synthetic noise; interestingly, this is not true for keyboard noise, where ASR augmentation also works best.

---

[17] Synthetic data corruption rate is a design decision and can be made to simulate the expected natural noise or be more challenging as a stress test, depending on practitioner's goals.

	XQuAD_{EN}		ASR		MT		Keyboard	
BERT Model	EM	F1	EM	F1	EM	F1	EM	F1
BERT	72.77	84.66	52.94	67.13	68.82	79.98	69.16	81.84
+ Named entity repair	**72.94**	**84.78**	53.03	67.34	68.82	80.05	69.58	82.22
+ Content word repair	**72.94**	84.77	52.61	67.01	68.32	79.76	70.25	**82.60**
+ Augmentation	72.35	83.89	**64.37**	**75.89**	**68.90**	**80.83**	**70.76**	82.43

Table 6: Effect of question repair and data augmentation on BERT performance on three types of natural noise. Results on synthetic noise and data augmentation score breakdown by interface can be found in Appendix F.

Although our results are preliminary, they suggest that augmentation could prove useful in enabling effective question answering in the real world.

To better understand where ASR and MT augmentation helps, we compare the performance of augmented and baseline BERT on additional challenge sets, synthesizing some common noise artifacts in isolation. We find that ASR noise augmentation improves robustness to omission of punctuation: ASR-augmented model achieves 82.7 F1 on questions with no punctuation and 82.9 F1 on questions without the final question mark (compared to 79.2 and 79.6 F1 for the baseline). Following the definitions in §4.1, we also experiment with removal of function and content words: both augmented models outperform baseline when all function words are dropped (76.1 F1 for ASR, and 70.2 F1 for MT, and 67.8 F1 for baseline), and ASR augmentation helps when all content words are dropped (68.6 F1 vs. 66.0 F1 for baseline). Finally, we replace one randomly sampled named entity (of type LOC, ORG, or PER) per question with a placeholder, and the performance of ASR-augmented BERT drops less than that of the baseline BERT (by 2.3% and 3.2% respectively). This analysis suggests that ASR augmentation can make models more robust to errors in punctuation, named entities, and content words, and both ASR and MT could help with function word errors.

On the utility of synthetic challenge sets: We advocate that dataset designers always obtain natural data (with natural noise) when possible. However, in the circumstances where collecting natural data is difficult, synthetic data can be useful when reasonably constructed. While the distribution of errors in our synthetically generated challenge sets differs from that in the natural ones (Table 3), we find that the model performance ranking is consistent across all types of noise (Table 4), showing that synthetic noise sets could act as a proxy for model selection. Moreover, augmenting training data with synthetic noise improves model robustness to natural noise for all noise types in this study (Table 6), suggesting that synthetic noise generators may be capturing some aspects of natural noise. Our proposed generators could serve as templates for synthesizing interface noise when collecting natural data is infeasible, but individual practitioners should carefully identify and simulate the likely sources of error appropriate for their applications.

5 Related Work

Question Answering QA systems have a rich history in NLP, with early successes in domain-specific applications (Green et al., 1961; Woods, 1977; Wilensky et al., 1988; Hirschman and Gaizauskas, 2001). Considerable research effort has been devoted to collecting datasets to support a wider variety of applications (Quaresma and Pimenta Rodrigues, 2005; Monroy et al., 2009; Feng et al., 2015; Liu et al., 2015; Nguyen, 2019; Jin et al., 2019) and improving model performance on them (Lally et al., 2017; Wang et al., 2018; Yu et al., 2018; Yang et al., 2019). We too focus on QA systems but center the utility to users rather than new applications or techniques.

There has also been interest in studying the interaction between speech and QA systems. Lee et al. (2018a) examine transcription errors for Chinese QA, and Lee et al. (2018b) propose Spoken SQuAD, with spoken contexts and text-based questions, but they address a fundamentally different use case of searching through speech. Closest to our work is that of Peskov et al. (2019), which studies mitigating ASR errors in QA, assuming white-box access to the ASR systems. Most such work automatically generates and transcribes speech using TTS–ASR pipelines, similar to how our synthetic set is constructed. However, our results show that TTS does not realistically replicate human voice variation. Besides, stakeholders relying on commercial transcription services will not have white-box access to ASR; our post-hoc mitigation strategies would be better suited for such cases.

Challenge sets Model robustness evaluation with adversarial schemes is common in NLP tasks (Smith, 2012), including dependency parsing (Rimell et al., 2009), information extraction (Schneider et al., 2017), natural language inference (Marelli et al., 2014; Naik et al., 2018; Glockner et al., 2018), machine translation (Isabelle et al., 2017; Belinkov and Bisk, 2018; Bawden et al., 2018; Burlot and Yvon, 2017) and QA (Jia and Liang, 2017; Aspillaga et al., 2020). Unlike most prior work, we do not create our challenge sets to break QA systems, but rather for a more realistic evaluation of the systems' real-world utility.

6 Conclusion

In this work, we advocate for QA evaluations that reflect challenges associated with real-world use. In particular, we focus on questions that are written in another language, spoken, or typed, and the noise introduced into them by the corresponding interface (machine translation, speech recognition, or keyboard). We analyze the effect of synthetic and natural noise in each interface and find that these errors can be diverse, nuanced, and challenging for traditional QA systems. Although we present an initial exploration of mitigation strategies, our primary contribution lies not in the specific challenge sets we construct or in developing new algorithms, but rather in identifying and describing one class of problems that practical QA systems must consider and providing a framework to measure them. We hope insights derived from our study stimulate research in making QA systems ready to face real-world users. We emphasize three considerations:

Sources of error: This work studies errors introduced at the interface stage of QA pipelines. These errors are nearly ubiquitous, as users always interact with QA systems through some kind of interface. Thus, it is important for QA system designers to be mindful of distortions those might introduce. Our analysis can be extended to study the impact of interface-specific factors: for example, how errors vary by keyboard layout (e.g. QWERTY vs. Dvorak or language-specific layouts like AZERTY) or preferred way of typing (e.g. using physical keyboards vs. swipe typing). Another fruitful area of study could lie in examining the accumulated impact of errors resulting from interface combinations (e.g. machine translation of ASR-transcribed queries) and the effects of such interface noise in languages other than English. However, interface distortion represents only one source of error that occurs in practical deployment, and future research would study further sources of variation such as how users may adapt their questions according to the interface used.

Context-driven evaluation: This work focuses on practical evaluation of QA systems that takes into account the challenges associated with their real-world deployment. We hope to encourage development of future user-centered or participatory design approaches to building QA datasets and evaluations, where practitioners work with potential users to understand user requirements and the contexts in which systems are used in practice.

Community priorities for QA systems: While leaderboards on established benchmarks have facilitated rapid progress (Rajpurkar et al., 2016, 2018) and bolstered development of a variety of semantic models (Xiong et al., 2018; Liu et al., 2018; Huang et al., 2018; Devlin et al., 2019), we call for practitioners to consider the orthogonal direction of *system utility* in their model design. We believe these subareas to be complementary, and community attention towards both will help produce NLP systems that are both accurate and *usable*.

A Reproducibility details of models

We use the pre-trained AllenNLP implementations of BiDAF and BiDAF-ELMo[18] (Gardner et al., 2018) and the HuggingFace implementation of BERT.[19] We fine-tune BERT and RoBERTa on SQuAD with a learning rate of $3e{-}5$ for 2 epochs, with a maximum sequence length of 384. All models achieve good performance on the SQuAD dataset. Our trained models achieve the following F1 scores on SQuAD development set: BiDAF: 77.82, BiDAF-ELMo: 80.68, BERT: 88.75, RoBERTa: 89.93.

B Keyboard noise in the wild

Common examples of keyboard typos include replacing a character with the one corresponding to an adjacent key *(frame→framd)*, inserting or deleting characters *(between→betwen, agency→agenchy)*, and swapping adjacent characters within words *(beroids→beriods)*. Such errors exist even in textual QA datasets collected in relatively controlled settings: for example, all the error examples above actually occur in SQuAD. In a real-life situation of information need, where the user produces the question without being exposed to the context and the answer, these errors will likely be even more pervasive. We qualitatively analyze a sample from a dataset of questions collected from the Yahoo! Answers platform (Miao et al., 2010), randomly selecting 50 questions from each topic (Science, Internet, and Hardware). We manually identify non-standard spellings and discard ones that are intentional, such as slang *(thanks→thanx)* or expression of emotion *(so→sooo)*. Since we are specifically interested in the errors that happen in the process of typing, we also separate out errors that could have originated in the user's mind; for example, the most frequent class of errors is omission or insertion of apostrophes in contractions, possessives and plurals, but all of them could plausibly be explained by the user's intention. Other common error types we find are incorrect whitespace placement and character substitutions (mostly plausible human errors), and character insertions, deletions or swapping adjacent characters within words (mostly interface errors); statistics and error examples can be found in Table 7.

Error type	Examples	#Errors
Apostrophe	*it's→its, devices→device's*	55 (0)
Whitespace	*anyone→any one, a lot→alot*	18 (4)
Deletion	*too→to, school→schol*	18 (10)
Substitution	*warranty→warrenty, will→well*	12 (2)
AdjSwap	*type→tpye, piece→peice*	11 (9)
Insertion	*answer→asnswer, lose→loose*	9 (5)
KeySwap	*of→if*	1 (1)

Table 7: Examples of common error types observed in a manual analysis of the Yahoo! Answers questions. Examples identified as interface errors are highlighted in blue. #Errors is total number of typographical errors, with # of interface errors in parentheses.

C Filtering interface misspellings

Our source of human keyboard errors is the Wikipedia list of common English misspellings; some of them are likely to occur in the process of typing (e.g. *and→adn*), while others can plausibly be explained by user misconception (e.g. *recieve→receive*). Since our work focuses on interface errors specifically, we would like to only retain errors from the former category.

Our filtering approach is based on two assumptions: (a) interface errors must be plausible under the keyboard layout, and (b) misspellings that preserve pronunciation of the original word (e.g. *article→artical*) are more likely to be non-interface errors coming from users themselves. We use a two-step filtering heuristic: first, we retain only error categories likely to be explained by the interface noise (character deletion and insertion, adjacent character swap or adjacent key swap in QWERTY layout), and then discard spellings with similar pronunciations. Pronunciations are obtained via the Epitran G2P system (Mortensen et al., 2018), and similarity is determined by weighted edit distance.

On a sample of 100 Wikipedia misspellings manually labeled as interface or non-interface errors, the proposed heuristic shows 83% agreement with human annotation. Applying the heuristic to the initial 4,518 word–spelling pairs, we obtain a set of 1,742 interface errors for 1,489 English words.

D Voice variation in ASR

This section describes the details of the voice variation experiments discussed in §4.1. The numbers used to generate Figures 1a and 1b are presented in Tables 8 and 10 respectively.

---

[18] github.com/allenai/allennlp-hub

[19] github.com/huggingface/pytorch-transformers

Synthetic variation We generate the synthetic voices using Google English Text-to-Speech system with four different accent settings (Australian, British, Indian, and US) and two gender settings (male and female voices). The performance of all models on these voices is presented in Table 8. All QA models achieve highest F1 score when the questions are voiced with a US accent, which is likely explained by the ASR component being optimized for this accent specifically. Neither gender setting consistently leads to best performance across all models and accents. BiDAF and RoBERTa achieve highest scores when the US female synthetic voice is used, and BiDAF-ELMo and BERT perform best with the US male synthetic voice.

Natural variation We record the spoken versions of the 1,190 XQuAD questions voiced by three human annotators: H1 (Indian female), H2 (Russian female), and H3 (Indian male). The same three annotators and an additionally recruited annotator H4 (Scottish male) also voiced the same random sample of 100 XQuAD questions to measure the effect of voice variation in content-controlled setting. The summary statistics (mean and standard deviation) for the sample of speakers are shown in Figure 1b, and the breakdown of each model's score by speaker is presented in Table 10. To collect a set of recordings that is more representative of the real-life use cases, we do not control for recording conditions and other confounds, so our per-speaker results alone are not meant to be taken as evidence of the ASR or QA models being better-tuned for any of the mentioned demographics.

E Input language variation in MT

Table 9 presents the results of the query language variation experiment (§4.1, Figure 2). In this experiment, we use XQuAD human translation of questions into ten languages as inputs, translating them back into English through the Google Translation API. The table also reports the results on the original English SQuAD questions to serve as a skyline. As expected, lower-resource languages and languages that are more typologically divergent from English (the QA system's language) pose the biggest challenge for the MT–QA pipeline.

F Robustness experiments

Table 11 presents the question repair and data augmentation results on both synthetic and natural noise for all interfaces. Synthetic noise sets were used for development and tuning in all experiments. Table 11 also breaks down data augmentation results by the specific augmentation noise source. Training on ASR noise proves helpful for natural keyboard noise as well as natural ASR noise, and robustness to natural translation noise is only improved by augmenting the data with its synthetic counterpart.

G ASR system benchmarking

To benchmark both the ESPnet CommonVoice ASR system, which we use for data augmentation, and the Google ASR, which was used to create ASR challenge sets from recorded XQuAD questions, we also transcribe the natural and synthetic challenge set recordings with ESPnet ASR. ESPnet achieves 56.8% and 70.1% WER for synthetic and natural voices respectively, while Google ASR gets a WER of 16.6% and 30.7% respectively (Table 3).

H Numeral handling and ASR interfaces

Correctly transcribing numerals is often important for producing a correct answer in an ASR–QA pipeline. Even a different representation of the same quantity in the question and in the context passage creates additional difficulties for the QA system. To additionally analyze the effect of handling numerals in ASR engines, we combine BERT with Kaldi (Povey et al., 2011) or Google speech recognizers and compare their performance on the portion of XQuAD questions containing numerals (XQUAD-NUMBERS) and the remaining questions (XQUAD-NONUM). With the questions narrated by human annotators, the QA pipeline performs worse on XQUAD-NUMBERS than XQUAD-NONUM with either Kaldi (38.39 F1 and 44.30 F1 respectively) or Google ASR (64.44 F1 and 70.86 F1 respectively). In case of Kaldi, we hypothesize that the discrepancy might be partially explained by the speech recognizer outputting numbers in their spelled-out form rather than numeric form. To test this hypothesis, we convert all numerals in the original written XQUAD-NUMBERS questions into their spelled-out form and observe a drop in performance from 87.10 F1 to 82.88 F1 on this subset. However, the representation mismatch is only one of many challenges: unlike Kaldi, Google ASR outputs numerals as digits, but the corresponding pipeline still shows worse performance on spoken XQUAD-NUMBERS.

Abstract

Referential games offer a grounded learning environment for neural agents which accounts for the fact that language is functionally used to communicate. However, they do not take into account a second constraint considered to be fundamental for the shape of human language: that it must be learnable by new language learners.

Cogswell et al. (2019) introduced *cultural transmission* within referential games through a changing population of agents to constrain the emerging language to be learnable. However, the resulting languages remain inherently biased by the agents' underlying capabilities.

In this work, we introduce Language Transmission Simulator to model both cultural and architectural evolution in a population of agents. As our core contribution, we empirically show that the optimal situation is to take into account also the learning biases of the language learners and thus let language and agents *co-evolve*. When we allow the agent population to evolve through architectural evolution, we achieve across the board improvements on all considered metrics and surpass the gains made with *cultural transmission*. These results stress the importance of studying the underlying agent architecture and pave the way to investigate the *co-evolution* of language and agent in language emergence studies.

1 Introduction

Human languages show a remarkable degree of structure and complexity. In the evolution of this complex structure, several different intertwined *pressures* are assumed to have played a role. The first of these pressures concerns the function of language: as language is to communicate, it should allow effective communication between proficient language users (e.g. Smith and Kirby, 2012). This pressure is strongly intertwined with the nature of the proficient user: what features of language allow effective communication depends on the abilities of the user to use the language.

A second pressure on the shape of human language stems from the fact that language must be *learnable*. Unlike animal languages, which are taken to be mostly innate, human languages must be re-acquired by each individual (Pinker and Bloom, 1990; Hurford, 1998). A language can only survive if it can successfully be transmitted to a next generation of learners. In the field of language evolution, this transmission process is referred to as *cultural transmission*, while the process of change that occurs as a consequence is called *cultural evolution*.[1] Like the pressures arising from the function of language, the way that cultural evolution shapes language also depends on the language users: what is learnable depends on the inductive biases of the learner.

Computationally, the emergence of language can be studied through simulation with artificial agents and by investigating the resulting languages for structure, level of compositionality, and morphosyntactic properties (Kirby, 2001; Kirby and Hurford, 2002). Originally based on logic and symbolic representations (Kirby, 2001; Christiansen and Kirby, 2003), with the advent of modern deep learning methods, there has been a renewed interest in simulating the emergence of language through neural network agents (i.a. Lazaridou et al., 2017;

---

[1] The importance of cultural evolution for the emergence of structure is supported by a number of artificial language learning studies (e.g. Saldana et al., 2018) and computational studies using the Iterated Learning paradigm, in which agents learn a language by observing the output produced by another agent from the previous 'generation' (e.g. Kalish et al., 2007; Kirby et al., 2008, 2015).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2993–3004
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

Havrylov and Titov, 2017). Such work typically involves the use of *referential games* (Lewis, 1969), in which two or more agents have to emerge a language to obtain a shared reward.

These studies are motivated by the first pressure: language as a tool for effective communication. However, they fail to consider the second pressure: language must be learnable by new agents. They also fail to study the impact of the learning biases of the artificial agents themselves, which underlies both pressures. In a recent study, Cogswell et al. (2019) proposed a method to include cultural evolution in a language emergence game. Their approach is more naturally aligned with pressures in humans language evolution than single agent referential games (see e.g. Wray and Grace, 2007), but fails to account for the fact that cultural evolution and the learning biases of the artificial agents are two sides of the same coin: what language is learnable depends on the learning biases of the learner.

In this paper, we will therefore integrate the three components described above – communication, cultural evolution and learning biases – and setup a framework in which their interaction can be studied. This framework, which we refer to with the term Language Transmission Simulator, consists of *a referential game*, played by *a changing population of agents* – simulating cultural evolution – which are subject to *architectural evolution* – simulating the learning biases of the learners and allowing them to *co-evolve* with the language.

Our contributions are three-fold fold:

- We introduce the *Language Transmission Simulator*, that allows to model both cultural and architectural evolution in a population of agents;
- We collect a large number of tests from previous work and combine them into an extensive test suits for language emergence games;
- We demonstrate that emerging languages benefit from including cultural transmission *as well as* architectural evolution, but the best results are achieved when languages and agents can co-evolve.

2 Related Work

Much work has been done on the emergence of language in artificial agents and investigating its subsequent structure, compositionality and morphosyntax (Kirby, 2001; Kirby and Hurford, 2002). Originally, such work was based on logic and symbolic representations (Kirby, 2001; Christiansen and Kirby, 2003), but with the advent of modern deep learning (LeCun et al., 2015), there has been a renewed interest in simulating the emergence of language through neural network agents (i.a. Foerster et al., 2016; Kottur et al., 2017; Choi et al., 2018; Lazaridou et al., 2017; Havrylov and Titov, 2017; Mordatch and Abbeel, 2018). In the exploration of language emergence, different training approaches and tasks have been proposed to encourage agents to learn and develop communication. In a typical setup, two players aim to develop a communication protocol in which one agent must communicate information it has access to (typically an image), while the other must guess it out of a line-up (Evtimova et al., 2018; Lazaridou et al., 2017).

Kottur et al. (2017) show that 'natural' language does not arise naturally in these communication games and it has to be incentivised by imposing specific restrictions on games and agents. Havrylov and Titov (2017) first demonstrated that using straight-through estimators were more effective than reinforcement learning in a collaborative task, and that optimizing rewards can lead to structured protocols (i.e. strings of symbols) to be induced from scratch. Mordatch and Abbeel (2018) find that syntactic structure emerges in the stream of symbol uttered by agents, where symbols and syntax can be mapped to specific meanings or instructions. Choi et al. (2018) use qualitative analysis, visualization and a zero-shot test, to show that a language with compositional properties can emerge from environmental pressures.

Chaabouni et al. (2019) find that emerged languages, unlike human languages, do not naturally prefer non-redundant encodings. Chaabouni et al. (2020) further find that while generalization capabilities can be found in the languages, compositionality itself does not arise from simple generalization pressures. (Rodríguez Luna et al., 2020) encourage desirable properties of human languages, such as compositionality, to emerge through well-crafted auxiliary pressures. Finally, Harding Graesser et al. (2019) demonstrate with experiments on populations of agents that language can evolve and simplify through the interactions of different communities.

Cogswell et al. (2019) build upon the emergent language research by introducing cultural transmission as a pressure in referential games. They use a pool of agents with a resetting mechanism and show that this further encourages the emerging language to display compositional properties and structure allowing it to generalize better. Pairing agents with one another in a larger population setting introduces cultural evolution, but it is the pressure introduced by the partial resetting which forces remaining agents to emerge a language that is quickly learnable by a new agent. While Cogswell et al. (2019) is the most related work to ours, an important difference is that they focus on cultural evolution only, without taking into account the learning biases of the agents via modelling architectural evolution.

3 Approach

In this paper, we introduce architectural evolution in language emergence games and study the interaction between cultural and architectural evolution with a range of different metrics. Below, we first give a definition of the referential game we consider (Subsection 3.1). We then briefly explain our Language Transmission Simulator (Section 3.2 and how we model cultural and architectural evolution within it (Section 3.3 and 3.4 respectively).

3.1 Referential games

We study language emergence in a referential game inspired by the signalling games proposed by Lewis (1969). In this game, one agent (the *sender*) observes an image and generates a discrete message. The other agent (the *receiver*) uses the message to select the right image from a set of images containing both the sender image and several distractor images. Since the information shown to the sender agent is crucial to the receivers success, this setup urges the two agents to come up with a communication protocol that conveys the right information.

Formally, our *referential* game is similar to Havrylov and Titov (2017):

1. The meaning space of the game consists of a collection D of K images $\{d_0, d_1, ..., d_K\}$, represented by z-dimensional feature vectors.
2. In each round i of the game, a target item d_i is randomly sampled from D, along with a set C of n distractor items.
3. The sender agent s of the game, parametrised by a neural network, is given item d_i, and generates a discrete message m_i from a vocabulary V. The message is capped to a max message length of L.
4. The receiver agent r, also parametrised by a neural network, receives message m_i and uses it to identify d_i in the union of d_i and C.

We use $z = 512$, and $n = 3$ and train agents with Gumbel-Softmax (Jang et al., 2017a) based on task-success.

3.2 Language Transmission Simulator

In Language Transmission Simulator, depicted in Figure 1, we simulate a population of communicating agents. In every training iteration, two random agents are sampled to play the game. This forces the agents to adopt a simpler language naturally: to succeed they must be able to communicate or understand all opposing agents. In our setup, agents are either sender or receiver, they do not switch roles during their lifetime.

3.3 Cultural evolution in referential games

Following Cogswell et al. (2019), we simulate cultural evolution by periodically replacing agents in the population with newly initialised agents. Cultural evolution is implicitly modelled in this setup, as new agents have to learn to communicate with agents that already master the task. Following Cogswell et al. (2019), we experiment with three different methods to select the agents that are replaced: randomly (no selection pressure), replacing the oldest agents or replacing the agents with the lowest fitness (as defined in Section 3.5). We call these setups `cu-random`, `cu-age` and `cu-best`, respectively.

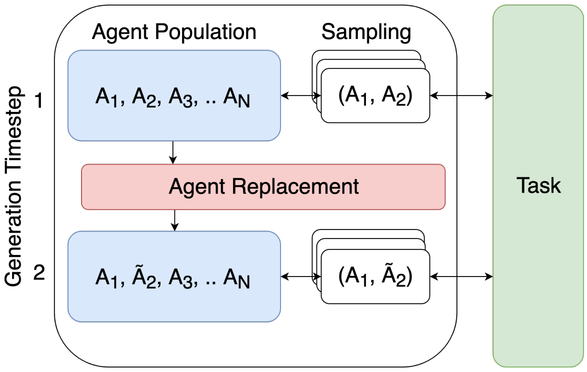

Figure 1: The Language Transmission Simulator: Agent pairs are randomly sampled from each population and trained. After l training steps, a portion α of the population is culled.

3.4 Architectural evolution in referential games

To model architectural evolution, rather than periodically replacing agents with randomly initialised new agents, we instead mutate the most successful agents and replace the worst agents with variations of the best agents, as outlined in Section 3.4.2. Note that cultural evolution is still implicitly modelled in this setup, as new agents still have to learn to communicate with older agents. Therefore, we call this setup with the term `co-evolution`.

3.4.1 Culling

We refer to the selection process and subsequent mutation or re-initialisation step as *culling*. In biology, culling is the process of artificially removing organisms from a group to promote certain characteristics, so, in this case, culling consists of removing a subset of the worst agents and replacing them with variations of the best architecture. The proportion of agents from each population selected to be mutated is determined by the culling rate α, where $\alpha \in [0, 1)$. The culling interval l defines the number of iterations between culling steps. A formalisation of the LTE can be found in appendix A.1.

3.4.2 Mutation Algorithm

Our mutation algorithm is an intentionally simple implementation of a Neural Architectural Search (NAS). NAS focuses on searching the architecture space of networks, unlike many traditional evolutionary techniques which often include parameter weights in their search space. We opted to use the DARTS (Differentiable Architecture Search) RNN search space defined by Liu et al. (2018), which has obtained state-of-the-art performance on benchmark natural language tasks (Li and Talwalkar, 2019).

The DARTS search space includes recurrent cells with up to N nodes, where each node $n_1, n_2, ..., n_N$ can take the output of any preceding nodes including n_0, which represents the cell's input. All potential connections are modulated by an activation function, which can be the identity function, Tanh, Sigmoid or ReLU. Following Liu et al. (2018) and Pham et al. (2018), we enhance each operation with a highway bypass (Zilly et al., 2016) and the average of all intermediate nodes is treated as the cell output.

To sample the initial model, we sample a random cell with a single node ($N = 1$). As this node must necessarily be connected to the input, the only variation stems from the possible activation functions applied to the output of n_1, resulting in four possible starting configurations. We set a node cap of $N = 8$. We mutate cells by randomly sampling an architecture which is one edit step away from the previous architecture. Edit steps are uniformly sampled from i) changing an incoming connection, ii) changing an output operation or iii) adding a new node; the mutation location is uniformly sample from all possible mutations.[2]

3.5 Fitness Criterion

The fitness criterion that we use in both the `cu-best` and `co-evolution` setup is based on task performance. However, rather than considering agents' performance right before the culling step, we consider the age of the youngest agent in the population (defined in terms of number of batches that it was trained) and for every agent compute their performance up until *when they had that age*. For any agent a_j in population $\mathbf{A}$ this is defined as:

$$\text{fitness}(a_j) = \frac{1}{\mathcal{T}_A} \sum_{t=0}^{\mathcal{T}_A} \mathcal{L}(a_j^t) \qquad (1)$$

where $\mathcal{T}_A = \min_{a \in A} \mathcal{T}(a)$ is the age $\mathcal{T}(a)$ of the youngest agent in the population, and $\mathcal{L}(a_j^t)$ is the loss of agent a_j at time step t. This fitness criterion is not biased towards older agents, that have seem already more data and have simply converged more. It is thus not only considering task performance but also the *speed* at which this performance is reached.

4 Experiments

We test the LTE framework on a compositionally defined image dataset, using a range of different selection mechanisms.

4.1 Dataset

In all our experiments, we use a modified version of the Shapes dataset (Andreas et al., 2015), which consists of 30 by 30 pixel images of 2D objects, characterised by shape (circle, square, triangle), colour (red, green, blue), and size (small, big). While every image has a unique symbolic description – consisting of the shape, colour and size of the object and its horizontal and vertical position in a 3x3 grid – one symbolic representation maps to multiple images, that differ in terms of exact pixels and object location. We use 80k, 8k, 40k images for train, validation and test sets, respectively. Some example images are depicted in Figure 2.

---

[2] For a formal description of the mutation process, we refer to Appendix A.2.

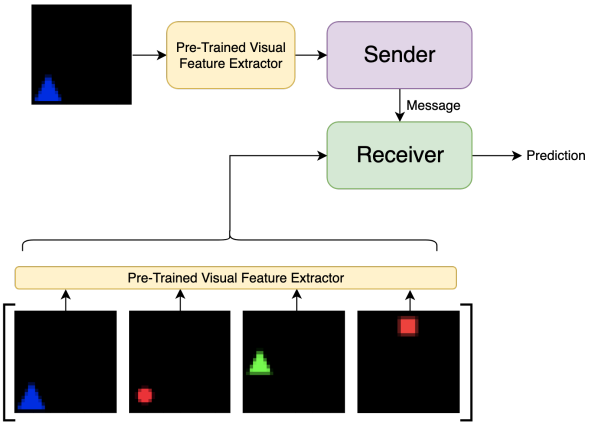

Figure 2: The modified Shapes task consists of showing an image the sender, and then letting the receiver deduce from the sender's message which image out of the target and k distractors is the correct one.

We pre-train a CNN feature extractor for the images in a two-agent setting of the task (see Appendix A.4 for more details).

4.2 Architecture and Training

For our co-evolution experiments, we use the DARTS search space as described above. For all cultural evolution approaches, we use an LSTM (Hochreiter and Schmidhuber, 1997) for both the sender and receiver architecture (see Appendix A.3 for more details). The sender and receiver models have a hidden size of 64 for the recurrent layer and an embedding layer of size 64. Further, we use a vocabulary size V of 4, with an additional bound token serving as the indicator for beginning and end-of-sequence. We limit the maximum length of a sentence L to 5. [3]

We back-propagate gradients through the discrete step outputs (message) of the sender by using the Straight-Through (ST) Gumbel-Softmax Estimator (Jang et al., 2017b). We run all experiments with a fixed temperature $\tau = 1.2$. We use the default Pytorch (Paszke et al., 2017) Adam (Kingma and Ba, 2015) optimiser with a learning rate of 0.001 and a batch-size of 1024. Note that the optimiser is reset for every batch.

For all multi-agent experiments we use a population size of 16 senders and 16 receivers. The culling rate α is set to 0.25 or four agents, and we cull (re-initialise or mutate) every $l = 5k$ iterations. We run the experiments for a total of $I = 500k$ iterations, and evaluate the populations before each culling step.

4.3 Evaluation

We use an range of metrics to evaluate both the population of agents and the emerging languages.

Jaccard Similarity We measure the consistency of the emerged languages throughout the population using *Jaccard Similarity*, which is defined as the ratio between the size of the intersection and the union of two sets. We sample 200 messages per input image for each possible sender-receiver pair and average the Jaccard Similarity of the samples over the population. A high Jaccard Similarity between two messages is an indication that the same tokens are used in both messages.

Proportion of Unique Matches We compute how similar the messages that different agents emit for the same inputs by looking at all possible (sender, message) pairs for one input and assess whether they are the same. This metric is 1 when all agents always emit the same messages for the same inputs.

Number of Unique Messages We compute the average *number of unique messages* generated by each sender in the population. An intuitive reference point for this metric is the number of images with distinct symbolic representations. If agents generate more messages than expected by this reference point, this demonstrates that they use multiple messages for the images that are – from a task perspective – identical.

Topographic Similarity Topographic similarity, used in a similar context by Lazaridou et al. (2018), represents the similarity between the meaning space (defined by the symbolic representations) and the signal space (the messages sent by an agent). It is defined as the correlation between the distances between pairs in meaning space and the distances between the corresponding messages in the signal space. We compute the topographic similarity for an agent by sampling 5,000 pairs of symbolic inputs and corresponding messages and compute the Pearson's ρ correlation between the cosine similarity of the one-hot encoded symbolic input pairs and the cosine similarity of the one-hot encoded message pairs.

---

[3] The values for V and L were picked to provide a strong communication bottleneck to promote the emergence of structured and compressed languages, following the intuitions from Kottur et al. (2017) that natural language patterns do not emerge 'naturally'.

Average Population Convergence To estimate the speed of learning of the agents in the population, estimate the *average population convergence*. For each agent, at each point in time, this is defined as the agents average performance from the time it was born until it had the age of the current youngest agent in the population (analogous to the fitness criterion defined in Section 3.5). To get the average population convergence, we take we average those values for all agents in the population.

Average Agent Entropy We compute the average certainty of sender agents in their generation process by computing and averaging their *entropy* during generation.

5 Results

We now present a detailed comparison of our cultural and co-evolution setups. For each approach, we averaged over four random seeds, the error bars in all plots represent the standard deviation across these four runs. To analyse the evolution of both agents and languages, we consider the development of all previously outlined metrics over time. We then test the best converged languages and architectures in a single sender-receiver setup, to assess the impact of cultural and genetic evolution more independently. In these experiments, we compare also directly to a single sender-receiver baseline, which is impossible for most of the metrics we consider in this paper. Finally, we briefly consider the emerged architectures from a qualitative perspective.

5.1 Task performance

We first confirm that all setups in fact converge to a solution to the task. As can be seen in Figure 3, all populations converge to a (close to perfect) solution to the game. The `cu-age` approach slightly outperforms the other approaches, with a accuracy that surpasses the 95% accuracy mark. Note that, due to the ever changing population, the accuracy at any point in time is an average of both 'children' and 'adults', that communicate with different members of the population.

6 Analysis

In this section we analyse the resulting behaviour and success of agents in Language Transmission Simulator. We first use standard approaches such as average agent entropy and loss (convergence) to measure the success of agents with respect to their language and the task. Secondly, we use other metrics to analyse the emergent language itself in terms of consistency and diversity by using Jaccard Similarity, the proportion of unique matches, the number of unique messages, and the topographic similarity. Thirdly, we perform a qualitative analysis of the architecture that emerge from our Language Transmission Simulator. Finally, we design Frozen Experiments, in which we test the emerged languages and architectures in a 1v1 setting with a fresh agent. This allows us to compare and measure the the improvement gains made by the architecture and those made by the language which emerged. We show through these experiments that the co-evolution setting leads to a language that is both more successful and easier to learn for a given new agent.

Figure 3: Average Population Accuracy of final populations.

6.1 Agent behaviour

To assess the behaviour of the agents over time, we monitor their average message entropy convergence speed. As can be seen in Figure 4, the `co-evolution` setup results in the lowest average entropy scores, the messages that they assign to one particular image will thus have lower variation than in the other setups. Of the cultural evolution setups, the lowest entropy score is achieved in the `cu-best` setup.

Figure 5 shows the average population convergence over time. Also in this case, we observe a clear difference between cultural evolution only and co-evolution, with an immediately much lower convergence time for co-evolution and a slightly downward trending curve.

6.2 Language Analysis

To check the consistencies of languages within a population, we compare the Jaccard Similarity and the Average Proportion of Unique Matches, which we plot in Figure 6. This shows that, compared to cultural evolution only, not only are the messages

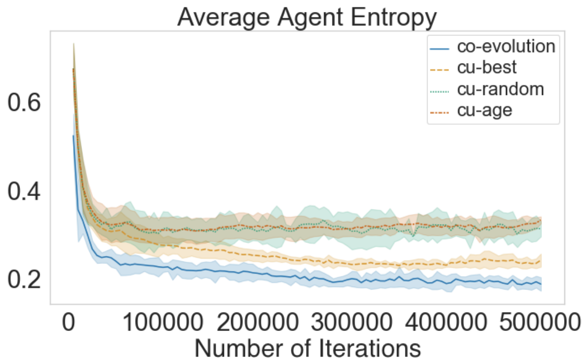

Figure 4: Average agent entropy over time.

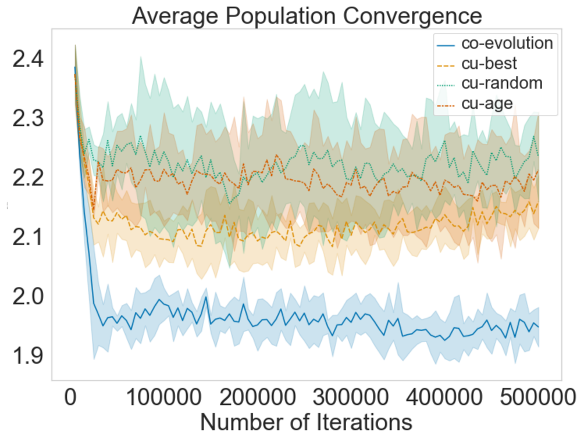

Figure 5: Average convergence for all cultural transmission modes and evolution.

in co-evolution more similar across agents (higher Jaccard Similarity), but also that agents are considerably more aligned with respect to the same inputs (less unique matches).

To assess the level of structure of the emerged languages, we plot the average Topographic Similarity and the Average Number of Unique Messages generated by all senders (Figure 7). The co-evolution condition again outperforms all cultural only conditions, with a simpler language (the number of the unique messages closer to the symbolic reference point) that is structurally more similar to the symbolic representation of the input (higher Topographical Similarity).

6.3 Architecture Analysis

In Figure 8 we show the co-evolution of an agent and a sample of its language during three selected iterations in the co-evolution setup. Strikingly, the best sender architecture does not evolve from its original form, which could point towards the limitations of of our search strategy and space. On

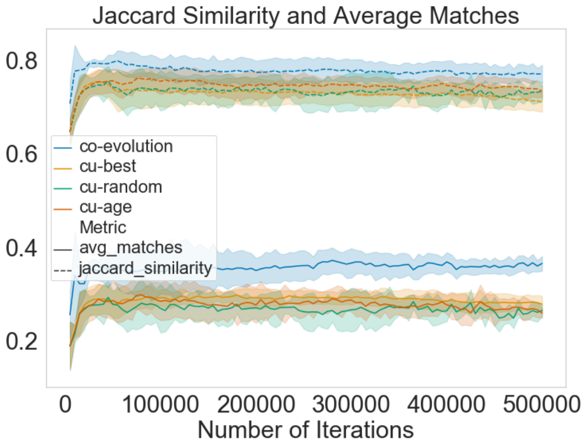

Figure 6: Average Jaccard Similarity and proportion of message matches for all cultural transmission modes and evolution

the contrary, the receiver goes through quite some evolution steps and converges into a significantly more complex architecture than its original form. We observe a unification of language throughout evolution in Figure 8, which is also supported by Figure 7. The population of senders starts out 11 different unique messages and ends with only two to describe the same input image. We will leave more detailed analysis of the evolved architectures for future work.

6.4 Frozen Experiments

With a series of experiments we test the a priori suitability of the evolved languages and agents for the task at hand, by monitoring the accuracy of new agents that are paired with converged agents and train them from scratch.

We focus, in particular, on training receivers with a frozen sender from different setups, which allows us to assess 1) whether cultural evolution made languages evolve to be more easily picked up by new agents 2) whether the genetic evolution made architectures converge more quickly when faced with this task. We compare the accuracy development of:

- An LSTM receiver trained with a frozen sender taken from `cu-best`;
- An evolved receiver trained with a frozen evolved sender.

For both these experiments, we compare with two baselines:

- The performance of a receiver agent trained from scratch along with a receiver agent

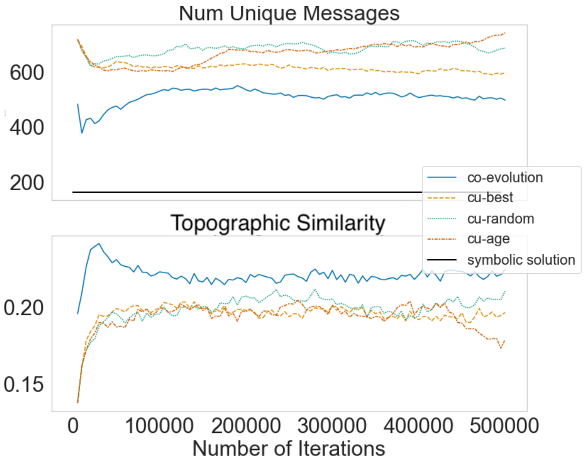

Figure 7: Average Number of Unique Messages and Topographic Similarity for all cultural evolution modes and co-evolution. For comparison, we also plot the number of unique messages for a symbolic solution that fully encodes all relevant features of the image (since we have three possible shapes and colours, two possible sizes, and a 3 × 3 grid of possible positions, this symbolic reference solution has $3 \times 3 \times 2 \times 9 = 162$ distinct messages.

that has either the `cu` architecture or the evolved `co` architecture (`cu-baseline` and `co-baseline`, respectively);

- The performance of an agent trained with an agent that is *pretrained* in the single agent setup, with either the `cu` architecture or an evolved architecture (`cu-baseline-pretrained` and `co-baseline-pretrained`).

Each experiment is run 10 times, keeping the same frozen agent. The results confirm cultural evolution contributes to the learnability and suitability of emerging languages: the `cu-best` accuracy (green line) converges substantially quicker and is substantially higher than the `cu-baseline-pretrained` accuracy (orange line). Selective pressure on the language appears to be important: the resulting languages are only easier to learn in the `cu-best` setup.[4] In addition, they show that the agents benefit also from the genetic evolution: the best accuracies are achieved in the co-evolution setup (red line). The difference between the `cu-baseline` (blue) and the `co-baseline` (brown) further shows that even if the evolved architectures are trained from scratch, they perform much better than a baseline model trained from scratch. The difference between the `co-baseline-pretrained` (only genetic evolution, purple line) and the co-evolution of agents and language line (red line) illustrates that genetic evolution alone is not enough: while a new evolved receiver certainly benefits from learning from a (from scratch) pretrained evolved sender, without the cultural transmission pressure, it's performance is still substantially below a receiver that learns from an evolved sender whose language was evolved as well.

7 Conclusion

In this paper, we introduced a language transmission bottleneck in a referential game, where new agents have to learn the language by playing with more experienced agents. To overcome such bottleneck, we enabled both the cultural evolution of language and the architectural evolution of agents, using a new Language Transmission Simulator. Using a battery of metrics, we monitored their respective impact on communication efficiency, degree of linguistic structure and intra-population language homogeneity. While we could find important differences in between cultural evolution strategies, it is when we included architectural evolution that agents scored best. In a second experiment, we paired new agents with evolved languages and agents and again confirmed that, while cultural evolution makes a language easier to learn, co-evolution leads to the best communication.

In future research, we would like to apply the Language Transmission Simulator on new, more complex tasks and further increase our understanding of the properties of the emerged languages and architectures. Recent research has also found that relaxing the vocabulary size V and sequence length L constraints can lead to greater syntactic structure in emergent languages (van der Wal et al., 2020). We thus hope to investigate further relaxation of hyper-parameters and other neuro-evolution techniques in future work.

Acknowledgments

We would like to thank Angeliki Lazaridou for her helpful discussions and feedback on previous iterations of this work.

---

[4] `cu-age` and `cu-random` are ommitted from the plot for clarity reasons.

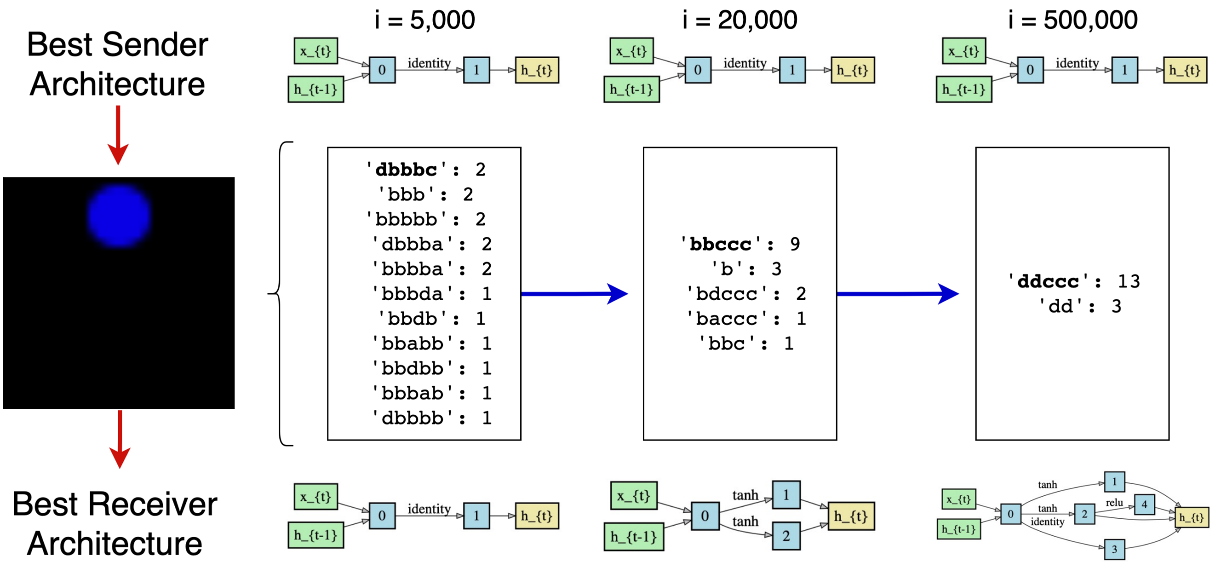

Figure 8: Evolution of the best sender and receiver architecture according to convergence, and the evolution of the population's message description of the same input through iterations. The bold messages represent the message outputted by the best sender whose architecture is pictured above. The count of each message represents the number of agents in the population which uttered this exact sequence.

A Appendix

A.1 Language Transmission Engine

We formalise our Language Transmission process in the pseudo code shown in Algorithm 1. We select hyper-parameters l as the number of iterations or batches shown between culling steps, and I as the total number of iterations.

Algorithm 1 Language Transmission Engine

```
$S \leftarrow \{s_0, s_1 ..., s_N\}$
$R \leftarrow \{r_0, r_1 ..., r_N\}$
$i \leftarrow 1$
while $i \leq I$ do
    for batch $b$ in $D$ do
        Sample $\hat{s}$ from $S$
        Sample $\hat{r}$ from $R$
        $\mathbf{train}(\hat{s}, \hat{r}, b)$
        if $i \bmod l = 0$ then
            $\mathbf{cull}(S, R)$
        end if
        $i \leftarrow i + 1$
    end for
end while
```

A.2 Mutation Algorithms Pseudo-code

The genotype mutation is described in pseudo-code by algorithm 2, and takes as input a genotype containing nodes describing the cell. The genotype is mutated by either changing the input connection or primitive (output activation function) for a randomly sampled node n, or adding a new node altogether. See section 3.4.2 for explanations on the workings of the DARTS cell structure.

Algorithm 2 Genotype-level Mutation

```
procedure $\mathbf{mg}(genotype)$
    $g \leftarrow copy(genotype)$
    $a \leftarrow \mathcal{U}(1, 3)$
    $n \leftarrow \mathcal{U}(1, len(g))$
    if $a = 1$ then
        $p \leftarrow \mathcal{U}[ReLU, I, \tanh, \sigma]$
        $n.activation \leftarrow p$
    end if
    if $a = 2$ then
        $r \leftarrow \mathcal{U}(1, n)$
        $n.connection \leftarrow r$
    end if
    if $a = 3$ then
        $n' \leftarrow new\_node()$
        $p \leftarrow \mathcal{U}[ReLU, I, \tanh, \sigma]$
        $r \leftarrow \mathcal{U}(1, len(g))$
        $n'.activation \leftarrow p$
        $n'.connection \leftarrow r$
        $g.append(n')$
    end if
    return $g$
end procedure
```

Algorithm 3 Population-level Mutation

```
procedure $\mathbf{mutate}(\mathbf{P})$
    $p' \leftarrow \arg\min_{convergence}(P)$
    $\mathbf{p} \leftarrow \pi(P)$
    for $p_i$ in $\mathbf{p}$ do
        $p_i.genotype \leftarrow \mathbf{mg}(p'.genotype)$
    end for
end procedure
```

In order to mutate a population $\mathbf{P}$ using π as a replacement policy, we use the process outlined in algorithm 3.

A.3 Agent Architecture

A.3.1 Sender Architecture

The sender architecture comprises of a linear layer input mapping the input feature size (512) to the hidden size. The image feature vector is therefore mapped to the same dimension as the RNN layer, where it is used as the initial hidden state. When training, for each step of the sender RNN we apply the cell and use the straight-through Gumbel-

Softmax trick to be able back-propagate gradients through the discrete message output. During evaluation however, we sample the categorical distribution at each step to produce each token in the sentence.

A.3.2 Receiver Architecture

The receiver architecture is simpler and takes as an input the message outputted by the sender and outputs a vector of input feature size (512). A single embedding matrix is used to encode the sender's message. During training the message is linearly transformed using the embedding matrix, while during the evaluation pass the discrete message outputs of the sender are used to map to the specific embedding dimensions. The embedded message is then passed to the RNN layer, and the final state of the RNN is linearly mapped back to the feature size. Doing so allows us to obtain a prediction for each image feature (distractors and true image), by comparing the alignment between the receiver output and the respective feature vectors.

A.4 Feature Extraction

In order to obtain image features, we pre-trained a convolutional model on the task using the raw image as input. Due to the input size requirements of the convolutional model, we resize the images linearly to be 128 by 128 (height, width) by 3 (RGB channels). We used early stopping conditions on the validation accuracy, an embedding size of 256, and hidden size of 512. The two agents are otherwise trained with the same parameters as other experiments: vocab size and max sentence length of 5, Adam optimizer with learning rate of 0.001.

For the visual module itself, we used a similar architecture to that in Choi et al. (2018) albeit smaller. We used a five-layer convolution network with 20 filters, and a kernel size and stride of 3 for all layers. For every convolutional layer, ReLU activation was applied on the output, after a Batch normalization step with no bias parameter. The linear layer which followed the convolutional layers had output dimensions of 512 and a ReLU activation function. This allows us to obtain image features of size 512, which we then used for all experiments.

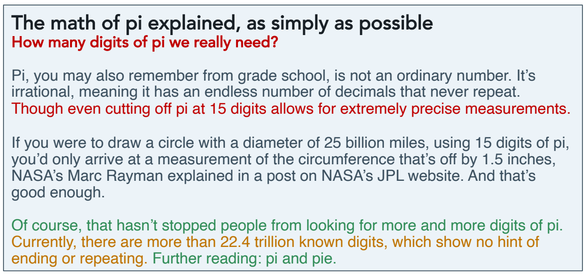
Abstract

Answer Sentence Selection (AS2) is an efficient approach for the design of open-domain Question Answering (QA) systems. In order to achieve low latency, traditional AS2 models score question-answer pairs individually, ignoring any information from the document each potential answer was extracted from. In contrast, more computationally expensive models designed for machine reading comprehension tasks typically receive one or more passages as input, which often results in better accuracy. In this work, we present an approach to efficiently incorporate contextual information in AS2 models. For each answer candidate, we first use unsupervised similarity techniques to extract relevant sentences from its source document, which we then feed into an efficient transformer architecture fine-tuned for AS2. Our best approach, which leverages a multi-way attention architecture to efficiently encode context, improves 6% to 11% over non-contextual state of the art in AS2 with minimal impact on system latency. All experiments in this work were conducted in English.

1 Introduction

AS2 models for open-domain QA typically consider sentences from webpages as independent candidate answers for a given question. For any webpage containing potential answer candidates for a question, AS2 models first extract individual sentences, then independently estimate their likelihood of being correct answers; this approach enable highly efficient processing of entire documents. However, under this framework, context information from the entire webpage (global context), which could be crucial for selecting correct answers, is ignored. Conversely, current systems in Machine Reading (MR) (Huang et al., 2019; Kwiatkowski et al., 2019a; Lee et al., 2019; Joshi et al., 2020a) uses a much larger context from the retrieved documents. MR models receive a question and one or more passages retrieved through a search engine as input; they then select one or more spans from the input passages to return as answer.



The math of pi explained, as simply as possible
How many digits of pi we really need?

Pi, you may also remember from grade school, is not an ordinary number. It's irrational, meaning it has an endless number of decimals that never repeat. Though even cutting off pi at 15 digits allows for extremely precise measurements.

If you were to draw a circle with a diameter of 25 billion miles, using 15 digits of pi, you'd only arrive at a measurement of the circumference that's off by 1.5 inches, NASA's Marc Rayman explained in a post on NASA's JPL website. And that's good enough.

Of course, that hasn't stopped people from looking for more and more digits of pi. Currently, there are more than 22.4 trillion known digits, which show no hint of ending or repeating. Further reading: pi and pie.

Figure 1: Candidate sentence (in orange) for question "*how many digits are in pi?*". Local context is shown in green, while global context is shown in red.

While being potentially more accurate, MR models typically have higher computational requirements (and thus higher latency) than AS2 models. That is because MR models need to process passages in their entirety before an answer can be extracted; conversely, AS2 systems break down paragraphs in candidate sentences, and evaluate them all at once in parallel. Therefore, in many practical applications, MR models are only used to examine 10 to 50 candidate passages; in contrast, AS2 approaches can potentially process hundreds of documents, e.g., (Matsubara et al., 2020; Soldaini and Moschitti, 2020).

In this work, we study techniques that can combine the efficacy of MR models with the efficiency of AS2 approaches, while keeping a single sentence as target answer, as in related AS2 works[1]. In particular, we focus our efforts on improving accuracy of AS2 systems without affecting their latency.

Early neural models for retrieval-based QA focused on incorporated neighboring sentences (local context) to improve performance. For example, Tan et al. (2017) proposed a neural architecture based on gated recurrent units to encode question, answer, and local context; their approach, while effective at the time, shows a significant gap to the current state-of-the-art models (Garg et al., 2020). Min et al. (2018) studied neural efficient models for MR by optimizing answer candidate extraction. More recently, researchers have focused in including source document information in transformer models. For example, Joshi et al. (2020b) proposed a contextualized model for MR that augments named entities in candidate passages with snippets extracted from Wikipedia pages. Their approach, while interesting, is limited to entities-based context, and specific to Wikipedia and MR domain. For AS2, Lauriola and Moschitti (2021) proposed a model that uses local context as defined by the preceding and following sentences of the target answer. They also introduced a simple bag-of-words representation of documents as global context, which did not show significant improvement over non-contextual AS2 models.

Unlike previous efforts, our approaches consider both *local context* (that is, the sentences immediately preceding or succeeding a candidate answer), as well as *global context* (phrases in documents that represent the overall topics of a page), as they can both uniquely contribute to the process of selecting the right answer. As shown in the example in Figure 1, local context can help disambiguate cases where crucial entities are not present in the candidate answer (there's no mention of *"pi"* in *"[c]urrently, there are more than 22.4 trillion known digits"*); conversely, global context can help reaffirm the relevance of a candidate answer in cases where noisy information is extracted as local context (in the example, *"[f]urther reading: pi and pie"* does not contain any relevant information).

The contributions of this work are: (**i**) first, we introduce two effective techniques to extract relevant local and global contexts for a given question and candidate answer; (**ii**) then, we propose three different methods for combining contextual information for AS2 tasks; (**iii**) finally, we evaluate our approaches on two AS2 datasets: ASNQ (Garg et al., 2020) and a benchmark dataset we built to evaluate real-world QA systems. Results show that our most efficient system, which leverages a multi-way attention architecture, can improve over the previous non-contextual state of the art model for AS2 by up to 11%; furthermore, these results are achieved while maintaining similar efficiency to the best-performing, non-contextual AS2 systems, making our approach a viable strategy for latency-sensitive applications. Code and models are made available at `https://github.com/alexa/wqa-contextual-qa`.

Question: "where did the potter's wheel first develop"
Corrent Answer: "Tournettes, in use around 4500 BC in the Near East, were turned slowly by hand or by foot while coiling a pot"
Sentence selected by N-grams: "In the Iron Age, the potter 's wheel in common use had a turning platform about one metre (3 feet) above the floor, connected by a long axle to a heavy flywheel at ground level. Use of the potter's wheel became widespread throughout the Old World but was unknown in the Pre-Columbian New World, where pottery was handmade by methods that included coiling and beating."

Question: "where do pineapples come from in the world"
Correct answer: "In 2016, Costa Rica, Brazil, and the Philippines accounted for nearly one-third of the world's production of pineapple."
Sentence selected by Cosine Similarity: "The plant is indigenous to South America and is said to originate from the area between southern Brazil and Paraguay"

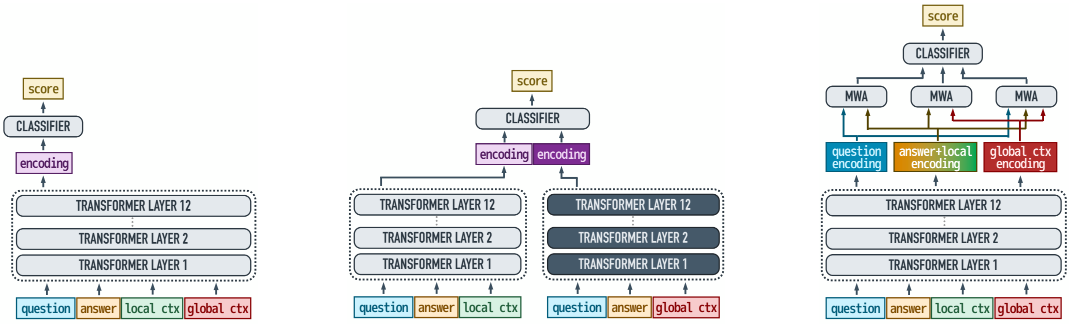
Table 1: Examples of **global context** selected via N-gram similarity (top) and cosine similarity (bottom). Overall, the N-gram approach tends to select longer context sentences than Cosine's, which in turn leads to fewer context sentences being included in the global context (as we limit it to 128 tokens). Empirically, we also noticed that N-gram selected context sentences also contain more noise.

2 Methodology

Our approach to ranking candidate answer consists of two components: the first (Section 2.1) is responsible for extracting context for each candidate answer, while the second (Section 2.2) encodes information from local and global contexts to score each question / candidate answer pair.

2.1 Context Construction

As previously mentioned, our proposed method for contextualizing answers relies on enriching them with information encoded in sentences adjacent to them, as well as from sentences throughout the document each potential answer comes from; we will define these extraction processes in this section.



(a) (b) (c)

Figure 2: From left to right, the three approaches we evaluated in this work: context concatenation (Figure 2a), context ensemble (Figure 2b), and multi-way attention (Figure 2c).

In the rest of this work, we will use Q to refer to a question and $\mathcal{D} = \{D_1, \dots, D_i, \dots, D_N\}$ to indicate a collection of documents containing potential answers for Q. Each document D_i is comprised of an ordered sequence of sentences $D_i = \langle C_{i,1}, \dots, C_{i,j}, \dots, C_{i,M} \rangle$; each sentence $C_{i,j}$ could be used either as candidate answer, or as context for another candidate.

2.1.1 Local Context

Similarly to previous work (Tan et al., 2017; Lauriola and Moschitti, 2021), we define local context $\text{Loc}_k(C_{i,j})$ for candidate $C_{i,j}$ as the sentences immediately preceding and succeeding each answer candidate within a window of $2k+1$ sentences, i.e., $\text{Loc}_k(C_{i,j}) = \langle C_{i,j-k}, \dots C_{i,j-1}, C_{i,j+1} \dots C_{i,j+k} \rangle$. In our experiments, we tried constructing a local context of up to six sentences; however, we observed diminishing return when using more than the previous and next sentences (i.e., $k = 1$) at the expense of more computational complexity. Therefore, the results presented in this work use two adjacent sentences as local context.

2.1.2 Global Context

Unlike local context, there are many potential approaches to extracting information that can be used to understand relevancy of a candidate answer to a question. We proposed and evaluated two different techniques for extracting global context $\text{Glo}_h(C_{i,j})$ (examples for both are shown in Table 1).

N-gram Overlap Similarly, to Joshi et al. (2020b), we experimented with selecting sentences as global context based on their n-gram overlap with question and candidates.

In detail, we first extract the set of all unigrams, bigrams, and trigrams from question Q and candidate $C_{i,j}$, which we denote as $\text{Ng}_{1,2,3}(Q, C_{i,j})$; then, we repeat the same procedure for all $\{C_{i,p} \subset \mathcal{D} \text{ where } p \neq j\}$ to obtain $\text{Ng}_{1,2,3}(C_{i,p})$. Finally, we score each sentence as follows:

$$\text{Score}_{ngrams}(C_{i,p}|Q, C_{i,j}) = \frac{|\text{Ng}_{1,2,3}(C_{i,p}) \cap \text{Ng}_{1,2,3}(Q, C_{i,j})|}{|\text{Ng}_{1,2,3}(Q, C_{i,j})|} \quad (1)$$

and pick the top h sentences as global context.

Semantic Similarity N-grams overlap can only extract spans of text that are lexically similar to either the query or candidate. To better capture context that is topically relevant to an answer, we also propose to use cosine distance between sentence embeddings to approximate semantic similarity.

Given a sentence encoder model[2] $\mathcal{M}$, we first obtain a representations for the question-answer pair $\mathcal{M}(Q \oplus C_{i,j})$ and context sentences $\{\mathcal{M}(C_{i,p})$ for all $p = \{1, \dots, M\}, p \neq j$; then we pick the top h sentences maximizing the following cosine similarity score as global context:

$$\text{Score}_{sim}(C_{i,p}|Q, C_{i,j}) = \frac{\mathcal{M}(Q \oplus C_{i,j}) \cdot \mathcal{M}(C_{i,p})}{||\mathcal{M}(Q \oplus C_{i,j})|| \; ||\mathcal{M}(C_{i,p})||}, \quad (2)$$

where $\oplus$ indicates string concatenation.

2.2 Contextual AS2 Models

Once local context $\text{Loc}_k(C_{i,j})$ and global context $\text{Glo}_h(C_{i,j})$ are extracted for candidate $C_{i,j}$, we encode them in conjunction with candidate answer and question to estimate the likelihood of $C_{i,j}$ being a correct answer for Q. Our approaches (summarized in Figure 2) consume up to $h = 5$ sen-

[2] In our experiments, we use non-finetuned RoBERTa$_{\text{BASE}}$ model (Liu et al., 2019).

Model	**P@1**	**MAP**	**MRR**	**Latency**
No Context (Garg et al., 2020)	0.596	0.685	0.706	**5.49**
Local Context (Lauriola and Moschitti, 2021)	0.653	0.732	0.752	5.62
Global Context	0.622	0.698	0.722	5.67
Context Concat	0.631	0.726	0.743	5.76
Context Ensemble	**0.668**	**0.743**	**0.765**	7.41
MWA	0.661	0.742	0.758	5.82

Table 2: Results on the ASNQ Test Set. The latency is reported in micro-seconds (μs) per sample (± 0.1 μs with 95% CI).

tences as global context so not to exceed 128 tokens. [3] Similarly, to other efforts in this area (e.g., (Garg et al., 2020)), we leverage state-of-the-art transformer models to estimate said probability. Specifically, we studied three approaches to encode question and answer context. Although the methods we proposed can be easily combined with any transformer architecture, all models described here are initialized from a RoBERTa$_{\text{BASE}}$ checkpoint.

Context Concatenation A simple baseline (van Aken et al., 2019; Joshi et al., 2020b) for encoding multiple contexts is to concatenate each question, candidate answer, and local/global context text and feed them through transformer model (Fig. 2a); the resulting encoding is then projected to a probability distribution using a dense feed-forward layer. This baseline relies on the transformer self-attention mechanism to implicitly model relations between local and global context.

Context Ensemble As mentioned in Section 1, local and global contexts might capture different aspects of the source document of a candidate answer. To empirically verify this hypothesis, we evaluated an ensemble model that encodes local and global contexts separately using two independent transformer models (Figure 2b). The two models are independently trained for AS2; then, their encodings are concatenated and passed to a feed-forward layer to estimate relevance of candidate $C_{i,j}$ for question Q. The top 3 layers[4] model is once again fine tuned on the training set.

Model	**P@1**	**MAP**	**MRR**
No Context		*baseline*	
Global Context	+3.95%	+2.52%	+2.29%
Local Context	+3.59%	+2.89%	+2.21%
Context Concat	+1.52%	+2.33%	+1.34%
Context Ensemble	**+5.92%**	**+4.10%**	**+3.39%**
MWA	+5.56%	+3.92%	+3.08%

Table 3: Results on the WQA Test Set.

Multi-way Attention (MWA) While leveraging independent encoders for local and global contexts can lead to an improvement in performance compared to using a single encoder, it also doubles computational requirements. Therefore, we also explored techniques that incorporate inductive biases into transformer models and achieve efficiency comparable to the context concatenation approach. One such approach is, as shown in Figure 2c, to combine a transformer model with a multi-way attention mechanism (Tan et al., 2018), which has been shown to be effective for commonsense reasoning tasks (Huang et al., 2019). This approach still uses a single transformer model to produce an encoding for a sequence of question, candidate answer, local context, and global context; however, similarly to the ensemble model, the additional attention mechanism forces the encoder to selectively look at local and global contexts separately.

3 Experiments

3.1 Setup

In order to validate the effectiveness of the proposed context modeling techniques, we evaluated our results on two datasets: ASNQ and WQA.

ASNQ The Answer Sentence Natural Questions dataset (Garg et al., 2020) is a large collection of 59,914 questions and 24,732,396 candidate answers. It was obtained by extracting sentence candidates from the Google Natural Question (NQ) benchmark (Kwiatkowski et al., 2019b). We use the train, development, and test splits proposed by Soldaini and Moschitti (2020).

WQA The Web-based Question Answering is an in-house dataset built by Alexa AI as part of the effort of understanding and benchmarking QA systems. The creation process includes the following steps: (i) Given a set of questions, a search engine is used to retrieve up to 100 web pages from an index containing hundreds of million pages. (ii) From the set of retrieved documents, all candidate

---

[3] Using up 5 sentences resulted in 3.02 (n-gram context) and 2.85 (cosine context) sentences being selected on average for the ASNQ dataset.

[4] We tested with approaches for gradual unfreezing of the top k layers; $k = 3$ yielded the best validation scores.

Technique	P@1	MAP	MRR
N-gram Overlap	0.638	0.725	0.746
Cosine Similarity	0.661	0.742	0.758

Table 4: Comparison of global context extraction techniques on the ASNQ test set when used with MWA.

sentences are extracted and ranked using AS2 models from Garg et al. (2020); and (iii) at least 25 candidates for each question are annotated by humans. Overall, the version of WQA we used contains 6,962 questions and 283,855 candidate answers. We reserved 3,000 questions for evaluation, 808 for development, and used the rest for training [5].

Models were trained on a single machine with 8 NVIDIA Tesla V100 GPUs with 32 GB of memory each. We used model implementations from the Transformers library when available (Wolf et al., 2020). All our experiments were computed using mixed precision through NVIDIA apex[6]. Latency was measured on single GPU with a fixed batch size of 128. Tokenization and time to transfer tensors to the GPU was not included in the latency values.

3.2 Results and Discussion

Results on the ASNQ and WQA are summarized in tables 2 and 3, respectively. Overall, we observe that the context ensemble model achieves the best performance; however, as observed in Section 2.2, this model is twice as large as a RoBERTa$_{\text{BASE}}$ model, thus it is a rather expensive solution.

Among our baselines, we note that local context outperforms the model leveraging the global context. This observation suggests that local information carries more importance in understanding the semantic relationship between question and candidate answers. Surprisingly, we observe that simply concatenating local and global contexts achieves worse performance of local context alone, and it even underperforms the global context method on WQA. This suggests that, without any additional structure, the self-attention mechanism of the transformer cannot effectively distinguish and leverage information from the local and global contexts.

We note that MWA achieves near identical performance to the ensemble model on both datasets, suggesting that a controlled attention mechanism can overcome limitations in the representation for vanilla transformers, while reducing latency by 21.5% and memory usage by 89%. MWA also matches the latency of the context concatenation model, while improving it by 4.8% and 3.9% in P@1 on ASNQ and WQA, respectively.

Finally, we study the effect of our proposed global extraction techniques in Table 4. We observe that, among the two proposed algorithms, the cosine similarity approach significantly outperforms the N-gram based method. This confirms that pre-trained language models can better select context semantically related to question and candidates.

We note n-gram overlap is less computationally taxing, as it can be efficiently implemented as a set of sparse operations over bag of word representations of the question and answer candidates. On the other hand, for cosine similarity, it is necessary to compute Score$_{sim}(C_{i,p}|Q, C_{i,j})$ for all context sentences using a transformer model. Recently introduced transformer architecture variants could be used to either speed up this similarity computation (Cao et al., 2020), or compute query and text representation independently (Khattab and Zaharia, 2020). We leave the evaluation of these techniques to future work.

4 Conclusions

For efficiency reasons, traditional AS2 models are designed to estimate answer relevancy by only comparing question and candidates. In this work, we described and evaluate several techniques to incorporate local and global contexts in the answer selection process. The results of our experiments show that our proposed methods significantly outperform non-contextual approaches; further, we empirically demonstrate that local and global contexts can be effectively combined to further improve ranking performance.

Abstract

Pre-trained language models like BERT achieve superior performances in various NLP tasks without explicit consideration of syntactic information. Meanwhile, syntactic information has been proved to be crucial for the success of NLP applications. However, how to incorporate the syntax trees effectively and efficiently into pre-trained Transformers is still unsettled. In this paper, we address this problem by proposing a novel framework named Syntax-BERT. This framework works in a plug-and-play mode and is applicable to an arbitrary pre-trained checkpoint based on Transformer architecture. Experiments on various datasets of natural language understanding verify the effectiveness of syntax trees and achieve consistent improvement over multiple pre-trained models, including BERT, RoBERTa, and T5.

1 Introduction

Pre-trained language models like BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2020) and T5 (Raffel et al., 2019) become popular in recent years and achieve outstanding performances in various NLP benchmarks. These models often choose a Transformer architecture largely owing to its attractive scalability. Studies (Hewitt and Manning, 2019; Jawahar et al., 2019) have shown that a pre-trained transformer is able to capture certain syntactic information implicitly by learning from sufficient examples. However, there is still a big gap between the syntactic structures implicitly learned and the golden syntax trees created by human experts.

On the other hand, syntax tree is a useful prior for NLP-oriented neural networks (Kiperwasser and Ballesteros, 2018). For example, Tree-LSTM (Tai et al., 2015) extends the sequential architecture of LSTM to a tree-structured network. Linguistically-informed self-attention (LISA) (Strubell et al., 2018) proposes a multi-task learning framework for semantic role labeling, which incorporates syntactic knowledge into Transformer by training one attention head to be attended to its parent in a syntax tree. In addition, Nguyen et al. (2020) integrate tree-structured attention in Transformer with hierarchical accumulation guided by the syntax tree.

Although there are numerous works on syntax-enhanced LSTM and Transformer models, none of the previous works have addressed the usefulness of syntax-trees in the pre-training context. It is straight-forward to ask: *it is still helpful to leverage syntax trees explicitly in the pre-training context?* If the answer is yes, *can we ingest syntax trees into a pre-trained checkpoint efficiently without training from scratch for a specific downstream application?* This is an appealing feature in practice because pre-training from scratch is a huge waste of energy and time.

In this paper, we propose Syntax-BERT to tackle the raised questions. Unlike a standard BERT, which has a complete self-attention typology, we decompose the self-attention network into multiple sub-networks according to the tree structure. Each sub-network encapsulates one relationship from the syntax trees, including ancestor, offspring, and sibling relationships with different hops. All sub-networks share the same parameters with the pre-trained network, so they can be learned collaboratively and inherited directly from an existing checkpoint. To select the task-oriented relationships automatically, we further adopt a topical attention layer to calculate the relative importance of syntactic representations generated by different sub-networks. Finally, the customized representation is calculated by weighted summation of all

sub-networks.

We conduct extensive experiments to verify the effectiveness of Syntax-BERT framework on various NLP tasks, including sentiment classification, natural language inference, and other tasks in the GLUE benchmark. Experimental results show that Syntax-BERT outperforms vanilla BERT models and LISA-enhanced models consistently with multiple model backbones, including BERT, RoBERTa, and T5. Specifically, it boosts the overall score of GLUE benchmark from 86.3 to 86.8 for T5-Large (Raffel et al., 2019) checkpoint, which is already trained on a huge amount of data. This improvement is convincing since only a few extra parameters are introduced to the model.

Our **major contributions** are as follows:

- To the best of our knowledge, Syntax-BERT is one of the first attempts to demonstrate the usefulness of syntax trees in pre-trained language models. It works efficiently in a plug-and-play fashion for an existing checkpoint without the need for pre-training from scratch.
- To integrate syntax trees into pre-trained Transformers, we propose a novel method that decomposes self-attention networks into different aspects and adopts topical attention for customized aggregation. As shown in the ablation study, this design benefits from syntactic structures effectively while retaining pre-trained knowledge to the largest extent.
- Syntax-BERT shows consistent improvement over multiple pre-trained backbone models with comparable model capacities. It can be combined with LISA to achieve further enhancement, indicating that these two algorithms are complementary to each other.

2 Related Work

2.1 Pre-trained language models

Recently, pre-trained language models have received significant attention from the natural language processing community. Many excellent pre-trained language models are proposed, such as BERT, RoBERTa and T5. Transformer (Vaswani et al., 2017) is a typical architecture for pre-training language models, which is based on the self-attention mechanism and is much more efficient than RNNs. BERT (Devlin et al., 2019) is a representative work that trains a large language model on the free text and then fine-tunes it on specific downstream tasks separately. BERT is pre-trained on two auxiliary pre-training tasks, Masked Language Model (MLM) and Next Sentence Prediction (NSP). RoBERTa (Liu et al., 2020) is an improved variant of BERT which utilizes dynamic masks. In RoBERTa, the NSP task is cancelled, but the full-sentence mechanism is considered. At the same time, the size of RoBERTa's training data ($\sim$160GB) is ten times the size of BERT's training data. Moreover, Raffel et al. (2019) explore the effectiveness of multiple transfer learning techniques and apply these insights at scale to create a new model T5 (Text to Text Transfer Transformer). With T5, they reform all NLP tasks into a unified text-to-text format where the input and output are always text strings. This is in contrast to BERT-style models that only output either a class label or an input span.

2.2 Syntax-aware models

Syntax is a crucial prior for NLP-oriented neural network models. Along this direction, a range of interesting approaches have been proposed, like Tree-LSTM (Tai et al., 2015), PECNN (Yang et al., 2016), SDP-LSTM (Xu et al., 2015), Supervised Treebank Conversion (Jiang et al., 2018), PRPN (Shen et al., 2018), and ON-LSTM (Shen et al., 2019).

Recent works also investigate syntactic knowledge in the context of Transformer, which are more related to this paper. For instance, Syntax-Infused Transformer (Sundararaman et al., 2019) feeds the extra syntactic features into the Transformer models explicitly, but it only considers simple syntactic features and does not provide a generic solution to incorporate tree-structured knowledge. Strubell et al. (2018) present a neural network model named LISA (Linguistically-Informed Self-Attention) that learns multi-head self-attention in a multi-task learning framework consisting of dependency parsing, part-of-speech tagging, predicate detection, and semantic role labeling. They also show that golden syntax trees can dramatically improve the performance of semantic role labeling. Moreover, Nguyen et al. (2020) propose a hierarchical accumulation approach to encode parse tree structures into self-attention mechanism. However, these approaches are designed for training a Transformer from scratch without benefiting from pre-trained checkpoints. Instead, our frame-

work works in a plug-and-play mode and retains the pre-trained knowledge as much as possible for downstream applications. Concurrent to our work, Sachan et al. (2020) investigate popular strategies for incorporating dependency structures into pre-trained language models, revealing essential design decisions are necessary for strong performances. In addition, Hewitt and Manning (2019) design two sets of probes to determine whether the embedded space can be converted into syntactic information space through a linear transformation. It gives the evaluation metrics to examine how much syntactic information is included in a model.

3 Syntax-BERT

Syntax-BERT is a variant of pre-trained Transformer models, which changes the flow of information in a standard BERT network via a syntax-aware self-attention mechanism. First, the overall architecture of Syntax-BERT is presented in Section 3.1. Then, we introduce the construction of syntax trees and corresponding masks in Section 3.2. The details of syntactic attention layers will be described in Section 3.3.

3.1 Architecture

As mentioned earlier, one limitation of vanilla Transformer is that it simply uses a fully-connected topology of tokens in the pre-trained self-attention layer. Although the self-attention mechanism automatically calculates a relevance score for each token pair, it still suffers from optimization and over-fitting problems, especially when the training data is limited. Some previous works have tried to induce syntactic structure explicitly into self-attention. For instance, in Linguistically-Informed Self-Attention (LISA) (Strubell et al., 2018), syntax tree is incorporated by training one attention head to be attended to the parent of each token. However, other structural features such as siblings and children are discarded in the model. Moreover, it can not distinguish the usefulness of multiple syntactic features while largely retain the knowledge from a pre-trained checkpoint.

Syntax-BERT is designed to incorporate grammatical and syntactic knowledge as prior in the self-attention layer and support fine-grained adaptation for different downstream tasks. Specifically, it generates a bunch of sub-networks based on sparse masks reflecting different relationships and distances of tokens in a syntax tree. Intuitively, the tokens inside a sub-network often semantically related to each other, resulting in a topical representation. Therefore, we can adopt a topical attention layer to aggregate task-oriented representations from different sub-networks.

The overall architecture of Syntax-BERT is illustrated in Figure 1. As shown in the left part of this figure, we generate syntax masks for the input sentence in two steps. First, the input sentence is converted into the corresponding tree structure by a syntax parser. Second, we extract a bunch of syntax-related masks according to different features incorporated in the syntax tree. Next, the sentence is embedded similar to a standard BERT (token + positional + field embedding) and served as input to the self-attention layer. Each self-attention layer in the Syntax-BERT is composed of two kinds of attention modules, namely *masked self-attention* and *topical attention*. In a *masked* *self-attention* module, we apply syntactic masks to the fully-connected topology, generating topical sub-networks that share parameters with each other. Furthermore, the representations from different sub-networks are aggregated through a *topical attention* module so that the task-related knowledge can be distilled to the final representation vector.

3.2 Masks induced by syntax tree

Generically, a syntax tree is an ordered, rooted tree that represents the syntactic structure of a sentence according to some context-free grammar. It can be defined abstractly as $T = \{R, \mathcal{N}, \mathcal{E}\}$, where R is the root of syntax tree, $\mathcal{N}$ and $\mathcal{E}$ stands for node set and edge set respectively. The most commonly-used syntax trees are constituency trees (Chen and Manning, 2014) and dependency trees (Zhu et al., 2013), and we use both of them in our experiments unless notified.

To utilize the knowledge in a syntax tree effectively, we introduce syntax-based sub-network typologies in the self-attention layer to guide the model. Each sub-network shares the same model parameters with the global pre-trained self-attention layer, while each sub-network reflects a specific aspect of the syntax tree. This procedure can be easily implemented by multiple masks applied to the complete graph topology.

Without loss of generality, we design three categories of masks reflecting different aspects of a tree structure, namely *parent mask*, *child mask*, and *sibling mask*. For a pairwise inference task that contains a pair of sentences as input, we also apply another mask, i.e., *pairwise mask*, to capture the inter-sentence attention. Moreover, the distances between nodes (tokens) in a tree incorporate semantic relatedness. Starting from a node A, along the edges of a syntax tree, the minimum number of edges required to reach another node B can be regarded as the distance between A and B, written as $dist(A, B)$. We create fine-grained masks according to the distance between two nodes to enable customized aggregation of task-oriented knowledge.

Mathematically, a mask can be denoted by $M \in \{0,1\}^{n\times n}$, where $M_{i,j} \in \{0,1\}$ denotes if there is a connection from token i to token j, and n is the number of tokens in the current sentence.

In the **parent mask** with certain distance d, we have $M^p_{i,j,d} = 1$ if and only if the node i is the parent or ancestor of node j, at the same time $dist(i,j) = d$. Otherwise, the value will be set as zero.

In the **child mask** with certain distance d, we have $M^c_{i,j,d} = 1$ if and only if the node i is the child or offspring of node j, at the same time $dist(i,j) = d$. In other words, node j is the parent or ancestor of node i.

In the **sibling mask** with certain distance d, we have $M^s_{i,j,d} = 1$ if and only if we can find their lowest common ancestor and $dist(i,j) = d$. Note that if two nodes are in the same sentence, we can always find the lowest common ancestor, but the value should be zero if the corresponding nodes come from different sentences (in pairwise inference tasks).

The **pairwise mask** captures the interaction of multiple sentences in a pairwise inference task. We have $M^{pair}_{i,j} = 1$ if and only if both node i and j are from different sentences. we do not consider the distances in-between as the nodes are from different trees.

3.3 Syntactic attention layers

A block of Syntax-BERT contains two kinds of attention modules: *masked self-attention* and *topical attention*. The operations in a *masked self-attention* are similar to a standard self-attention except that we have sparse network connections as defined in the masks. The *masked self-attention* can be formulated as an element-wise multiplication of dot-product attention and its corresponding mask:

$$\begin{aligned} &MaskAtt(Q,K,V,M) = \sigma\left(\frac{QK^\top \odot M}{\sqrt{d}}\right)V \\ &A_{i,j} = MaskAtt(HW^Q_i, HW^K_i, HW^V_i, M_j) \\ &H_j = (A_{1,j} \oplus A_{2,j} \oplus ... \oplus A_{k,j})W^O, j \in 1,...,m \end{aligned} \quad (1)$$

where Q, K, V represent for the matrix of query, key and value respectively, which can be calculated by the input representation H. M represents for the matrix of syntax mask and $\odot$ denotes an operator for element-wise production; σ stands for softmax operator; $A_{i,j}$ denotes the attention-based representation obtained by the i^{th} head and j^{th} sub-network; W^Q_i, W^K_i and W^V_i represent for the parameters for linear projections; M_j denotes the mask for the j^{th}sub-network; and H_j denotes the corresponding output representation.

The output representations from different sub-networks embody knowledge from different syntactic and semantic aspects. Therefore, we leverage

another attention layer, named *topical attention* to perform a fine-grained aggregation of these representations. The most distinct part of a *topical attention* is that q_{task} is a trainable query vector for task-specific embedding. Thus, the *topical attention* layer is able to emphasize task-oriented knowledge captured by numerous sub-networks.

$$\begin{aligned} &TopicAtt(q_{task}, K, V) = \sigma(\frac{q_{task}K^\top}{\sqrt{d}})V \\ &H^O = TopicAtt(q_{task}, HW^K, HW^V) \end{aligned} \tag{2}$$

where d denotes the size of hidden dimension, $q_{task} \in R^{1\times d}$ is a task-related learnable query embedding vector; σ stands for the softmax operator; $H = (H_1, H_2, ..., H_m)^\top \in R^{m\times d}$ is the output representation collected by multiple sub-networks; W^K and W^V are parameters in the feed-forward operations; and H^O stands for the final text representation.

4 Experiments

First, we run experiments on the Stanford Sentiment Treebank (SST) dataset (Socher et al., 2013) in Section 4.1, which is designed to study the syntactic and semantic compositionality of sentiment classification. Second, in Section 4.2, we evaluate the performance of Syntax-BERT on two natural language inference datasets: SNLI and MNLI. Then, more empirical results on the GLUE benchmark and a comprehensive ablation study will be presented in Section 4.3 and 4.4 respectively. At last, we present the analysis of the structural probes in Section 4.5.

The statistics of all datasets adopted in this paper are summarized in Table 1. For each dataset, we optimize the hyper-parameters of Syntax-BERT through grid search on the validation data. Detailed settings can be found in the appendix. In our experiments, we set the maximum value of $dist(A, B)$ in a syntax tree as 15 and use both dependency and constituency trees unless specified. Thus, we have totally 90 ($15 \times 3 \times 2$) sub-networks for single-sentence tasks and 92 ($(15 \times 3 + 1) \times 2$) sub-networks for pairwise inference tasks. We adopt Transformer (Vaswani et al., 2017), BERT-Base, BERT-Large (Devlin et al., 2019), RoBERTa-Base, RoBERTa-Large (Liu et al., 2020) and T5-Large (Raffel et al., 2019) as backbone models and perform syntax-aware fine-tuning on them. We also compare with LISA (Linguistically-Informed Self-Attention) (Strubell et al., 2018), a state-of-the-art method that incorporates linguistic knowledge into self-attention operations. Specifically, LISA (Strubell et al., 2018) adopt an additional attention head to learn the syntactic dependency in the tree structure, and the parameters of this additional head are initialized randomly.

4.1 Stanford Sentiment Treebank

The SST dataset contains more than 10,000 sentences collected from movie reviews from the *rottentomatoes.com* website. The corresponding constituency trees for review sentences are contained in the dataset, where each intermediate node in a tree represents a phrase. All phrases are labeled to one of five fine-grained categories of sentiment polarity. SST-2 is a binary classification task. We follow a common setting that utilizes all phrases with lengths larger than 3 as training samples, and only full sentences will be used in the validation and testing phase. The hyper parameters for each model are selected by grid search and listed in the appendix. We compare Syntax-BERT with vanilla baselines and LISA-enhanced models. The results are listed in Table 2. As shown in the table, our model achieves 4.8 and 4.9 absolute points improvements respectively against the vanilla Transformer with comparable parameter size. By combining our framework with LISA, the results can be further boosted obviously. This indicates that our mechanism is somewhat complementary to LISA. LISA captures the syntactic information through an additional attention head, whereas our framework incorporates syntactic dependencies into original pre-trained attention heads and increases the sparsity of the network. We can see that *Syntax-Transformer + LISA* performs the best among all settings, and similar trends are demonstrated on the BERT-Base and BERT-Large checkpoints.

Table 3: Comparison with SOTA models on NLI datasets.

4.2 Natural Language Inference

The Natural Language Inference (NLI) task requires a model to identify the semantic relationship (entailment, contradiction, or neutral) between a premise sentence and the corresponding hypothesis sentence. In our experiments, we use two datasets for evaluation, namely SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018). We utilize the Stanford parser (Klein and Manning, 2003) to generate constituency and dependency trees for the input sentences. The MNLI dataset has two separate sets for evaluation (matched set and mismatched set), and we report the average evaluation score of these two sets.

The test accuracies on SNLI and MNLI datasets are shown in Table 3. The syntactic prior information helps the Transformer to perform much better on the NLI tasks. The accuracies on the SNLI and MNLI datasets have been improved by 1.9 and 2.7, respectively, by applying our framework to a vanilla Transformer. The LISA-enhanced transformer can also outperform vanilla transformer on NLI tasks, but the accuracy improvement is not as large as Syntax-Transformer. When the backbone model is BERT-Base or BERT-Large, consistent conclusions can be drawn from the experimental results. It is worth noting that the syntax-enhanced models for BERT-large do not show much gain based on the vanilla counterparts. This may because BERT-Large already captures sufficient knowledge for NLI tasks in the pre-training phase.

4.3 GLUE Benchmark

The GLUE benchmark (Wang et al., 2019) offers a collection of tools for evaluating the performance of models. It contains single-sentence classification tasks (CoLA and SST-2), similarity and paraphrase tasks (MRPC, QQP, and STS-B), as well as pairwise inference tasks (MNLI, RTE, and QNLI). We use the default train/dev/test split. The hyper-parameters are chosen based on the validation set (refer to the appendix for details). After the model is trained, we make predictions on the test data and send the results to GLUE online evaluation service[1] to obtain final evaluation scores.

The evaluation scores on all datasets in GLUE benchmark are illustrated in Table 4. The performances of BERT-Base, BERT-Large, RoBERTa-Base, RoBERTa-Large, and T5-Large are reproduced using the official checkpoint provided by respective authors. We only use self-contained constituency trees for the SST-2 dataset while other datasets are processed by Stanford parser[2] to extract both dependency trees and constituency trees. For a fair comparison, all results of baseline models are reproduced by our own, which are close to the reported results.

As shown in the table, syntax-enhanced models always outperform corresponding baseline models. Most notably, Syntax-RoBERTa-Base achieves an average GLUE score of 82.1, lifting 1.3 scores from a standard RoBERTa-Base with the same setting. This is impressive as only a few extra parameters are introduced to the baseline model. Particularly, the improvements on CoLA and SST-2 datasets are fairly large, showing the generalization capability of Syntax-BERT and Syntax-RoBERTa on smaller datasets. Even on T5-Large, which is trained on more data and holds more advanced performances, our approach still outperforms the base model marginally (statistically significant under 4.3 p-value using paired t-test). We can see that more training data will improve the generalization

capability of the model and compensate for the lack of syntax priors. On the other hand, syntactic information is useful in most cases, especially when training data or computation power is limited.

4.4 Ablation Study

For a comprehensive understanding of the model design, we conduct ablation study with the following settings. (1) *without topical attention*: the topical attention layer is removed, and a simple summation layer is replaced instead; (2) *without syntax tree:* all the syntactic masks generated by the syntax trees are replaced by randomly generated masks, while the parameter size of the model remains unchanged; (3) *without constituency/dependency tree*: only one kind of syntax tree is used in the model; (4) *without parent / child / sibling / pairwise masks*: the corresponding masks are removed in the implementation.

As shown in Table 5, all datasets benefit from the usage of syntactic information. Generally, parent/child masks are of more importance than the sibling masks. Moreover, the topical attention layer is crucial to the performance of Syntax-BERT model, indicating the advantage of decomposing self-attention into different sub-networks and performing fine-grained aggregation. In addition, the pairwise mask is important on STS-B dataset and shows the benefit of cross-sentence attention.

4.5 Structural Probe

Our method ingests syntax trees into the model architecture directly. To examine if the representation learned by the model also captures syntactic knowledge effectively, we follow Hewitt and Manning (2019) to reconstruct a syntax tree of the entire sentence with linear transformation learned for the embedding space. If the syntax tree can be better reconstructed, the model is viewed to learn more syntactic information. We evaluate the tree on *undirected attachment score* – the percent of undirected edges placed correctly, and *Spearman correlation* between predicted and the actual distance between each word pair in a sentence. We probe models for their ability to capture the Stanford Dependencies formalism (de Marneffe et al., 2006). As shown in Table 6, for both metrics, the syntax-aware models get better scores than corresponding baseline models, indicating that Syntax-BERT is able to incorporate more syntax information than its vanilla counterparts.

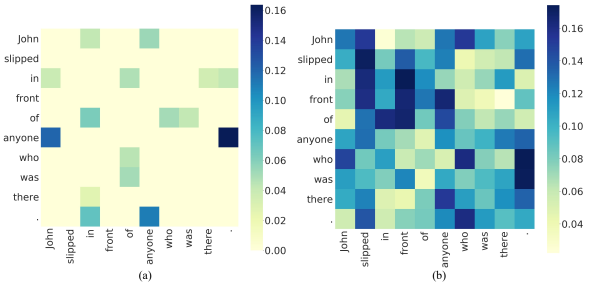

Figure 2: For an example sentence input, (a) The self-Attention scores of Syntax-Transformer corresponding to the sibling mask with $dist = 3$. (b) The self-attention scores of a vanilla Transformer.

5 Discussion

5.1 Complexity analysis

First, we choose BERT-Base as the base model to analyze the space complexity. As reported in (Devlin et al., 2019), the number of trainable parameters in BERT-Base is about 110 million. Following (Strubell et al., 2018), LISA-BERT-Base replaces one attention head in BERT-Base with a bi-affine attention head. Such an operation only adds a trainable matrix — the bi-affine transformation matrix — in each layer, which brings about 0.6 million extra parameters. Syntax-BERT-Base introduces a topical attention layer, which contains 1.0 million parameters in total for the BERT-Base version, while other parameters are inherited from vanilla BERT. Therefore, both LISA and Syntax-BERT add few parameters to the model and do not affect its original space complexity.

We now analyze the time complexity of Syntax-BERT. Assume the number of tokens in each sentence is N. First, constructing syntactic trees for each sentence and extract masking matrices can be prepossessed in the training phase or finish in $O(N^2)$ in the online inference phase. The time complexity of the embedding lookup layer is $O(N)$. Then, the attention score is calculated by $QK^\top \odot M$ with complexity $O(D_Q N^2)$, where D_Q is the dimension of Q. Assume we have M sub-networks. The complexity of masked self-attention is $O(MD_Q N^2)$. In the topical attention, the calculation process is very similar to traditional self-attention, only replacing Q with a task-related vector. So it does not change the time complexity of BERT. Finally, to get output representation, subsequent softmax and scalar-vector multiplication hold $O(D_V N)$ complexity, where D_V is the dimension of V for the topical attention. As such, the overall time complexity of Syntax-BERT is $O(N) + O(MD_Q N^2) + O(D_V N) = O(MD_Q N^2)$. When M is small, the model has the same time complexity as vanilla BERT. Moreover, as the sub-networks are usually very sparse, the time complexity can be further improved to $O(MD_Q E)$ by a sparse implementation. Here $E \ll N^2$ denotes the average number of edges in a sub-network.

5.2 Case Study

We select the sentence "John slipped in front of anyone who was there" in the CoLA dataset for case study. The task is to examine if a sentence conforms to English grammar. This sentence should be classified as negative since we use *everyone* instead of *anyone*. Syntax-Transformer classifies it correctly, but the vanilla transformer gives the wrong answer.

As visualized in Figure 2(a), the relationship between word pair *("anyone", ".")* has been highlighted in one of the sub-networks, and the corresponding topical attention score for this sub-network in Syntax-Transformer is also very high. This shows a good explainability of Syntax-Transformer by correctly identifying the error term "anyone", following a rule that "anyone" is seldom matched with the punctuation ".". However, a vanilla Transformer shows less meaningful self-attention scores, as illustrated in Figure 2(b). We give a briefing here, and please refer to the appendix for a complete description.

6 Conclusion

In this paper, we present Syntax-BERT, one of the first attempts to incorporate inductive bias of syntax trees to pre-trained Transformer models like BERT. The proposed framework can be easily plugged into an arbitrary pre-trained checkpoint, which underlines the most relevant syntactic knowledge automatically for each downstream task. We evaluate Syntax-BERT on various model backbones, including BERT, RoBERTa, and T5. The empirical results verify the effectiveness of this framework and the usefulness of syntax trees. In the future, we would like to investigate the performance of Syntax-BERT by applying it directly to the large-scale pre-training phase. Moreover, we are aiming to exploit more syntactic and semantic knowledge, including relation types from a dependency parser and concepts from a knowledge graph.

A Detailed settings

Here we provide detailed settings for reproduction. The open-source code will be released when this paper is officially published.

A.1 Stanford Sentiment Treebank

For raw Transformers, the number of layers is set as 12 and hidden dimension for each intermediate layer is set as 512. The probability of dropout is 0.1, and the hidden dimension of the final fully-connected layer is 2000. The word embedding vectors are initialized by GloVe (glove.840B.300d[3]) (Pennington et al., 2014) and fine-tuned during training. We use Adam optimizer with an initial learning rate 1e-4.

A.2 Natural Language Inference

For raw Transformers, we set layer number as 12, the hidden dimension of intermediate layers as 512, dropout ratio as 0.15, and the dimension of fully connected layer before Softmax activation as 2000. Learning rate is initialized as 5e-4, and Adam optimizer is used along with exponential learning rate decay of 0.9.

B Connection to GNN

A Transformer layer can be viewed as a special kind of Graph Neural Network (GNN), where each node represents for a word and all nodes construct a complete graph. To improve training speed and generalization ability, there are some previous works that advocate sparse architectures. For instance, Sparse Transformer (Child et al., 2019) separates the full self-attention operation across several steps of attention for image classification. Star-Transformer (Guo et al., 2019) sparsifies the architecture by shaping the fully-connected network into a star-shaped structure consisting of ring connections and radical connections. In the architecture of Syntax-BERT, we also introduce sparsity to the complete graph network by decomposing it into multiple sub-networks. The most salient part of our approach is that the inductive bias is designed by syntax tree, which is a crucial prior for NLP tasks. In addition, as shown previously in Table 5, a random decomposition of the network also result in moderate performance enhancement. Similar phenomena is also reported in the image classification scenario with Graph Convolutional Network (GCN) (Gürel et al., 2019).

DISK-CSV: Distilling Interpretable Semantic Knowledge with a Class Semantic Vector

Housam Khalifa Bashier Babiker [1], **Mi-Young Kim**[2], **Randy Goebel**[1]

Abstract

Neural networks (NN) applied to natural language processing (NLP) are becoming deeper and more complex, making them increasingly difficult to understand and interpret. Even in applications of limited scope on fixed data, the creation of these complex "black-boxes" creates substantial challenges for debugging, understanding, and generalization. But rapid development in this field has now lead to building more straightforward and interpretable models. We propose a new technique (DISK-CSV) to distill knowledge concurrently from any neural network architecture for text classification, captured as a lightweight interpretable/explainable classifier. Across multiple datasets, our approach achieves better performance than the target black-box. In addition, our approach provides better explanations than existing techniques.

1 Introduction

Deep Neural Networks (DNNs) are popular in many applications, including computer vision and natural language processing. However, two major factors still require attention: (1) understanding the classifier's prediction for the end-users to develop trust in the model, and to enable machine learning engineers to refine it. This is especially true for high-stakes domains such as clinical decision support. There has been attention on models that attempt to make a neural network explainable, for instance, (Sundararajan et al., 2017), and (Ribeiro et al., 2016), which create post-hoc explanations to support explainability. Secondly, (2) artificially high numbers of parameters make the inference time expensive.

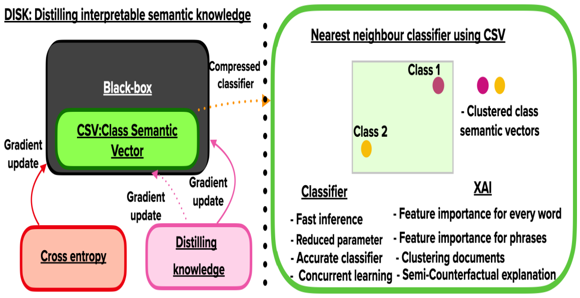

Figure 1: Our proposed model.

Neural networks tend to be deep, with millions of parameters. For example, GPT-2 (Radford et al., 2019) needs over 1.5 billion parameters. As a result, they are compute-intensive, thus making it difficult to deploy in real-world applications. We here propose a model-agnostic interpretable knowledge distillation method for neural network text classification.

As shown in Figure 1, we learn a class semantic vector for each output class, concurrently when training the black box. We then use the semantic vectors to create the nearest neighbor classifier (compressed interpretable/explainable classifier) from the black-box version. Knowledge distillation refers to the process of transferring the implicit knowledge learned by a teacher model to a student model (Liu and Matwin, 2018). Dark knowledge refers to the salient information hidden in the predicted probabilities for all classes, which are more informative than the predicted classes themselves. Our contributions can be summarized as follows:

- We propose a knowledge distillation method where dark knowledge can be learned concurrently by a student model, while building a black-box model.

- We propose an interpretable classifier, which provides a user explanation for predicting a single class label.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3021–3030
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

- We integrate a clustering technique within our interpretable classifier model.

- We provide an interactive explanation mode, where users can directly request a word or a phrase query and receive feedback.

- Our smaller model shows even better performance than the original black-box, with drastically reduced hyper-parameters. That smaller model can be deployed as an on-line service in real-time applications in resource-restricted devices.

2 Related Work

This work has connection with research on explainablity and model compression.

Explainability. Most of the existing explainable AI (XAI) techniques for Natural Language Processing text classification focus on assigning a score to each word in the document w.r.t. predicted class, typically using gradient-based or perturbation-based methods (Arras et al., 2017; Sundararajan et al., 2017; Shrikumar et al., 2017a; Bach et al., 2015). The most popular technique for model-agnostic explanation is LIME (Ribeiro et al., 2016), which focuses on creating an interpretable classifier by approximating it locally, with a linear model.

The main drawback of these methods is that those explanations are not faithful to the target model (Rudin, 2018). There are other methods, which focused on constructing a self-explainable network (Bastings et al., 2019) and (Lei et al., 2016). These techniques have limited explanations and thus do not explain phrases. Our work is different from post-hoc and self-explainable approaches as it attempts to learn an explainable smaller classifier concurrently with the target black-box model. Our explanations are also generated from the interpretable classifier itself, without extra calculation as in post-hoc techniques.

Model compression. A variety of research devoted their efforts to compressing large networks to accelerate inference, transfer, and storage. One of the earliest attempts focused on pruning unimportant weights (LeCun et al., 1990). Other methods focused on modifying devices to improve floating point operations (Tang et al., 2018). In contrast, some works focused on quantizing neural networks (Wu et al., 2018). Other investigations have focused on knowledge distillation, i.e., the ability to transfer the knowledge from a larger model to a smaller model (Ba and Caruana, 2014) and (Hinton et al., 2015). However, the main drawbacks of the methods mentioned above are that: (1) they only work with pre-trained networks, (2) the compressed models are still treated as black-box, and (3) the compression techniques require another training step or additional computation which complicates the process. In contrast, we concurrently transfer the knowledge from the black-box into a smaller interpretable model.

3 DISK-CSV

In a text classification task, an input sequence $x = \langle x_1, ..., x_l \rangle, x_i \in \mathbb{R}^d$, where l is the length of the input text and d is the vector dimension, is mapped to a distribution over class labels using a parameterized θ neural network model (e.g., a Long Short Term Memory network (LSTM), Transformer, etc.), which we denote as $\mathcal{F}(x; \theta)$. The output y is a vector of class probabilities, and the predicted class $\hat{y}$ is a categorical outcome, such as an entailment decision. In this work, we are interested in learning a simpler compressed nearest neighbor classifier (e.g., easy-to-explain its prediction) from any neural network model, but concurrently, while training the larger model. We refer to the large model (black-box) as $\mathcal{T}$ and the smaller interpretable/explainable model as $\mathcal{S}$.

We call our method **DISK-CSV** - **D**istilling **I**nterpretable **S**emantic **K**nowledge with a **C**lass **S**emantic **V**ector. In the next subsections we provide the following details for **DISK-CSV**: (a) how to distill knowledge from $\mathcal{T}$ into $\mathcal{S}$, (b) how to construct interpretable representations for $\mathcal{S}$, and (c) how to interact with the model to achieve better explainability (e.g., by clustering data, explaining essential phrases, and providing a semi-counterfactual explanation). Neural networks learn by optimizing a loss function to reflect the true objective of the end-user. For $\mathcal{S}$, our objective is to generalize in the same way as $\mathcal{T}$ and approximate an explanation for each prediction. To demonstrate our idea, we show how we can learn $\mathcal{S}$ concurrently with a long short-term memory network (LSTM) and then discuss how it can be generalized to different types of architectures for text classification. An LSTM network processes the input word by word, and at time-step t, the memory c_t and the hidden state h_t are updated. The last state $h_l \in \mathbb{R}^d$ is fed into a linear layer with parameters

$\boldsymbol{W} \in \mathbb{R}^{d\times k}$ which gives a probability distribution over k classes:

$$p(y|x) = \frac{\exp(h_l \cdot \boldsymbol{W})}{\sum_{i=1}^{k} \exp(h_l \ \cdot \boldsymbol{W})_k}, \qquad (1)$$

The classifier uses cross-entropy loss to penalize miss-classification as $\mathcal{L}^{classifier} = -\frac{1}{k}\sum_{i=1}^{k} r_i \log(y_i)$, where $r \in \mathbb{R}^k$ is the one-hot represented ground truth and r_i is the target probability (0 or 1) for class i. The network's weights are updated via back-propagation when training the black-box. We intend to augment the neural nets that typically use embeddings to represent discrete variables (e.g., words) as continuous vectors. Words that have a similar context will have similar meanings. The simplest form of concurrent knowledge distillation is to transfer the knowledge from the embedding space of $\mathcal{T}$ into a k-**C**lass **S**emantic **V**ectors (**CSV**s) $v_i \in v$, where the dimension of each v_i is equal to the dimension of the embedding vector x_i, and k is the number of target classes. In other words, for each class label, we would like to learn a vector that captures the semantic information related to that class from the embedding layer.

These semantic vectors have the following properties: (1) Each vector v_i should capture/encode the semantics about the class i from the black-box; (2) These vectors are used by the nearest neighbor classifier for the prediction of the correct class label; (3) By using cosine similarity, we can compute the contribution of each word in the input with the corresponding v_i to the class i; (4) These vectors add another level of abstraction by explaining the feature importance of a phrase that expands a single word, and (5) The weights of the CSV are initialized in the same way we initialize the embedding layer and adjusted via back-propagation. We reformulate the optimization of $\mathcal{T}$ to update/adjust the weights of the **CSV**s as follows:

$$\mathcal{L} = \mathcal{L}^{classifier} + \lambda_1 \overbrace{\left(1 - \frac{\bar{x} \bullet tanh(v_{\hat{y}})}{\|\bar{x}\| \, \|tanh(v_{\hat{y}})\|}\right)}^{Semantics} \\ + \underbrace{\lambda_2 \left(1 - \frac{h_l \bullet tanh(v_{\hat{y}})}{\|h_l\| \, \|tanh(v_{\hat{y}})\|}\right)}_{Hidden-knowledge} \\ -\lambda_3 \left(\overbrace{D}^{Vectors-separation} \right) \qquad (2)$$

where D is the pairwise Euclidean distance defined as $D = \frac{\sum_i \sum_j ((v_i - v_j)(v_i - v_j)^T)}{2}$, $\hat{y}$ is the index of the predicted class with the highest probability, and $\{\lambda_1, \lambda_2, \lambda_t r3\}$ are used to weight the importance of the terms. In what follows, we discuss the new terms added to the optimization problem.

Capturing semantics: The second term of Equation 2 is the second loss function we use, which attempts to encode the information of semantically consistent sentences in a single **CSV** $v_{\hat{y}}$. An obvious way to learn semantic information is to minimize the cosine distance between the average of the embedding $\bar{x}$ of the input sentence x and the predicted class semantic vector $v_{\hat{y}}$. This objective will ensure that the vector v_i captures the semantics of consistent inputs to encourage semantic consistency.

Hidden knowledge extraction: The last hidden state h_l in recurrent nets is typically used by the output layer as the feature vector to predict the class label. As a result, the salient information learned by $\mathcal{T}$ is encoded in this feature vector. To distill this knowledge and enrich the representation of v_i so that $\mathcal{S}$ generalizes well, we again minimize the cosine distance between the class semantic vector v_i and the last hidden state h_l in the third loss function, which is the third term in Equation 2. This objective allows the model $\mathcal{S}$ to generalize similarly to the black-box $\mathcal{T}$. The only constraint here is that the dimension of h_l must be the same as that of x_i so that we can minimize the cosine distance, i.e., $h_l \in \mathbb{R}^d$.

Vector-separation: Our ultimate goal is to create a simple interpretable nearest neighbor classifier $\mathcal{S}$ from the black-box. Therefore, we want to make sure that the **CSV**s are well separated from each other so that the cosine distance is maximum between them. To address this problem, we maximize the pairwise Euclidean distance between these vectors using the fourth term in Equation 2.

3.1 The smaller interpretable classifier $\mathcal{S}$ based on CSV

Our smaller model $\mathcal{S}$ is the nearest neighbor classifier, which relies mainly on the semantic information encoded in the vectors v learned via back-propagation when training $\mathcal{T}$. The model $\mathcal{S}$ takes the input sentence and computes the average $\bar{x}$ of the input embedding. Then we compute the cosine distance between $\bar{x}$ and each v_i. Finally, the target class is decided as the index i of the v_i with the lowest cosine distance. Besides, this classifier is interpretable, i.e., we can understand the mechanism of making a prediction. It can also be easily transferred or stored. The smaller model extracts the semantics from the larger model concurrently when training the black-box model. The algorithm is summarized in Figure 2.

```
Input: Sentence embedding $x$, CSVs $v$, $Dist = 5$
Output: Predicted class $\hat{y}$
$\bar{x}$ = average˙emebdding($x$)
for Each vector $v_i \in v$ do
    $tmpDist$ = CosineDistance ($v_i, \bar{x}$)
    if $tmpDist < Dist$ then
        $\hat{y} \leftarrow i$
        $Dist \leftarrow tmpDist$
    end if
end for
```

Figure 2: Our smaller model $\mathcal{S}$ using **CSV**.

3.2 Explainability

Our model $\mathcal{S}$ provides four levels of explanations for text classification: (1) Word feature importance, (2) Document clustering, (3) End-user interaction through phrase feature importance, and (4) Semi-counterfactual explanation.

- **Word feature importance**: To understand the contribution of each word w.r.t. predicted class $\hat{y}$, we rely on the semantic similarity between each x_i and the nearest class vector $v_{\hat{y}}$. A word with high semantic similarity with the predicted $v_{\hat{y}}$ will have a high contribution to the predicted class. To understand the semantic contribution of each word in the input, we calculate the semantic similarity of every word to $v_{\hat{y}}$ using cosine similarity between the embedding vector of the input word and $v_{\hat{y}}$.

- **Document clustering**: Every text instance is clustered around its class semantic vector by computing the mean (x-axis) and the standard deviation (y-axis) of the elements in the vector $(\frac{\bar{x}+tanh(v_{\hat{y}})}{2})$ for each $\bar{x}$, where $v_{\hat{y}}$ is the nearest **CSV** to the input document. We found that the 2-D points (mean, standard deviation) of the elements in the vector $(\frac{\bar{x}+tanh(v_{\hat{y}})}{2})$ for the instances belonging to a specific class are close to each other and far from those of the instances belonging to other classes. The merit is that we do not need to use a clustering algorithm.

- **End-user interaction through phrase feature importance**: Word feature importance is sometimes not enough to explain a model's prediction. The end-user might also be interested in querying the classifier to answer different types of questions. For example, in the situation where the model shows the feature importance (in sentiment classification) of each individual word "not," "too," and "bad," an end-user might also be interested in the importance of the phrase "not too bad," which cannot be calculated just by merging the three different feature importance values. Our approach is capable of giving feedback to the user's query about a phrase. To obtain the feature importance for a phrase, we average the embedding vectors of the words in the phrases and then compute the cosine similarity w.r.t. the predicted **CSV** $v_{\hat{y}}$.

- **Semi-counterfactual explanation**: Our approach is also capable of providing a semi-counterfactual explanation, i.e., explaining a semi-casual situation (i.e., what kind of features prevent the classifier from changing the prediction to another class). We can provide a feature importance value w.r.t. non-predicted classes by calculating the cosine similarity between the embedding vector of each word/phrase and the class semantic vector of a non-predicted class). Through this semi-counterfactual explanation, the user can reason that "if the feature X had not occurred, the class prediction would have been changed."

3.3 Generalizing to other models

Our method can be adapted to a variety of architectures such as Bi-LSTM, GRU, and RNNs, as it requires access to only the last hidden state (feature vector) and the embedding layer from the network. A further restriction is that the feature vector used in the output layer must have the same dimension as the embedding feature vector. For the Transformer, to handle the dimensionality issue, we average the Transformer's representations before the output layer as the feature vector.

4 Experiments

4.1 Datasets

The summary of the datasets is shown in Table 1.

IMDB reviews were proposed by (Maas et al., 2011) for sentiment classification from movie reviews. It consists of two classes, i.e., positive and negative sentiments.

AGnews was proposed by (Zhang et al., 2015a) for researchers to test machine learning models for news classification. It consists of four classes (sports, world, business, and sci/tech).

DBpedia ontology classification dataset proposed by (Zhang et al., 2015b) consists of 15 non-overlapping ontology classes [1].

HealthLink constructed by Alberta Health Services, Canada. It contains a set of text transcripts written by registered nurses while talking with callers to the Tele-Health service in real-time. It consists of 2 classes ("go to hospital" and "home care"), and each class can be sub-categorized into sub-classes. This dataset will be available based on request.

Data set	Classes	Max length	Train size	Test size	Vocabulary size
IMDB	2	50	25000	25000	10000
HealthLink	2	20	60475	15119	23174
DBpedia	15	32	5600	63000	50002
AGnews	4	20	102080	25520	59706

Table 1: Summary of the datasets used in our experiments

4.2 Baselines

We compare our approach with several models for text classification including Transformers (Vaswani et al., 2017), IndRNN (Li et al., 2018), BLSTM (Zhou et al., 2016), hierarchical attention (Yang et al., 2016), LSTM (Hochreiter and Schmidhuber, 1997) and GRU (Cho et al., 2014).

Transformer employs a multi-head self-attention mechanism based on scaled dot-product attention. We use only the encoder layer, and average the new representations before arriving in the classification's output layer.

IndRNN is an improvement over RNNs, where neurons in the same layer are independent of each other and connected across layers. We use the last hidden state as the feature vector.

Bi-LSTM employs an attention-based bidirectional mechanism on the LSTM network, which captures the salient semantic information (word-attention) in a sentence. These attentions enable the network to attend differently to more and less critical content when learning the representation. The last hidden state is used for classification.

Hierarchical attention provides two levels of attention mechanisms applied to the word and sentence level. In this paper, we use a sentence level-attention mechanism applied on a Bi-LSTM. The feature vector for classification is based on aggregating the hidden representation values (following the authors' implementation).

LSTM and GRU process the input word by word, and the last hidden state is used as the feature vector for classification.

4.3 Network configuration and training

We tokenize sentences and use the top N words that appeared in every instance for the vocabulary size. We did not use any pre-trained embeddings, and thus we randomly initialized the embedding layer. We also randomly initialized the **CSV**s. We did not use any hyper-parameter tuning on the validation as we are not focusing on achieving state-of-the-art predictive accuracy. Instead, we want to show that our method can achieve similar/better performance to the black-box, and provides a better explanation than existing approaches. The word embedding, semantic vector, and feature vector (at the output layer) dimensions are 128. For training each network, we use the Adam optimizer (Kingma and Ba, 2017) with a batch size of 64 and a learning rate of 0.0001. We also used a dropout with a probability 0.5.

4.4 Results and analysis

4.4.1 Classifier performance

We trained six different models (architectures) on four datasets. We have tried different values as the weight of each proposed loss term. The results depicted in Table 2 show that our semantic distillation approach captures more useful information from the training data than the baseline black-box. Our smaller model outperforms the black-boxes on all datasets, achieving better performance than the black-box. The new optimization problem does not affect the performance of the black-box model (see BBO (Black-Box with our new Objective function) in Table 2).

4.4.2 Explainability

In this part of our experiments, we focus on local explanations for text classification, i.e., explaining the output made by our proposed nearest neighbor classifier using **CSV** for an individual instance. Local explanations should exhibit high local fidelity, i.e., they should match the underlying model behavior. We evaluate our technique against the following methods:

---

[1] Because of computation time, we experimented with only a small number of samples.

Table 2: Comparison of our test performances with the baseline neural architectures on four datasets. Our nearest neighbour classifier achieves better performance than the black-box models. For the black-box models, we followed the implementation proposed by the authors of each baseline.

- **Random**. A random selection of words from the input sentence.
- **LIME** (Ribeiro et al., 2016) is a model-agnostic approach which involves training an interpretable model such as a linear model on instances created around the specific data point by perturbing the data. We evaluated by training the linear classifier using ~ 5000 samples.

We show the effectiveness of our method in explaining the prediction on three architectures (Transformer, IndRNN and hierarchical attention network) in Figures 3-8.

Automatic evaluation. We use model-agnostic evaluation metrics to demonstrate the effectiveness of our approach. (Nguyen, 2018) found that human evaluation correlates moderately with automatic evaluation metrics for local explanations. Hence, in our experiments, we use the idea of automatic evaluation to verify whether or not our explanations are faithful to what the model computes. We measure the local fidelity by deleting words in the order of their estimated importance for the prediction, then evaluate the change in F1 score w.r.t. the predicted class when no word is deleted. This type of evaluation is similar to other metrics used for model interpretation (Nguyen, 2018; Arras et al., 2017) except that we use F1 instead of classification accuracy. Results are shown in Figures 3-4. We obtained the plots by measuring the effect of word deletions and reporting the F1 when the classifier prediction changes. A larger drop in F1 indicates that the method could identify the words contributing most towards the predicted class by our classifier. Through Figures 3, 4 and 5, we can clearly see that our approach is capable of identifying the most salient features better than LIME. Please note that LIME requires probabilities (as the classifier's output), and hence we convert the outputs made by our nearest neighbor into valid probabilities.

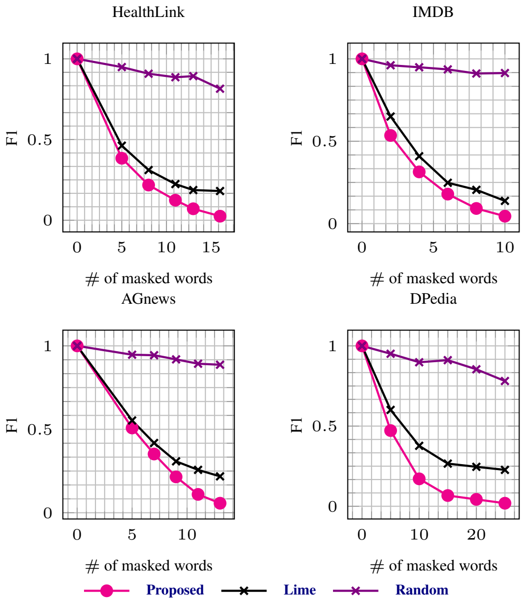

Figure 3: Change of F1 according to the number of masked important words. (Teacher model: Transformer)

Change in log-odds. Another automatic metric for evaluating explainability methods is to observe the change in the log-odds ratio (for the output probabilities). This metric has been used for a model's explanations (Shrikumar et al., 2017b; Chen et al.,

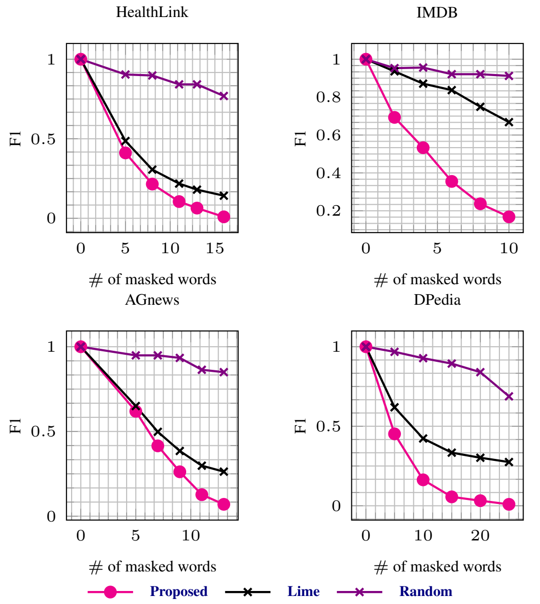

Figure 4: Change of F1 according to the number of masked words. (Teacher model: INDRNN)

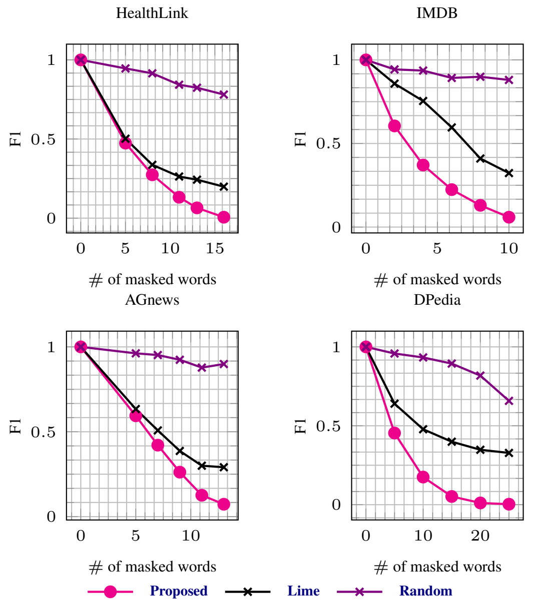

Figure 5: Change of F1 according to the number of masked words. (Teacher model: Hierarchical attention network)

2018). We normalize the cosine distance into valid probability distributions. This metric requires no knowledge of the underlying feature representation, and it requires access to only the instances. A log-odds ratio is a fine-grained approach, as it uses actual probability values instead of the predicted label as used in the previous experiment. But like the previous experiment, instead of tracking the change in F1, we observe the change in probabilities. We mask the top k features ranked by semantic similarity, and zero paddings replace those masked words. We then feed the input and measure the drop of the value between the target class's probability when no word is deleted and when k words are removed. Results are shown in Figures 6-8 reveal the effectiveness of our approach in capturing the words that affect the classifier's prediction. The experimental results show that our method delivers more insightful explanations than LIME.

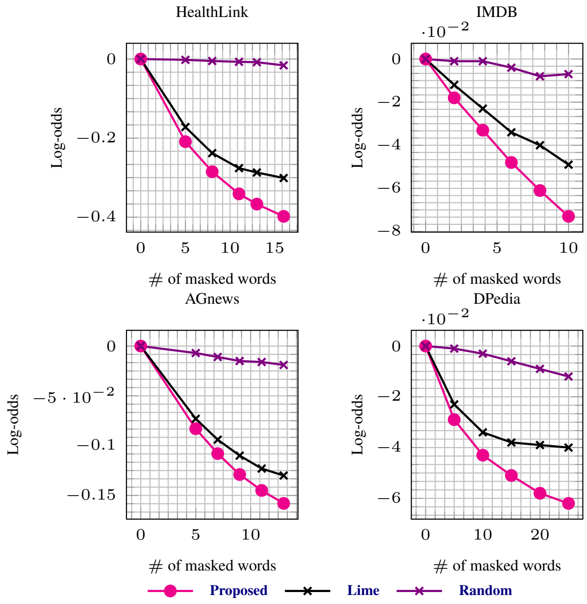

Figure 6: Change of log-odds according to the number of masked words. Lower log-odds scores are better. (Teacher model:Transformer)

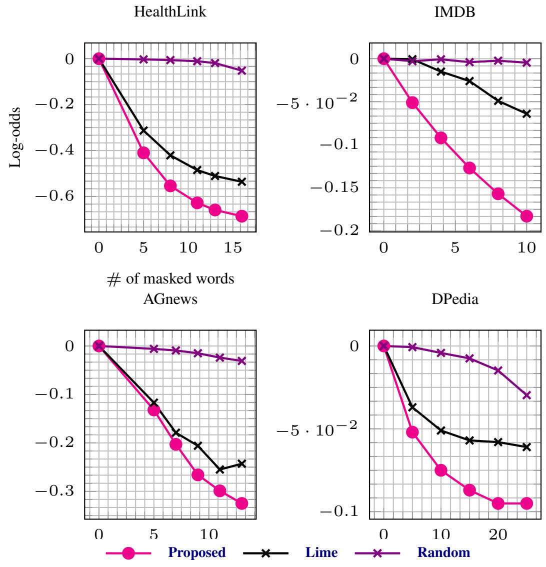

Figure 7: Change of log-odds according to the number of masked words. (Teacher model: INDRNN)

Interactive explanations. In some cases, end-users are interested in understanding the contribution of phrases instead of words. In addition, an end-user might be interested in understanding the

Example	Pos	Neg	Example	Home care	Go to hospital	Example	Home care	Go to hospital

Table 3: XAI capability. Explaining word/phrase contributions and also providing contributions to other classes (semi-counterfactual explanation).

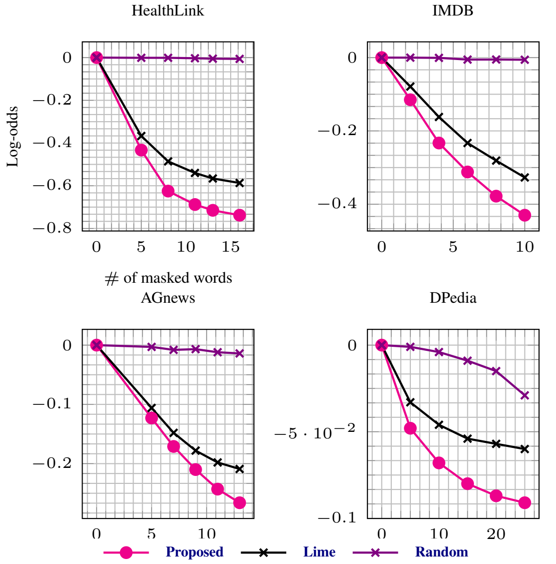

Figure 8: Change of log-odds according to the number of masked words. Lower log-odds scores are better. (Teacher model: Hierarchical attention network)

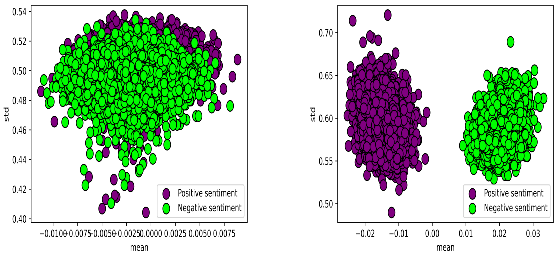
contribution of a word/phrase w.r.t. other classes, not only to the predicted class (semi-counterfactual explanation). Our model's results in support of these interests are shown in Table 3. Our technique can identify the contributions of phrases instead of words, and it can provide evidence w.r.t. other classes. For example, our method can recognize that "bad cough" has a stronger semantic contribution than "cough" w.r.t. the label "going to the hospital." Our approach can also recognize the difference between "mild chest pain" and "chest pain." In sentiment analysis, our method understands that "good" contributes to a positive sentiment while "not good" contribute to negative sentiment. Also, note that "very good" contributes more importantly to a positive sentiment than "good."

Clustering textual data. Another feature of the **CSV** classifier is the ability to cluster documents via **CSV**s without using dimensionality reduction techniques such as PCA clustering algorithms. Results of document clustering based on the distilled knowledge from the Transformer on the IMDB and AGnews are shown in Figure 9 and 10. The clusters explain our classifier's behavior and hence provide a global explanation of the model's prediction. We also show the critical role of using the pairwise Euclidean distance in our classification by clustering sentences into their predicted classes.



(a) Without Euclidean distance loss. (b) With Euclidean distance loss.

Figure 10: Sentence clustering on the predicted class using Euclidean distance vs. without Euclidean distance. (Dataset: AGnews)

Parameter reduction. We compare the number of parameters used by our nearest neighbor classifier and that of the black-box approach, using the HealthLink data in Table 4. The number of parameters used by our compressed classifier is less than that of each black-box. Our model relies only on the embeddings and the **CSV**s, and the rest of the layers are dropped. The number of parameters of the proposed classifier is the same for all architectures because our classifier has the same size of the embedding layer and **CSV**s on each black-box architecture. Our model also reduced the inference time from $0.037 - 0.085$ seconds to 0.007 seconds, as shown in Table 4.

Method	# of parameters	# of dropped parameters	Inference time
Transformer			
Black-box	3049602	83074	0.085
DISK-CSV	**2966528**		**0.007**

DISK-CSV	**2966528**		**0.007**

Table 4: Number of parameters used for black-box and our proposed model. We also compare the inference time.

Semantics. We compare our proposed method's performance with and without capturing the semantic information (Equation 2). Results depicted in Table 5 show the importance of encoding semantic into the class discriminative vector.

	Proposed				Without semantic			
	F1	**Accuracy**	**Precision**	**Recall**	**F1**	**Accuracy**	**Precision**	**Recall**
Dpedia	0.8806	0.9438	0.8811	0.8809	0.0425	0.624	0.0693	0.0582

Table 5: The impact of first term in Equation 2 on the classifier's performance

Analyzing words. We are interested in what kind of words contribute most to the class prediction. For this analysis, we exploit the word-level sentiment annotation (Opinion Lexicon) provided by Liu [2] to track the top 10 words whose importance was the highest when predicting the sentiment class in the IMDB dataset. We evaluated the number of words contributing to each of the negative and positive sentiments on 1000 movie reviews. Table 6 shows that our approach can identify more salient words that lead to correct sentiment classification, i.e., our method can pick better sentiment lexicons than LIME.

	Proposed	Lime	Random
Positive sentiment	**597**	423	286
Negative sentiment	**382**	353	236

Table 6: The number of words in each sentiment class for 1000 samples from the test set.

4.5 Discussion

We have shown that semantic information can be extracted and used to create a simple interpretable/explainable classifier that performs better than the target black-box models. This simple classifier has the following proprieties:

- It captures the discriminative representations encoded by the black-box and encodes them in the **CSV**.
- For text classification, the distance is the lowest between the text input and the **CSV** of the correct class, and is high for the other **CSV**s of the incorrect classes.

5 Conclusion and Future Work

We have explored an approach to knowledge distillation concurrently from any black-box model to produce a simple, explainable classifier. The distilled model achieves better results than the original black-box models in terms of the model's performance. Also, we showed that our distilled model provides a better explanation than LIME.

We have also proposed new types of explanations: First, a user can query with any-length phrases and receive feedback about the phrase's contribution to the classes. Second, we also provide word(feature) importance to non-predicted classes, which can be used as a semi-counterfactual explanation. Third, we showed how we could cluster the documents without employing the existing clustering method.

In future work, we would like to extend this idea to pre-trained networks, and we also plan to more deeply investigate the value of counterfactual explanations.

Abstract

Since the popularization of the Transformer as a general-purpose feature encoder for NLP, many studies have attempted to decode linguistic structure from its novel multi-head attention mechanism. However, much of such work focused almost exclusively on English — a language with rigid word order and a lack of inflectional morphology. In this study, we present decoding experiments for multilingual BERT across 18 languages in order to test the generalizability of the claim that dependency syntax is reflected in attention patterns. We show that full trees can be decoded above baseline accuracy from single attention heads, and that individual relations are often tracked by the same heads across languages. Furthermore, in an attempt to address recent debates about the status of attention as an explanatory mechanism, we experiment with fine-tuning mBERT on a supervised parsing objective while freezing different series of parameters. Interestingly, in steering the objective to learn explicit linguistic structure, we find much of the same structure represented in the resulting attention patterns, with interesting differences with respect to which parameters are frozen.

1 Introduction

In recent years, the attention mechanism proposed by Bahdanau et al. (2014) has become an indispensable component of many NLP systems. Its widespread adoption was, in part, heralded by the introduction of the Transformer architecture (Vaswani et al., 2017a), which constrains a soft alignment to be learned across discrete states in the input (self-attention), rather than across input and output (e.g., Xu et al., 2015; Rocktäschel et al., 2015). The Transformer has, by now, supplanted the popular LSTM (Hochreiter and Schmidhuber, 1997) as NLP's feature-encoder-of-choice, largely due to its compatibility with parallelized training regimes and ability to handle long-distance dependencies.

Certainly, the nature of attention as a distribution over tokens lends itself to a straightforward interpretation of a model's inner workings. Bahdanau et al. (2014) illustrate this nicely in the context of `seq2seq` machine translation, showing that the attention learned by their models reflects expected cross-lingual idiosyncrasies between English and French, e.g., concerning word order. With self-attentive Transformers, interpretation becomes slightly more difficult, as attention is distributed across words within the input itself. This is further compounded by the use of multiple layers and heads, each combination of which yields its own alignment, representing a different (possibly redundant) view of the data. Given the similarity of such attention matrices to the score matrices employed in arc-factored dependency parsing (McDonald et al., 2005a,b), a salient question concerning interpretability becomes: Can we expect some combination of these parameters to capture linguistic structure in the form of a dependency tree, especially if the model performs well on NLP tasks? If not, can we relax the expectation and examine the extent to which subcomponents of the linguistic structure, such as subject-verb relations, are represented? This prospect was first posed by Raganato et al. (2018) for MT encoders, and later explored by Clark et al. (2019) for BERT. Ultimately, the consensus of these and other studies (Voita et al., 2019; Htut et al., 2019; Limisiewicz et al., 2020) was that, while there appears to exist no "generalist" head responsible for extracting full dependency structures, standalone heads often specialize in capturing individual grammatical relations.

Unfortunately, most of such studies focused their

experiments entirely on English, which is typologically favored to succeed in such scenarios due to its rigid word order and lack of inflectional morphology. It remains to be seen whether the attention patterns of such models can capture structural features across typologically diverse languages, or if the reported experiments on English are a misrepresentation of local positional heuristics as such. Furthermore, though previous work has investigated how attention patterns might change after fine-tuning on different tasks (Htut et al., 2019), a recent debate about attention as an explanatory mechanism (Jain and Wallace, 2019; Wiegreffe and Pinter, 2019) has cast the entire enterprise in doubt. Indeed, it remains to be seen whether fine-tuning on an explicit structured prediction task, e.g. dependency parsing, can force attention to represent the structure being learned, or if the patterns observed in pretrained models are not altered in any meaningful way.

To address these issues, we investigate the prospect of extracting linguistic structure from the attention weights of multilingual Transformer-based language models. In light of the surveyed literature, our research questions are as follows:

1. Can we decode dependency trees for some languages better than others?
2. Do the same layer–head combinations track the same relations across languages?
3. How do attention patterns change after fine-tuning with explicit syntactic annotation?
4. Which components of the model are involved in these changes?

In answering these questions, we believe we can shed further light on the (cross-)linguistic properties of Transformer-based language models, as well as address the question of attention patterns being a reliable representation of linguistic structure.

2 Attention as Structure

Transformers The focus of the present study is mBERT, a multilingual variant of the exceedingly popular language model (Devlin et al., 2019). BERT is built upon the Transformer architecture (Vaswani et al., 2017b), which is a self-attention-based encoder-decoder model (though only the encoder is relevant to our purposes). A Transformer takes a sequence of vectors $\mathbf{x} = [\mathbf{x_1}, \mathbf{x_2}, ...\mathbf{x_n}]$ as input and applies a positional encoding to them, in order to retain the order of words in a sentence. These inputs are then transformed into query (Q), key (K), and value (V) vectors via three separate linear transformations and passed to an attention mechanism. A single attention head computes scaled dot-product attention between K and Q, outputting a weighted sum of V:

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^\top}{\sqrt{d_k}}\right)V \tag{1}$$

For multihead attention (MHA), the same process is repeated for k heads, allowing the model to jointly attend to information from different representation subspaces at different positions (Vaswani et al., 2017b). Ultimately, the output of all heads is concatenated and passed through a linear projection W^O:

$$H_i = \text{Attention}\left(QW_i^Q, KW_i^K, VW_i^V\right) \tag{2}$$

$$\text{MHA}(Q, K, V) = \text{concat}(H_1, H_2, ..., H_k)W^O \tag{3}$$

Every layer also consists of a feed-forward network (FFN), consisting of two Dense layers with ReLU activation functions. For each layer, therefore, the output of MHA is passed through a LayerNorm with residual connections, passed through FFN, and then through another LayerNorm with residual connections.

Searching for structure Often, the line of inquiry regarding interpretability in NLP has been concerned with extracting and analyzing linguistic information from neural network models of language (Belinkov and Glass, 2019). Recently, such investigations have targeted Transformer models (Hewitt and Manning, 2019; Rosa and Mareček, 2019; Tenney et al., 2019), at least in part because the self-attention mechanism employed by these models offers a possible window into their inner workings. With large-scale machine translation and language models being openly distributed for experimentation, several researchers have wondered if self-attention is capable of representing syntactic structure, despite not being trained with any overt parsing objective.

In pursuit of this question, Raganato et al. (2018) applied a maximum-spanning-tree algorithm over the attention weights of several trained MT models, comparing them with gold trees from Universal Dependencies (Nivre et al., 2016, 2020). They found that, while the accuracy was not comparable to that of a supervised parser, it was nonetheless higher than several strong baselines, implying that some structure was consistently represented. Clark et al. (2019) corroborated the same findings for BERT when decoding full trees, but observed that individual dependency relations were often tracked by specialized heads and were decodable with much higher accuracy than some fixed-offset baselines. Concurrently, Voita et al. (2019) made a similar observation about heads specializing in specific dependency relations, proposing a coarse taxonomy of head attention functions: *positional*, where heads attend to adjacent tokens; *syntactic*, where heads attend to specific syntactic relations; and *rare words*, where heads point to the least frequent tokens in the sentence. Htut et al. (2019) followed Raganato et al. (2018) in decoding dependency trees from BERT-based models, finding that fine-tuning on two classification tasks did not produce syntactically plausible attention patterns. Lastly, Limisiewicz et al. (2020) modified UD annotation to better represent attention patterns and introduced a supervised head-ensembling method for consolidating shared syntactic information across heads.

Does attention have explanatory value? Though many studies have yielded insight about how attention behaves in a variety of models, the question of whether it can be seen as a "faithful" explanation of model predictions has been subject to much recent debate. For example, Jain and Wallace (2019) present compelling arguments that attention does not offer a faithful explanation of predictions. Primarily, they demonstrate that there is little correlation between standard feature importance measures and attention weights. Furthermore, they contend that there exist *counterfactual* attention distributions, which are substantially different from learned attention weights but that do not alter a model's predictions. Using a similar methodology, Serrano and Smith (2019) corroborate that attention does not provide an adequate account of an input component's importance.

In response to these findings, Wiegreffe and Pinter (2019) question the assumptions underlying such claims. Attention, they argue, is not a *primitive*, i.e., it cannot be detached from the rest of a model's components as is done in the experiments of Jain and Wallace (2019). They propose a set of four analyses to test whether a given model's attention mechanism can provide meaningful explanation and demonstrate that the alternative attention distributions found via adversarial training methods do, in fact, perform poorly compared to standard attention mechanisms. On a theoretical level, they argue that, although attention weights do not give an *exclusive* "faithful" explanation, they do provide a meaningful *plausible* explanation.

This discussion is relevant to our study because it remains unclear whether or not attending to syntactic structure serves, in practice, as plausible explanation for model behavior, or whether or not it is even capable of serving as such. Indeed, the studies of Raganato et al. (2018) and Clark et al. (2019) relate a convincing but incomplete picture — tree decoding accuracy just marginally exceeds baselines and various relations tend to be tracked across varying heads and layers. Thus, our fine-tuning experiments (detailed in the following section) serve to enable an "easy" setting wherein we explicitly inform our models of the same structure that we are trying to extract. We posit that, if, after fine-tuning, syntactic structures were still *not* decodable from the attention weights, one could safely conclude that these structures are being stored via a non-transparent mechanism that may not even involve attention weights. Such an insight would allow us to conclude that attention weights cannot provide even a plausible explanation for models relying on syntax.

3 Experimental Design

To examine the extent to which we can decode dependency trees from attention patterns, we run a tree decoding algorithm over mBERT's attention heads — before and after fine-tuning via a parsing objective. We surmise that doing so will enable us to determine if attention can be interpreted as a reliable mechanism for capturing linguistic structure.

3.1 Model

We employ mBERT[1] in our experiments, which has been shown to perform well across a variety of NLP tasks (Hu et al., 2020; Kondratyuk and Straka, 2019a) and capture aspects of syntactic structure cross-lingually (Pires et al., 2019; Chi et al., 2020). mBERT features 12 layers with 768 hidden units and 12 attention heads, with a joint WordPiece sub-word vocabulary across languages. The model was trained on the concatenation of WikiDumps for the top 104 languages with the largest Wikipedias,where principled sampling was employed to enforce a balance between high- and

---

low-resource languages.

3.2 Decoding Algorithm

For decoding dependency trees, we follow Raganato et al. (2018) in applying the Chu-Liu-Edmonds maximum spanning tree algorithm (Chu, 1965) to every layer/head combination available in mBERT ($12 \times 12 = 144$ in total). In order for the matrices to correspond to gold treebank tokenization, we remove the cells corresponding to the BERT delimiter tokens (`[CLS]` and `[SEP]`). In addition to this, we sum the columns and average the rows corresponding to the constituent subwords of gold tokens, respectively (Clark et al., 2019). Lastly, since attention patterns across heads may differ in whether they represent heads attending to their dependents or vice versa, we take our input to be the element-wise product of a given attention matrix and its transpose ($A \circ A^{\top}$). We liken this to the joint probability of a head attending to its dependent and a dependent attending to its head, similarly to Limisiewicz et al. (2020). Per this point, we also follow Htut et al. (2019) in evaluating the decoded trees via Undirected Unlabeled Attachment Score (UUAS) — the percentage of undirected edges recovered correctly. Since we discount directionality, this is effectively a less strict measure than UAS, but one that has a long tradition in unsupervised dependency parsing since Klein and Manning (2004).

3.3 Data

For our data, we employ the Parallel Universal Dependencies (PUD) treebanks, as collected in UD v2.4 (Nivre et al., 2019). PUD was first released as part of the CONLL 2017 shared task (Zeman et al., 2018), containing 1000 parallel sentences, which were (professionally) translated from English, German, French, Italian, and Spanish to 14 other languages. The sentences are taken from two domains, **news** and **wikipedia**, the latter implying some overlap with mBERT's training data (though we did not investigate this). We include all PUD treebanks except Thai.[2]

3.4 Fine-Tuning Details

In addition to exploring pretrained mBERT's attention weights, we are also interested in how attention might be guided by a training objective that learns the exact tree structure we aim to decode. To this end, we employ the graph-based decoding algorithm of the biaffine parser introduced by Dozat and Manning (2016). We replace the standard BiLSTM encoder for this parser with the entire mBERT network, which we fine-tune with the parsing loss. The full parser decoder consists of four dense layers, two for head/child representations for dependency arcs (dim. 500) and two for head/child representations for dependency labels (dim. 100). These are transformed into the label space via a bilinear transform.

After training the parser, we can decode the fine-tuned mBERT parameters in the same fashion as described in Section 3.2. We surmise that, if attention heads are capable of tracking hierarchical relations between words in any capacity, it is precisely in this setting that this ability would be attested. In addition to this, we are interested in what individual *components* of the mBERT network are capable of steering attention patterns towards syntactic structure. We believe that addressing this question will help us not only in interpreting decisions made by BERT-based neural parsers, but also in aiding us developing syntax-aware models in general (Strubell et al., 2018; Swayamdipta et al., 2018). As such — beyond fine-tuning all parameters of the mBERT network (our basic setting) — we perform a series of ablation experiments wherein we update only one set of parameters per training cycle, e.g. the Query weights W_i^Q, and leave everything else frozen. This gives us a set of 6 models, which are described below. For each model, all non-BERT parser components are always left unfrozen.

- KEY: only the K components of the transformer are unfrozen; these are the representations of tokens that are paying attention *to* other tokens.
- QUERY: only the Q components are unfrozen; these, conversely, are the representations of tokens being paid attention to.
- KQ: both keys and queries are unfrozen.
- VALUE: semantic value vectors per token (V) are unfrozen; they are composed after being weighted with attention scores obtained from the K/Q matrices.
- DENSE: the dense feed-forward networks in the attention mechanism; all three per layer are unfrozen.
- NONE: The basic setting with nothing frozen; all parameters are updated with the parsing

---

[2] Thai is the only treebank that does not have a non-PUD treebank available in UD, which we need for our fine-tuning experiments.

loss.

We fine-tune each of these models on a concatenation of all PUD treebanks for 20 epochs, which effectively makes our model multilingual. We do so in order to 1) control for domain and annotation confounds, since all PUD sentences are parallel and are natively annotated (unlike converted UD treebanks, for instance); 2) increase the number of training samples for fine-tuning, as each PUD treebank features only 1000 sentences; and 3) induce a better parser through multilinguality, as in Kondratyuk and Straka (2019b). Furthermore, in order to gauge the overall performance of our parser across all ablated settings, we evaluate on the test set of the largest non-PUD treebank available for each language, since PUD only features test partitions. When training, we employ a combined dense/sparse Adam optimiser, at a learning rate of $3 * 10^{-5}$. We rescale gradients to have a maximum norm of 5.

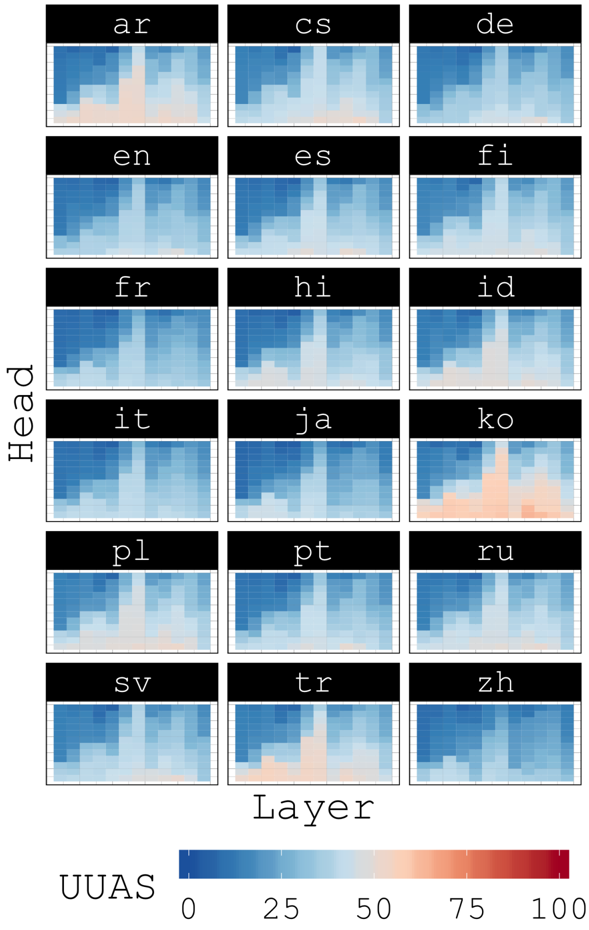

Figure 1: UUAS of MST decoding per layer and head, across languages. Heads (y-axis) are sorted by accuracy for easier visualization.

4 Decoding mBERT Attention

The second row of Table 1 (PRE) depicts the UUAS after running our decoding algorithm over mBERT attention matrices, per language. We see a familiar pattern to that in Clark et al. (2019) among others — namely that attention patterns extracted directly from mBERT appear to be incapable of decoding dependency trees beyond a threshold of 50–60% UUAS accuracy. However, we also note that, in all languages, the attention-decoding algorithm outperforms a BASELINE (row 1) that draws an (undirected) edge between any two adjacent words in linear order, which implies that some non-linear structures are captured with regularity. Indeed, head 8 in layer 10 appears to be particularly strong in this regard, returning the highest UUAS for 7 languages. Interestingly, the accuracy patterns

Figure 2: Left: UUAS per relation across languages (best layer/head combination indicated in cell). Right: Best UUAS as a function of best positional baseline (derived from the treebank), selected relations.

across layers depicted in Figure 1 tend to follow an identical trend for all languages, with nearly all heads in layer 7 returning high within-language accuracies.

It appears that attention for some languages (Arabic, Czech, Korean, Turkish) is comparatively easier to decode than others (French, Italian, Japanese, Chinese). A possible explanation for this result is that dependency relations between content words, which are favored by the UD annotation, are more likely to be adjacent in the morphologically rich languages of the first group (without intervening function words). This assumption seems to be corroborated by the high baseline scores for Arabic, Korean and Turkish (but not Czech). Conversely, the low baselines scores and the likewise low decoding accuracies for the latter four languages are difficult to characterize. Indeed, we could not identify what factors — typological, annotation, tokenization or otherwise — would set French and Italian apart from the remaining languages in terms of score. However, we hypothesize that the tokenization and our treatment of subword tokens plays a part in attempting to decode attention from Chinese and Japanese representations. Per the mBERT documentation,[3] Chinese and Japanese Kanji character spans within the CJK Unicode range are character-tokenized. This lies in contrast with all other languages (Korean Hangul and Japanese Hiragana and Katakana included), which rely on whitespace and WordPiece (Wu et al., 2016). It is thus possible that the attention distributions for these two languages (at least where CJK characters are relevant) are devoted to composing words, rather than structural relations, which will distort the attention matrices that we compute to correspond with gold tokenization (e.g. by maxing rows and averaging columns).

Relation analysis We can disambiguate what sort of structures are captured with regularity by looking at the UUAS returned per dependency relation. Figure 2 (left) shows that adjectival modifiers (`amod`, mean UUAS = 85 ±12) and determiners (`det`, 88 ± 6) are among the easiest relations to decode across languages. Indeed, words that are connected by these relations are often adjacent to each other and may be simple to decode if a head is primarily concerned with tracking linear order. To verify the extent to which this might be happening, we plot the aforementioned decoding accuracy as a function of select relations' positional baselines in Figure 2 (right). The positional baselines, in this case, are calculated by picking the most frequent offset at which a dependent occurs with respect to its head, e.g., -1 for `det` in English, meaning one position to the left of the head. Interestingly, while we observe significant variation across the positional baselines for `amod` and `det`, the decoding

---

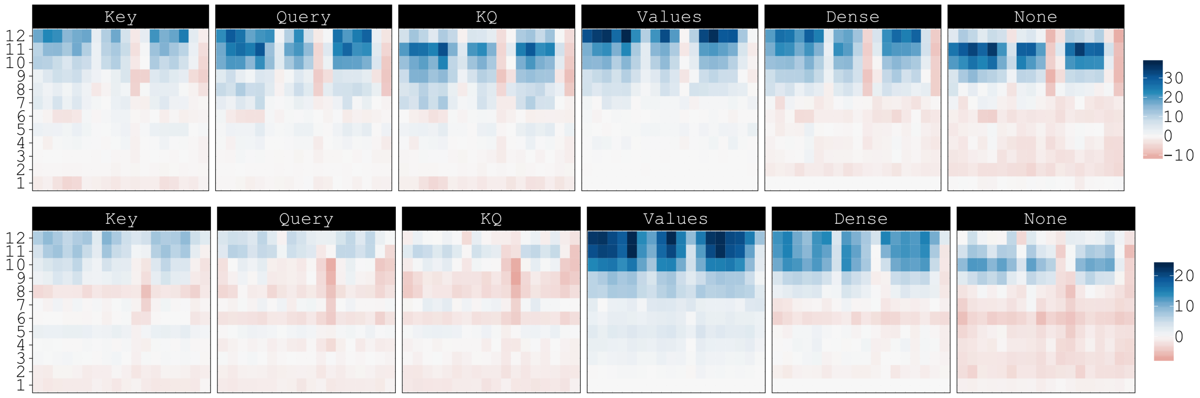

Figure 3: (Top) best scores across all heads, per language; (bottom) mean scores across all heads, per language. The languages (hidden from the X-axis for brevity) are, in order, *ar, cs, de, en, es, fi, fr, hi, id, it, ja, ko, pl, pt, ru, sv, tr, zh*

accuracy remains quite high.

In slight contrast to this, the core subject (`nsubj`, 58 ± 16 SD) and object (`obj`, 64 ± 13) relations prove to be more difficult to decode. Unlike the aforementioned relations, `nsubj` and `obj` are much more sensitive to the word order properties of the language at hand. For example, while a language like English, with Subject-Verb-Object (SVO) order, might have the subject frequently appear to the left of the verb, an SOV language like Hindi might have it several positions further away, with an object and its potential modifiers intervening. Indeed, the best positional baseline for English `nsubj` is 39 UUAS, while it is only 10 for Hindi. Despite this variation, the relation seems to be tracked with some regularity by the same head (layer 3, head 9), returning 60 UUAS for English and 52 for Hindi. The same can largely be said for `obj`, where the positional baselines return 51 ± 18. In this latter case, however, the heads tend to be much differently distributed across languages. Finally, he results for the `obj` relation provides some support for our earlier explanation concerning morphologically rich languages, as Arabic, Czech, Korean and Turkish all have among the highest accuracies (as well as positional baselines).

5 Fine-Tuning Experiments

Next, we investigate the effect fine-tuning has on UUAS decoding. Row 3 in Table 1 (NONE) indicates that fine-tuning does result in large improvements to UUAS decoding across most languages, often by margins as high as $\sim 30\%$. This shows that with an explicit parsing objective, attention heads are capable of serving as explanatory mechanisms for syntax; syntactic structure can be made to be transparently stored in the heads, in a manner that does not require additional probe fitting or parameterized transformation to extract.

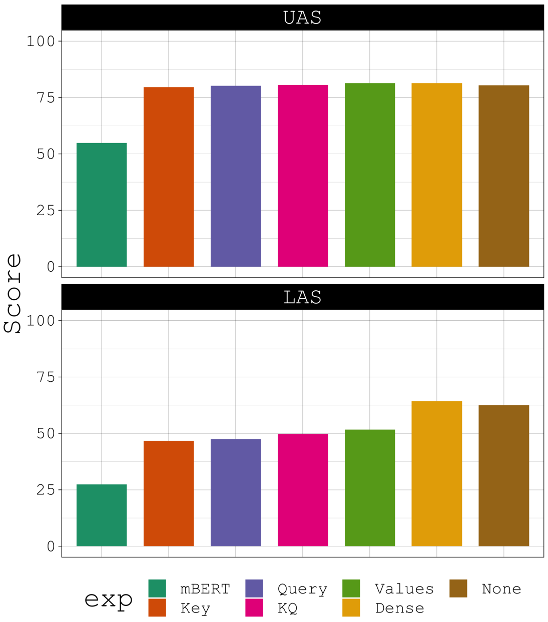

Figure 4: Mean UAS and LAS when evaluating different models on language-specific treebanks (Korean excluded due to annotation differences). MBERT refers to models where the entire mBERT network is frozen as input to the parser.

Given that we do manage to decode reasonable syntactic trees, we can then refine our question — what components are capable of learning these trees? One obvious candidate is the key/query component pair, given that attention weights are a scaled softmax of a composition of the two. Figure 3 (top) shows the difference between pretrained

UUAS and fine-tuned UUAS per layer, across models and languages. Interestingly, the best parsing accuracies do not appear to vary much depending on what component is frozen. We do see a clear trend, however, in that decoding the attention patterns of the fine-tuned model typically yields better UUAS than the pretrained model, particularly in the highest layers. Indeed, the lowest layer at which fine-tuning appears to improve decoding is layer 7. This implies that, regardless of which component remains frozen, the parameters facing any sort of significant and positive update tend to be those appearing towards the higher-end of the network, closer to the output.

For the frozen components, the best improvements in UUAS are seen at the final layer in VALUE, which is also the only model that shows consistent improvement, as well as the highest average improvement in mean scores[4] for the last few layers. Perhaps most interestingly, the mean UUAS (Figure 3 (bottom)) for our "attentive" components – keys, queries, and their combination – does not appear to have improved by much after fine-tuning. In contrast, the maximum does show considerable improvement; this seems to imply that although all components appear to be more or less equally capable of learning decodable heads, the attentive components, when fine-tuned, appear to sharpen fewer heads.

Note that the only difference between keys and queries in an attention mechanism is that keys are transposed to index attention from/to appropriately. Surprisingly, KEY and QUERY appear to act somewhat differently, with QUERY being almost uniformly better than KEY with the best heads, whilst KEY is slightly better with averages, implying distinctions in how both store information. Furthermore, allowing both keys and queries seems to result in an interesting contradiction – the ultimate layer, which has reasonable maximums and averages for both KEY and QUERY, now seems to show a UUAS drop almost uniformly. This is also true for the completely unfrozen encoder.

Supervised Parsing In addition to decoding trees from attention matrices, we also measure supervised UAS/LAS on a held-out test set.[5] Based on Figure 4, it is apparent that all settings result in generally the same UAS. This is somewhat expected; Lauscher et al. (2020) see better results on parsing with the entire encoder frozen, implying that the task is easy enough for a biaffine parser to learn, given frozen mBERT representations.[6] The LAS distinction is, however, rather interesting: there is a marked difference between how important the dense layers are, as opposed to the attentive components. This is likely not reflected in our UUAS probe as, strictly speaking, labelling arcs is not equivalent to searching for structure in sentences, but more akin to classifying pre-identified structures. We also note that DENSE appears to be better than NONE on average, implying that non-dense components might actually be hurting labelling capacity.

In brief, consolidating the two sets of results above, we can draw three interesting conclusions about the components:

1. **Value** vectors are best aligned with syntactic dependencies; this is reflected both in the best head at the upper layers, and the average score across all heads.
2. **Dense** layers appear to have moderate informative capacity, but appear to have the best learning capacity for the task of arc labelling.
3. Perhaps most surprisingly, **Key** and **Query** vectors do not appear to make any outstanding contributions, save for sharpening a smaller subset of heads.

Our last result is especially surprising for UUAS decoding. Keys and queries, fundamentally, combine to form the attention weight matrix, which is precisely what we use to decode trees. One would expect that allowing these components to learn from labelled syntax would result in the best improvements to decoding, but all three have surprisingly negligible mean improvements. This indicates that we need to further improve our understanding of how attentive structure and weighting really works.

Cross-linguistic observations We notice no clear cross-linguistic trends here across different component sets; however, certain languages do stand out as being particularly hard to decode from the fine-tuned parser. These include Japanese, Korean, Chinese, French and Turkish. For the first three, we hypothesise that tokenization clashes with

---

[4] The inner average is over all heads; the outer is over all languages.

[5] Note that the test set in our scenario is from the actual, non-parallel language treebank; as such, we left Korean out of this comparison due to annotation differences.

[6] Due to training on concatenated PUD sets, however, our results are not directly comparable/

mBERT's internal representations may play a role. Indeed, as we hypothesized in Section 3.2, it could be the case that the composition of CJK characters into gold tokens for Chinese and Japanese may degrade the representations (and their corresponding attention) therein. Furthermore, for Japanese and Korean specifically, it has been observed that tokenization strategies employed by different treebanks could drastically influence the conclusions one may draw about their inherent hierarchical structure (Kulmizev et al., 2020). Turkish and French are admittedly more difficult to diagnose. Note, however, that we fine-tuned our model on a concatenation of all PUD treebanks. As such, any deviation from PUD's annotation norms is therefore likely to be heavily penalised, by virtue of signal from other languages drowning out these differences.

6 Conclusion

In this study, we revisited the prospect of decoding dependency trees from the self-attention patterns of Transformer-based language models. We elected to extend our experiments to 18 languages in order to gain better insight about how tree decoding accuracy might be affected in the face of (modest) typological diversity. Surprisingly, across all languages, we were able to decode dependency trees from attention patterns more accurately than an adjacent-linking baseline, implying that some structure was indeed being tracked by the mechanism. In looking at specific relation types, we corroborated previous studies in showing that particular layer-head combinations tracked the same relation with regularity across languages, despite typological differences concerning word order, etc.

In investigating the extent to which attention can be guided to properly capture structural relations between input words, we fine-tuned mBERT as input to a dependency parser. This, we found, yielded large improvements over the pretrained attention patterns in terms of decoding accuracy, demonstrating that the attention mechanism was learning to represent the structural objective of the parser. In addition to fine-tuning the entire mBERT network, we conducted a series of experiments, wherein we updated only select components of model and left the remainder frozen. Most surprisingly, we observed that the Transformer parameters designed for composing the attention matrix, K and Q, were only modestly capable of guiding the attention towards resembling the dependency structure. In contrast, it was the Value (V) parameters, which are used for computing a weighted sum over the KQ-produced attention, that yielded the most faithful representations of the linguistic structure via attention.

Though prior work (Kovaleva et al., 2019; Zhao and Bethard, 2020) seems to indicate that there is a lack of a substantial change in attention patterns after fine-tuning on syntax- and semantics-oriented classification tasks, the opposite effect has been observed with fine-tuning on negation scope resolution, where a more explanatory attention mechanism can be induced (Htut et al., 2019). Our results are similar to the latter, and we demonstrate that given explicit syntactic annotation, attention weights do end up storing more transparently decodable structure. It is, however, still unclear which sets of transformer parameters are best suited for learning this information and storing it in the form of attention.

Acknowledgements

Our experiments were run on resources provided by UNINETT Sigma2 - the National Infrastructure for High Performance Computing and Data Storage in Norway, under the NeIC-NLPL umbrella. Mostafa and Anders were funded by a Google Focused Research Award. We would like to thank Daniel Dakota and Ali Basirat for some fruitful discussions and the anonymous reviewers for their excellent feedback.

Extractive Summarization Considering Discourse and Coreference Relations based on Heterogeneous Graph

Abstract

Modeling the relations between text spans in a document is a crucial yet challenging problem for extractive summarization. Various kinds of relations exist among text spans of different granularity, such as discourse relations between elementary discourse units and coreference relations between phrase mentions. In this paper, we propose a heterogeneous graph based model for extractive summarization that incorporates both discourse and coreference relations. The heterogeneous graph contains three types of nodes, each corresponds to text spans of different granularity. Experimental results on a benchmark summarization dataset verify the effectiveness of our proposed method.

1 Introduction

Automatic summarization aims to condense the information of the input document into a shorter summary. The task has two main paradigms: extractive summarization and abstractive summarization. Generating summary sentences from scratch, abstractive summarizers can generate concise and flexible summaries. However, they also suffer from the problem of not being able to reproduce factual details correctly (See et al., 2017). On the other hand, extractive summarization aims to select salient text spans (mostly sentences) from the input document. Compared to abstractive summarizers, extractive summarizers have the advantage of being efficient and factually reliable. In this paper, we will focus on extractive summarization.

For extractive summarization, it is crucial to model the relations between text spans throughout the document. Between text spans of different granularity, there exist many different kinds of relations (Figure 1). For example, coreference relations exist between mention phrases of the same entity, and discourse relations exist between Elementary Discourse Units (EDUs) within a document. Due to its complex nature, modeling the various relations among text spans of a document remains an open challenge.

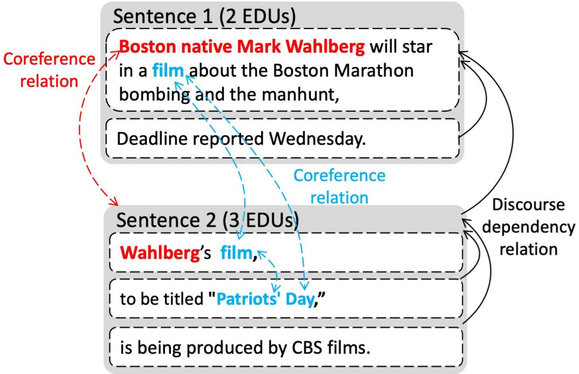

Figure 1: Relations among text spans of different granularity.

To capture inter-sentential relations, some recent works utilize recurrent neural networks (RNNs) or Transformer (Vaswani et al., 2017) based encoders on top of the acquired sentence representations (Cheng and Lapata, 2016; Nallapati et al., 2016; Liu and Lapata, 2019). However, empirical observations show that these sentence-level encoders do not bring much performance gain (Liu and Lapata, 2019). Graph structure is an intuitive way to model long-range dependencies among text spans throughout a document. Early works build connectivity graphs based on content similarity between sentences (Erkan and Radev, 2004; Mihalcea and Tarau, 2004). Some recent works incorporate discourse or coreference relations into the graph structure and utilize graph neural networks (GNNs) to obtain a high-level representation of text spans (Yasunaga et al., 2017; Xu and Durrett, 2019; Xu et al., 2020). Most of these works operate on homogeneous graphs with only one type of nodes, such as Approximate Discourse Graph (ADG) (Christensen et al., 2013) or Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) dependency graph. As illustrated in Figure 1, the various types of relations exist between text spans of different

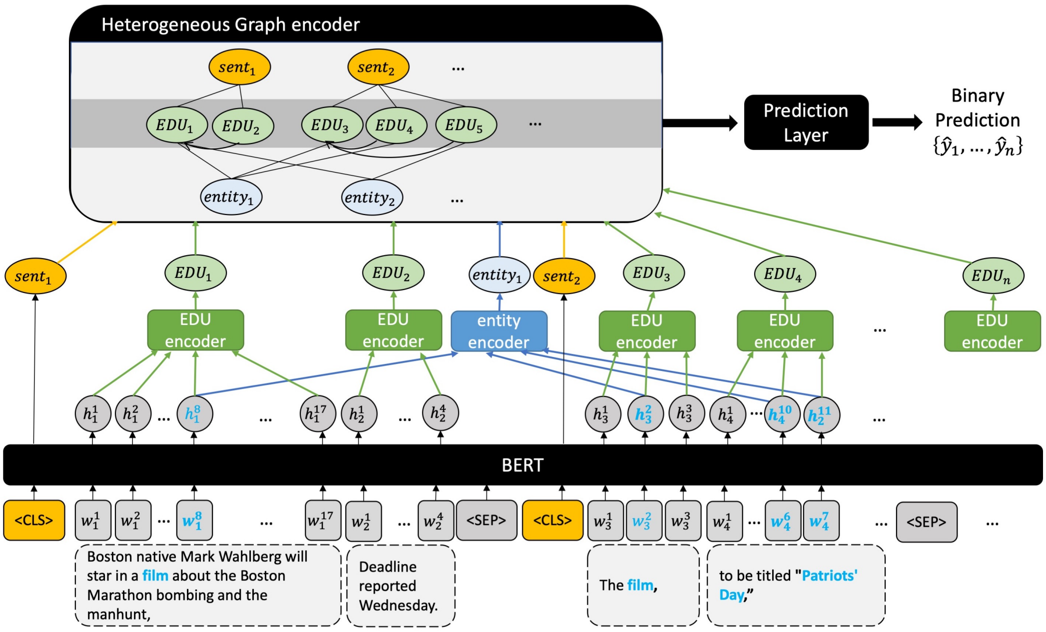

Figure 2: System overview.

granularity. Thus, homogeneous graphs may not be an ideal way to encode the various types of relations between text spans.

In this paper, we propose a novel heterogeneous graph based model for extractive summarization. Heterogeneous graphs are graphs that contain multiple node types and/or multiple edge types, which is in contrast to homogeneous graphs that have only one type of nodes and one type of edge. Heterogeneous graphs have been widely studied and applied to model data structures such as citation networks (Yu et al., 2012), recommendation systems (Dong et al., 2012), etc. In this work, we use heterogeneous graph to model the document structure with three types of nodes of different granularity: sentence nodes, EDU nodes, and entity nodes.

We also try to encode both discourse and coreference relations into the graph structure. We encode the discourse relations with the edges between EDU nodes. As for the coreference relations, edges between EDU nodes and entity nodes are introduced. Instead of extracting salient sentences like most existing extractive summarizers, our model extracts salient EDUs. To identify salient EDUs in a certain sentence, we add edges between sentence nodes and their constituent EDU nodes. To the best of our knowledge, we are the first to utilize heterogeneous graph to incorporate multiple types of relations simultaneously for extractive summarization.

2 Proposed Method

Given an input document D with n EDUs $\{d_1, d_2, ..., d_n\}$, we formulate extractive summarization as a sequence labeling problem. The model predicts a sequence of binary labels $Y = \{y_1, y_2, ..., y_n\}$, where $y_i = 1$ indicates that the i^{th} EDU should be included in the summary.

Figure 2 provides an overview of our proposed model. First, a BERT encoder is used to embed the input document D. With the EDU and entity encoders, we acquire the initial node representation of the heterogeneous graph. We then apply a heterogeneous graph encoder to obtain high-level node representations. Finally, we make predictions based on the EDU node representations.

2.1 Heterogeneous Graph Construction

We represent each input document D with a heterogeneous graph $G = \{V, E\}$, where V and E are the set of nodes and edges, respectively.

Given document D with m sentences $\{s_1, ..., s_m\}$, we first segment the sentences into n sub-sentential EDUs $\{d_1, ..., d_n\}$ and perform RST discourse parsing to identify the relations between the EDUs. In addition, we perform coreference resolution to identify the mentions and the coreference relations between them. The mentions in D are then clustered into k entities $\{e_1, ..., e_k\}$, with each entity e_i representing a cluster of mentions among which coreference relations holds.

The set of nodes $V = V_s \cup V_d \cup V_e$ consists of m

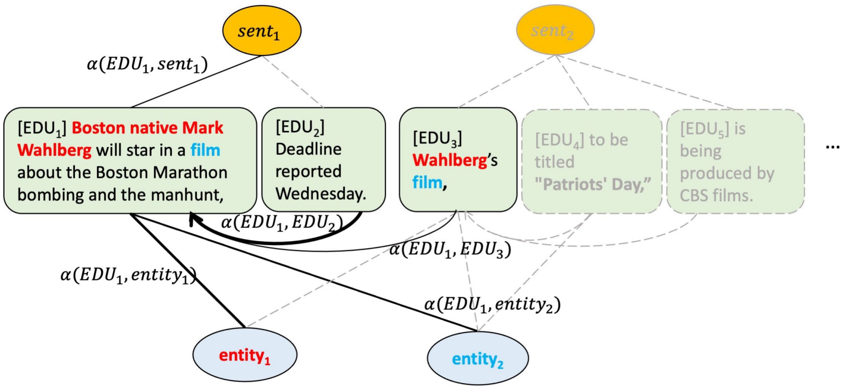

Figure 3: Graph attention mechanism.

sentence nodes V_s, n EDU nodes V_d, and k entity nodes V_e. There are three types of edges in E. First, we use edges between EDU nodes to represent the discourse structure of the document. Similar to Xu et al. (2020), we derived the discourse dependency links between EDU nodes based on the RST tree of the document. The discourse dependency links are directional, which capture the dependency relations going from satellite to nucleus EDUs. Second, we use edges between EDU nodes and entity nodes to embed the coreference relations. If EDU d_i contains a mention of entity e_j, then we add an undirected edge (d_i, e_j) to E. In this way, each entity indirectly connects all EDUs with mentions of the entity. Third, we also link each sentence node to its constituent EDU nodes undirectionally.

The proposed heterogeneous document graph enables us to simultaneously model various relations between different sizes of text spans: sentence, EDU, entity phrase efficiently.

2.2 Graph Node Initialization

Following the settings in Liu and Lapata (2019), we utilize pretrained BERT (Devlin et al., 2019) to encode the input document D. We insert the ⟨CLS⟩ and ⟨SEP⟩ special tokens to the beginning and the end of each sentence s_i, respectively. With the BERT output vectors, we acquire the initial representations of each node in V as follows:

Sentence Representations

For each sentence node s_i, we take the BERT output vector of the ⟨CLS⟩ token before s_i as the sentence node representation $sent_i$.

EDU Representations

We use a self-attention based EDU encoder to encode each EDU node d_i. Given an EDU d_i with tokens $\{w_i^j\}$, we obtain its node representation EDU_i by taking self-attention on the BERT output vectors $\{h_i^j\}$ of the tokens:

$$\alpha_{ij} = v_2 ReLU(W_1 h_i^j + b_1) \tag{1}$$

$$a_{ij} = softmax_j(\alpha_{i1}, \alpha_{i2}, ...) \tag{2}$$

$$EDU_i = \sum_j a_{ij} h_i^j \tag{3}$$

Entity Representations

The structure of the entity encoder is identical to the EDU encoder. For each entity e_i, we consider all mentions of it. By taking self-attention among the BERT output vectors which correspond to tokens of these mentions, we can acquire the entity representation $entity_i$.

2.3 Heterogeneous Graph Encoder

We initialize the representation of each node in G with the sentence representations ($sent_i$), EDU representations (EDU_i), and entity representations ($entity_i$) acquired in section 2.2.

We apply graph attention networks (GAT) (Veličković et al., 2018) to update the node representations in G. For each iteration, we update the representation h_i of node i with the representations of its neighbors $\{h_j\}$ based on the attention weights α_{ij}:

$$\alpha_{ij} = LeakyReLU(W_a[W_q h_i; W_k h_j]) \tag{4}$$

$$a_{ij} = softmax_j(\alpha_{i1}, \alpha_{i2}, ...) \tag{5}$$

$$h_i \leftarrow W_t(\sigma(\sum_j a_{ij} W_v h_j) + h_i) \tag{6}$$

An example of the graph attention mechanism is illustrated in Figure 3, where the subgraph around node EDU_1 is highlighted. EDU_1 has five neighbors: a sentence node ($sent_1$), two EDU nodes (EDU_2, EDU_3), and two entity nodes ($entity_1$, $entity_2$.) We first calculate the attention weights α across the five neighbors of EDU_1 using equation

4, and update the node representation of EDU_1 accordingly.

Although a single GAT network only considers the first-degree neighbors, we can obtain a higher-level representation for each node in G by updating the node representations for several iterations.

2.4 Prediction Layer

We feed the final representation of the EDU nodes (EDU_i) to the prediction layer with sigmoid activation to predict binary labels:

$$\hat{y}_i = \sigma(W_p EDU_i + b_p) \tag{7}$$

The training loss of the model is the binary cross-entropy loss against the oracle extraction labels.

3 Experiment

3.1 Dataset

We evaluated our proposed model on the benchmark CNN/DailyMail dataset (non-anonymized version) (Hermann et al., 2015). We used the standard dataset split, which contains 287,227 / 13,368 / 11,490 documents for training, validation, and test split, respectively.

We used the Stanford CoreNLP (Manning et al., 2014) to split sentences. Further, we used the RST discourse parser proposed by Ji and Eisenstein (2014) for both discourse segmentation and discourse parsing. For coreference resolution, we used the spanBERT-based (Joshi et al., 2020) version of the end-to-end coreference resolver proposed by Lee et al. (2017).

Since the CNN/DailyMail dataset only contains abstractive gold summaries, we have to construct oracle labels heuristically. We obtained the oracle labels on EDU-level with the heuristic algorithm based on ROUGE (Lin, 2004), similar to the one in Liu and Lapata (2019). For each document, we selected up to 5 EDUs.

3.2 Experimental Settings

We used the base model of Longformer (Beltagy et al., 2020) to encode the input document. The length of each document is truncated to 1024 BPEs. The hidden size of the EDU encoder and the entity encoder is 128. Based on the evaluation losses on the validation set, we set the number of iterations of the GAT layer to 3. Also, the number of attention heads is set to 8, with each head having a hidden size 64.

Model	R-1	R-2	R-L
LEAD-3	40.34	17.70	36.57
Oracle(sent)	52.59	31.24	48.87
Oracle(EDU)*	55.96	34.64	53.26
BanditSum (Dong et al., 2018)	41.50	18.70	37.60
NEUSUM (Zhou et al., 2018)	41.59	19.01	37.98
HIBERT (Zhang et al., 2019)	42.37	19.95	38.83
HSG (Wang et al., 2020)	42.95	19.76	39.23
BertSum (sent) (Liu and Lapata, 2019)	43.25	20.24	39.63
BertSum (EDU)*	42.73	20.03	40.16
DiscoBERT* (Xu et al., 2020)	**43.77**	**20.85**	40.67
Proposed*	43.61	20.81	**41.12**

Table 1: Results on the test set of CNN/DailyMail dataset. Models with * superscript are EDU-based extractive models.

During training, we used a batch size of 32. We used Adam optimizer with $\beta_1 = 0.9$ and $\beta_2 = 0.999$ and followed the learning rate scheduling in Vaswani et al. (2017) with warm-up of 4000 steps. All models are trained for 50000 steps. We selected the top-3 checkpoints based on the evaluation losses on the validation set and report the average scores of them on the test set.

3.3 Results and Analysis

Table 1 shows the results on CNN/DailyMail dataset. The first part contains the **LEAD-3** baseline and **Oracle** upper bounds. The second part of the table includes other sentence based extractive models, and the third part includes other EDU based extractive models. In the last row of the table, we present the evaluation scores of our proposed model.

As Table 1 shows, our proposed model outperforms the **BertSum(EDU)** baseline by a significant margin (0.88/0.78/0.96 on F_1 of R-1/R-2/R-L). Our proposed model also outperforms the **BertSum(sent)** model and other sentence based extractive summarization baseline models. The proposed model is comparable to the state-of-the-art EDU-extraction model **DiscoBERT** in R-1 and R-2 metrics, and outperforms it in R-L metrics. **DiscoBERT** incorporates a strict RST-based rule during both oracle label construction and post-processing stages to ensure discourse consistency. Since the purpose of this paper is to propose a heterogeneous graph based method for modeling text span relations, we will leave the question of discourse consistency to future work.

Ablation Study

We conduct an ablation study on the components of our proposed model (Table 3). First, we remove the RST dependency edges between EDU nodes (**-discourse**). Next, we remove the corefer-

EDUs with coreferent entity	Rank$_{\text{coref}}$	Rank$_{\text{w/o coref}}$	Oracle Label
Mexican state oil company Pemex said 45 workers were injured ...	1	2	1
... two of them are in serious condition	2	1	0
Kim was accused of stabbing U.S. ambassador Mark Lippert ...	1	3	1
Before Lippert was supposed to give a speech, the attacker slashed him in the face a jaw	3	1	0
Kim stabbed Lippert with a 10-inch knife	2	2	0

Table 2: Qualitative studies on CNN/DailyMail dataset.

Model	R-1 (ΔR-1)	R-2 (ΔR-2)	R-L (ΔR-L)
Proposed	43.61	20.67	40.95
- discourse	43.42(**-0.19**)	20.54(**-0.13**)	40.77(**-0.18**)
- coref	43.51(-0.10)	20.61(-0.06)	40.85(-0.10)
- sent	43.57(-0.04)	20.66(-0.01)	40.90(-0.05)

Table 3: Ablation studies on CNN/DailyMail dataset.

ential edges between EDU nodes and entity nodes (**-coref**). The results of the ablation study show that discourse information plays an important role in our proposed model, while adding coreference information also gives a gain in performance. We also try to remove the edges between sentence nodes and their constituent EDU nodes (**-sent**). However, linking the sentence and EDU nodes does not seem to have a significant impact on model performance.

Qualitative Analysis

We also conduct a qualitative analysis of the proposed model. The effectiveness of discourse relations is more straight-forward and widely studied in previous research. Thus, we focus on the analysis of the role of coreference information in our proposed summarization model.

In the heterogeneous document graph, EDUs containing the same entity phrase are indirectly connected through the node of the given entity. By analyzing the output of the full proposed model and the model without coreference information (**-coref**), we found that the models rank the importance of coreferent EDUs differently. Table 2 indicates a common pattern of the improved cases by incorporating coreference information. The table shows examples of coreferent EDUs and the ranking of their likelihood scores to be included in the summary. Comparing the EDU ranking of the full model (**Rank$_{\text{coref}}$**) and the model without coreference information (**Rank$_{\text{w/o coref}}$**), we argue that the model with coreference information is better in discriminating the important EDUs among all EDUs sharing the same entity.

4 Related Work

Graph based Summarization

Graph based summarization models have been broadly explored. Early works build connectivity document graphs based on inter-sentential similarity (Erkan and Radev, 2004; Mihalcea and Tarau, 2004). With the promising results of graph neural networks (GNNs)(Kipf and Welling, 2017; Veličković et al., 2018), some recent works utilize GNN to incorporate external knowledge into the model. For instance, Yasunaga et al. (2017) utilizes a sentence-level ADG graph to model discourse and coreference relations. Some works convert the RST tree of the input document into dependency form in either sentence or EDU level (Xu and Durrett, 2019; Xu et al., 2020). Most of these models operate on homogeneous graphs with only one type of node. One of the major disadvantages of homogeneous graphs is that they can only embed one relation type in a single graph, since there is only one type of node and one type of edge.

Fewer summarization models operate on heterogeneous graphs with different types of nodes. Wei (2012) introduces a heterogeneous graph of sentence, word, and topic nodes, and Wang et al. (2020) also utilizes a heterogeneous graph of sentence and word nodes. However, neither of the above works incorporates external knowledge into the graph.

EDU based Extractive Summarization

Li et al. (2016) illustrates the potential of using EDU as the extraction unit for summarization. Xu et al. (2020) also introduces an end-to-end EDU based extractive summarization model. By using a heuristic based on RST dependency structure, they enhanced the grammaticality and discourse consistency of the extracted summary.

5 Conclusion

In this paper, we proposed a novel heterogeneous graph based model for extractive summarization. By introducing nodes of different granularity, the heterogeneous graph has the capacity to embed various types of relations between text spans. Experiments on CNN/DailyMail benchmark dataset illustrated the effectiveness of our proposed method.

Abstract

We introduce a Content-based Document Alignment approach (CDA), an efficient method to align multilingual web documents based on content in creating parallel training data for machine translation (MT) systems operating at the industrial level. CDA works in two steps: (i) projecting documents of a web domain to a shared multilingual space; then (ii) aligning them based on the similarity of their representations in such space. We leverage lexical translation models to build vector representations using TF×IDF. CDA achieves performance comparable with state-of-the-art systems in the WMT-16 Bilingual Document Alignment Shared Task benchmark while operating in multilingual space. Besides, we created two web-scale datasets to examine the robustness of CDA in an industrial setting involving up to 28 languages and millions of documents. The experiments show that CDA is robust, cost-effective, and is significantly superior in (i) processing large and noisy web data and (ii) scaling to new and low-resourced languages.

1 Introduction

Online machine translation (MT) services require industrial-scale training data, i.e., significantly large and high-quality parallel sentences, to build accurate models. Exploiting the web for multilingual content has become a usual strategy in collecting large-scale parallel sentences for MT (Uszkoreit et al., 2010; Smith et al., 2013; Buck and Koehn, 2016a). Structural Translation Recognition for Acquiring Natural Data (STRAND) (Resnik and Smith, 2003) is a standard pipeline to extract parallel data from the web, consisting in three steps: (i) bilingual document alignment for an input set of documents, (ii) sentence alignment for each aligned document pair, and (iii) sentence filtering for non-translation or boilerplate cleaning. The first step of identifying bilingual documents is technically challenging and made more complicated by the presence of large and noisy documents from web data.

In the WMT-16 Bilingual Document Alignment Shared Task (WMT16-BDAST), two standard approaches for identifying parallel pages[1] were studied: 1) URL matching heuristic (Smith et al., 2013) as a baseline and 2) content similarity as a solution to maximize the performance in identifying parallel documents. The benchmark on English-French document alignment task shows that the best top-1 recall (R@1) for each approach are 59.8% and 89.1%, respectively, as evaluated on the test set (Buck and Koehn, 2016a,b). The results, albeit conducted within English-French setting, indicate that leveraging document content can lead to a significant increase, up to 30 percent points in recall, and contributes ∼50% novel bilingual document pairs.

The URL matching heuristic approach, named URL, identifies parallel pages using language identifiers, typically from ISO 639, annotated in the addresses. Pages, or web-documents, in different languages from a domain are aligned if their URLs are matchable after their language-identifier being removed (Smith et al., 2013). The strategy can identify a candidate at a decent cost by comparing two URLs without significant preprocessing needed. For example, the following URLs are a match: `xyz.ca/index.htm` and `xyz.ca/fr/index.htm` after removing "`fr/`" from the second URL. On the contrary, cost is the major issue when comparing content as it often requires language-specific processing and sophisticated modelings for cross-language normalization and alignment. The problem becomes even more challenging when dealing with web data and for

---

[1] "page" and "document" interchangeably refer to the content of a web page.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3053–3061
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

low-resourced languages.

We optimize the cost for the latter approach to enable its application at scale. Specifically, we design CDA to project multilingual documents to a shared multilingual space for direct similarity measurement. Therefore, we can run the STRAND pipeline for multiple languages at once to keep the pre-processing cost *monotonic* with respect to the number of languages and documents. In particular, we design CDA with two key objectives: i) minimal data processing cost and ii) fast scaling to new languages. The latter is also crucial to the language expansion in online MT services. Our contribution is three-fold:

- We present an optimized, efficient, and scalable framework that can perform multilingual document alignment at state-of-the-art performance in one go.
- To facilitate the development and evaluation, we created two web-scale datasets, which are much larger and have many more languages than what is currently publicly available.
- We study the contribution of CDA in multiple applications involving parallel sentence extraction for MT and mutual complement between URL and CDA.

We tested CDA with multiple large-scale datasets of web documents. We also studied the applications of CDA within an industrial setting, including (i) extracting more and better parallel sentences from an extremely large-scale dataset, (ii) producing better MT models, and (iii) improving yield, measured by the amount of extracted parallel content, for both URL and CDA in the STRAND pipeline. The experimental results show that, despite its minimality, CDA (i) is on par with the top systems from WMT16-BDAST, which use expensive bilingual resources, and (ii) can double the amount of parallel data extracted by previous URL-based approaches. Most importantly, we show that CDA provides robust performance when dealing with millions of documents and processing up to 28 languages, including low-resourced languages.

In the remainder of this paper, we summarize the previous work regarding document alignment in Section 2. We then describe the proposed system and our experiments in sections 3 and 4, respectively. Finally, we derive the conclusions of the paper in Section 5.

2 Related Work

Aligning multilingual documents is the key required processing in most multilingual text processing pipelines, including cross-lingual information retrieval (Steinberger et al., 2002; Pouliquen et al., 2004; Vulic and Moens, 2015; Jiang et al., 2020) and parallel data extraction. In the context of creating parallel training data for MT, the problem has been studied in the literature for comparable corpora (Munteanu et al., 2004; Vu et al., 2009; Pal et al., 2014) and web-structured parallel data extraction (Resnik, 1999; Uszkoreit et al., 2010; Buck and Koehn, 2016a). We focus on the latter in this paper.

WMT-16 Bilingual Document Alignment Shared Task is a recent shared-task focusing on identifying bilingual documents from crawled websites (Buck and Koehn, 2016b). The top 3 systems are **YODA** (Dara and Lin, 2016), **NOVALINCS** (Gomes and Pereira Lopes, 2016), and **UEDIN1 COSINE** (Buck and Koehn, 2016b). The first two require costly features, such as (i) n-gram comparison after translating all non-English text into English (Dara and Lin, 2016), and (ii) phrase-table of statistical MT (SMT) as a dictionary (Gomes and Pereira Lopes, 2016). **UEDIN1 COSINE** (Buck and Koehn, 2016b), on the other hand, only uses TF × IDF-weighted with Cosine similarity. Interestingly, this method performs surprisingly well even without French-to-English translations, dropping just 3.4% in recall, from 93.7% to 90.3%. Though the finding can be due to the English and French lexicons' overlap, it suggests that TF × IDF with proper normalization is useful to compare document representations from sub-domains. Our proposed method exploits this aspect.

Given the advent of deep neural network modeling, document embeddings are among the main interests in general NLP applications (Le and Mikolov, 2014; Cer et al., 2018; El-Kishky and Guzmán, 2020). This line of research, however, is *not* technically related to our problem setting. Specifically, the cost to run a neural inference over a web-scale setting is prohibitively high, e.g., processing a dataset of several billion pages from CommonCrawl[2] is not feasible. To have an idea, the Cloud Translation[3] cost to translate a webpage having 20,000 characters is \$0.4 as of Jan 2021.

3 Proposed System

We describe our method to identify parallel pages from a web domain. Specifically, pages in different languages are projected to a shared space, where their similarity can be measured.

Problem Definition Let $D = \{d_1, d_2, \ldots, d_n\}$ be the n pages from a domain, each page d_i is described by its content c_i in language L_i. The problem is to identify all (d_i, d_j) of different languages, $L_i \neq L_j$, and c_i and c_j are translational equivalent.

Multilingual Space Let $\mathcal{L} = \{L_1, L_2, \ldots\}$ be the set of languages found in D and let D_i be the set of documents in L_i. Thus, $D = \bigcup_{L_i \in \mathcal{L}} D_i$, where each D_i is associated with a lexicon V_i. Without loss of generality, we project documents from two languages, L_α and L_β, into a common space as follows. We first define alignment between two lexicons V_α and V_β as:

$$\begin{aligned}\mathcal{A} = \big\{ &(a, b) : a \in V_\alpha, b \in V_\beta, \\ &P_{\alpha\to\beta}(a, b) + P_{\beta\to\alpha}(b, a) \\ &\geq P_{\alpha\to\beta}(a, w) + P_{\beta\to\alpha}(w, a), \forall w \in V_\beta \big\},\end{aligned}$$

where $P_{\alpha\to\beta}$ and $P_{\beta\to\alpha}$ are lexical translation models from L_α to L_β, and vice versa[4]. It should be noted that $\mathcal{A}$ defines a common space, $\mathbb{R}^{|\mathcal{A}|}$, where the dimensions are all word pairs. However, we can simplify the approach by mapping all languages in the space of a pivot language, i.e., α. Thus, we define $\Pi_\alpha : D_\beta \longrightarrow \mathbb{R}^{|V_\alpha|}$ that maps documents $d_\beta \in D_\beta$ into the same space of D_α, as:

$$\begin{aligned}\Pi_\alpha(d_\beta) &= \Pi_\alpha\Big(w_1, w_2, \ldots, w_{|d_\beta|}\Big) \\ &= \vec{x} = \big(x_1, x_2, \ldots, x_{|V_\alpha|}\big) \qquad (1)\end{aligned}$$

We define a lexical mapping for document d_β as $M(d_\beta) = d_{\beta\to\alpha} = \{w'_1, ..., w'_{|d_{\beta\to\alpha}|} | (w_i, w'_j) \in \mathcal{A}\}$, which maps d_β into language α. Similar, we denote the mapping for a document collection D_β as $D_{\beta\to\alpha} = \{M(d_\beta) : \forall d_\beta \in D_\beta\}$. Finally, we compute the TF×IDF representation of d_β as follows, $\forall w_i \in V_\alpha$:

- TF(w_i) = number of occurrences of w_i in $d_{\beta\to\alpha}$; and
- IDF$(w_i) = \log\Big(1 + \frac{|D_{\beta\to\alpha}|}{1+\#(w_i, D_{\beta\to\alpha})}\Big)$, where $\#(w, D)$ returns the number of documents in D containing w.

We compute x_i in Eq. 1 using TF(w_i) × IDF(w_i).

Aligning Multilingual Documents Two documents are considered a good pair if their representations are similar, according to a similarity threshold t. We compute the similarity between d_i and d_j as the dot-product between, $v_i \cdot v_j \in [0..1]$ (we normalized the vector representations with ℓ_2). In practice, we use English to build the multilingual space as it is the dominant language on the Internet and in most multilingual websites.

4 Experiments

We examine the efficacy of CDA in this section. First, we describe (i) the pipeline setup for the experiments and (ii) our effort in creating suitable benchmark data and selecting relevant resources in Section 4.1, and Section 4.2, respectively. We then address the following performance aspects of CDA:

1. The performance in multilingual document alignment.
2. The impact of CDA, compared to URL, in an end-to-end STRAND pipeline.
3. The by-product applications of CDA in identifying (i) novel language identifiers beyond ISO 639 for URL and (ii) web-domains containing multilingual data that are not detectable using language identifiers.
4. The cost required to enable the support to a new language.

4.1 Pipeline Setup

Figure 1 depicts the STRAND pipeline for our experiments.

- The **input** is constituted by web documents of multiple domains. The **output** is a set of parallel sentence pairs extracted from the pipeline. Each document has a web address and a raw HTML source.
- The **pre-processing** step groups input documents by domain to create data for document alignment step using URL and CDA. For CDA, additionally, it extracts the

---

[4] It can be easily shown that the proposed aligned is symmetric, i.e., the other condition $P_{\alpha\to\beta}(a, b) + P_{\beta\to\alpha}(b, a) \geq P_{\alpha\to\beta}(w, b) + P_{\beta\to\alpha}(b, w), \forall w \in V_\alpha$ holds.

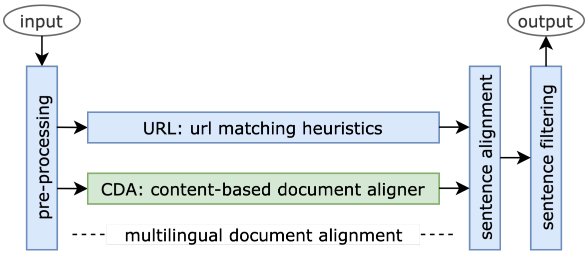

Figure 1: A STRAND pipeline that uses URL to align document and CDA as a replacement.

text content from HTML structure, using the following tags: `title, h1..h6, label, blockquote, dd, dt, p, pre, q, div`. This helps remove boilerplate effectively from being considered in the calculation. We use Python's `langid` package to identify the language of a page.

- **Document alignment** is performed by either URL or CDA. For URL, we use a similar set of language identifiers from BDAST's baseline[5].
- For each aligned document pair, the **sentence alignment** step aligns text segments, called sentence pair candidates, of the aligned pages based on the DOM structure (Smith et al., 2013).
- Finally, the **sentence filtering** step removes low-quality pairs (Xu and Koehn, 2017; Sánchez-Cartagena et al., 2018) or duplications. The filter we used in this experiment has approximately 90% F1 score for each language pair.

4.2 Dataset and Resource

We describe the datasets and resources used in the experiments.

4.2.1 Dataset

We collect and create the following datasets to study CDA performance in (i) matching parallel content, (ii) handling large datasets, and (iii) extending its use to new languages.

WMT-16 Shared Task First, we use the benchmark dataset provided for WMT-16 Shared Task on Bilingual Document Alignment. We evaluate and compare CDA with other English–French document alignment methods on the BDAST's training set. The dataset consists of 348,858 and 225,043 English and French documents from 49 web-domains, respectively. Each document has a web address and a clean content. Besides, French documents are translated into English using a standard SMT model. This translation is to study the potential upper-bound performance when having full translations. An alignment candidate has one document from each language, English or French, from the same domain. Thus, there are more than 4.2e9 possible alignments between the documents. The golden data has 1,624 pairs provided by WMT16-BDAST. In this set, the number of labeled alignments per domain ranges from 4 (e.g., `www.eohu.ca`) to 236 (e.g., `tsb.gc.ca`). The pairs generated by a system are first filtered by 1-1 rule: each document should participate in at most one alignment. A system is evaluated based on the recall achieved on these 1,624 pairs.

WMT-16 Deep Crawl The previous benchmark has two limitations. First, the size of the dataset is relatively small compared to a typical web-scale setting[6]. Second, the choice of English–French is not representative of the ultimate goal — finding more and better parallel data to enable MT in low-resourced languages. English–French has been the most studied pair in MT task. Besides, their lexicons are also highly overlapped (Lewis, 2009).

We address this problem, creating a larger dataset of more than 14MM pages using the same set of 49 domains. Specifically, we used these domains and URLs as seeds and recursively downloaded all reachable pages from those seeds. We did not download pages that link to external domains. This exercise resulted in a dataset consisting of 8.7MM and 5.5MM pages for English and 28 other languages. These languages include: Arabic, Bulgarian, Chinese Simplified, Chinese Traditional, Croatian, Czech, Danish, Dutch, English, Estonian, Finnish, French, German, Hebrew, Hungarian, Indonesian, Italian, Japanese, Korean, Malay, Norwegian, Polish, Portuguese, Russian, Slovak, Spanish, Swedish, Thai, and Turkish.

CommonCrawl Sextet Previous datasets share the same domains that are heavily biased toward French content (see Table 3). We leverage a monthly crawl from CommonCrawl, specifically

---

[5] https://github.com/christianbuck/wmt16-document-alignment-task/blob/master/languagestripper.py

[6] A typical multilingual domain can have thousands to millions of pages; e.g. `nato.int` and `microsoft.com` have 3e5 and 38e6 pages, respectively, indexed by Google[7].

Dataset	#Dom.	#EN-docs	#XX-docs	#$\mathcal{L}$
WMT-16 Shared Task	49	348,858	225,043	En+Fr
WMT-16 Deep Crawl	49	8.7MM	5.5MM	En+28
CommonCrawl Sextet	662	17.6MM	4.1MM	En+6

Table 1: Summary of Benchmark Datasets for Document Alignment Task. Each dataset is described by the number of web-domains (#Dom.), English documents (#EN-docs), non-English documents (#XX-docs), and languages (#$\mathcal{L}$).

`CC-MAIN-2017-17`[8], to create a better distribution dataset to validate CDA. We select pages from the crawl having pages in Chinese, Czech, Italian, Japanese, Russian, and Turkish. We only keep the following top-level domains: `.cn`, `.tw`, `.cz`, `.it`, `.jp`, `.ru`, `.tr`, `.edu`, `.gov`, and `.org`. The process results in a dataset of 600+ domains with 17.6MM and 4.1MM pages in English and six selected languages. Table 1 summarizes the datasets considered in our experiments.

4.2.2 Resource

Lexical translation dictionaries are the significant resource required in our proposed method to support a new language pair. Our experiments used the lexical translation dictionaries created by methods introduced for traditional SMT (Brown et al., 1993) and neural-based MT (Lample et al., 2018).

In particular, we use IBM-1 models for popular languages that have sufficient parallel data from general domains (Koehn, 2005). We use the GIZA++ toolkit (Och and Ney, 2003) to create IBM-1 models. Collecting such parallel data for the low-resourced languages is generally challenging. We instead leverage the advances in multilingual embeddings from the MUSE project[9] (Lample et al., 2018). We create translation probability between two words by their normalized embedding similarity score.

4.3 Bilingual Document Alignment Results

We evaluate the performance of CDA under the WMT-16 Shared Task benchmark. We conduct experiments on both settings, using the original text and using full translations. The latter setting allows us to understand the possible benefit of the expensive step, full document translation. Besides, the construction of V_{L_i} is crucial to the distinction of the representations. Therefore, we examine the impact of the vocabulary size of V_{L_i} to the alignment result. Specifically, we construct V_{L_i} by selecting the top frequent tokens after removing stop-words and the first k frequent tokens. We empirically set k to be 100. We experiment with three different sizes for V_{L_i}: 2,000, 10,000, and 20,000. Finally, we compare the results of CDA with the baseline URL and the top-3 systems of the WMT-16 Bilingual Document Alignment Shared Task. The evaluation metric is the percentage of the 1,624 golden pairs found in the top-1 alignment for each English document. Table 2 shows the result.

baseline: URL	67.9	
content-based systems	**align w. org. text**	**align w. trans. text**
YODA (Dara and Lin, 2016)	n/a	**93.71**
NOVALINCS (Gomes and Pereira Lopes, 2016)	90.50	n/a
UEDIN1 COSINE (Buck and Koehn, 2016b)	90.25†	93.65†
CDA: |V|=2,000	87.17	90.95
CDA: |V|=10,000	**90.40**	91.02
CDA: |V|=20,000	90.33	89.90

[†] *average performance of valid and test splits*

Table 2: Comparison of the baseline URL, top-3 performing systems from WMT16-BDAST and CDA under different settings of vocabulary size, using either original text (original documents in English and French) or translated text (documents in English and the English translations of documents in French)

For alignments using original text, the results indicate that CDA achieves similar performance with the state-of-the-art methods from BDAST. The result shows the efficacy of the proposed alignment method. The results also show that the vocabulary size, or the vector representations' size, impacts the performance. $|V| = 10,000$ yields the best result among the three settings. Second, even though using full translation is better, the performance gains are negligible with respect to the processing cost required for building the MT models and translating all the data into an anchor language. Since CDA does not exploit bi-gram features, its performance is relatively lower, up to 3%, compared to the state of the art. In short, the result suggests an optimal configuration for CDA with a vocabulary size of 10,000.

4.4 Multilingual Document Alignment Results

It was showed in WMT16-BDAST that content-based methods could add 60% more English–French document pairs compared to URL. This section aims to verify this in a multilingual setting, mainly when operating with a significantly higher number of languages and domains using WMT-16 Deep Crawl and CommonCrawl Sextet, respectively.

On WMT-16 Deep Crawl Table 3 shows the number of parallel documents and sentences extracted by an end-to-end STRAND pipeline, after filtering and duplication removal, described in Section 4.1. The result shows that CDA contributes an extra of 53%, 75%, and 195% in *clean* parallel sentences compared to URL for French alone, and when French is and is not considered, in this more extensive and more realistic setting, respectively. It also suggests that CDA is effective and can significantly increase the number of parallel sentences extracted for low-resourced languages. Finally, the result indicates that our proposed method is robust in a multilingual setting.

On CommonCrawl Sextet Table 4 shows the result in English parallel tokens extracted from the pipeline using URL and CDA in the document alignment step. The result shows similar gains as in the previous experiment, except for Czech — increasing $7\times$ more parallel tokens. Our post-hoc analysis discovers non-standard language identifiers missing for URL processing, e.g., `ces` or `cesky`.

To confirm the study, we randomly selected 1,320 English–Turkish document pairs identified by CDA for human verification since we do not have annotated data. The outcome indicates that the accuracy of the document pairs is at 91.5%. Information on these datasets is described here: `github.com/alexa/wqa_dataset`.

4.5 Industrial Benchmarks

We conducted multiple internal experiments to examine the performance of CDA over URL under an industrial setting. Specifically, we focus on three application aspects of CDA: (i) robustness, (ii) identifying non-standard language identifiers for URL, (iii) identifying multilingual web-domains. Due to business security reasons, we do not name the specific languages considered in this study. We do not provide some details of the experiment setting, which are not critical to illustrate our findings.

Language	# Document Pairs		# Sentence Pairs		
	URL	CDA	URL	CDA	CDA\URL
Arabic	3,266	2,896	36,262	39,590	24,065
Bulgarian	1,184	1,070	9,292	1,748	1,359
Chinese-S	2,805	2,160	30,519	27,666	13,289

Turkish	1,057	2,041	9,598	18,412	10,789
All	159,343	222,283	3,134K	4,761K	2,349K
All\French	43,672	78,311	481,333	1,193K	937,683

Table 3: Comparison of yields, number of clean document pairs and sentence pairs, produced via URL and CDA on WMT-16 Deep Crawl. Column **CDA\ URL** reports the number of novel sentence pairs exclusively extracted via CDA.

4.5.1 Robustness Benchmark

We ran the STRAND pipeline end-to-end to extract parallel sentence pairs from document pairs identified by URL and CDA replacing URL. We employ a crawl dataset larger than a typical monthly crawl archive from CommonCrawl. The dataset is also considered densely multilingual. We target six mid-tier languages that are *not* in the top-10 high-resourced languages. It shows that CDA can increase additional 27% English parallel tokens over the selected languages.

Automatic Evaluation We first study the quality of the extracted parallel data, especially the addition of 27% produced by CDA, using automatic MT evaluation. Specifically, for each language, we compare the translation models trained by two equal-sized parallel sentence pairs sampled from the exclusive pairs extracted by URL and CDA individually, i.e., after removing common pairs extracted by both methods. We train vanilla

Lang.	#Dom.	#EN-docs	#XX-docs	$\frac{\lvert CDA\rvert}{\lvert URL\rvert}$
Turkish	37	1,434,923	71,034	1.77
Czech	69	2,333,914	831,072	7.07
Japanese	84	2,097,664	757,872	1.90
Russian	125	2,918,594	1,163,258	1.09
Italian	239	5,770,684	1,112,868	1.05
Chinese	108	3,061,782	207,211	0.99
All	662	17,617,561	4,143,315	1.24

Table 4: Parallel English tokens extracted by CDA and URL on CommonCrawl Sextet

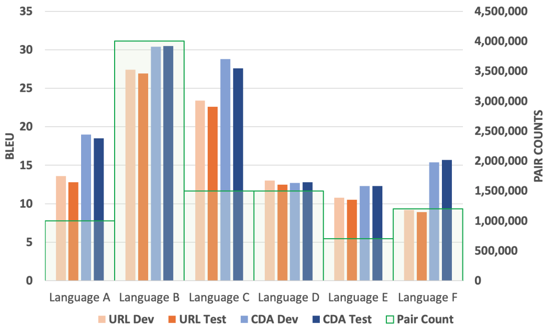

Figure 2: Automatic evaluation of MT models trained by the same amount of pairs sampled from pairs extracted exclusively by either URL or CDA. The primary y-axis (left) indicates the BLEU score, while the secondary y-axis (right) indicates the number of parallel pairs.

`seq2seq` models using Sockeye[10]. We report the MT performance in BLEU scores on our MT evaluation data in Figure 2. The results indicate that the models trained using novel sentence pairs extracted by CDA consistently give better translation models.

Human Evaluation We had linguists manually verify the extracted parallel sentence pairs produced by the pipeline using either URL or CDA. Specifically, we randomly sampled 500 sentence pairs extracted from each pipeline using either URL and CDA for Language A and Language E for human evaluation (we do not remove the common pairs in this evaluation). The selection of these languages is based on their low performance reported during the automatic evaluation in Figure 2. Table 5 shows the result in terms of precision and recall. In general, we find that the quality of pairs produced by both methods is typically comparable. The result also confirms the robustness of our proposed CDA under stress evaluations.

	URL	CDA
Language A	P=96, R=87	P=98, R=89
Language E	P=94 ,R=81	P=92, R=90

Table 5: Human verification for parallel sentence pairs extracted from URL and CDA in precision (P) and recall (R).

4.5.2 Identifying Non-standard Language Identifiers for URL

Even though URL method operates decently fast, it requires language identifiers usually collected manually. This task is challenging as language identifiers used in different web-domains typically do not follow any standard. For example, the language patterns for Czech may include `czech`, `cze`, `ces`, `cz`, `cs`, `cesky`. The result in Table 4 also suggests the limitation of URL for Czech language. In this exercise, we examine URL pairs matched by CDA method to extract relevant language identifiers. Specifically, we focus on URL pairs distanced by *one* token and extract the different tokens as candidates. For example, `en` and `vi_vn` are extracted as candidates for (`www.visitsingapore.com/en/`, `www.visitsingapore.com/vi_vn/`). We curated the candidates, identified additional novel language identifiers, and feeded them to URL method. The exercise helped significantly increase the yields for multiple low-resourced languages at 453%, 295%, and 266%. For example, we found additional identifiers for Chinese language: `chs`, `chn`, `c`, `zho`, `zht`, `cht`, `webcn`, `sc`, `tc`, `chinese_gb`, `chinese_big5`, besides other popular `zh`, `chi`, and `zho`.

4.5.3 Identifying Multilingual Web-domains

We study the application of URL and CDA in identifying densely multilingual web-domains. Specifically, we compare the yield of parallel content, in the total number of extracted parallel English tokens, from two different datasets processed by the same pipeline. The datasets differ in whether their web-domains are identified as multilingual by URL or CDA.

On a sufficiently large dataset, we first ran URL and selected those web-domains having at least 100 candidate pairs. Subsequently, we ran CDA and selected those with at least 100 candidate pairs on the remaining of the dataset, i.e., those not selected by URL. We randomly selected 10,000 domains from

---

[10] https://github.com/awslabs/sockeye

	Domains by URL	**Domains by CDA**
Parallel Token Count	23.3MM	69.5MM
Host Count	10,000	10,000
Dataset Size (TB)	6	3.1

Table 6: Number of parallel English tokens (in MM) from two deep crawls seeded by URL and CDA.

each group to create the two datasets, namely "Domains by URL" and "Domains by CDA," respectively. We applied the same pipeline using both methods for aligning documents on each dataset. We then computed the yield of parallel English tokens extracted from each setting. Table 6 shows the results. These indicate that CDA can identify densely multilingual web-domains effectively.

In particular, given the same number of web-domains, the dataset identified by CDA can produce almost 3× more parallel data with a size of only half of the dataset identified by URL. This finding suggests that the yield of parallel content from web-domains identified by CDA is 6× higher than those identified by URL. The finding is essential in optimizing the parallel extraction pipeline and identifying better densely multilingual web content.

4.6 Cost Analysis

As presented, we anticipate two cost types when extending CDA to support a new language: (i) building a lexical translation model and (ii) processing more documents. The former is a one-time cost, while the latter is dataset dependent.

Specifically, we have shown in Section 4.2.2 that a lexical translation model can be built using either statistical method IBM-1 with parallel data or neural-based unsupervised method (Lample et al., 2018); we observed comparable performance of CDA when using a model built by these methods. Given the rapid advance in deep neural language models, it is increasingly possible to obtain such resources for low-resourced languages. This suggests that we will be able to leverage recent advances in neural-based NLP to continuously extend CDA for many more languages.

Regarding the execution time, the primary bottleneck typically is due to the scoring of all possible alignments between English and non-English documents. Even though this scoring step is quadratic, this workload is perfectly parallel. With proper engineering optimization, we empirically found out that it is possible to bring the run-time for CDA to be within 2.5× than the one of URL's for 20 low-resourced languages and on a sufficiently large dataset. This optimized cost is crucial in enabling a spectrum of multilingual applications, including cross-lingual information retrieval and enabling MT services for scarce languages.

5 Conclusion

We presented our content-based document alignment for web data, CDA, which projects multilingual documents to a common space for similarity calculation. We also described our effort to collect and create benchmark datasets to study different performance aspects of the proposed method. The results show that CDA is efficient when projecting multilingual documents in one go for as many as 28 languages. Moreover, we also explain the different types of benchmarking for CDA under industrial settings.

The results show that our proposed method is robust when processing huge datasets and useful in identifying non-standard language identifiers and multilingual web-domains. Finally, and most importantly, the only significant resource required by CDA is the lexical translation dictionary: this can be easily built thanks to the recent advance in learning multilingual embeddings.

Future applications of CDA can be many. For example, the URLs paired with CDA can be used to improve the coverage for URL-based methods (e.g., Czech case in Table 4) and to study the web structure of multilingual content. Moreover, the robustness and extensibility of CDA make it applicable to other multilingual processing systems, including cross-lingual search and retrieval.

Acknowledgements

We thank Chris Bissell, Jeremiah Hankins, Kwang Hyun Jang, Daniel Marcu, Masud Moshtaghi, Akash Patel, Chris de Vries, Renxia Wang, William Wong, and members of the Alexa AI Search team in Manhattan Beach, CA for their helpful feedback on earlier drafts of the manuscript. Abstract

Numerical tables are widely used to present experimental results in scientific papers. For table understanding, a metric-type is essential to discriminate numbers in the tables. We introduce a new information extraction task, metric-type identification from multi-level header numerical tables, and provide a dataset extracted from scientific papers consisting of header tables, captions, and metric-types. We then propose two joint-learning neural classification and generation schemes featuring pointer-generator-based and BERT-based models. Our results show that the joint models can handle both in-header and out-of-header metric-type identification problems.

Models	Task 1		Task 2

1 Introduction

Tables are powerful tools for presenting data efficiently in row and column views. In scientific papers, numerical tables are commonly used to show experimental results for facilitating data analysis. Examples of numerical tables in scientific papers are shown in Figure 1.

Tables have the ability to cover multiple categories written in table headers by incorporating several header sets in a hierarchical view, called multi-level header tables. Scientific papers have strict guidelines about tables; for example, one states that a similar type of text is written in the same level of header. Figure 1a shows a multi-level header example in the column part, with task type (*Task 1* and *Task 2*) in the first header-level and metric-type (*Prec* and *Rec*) in the second. The table also has a row header specifying the model type (*Model A*, *Model B*, *Model C*, and *Model D*). In the real-world, this header-type information is limited due to the unknown table scheme. However, we assume tables in scientific papers follow the rule of categorizing a similar type of header name in the same header-level.

To understand the numbers in the tables, metric-types are important for discriminating the numbers. A comparison between numbers is applied for numbers in the same metric-type with different categories. For the table in Figure 1a, we cannot compare the number 60 for *Model A* in the first column with 60 in the second one because they have a different metric-type: *Prec* and *Rec*. Computing numbers with different metric-types will result in inaccurate analysis.

Different tables may have different ways of writing their header name, such as using abbreviations like *p*, *pre*, or *prec* to refer to *precision*. Due to the lexical diversity of header names, metric-type identification becomes more challenging. Using a rule-based metric-type tagging or a limited set of metric-types in a dictionary is not enough to cover the diversity. Since tables in scientific papers typically have logical captions and logical categorization of the header-level, we introduce a metric-type identification task that locates the metric-type in the headers by using the caption and header name as inputs. For the example shown in Figure 1a, the metric-type is located in the second level of the column header.

We also cover tables that do not mention metric-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3062–3071
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

types in their header (out-of-headers), as shown in Figure 1b. In these cases, the metric-types are identified in the caption. To cover metric-types located both in the headers and not in the headers, we propose a joint framework of metric-type location prediction and metric-type token generation for the metric-type identification task in multi-level header tables.

Our contributions are as follows:

- We introduce a metric-type identification task for multi-level header tables and propose joint location prediction and generation models to solve the task.
- We provide a dataset consisting of multi-level header numerical tables, captions, and metric-types, extracted from scientific papers. Our datasets will be publicly available[1].
- We introduce a multi-level header table encoder mechanism to obtain table header representations and propose a pointer-generator-based model to cover out-of-headers in the metric-type identification task.
- We fine-tune a general pre-trained encoder (BERT) and a domain-specific encoder (SciBERT) in our task and present the experimental results. We show that the models incorporating the pre-trained encoders lead to significant performance gains, especially when using a domain-specific one.

2 Related Work

Table information extraction is beneficial to cover unknown table schemes and understand the table contents. Milosevic et al. (2019) proposed a framework for table information extraction in biomedical domains by defining rules for all possible variables. Specifically, for numerical variables, they retrieved metric-types by searching a set of possible tokens in the dictionary. Focusing on numerical tables, Nourbakhsh et al. (2020) extracted metric-types in earning reports by using similarity scores between the corresponding non-numeric text for the leftmost cells and stored metric-types.

The work closest to ours is the one by Hou et al. (2019), who used tables from the experimental result section, combined with the title and abstract as document representations to extract triples of tasks, dataset, and metric for leaderboard construction. In our study, we represent the tables in more generic ways, preventing the original table structure in the multi-level headers form. We intend to retain the ability of a table to cover complex categorization in the headers and efficiently present all values. A previous study that also explored multi-dimensional tables was done by Milosevic et al. (2016) to automatically detect table structures from XML tables.

Our pointer-generator-based model in the metric-type generation scheme is inspired by the promising results of the pointer-generator network (See et al., 2017) in the summarization task. The network deals with the out-of-vocabulary issue by joint copying from source texts and generating from vocabularies.

Recent studies have shown that pre-trained encoders can be successfully fine-tuned for downstream NLP tasks, thus avoiding the need to train a new model from scratch. A pre-trained encoder BERT (Devlin et al., 2019) was trained on the BooksCorpus (800M words) and Wikipedia (2,500M words). For better-contextualized representation in the scientific domain, Beltagy et al. (2019) introduced a domain-specific BERT model, SciBERT, which was trained on 1.14M papers from Semantic Scholar. Friedrich et al. (2020) implemented both BERT and SciBERT on their models to solve the information extraction task and achieved significant performance gains.

3 Metric-Type Identification for Numerical Tables

3.1 Datasets

We automatically extracted tables from the PDF files of scientific papers in the computational linguistics domain using PDFMiner and Tabula as extraction tools and filtered only numerical tables related to experimental results using the keywords *evaluation*, *result*, *comparison*, and *performance*. We used papers from the ACL and EMNLP conferences (2016 to 2019) on the ACL Anthology website as data sources.

In tables in actual scientific papers, knowledge about the table semantics is rarely provided. On the basis of how information is "read" from a table, Hurst (2000) separated functional table areas into access cells and data cells. Access cells consist of column headers and/or row headers. We define data structure on the basis of their functional areas: table caption (capt), row headers (rh), column headers

---

[1] Dataset is available on https://github.com/titech-nlp/metrictable

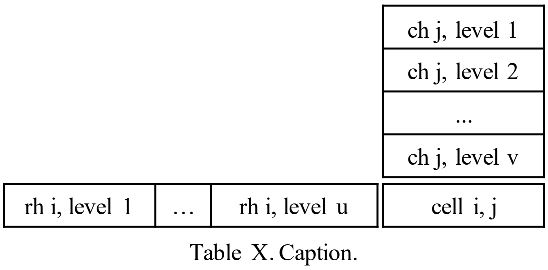

Figure 2: Table structure.

(ch), and cells. Headers in the row and column parts have several levels, and we assume that header names in the same level have the same type. Figure 2 shows our table structure.

We hired several qualified workers in the computer science field to manually check the extracted table structure to ensure the separation of row headers, column headers, and cells was correct, as shown in Figure 3. Then, they annotated the metric-type of the tables by prioritizing the locating of the metric-type in a specific header-level. The annotators were able to identify the metric-types of approximately 70% of the tables in their headers, and they determined the metric-type of the rest of the tables on the basis of information from the table captions. When no metric-type was mentioned in the headers, we assumed the metric-type was the same for all table values. The structures from the example in Figure 3 are capt: "*model comparison in task 1 and 2*"; rh level 1: [*models, models, models, models*]; rh level 2: [*model a, model b, model c, model d*]; ch level 1: [*task 1, task 1, task 2, task 2*]; ch level 2: [*prec, rec, prec, rec*]; and metric-type: [*prec, rec, prec, rec*] (identified in ch level 2).

We split our dataset into training, validation, and test sets. The statistics of our dataset are provided in Table 1.

	Train	**Val**	**Test**
No. of tables	1,084	136	135
Average row/column	6	6	5
Max level:			
- row header	9	6	4
- column header	6	5	6
Vocab size:			
- headers	8,270	1,435	1,230
- all metric-types	807	175	185
- unique metric-types	90	22	28

Table 1: Dataset statistics in training, validation, and test sets.

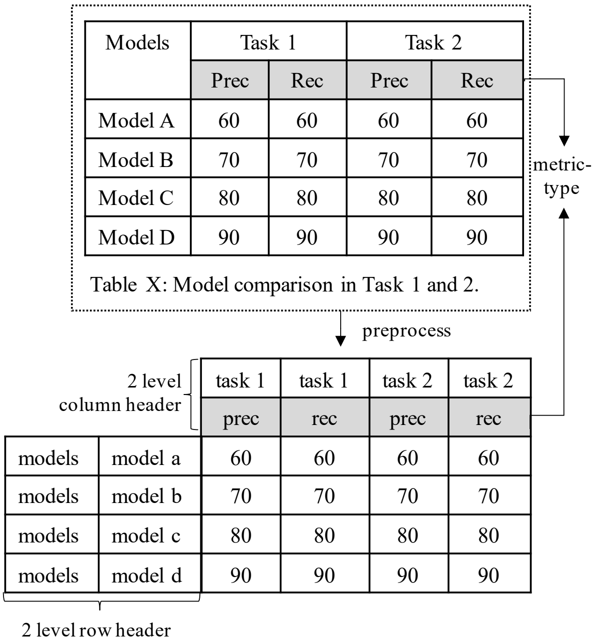

Figure 3: Illustration of table preprocessing.

3.2 Problem Definition

Let Table $= \{capt, rh_k^i, ch_l^j, cell_{ij}\}$, where $1 \leq i \leq n_r, 1 \leq j \leq n_c, 1 \leq k \leq u, 1 \leq l \leq v$ denote an $n_r \times n_c$ table with the u level of rh and v level of ch. The task is to identify metric-type set ($\hat{m}$) in the specific level of row header (rh_k) and column header (ch_l). To handle tables that do not include metric-types in their headers, we generate $\hat{m}$ by using information from the table caption. The formulation of the metric-type identification is as follows:

$$\hat{m} = \begin{cases} \{rh_k^i\}_{i=1}^{n_r}, k \in \{1, ..., u\} & \text{if } \hat{m} \text{ in } rh \\ \{ch_l^j\}_{j=1}^{n_c}, l \in \{1, ..., v\} & \text{if } \hat{m} \text{ in } ch \\ \{w_m\}_{\times j}, w_m \in W_m \text{ or} & \\ \qquad\qquad w_m \in capt & \text{otherwise,} \end{cases} \tag{1}$$

where W_m is a set of metric-types in the vocabulary.

4 Models

We propose neural models to identify the metric-type for multi-level header tables by means of a joint model of metric-type location prediction and metric-type token generation.

4.1 Pointer-Generator with Supervised Attention Model

We obtain the representations of captions and header-levels by using a BiLSTM encoder and then capture header-level weights using supervised attention between the header-level encoder and the metric-type header-location outputs. In the generation scheme, we adopt the pointer-generator network to take into account captions as source texts and the metric-type vocabulary in the metric-type generation gate. The architecture of our model is shown in Figure 4.

Header encoder We use the vector representation of each header-level by averaging the vectors of all header name tokens in the same level. Given E_{rh_k} and E_{ch_l} as the averages of the initial vector representations of the row and column header-level vectors, respectively, we use the BiLSTM encoder with the dot attention mechanism proposed by Luong et al. (2015) to obtain the representations of the row and column header-levels and select the last hidden state of the last level combined with the weighted hidden states as header-level contexts, as follows:

$$C_{rh} = [C_{rh_u}; \sum_{k=1}^{u} a_{rh_k} C_{rh_k}], \tag{2}$$

$$C_{ch} = [C_{ch_v}; \sum_{l=1}^{v} a_{ch_l} C_{ch_l}]. \tag{3}$$

Caption encoder As with the headers, we use the BiLSTM encoder with attention a_{capt_i} to compute the context vector of caption C_{capt}.

Metric-type header-location gates We feed the concatenation of the row and column header contexts to the softmax layer to obtain the metric-type header-location probability:

$$p_{hloc} = \text{softmax}([C_{rh}; C_{ch}]), \tag{4}$$

which includes the probabilities of the metric-types located in row headers (p_{rh}), located in column headers (p_{ch}), or not located in the headers (p_{capt}), where $p_{rh} + p_{ch} + p_{capt} = 1$.

Metric-type header-level gates Since the attention scores a_{rh_k} and a_{ch_l} capture the relevant header-level information in row and column, these attention scores are used as header-level weights as follows:

$$\mathrm{w}_{hlevel_i} = [a_{rh_k} p_{rh}; a_{ch_l} p_{ch}], \tag{5}$$

where $i \in \{1, ..., u, (u+1), ..., (u+v)\}$ as a header-level index.

Metric-type generation gates In our pointer-generator network, we use the sigmoid layer to obtain a switch copy probability:

$$p_{copy} = \text{sigmoid}(C_{capt}), \tag{6}$$

which lets us choose between copying word w_{capt} from a table caption and generating word w_m from the metric-type vocabulary, where $p_{copy} \in [0, 1]$. We use a softmax function to compute the probability distribution over the metric-type vocabulary:

$$P_{vocab}(w_m) = \text{softmax}(C_{capt}). \tag{7}$$

Then, we obtain the following probability distribution over the extended vocabulary:

$$\begin{aligned} P(w_m) = p_{copy} \sum_{i:w_i=(w_m)}^{n} a_{capt_i} + \\ (1 - p_{copy}) P_{vocab}(w_m), \end{aligned} \tag{8}$$

where i is the index of metric-type tokens in the vocabulary.

Learning objective For training, we exploit the negative log-likelihood objective as the loss function. In addition, we adopt supervised attention (Liu et al., 2016) for jointly supervising the row and column header-level attention to obtain the metric-type header-level. We combine all loss functions in the location classification and token generation model, and define α as the weight as follows:

$$\begin{aligned} \mathcal{L} = -((1 - \alpha)(\sum_{c} z_{hloc} \log p_{hloc_c} + \\ \sum_{i=1}^{u+v} \log \mathrm{w}_{hlvl_i}) + \alpha(\log p_{copy} + \\ \log P_{vocab}(w_m))), \end{aligned} \tag{9}$$

where $c \in \{capt, rh, ch\}$ is the metric-type header-location classes and z_{hloc} is the binary indicator (0 or 1) of each corresponding class.

4.2 Fine-tuning BERT-based Model

Input representation Input text in a fine-tuned BERT-based model is preprocessed by inserting two special tokens, [CLS] and [SEP]. In the original BERT architecture, [CLS] is appended to the beginning of input as the representation of the entire input sequence, and [SEP] is inserted after each input type as a sign of a segment boundary. For example, in question-answering tasks with two

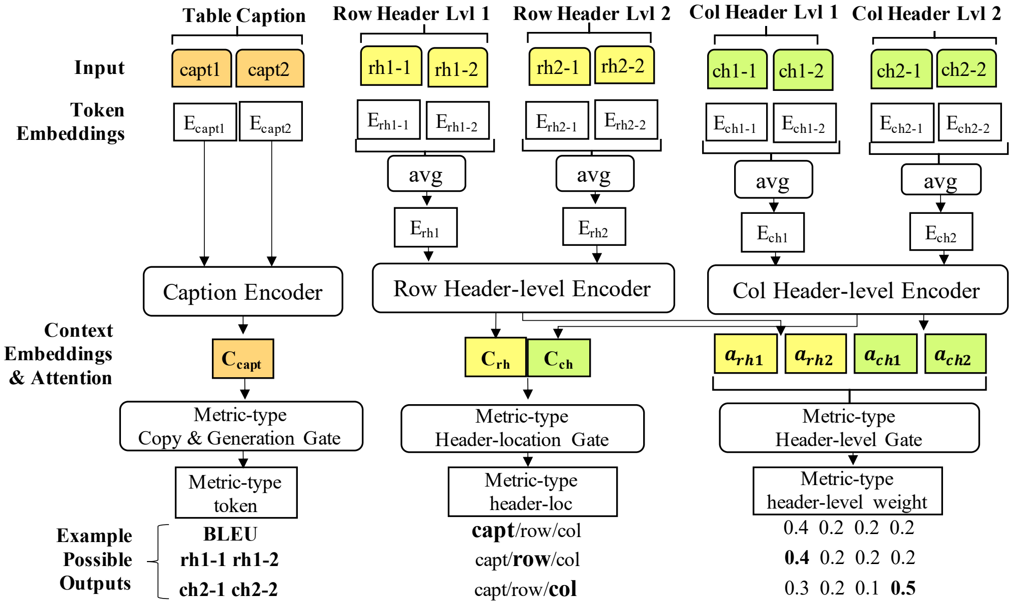

Figure 4: Architecture of proposed pointer-generator-based model to identify metric-types in tables.

types of input text, pairs of question and answer, a [CLS] token is appended before question tokens, and [SEP] tokens are placed after question and after answer tokens, to separate the question and answer segments. Following Liu and Lapata (2019), we customize these preprocessing schemes by inserting [CLS] before each segment and inserting [SEP] after each segment. We divide our inputs into several segments: caption, row header level 1 to u, and column header level 1 to v.

The input text after preprocessing is denoted as a sequence of tokens $X = (x_1, x_2, \cdots, x_n)$. There are three kinds of embedding assigned to each x_i: token embeddings representing the meaning of each token, segmentation embeddings indicating the segment boundaries of a sequence of tokens, and position embeddings covering token position within the sequences. Since BERT only covers two segments in its input, we treat the odd segment as segment A and the even one as segment B. The sum of these three embeddings is fed to a bidirectional Transformer layer of BERT.

We use the token representations from the top hidden layers of the pre-trained Transformer as context embeddings. We assume the context vectors of each [CLS] token can represent the segment sequences better. As shown in Figure 5, we denote the input embedding as E, the final hidden vector of the [CLS] token for the i^{th} input segment as $C_i \in \mathbb{R}_H$, and the final hidden vector for the j^{th} input token as $T_j \in \mathbb{R}_H$.

We use a metric-type header-location gate and a metric-type header-level gate for metric-type location classification, and a metric-type generation gate to generate metric-type tokens from vocabulary covering out-of-header metric-types. Our BERT-based model architecture is shown in Figure 5.

Metric-type header-location gates We feed the first segment context C_1 to the softmax layer to obtain the metric-type header-location probability:

$$p_{hloc} = \text{softmax}(C_1). \tag{10}$$

Metric-type header-level gates In our task, segments are used to represent the table section that is most related to metric-type. We incorporate the segment context C_i to the sigmoid layer to obtain the probability of the metric-type being located in a specific header-level:

$$p_{hlevel_i} = \text{sigmoid}(C_i). \tag{11}$$

The probabilities are then normalized to all segments as a weight score of the header-level:

$$\text{w}_{hlevel_i} = \frac{p_{hlevel_i}}{\sum_{i=1}^{n} p_{hlevel_i}}. \tag{12}$$

Metric-type generation gates We use a softmax function based on the first segment context C_1 to compute a probability distribution over the metric-type vocabulary:

$$P_{vocab}(w_m) = \text{softmax}(C_1). \tag{13}$$

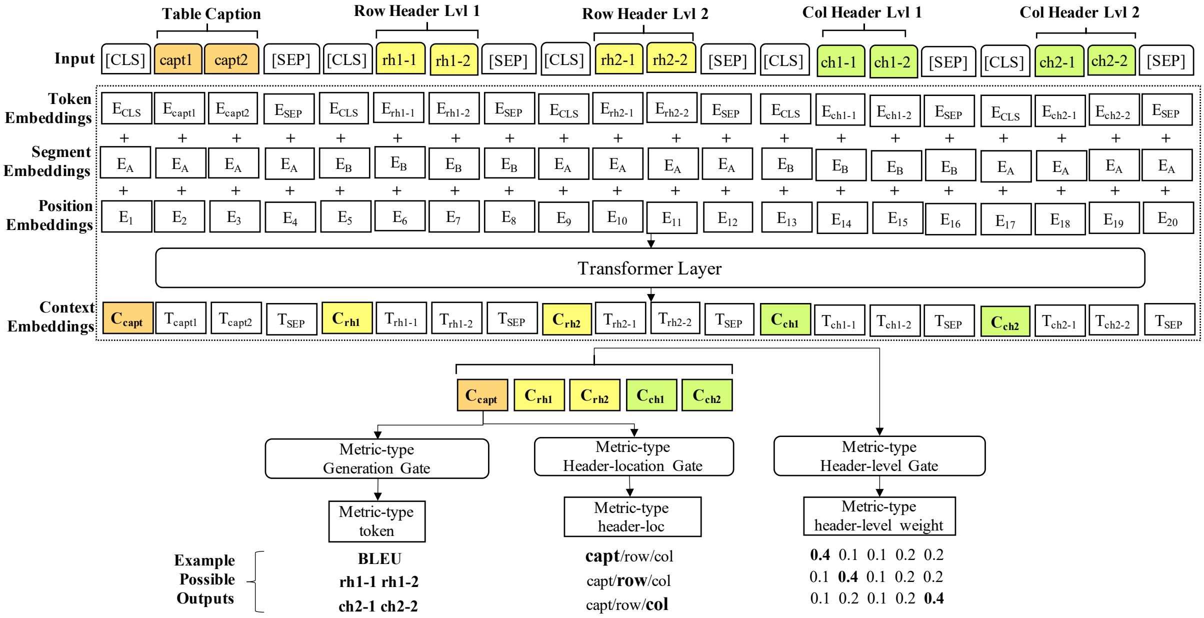

Figure 5: Architecture of proposed BERT-based model to identify metric-types in tables.

Learning objective We combine all loss functions in the metric-type header-location, metric-type header-level, and metric-type generation gates:

$$\mathcal{L} = -((1-\alpha)(\sum_{c} z_{hloc} \log p_{hloc_c} + \sum_{i=1}^{n} \log \mathrm{w}_{hlvl_i}) + \alpha \log P_{vocab}(w_m)), \quad (14)$$

where α is the weight of the metric-type generation functions.

5 Experimental Settings

5.1 Baseline Model

We use two SVM classification models as baselines: a metric-type location prediction model and a metric-type token prediction model from the vocabulary of metric-types. We use tf.idf of the concatenation header name tokens for all levels as input representations in the first model and tf.idf of the caption tokens in the second one. We tuned hyperparameters of the SVM model and reported the best results.

5.2 Metrics Evaluation

We use accuracy metrics to evaluate the metric-type location and generated metric-type tokens.

Metric-type location accuracy The target of the metric-type location prediction model is the metric-type located in the row headers, in the column headers, or not found in the headers. The accuracy of header-location (acc_{hloc}) is the rate of correct header-location predictions.

Since details about the metric-type location in the header-level are needed to identify metric-type token lists, we also compute the accuracy of metric-type header-level (acc_{hlevel}) using the ratio of correct header-level predictions to the total number of predictions.

Metric-type token accuracy Let $\hat{m} = (\hat{w}_{m_1}, ..., \hat{w}_{m_n})$ denote the sequence of predicted metric-type tokens for n_r rows or n_c columns (depending on the header-location prediction), and $m = (w_{m_1}, ..., w_{m_n})$ denote the target ones: for example, $\hat{m} = (\text{f1, f1, f1})$ and $m = (\text{f-1, f-1, f-1})$. We calculate the metric-type token accuracy using string matching of all token lists in $\hat{m}$ and m:

$$acc_m^{sm} = \frac{\text{\# correct } \hat{m}}{\text{\# } \hat{m}}, \quad (15)$$

and string matching of each token pair $\hat{w}_{m_i}$ and w_{m_i} in the token lists:

$$acc_{m\_token}^{sm} = \frac{\text{\# correct } \hat{w}_m}{\text{\# } \hat{w}_m}. \quad (16)$$

To cover token prediction with an abbreviation, we compute the metric-type token accuracy based on the ordered character matching as follows:

$$acc_{m\_token}^{ocm} = \frac{d}{\text{\# } \hat{w}_m}, \quad (17)$$

Model	acc_{hloc}	acc_{hlevel}	acc^{sm}_{m}	$acc^{sm}_{m\_tok}$	$acc^{ocm}_{m\_tok}$

where d is the number of $\hat{w}_m$ whose characters are all found in w_m in the same order. For example, the predicted token *RG1* is regarded as correct when the reference token is *ROUGE-1*.

5.3 Implementation Details

We implemented our models using the AllenNLP library (Gardner et al., 2018). In our pointer-generator-based model, we used pre-trained word embeddings for initialization and two-layer BiLSTMs with 256 hidden sizes in both the caption and header-level encoders. We used dropout (Srivastava and Hovy, 2014) with the probability $p = 0.1$. For optimization in the training phase, we used Adam as the optimizer with a batch size of 10 and a learning rate of 3×10^{-3} and 3×10^{-5} in pointer-generator-based and BERT-based, respectively, with a slanted triangular schedule (Howard and Ruder, 2018). We trained the model for a maximum of 20 epochs with early stopping on the validation set (patience of 10) and set α to 0.5. We used the original BERT and the domain-specific SciBERT uncased model to fine-tune our BERT-based model.

6 Results

6.1 Experimental Results

Model comparison The performances of the proposed and baseline models are shown in Table 2. We can see that the Pointer-Generator Supervised-Attention model initialized by Glove embeddings outperformed the baseline in predicting metric-type location. The accuracy of this model in the metric-type generation part mostly scored better than the baseline. However, the performances dropped significantly when the input

Table 7: Example of table caption, headers, and predicted metric-type.

was initialized by BERT as well as by SciBERT. BERT and SciBERT embeddings failed to guide our pointer-generator-based model in the metric-type identification task, especially in generating metric-type tokens.

The accuracy of our BERT-based model was significantly better than the others, achieving header-location and header-level prediction accuracy of more than 90% and generation accuracy improvement of more than 7 points (%). The fine-tuned BERT-based model using a domain-specific SciBERT led to significant performance gains in all metrics.

The effect of copy mechanism We evaluated our pointer-generator-based model using an ablation test, as shown in Table 3. As we can see, the performances of our generation model without a copy mechanism decreased. This demonstrates that incorporating the copy mechanism is beneficial in a metric-type token generation. Our model had the worst accuracy when it ran without a pointer-generator network since the location prediction model alone failed to handle out-of-header metric-types.

The effect of segment embeddings Table 4 shows the effect of segment embeddings in our BERT-based model. The accuracies of Fine-tuned BERT and the SciBERT model without segment embeddings both decreased. This means that segment embeddings successfully discriminate header-level boundaries in the input representation of BERT-based models.

6.2 Qualitative Analysis

We analyzed the errors of our pointer-generator-based and fine-tuned SciBERT models by means of the confusion matrices shown in Tables 5 and 6. For better understanding, we simply define our outputs in the matrices as "LRow" for metric-type located in row headers, "LCol" for metric-type located in column headers, "CCapt" for metric-type copied from the caption, and "Gen" for metric-type generated from the vocabulary. The matrix for the fine-tuned SciBERT model does not include the CCapt class since this model does not contain a copy mechanism.

As shown in the Table 5, the most correct classifications were for copying from the header (row and column), while the highest confusions were for copying from the caption and generation from the vocabulary. The accuracy of generating correct metric-type tokens from the vocabulary was 27.78%, and the accuracy of copying a metric-type from the caption was 75%. The copying mechanism contributes to a better performance than generation one.

From the confusion matrix of the SciBERT-based model in Table 6, we can see that the highest confusion was for copying from the header. We also computed the accuracy of generated metric-type tokens and found that just 58.7% of the generated tokens were correct.

We also investigated the errors in the predicted metric-type tokens. We found that the models tended to generate more generic metric-types; for example, they extracted *score* as a prediction for the target *accuracy*. On the other hand, our models generated similar terms to the ground truth metric-type, such as generating the metric-type *pearson's* for the target *r*. The examples are shown in Table 7.

7 Conclusion

In this work, we provided multi-level header numerical table datasets extracted from scientific papers consisting of header tables, captions, and metric-types. We introduced a metric-type identification task for multi-level header numerical tables, and proposed joint location prediction and generation models to solve the task. We have shown that our proposed model can identify metric-types from the multi-level header tables, both when the metric-types are included in the headers and when they are not.

Our datasets only cover scientific papers in the computational linguistic domain. The generalization of our results beyond domain still remains an open question due to the difficulties of collecting comparable datasets in other domains without additional annotation by human experts.

Abstract

Affect preferences vary with user demographics, and tapping into demographic information provides important cues about the users' language preferences. In this paper, we utilize the user demographics, and propose EmpathBERT, a demographic-aware framework for empathy prediction based on BERT. Through several comparative experiments, we show that EmpathBERT surpasses traditional machine learning and deep learning models, and illustrate the importance of user demographics to predict empathy and distress in user responses to stimulative news articles. We also highlight the importance of affect information in the responses by developing affect-aware models to predict user demographic attributes.

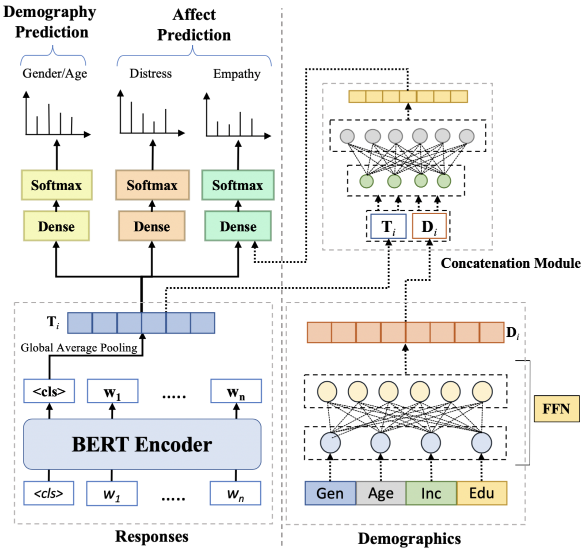

Figure 1: EmpathBERT architecture.

1 Introduction

Modeling complex human reactions and affect from text has been a challenging research area with innovations focusing on sentiment and emotion understanding (Picard, 1997; Li and Liu, 2015; Rosenthal et al., 2017; Socher et al., 2011, 2013). The study of non-trivial human reactions has been limited. These methods, often rooted in psychological theories, have turned out to be more complex in terms of annotation and modeling (Strapparava and Mihalcea, 2007). A critical affective phenomena, *empathy*, has received surprisingly less attention.

Empathy assesses feelings of sympathy towards *others*, and Distress measures anxiety and discomfort oriented towards *self* (Davis, 1980). Empathy has been positively associated to a number of well-being activities, such as volunteering (Batson et al., 1987), charity (Pavey et al., 2012), and longevity (Poulin et al., 2013), and in consumer marketing, advertising and customer interfaces (Wang et al., 2016; Escalas and Stern, 2003). Works on empathy in text have focused on spoken dialogue, addressing conversational agents, psychological interventions, or call center transcripts (McQuiggan and Lester, 2007; Fung et al., 2016; Pérez-Rosas et al., 2017; Alam et al., 2018; Demasi et al., 2019). Buechel et al. (2018) collected an empathy-distress dataset by leveraging users' reactions to textual stimulus content. Sedoc et al. (2019) constructed an empathy lexicon by obtaining word ratings from document-level ratings from this dataset. Xiao et al. (2012); Gibson et al. (2015); Khanpour et al. (2017) presented predictive models for empathy in the healthcare domain. However, we believe none of the above works focus on (a) predicting empathy from textual reactions, and (b) studying the impact of demographics on the expression of empathy.

Language preferences vary with user demographics (Tresselt and Mayzner, 1964; Eckert and McConnell-Ginet, 2013; Garimella et al., 2016; Lin et al., 2018; Loveys et al., 2018), and this has led to studies leveraging the user demographic information to obtain better language representations and classification models for various NLP

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3072–3079

tasks (Volkova et al., 2013; Bamman et al., 2014; Hovy, 2015; Garimella et al., 2017). Owing to the recent success of large language models such as BERT (Devlin et al., 2018) and GPT-2 (Radford et al., 2019) in improving the performances of several downstream tasks, we propose a BERT-based demographic-aware framework for empathy (distress) prediction, and through several comparative experiments, show that it surpasses existing baselines and demographic-agnostic approaches.

This paper makes three main contributions. **(1)** We present EMPATHBERT, a demographic-aware empathy (distress) prediction framework, using BERT-based models infused with demographic information. **(2)** Through comparisons against several baseline and demographic-agnostic approaches, we illustrate the importance of user demographics in end-to-end modeling and predicting empathy (distress). **(3)** Conversely, we show that empathy (distress) also contributes to demographic attribute prediction, by developing affect-aware models for demographic attribute prediction, backed by empirical comparison with baselines and generic models. To the best of our knowledge, ours is the first computational effort addressing empathy (distress) through the lens of demographic biases, a phenomenon well-understood in psychology.

2 Dataset

We use the empathy-distress dataset introduced by Buechel et al. (2018). It consists of 418 news articles from popular news platforms, and responses to them from 403 annotators (5 articles each), resulting in a total of 2,015 responses. Filtering the responses that deviated from the task description led to 1,860 responses (empathy: 916, distress: 905) , with a total token count of 173,686 (min: 52, max: 198, median: 84). The number of responses per article ranges from 1 to 7, with an average of 4.46 responses per article. We report some example responses from the dataset in Table 1[1]. We focus on the responses only, and use the empathy (distress) tags associated with these responses. We group the data into binary classes for age (C_0: < 35, C_1: ≥ 35), income (C_0: $\leq \$50,000$, C_1: $> \$50,000$), and education ($C_0$: no degree, C_1: bachelor's or above), to mitigate class imbalances.[2] The resulting dataset is balanced for all dimensions, with a maximum deviation of 5.5% (age) among classes.

3 EMPATHBERT

In this section, we describe our approach for demographic-aware empathy (distress) prediction from text. Figure 1 shows the proposed architecture. Our model takes as input a response (a sequence of words $w_1, w_2, \ldots, w_n$) and demographic information of the corresponding annotator. We represent the response using BERT, a bidirectional Transformer-based (Vaswani et al., 2017) language model. We use the final 768-dimensional hidden vector corresponding to the [CLS] token as the aggregate sequence representation. We employ cross-domain pre-training (Sun et al., 2019), fine-tuning, and multi-task fine-tuning (Liu et al., 2019) techniques to customize BERT for our tasks.

Cross-domain Pre-training (PT). We use the pre-trained BERT language model trained on the English Wikipedia and Book Corpus (Zhu et al., 2015) datasets for masked word and next sentence prediction, and perform further pre-training on demographic-specific datasets to introduce demographic-specific language preferences. This enables slanting the BERT model towards a specific demographic group. For this, we use a corpus different from the empathy dataset in two scenarios. (1) ALL: train the BERT model on all of the external corpus, and (2) DEMOGRAPHIC-SPECIFIC: train only on the demographic-specific samples from the external corpus.

Fine-tuning Only (tBERT). BERT-based fine-tuning has had significant success, due to the ease in implementation and performance gains reported for various NLP tasks (Huang et al., 2019; Liu and Lapata, 2019). We fine-tune BERT for sequence classification by adding a classification layer, where the input is response represented by the hidden vector of the [CLS] token, and output is the prediction for empathy (distress). We train on generic data and demographic-specific portions, and compare the performances to study the demographic effect on empathy (distress) prediction.

Multi-task Fine-tuning (tBERT-MT). We fine-tune BERT in multi-task learning (MTL) setup for classification, similar to (Liu et al., 2019), where the tasks under consideration are empathy (distress) classification and demographic attribute prediction. Both the tasks have shared BERT layers, while the classification heads containing the final dense and

[1] Please refer to Buechel et al. (2018) for further details on the dataset.

[2] We do not study race; it has even heavier class-imbalance.

TEXT	DEMOGRAPHIC ATTRIBUTES	SCORE
A 6.4 magnitude on the Richter scale earthquake has shaken up the whole capital of Santiago, Chile. Chile is very propense to earthquakes and natural disasters. We have heard of an earthquake that scaled out to be 8.8 and destroys over 200 thousand homes in Chile. I feel very bad for the people who died. and send out my compassion to the family of the 55 dead in this earthquake.	Female, Age $\geq$ 35, Education $<$ Bachelors, Income $\leq$ \$50,000	0.84
This is just crazy, you have to feel for the mother, but at the same time what kind of apartment has that many violations and is still not punished. They need to sue them and anybody involved with this. I can't believe that in today's society that tragedies like this are tolerated. Somebody needs to go to jail for the death of this little girl and the injuries that her mother suffered. I can't imagine what the mother is going through and she probably blames herself. Things like this should just not happen.	Male, Age $\geq$ 35, Education $\geq$ Bachelors, Income $\leq$ \$50,000	0.82

Table 1: Qualitative examples of high empathy (above) and high distress (below) with scores on empathy and distress dimensions as predicted by our **tBERT-C (fnn)** model.

softmax layers are specific to each task. We replace the final dense and softmax layers in tBERT setup with multiple classification heads based on the number of tasks. We experiment with (1) *Alternative training*: In each epoch, we cyclically train only one classification head, freezing the parameters of the remaining heads; and (2) *Parallel training*: In each epoch, we train the model end-to-end on the joint loss from all the classification heads.

Explicit Demographic Knowledge. PT, tBERT and tBERT-MT intrinsically infuse demographic information. We also incorporate this explicitly by concatenating a *demographic vector* $\vec{d}$ to the output of the global average pooling layer (Lin et al., 2013) from tBERT or tBERT-MT (concatenation in Figure 1) in two ways. (1) **tBERT-[MT]-C**: $\vec{d}$ is a d-dimensional one-hot encoding vector (d: number of demographics). (2) **tBERT-[MT]-C (fnn)**: $\vec{d}$ is the output of a feedforward neural network (FNN), the input for which is a one-hot encoding vector. Three dense layers are stacked before the task-specific heads, and this model is trained end-to-end for empathy (distress) prediction. In tBERT-MT where one of the tasks heads predicts a demographic attribute, the corresponding binary value in $\vec{d}$ is removed. To assess the contribution of specific attributes, we also propose to concatenate a 1-bit encoding (**tBERT-[MT]-C (attribute)**) for each given attribute.

4 Experiments

We model empathy (distress) prediction as a binary classification task. To study the efficacy of empathy (distress) to predict demography attributes, we also conduct experiments for empathy (distress)-aware demographic attribute prediction. Such a prediction can be used for further demographic removal from text to mitigate adversarial attacks and protect privacy of users (Elazar and Goldberg, 2018).

Implementation Details (1) Cross-domain Pretraining: We use the Blog Authorship Corpus[4] (Schler et al., 2006), which consists of 681,288 blogposts and self-provided demographic attributes, gender, age, industry, and astrological sign of the corresponding 19,320 bloggers to further pre-train BERT. Out of these we use the gender attribute to pre-train for male-specific and female-specific pre-training experiments. We train the model on the *Masked Language Model task* (Taylor, 1953) for 10 epochs using a learning rate of 3e-5. (2) Finetuning: We train the model end-to-end (110M parameters) using binary cross-entropy loss and decoupled weight decay Adam optimizer (Loshchilov and Hutter, 2017), in batches of 32. The best performance is observed when the maximum input sequence length is set to 150, learning rate to 3e-5, and number of epochs to 3. (3) Explicit Demographic Attributes: We use gender, age, education and income attributes corresponding to each annotator in the empathy dataset. The d-dimensional vector size 4 resulting in a 16-d FFN output.

Evaluation metrics. We use five-fold cross validation (five random shuffled restarts) with 80-20

train-test proportions, and report the F1 and accuracy (Ac) averaged across the 5 runs on the test set.
Baselines. We compare our model against the Random Forest (RF) model with Glove embeddings (Pennington et al., 2014) for text and demographic attributes (excluding the prediction attribute) as one-hot vectors as features. We also report performance against deep learning baselines, CNN (Kim, 2014), biLSTM, and biLSTM with Attention (Yang et al., 2016) and the pre-trained BERT without further training.

4.1 Results

Table 2 shows the accuracies using BERT for pretraining (PT), fine-tuning (tBERT), and both (PT + tBERT) for gender-specific empathy (distress) prediction. On the M and F test sets, models trained on the same demographic subset (M or F) outperform those trained on the opposite subset or A_s. The acccuracies of plain BERT are 48.37, 49.49, and 50.42 on A_s, M, and F test sets respectively for empathy prediction. tBERT outperforms all other variants. The results support our hypothesis that empathy is dependent on and influenced by the gender associated with the author. We note similar patterns for age, income, and education (Table 3).

Table 4 shows results for empathy (distress) prediction using tBERT-[MT]-[C (fnn/attribute)] variants trained on the full dataset. In the notation, we replace [MT] with the heads on which the multitasking is performed. For example tBERT-MT-(E+D)-G-C implies fine-tuned BERT with empathy prediction, distress prediction, and gender prediction multi-tasking heads with demographic information concatenated to the text representation directly before classification.[5] We report performances on demographic-wise test sets (A, M, F).
Insights: (1) **tBERT** variants with a single training objective outperform all baselines. (2) Performance of **tBERT-MT** varies with the affect dimension. Empathy prediction shows marginal loss in performance with explicit concatenation (**tBERT-C**) and further loss in the multitask setup. (3) For distress, introduction of gender as the demographic attribute shows an observable improvement across different test sets. (4) A similar trend is observed for age. Table 5 shows performance of age and gender prediction with empathy (distress)-aware models on affect-wise test sets (Empathy (Em) and Distress (Dist)). Empathy-aware gender prediction models show consistent improvement over baselines, with **tBERT (G)** reporting the best score when tested on the complete dataset and empathy-specific test set. **tBERT (A)** helps improve the accuracies for age prediction by atleast 5% over baselines for the com-

Table 5: F1 values of affect-aware demography prediction.

plete (All) test set. For the empathy-specific test set, best results are observed with MTL (**tBERT-MT-(E+D)**). We infer that while having affect-aware demographic prediction models do improve performance over fine-tuned models, they may also lead to a marginally negative impact. The overall inference from above experiments is that demographic-aware models aid affect predictions but the reverse relationship is much weaker. End-to-end training across a variety of train sets and demographic attributes establishes that the variance observed in language preferences and expressions has an impact on the manner of expressing empathy and distress in reactions.

5 Conclusion

We proposed a novel demographic-aware empathy prediction framework based on fine-tuning and multi-tasking using BERT, showed that it surpasses existing methods, and illustrated the impact of demography in modeling subjective phenomena such as empathy and distress. Our framework is generalizable, and we extended it to empathy-aware demography prediction, and showed that empathy also improves demographic prediction. We believe this is a significant checkpoint towards developing models for empathy (distress), and tapping into demographic information while doing so.

Are Neural Networks Extracting Linguistic Properties or Memorizing Training Data? An Observation with a Multilingual Probe for Predicting Tense

Abstract

We evaluate the ability of BERT embeddings to represent tense information, taking French and Chinese as a case study. In French, the tense information is expressed by verb morphology and can be captured by simple surface information. On the contrary, tense interpretation in Chinese is driven by abstract, lexical, syntactic and even pragmatic information. We show that while French tenses can easily be predicted from sentence representations, results drop sharply for Chinese, which suggests that BERT is more likely to memorize shallow patterns from the training data rather than uncover abstract properties.

1 Introduction

The success of deep learning in many NLP tasks is often attributed to the ability of neural networks to learn, without any supervision, relevant linguistic representations. Many works have tried to identify which linguistic properties are encoded in the words and phrases embeddings uncovered during training. For instance, Belinkov et al. (2017) and Peters et al. (2018) studies the capacity of neural networks to uncover morphological information and Linzen et al. (2016), Tenney et al. (2019) or Hewitt and Manning (2019) (among many other) syntactic information. These works are based on the definition and study of *linguistic probes*: a *probe* (Alain and Bengio, 2017) is trained to predict linguistic properties from the representation of language; achieving high accuracy at this task implies these properties were encoded in the representation.

However, as pointed out by Hewitt and Manning (2019), these approaches suffer from a major drawback: there is no guarantee that the probes' good performances result from the ability of the representations to capture relevant linguistic properties rather than to memorize a large number of labeling decisions. Indeed, in most of the tasks considered so far, labels could be deduced directly from surface information, namely the word form (its morphology) and the word position in the sentence. Given the huge number of parameters of current models, there is a high risk that they are only able to extract and memorize lexically-marked patterns from training data with low (if any) generalization power.

To shed new light on this question, we consider, in this work, a multilingual linguistic probe, the goal of which is to predict the tense of a sentence (i.e. the location in time of an utterance). We compare the performance of this probe on two languages, French, which expresses tense by the verb morphology, and Chinese, in which, as explained in §2, the tense is expressed by a combination of lexical, syntactic and pragmatic cues. If intuitively the tense can be predicted from simple surface patterns in French, predicting the tense of a Chinese sentence requires capturing the interaction of all sentence-level factors related to time, and sometimes even the contextual information from the previous utterances. Contrasting the performance achieved by the probe on several languages ensures that the linguistic properties we detect are actually captured by the representation learned by BERT and not by the probe, and thus to avoid a common pitfall of this kind of approaches (Belinkov and Glass, 2019; Barrett et al., 2019).

This work has two main contributions: first, we highlight the interest of contrasting linguistic probes on different languages; second, our experiments (§3-4) show that BERT has a preference for learning lexically marked features

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3080–3089
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

over lexically unmarked features and, consequently, is not able to extract an abstract representation that can be applied to (groups of) words that have not been seen at training time.

2 Tense and Aspect

Languages can roughly be classified under two categories: tense language and aspect language, depending on how they denote time relations (Xiao and McEnery, 2004). Tense indicates the temporal location of a situation, while aspect, according to Comrie (1998), refers to "the different ways of viewing the internal temporal constituency of a situation" and denotes how speakers view it in terms of its duration, frequency and whether or not it is completed. In tense language, like English or French, the tense and aspect are often encoded simultaneously in verb morphology. For example, the simple past in English locates a situation before the speech time and is often indicated by the *-ed* inflection(e.g. *worked*). Similarly, the French past tense *imparfait* is marked by the *-ait* inflection in *il travaillait* (he worked). Contrary to these two tense languages, Mandarin Chinese does not have a grammatical category of tense (Smith, 1997) and the verb morphology never changes. Figure 1 presents five sentences with the Chinese verb 加班 (*jiaban*, work overtime): while these sentences have different tenses (simple past, present progressive, habitual present, past progressive and future), the form of the verb is always the same.

The notion of tense in Mandarin Chinese is lexicalized and is often indicated by content words like adverbs of time; aspectual information is systematically conveyed by aspect markers. As an aspect language, the temporal interpretation of a verb is tightly related to the notion of *aspect*. For instance, as noticed by Lin (2006), a verb marked by a perfective aspect particle such as 了 *(le)* often gets a past interpretation, such as in the first sentence of Figure 1. And imperfective aspect privileges a present interpretation: in the example 1.2, the same verb is marked by the imperfective aspect particle 在 *(zai)*, which explains why the sentence gets a present interpretation.

However, according to the genre of the text, only 2% to 12% of verbs in Chinese have aspect markers (McEnery and Xiao, 2010)[1] and the tenses should often be inferred from contextual cues like lexical and syntactic features when there is no explicit aspect marker(Saillard, 2014). For instance, in the absence of aspect marker in sentence 1.3, the adverb 常常 (*changchang*, often) leads to a habitual present interpretation. These contextual cues can even invalidate the default correlation of time and aspect we have previously described, as in example 1.4, in which the verb group gets a past interpretation even if it is marked by an imperfective aspect particle because of the past temporal context introduced by the adverbial clause. Finally, in example 1.5, the modal auxiliary 会 *(hui)* and temporal expression 晚上 (*wanshang*, tonight/in the evening) lead to a future-tense interpretation.

Thus, unlike French and English, the time of a Chinese sentence can only rarely be deduced from a surface analysis of the sentence (i.e. from the characters composing its words) and in order to determine the tense, it is necessary to take into account both syntactic and even pragmatic information.

3 Creating a Corpus Annotated with Tense Information[2]

The tense prediction task we consider in this work requires corpora in which the tense of each verb is identified. To the best of our knowledge, there is no such publicly available corpus. For languages such as French or English, in which tenses are described by verb morphology, it is possible to easily build such corpus from morpho-syntactically labeled treebanks (e.g. from the UD project (Zeman et al., 2020)). However, this approach cannot be readily generalized to languages such as Chinese, in which, time is not explicitly marked.

We propose to leverage parallel French-Chinese corpora to obtain tense annotations for Chinese sentences automatically. Our approach relies on two hypotheses. First, we assume that the tense of a translated sentence (target sentence) is the same as the tense of

---

[1] Aspect markers occur more frequently in narrative texts than in expository texts

[2] **The code of all our experiments as well as the corpora we used in this work can be downloaded from `https://github.com/bingzhilee/tense_Representation_Bert`.**

(1)	他	加班	了。
	Ta	jiaban	le
	Pron.3sg	work_overtime	Pfv

Figure 1: Examples of different ways to express the tense in Chinese: tenses are indicated by both aspect markers and a combination of lexical and syntactic cues and not by the verb morphology as in French or English. Ipfv describes one of the two imperfective aspect markers and Pfv one of the two perfective aspect markers

its original (source) sentence ignoring translationese effects (Toury, 2012; Baker et al., 1993). Second, we decided to associate each sentence with the tense of its main clause and not label each verb tense. This assumption allows us to mitigate errors related to the verbal structures identifications and misalignments between Chinese and French verbs as labels are defined at the sentence level.

We considered, in this work, the French-Chinese NewsCommentary[3] parallel corpus (Barrault et al., 2019). To extract tense information, we use the `Stanza` pipeline (Qi et al., 2020) with its pretrained French model to find the root of each sentence and extract its tense and its mode from its (automatic) morphological analysis. We also use the dependency analysis to identify periphrastic catena expressing future (*aller* + Infinitive) or past (*venir de* + Infinitive). With these information, we can define the tense of each sentence easily by mapping the tense of the root verb to one of the three labels Present, Past or Future[4] and the tense of a Chinese sentence is defined as the tense of its French translation.

We evaluate our tense extraction procedure on the Pud corpus[5]. It appears that `Stanza` is able to correctly predict the tense of 95% of the sentences (i.e. identify the root of the sentence and correctly predict its morphological information). Therefore, we consider that the tense labels are predicted with sufficient quality to measure a model's ability to capture time information. However, most of the prediction errors are due to the same construction: the auxiliary *être* followed by the past participle of the verb, that can be used to form either the passive voice or the *passé composé* tense of a verb. As a result, most of our corpus' passive sentence is labeled as Past while they are at the present tense.

In the end, this procedure results in a corpus of 4,764 documents containing 174,347 Chinese and French sentences annotated with tense information. As expected, most of the sentences are in the present tense and the corpus is highly unbalanced: 67% of the examples are labeled Present, 27% Past and only 6% Future. Our corpus also confirms the observations reported in section 1 on the limited use of temporal markers in Chinese: only 16% of the sentences have an explicit temporal marker.[6] We consider 80% of the data for

---

[3] We consider the 15th version of the corpus as, according to our preliminary experiments, most other parallel corpora (e.g. OpenSubtitles) contains almost exclusively sentences in the present tense.

[4] This mapping is more precisely defined in Appendix A Table 2

[5] Pud is a UD corpus that has not been used to train the `Stanza` models.

4 Experimental Results

Models The task of tense prediction consists in finding, given a representation $\mathbf{x} \in \mathbb{R}^n$ of a sentence, a label describing its tense (see §3 for a definition of these labels). We consider three models. The first one, denoted featSVM, uses a SVM and a set of handcrafted features designed to capture the information identified as relevant for determining the tense of a Chinese sentence. We rely on the theoretical study of Smith and Erbaugh (2005) to define the features:[7] indicators to describe the presence of aspectual markers (e.g. 了 or 过) or temporal adverbs (e.g. 昨天 *(yesterday)* or 明天 *(tomorrow)*), the sentence root verb, modal auxiliaries (e.g. 会 *(will (probably))*, ...

Our second model, denoted BertSVM is a simple SVM that uses, as sole sentence representation, the embeddings generated by pretrained multilingual Bert. We used the second-to-last hidden layer of all tokens in the sentence and did average pooling. The embeddings on [CLS] and [SEP] were masked to zero before pooling, so they are not included(Xiao, 2018). These representations are kept unchanged. Finally, we consider fineBert a neural network in which Bert pretrained language representation are fine-tuned on the tense prediction task. More precisely, we stack a *softmax* layer on top of the pre-trained Bert model and estimate the weights of this layer while updating Bert parameters by minimizing the cross-entropy loss.

We used Google's pre-trained Multilingual cased Bert in our experiments. It was trained on the entire Wikipedia dump for each language. The French and Chinese training sets have comparable sizes. The performance of mBert on XNLI cross-lingual classification is similar for these two languages: 76.9 for French and 76.6 for Chinese (Martin et al., 2019; Devlin et al., 2018).

In our experiments, we used the SVM implementation provided by the sklearn library (Pedregosa et al., 2018) and TensorFlow in our fine-tuning experiment. Hyperparameters of the SVM have been chosen by 5-folds cross-validation.

Results We evaluate the results of the tense prediction task using both micro and macro precision to account for the imbalance between classes.[8] Results are reported in Table 1.[9] As expected, the best results both for French and Chinese are achieved by fineBert, the model in which the word and sentence representations are tailored to the tense prediction task. The relatively good performance of the featSVM shows the relevance of the considered features and validates the theoretical analysis of Smith and Erbaugh (2005). It also highlights the difficulty of defining handcrafted features generic enough to capture time information in all conditions.

Comparing performances achieved on Chinese and French is particularly interesting since it shows that our very simple architecture is able to predict almost perfectly the tense of French sentences (which can be deduced directly from the morphology of the verb and therefore from a surface analysis) but that its performance drops drastically when applied to Chinese sentences, the tense of which has to be inferred from a wide array of both lexical and syntactic cues. This observation suggests that the model is only memorizing patterns from

---

future have no explicit markings

[7] See Appendix B for a full description of the features considered.

[8] The macro-precision calculates the precision independently for each class, then takes the average (so all classes are treated equally), while the micro-precision aggregates the all classes' contributions to calculate the average metric.

[9] Table 3 in Appendix C provides the precision for each class.

the training set rather than inferring a meaningful representation of the sentence.

To corroborate this interpretation, we have evaluated the performance of fineBert in terms of the similarity between the test and train data: for each language, we have trained a 5-gram language model with Kneser-Ney smoothing using `KenLM` (Heafield et al., 2013) and divided the test set sentences into 3 groups of equal size according to the probability that the sentence was generated by the language model.[10] Because of the way tense is expressed in Chinese, ensuring that the verb of the test sentences are not in the train set is not enough. It appears, as expected, that performance drops significantly when the similarity of train and test sentences decreases: for Chinese (resp. French), the macro precision drops from 70% (resp. 96%) for the test phrases that are the most similar to the train set to 66% (resp. 93%) for the test phrases that are the most different from the train set, while their similarity with the train set (measured as the mean of $\log_{10} p(x)$ over the test test) drops from -30.62 to -93.93 (resp. -70.4 to -231.18). Detailed results are presented in Appendix D.

These results clearly show that the higher the similarity with the train sentences is, the more accurate the model is. Again, this observation questions the capacity of the model to capture relevant linguistic properties rather than simply memorizing the training data.

Discussion Our experiments clearly show that Bert prefers learning lexically marked features rather than lexically unmarked features. These results indicate that, even if several confounders exist, neural networks tend to memorize shallow patterns from the training data rather than uncover abstract linguistic properties.

There is a first well-known confounding factor when interpreting probing results: high classification accuracy could result from the fact that the probe has learned the linguistic task and not from the properties captured by the representation. In our work, we avoid this pitfall by considering a multilingual probe setting: our conclusions are not based on an absolute score but on the comparison of the performance achieved in French and Chinese by the same probe.

The difference in performance between the French and Chinese models is a second confounder. This difference can result from either the training set size or the model's architecture tailored to extract only lexically-marked information. In recent work, Warstadt et al. (2020) suggests that it may be possible that, if more data were available, Bert could eventually learn to predict Chinese tense. However,it must be pointed out that the French model achieves a precision of 76.9% and the Chinese model a precision of 76.6% on the XLNI cross-lingual classification task, the standard evaluation benchmark of sentence representation models. Therefore, we believe that our conclusions are not biased by the language modeling performance.

There is a third and last possible confounder: it is possible that, as explained in §2, sometimes, in Chinese the cues to tense may appear in an earlier sentence. Gong et al. (2012) showed that the tense of previous sentences has a close relation to the current sentence. Considering contextual features in our feature-based SVM classifier only increases the accuracy by 2%, therefore, we believe that this factor has only a moderate impact.

5 Conclusion

We have shown that the performance of a tense prediction model varies dramatically depending on how the language expresses time, a result that suggests that Bert is more likely to memorize shallow patterns from the train set rather than uncover abstract properties. Our work also highlights the interest of comparing linguistic probes across languages which opens up a new avenue for research.

Acknowledgments

We sincerely thank the reviewers and Program Chairs for their careful reviews and insightful comments, which are of great help in improving the manuscript. We would like to express special gratitude to Professor Claire Saillard, this work would not have been possible without her helpful comments and advice.

---

[10] More precisely, we have ordered the sentences of the test set according to their probability estimated by the language model and considered the 5,814 first (resp. last) sentences as the most different (resp. similar) from the train set.

A Mapping of French Tense

When building our corpus, the tense of each sentence was deduced from the automatic morphological analysis of its root verb using the mapping defined in Table 2.

French passé composé describes a situation that was completed in the past and emphasizes its results in the present. Smith (1997)considers that the Passé composé presents two tense values. When used to present a given state of things, passé composé is temporally present. When used to denote past facts, passé composé, called a preterit by Smith, is temporally past. Which tense value of passé composé should we take into account, the perfect present or past? Concerning the translation of perfect present into Chinese, it’ s interesting to read the corpus study of Xiao and McEnery (2004), according to which the perfect present tense of English is most frequently (71%) translated into Chinese by perfective aspect. Whereas in Chinese, Lin (2006) contends a preferential correlation between perfective aspect and past tense. We have thus decided to classify the passé composé into the Past category.

B Features used in featSVM

1. **Root verb**: The root verb may denote some intrinsic features related to tense(Xiao and McEnery, 2004) In the automatic morphological analysis generated by Stanza, the root word is the verb with a dependency label of *root*, or the Chinese adjectives (Chinese adjectives can be used as verbs) governed by root directly.

2. **Aspect markers**: Perfective aspect marker (了 le, 过 guo) and the imperfective aspect marker (着 zhe).We didn’t consider another imperfective aspect marker (在 zai) because `Stanza` didn’t annotate this marker.

3. **Temporal nouns**: We have extracted a list of temporal nouns. These words have been annotated by `Stanza` with the dependency label *nmod:tmod*. A complex sentence could contain multiple *nmod:tmod* words. We only consider the one that is governed by its root verb or by the verb governed directly by the root word. This list mainly contains words like 现在 *(now)*, 明天 *(tomorrow)*, 刚才 *(just now)*.

4. **Temporal adverbs**: We have determined a list of adverbs with temporal connotation. For example, 已经 *(already)*, 一直 *(always)*, 曾 *(once)*. These adverbs have been annotated by `Stanza` with the dependency label *advmod*. Like the temporal nouns, we only take into account the temporal adverb directly governed by the root word.

5. **Modal auxiliaries**: Words that express necessity, expectation, possibility of the action described by the verb. The bounded situation in the future in Chinese is often expressed by modal auxiliaries 要 *(is going to)* or 会 *(it is probable that)*.

6. **Contextual tense**: We consider the tense of the previous sentence as contextual tense, which provides contextual temporal cues for some Chinese sentences that have no temporal words or aspect markers at all.

7. **Words and POS patterns**: Combinations of word and POS tag for each word in the whole sentence. These features are expected to capture some special syntactic structure. For example, the structure 就要 + predicate + 了 *(...is going to happen)* indicates a near-future situation.

C Performance of different models for each class

Table 3 presents the results of different classifiers for each tense category. It shows that more frequent data are more likely to be better predicted: the Present class (67% of the examples) gets the highest score for all classifiers except French FINEBERT.

D Results of the performance of FineBert

Table 4 details the performance of FINEBERT and the impact of the similarity between the train and test sentences. The similarity is measured as the mean of $\log_{10} p(x)$ over the test test.

Tense predicted for the root verb	Label of the sentence
présent de l'indicatif	PRESENT
présent du conditionnel	PRESENT
présent de l'impératif	PRESENT
imparfait	PAST
plus-que-parfait	PAST
passé simple	PAST
passé récent	PAST
passé composé	PAST
futur simple	FUTURE
futur proche	FUTURE

Is Supervised Syntactic Parsing Beneficial for Language Understanding Tasks? An Empirical Investigation

Abstract

Traditional NLP has long held (supervised) syntactic parsing necessary for successful higher-level semantic language understanding (LU). The recent advent of end-to-end neural models, self-supervised via language modeling (LM), and their success on a wide range of LU tasks, however, questions this belief. In this work, we empirically investigate the usefulness of supervised parsing for semantic LU in the context of LM-pretrained transformer networks. Relying on the established fine-tuning paradigm, we first couple a pretrained transformer with a biaffine parsing head, aiming to infuse explicit syntactic knowledge from Universal Dependencies treebanks into the transformer. We then fine-tune the model for LU tasks and measure the effect of the intermediate parsing training (IPT) on downstream LU task performance. Results from both monolingual English and zero-shot language transfer experiments (with intermediate target-language parsing) show that explicit formalized syntax, injected into transformers through IPT, has very limited and inconsistent effect on downstream LU performance. Our results, coupled with our analysis of transformers' representation spaces before and after intermediate parsing, make a significant step towards providing answers to an essential question: how (un)availing is supervised parsing for high-level semantic natural language understanding in the era of large neural models?

1 Introduction

Structural analysis of sentences, based on a variety of syntactic formalisms (Charniak, 1996; Taylor et al., 2003; De Marneffe et al., 2006; Hockenmaier and Steedman, 2007; Nivre et al., 2016, 2020, *inter alia*), has been the beating heart of NLP pipelines for decades (Klein and Manning, 2003; Chen and Manning, 2014; Dozat and Manning, 2017; Kondratyuk and Straka, 2019), establishing rather strong common belief that high-level semantic language understanding (LU) crucially depends on explicit syntax. The unprecedented success of neural language learning models based on transformer networks (Vaswani et al., 2017), trained on unlabeled corpora via language modeling (LM) objectives (Devlin et al., 2019; Liu et al., 2019b; Clark et al., 2020, *inter alia*) on a wide variety of LU tasks (Wang et al., 2018; Hu et al., 2020), however, questions this widely accepted assumption.

The question of necessity of supervised parsing for LU and NLP in general has been raised before. More than a decade ago, Bod (2007) questioned the superiority of supervised parsing over unsupervised induction of syntactic structures in the context of statistical machine translation. Nonetheless, the NLP community has since still managed to find sufficient evidence for the usefulness of explicit syntax in higher-level LU tasks (Levy and Goldberg, 2014; Cheng and Kartsaklis, 2015; Bastings et al., 2017; Kasai et al., 2019; Zhang et al., 2019a, *inter alia*). However, we believe that the massive improvements brought about by the LM-pretrained transformers – unexposed to any explicit syntactic signal – warrant a renewed scrutiny of the utility of supervised parsing for high-level language understanding.[1,2] The research question we address in this work can be summarized as follows:

---

[1] **Disclaimer 1:** In this work, we make a clear distinction between Computational Linguistics (CL), i.e., the area of linguistics leveraging computational methods for analyses of human languages and NLP, the area of artificial intelligence tackling human language in order to perform intelligent tasks. This work scrutinizes the usefulness of supervised parsing and explicit syntax only for the latter. We find the usefulness of explicit syntax in CL to be self-evident.

[2] **Disclaimer 2:** The purpose of this work is definitely not to invalidate the admirable efforts on syntactic annotation and modeling, but rather to make an empirically driven step towards a deeper understanding of the relationship between LU and formalised syntactic knowledge, and the extent of its impact to modern semantic LU and applications.

April 19 - 23, 2021.

(RQ) *Is explicit structural language information, provided in the form of a widely adopted syntactic formalism (Universal Dependencies, UD) (Nivre et al., 2016) and injected in a supervised manner into LM-pretrained transformers beneficial for transformers' downstream LU performance?*

While existing body of work (Lin et al., 2019; Tenney et al., 2019; Liu et al., 2019a; Kulmizev et al., 2020; Chi et al., 2020) probes transformers for structural phenomena, our work is more pragmatically motivated. We directly evaluate the effect of infusing structural language information from UD treebanks, via intermediate dependency parsing (DP) training, on transformers' performance in downstream LU. To this end, we couple a pretrained transformer with a biaffine parser similar to Dozat and Manning (2017), and train the model (i.e., fine-tune the transformer) for DP. Our parser on top of RoBERTa (Liu et al., 2019b) and XLM-R (Conneau et al., 2020) produces DP results which are comparable to state of the art. We then fine-tune the syntactically-informed transformers for three downstream LU tasks: natural language inference (NLI) (Williams et al., 2018; Conneau et al., 2018), paraphrase identification (Zhang et al., 2019b; Yang et al., 2019), and causal commonsense reasoning (Sap et al., 2019; Ponti et al., 2020). We quantify the contribution of explicit syntax by comparing LU performance of the transformer exposed to intermediate parsing training (IPT) and its counterpart directly fine-tuned for the downstream task. We investigate the effects of IPT (1) *monolingually*, by fine-tuning English transformers, BERT and RoBERTa, on an English UD treebank and for (2) downstream *zero-shot language transfer*, by fine-tuning massively multilingual transformers (MMTs) – mBERT and XLM-R (Conneau et al., 2020) – on treebanks of downstream target languages, before the downstream fine-tuning on source language (English) data.

While intermediate parsing training is obviously not the only way of bringing syntactic knowledge to downstream tasks (Kuncoro et al., 2019; Swayamdipta et al., 2019; Kuncoro et al., 2020), it is arguably the most straightforward way of injecting syntactic signal in the context of the predominant pretraining-fine-tuning paradigm that has, nonetheless, not been investigated up to this point. Other methods of bringing syntactic signal to downstream tasks such as knowledge distillation (Kuncoro et al., 2020) and pre-training on shallow trees instead of sequences (Swayamdipta et al., 2019) have failed to demonstrate significant gains on higher-level LU tasks.

Our results also render supervised UD parsing largely inconsequential to LU. We observe limited and inconsistent gains only in zero-shot downstream language transfer: further analyses reveal that (1) intermediate LM training yields comparable gains and (2) IPT only marginally changes representation spaces of transformers exposed to sufficient amount of language data in LM-pretraining. We hope that these empirical findings will shed new light on the relationship between supervised parsing (and manually labeled treebanks) and LU with transformer networks, and guide further similar investigations in future work, in order to fully understand the impact of formal syntactic knowledge on LU performance with modern neural architectures.

2 Related Work

Bringing Explicit Syntax to LMs. Previous work has attempted to enrich language models with explicit syntactic knowledge in ways other than intermediate parsing training. Swayamdipta et al. (2019) modify the pretraining objective of ELMo (Peters et al., 2018) to learn from shallowly parsed (i.e., chunked) corpora. They, however, report no notable improvements on downstream tasks. Kuncoro et al. (2019) propose to distil the knowledge from a Recurrent NN Grammar (RNNG) teacher trained on a small syntactically annotated corpus (by modeling the joint probability of surface sequence and phrase structure tree) into an LSTM-based student pretrained on a much larger corpus. They show that distillation helps the student in structured prediction tasks, but their downstream evaluation does not involve LU tasks. Their subsequent work (Kuncoro et al., 2020) replaces the RNN student with BERT (Devlin et al., 2019): syntactic distillation again helps structured prediction, but hurts (slightly) the performance on LU tasks from the GLUE benchmark (Wang et al., 2018).

Transformer-Based Dependency Parsing. Building on the success of preceding neural parsers (Chen and Manning, 2014; Kiperwasser and Goldberg, 2016), Dozat and Manning (2017) proposed a biaffine parsing head on top of a Bi-LSTM encoder: contextualized word vectors are fed to two feed-forward networks, producing dependent- and head-specific token representations, respectively. Arc and relation scores are produced via biaffine products between these dependent- and head-specific representation matrices. Finally, the Edmonds algorithm induces the optimal tree from pairwise arc predictions. Most recent DP work (Kondratyuk and Straka, 2019; Üstün et al., 2020) replaces the Bi-LSTM encoder with multilingual BERT's transformer, reporting state-of-the-art parsing performance. Kondratyuk and Straka (2019) fine-tune mBERTs parameters on the concatenation of all UD treebanks, whereas Üstün et al. (2020) freeze the original transformer's parameters and inject adapters (Houlsby et al., 2019) for parsing.

We propose and work with a simpler transformer-based biaffine parser: we apply biaffine attention directly on representations from transformer's output layer, eliminating the head- and dependendant-based feed-forward mapping. Despite this simplification, our biaffine parser produces DP results comparable to current state-of-the-art parsers.

Syntactic BERTology. The substantial body of syntactic probing work shows that BERT (Devlin et al., 2019) (a) encodes text in a hierarchical manner (i.e., it encodes some implicit underlying syntax) (Lin et al., 2019); and (b) captures specific shallow syntactic information (parts-of-speech and syntactic chunks) (Tenney et al., 2019; Liu et al., 2019a). Hewitt and Manning (2019) find that linear transformations, when applied on BERT's contextualized word vectors, reflect distances in dependency trees. This suggests that BERT encodes sufficient structural information to reconstruct dependency trees (though without arc directionality and relations). Chi et al. (2020) extend the analysis to multilingual BERT, finding that its representation subspaces may recover trees also for other languages. They also provide evidence that clusters of head–dependency pairs roughly correspond to UD relations. Similarly, Kulmizev et al. (2020) show that BERT's latent syntax corresponds more to UD trees than to shallower SUD (Gerdes et al., 2018) structures. Despite the evident similarity between BERT's latent syntax and formalisms such as UD, there is ample evidence that BERT insufficiently leverages syntax in downstream tasks: it often produces similar predictions for syntactically valid as well as for structurally corrupt sentences (e.g., with random word order) (Wallace et al., 2019; Ettinger, 2020; Zhao et al., 2020).

Intermediate Training. Sometimes called Supplementary Training on Intermediate Labeled-data Tasks (STILT) (Phang et al., 2018), intermediate training is a transfer learning setup in which one trains an LM-pretrained transformer on one or more supervised tasks (ideally with large training sets) before final fine-tuning for the target task. Phang et al. (2018) show that intermediate NLI training of BERT on the Multi-NLI dataset (Williams et al., 2018) benefits several language understanding tasks. Subsequent work (Wang et al., 2019; Pruksachatkun et al., 2020) investigated many combinations of intermediate and target LU tasks, failing to identify any universally beneficial intermediate task. In this work we use DP as an intermediate training task (IPT) for LM-pretrained transformers.

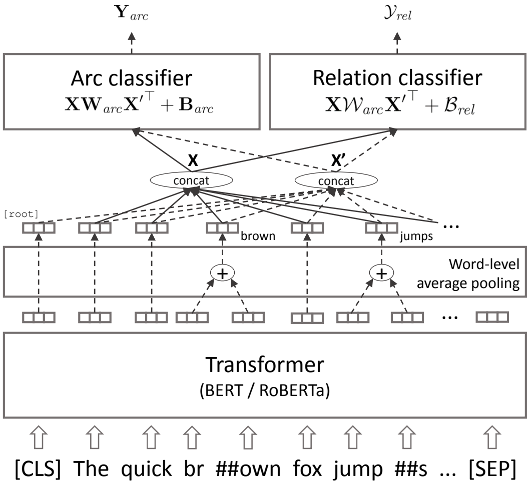

Figure 1: Architecture of our transformer-based biaffine dependency parser.

3 Methodology

Biaffine Parser. Our parsing model, illustrated in Figure 1, consists of a biaffine attention layer applied directly on the transformer's output (BERT, RoBERTa, mBERT, or XLM-R). We first obtain word-level vectors by averaging transformed representations of their constituent subwords, produced by the transformer. Let $\mathbf{X} \in \mathbb{R}^{N \times H}$ denote the encoding of a sentence with N word-level tokens, consisting of N H-dimensional vectors (where H is the transformer's hidden size). We use the transformed representation of the sentence start token (e.g., `[CLS]` for BERT), $\mathbf{x}_{CLS} \in \mathbb{R}^{H}$, as the representation for the `root` node of the parse tree, and prepend it to $\mathbf{X}$, $\mathbf{X}' = [\mathbf{x}_{CLS}; \mathbf{X}] \in \mathbb{R}^{(N+1) \times H}$. We then use $\mathbf{X}$ as the representation of syntactic dependants and $\mathbf{X}'$ as the representation of dependency heads. We then directly compute the arc and relation scores as biaffine products of $\mathbf{X}$ and $\mathbf{X}'$:

$$\mathbf{Y}_{arc} = \mathbf{X}\mathbf{W}_{arc}\mathbf{X}'^{\top} + \mathbf{B}_{arc};\ \ \mathbf{Y}_{rel} = \mathbf{X}\mathbf{W}_{rel}\mathbf{X}'^{\top} + \mathbf{B}_{rel}$$

where $\mathbf{W}_{arc} \in \mathbb{R}^{H \times H}$ and $\mathbf{W}_{rel} \in \mathbb{R}^{H \times H \times R}$ denote, respectively, the arc classification matrix and relation classification tensor (with R as the number of relations); $\mathbf{B}_{arc}$ and $\mathbf{B}_{rel}$ denote the corresponding bias parameters. We greedily select the dependency head for each word by finding the maximal score in each row of $\mathbf{Y}_{arc}$: while this is not guaranteed to produce a tree, Zhang et al. (2017) show that in most cases it does.[3] Our arc prediction loss is the cross-entropy loss with sentence words (plus the `root` node) as categorical labels: this implies a different number of labels for different sentences. We compute the relation prediction loss as a cross-entropy loss over gold arcs. Our final loss is the sum of the arc loss and relation loss.

Note that, in comparison with the original biaffine parser (Dozat and Manning, 2017) and its other transformer-based variants (Kondratyuk and Straka, 2019; Üstün et al., 2020), we feed word-level representations derived from the transformer's output directly to biaffine products, omitting the dependent- and head-specific MLP transformations. Deep task-specific architectures go against the fine-tuning idea: deep transformers have plenty of their own parameters that can be tuned for DP. We want to propagate as much of the explicit syntactic knowledge as possible into the transformer: a deep(er) DP-specific architecture on top of the transformer would impede the propagation of this knowledge to the transformer's parameters.

Downstream Models. After IPT, we fine-tune transformers for two *types* of LU tasks: (1) *sequence classification* (SEQC) tasks, where a sequence of text needs to be assigned a discrete label; and (2) *multiple choice classification* (MCC) tasks where we need to select the correct answer between two or more options for a given a premise and/or question. For SEQC, we simply apply a softmax classifier on the transformed representation of the sequence start token: $\mathbf{y} = \mathit{softmax}\left(\mathbf{x}_{CLS}\mathbf{W}_{sc} + \mathbf{b}_{sc}\right)$ (with $\mathbf{W}_{sc} \in \mathbb{R}^{H \times C}$ and $\mathbf{b}_{sc} \in \mathbb{R}^{C}$ as classifier's parameters and C as the number of task's labels).

For MCC tasks, we first concatenate each of the offered answer choices (independently of each other) to the premise and/or question, and encode it with the transformer. Since some of these tasks, e.g., COPA (Roemmele et al., 2011; Ponti et al., 2020), have very small training sets, we would like to support model transfer between different MCC tasks. Different multiple-choice classification tasks, however, may differ in the number of choices: a classifier with the number of parameters depending on the number of labels is thus not a good fit; instead, we follow Sap et al. (2019) and Ponti et al. (2020), and couple the transformer with a feed-forward network outputting a single scalar for each answer. Let $\mathbf{x}^{i}_{CLS} \in \mathbb{R}^{H}$ be the representation of the sequence start token (i.e., `[CLS]` or `<s>`) for the concatenation of the premise/question and the i-th answer. We obtain the score for the i-th answer as follows:

$$y_i = \mathbf{W}^{o}_{mcc} \tanh\left(\mathbf{W}^{h}_{mcc}\mathbf{x}^{i}_{CLS} + \mathbf{b}^{h}_{mcc}\right)$$

with $\mathbf{W}^{h}_{mcc} \in \mathbb{R}^{H \times H}$, $\mathbf{b}^{h}_{mcc} \in \mathbb{R}^{H}$ and $\mathbf{W}^{o}_{mcc} \in \mathbb{R}^{1 \times H}$ as parameters. We then apply a softmax function on the concatenation of y_i scores of all answers: $\mathbf{y} = \text{softmax}([y_1, \ldots, y_K])$, with K as the number of answers (i.e., labels) in the task. Finally, we compute the cross-entropy loss on $\mathbf{y}$.

4 Experimental Setup

We now detail experimental setup, where LU fine-tuning follows Intermediate Parsing Training (IPT).

4.1 Sequential Fine-Tuning

Our primary goal is to identify if injection of explicit syntax into transformers via supervised parsing training improves their downstream LU performance – this translates into sequential fine-tuning: (1) we first attach a biaffine parser from §3 on the transformer and train the whole model on a UD treebank; (2) we then couple the syntactically-informed transformer with the corresponding downstream classification head and perform final fine-tuning. We then compare the downstream performance of transformers with and without the IPT step.

Mono- vs. Cross-Lingual IPT Experiments. In the monolingual setup, we work with English (EN) transformers, BERT and RoBERTa, pretrained on EN corpora. In the zero-shot language transfer setup, where we work with multilingual models, mBERT and XLM-R (Conneau et al., 2020), we first train transformers via IPT on the UD treebank of the target language (i.e., a language with no downstream training data) before fine-tuning it on the EN training set of the LU task. We experiment with four target languages: German (DE),

---

[3] They also show the performance of greedy decoding to match that of decoding algorithms that produce optimal trees.

French (FR), Turkish (TR), and Chinese (ZH).[4]

Standard vs. Adapter-Based Fine-Tuning. Standard fine-tuning updates all transformer's parameters, which, for tasks with large training sets may have some drawbacks: (i) fine-tuning may last long and (ii) task-specific information may overwrite the useful distributional knowledge obtained during LM-pretraining. *Adapter-based fine-tuning* (Houlsby et al., 2019; Pfeiffer et al., 2020) remedies for these potential issues by keeping the original transformer's parameters frozen and inserting new *adapter parameters* in transformer layers. In fine-tuning, both sets of parameters are used to make predictions, but we only update adapters based on loss gradients. As the number of adapter parameters is only a fraction of the number of original parameters (3-8%), fine-tuning is also much faster.

Therefore, to account for the possibility of forgetting distributional knowledge in standard IPT fine-tuning, we also carry out adapter-based IPT. We follow Houlsby et al. (2019) and inject two *bottleneck adapters* into each transformer layer: first after the multi-head attention sublayer and another after the feed-forward sublayer. In downstream LU tasks, however, we unfreeze the original transformer parameters and fine-tune them together with adapters (now containing syntactic knowledge).

4.2 Language Understanding Tasks

We now outline the downstream LU tasks. For brevity, we report all the technical training and optimization details in the Supplementary Material.

NLI is a ternary sentence-pair classification task. We predict if the hypothesis is *entailed* by the premise, *contradicts* it, or neither. For monolingual EN experiments, we use Multi-NLI (Williams et al., 2018). In zero-shot transfer experiments, we train on EN Multi-NLI and evaluate on target language (DE , FR , TR , ZH) test portions of the multilingual XNLI dataset (Conneau et al., 2018). Models trained on the Multi-NLI datasets have been shown, however, to capture certain heuristics (e.g., lexical overlap) useful for many training instances rather than more complex and generalizable language inference (McCoy et al., 2020). Because of this, we additionally evaluate on the HANS dataset (McCoy et al., 2020), consisting of adversarial examples on which models that capture such heuristics fail.

Paraphrase Identification is a binary classification task where we predict if two sentences are mutual paraphrases. For EN, we train, validate, and test on respective portions of the PAWS dataset (Zhang et al., 2019b). In zero-shot language transfer, we evaluate on the test DE , FR , and ZH portions of the PAWS-X dataset (Yang et al., 2019).

Commonsense Reasoning. We evaluate on two multiple-choice classification (MCC) datasets. In monolingual evaluation, we use the SocialIQA (SIQA) dataset (Sap et al., 2019), testing models' ability to reason about social interactions. Each SIQA instance consists of a premise, a question, and three possible answers. For zero-shot language transfer experiments, we resort to the recently published XCOPA dataset (Ponti et al., 2020), obtained by translating test portions of the EN COPA (Choice of Plausible Alternatives) dataset (Roemmele et al., 2011) to 11 languages. As mentioned, (X)COPA is an MCC task, with each instance containing a premise, a question,[5] and two possible answers. Due to the very limited size of the EN COPA training set (mere 400 instances), we follow Ponti et al. (2020) and evaluate the models fine-tuned on SIQA (EN) on the XCOPA test portions (in TR and ZH).

4.3 Training and Optimization Details

All the transformer models with which we experiment – EN BERT, mBERT, EN RoBERTa, and XLM-R have $L = 12$ layers and hidden representations of size $H = 768$. We apply a dropout ($p = 0.1$) on the transformer outputs before forwarding them to the task-specific classification heads (i.e., biaffine parsing head in intermediate parsing training, and MCC or SEQC heads in downstream fine-tuning). We optimize the parameters using the Adam algorithm (Kingma and Ba, 2015): we found the initial learning rate of 10^{-5} to offer stable convergence in both intermediate parsing training and downstream fine-tuning for all LU tasks. We train for at most 30 epochs over the respective training set, with early stopping based on the development loss.[6] On UD treebanks and

---

[4] Selected languages vary in typological and etymological proximity to EN as the source language: DE is in the same (Germanic) branch of Indo-European languages, FR is from the different branch of the same family, whereas TR (Turkic) and ZH (Sino-Tibetan) belong to different language families.

[5] While SIQA has unconstrained questions, (X)COPA has only two question types: a) What is the CAUSE of this (premise)? and b) What is the RESULT of this (premise)?

[6] We measure the development loss every U update steps and stop the training if the loss does not decrease over 10 consecutive measurements. We set $U = 500$ in NLI training and $U = 250$ in all other training procedures.

Table 2: Downstream LU performance of monolingual EN transformers (BERT and RoBERTa). **None**: no IPT; **Standard**: IPT via standard fine-tuning; **Adapter**: IPT via adapter-based fine-tuning.

SIQA we train in batches of size 8, whereas on Multi-NLI and PAWS we train in batches of size 32. In Adapter-based IPT, we set the adapter size to 64 and use GELU (Hendrycks and Gimpel, 2016) as the activation function in adapter layers.

5 Evaluation

We first discuss parsing performance of our novel biaffine parser (see §3). We then show transformers' downstream LU performance after IPT, both in monolingual EN setting and in zero-shot transfer.

5.1 Results and Discussion

Parsing Performance. In order to judge the benefits of IPT in downstream LU, we must first verify parsing performance of our biaffine parser, i.e., that we successfully fine-tune transformers for DP. Table 1 shows that our biaffine parser gives state-of-the-art performance for all five languages in our study. Our (m)BERT-based parser outperforms UDify (Kondratyuk and Straka, 2019), also based on mBERT, for EN, FR, and TR, and performs comparably for ZH.[7] Our parser based on XLM-R additionally yields an improvement over UDify for DE as well. It is worth noting that UDify trains the mBERT-based parser (1) on the concatenation of all UD treebanks and that it (2) additionally exploits gold UPOS and lemma annotations. We train our parsers only on the training portion of the respective treebank without using any additional morpho-syntactic information.[8] Our mBERT-based parser outperforms our XLM-R-based parser only for ZH: this is likely due to a tokenization mismatch between XLM-R's subword tokenization for ZH and gold tokenization in the ZH-GSD treebank.[9]

Monolingual EN Results. Table 2 quantifies the effects of applying IPT with the EN-EWT UD treebank to BERT and RoBERTa. We report downstream LU performance on NLI, PAWS, and SIQA. The reported results do not favor supervised parsing (i.e., explicit syntax): compared to original transformers that have not been exposed to any explicit syntactic supervision, variants exposed to UD syntax via IPT (Standard, Adapter) fail to produce any significant gains for any of the downstream LU tasks. One cannot argue that the cause of this might be forgetting (i.e., overwriting) of the distributional knowledge obtained in LM pretraining during IPT: Adapter IPT variants, in which all distributional knowledge is preserved by design, also fail to yield any significant LU gains. IPT yields the largest gain (+3.4%) for BERT on HANS – the NLI dataset consisting of adversarial examples for which syntax deliberately affects the sentence meaning more directly. The same effect, however, is not there for RoBERTa, suggesting that the additional syntactic knowledge that BERT gets through IPT, RoBERTa seems to obtain through larger-scale pretraining.

Zero-Shot Language Transfer. We show the results obtained for zero-shot downstream language

---

[7] Our mBERT-based parser performs poorly for DE: the cause of it is unclear and this requires further investigation.

[8] Also, since absolute parsing performance is not the primary objective of this work, we did not perform extensive language-specific hyperparameter tuning. One could likely obtain better parsing scores than what we report in Table 1 with careful language-specific model selection.

[9] We explain this mismatch in the Appendix.

Transformer	Parse FT	XNLI DE	XNLI FR	XNLI TR	XNLI ZH	PAWS-X DE	PAWS-X FR	PAWS-X ZH	XCOPA TR	XCOPA ZH
mBERT	None	71.0	73.7	**63.0**	70.3	85.1	86.3	76.4	52.0	61.2
	Standard	71.4	72.9	61.5	**70.4**	85.4	86.9	**79.8**	**57.4**	**65.4**
	Adapter	**71.7**	**74.8**	62.5	70.2	**85.8**	**87.1**	78.7	50.4	61.6
XLM-R	None	77.1	**78.1**	73.4	73.8	**88.3**	**89.3**	**81.4**	**61.2**	66.4
	Standard	76.1	77.2	73.1	73.8	86.4	89.2	81.1	59.2	**67.4**
	Adapter	**77.8**	76.4	**73.9**	**74.7**	86.7	88.7	80.7	57.4	65.6

Table 3: Performance of multilingual transformers, mBERT and XLM-R, in zero-shot language transfer for downstream LU tasks, with and without prior intermediate dependency parsing training on target language treebanks.

transfer setup, for both mBERT and XLM-R, in Table 3. Again, these results do not particularly favor the intermediate injection of explicit syntactic information in general. However, in few cases we do observe gains from the intermediate target-language parsing training: e.g., 3% gain on PAWS-X for ZH as well as 4% and 5% gains on XCOPA for ZH and TR, respectively. Interestingly, all substantial improvements are obtained for mBERT; for XLM-R, the improvements are less consistent and less pronounced. This might be due to XLM-R's larger capacity which makes it less susceptible to the "curse of multilinguality" (Conneau et al., 2020): with the subword vocabulary twice as large as mBERT's, XLM-R is able to store more language-specific information. Also, XLM-R has seen substantially more target language data in LM-pretraining than mBERT for each language. This might mean that the larger IPT gains for mBERT come from mere exposure to additional target language text rather than from injection of explicit syntactic UD signal (see further analyses in §5.2).

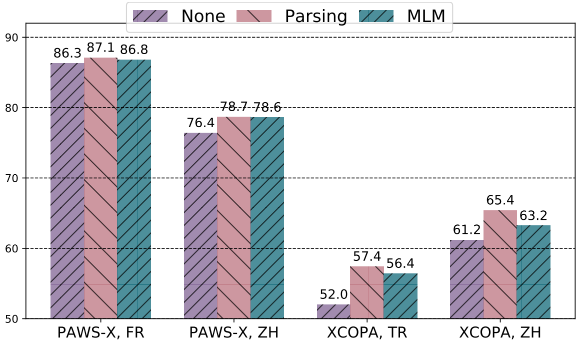

Figure 2: Comparison of IPT and ILMT in zero-shot language transfer experiments with mBERT on PAWS-X (FR and ZH) and XCOPA (TR and ZH). **None**: no intermediate training; **Parsing**: intermediate parsing training; **MLM**: intermediate masked LM training.

5.2 Further Analysis and Discussion

We first compare the impact of IPT with the effect of additional LM training on the same raw data. We then quantify the topological modification that IPT makes in transformers' representation spaces.

Explicit Syntax or Just More Language Data? We scrutinize the IPT gains that we observe in some zero-shot language transfer experiments. We hypothesize that these gains may, at least in part, be credited to transformer simply seeing more target language data. To investigate this, we replace IPT with intermediate (masked) language modeling training (ILMT) on the same data (i.e., sentences from the respective treebank used in IPT) before final downstream LU fine-tuning. Because MLM is a self-supervised objective, we can credit all differences in downstream LU performance between ILMT and IPT variants of the same pretrained transformer to supervised parsing, i.e., to the injection of explicit UD knowledge.

ILMT Details. We mask 15% of subword tokens in each sentence and predict them with a linear classifier applied on transformed representations of `[MASK]` tokens. We compute the cross-entropy loss and use the same hyperparameter configuration as described in §4.3. The development set, used for early stopping, is subdued to fixed masking, whereas we mask the training sentences dynamically, before feeding them to the transformer.

Results. We run this analysis for setups in which we observe substantial gains from IPT: PAWS-X for mBERT (*Adapter* fine-tuning, for FR and ZH) and XCOPA for mBERT (*Standard* fine-tuning, TR and ZH). The comparison between IPT and ILMT for these setups is provided in Figure 2. Like IPT, ILMT on mBERT generates downstream gains over direct downstream fine-tuning (i.e., no intermediate training) in all four setups. The gains from ILMT (with the exception of XCOPA for ZH) are almost as large as gains from IPT. This suggests that most of the gain with IPT comes from seeing more target language text, and prevents us from concluding that the explicit syntactic annotation is

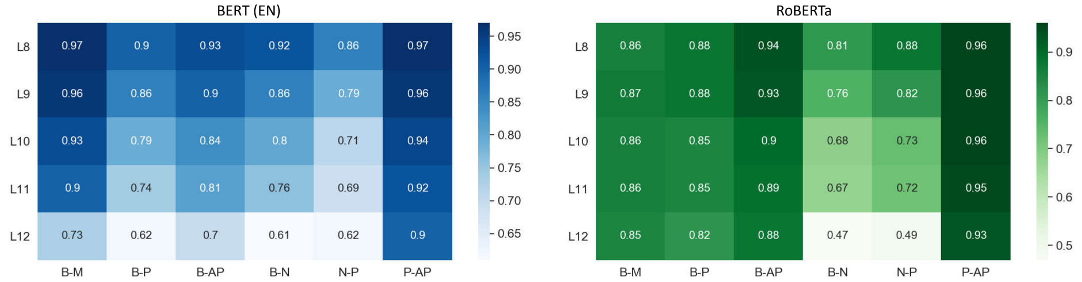

Figure 3: Topological similarity (l-CKA) for pairs of BERT and RoBERTa variants, before and after different fine-tuning steps (B, M, P, AP, and N). **Rows**: transformer layers; **Columns**: pairs of transformer variants in comparison.

responsible for the LU improvements in zero-shot downstream transfer. This interpretation is corroborated by the fact that IPT gains roughly correlate with the amount of language-specific data seen in LM-pretraining: the gains are more prominent for mBERT than for XLM-R and for TR and ZH than for FR and DE (see Table 3).

Changes in Representation Spaces. Finally, we analyze how fine-tuning transformers on different tasks modifies the topology of their representation spaces. We encode the set of sentences S from the test portions of treebanks used in IPT[10] with different variants: (a) Base (B): original LM-pretrained transformer, no further training; (b) MLM (M): after ILMT; (c) Parsing (P): after Standard IPT; and (d) Adapter-Parsing (AP): after Adapter-based IPT; for monolingual transformers (BERT and RoBERTa), also with (e) NLI (N): after NLI fine-tuning (without any intermediate training). We analyze the representations in each transformer layer separately: we represent each sentence $s \in S$ with the average of subword vectors from that layer (excluding sequence start and end tokens). Let $\mathbf{X}_1$ and $\mathbf{X}_2 \in \mathbb{R}^{|S| \times H}$ contain corresponding representations of sentences from S from the i-th layer of two transformer variants (e.g., B and P). We measure the topological similarity of the i-th layers of the two transformers with the linear centered kernel alignment (l-CKA) (Kornblith et al., 2019):[11]

$$l\text{-}CKA(\mathbf{X}_1, \mathbf{X}_2) = \frac{\left\|\mathbf{X}_2^\top \mathbf{X}_1\right\|_F^2}{\left(\left\|\mathbf{X}_1^\top \mathbf{X}_1\right\|_F\right)\left(\left\|\mathbf{X}_2^\top \mathbf{X}_2\right\|_F\right)}.$$

Although not invariant to all linear transformations, l-CKA is invariant to orthogonal projection and isotropic scaling, which suffices for our purposes. We base our analysis on the following assumption: the extent of change in transformers' representation space topology (reflected by l-CKA), is proportional to the novelty of knowledge injected in fine-tuning. Put differently, injection of new (i.e., missing) knowledge should substantially change the topology of the space (low l-CKA score).

Figure 3 shows the heatmap of l-CKA scores for pairs of BERT and RoBERTa variants, for layers L8-L12.[12] Comparing B-P and B-N reveals that IPT changes the topology of BERT's higher layers roughly as much as NLI fine-tuning does, implying that both the English UD treebank (EN -EWT) and Multi-NLI data contain a non-negligible amount of novel knowledge for BERT. However, the direct N-P comparison shows that IPT and NLI enrich BERT (also RoBERTa) with different type of knowledge, i.e., they change the representation spaces of its layers in different ways. This suggests that the transformers cannot acquire the missing knowledge needed for NLI from IPT (i.e., from EN -EWT), and explains why IPT is not effective for NLI.

IPT (comparison B-P) injects more new information than ILMT (comparison B-M), and this is more pronounced for BERT than for RoBERTa. IPT and ILMT change RoBERTa's parameters much less than BERT's (see B-M and B-P l-CKA scores for L11/L12), which we interpret as additional evidence, besides RoBERTa consistently outscoring BERT, that RoBERTa encodes richer language representations, due to its larger-scale and longer training. It also agrees with suggestions that BERT is "undertrained" for its capacity (Liu et al., 2019b).

Very high B-P (and B-AP) l-CKA scores in lower layers suggest that the explicit syntactic knowledge from human-curated treebanks is redundant w.r.t. the structural language knowledge transformers obtain through LM pretraining. This is consistent with concurrent observations (Chi et al., 2020; Kul-

---

[10] IPT itself only consumes train and development portions of UD treebanks. We can thus safely use sentences from test portions in this analysis, without risking information leakage.

[11] $\mathbf{X}_1$ and $\mathbf{X}_2$ must first be column-wise mean-centered.

[12] Most l-CKA scores in layers L1-L7 are very high (≥ 0.9) and provide little insight. See the Supplementary Material.

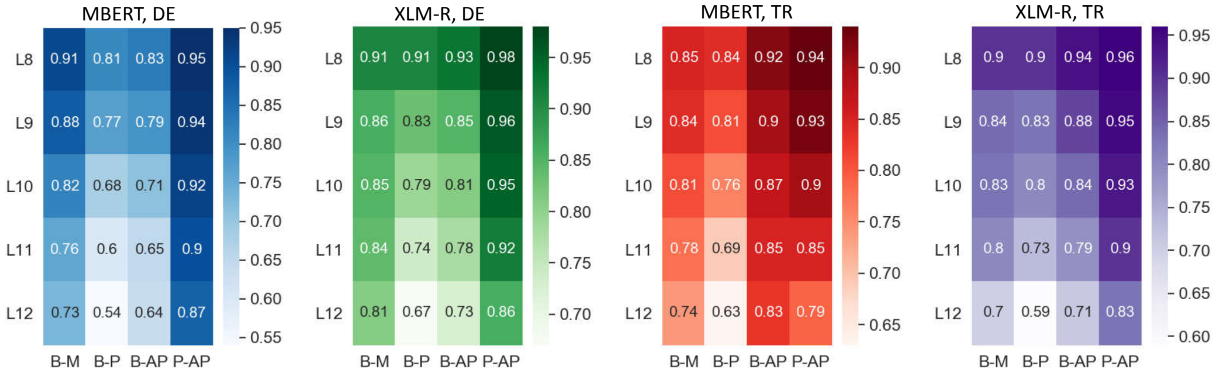

Figure 4: Analysis of topological similarity (l-CKA) for variants of mBERT and XLM-R before and after IPT and ILMT (B, M, P, AP) in zero-shot transfer experiments. Results shown for intermediate parsing on DE and TR data.

mizev et al., 2020) showing (some) correspondence between structural knowledge of (m)BERT and UD syntax. Finally, we observe highest l-CKA scores in the P-AP column, suggesting that Standard and Adapter IPT inject roughly the same syntactic information, despite different fine-tuning mechanisms.

Figure 4 illustrates the results of the same analysis for language transfer experiments, for DE and TR (scores for FR and ZH are in the Appendix). The effects of ILMT and IPT (B-M, B-P/B-AP) for DE and TR with mBERT and XLM-R resemble those for EN with BERT and RoBERTa: ILMT changes transformers less than IPT. The amount of new syntactic knowledge IPT injects is larger (l-CKA scores are lower) than for EN , especially for XLM-R (vs. RoBERTa for EN). We believe that it reflects the relative under-representation of the target language in the model's multilingual pretraining corpus (e.g., for TR): this leads to poorer representations of target language structure by mBERT and XLM-R compared to BERT's and RoBERTa's representation of EN structure. This gives us two seemingly conflicting empirical findings: (a) IPT appears to inject a fair amount of target-language UD syntax, but (b) this translates to (mostly) insignificant and inconsistent gains in language transfer in LU tasks (especially so for XLM-R, cf. Table 3). A plausible reconciling hypothesis is that there is a substantial mismatch between the type of structural information we obtain through supervised (UD) parsing and the type of structural knowledge beneficial for LU tasks. If true, this hypothesis would render supervised parsing rather unavailing for high-level language understanding, at least in the context of LM-pretrained transformers, the current state of the art in NLP. This warrants further investigation, and we hope that our work will inspire further discussion and additional studies.

6 Conclusion

We thoroughly examined the effects of leveraging formalized syntactic structures (UD) in state-of-the-art neural language models (e.g., RoBERTa, XLM-R) for downstream language understanding (LU) tasks, both in monolingual and language transfer settings. The key results, obtained through intermediate parsing training (IPT) based on a state-of-the-art-level dependency parser, indicate that explicit syntax, at least in our extensive experiments, provides negligible impact on LU tasks.

Besides offering extensive empirical evidence of the mismatch between explicit syntax and improved LU performance with state-of-the-art transformers, this study sheds new light on some fundamental questions such as the one in the title. Similar to word embeddings (Mikolov et al., 2013) removing sparse lexical features from the NLP horizon, will transformers make supervised parsing obsolete for LU applications or not? More dramatically, in the words of Rens Bod (2007): "Is the end of supervised parsing in sight" for semantic LU tasks?[13]

We thank the anonymous reviewers (especially R2!) for the exceptionally meaningful and helpful comments. Goran Glavaš is supported by the Baden Württemberg Stiftung (Eliteprogramm, AGREE grant). The work of Ivan Vulić is supported by the ERC Consolidator Grant LEXICAL: Lexical Acquisition Across Languages (no. 648909).

---

[13] The answer is 'Probably no': formalized syntactic structures will still be an important source of inductive bias, especially in setups without sufficient text data for large-scale pretraining; our experiments, however, validate that state-of-the-art transformer models can implicitly capture that inductive bias in high-resource setups and for major languages.

A Reproducibility

We first provide details on where to obtain datasets and code used in this work.

A.1 Datasets

Table 5 lists the sizes (in number of sentences) of Universal Dependencies treebanks that we use for our intermediate parsing training and evaluation of our biaffine dependency parsers. The UD treebanks v.2.5, which we used in this work, are available at: `http://hdl.handle.net/11234/1-3105`. In Table 6 we provide links to language understanding datasets used in our study.

A.2 Code and Dependencies

We make our code available at: `https://github.com/codogogo/parse_stilt`. Our code is built on top of the HuggingFace Transformers framework: `https://github.com/huggingface/transformers` (v. 2.7). Table 4 details the LM-pretrained transformer models from this framework which we exploited in this work. Besides the Transformers library, our code only relies on standard Python's scientific computing libraries (e.g., `numpy`).

B ZH Tokenization: XLM-R vs. GSD

A word-level token from the parse tree normally corresponds to one or more transformer's subword tokens: we thus average subword vectors to obtain word vectors for biaffine parsing. For XLM-R and the ZH GSD treebank, however, a single XLM-R's subword token often corresponds to two treebank tokens. E.g., the sequence “只是二選一做決擇” with treebank tokenization [‘只’, ‘是’, ‘二’, ‘選’, ‘一’, ‘做’, ‘決擇’] is tokenized as [‘只是’, ‘二’, ‘選’, ‘一’, ‘做’, ‘決’, ‘擇’] by XLM-R. Two treebank tokens, ‘只’ and ‘是’, are captured with a single XLM-R “subword” token, ‘只是’. To ensure that each XLM-R subword token corresponds to exactly one treebank token, we inject spaces between treebank tokens before XLM-R tokenization: we then obtain the subword tokenization [‘只’, ‘是’, ‘二’, ‘選’, ‘一’, ‘做’, ‘決, ‘擇’]. However, this is suboptimal for XLM-R: its representations of tokens ’只’ and ’是’ are probably less reliable than that of the ’只是’ token. We believe this is why mBERT (without tokenization mismatches for ZH) outperforms XLM-R in ZH parsing.

C Complete Topology Analysis Results

Finally, we show the complete results (for all layers, all transformers, and all languages covered in our experiments) of our topological analysis of transformers' representations before and after different fine-tuning steps. Figure 5 shows the analysis results for monolingual EN transformers, BERT and RoBERTa. Figure 6 and Figure 7 show the results for multilingual transformers, mBERT and XLM-R, respectively, for all four target languages included in our experiments: DE , FR , TR , and ZH .

Name	Lang	Vocab	Params	URL
BERT	EN	29K	110M	https://huggingface.co/bert-base-cased
RoBERTa	EN	50K	110M	https://huggingface.co/roberta-base

Facilitating Terminology Translation with Target Lemma Annotations

Abstract

Most of the recent work on terminology integration in machine translation has assumed that terminology translations are given already inflected in forms that are suitable for the target language sentence. In day-to-day work of professional translators, however, it is seldom the case as translators work with bilingual glossaries where terms are given in their dictionary forms; finding the right target language form is part of the translation process. We argue that the requirement for apriori specified target language forms is unrealistic and impedes the practical applicability of previous work. In this work, we propose to train machine translation systems using a source-side data augmentation method[1] that annotates randomly selected source language words with their target language lemmas. We show that systems trained on such augmented data are readily usable for terminology integration in real-life translation scenarios. Our experiments on terminology translation into the morphologically complex Baltic and Uralic languages show an improvement of up to 7 BLEU points over baseline systems with no means for terminology integration and an average improvement of 4 BLEU points over the previous work. Results of the human evaluation indicate a 47.7% absolute improvement over the previous work in term translation accuracy when translating into Latvian.

1 Introduction

Translation into morphologically complex languages involves 1) making a lexical choice for a word in the target language and 2) finding its morphological form that is suitable for the morphosyntactic context of the target sentence. Most of the recent work on terminology translation, however, has assumed that the correct morphological forms are apriori known (Hokamp and Liu, 2017; Post and Vilar, 2018; Hasler et al., 2018; Dinu et al., 2019; Song et al., 2020; Susanto et al., 2020; Dougal and Lonsdale, 2020). Thus previous work has approached terminology translation predominantly as a problem of making sure that the decoder's output contains *lexically* and *morphologically* prespecified target language terms. While useful in some cases and some languages, such approaches come short of addressing terminology translation into morphologically complex languages where each word can have many morphological surface forms.

For terminology translation to be viable for translation into morphologically complex languages, terminology constraints have to be *soft*. That is, terminology translation has to account for various natural language phenomena, which cause words to have more than one manifestation of their root morphemes. Multiple root morphemes complicate the application of *hard* constraint methods, such as constrained-decoding (Hokamp and Liu, 2017). That is because even after the terminology constraint is striped from the morphemes that encode all grammatical information, the remaining root morphemes still can be too restrictive to be used as hard constraints because, for many words, there can be more than one root morpheme possible. An illustrative example is the consonant mutation in the Latvian noun *vācietis* ("the German") which undergoes the mutation t→š, thus yielding two variants of its root morpheme *vācieš-* and *vāciet-* (Bergmanis, 2020). If either of the forms is used as a hard constraint for constrained decoding, the other one is excluded from appearing in the sentence's translation.

We propose a necessary modification for the method introduced by Dinu et al. (2019), which allows training neural machine translation (NMT)

systems that are capable of applying terminology constraints: instead of annotating source-side terminology with their exact target language translations, we annotate randomly selected source language words with their target language lemmas. First of all, preparing training data in such a way relaxes the requirement for access to bilingual terminology resources at the training time. Second, we show that the model trained on such data does not learn to simply *copy* inline annotations as in the case of Dinu et al. (2019), but learns *copy-and-inflect* behaviour instead, thus addressing the need for *soft* terminology constraints.

Our results show that the proposed approach not only relaxes the requirement for apriori specified target language forms but also yields substantial improvements over the previous work (Dinu et al., 2019) when tested on the morphologically complex Baltic and Uralic languages.

2 Method: Target Lemma Annotations

To train NMT systems that allow applying terminology constraints Dinu et al. (2019) prepare training data by amending source language terms with their exact target annotations (**ETA**). To inform the NMT model about the nature of each token (i.e., whether it is a source language term, its target language translation or a regular source language word), the authors use an additional input stream—source-side factors (Sennrich and Haddow, 2016). Their method, however, is limited to cases in which the provided annotation matches the required target form and can be copied verbatim, thus performing poorly in cases where the surface forms of terms in the target language differ from those used to annotate source language sentences (Dinu et al., 2019). This constitutes a problem for the method's practical applicability in real-life scenarios. In this work, we propose two changes to the approach of Dinu et al. (2019). **First**, when preparing training data, instead of using terms found in either IATE[2] or Wiktionary as done by Dinu et al. (2019), we annotate random source language words. This relaxes the requirement for curated bilingual dictionaries for training data preparation. **Second**, rather than providing exactly those target language forms that are used in the target sentence, we use target lemma annotations (**TLA**) instead (see Table 1 for examples). We hypothesise that in order to benefit from such annotations, the NMT model will have to learn *copy-and-inflect* behaviour instead of simple *copying* as proposed by Dinu et al. (2019).

Our work is similar to work by Exel et al. (2020) in which authors also aim to achieve *copy-and-inflect* behaviour. However, authors limit their annotations to only those terms for which their base forms differ by no more than two characters from the forms required in the target language sentence. Thus wordforms undergoing longer affix change or inflections accompanied by such linguistic phenomena as consonant mutation, consonant gradation or other stem change are never included in training data.

3 Experimental Setup

Languages and Data. As our focus is on morphologically complex languages, in our experiments we translate from English into Latvian and Lithuanian (Baltic branch of the Indo-European language family) as well as Estonian (Finnic branch of the Uralic language family). For comparability with the previous work, we also use English-German (Germanic branch of the Indo-European language family). For all language pairs, we use all data that is available in the Tilde Data Libarary with an exception for English-Estonian for which

we use data from WMT 2018. The size of the parallel corpora after pre-processing using the Tilde MT platform (Pinnis et al., 2018) and filtering tools (Pinnis, 2018) is given in Table 2.

To prepare data with TLA, we first lemmatise and part-of-speech (POS) tag the target language side of parallel corpora. For lemmatisation and POS tagging, we use pre-trained Stanza[3] (Qi et al., 2020) models. We then use *fast_align*[4] (Dyer et al., 2013) to learn word alignments between the target language lemmas and source language inflected words. We only annotate verbs or nouns. To generate sentences with varying proportions of annotated and unannotated words, we first generate a sentence level annotation threshold uniformly at random from the interval $[0.6, 1.0)$. Similarly, for each word in the source language sentence, we generate another number uniformly at random from the interval $[0.0, 1.0)$. If the latter is larger than the sentence level annotation threshold, we annotate the respective word with its target language lemma. We use the original training data and annotated data with a proportion of 1:1. We follow Dinu et al. (2019) to prepare ETA and replicate their results.

For validation during training, we use development sets from the WMT news translation shared tasks. For EN-ET and EN-DE, we used the data from WMT 2018, for EN-LV – WMT 2017, and for EN-LT – WMT 2019.

MT Model and Training. For the most part, we use the default configuration of the Transformer (Vaswani et al., 2017) NMT model implementation of the Sockeye NMT toolkit (Hieber et al.). The exception is the use of source-side factors (Sennrich and Haddow, 2016) with the dimensionality of 8 for systems using inline target lemma annotations. We train all models using early stopping with the patience of 10 based on their development set perplexity (Prechelt, 1998).

Evaluation Methods and Data. In previous work, methods were tested on general domain data[5] annotated with exact surface forms of general-domain words from IATE and Wiktionary. Although data constructed in such a way is not only artificial but also gives an oversimplified view on terminology translation, we do use the data from IATE to validate our re-implementation of the method from Dinu et al. (2019). Other than that, we test on the Automotive Test Suite[6] (ATS): a data set containing translations of the same 768 sentences in English, Estonian, German, Latvian, and Lithuanian. ATS contains about 1.1k term occurrences from a glossary prepared by professional translators. When annotating terms in the source text, we use only the dictionary forms of term translations, since in practical applications having access to the correct inflections (surface forms) is unrealistic.

We compare our work with an NMT system without means for terminology integration (**Baseline**) and the previous work by Dinu et al. (2019) (**ETA**). Although our preliminary experiments with constrained decoding (Post and Vilar, 2018) (**CD**) confirmed the findings by Dinu et al. (2019) that strict enforcement of constraints leads to lower-than-baseline quality, we nevertheless include them for completeness sake.

Similarly to the previous work, we use two auto-

Table 4: Results of human evaluation: term (on the left) and sentence (on the right) translation quality judgements in %. Sentence comparison is pairwise contrasting TLA vs Baseline and TLA vs ETA. κ-free: inter-annotator agreement according to free marginal kappa (Randolph, 2005).

matic means for evaluation: BLEU (Papineni et al., 2002) and lemmatised term exact match accuracy. We use BLEU as an extrinsic evaluation metric as we expect that, when successful, the methods for terminology translation should yield substantial overall translation quality improvements due to correctly translated domain-specific terms. For significance testing, we use pairwise bootstrap resampling (Koehn, 2004). We use lemmatised term exact match accuracy as an intrinsic metric because it directly measures the adequacy of terminology translation (i.e., whether or not the correct lexeme appears in the target sentence).

We are aware that the automatic evaluation methods are merely an approximation of translation quality. For example, we use lemmatised term exact match accuracy to measure term use in target language translations; however, it does not capture whether the term is inflected correctly. Thus human evaluation is in place. We use the EN-LV language pair to compare TLA against baseline and ETA. We use a 100 sentences large randomly selected ATS subset that contains 147 terms of the original test suite. We employ four professional translators and Latvian native speakers to compare each system's translations according to their overall translation quality and judge individual term translation quality. Specifically, given the original sentence and its two translations (in a randomised order), raters are asked to answer "which system's translation is better overall?". Raters are also given a list of the terms being evaluated and their reference translations (from the term collection) and are asked to classify translations as either "Correct", "Wrong lexeme", "Wrong inflection", or "Other". Figure 1 gives an example of the forms presented to raters during the human evaluation of term and overall translation quality. We report inter-annotator agreement using free marginal kappa, κ_{free} (Randolph, 2005).

4 Results

Automatic Evaluation. We first validate our re-implementation of ETA by testing on the English-German WMT 2017 test set annotated with terms from IATE as used by Dinu et al. (2019). Results (see columns 2 and 3 of Table 3) are similar to those of the previous work: on this data set, ETA yields minor translation quality improvements over the baseline (+0.2 BLEU) and considerable improvement (+14.5%) in term translation accuracy.

When evaluated on the ATS, systems using TLA always yield results that are better than the baseline both in terms of BLEU scores (+1.4–7 BLEU) and term translation accuracy (29.8%–47.8%) (see columns 4-11 of Table 3). Results also show that when compared to ETA, systems integrating terminology using TLA achieve statistically significant improvements in terms of BLEU scores for three out of four languages-pairs. An exception is EN-DE, for which both systems, ETA and TLA, perform similarly. Analysing reference translations of the EN-DE language pair, we find that as many as 87% of the German terms are used in their dictionary forms, which explains the comparable performance of systems trained using ETA and TLA on EN-DE.

Results also confirm the finding of the previous work by Dinu et al. (2019) and Exel et al. (2020), that the strict enforcement of constraints by constrained decoding leads to lower-than-baseline BLEU scores on all data sets for all languages. BLEU scores are abysmal when translating into the morphologically complex languages as for these languages citation form seldom happens to be the form required in the target language sentence. This result further illustrates why terminology constraints have to be *soft* when translating into morphologically complex languages.

Human Evaluation. Results of human evaluation of EN-LV systems are summarised in Table 4. First, we note that on this dataset, the baseline system translates terms correctly 55% of the time, yet it makes mistakes by choosing the wrong lexeme for most of the other cases (Table 4, left). The system using ETA, on the other hand, has a much lower rate of correctly translated terms – 45%, which roughly corresponds to the proportion of Latvian terms in the reference translations that are used in their dictionary forms (47%). The remaining cases are mistranslated by choosing the wrong inflected form. The system using TLA, in comparison, does very well as it gets terminology translations right 93% of the time. Examining the cases where terms had been mistranslated by choosing the wrong lexeme, we find that most of these cases are multi-word terms with some other word inserted between their constituent parts. The high κ-free values indicate almost perfect inter-annotator agreement suggesting that the task of term translation quality evaluation has been easy and results are reliable.

The overall sentence translation quality judgements (Table 4, right) also favour translations produced by the system using TLA deeming it better than or on par with the baseline system and system using ETA 97% of the time. The system using TLA is strictly favoured over its ETA counterpart for 61% of the translations. Again, annotators have reached an almost perfect agreement ($\kappa_{\text{free}} = 0.81$) when comparing the systems using TLA and ETA, suggesting that the task has been easy. These results clearly show that at least for the EN-LV language pair and the test set considered here, systems using TLA improve term translation quality by correctly choosing adequate translations and morpho-syntactically appropriate inflections.

Productivity of NMT models. Terminology translation frequently involves the translation of niche lexemes with rare or even unseen inflections. Thus the model's ability to generate novel wordforms is critical for high-quality translations. To verify if our NMT models are lexically and morphologically productive, we analysed Latvian translations of ATS produced by the system using TLA and looked for wordforms that are not present in either source or target language side of the training data. We found 72 such wordforms. Of those 45 or 62.5% were valid wordforms that were not present in training data, of which 28 were novel inflections related to ATS terminology use, while the remaining 17 where novel forms of general words. We interpret this as *some* evidence that the NMT model, when needed, generates novel wordforms. The remaining 27 or 37.5% were not valid, albeit sometimes plausible, Latvian language words, common types of errors being literal translations and transliterations of English words as well as words that would have been correct, if not for errors with consonant mutation.

5 Conclusions

We proposed TLA—a flexible and easy-to-implement method for terminology integration in NMT. Using TLA does not require access to bilingual terminology resources at system training time as it annotates ordinary words with lemmas of their target language translations. This simplifies data preparation greatly and also relaxes the requirement for apriori specified target language forms during the translation, making our method practically viable for terminology translation in real-life scenarios. Results from experiments on three morphologically complex languages demonstrated substantial and systematic improvements over the baseline NMT systems without means for terminology integration and the previous work both in terms of automatic and human evaluation judging term and overall translation quality.

Abstract

We propose a novel hybrid approach to lemmatization[1] that enhances the seq2seq neural model with additional lemmas extracted from an external lexicon or a rule-based system. During training, the enhanced lemmatizer learns both to generate lemmas via a sequential decoder and copy the lemma characters from the external candidates supplied during run-time. Our lemmatizer enhanced with candidates extracted from the Apertium morphological analyzer achieves statistically significant improvements compared to baseline models not utilizing additional lemma information, achieves an average accuracy of 97.25% on a set of 23 UD languages, which is 0.55% higher than obtained with the Stanford Stanza model on the same set of languages. We also compare with other methods of integrating external data into lemmatization and show that our enhanced system performs considerably better than a simple lexicon extension method based on the Stanza system, and it achieves complementary improvements w.r.t. the data augmentation method.

1 Introduction

State-of-the-art lemmatization systems are based on attentional sequence-to-sequence neural architectures operating on characters that transform the surface word form into its lemma (Kanerva et al., 2018; Qi et al., 2018). Like any other supervised learning model, these systems are dependent on the amount and quality of the existing training data. Attempts to develop even more accurate lemmatization systems can focus on improving the model's architecture or obtaining additional data. While annotating additional data is an ongoing process for many smaller languages in the Universal Dependencies (UD) collection, there are also other data sources available that can be useful for improving lemmatization systems. In particular, we refer to existing rule-based morphological analyzers, lexicons, and other such resources.

Three potential sources for extracting additional lemma candidates are Apertium, Unimorph, and UD Lexicons initiatives. Apertium[2] is an open-source rule-based machine translation platform (Forcada et al., 2011). It also includes rule-based morphological analyzers based on finite-state transducers that cover 80 languages. Unimorph[3] is a project aimed at collecting annotated morphological inflection data, including lemmas, from Wiktionary (Kirov et al., 2016), a free open dictionary for many languages. Currently, the Unimorph project covers 110 languages. UD Lexicons[4] is a collection of 53 morphological lexicons in CoNLL-UL format covering 38 languages. UD Lexicons mostly use Apertium and Giellatekno systems to generate the annotations (Sagot, 2018).

Several previous works have proposed methods to improve lemmatization systems by augmenting the training data with additional instances (Bergmanis and Goldwater, 2019; Kanerva et al., 2020). In this paper, we propose another approach that both modifies the model architecture and leverages additional data. Unlike previous work where the model gains from extracting extra knowledge from the additional data provided for training, our primary goal is to teach the model to use external resources, even those that may only be available later during test time. In particular, the proposed system is a dual-encoder model, which receives two inputs for each word: 1) the word form itself to be lemmatized and 2) (optionally) the lemma candidates for that word form extracted from a lexicon or generated by a rule-based system. Both inputs are encoded

with two different encoders and passed to the decoder. The decoder then learns via two separate attentional mechanisms to generate the lemma via the combination of the regular transduction and by copying characters from the external candidates. This way, the model is trained to use two sources of information–the regular training set and the options proposed by an external resource.

The experiments with several models enhanced with external data on 23 UD languages show that the best model using additional lemma candidates generated by the Apertium system achieves significantly higher results than the baseline models trained on the UD training set only. Also, we compare our method with other methods using external data. The enhanced system performs considerably better than a simple lexicon extension method based on the Stanza system, and it achieves complementary improvements w.r.t. the data augmentation method of Kanerva et al. (2020).

2 Related Works

Nowadays, state-of-the-art lemmatization systems are typically based on a neural sequence-to-sequence architecture, as demonstrated by the variety of systems presented at the CoNLL 2018 (Zeman et al., 2018) and SIGMORPHON 2019 (McCarthy et al., 2019) shared tasks. Several systems, including the TurkuNLP pipeline, the winner of the lemmatization track at CoNLL 2018 Shared task, use an attention-based translation model (Kanerva et al., 2018; Qi et al., 2018). The input to the system is the character sequence of a surface form (SF), which is "translated" into the lemma by an attention-based decoder. The input sequence can also be extended with POS tags (Qi et al., 2018) and morphological features (Kanerva et al., 2018).

Another approach was used by the UDPipe Future system, the second-best model at the CoNLL 2018 Shared Task. Straka (2018) proposed to produce a lemma by constructing a set of rules that transform the SF into a lemma. These rules can include copying, moving, or deleting a character in the SF, as well as additional rules for changing or preserving the casing. Thus, the lemmatization task is rendered into a multi-class classification task of choosing the correct transformation rule among the set of all possible rules generated from the training set. A year later, Straka et al. (2019) improved the result for the lemmatization by adding BERT contextual embeddings (Devlin et al., 2019) to the input, which made them the best lemmatization system at the SIGMORPHON 2019 Shared Task.

Several previous works have proposed to leverage additional data to improve lemmatization. In the simplest form, training data itself can be used to create a lexicon that maps word forms to its lemma. This strategy has been adopted by the Stanford neural lemmatization system (Qi et al., 2018), which creates such lexicons from the training sets and resorts to lemma generation only when the lexicon lookup fails. One can easily imagine extending such a lexicon with external resources. Rosa and Mareček (2018) adopted another simple way of using Unimorph lexicons to post-fix the morphological features and lemmas predicted by the UDPipe system (Straka and Straková, 2017). The post-fix is performed by simply looking up the SF from the Unimorph lexicon and, if the match is found, replacing the model prediction with the tags and lemmas found in the lexicon.

Another line of work has used additional data to augment the training data set. Bergmanis and Goldwater (2019) augmented their training set by first listing all non-ambiguous word-lemma pairs from Unimorph lexicons and then extracted sentences from Wikipedia that contained these words. They then trained the context-sensitive Lematus model (Bergmanis and Goldwater, 2018) on this extended partially lemmatized data set. Kanerva et al. (2018) used Apertium's morphological analyzer module to extend the training set for languages with tiny UD datasets. Apertium was used to generate all possible morphological analyses to 5000 sentences selected from the Wikipedia of the respective language. For each sentence, the most likely analysis sequence was then obtained via a disambiguating language model. The words that were assigned an Apertium-generated lemma during this process were added to the lemmatizer training set. In the subsequent work, Kanerva et al. (2020) extended the training data even more. They used Apertium to analyze all words found in the CoNLL 2017 web crawl dataset (Ginter et al., 2017) or in the Wikipedia of the respective language. All new words with unambiguous lemma and morphological analysis were added to the augmented training set.

3 Method

The core of the proposed model is the Stanford lemmatizer (Qi et al., 2018, 2020) which is a sequence-to-sequence model with attention. It takes character-

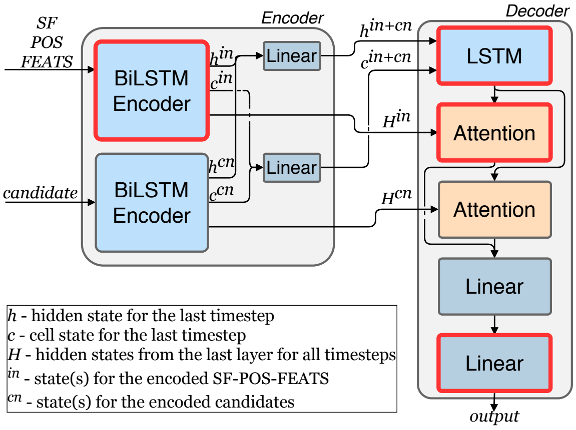

Figure 1: The architecture of the dual-encoder enhanced lemmatizer. Layers that comprise the original Stanza lemmatizer are marked with a bold red border.

level word representation and the POS tag as input and processes them with a bidirectional LSTM encoder. Then, it passes the encoder outputs to an LSTM decoder, which applies a soft dot attention layer after every LSTM cell. Finally, the output is constructed via greedy decoding.

We make several changes to the model architecture as shown in Figure 1. The components comprising the original Stanford lemmatizer are marked on the figure with the bold red border. First, we add another encoder that encodes the lemma candidates provided by the external system. The output representations of both encoders are combined with a linear layer and fed to the decoder. Secondly, we add another attention layer to the decoder that attends to the outputs of the second encoder. The outputs are finally combined with a linear layer. Finally, in addition to the POS tag, we also add morphological features to the first encoder's input.

Additionally, we implement the encoder dropout to simulate the situation when the external candidates are absent. The value of the encoder dropout that varies in the range of $\{0.0, 1.0\}$ defines the probability of discarding all candidates from a batch during training. Thus, the model will train only the main encoder based on this batch. This helps to train the model to perform more robustly in both situations when the candidates in the second encoder are present or absent.

4 Experiments

Data The models are trained and tested on the Universal Dependencies (UD) v2.5 corpora (Zeman et al., 2019). As additional external data, the lexicons from the Unimorph project (Kirov et al., 2016), UD Lexicons (Sagot, 2018), and lemmas generated with the Apertium morphological analyzer module (Forcada et al., 2011) are used. We also experiment with the lexicon constructed from the training set to simulate the situation when no additional data is available—this scenario assesses the effect of the second encoder without external data. The experiments are conducted on 23 languages from the UD collection. The basis of this selection was that all these languages are supported by both Unimorph, UD Lexicons, and Apertium.

To extract lemmas from the Unimorph lexicon, the input surface form (SF) is queried from the lexicon to retrieve the corresponding lemma. Some morphological forms in the Unimorph lexicons consist of several space-separated tokens; these were discarded. UD Lexicons are presented in the CoNLL-UL format, which is an extension of the CoNLL-U format. This makes the extraction process trivial since the lexicons are already pre-tokenized. For Apertium, all generated lemmas were stripped from special annotation symbols, and duplicate lemmas were removed. Finally, the simple training set based lexicon solution, similar to Qi et al. (2018), consists of two lookup dictionaries. The first lexicon maps SF-POS pairs to their lemmas, the second lexicon maps just SF's to their possible lemmas found in the training set. The lemma candidates for a SF are selected by first querying the input SF and POS tag from the SF-POS dictionary and, in case of failure, falling back to the SF dictionary.

Baselines As the first baseline, we compare our results with STANZA, the lemmatization module from the Stanza pipeline (Qi et al., 2020), which is a repackaging of the Stanford lemmatization system from the CoNLL 2018 Shared Task (Qi et al., 2018). We used the lemmatization models trained on the UDv2.5 available on the Stanza web page. As the DEFAULT baseline, we use our enhanced model, with the second encoder always being empty.

Experimental Setup We train four enhanced dual-encoder models that differ in the input to the second encoder. For all models, the input to the first encoder is the concatenation of SF characters, POS tag, and morphological features. During the training phase, gold POS tags and morphological features are supplied, while during inference, POS tags predicted with the Stanza tagger are used. The input to the second encoder is the following: for the second baseline (DEFAULT), it is always empty; for

Table 1: Lemmatization accuracy of the models enhanced with training the set lexicon (LEX), Unimorph lexicon (UNI), and Apertium systems (APT) as well as the DEFAULT (DEF)and STANZA baselines on 23 UD languages.

the LEXICON, UNIMORPH, and APERTIUM enhanced models, it contains the lemma candidate(s) from the training set based lexicon, Unimorph lexicons, and Apertium analyses respectively. If several possible candidates are returned for a SF, then these are concatenated. The encoder dropout for the LEXICON model is set to 0.8 to simulate the situation during testing for out-of-vocabulary (OOV) words where the second encoder will be empty. All models were trained in the HPC at the University of Tartu (University of Tartu, 2018) for a maximum of 60 epochs with stopping early if there was no improvement in the development accuracy in 10 epochs.

5 Results

Table 1 shows the results for all three enhanced systems and two baselines. The APERTIUM model outperforms other models for most languages, although the absolute differences are quite small. The LEXICON model and the DEFAULT baseline are on the same level on average, suggesting that supplying the model with lemmas extracted from the training set via the second encoder does not help to leverage the training data better. However, all enhanced models, including the DEFAULT model, perform better than the STANZA baseline, suggesting that omitting the lexicon heuristics and supplying the input tokens with both POS and morphological features might improve performance.

One-way ANOVA was performed to detect statistical difference between the systems.[5] A significant difference between the scores at the $p < 0.05$ level ($p = 0.038$) was found. Post hoc comparisons using one-sided paired t-tests showed that the mean accuracy of the APERTIUM-enhanced model is significantly greater compared to the the DEFAULT ($p_{adj} = 0.0005$), LEXICON

---

[5] The results for be_hse were extreme outliers and were not included in the comparison. The UNIMORPH-enhanced model was excluded from this test as its results did not conform to the normality requirement.

($p_{adj} < 0.0001$), UNIMORPH ($p_{adj} = 0.0001$) and STANZA ($p_{adj} < 0.0001$) systems with the p-value adjusted for multiple comparisons using the Bonferroni correction.

As the baseline model performances are already very high and the external information is expected to improve the lemmatization most for the new words unseen during training, we computed the accuracy of the out-of-vocabulary words (OOV) for the best performing APERTIUM model and the DEFAULT baseline. In this context, OOV words are those words in the test set that were not seen by the model during training. The results are shown in the right-most section of the Table 1. The improvements on the OOV words are variable, depending on the language, although on average, the improvement of the APERTIUM model over the DEFAULT baseline is more than 1%. We hypothesize that the direction and the magnitude of these effects are dependent on the coverage and the quality of the Apertium morphological analyzer.

6 Analysis of the Results

In this section, we analyze more thoroughly the potential of the proposed method. First, we compare our enhanced system with alternative methods for deploying external data, particularly with the data augmentation method proposed by Kanerva et al. (2020) and a lexicon extension method implemented based on the Stanza system (Qi et al., 2020). Secondly, we present more analyses to provide evidence towards the conclusion that the improvements presented for the enhanced model in the previous section can be attributed to our system's ability to make use of external resources supplied to the model via the second encoder.

6.1 Data Augmentation

We implemented the transducer augmentation method described by Kanerva et al. (2020). This method's basic idea relies on applying existing morphological analyzers (in this case, Apertium) to unannotated data to generate additional training instances. To obtain the augmentation data, we recreated the experiments of Kanerva et al. (2020) with 8K additional data. First, we collected a word frequency list for each language based on automatically annotated CoNLL2017 corpora (Ginter et al., 2017). For the languages not present in this dataset (Belarusian and Armenian), we used the wikidump to extract the word frequency list. Next, all words in the list were analyzed with the Apertium morphological analyzer. Then, we used the scripts[6] from the original experiments of Kanerva et al. (2020) to convert the Apertium analyses to the UD format and filter out ambiguous cases. Finally, the 8K most frequent words not already present in the training set together with their analyses were chosen and appended to the UD training set.

Although both the enhanced and augmented systems utilize Apertium as the external source, additional data usage differs. The augmented system uses Apertium to create extra labeled training data, while our enhanced model uses Apertium to generate additional lemma candidates to the words of the same initial training set. On the other hand, during test time, the augmented model must fully rely on the regularities learned during training, while our enhanced model can additionally look at the lemmas for words that were never seen during training.

The comparison of our APERTIUM-enhanced model and the augmented model is shown in the first two blocks of Table 2. The first two columns reintroduce the DEFAULT and APERTIUM-enhanced models' results from the Table 1, the third and the fourth columns show the same two models trained on the augmented training sets. Overall, the average results for both APERTIUM-enhanced and the augmented DEFAULT model (the column DEF+8K) are very similar, with the average of the APERTIUM-enhanced model being slightly higher (97.25 vs. 97.17). The APERTIUM-enhanced model is better in 15 languages out of 23 (underlined in the table), while the augmented model surpasses the enhanced model on 8 models. The APT+8K column shows the results of a model combining both augmentation and enhanced methods—the training data is first augmented with the additional 8K words and then additionally enhanced with the Apertium candidates via the second encoder. The combined approach scores are the best for 8 languages out of 23, resulting in an average improvement over the augmented DEFAULT model of 0.14% and over the APERTIUM-enhanced model of 0.06% in absolute. These results show that both augmentation and enhancement methods can contribute in complementary ways.

6.2 Lexicon Extension

Another simple baseline method for using external data is to use a lexicon or an external system first

and only resort to neural generation when the surface form (SF) is not present in the lexicon. This is essentially how the Stanza lemmatizer works. Stanza constructs a lexicon based on the training set. During inference, the prediction goes through a cascade of three steps: 1) if the SF is present in the lexicon, then the lemma is immediately retrieved from the lexicon. 2) If the SF is novel and is missing from the lexicon, an edit operation is generated that decides whether the SF itself or its lowered form is the lemma, or whether neither is true. 3) Only in the last case the lemma is generated by the sequential decoder. For testing out the lexicon extension system, we used the pretrained Stanza models but extended the lexicon stored in the Stanza system with additional items. Note that Stanza lexicons can only store one lemma per SF-POS combination. Thus, if any of the external lexicons contain ambiguous lemmas, the firstly encountered lemma is chosen for each word.

We extended the Stanza lexicons with both the Apertium 8K datasets used for training the augmented models in section 6.1 and the UD lexicons (Sagot, 2018). The results of these evaluations are shown in Table 3. The set of languages in this table is slightly different than in Table 1, only including those languages for which the UD lexicons are existent. The left block shows the results with various Stanza models. The first column shows the baseline Stanza results (taken from Table 1), the second and the third columns present the Stanza model with its lexicon extended with the UD lexicons and the 8K words, respectively. The original UD lexicon for Russian contained many erroneous lemmas due to poor post-processing, which skewed the average accuracy. Thus, we did additional post-processing to put it in line with other languages.

The average scores of the Stanza systems ex-

Table 3: Evaluation of the effect of the Stanza-based lexicon extension method; comparison with the Apertium-enhanced (Apt) and the Lexicon-enhanced systems (Lex+UD and Lex+8K).

tended with both UD and 8K lexicons remain roughly the same. However, when extending the Stanza with UD lexicons, most languages improve at least slightly, as shown with the underlined scores in the column Stanza+UD. Overall, on average, the simple lexicon extension method falls considerably behind our Apertium-enhanced model (97.63 vs. 98.00), the scores of which are again replicated in the first column of the right-most block.

However, the Apertium-enhanced model is not directly comparable to the Stanza models with extended lexicons because 1) the training data differs as the enhanced model has access to extra lemma candidates of the training set words during training and 2) the lexicons available during the test time are different. Thus, we also show in the last two columns of the right-hand block of Table 3 the results of two Lexicon-enhanced models (recall Section 4 and Table 1), similarly extended with the UD and 8K lexicons. The Lexicon-enhanced model has access to the same data as the Stanza model during both training (training set + the training set based lexicon) and testing.

While the Lexicon-enhanced model alone does not perform better than the Default baseline (see results in Table 1), adopting additional UD or 8K lexicons during test time increases the results to the same level with the Apertium-enhanced model. This shows that our proposed approach does not need additional resources during training—the model can be trained to use external sources based on the lexicon created from the training set. Then, the system's real benefits can be achieved when using extra resources later during test time. Without those resources, the model still performs on the same level as the non-enhanced baseline.

We hypothesize that our dual-encoder approach performs better than the Stanza with extended lexicon partly because of the differences in the usage of the external data. Since Stanza uses the lexicon resources as a first step in the cascade, it is prone to potential errors and noise in the lexicons. The dual-encoder model is safer against noise in this respect because the lemma candidates are not simply chosen as the prediction if present but are rather fed through the system that can decide how much to take or ignore from the given candidates. Also, because Stanza lexicons have the restriction of only one lemma per word-POS pair, the system might solve some ambiguities erroneously. Our approach is also more flexible in this respect, as the second encoder can be given several candidates, and again, the system learns to decide itself from which candidate how much to take. On average, there are 0.71 lemma candidates per input word, and 1.09 lemma candidates per input word when excluding those words that do not have external lemma candidates.

6.3 Effect of the Second Encoder

Next, we performed a set of evaluations to argue for the effect of the second encoder in the enhanced model. We suggest that the improvements presented in Table 1 for the APERTIUM-enhanced model over the DEFAULT baseline are indeed due to the input provided via the second encoder. To demonstrate that, we evaluated the test set for each language again, on the same model that was trained with Apertium lemma candidates but leaving the second encoder empty for the test time. For that, we retrained the APERTIUM-enhanced models with the encoder dropout of 0.8. This means that during training, 80% of the time, the lemma candidates provided for the second encoder are dropped, and the model trains only the main encoder. The reasoning for using the dropout is similar to one provided for the LEXICON-enhanced model in Section 3—if the lemma candidates are always provided during training, the model learns to rely equally on both encoders. Due to that, if the second encoder remains empty during testing, the performance degrades considerably. If, on the other hand, the dropout is used, then the model learns to make predictions both when the candidates in the second encoder are present and also when they are absent. The results of these experiments are shown in the right-most block of Table 2.

We first show in Table 2 that the results of the APERTIUM-enhanced models trained with dropout are equivalent to the results obtained without dropout as evidenced by the column $\text{APT}_{0.8}$. Next, when the second encoder is empty (column APT+E), the test results are similar to the ones obtained with the DEFAULT model, providing evidence that the improvements are indeed due to the extra info supplied via the second encoder during test time. Additionally, we emulated the scenario when extra lexicon information becomes available after training the model. In this case, it is straightforward to integrate this information into the system without having to retrain the model. The last two columns in Table 2 show the following scenarios on this respect: 1) Unimorph lexicons in addition to Apertium (7th column APT+UNI) and 2) UD lexicons (the last column APT+UD) in addition to Apertium. The results in Table 2 show that, on average, extending the Apertium system with these particular lexicons do not add any benefit. The reasons for that can be twofold: 1) The UD lexicons are for most languages constructed based on the Apertium system and thus might not add any extra information; 2) The coverage of Unimorph lexicons in terms of lemmas is typically smaller than of Apertium systems.

Table 4 shows some examples when the DEFAULT model predicted incorrect lemma while the APERTIUM-enhanced model predicted the correct one. In some cases, Apertium provided the only and correct candidate for the APERTIUM-enhanced model, which was picked as a final prediction. In other cases, several candidates are provided to the second encoder, and the enhanced model chooses the correct one in most of the cases. This indicates that the second encoder effectively learns how to use the candidates to better control the lemma generation.

6.4 Effect of Morphological Features

All dual-encoder models were trained with both POS and morphological features in the input, while the STANZA baseline only uses POS-tag information. Thus, the effect of the morphological features is a potential confounding factor when comparing the performance of the enhanced models to the STANZA baseline. To evaluate the effect of the morphological features, we trained the DEFAULT and APERTIUM-enhanced models with only providing POS-tag information to the input.

Figure 2 shows the improvement in accuracy over the DEFAULT model trained with POS-tags only of 1) the DEFAULT model trained with both POS-tags and morphological features, 2) the APERTIUM-enhanced model trained with only POS-tags, and 3) the APERTIUM-enhanced model trained with both POS-tags and morphological features. It can be seen that for some of the languages, the most improvement comes from adding morphological features to the input, while for other languages adding the second encoder gives the main boost. However, for most languages, combining the second encoder and morphological features provides the largest effect, which seems to be more complex than a linear combination of the two. We suppose that, in this scenario, the attention mechanism

Input	Def	Apt	Candidate(s)
папері ⟨*paperi*⟩	*папер ⟨*paper*⟩	**папір** ⟨*papir*⟩	папір ⟨*papir*⟩

Table 4: Examples for Ukrainian, German, and Belarusian words corrected by the enhanced model. All predictions of the DEFAULT (DEF) are incorrect, the ungrammatical ones are marked with *. The correct predictions of the APERTIUM-enhanced (APT) models are in **bold**. The last column shows the external candidates.

works differently—it allegedly takes the morphological features into account when picking the correct lemma from the multiple candidates.

7 Conclusion

We proposed a method for enhancing neural lemmatization by integrating external input into the model via a second encoder and showed that the system incorporating Apertium morphological analyzer significantly improved the performance over the baselines. Both Bergmanis and Goldwater (2019) and Kanerva et al. (2020) used external resources to augment the training data, and thus, the improvement of their system is dependent on the amount and quality of the extended data supplied during training. On the other hand, our method trains the system to use the external information provided during run-time, thus making it independent of the particular external data available during training.

We experimentally showed that the enhancing method is both slightly better and complementary to the data augmentation method of Kanerva et al. (2020). We also compared our system with a simple lexicon extension method implemented based on the Stanza system. When trained and tested in a comparable setting, the proposed enhanced system achieves considerably higher results.

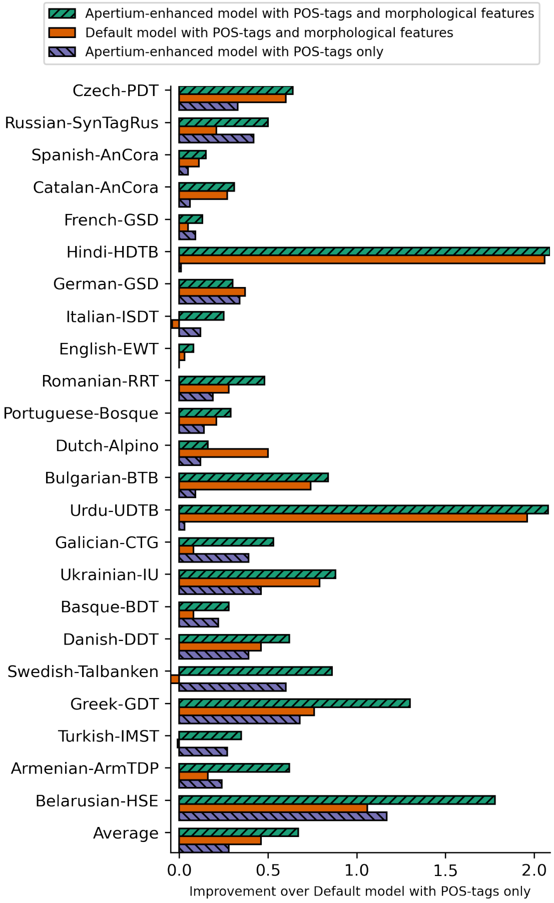

Figure 2: Independent and cumulative effects of the second encoder and the morphological features on the model's performance. The origin of the x-axis is the performance of the DEFAULT model with POS-tags only.

Although the model's computational complexity is increased by introducing the second encoder, it is counterbalanced by our model being more robust to noise and the ambiguities stemming from the external lexicons. Moreover, the main bottleneck in computation originates not from the neural network's increased size but can rather stem from the external system. For example, in our experiments, the main bottleneck in computation originated from executing the transducer-based Apertium morphological analyser. To overcome this bottleneck, one possible trade-off between the speed and accuracy is to precompile a candidate list large enough to cover the most frequent words for a given language. This is a problem that also simpler baseline methods adopting external resources have to address.

Finally, it is worth noting that the proposed method could be beneficial for less-resourced languages. However, establishing this claim would need more systematic experiments exploring specifically on this question, which we did not focus on in this paper. Still, because the significant improvements shown in this work are obtained on languages with larger datasets, the possible gains on smaller datasets can be larger.

Abstract

We introduce the task of historical text summarisation, where documents in historical forms of a language are summarised in the corresponding modern language. This is a fundamentally important routine to historians and digital humanities researchers but has never been automated. We compile a high-quality gold-standard text summarisation dataset, which consists of historical German and Chinese news from hundreds of years ago summarised in modern German or Chinese. Based on cross-lingual transfer learning techniques, we propose a summarisation model that can be trained even with no cross-lingual (historical to modern) parallel data, and further benchmark it against state-of-the-art algorithms. We report automatic and human evaluations that distinguish the historic to modern language summarisation task from standard cross-lingual summarisation (i.e., modern to modern language), highlight the distinctness and value of our dataset, and demonstrate that our transfer learning approach outperforms standard cross-lingual benchmarks on this task.

1 Introduction

The process of text summarisation is fundamental to research into history, archaeology, and digital humanities (South, 1977). Researchers can better gather and organise information and share knowledge by first identifying the key points in historical documents. However, this can cost a lot of time and effort. On one hand, due to cultural and linguistic variations over time, interpreting historical text can be a challenging and energy-consuming process, even for those with specialist training (Gray et al., 2011). To compound this, historical archives can contain narrative documents on a large scale, adding to the workload of manually locating important elements (Gunn, 2011). To reduce these burdens, specialised software has been developed recently, such as MARKUS (Ho and Weerdt, 2014) and DocuSky (Tu et al., 2020). These toolkits aid users in managing and annotating documents but still lack functionalities to automatically process texts at a semantic level.

Historical text summarisation can be regarded as a special case of cross-lingual summarisation (Leuski et al., 2003; Orăsan and Chiorean, 2008; Cao et al., 2020), a long-standing research topic whereby summaries are generated in a target language from documents in different source languages. However, historical text summarisation posits some unique challenges. Cross-lingual (i.e., across historical and modern forms of a language) corpora are rather limited (Gray et al., 2011) and therefore historical texts cannot be handled by traditional cross-lingual summarisers, which require cross-lingual supervision or at least large summarisation datasets in both languages (Cao et al., 2020). Further, language use evolves over time, including vocabulary and word spellings and meanings (Gunn, 2011), and historical collections can span hundreds of years. Writing styles also change over time. For instance, while it is common for today's news stories to present important information in the first few sentences, a pattern exploited by modern news summarisers (See et al., 2017), this was not the norm in older times (White, 1998).

In this paper, we address the long-standing need for historical text summarisation through machine summarisation techniques for the first time. We consider the German$_{|\text{DE}}$ and Chinese$_{|\text{ZH}}$ languages, selected for the following reasons. First, they both have rich textual heritage and accessible (monolingual) training resources for historical and modern language forms. Second, they serve as outstanding representatives of two distinct writing systems (DE

Table 1: Examples from our HISTSUMM dataset.

for alphabetic and ZH for ideographic languages), and investigating them can lead to generalisable insights for a wide range of other languages. Third, we have access to linguistic experts in both languages, for composing high-quality gold-standard modern-language summarises for DE and ZH news stories published hundreds of years ago, and for evaluating the output of machine summarisers.

In order to tackle the challenge of a limited amount of resources available for model training (e.g., we have summarisation training data only for the monolingual task with modern languages, and very limited parallel corpora for modern and historical forms of the languages), we propose a transfer-learning-based approach which can be bootstrapped even without cross-lingual supervision. To our knowledge, our work is the first to consider the task of historical text summarisation. As a result, there are no directly relevant methods to compare against. We instead implement two state-of-the-art baselines for standard cross-lingual summarisation, and conduct extensive automatic and human evaluations to show that our proposed method yields better results. Our approach, therefore, provides a strong baseline for future studies on this task to benchmark against.

The contributions of our work are three-fold: (1) we propose a hitherto unexplored and challenging task of historical text summarisation; (2) we construct a high-quality summarisation corpus for historical DE and ZH, with modern DE and ZH summaries by experts, to kickstart research in this field; and (3) we propose a model for historical text summarisation that does not require parallel supervision and provides a validated high-performing baseline for future studies. We release our code and data at `https://github.com/Pzoom522/HistSumm`.

2 Related Work

Processing historical text. Early NLP studies for historical documents focus on spelling normalisation (Piotrowski, 2012), machine translation (Oravecz et al., 2010), and sequence labelling applications, e.g., part-of-speech tagging (Rayson et al., 2007) and named entity recognition (Sydow et al., 2011). Since the rise of neural networks, a broader spectrum of applications such as sentiment analysis (Hamilton et al., 2016), information retrieval (Pettersson et al., 2016), and relation extraction (Opitz et al., 2018) have been developed.

We add to this growing literature in two ways. First, much of the work on historical text processing is focused on English$_{|\text{EN}}$, and work in other languages is still relatively unexplored (Piotrowski, 2012; Rubinstein, 2019). Second, the task of historical text summarisation has never been tackled before, to the best of our knowledge. A lack of non-EN annotated historical resources is a key reason for the former, and for the latter, resources do not exist in any language. We hope to spur research on historical text summarisation and in particular for non-EN languages through this work.

Cross-lingual summarisation. The traditional strands of cross-lingual text summarisation systems design pipelines which learn to translate and summarise separately (Leuski et al., 2003; Orăsan and Chiorean, 2008). However, such paradigms suffer from the error propagation problem, i.e., errors produced by upstream modules may accumulate and degrade the output quality (Zhu et al., 2020). In addition, parallel data to train effective translators is not always accessible (Cao et al., 2020). Recently, end-to-end methods have been applied to alleviate this issue. The main challenge for this research direction is the lack of direct corpora, leading to attempts such as zero-shot learning (Duan et al., 2019), multi-task learning (Zhu et al., 2019), and transfer learning (Cao et al., 2020). Although training requirements have been relaxed by these methods, our extreme setup with summarisation data only available for the target language and very limited parallel data, has never been visited before.

3 HistSumm Corpus

3.1 Dataset Construction

In history and digital humanities research, summarisation is most needed when analysing documentary and narrative text such as news, chronicles, diaries, and memoirs (South, 1977). Therefore, for DE we picked the GerManC dataset (Durrell et al., 2012), which contains Optical Character Recognition (OCR) results of DE newspapers from the years 1650–1800. We randomly selected 100 out of the 383 news stories for manual annotation. For ZH, we chose 『万历邸抄』 (*Wanli Gazette*) as the data source, a collection of news stories from the Wanli period of Ming Dynasty (1573–1620). However, there are no machine-readable versions of Wanli Gazette available; worse still, the calligraphy copies (see Appendix B) are unrecognisable even for non-expert humans, making the OCR technique inapplicable. Therefore, we performed a thorough literature search on over 200 related academic papers and manually retrieved 100 news texts[1].

To generate summaries in the respective modern language for these historical news stories, we recruited two experts with degrees in Germanistik and Ancient Chinese Literature, respectively. They were asked to produce summaries in the style of DE MLSUM (Scialom et al., 2020) and ZH LCSTS (Hu et al., 2015), whose news stories and summaries are crawled from the Süddeutsche Zeitung website and posts by professional media on the Sina Weibo platform, respectively. The annotation process turned out to be very effort-intensive: for both languages, the experts spent at least 20 minutes in reading and composing a summary for one single news story. The accomplished corpus of 100 news stories and expert summaries in each language, namely HistSumm (see examples in Tab. 1), were further examined by six other experts for quality control (see details in § 6.2).

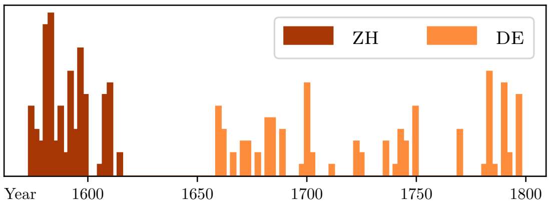

Figure 1: Publication time of HistSumm stories.

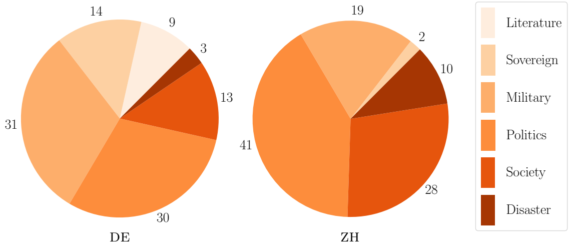

Figure 2: Topic composition of HistSumm.

	DE (word-level)		ZH (character-level)	
	HistSumm	MLSUM	HistSumm	LCSTS
L_{story}	268.1	570.6	114.5	102.5
L_{summ}	18.1	30.4	28.2	17.3
CR (%)	6.8	5.3	24.6	16.9

Table 2: Comparisons of mean story length (L_{story}), summary length (L_{summ}), and compression rate ($CR = L_{\text{summ}}/L_{\text{story}}$) for summarisation datasets.

3.2 Dataset Statistics

Publication time. As visualised in Fig. 1, the publication time of DE and ZH HistSumm stories exhibits distinguished patterns. Oldness is an important indicator of the domain and linguistic gaps (Gunn, 2011). Considering news in ZH HistSumm is on average 137 years older than its DE counterpart, such gaps can be expected to be greater. On the other hand, DE HistSumm stories cover a period of 150 years, compared to just 47 years for ZH, indicating the potential for greater linguistic and cultural variation within the DE corpus.

Topic composition. For a high-level view of HistSumm's content, we asked experts to manually classify all news stories into six categories (shown in Fig. 2). We see that the topic compositions of DE and ZH HistSumm share some similarities. For instance, Military (e.g., battle reports) and Politics (e.g., authorities' policy and personnel changes) together account for more than half the stories in both languages. On the other hand, we also have language-specific observations. 9% DE stories are about Literature (e.g., news about book publications), but this topic is not seen in ZH HistSumm. And while 14% DE stories are about

---

[1] Detailed references are included in the 'source' entries of ZH HistSumm's metadata.

Sovereign (e.g., royal families and Holy See), there are only 2 examples in ZH (both about the emperor; we found no record on any religious leader in Wanli Gazette). Also, the topics of Society (e.g., social events and judicial decisions) and Natural Disaster (e.g., earthquakes, droughts, and floods) are more prevalent in the ZH dataset.

Story length. In news summarisation tasks, special attention is paid to the lengths of news stories and summaries (see Tab. 2). Comparing DE HistSumm with the corresponding modern corpus DE MLSUM, we find that although historical news stories are on average 53% shorter, the overall compression rate (CRs) is quite similar (6.8% *vs* 5.8%), indicating that key points are summarised to similar extents. Following LCSTS (Hu et al., 2015), the table shows character-level data for ZH, but this is somewhat misleading. While most modern words are double-character, single-character words dominate the historical vocabulary, e.g., the historical word ‘朋’ (*friend*) becomes ‘朋友’ in modern ZH. According to Che et al. (2016), this leads to a character length ratio of approximately 1:1.6 between parallel historical and modern samples. Taking this into account, the CRs for the ZH HistSumm and LCSTS datasets are also quite similar to each other.

When contrasting DE with ZH (regardless of historical or modern), we notice that the compression rate is quite different. This might reflect stylistic variations with respect to how verbose news reports are in different languages or by different writers.

3.3 Vicissitudes of News

Compared with modern news, articles in HistSumm reveal several distinct characteristics with respect to writing style, posing new challenges for machine summarisation approaches.

Lexicon. With social and cultural changes over the centuries, lexical pragmatics of both languages have evolved substantially (Gunn, 2011). For DE, some routine concepts from hundreds of years ago are no longer in use today, e.g., the term ‘Brachmonat’ (№41), whose direct translation is *fallow month*, actually refers to *June* as the cultivation of fallow land traditionally begins in that month (Grimm, 1854). We observe a similar phenomenon in ZH HistSumm, e.g., ‘贡市’ (№24 and №31) used to refer to markets that were open to foreign merchants, but is no longer in use. For ZH, additionally, we notice that although some historical words are still in use, their semantics have changed over time, e.g., meaning of ‘闻’ has shifted from *hear* to *smell* (№53), and that of ‘走’ has changed from *run* to *walk* (№25).

Syntax. Another aspect of language change is that some historical syntax has been abandoned. Consider ‘daß derselbe noch länger allda/ biß der Frantz. Abgesandter von dannen widerum abreisen möge/ verbleiben soll’ (*the same should still remain there for longer, until the France Ambassador might leave again*) (№33). We find the subordinate clause is inserted within the main clause, whereas in modern DE it should be ‘daß derselbe noch länger allda verbleiben soll, biß der Frantz. Abgesandter von dannen widerum abreisen möge’. For ZH, inversion is common in historical texts but becomes rare in the modern language. For example, sentence ‘王氏之女成仙者’ (*Ms. Wang’s daughter who became a fairy*) (№65) where the attributive adjective is positioned after the head noun, should be ‘王氏之成仙（的）女’ according to modern ZH grammars. Also, we observe cases where historical ZH sentences without constituents such as subjects, predicates, objects, prepositions, etc. In these cases, contexts must be utilised to infer corresponding information, e.g., only by adding ‘居正’ (*Juzheng*, a minister’s name) to the context can we interpret the sentence ‘已，又为私书安之云’ (№20) as *‘after that, (Juzheng) wrote a private letter to comfort him’*. This adds extra difficulty to the generation of summaries.

Writing style. To inform readers, a popular practice adopted by modern news writers is to introduce key points in the first one or two sentences (White, 1998). Many machine summarisation algorithms leverage this pattern to enhance summarisation quality by incorporating positional signals (Edmundson, 1969; See et al., 2017; Gui et al., 2019). However, this rhetorical technique was not widely used in HistSumm, where crucial information may appear in the middle or even the end of stories. For instance, the keyword ‘Türck’ (*Turkish*) (№33) first occurs in the second half of the story; in article №7 of ZH HistSumm (see Tab. 1), only after reading the last sentence can we know the final outcome (i.e., the authority’s seal had been saved from fire).

4 Methodology

Based on the popular cross-lingual transfer learning framework of (Ruder et al., 2019), we propose a simple historical text summarisation framework (see Fig. 3), which can be trained even without supervision (i.e., parallel historical-modern signals).

Step 1. For both DE and ZH, we begin with respectively training modern and historical monolingual word embeddings. Specially, for DE, following the suggestions of Wang et al. (2019), we selected subword-based embedding algorithms (e.g., FastText (Joulin et al., 2017)) as they yield competitive results. In addition to training word embeddings on the raw text, for historical DE we also consider performing text normalisation (**NORM**) to enhance model performance. This orthographic technique aims to convert words from their historical spellings to modern ones, and has been widely adopted as a standard step by NLP applications for historical alphabetic languages (Bollmann, 2019). Although training a normalisation model in a fully unsupervised setup is not yet realistic, it can get bootstrapped with a single lexicon table to yield satisfactory performance (Ljubešić et al., 2016; Scherrer and Ljubešić, 2016).

For ideographic languages like ZH, word embeddings trained on stroke signals (which is analogous to subword information of alphabetic languages) achieve state-of-the-art performance (Cao et al., 2018), so we utilise them to obtain monolingual vectors. Compared with simplified characters (which dominate our training resources), traditional ones typically provide much richer stroke signals and thus benefit stroke-based embeddings (Chen and Sheng, 2018), e.g., traditional ‘葉’ (*leaf*) contains semantically related components of ‘艹’ (*plant*) and ‘木’ (*wood*), while its simplified version (‘叶’) does not.

Therefore, to improve the model performance we also conduct additional experiments on enhanced corpora which are converted to the traditional glyph using corresponding rules (**CONV**) (see § 5.3 for further details).

Step 2. Next, we respectively build two semantic spaces for DE and ZH, each of which is shared by historical and modern word vectors. This approach, namely cross-lingual word embedding mapping, aligns different embedding spaces using linear projections (Artetxe et al., 2018; Ruder et al., 2019). Given parallel supervision is very limited in real-world scenarios, we mainly consider two bootstrapping strategies: in a fully unsupervised (**UspMap**) style and through identical lexicon pairs (**IdMap**).

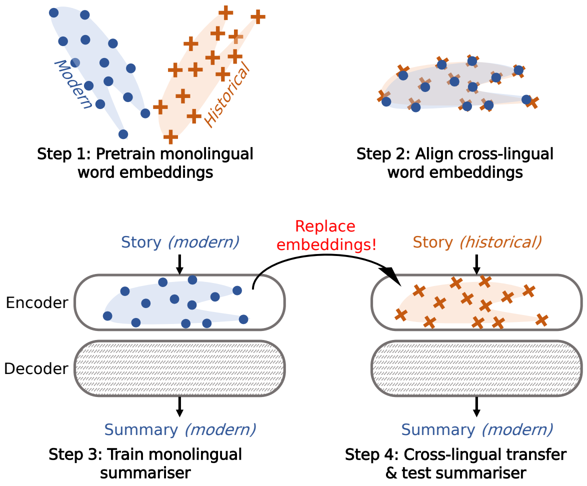

Figure 3: Illustration of our proposed framework.

While the former only relies on topological similarities between input vectors, the latter additionally takes advantage of words in the intersected vocabulary as seeds. Although their historical and current meanings can differ (cf. § 3.3), in most cases they are similar, providing very weak parallel signals (e.g., ‘Krieg’ (*war*) and ‘Frieden’ (*peace*) are common to historical and modern DE; ‘天’ (*universe*) and ‘人’ (*human*) to historical and modern ZH).

Step 3. In this step, for each of DE and ZH we use a large monolingual modern-language summarisation dataset to train a basic summariser that only takes modern-language inputs. Embedding weights of the encoder are initialised with the *modern* partition of corresponding cross-lingual word vectors in Step 2 and are frozen during the training process, while those of the decoder are randomly initialised and free to update through back-propagation.

Step 4. Upon convergence in the last step, we directly replace the embedding weights of the encoder with the *historical* vectors in the shared vector space, yielding a new model that can be fed with historical inputs but output modern sentences. This entire process does not require any external parallel supervision.

5 Experimental Setup

5.1 Training Data

Consistent with § 3.1, we selected DE MLSUM and ZH LCSTS as monolingual summarisation training sets. For monolingual corpora for word embedding training, to minimise temporal and domainal variation, we only considered datasets that were similar to articles in MLSUM, LCSTS, and HISTSUMM, i.e, with text from comparable periods and centred around news-related domains.

For modern DE, such resources are easy to access: we directly downloaded the DE News Crawl Corpus released by WMT 2014 workshops (Bojar et al., 2014), which contains shuffled sentences from online news sites. We then conducted tokenisation and removed noise such as emojis and links. For historical DE, besides the already included GerManC corpus, we also saved Deutsches Textarchiv (Nolda, 2019), Mercurius-Baumbank (Ulrike, 2020), and Mannheimer Korpus (Mannheim, 2020) as training data. Articles in these datasets are all relevant to news and have topics such as Society and Politics. Note that we only preserved documents written in 1600 to 1800 to match the publication time of DE HISTSUMM stories (cf. § 3.2). Apart from the standard data cleaning procedures (tokenisation and noise removal, as mentioned above), for historical DE corpora we replaced the very common slash symbols (/) with their modern equivalents: commas (,) (Lindemann, 2015). We also lower-cased letters and deleted sentences with less than 10 words, yielding 505K sentences and 12M words in total.

For modern ZH, we further collected news articles in the corpora released by He (2018), Hua et al. (2018), and Xu et al. (2020) to train better embeddings. For historical ZH, to the best of our knowledge, there is no standalone Ming Dynasty news collection except Wanli Gazette. Therefore, from the resources released by Jiang et al. (2020), we retrieved Ming Dynasty articles belonging to categories[2] of Novel, History/Geography, and Military[3]. Raw historical ZH text does not have punctuation marks, so we first segmented sentences using the Jiayan Toolkit[4]. Although Jiayan supports tokenisation, we skipped this step as the accuracy is unsatisfactory. Given that a considerable amount of historical ZH words only have one character (cf. § 3.2 and § 3.3), following Li et al. (2018) we simply treated characters as basic units during training. Analogous to historical DE, we removed sentences with less than 10 characters. The remaining corpus has 992k sentences and 28M characters.

5.2 Baseline Approaches

In addition to the proposed method, we also consider two strong baselines based on the Cross-lingual Language Modelling paradigm (XLM) (Lample and Conneau, 2019), which has established state-of-the-art performance in the standard cross-lingual summarisation task (Cao et al., 2020). More concretely, for DE and ZH respectively, we pretrain baselines on all available historical and modern corpora using causal language modelling and masked language modelling tasks. Next, they are respectively fine-tuned on modern text summarisation and unsupervised machine translation tasks. The former becomes the (**`XLM-E2E`**) baseline, which can be directly executed on HISTSUMM in an end-to-end fashion; the latter (**`XLM-Pipe`**) is coupled with the basic summariser for modern inputs in Step 3 of § 4 to form a translate-then-summarise pipeline.

5.3 Model Configurations

Normalisation and convention. We normalised historical DE text using cSMTiser (Ljubešić et al., 2016; Scherrer and Ljubešić, 2016), which is based on character-level statistical machine translation. Following the original papers, we pretrained the normaliser using RIDGES corpus (Odebrecht et al., 2017). As for the ZH character convention, we utilised the popular OpenCC[5] project which uses a hard-coded lexicon table to convert simplified input characters into their traditional forms.

Word embedding. As discussed in § 4, when training DE and ZH monolingual embeddings, we respectively ran subword-based FastText (Joulin et al., 2017) and stroke-based Cw2Vec (Cao et al., 2018). For both languages, we set the dimension at 100 and learned embeddings for all available tokens (i.e., `minCount` = 1). Other hyperparameters followed the default configurations. After training, we preserved the most frequent 50K tokens in each vocabulary (NB: historical ZH only has 13K unique tokens). To obtain aligned spaces for modern and historical vectors, we then utilised the robust VecMap framework (Artetxe et al., 2018) with its original settings.

Summarisation model. We implemented our main model based on the robust Pointer-Generator Network (See et al., 2017), which is a hybrid framework for extractive (to copy source expressions

---

[2] Following the topic taxonomy of Jiang et al. (2020).

[3] Sampling inspection confirmed that their domains are similar to those of Wanli Gazette.

`UspMap`	5.15	0.84	2.42
`IdMap`	5.98	1.33	2.90

Table 4: ROUGE F1 scores (%) of *standard* cross-lingual summarisation. Following Cao et al. (2020), for monolingual pretraining, we used corpora in § 5.3 (57M sentences) for modern ZH and annotated Gigaword (Napoles et al., 2012) (183M sentences) for EN; for summarisation training, we used LCSTS for EN→ZH and CNN/DM dataset (Hermann et al., 2015) for ZH→EN; for testing, we used the data released by Zhu et al. (2019).

via pointing) and abstractive (to produce novel words) summarisation models. After setting up the encoder and decoder (cf. in Step 3 of § 4), we started training with the default configurations. As for the two baselines which are quite heavyweight (XLM (Lample and Conneau, 2019) is based on BERT (Devlin et al., 2019) and has 250M valid parameters), we trained them from scratch with FP16 precision due to moderate computational power access. All other hyperparameter values followed the official XLM settings. To ensure the baselines can yield their highest possible performance, we trained them on the enhanced corpora, i.e., normalised DE (`NORM`) and converted ZH (`CONV`).

6 Results and Analyses

6.1 Automatic Evaluation

We assessed all models with the standard ROUGE metric (Lin, 2004), reporting F1 scores for ROUGE-1, ROUGE-2, and ROUGE-L. Following Hu et al. (2015), the ROUGE score of ZH outputs are calculated on character-level.

As shown in Tab. 3, for DE, our proposed methods are comparable to the baseline approaches or outperform the baselines by small amounts; for ZH, our models are superior by large margins. Given that XLM-based models require a lot more training resources than our model, we consider this a positive result. For comparison of the strengths and weaknesses of the models, we show their performance for a modern cross-lingual summarisation task in Tab. 4. To heighten the contrast we chose two languages (ZH and EN) from different families and with minimal overlap of vocabulary. As shown in Tab. 4, the XLM-based models outperform our method on this modern language cross-lingual summarisation task by large margins.

The difference in the performance of models on the modern and historical summarisation tasks illustrate key differences in the tasks and also some of the shortcomings of the models. Firstly, the great temporal gap (up to 400 years for DE and 600 years for ZH) between our historical and modern data hurts the XLM paradigm, which relies heavily on the similarity between corpora (Kim et al., 2020). In addition, Kim et al. (2020) also show that inadequate monolingual data size (less than 1M sentences) is likely to lead to unsatisfactory performance of XLM, even for etymologically close language pairs such as EN-DE. In our experiments we only have 505K and 992K sentences for historical DE and ZH (cf. § 5.1). On the other hand, considering the negative influence of the error-propagation issue (cf. § 2), the poor performance of `XLM-Pipe` is not surprising and is in line with observations of Cao et al. (2020) and Zhu et al. (2020). Our model instead makes use of cross-lingual embeddings, including bootstrapping from identical lexicon pairs. This approach helps overcome data sparsity issues for the historical summarisation tasks and is also successful at leveraging the similarities in the language pairs. However, its performance drops when the two languages are as far apart as EN and ZH.

When analysing the ablation results of the proposed method, on DE and ZH we found different trends. For DE, scores achieved by all the four setups show minor variance. To be specific, models bootstrapped with identical word pairs outperformed the unsupervised ones, and models trained on normalised data yielded stronger performance.

DE	Informativeness	Conciseness	Fluency	Currentness
`Expert`	4.85 (.08)	5.00 (.00)	4.94 (.03)	4.99 (.00)
`XLM-E2E`	2.26 (.20)	2.35 (.24)	**3.34** (.19)	3.67 (.23)
`UspMap+NORM`	2.51 (.18)	2.53 (.22)	3.28 (.22)	3.64 (.24)
`IdMap+NORM`	**2.52** (.18)	**2.54** (.20)	3.32 (.28)	**3.72** (.24)
ZH				
`Expert`	4.72 (.10)	4.98 (.01)	4.97 (.02)	4.90 (.04)
`XLM-E2E`	2.18 (.23)	2.21 (.27)	**2.80** (.22)	2.53 (.23)
`IdMap`	**2.39** (.19)	2.49 (.26)	2.66 (.25)	2.50 (.23)
`IdMap+CONV`	2.37 (.21)	**2.57** (.28)	2.78 (.24)	**2.59** (.25)

Table 5: Average human ratings on HISTSUMM (variance is in parentheses).

Among all tested versions, `UspMap+NORM` got the best score in ROUGE-2 and `IdMap+NORM` led in ROUGE-1 and ROUGE-L, indicating that the normalisation enhancement does benefit DE historical text summarisation models. For ZH, as predicted, with richer glyph information encoded, the stroke-based embedding method can better learn word semantics. We find that `UspMap+CONV` outperforms `UspMap` and `IdMap+CONV` outperforms `IdMap`. Adding identical words during mapping initialisation brings substantial benefits too: 3.58% and 2.52% ROUGE-L improvement for `IdMap` over `UspMap` and `IdMap+CONV` over `UspMap+CONV`, respectively.

6.2 Human Judgement

To gain further insights, we invited six experts to conduct human evaluations. Like the annotators in § 3.1, they also held degrees in Germanistik or Ancient Chinese Literature. Beyond the standard dimensions of summarisation evaluation (Informativeness, Conciseness, and Fluency), we added 'Currentness' as the fourth, which focuses on measuring 'to what extent a summary follows current rather than early linguistic styles'. We used a five-point Likert scale, with 1 for worst and 5 for best. For each language, experts were only asked to rate the gold-standard human summary and the summaries generated by the `XLM-E2E` baseline and the best two setups in § 6.1. For each of the 100 news stories in each language, 3 experts independently each rated the three model outputs and the human summary.

The final results are given in Tab. 5. When comparing different systems, we report statistical significance as the p-value of two-tailed t-tests with Bonferroni correction (Dror et al., 2018). We found that in all aspects the scores for the gold-standard summaries were always above 4 points, indicating the high quality of the gold-standard summaries. Across both languages, our models outperform the baseline for informativeness and conciseness ($p<0.01$) and achieve comparable levels of fluency and currentness. Summaries generated by `XLM-E2E` were slightly more fluent than our approach for both DE and ZH ($p<0.05$), indicating that the baseline has merit with respect to its language modelling abilities. However, it tended to make errors in understanding historical inputs and locating key points; e.g. the human reference for ZH article №57 is focused on the commander's decision of bursting the river to beat the rebel army ('宁夏之役中，魏学曾为了击溃叛乱部落，决定决河灌城'), but `XLM-E2E` summarises it as 黄河大堤水，比塔顶还高几丈' (*the surface of the river is several feet higher than the tower top*), which is fluent but irrelevant.

As for different setups of the proposed algorithm, for DE, in dimensions of Informativeness, Conciseness and Fluency, the performance of `UspMap+Norm` and `IdMap+NORM` was almost equally good. The improvement from utilising identical word pairs for cross-lingual word embedding mapping seems more evident for Currentness, i.e., the average score was 0.08 higher ($p<0.05$). For ZH, while `IdMap` and `IdMap+CONV` achieved close Informativeness scores, the latter outperforms the former in other three aspects by 0.08, 0.12, and 0.09 respectively ($p<0.01$). This observation indicates that when the lexical encoding is improved with enriched stroke-level information, the model is less likely to include redundant information in the summaries (i.e., conciseness score is higher), and the produced sentences are more fluent in terms of modern ZH grammars (see output examples in Appendix A).

6.3 Error Analysis

We further analysed model inputs with the lowest scores in § 6.2, and found that they were mostly for stories whose content was dissimilar to *any* sample in modern training sets. For instance, five ZH texts in HISTSUMM are on themes not seen in modern news (i.e., witchcraft (№65), monsters (№35 and №46), and abnormal astromancy (№8 and №28)). On these texts, even the best-performing `IdMap+CONV` model outputs a large number of [UNK] tokens and can merely achieve average Informativeness, Conciseness, Fluency, and Correctness scores of 1.41, 1.67, 1.83, and 1.60 respectively, which are significantly below its overall results in Tab. 5. This reveals the current system's shortcoming when processing inputs with theme-level *zero-shot* patterns. This issue is typically ignored in the cross-lingual summarisation literature due to the rarity of such cases in modern language tasks. However, we argue that a key contribution of our proposed task and dataset is that they together indicate new improvement directions beyond standard cross-lingual summarisation studies, such as the challenges of zero-shot generalisation and historical linguistic gaps (cf. § 3.3).

7 Conclusion and Future Work

This paper introduced the new task of summarising historical documents in modern languages, a previously unexplored but important application of cross-lingual summarisation that can support historians and digital humanities researchers. To facilitate future research on this topic, we constructed the first summarisation corpus for historical news in DE and ZH using linguistic experts. We also proposed an elegant transfer learning method that makes effective use of similarities between languages and therefore requires limited or even zero parallel supervision. Our automatic and human evaluations demonstrated the strengths of our method over state-of-the-art baselines. This paper is the first study of automated historical text summarisation. In the future, we will improve our models to address the issues highlighted in this study (e.g. zero-shot patterns and language change), add further languages (e.g., English and Greek), and increase the size of the dataset in each language.

Acknowledgements

This work is supported by the award made by the UK Engineering and Physical Sciences Research Council (Grant number: EP/P011829/1) and Baidu, Inc. Neptune.ai generously offered us a team license to facilitate experiment tracking.

We would like to express our sincerest gratitude to Qirui Zhang, Qingyi Sha, Xia Wu, Yu Hu, Silu Ding, Beiye Dai, Xingyan Zhu, and Juecheng Lin, who are all from Nanjing University, for manually annotating and validating the HISTSUMM corpus. We also thank Guanyi Chen, Ruizhe Li, Xiao Li, Shun Wang, Zhiang Chen, and the anonymous reviewers for their insightful and helpful comments.

A Output Samples

DE	№11
Story	Die Arbeiten im hiesigen Arsenal haben schon seit langer Zeit nachgelassen, und seitdem die Perser so sehr von den Russen geschlagen worden sind, hört man überhaupt nichts mehr von Kriegsrüstungen in den türkischen Provinzen. Die Pforte hatte nicht geglaubt, daß Rußland eine so starke Macht nach den Ufern des kaspischen Meeres abschicken, und daß der Krieg mit den Persern sobald eine so entscheidende Wendung nehmen würde. Alle kriegerischen Nachrichten, die wir jetzt aus den türkischen Provinzen erhalten, erstrecken sich blos auf die bewaffneten Räuber-Korps, die in der Gegend von Adrianopel noch immer ihren Unfug fortsetzen, der auch wohl nicht eher aufhören wird, bis die Pascha's selbst bestraft worden sind, die die Räuber beschützen. - Im Anfange dieses Monats erschien eine russische Fregatte am Eingange des schwarzen Meeres, ward durch Sturm vor den türkischen Forts vorbei in den Kanal getrieben, ohne daß die Kommandanten dieser Forts ihr den geringsten Widerstand entgegen stellen konnten, und legte sich, Bujukdere gegenüber, vor Anker. Sobald der Kapitän-Pascha dies erfuhr, verfügte er, daß jene Kommandanten abgesetzt werden sollten, und beschwerte sich bei dem hiesigen russischen Minister darüber, daß jenes Kriegsschiff sich unterstanden habe, wider alle Stipulationen der Traktaten in den Kanal einzulaufen. Nachdem aber der Zufall, wodurch dies geschehen ist, näher aufgeklärt war, widerrief der Kapitän-Pascha die Befehle, die gegen die Kommandanten der an dem Kanal gelegenen Forts erlassen wurden. Auch ward auf Ansuchen des russischen Gesandten der gedachten Fregatte aller mögliche Beistand geleistet, um sich repariren, und nach der Krimm, woher sie gekommen war, zurückkehren zu können. - Die Gesandten, welche die Pforte schon seit 2 Jahren nach Wien und Berlin bestimmt hat, sind noch immer hier; dies beweiset, daß alle Schwierigkeiten in Rücksicht dieser Missionen noch nicht gehoben sind Der nach Paris bestimmte türkische Gesandte wird aber, wie es heißt, bald abreisen. - Zwei sehr angesehene französische Offiziers, die in türkischen Dienst getreten waren, sind wieder aus demselben entlassen worden. *(The work in the arsenal has for a long time slacked off. And since the Persians were beaten so badly by the Russians, people have heard complete nothing about war armaments in the durkian provinces. The Porte would not have thought that Russia would send such a powerful force to the shores of the Caspian Sea, and that the war with the Persians would at the same time take such a decisive turn. All belligerent news, that we now receive from the Durkian provinces, extends only to the armed robber corps, which are in the area of Adrianopl still continuing their mischief, which is still unlikely to end until the pashas themselves, who protect the robbers, have been punished. - At the beginning of this month a Russian frigate appeared at the entrance to the Black Sea, was driven by a storm past the Durkian forts into the channel, without that the commanders of this fort could oppose it with the slightest resistance, and (the Russian frigate) presented itself across from Bujukdere at anchor. As soon as the captain Pasha found out about this, he decreed that those commanders should be deposed and complained to the local Russian minister about that that that grieg ship had dared to enter the canal, against all stipulations of the tracts.But after the coincidence, by which this happened, had been more clearly clarified, the captain-pasha recalled the orders, which would be enacted against the commanders of the fort on the canal. Also, at the request of the Russian confession, the intended frigate was given all possible assistance in order to repair itself and to be able to return to Grimm, whence it had come. - the confessions, that the gate has set for Vienna and Berlein for two years, are still here; this proves that all difficulties in regard to these missions have not yet been resolved, but the destined-for-Paris Durkian legate will, as it is said, soon be leaving. - two very highly respected French officers, who had entered Durk service, have been dismissed from the same.)*
`Expert`	Wie es zwischen Russland und der Türkei lief, war noch unsicher. *(How things would go between Russia and Turkey, was still uncertain.)*
`IdMap+NORM`	die [unk] des [unk] zeigen , dass der krieg mit den persern sobald eine so entschiedende wendung nehmen würde . die wendung eines blauen wunders ist nicht nur zu sehen , wie man es weitergeht . *([unk] show that the war with the Persians would very soon take such a decisive turn. The turning point of a blue miracle is not just to see how it goes on.)*
`UspMap+NORM`	die arbeiten im arsenal haben schon seite länger zeit nachgelassen , und seitedem die perser so sehr von den russen geschlagen worden sind , hört man überhaupt nichts mehr von kriegrüstungen in den durkischen provinzen . *(The work in the arsenal has for a long time slacked off. And since the persians were beaten so badly by the russians, people have heard complete nothing about war armaments in the durkian provinces.)*

Story	Jhre Königl. Majest. befinden sich noch vnweit Thorn/ vnd seynd Cosakische Deputirte vnter Wegs/ jhr factum bey Seiner Majest. zu justificiren, vnd wegen jhrer Treu Versicherung zu thun. Von den Fridens. Tractaten zwischen Pohlen vnd Schweden ist noch wenig zu melden. Seithero die Pohlen bey Marienburg den Schweden eine Schantz/ der Kessel genant/ Abgenommen/ ist nichts weiters vorgefallen/ auch hiesiger Stadt Völcker vor dem Haupt noch nichts tentirt, jedoch sagt man daß noch dise woche etwas vorgehen werde/ so bald nur alle Battereyen in den 3 Quartieren fertig/ vnd die Mörser darauff gebracht worden/ vmb solches mit Feur zu bezwingen/ weil mit dem Schiessen doch nichts zugewinnen/ vnd der Sturm vnmöglich zu wagen ist/ daß aber das Brau- vnd Proviant Hauß darin in brand geschossen/ vnd die darinnen befindliche Cavallerie also ruinirt werden/ daß sie keinen Außfall mehr thun können/ ist gewiß/ deßgleichen hat der Obriste Zaphlizky mit 2000. Mann den Elbingern daß Viehe weggetriben/ welche darauff mit 500. Mann außgefallen/ solches wider zu erobern/ seynd aber mehrentheils nidergemacht/ vnd 6. vornehme Officierer neben vielen Gemeinen gefangen worden. So ist auch auß Churland über Memmel sichere Zeitung einkommen/ daß Herr General Duglas nur 2000. Mann nach Liffland gebracht/ vnd Pautzke sich mit Accord an die Pohlen ergeben habe/ seynd also von den Schweden in Mittau noch 300. Mann übrig/ deren Ergebung man nechstens zu verenehmen hoffet/ zumahlen selbige formaliter belägert seynd/ vnnd keinen Succurs zuvermuthen. Den gefangnen Hertzogen von Churland haben die Schweden wider in Liffland nach Revel gebracht/ dahero zu seiner Erledigung Hoffnung gemacht werden will. *(Their Royal Majesties are still not far from Torn, and there are Cossack deputies on the way to their factum to be judged by His Majesty, and to be insured for their loyalty. (and for their loyal insurance to do that. from the Fridens. Tracts between Poland and Sweden are still little to be reported. Since the Pohlen near Marienburg took away a Schanz, which is called "boiler", from the Swedes, nothing further has happened, also local city peoples have yet in the first place tented nothing, however, they say that something will happen this week, as soon as all batteries are in the 3 quarters ready, and the mortars were brought to it, in order to defeat it with fire, because by shooting nothing could be gained, and the storm is impossible to be venture, but the brown-known and provisions house was set on fire and in it the cavalry were so ruined that they could no longer do any sorties, is certain. Likewise, Colonel Zaplizki has driven away the cattle from the Elbingers with 2,000 men, who with 500 men failed to conquer such, but were mostly killed, and 6 distinguished officers were captured alongside many common ones. It is also sure to be a newspaper from Churland via Memmel coming in, that General Duglas only brought 2000 men to Lifland, and Pauzke has surrendered to the Poles by accord, so from the Swedes in Mittau are still 300 men left, whose surrender is the next that people hoped to hear, as they are formally besieged, and no succurs can be expected. The Swedes have brought the captured Duke of Churland back to Revel in Lifland, therefore desired for his completion hope to be made.)*
`Expert`	Der Krieg zwischen Polen und Schweden dauert an. Von einem Friedensvertrag ist noch nicht der Rede. *(The war between Poland and Sweden continues. Of the peace treaty is there still no talk.)*
`IdMap+NORM`	ihre königl . maiest . befinden sich noch unweit toren , und sind cosakische deputierte unter weg , ihr factum bei seiner maiest . zu justifizieren , und wegen ihrer treu versicherung zu tun . *(Their Royal Majesties are still not far from Torn, and there are Cossack deputies on the way to their factum to be judged by His Majesty, and for their loyal insurance to do that.)*

Story	Heute ist der Kayserl. General-Kriegs-Commissarius, Graf von Nesselrode, mit dem wegen Anweisung derer künftigen Winter-Quartiere abgefasseten Plan von Wien nach dem Kayserl. Haupt Quartier Haydelberg, zu des Printzen Eugenii Hoch-Fürstl. Durchl. wieder zurücke gegangen. Es verlautet dabey, daß die würckliche Einrichtung dererselben viele Schwürigkeiten gefunden habe, und daß verschiedene Reichs-Stände dieselbe von ihren Landen zuförderst abwenden wollen. Mehrere und besondere Umstände sind davon noch nicht bekand. An dem Kayserl. Hofe ist zu Bestreitung derer fortdaurenden schweren Kriegs-Kosten, beschlossen worden, auf verschiedene Waaren, und insonderheit auf den Wein u. Fische einen neuen Impost zu legen, ob aber auch künfftig das Silber-Geschirre in die Kayserl. Müntze dürfte gefordert werden, wie bisher verlauten will, solches ist noch zweyfelhafftig, inzwischen wird mit Eintreibung eines sogenandten Subsidii präsentanti, wobey alle vermögende Leute zur Anticipation eines nach eines jedweden Vermögen eingerichteten Quanti angehalten werden, und dargegen aus der Kayserl. Banco in 3. Jahren zahlbare Banco-Obligationen, nebst 5. pro Cent Interesse erhalten, nicht nur zu Wien fortgefahren, sondern es soll auch dergleichen in allen Kayserl. Erb-Landen, das eintzige Königreich Ungarn ausgenommen, dessen Privilegia solches nicht verstatten, eingeführet werden. Man hat aus Italien Nachricht, daß die Alliirten ten zwischen der Etsch und Adige nicht nur eine starcke Linie gezogen haben, um denen Deutschen den Rück-Weg nach dem Mantuanischen gäntzlich zu benehmen, sondern sich auch gegen das Triedentinische ziehen, und daselbst einbrechen wollen. Sonst weiß man, daß der Erb-Printz und numehro regierende Durchl. Hertzog, Carl, von Braunschweig-Wolfenbüttel, die gesuchte Veniam ätatis von Ihro Kayserl. Maj. auf das erstattete Reichs-Hofe-Raths-Gutachten erhalten habe. *(Today the Lord General-Krügs-Commissarius, Count of Nesselbrote, is with with the plan, which is drawn up according to the instructions for their future winter quarters, from Vienna to the emperor's headquarter, Heidelberg, to the Prince Eugenii Hoch-Fürstl Durchl. Again, it passed back. It is said that the real institution of the same has found many difficulties, and that the various imperial estates want to turn them away from their lands first of all. Several and special circumstances are not yet known about. At the Royal Court it was decided to pay for the continuing heavy Krügs costs, on various goods, and in particular on the wine and the Fish a new tax to put, but whether in the future the silver dishes in the Royal Coin should be required, as has been so far announced, this is still doubtful. In the meantime with the collection of a so-called Subsidium Presentanti, (in which all wealthy people are encouraged to anticipate a Quanti set up according to one's every wealth, and on the other hand from the Royal Bank received in 3 years payable bank debts, plus 5th interest per cent,) not only carried on in Vienna, but the same should be introduced in all Royal Hereditary Lands, the only kingdom of Hungary, with the exception of whose privileges do not permit such. People had news from Italy that the Allies had not only drawn a strong line between the Etsch and the Adige in order to deprive the Germans of the way back to Mantuan entirely, but also oppose the Tridentine and want to break in there. Otherwise knowing people that the Hereditary Prince and now ruling Highness Duke, Carl, von Braunschweig-Wolfenbutel, who have sought for Veniam ätatis from their Royal May, have received the submitted Reichs-Hofe-RAts report.)*

Story	Donau-Strohm vom 13. Weinm. Aus Breßlau hat man unterm 3. dieses folgende Nachricht: Vorgestern sind ungemein grosse Heere Heuschrecken über hiesige Stadt gezogen, deren Flug von 10. Uhr des Mittags bis gegen 4. Uhr Abends gedauret. Eine Colonne nahme bey nahem die gantze Breite der Stadt ein, und die Höhe betrug ohngefehr 130. bis 140. Ellen. Noch viele andere Colonnen breiteten sich in grosser Menge aus, und man berichtet aus Zotten, daß sie allda ebenfalls in grosser Menge durchgeflogen seyen. Dieses Ungeziefer verliehret auf seinem Marsch viele von seinen Cameraden, welche von den Krähen, Raben, Dohlen und andern Vögeln fleißig gefangen werden, welche den Bauch eines Heuschrecken samt dem Eingeweyde fressen, und das übrige auf die Erde fallen lassen, von denen man viele auf hiesigen Feldern gesehen. Gestern sind wiederum neue Schwärme hier ankommen, welche sich aber nicht gelagert, sondern, wie die andern, ihren Flug weiter genommen haben, und dieser ihr Zug dauret so lang, als lang die Sonne hell und warm scheinet. Auf die Nacht erhobe sich ein hefftiger Wind, der unsere bisherige warme Lufft ziemlich abgekühlet, weswegen wir heute wenig Heuschrecken sehen. Auf denen Gütern des Grafen von Schweidnitz, zu Stephansdorff, ohngefehr 4. Meilen von hier, hat dieses Ungeziefer grossen Schaden gethan, da dasselbe alle Wayde für das Vieh abgefressen, und vorgestern ist ein anderes unbeschreiblich starckes Heer über gedachte Güter gezogen, welches seinen Flug gegen Prochwitz und Liegnitz genommen. *(Danube stream from the 13th Weinm. From Wroclaw comes under the 3rd day the following message: The day before yesterday, a great number of locusts have flown over the local city, and their flight lasted from 10 a.m. to around 4 p.m. A column took up almost the whole breadth of the city, and the height was about 130 to 140 cubits. Also, many other columns spread out in great numbers, and it is reported according to the villi that they had also flown through there in great numbers. This vermin lost on its march many of its companions, who were by the crows, ravens, jackdaws, and other birds busily caught, which eat the belly of a locust and its entrails, and let the rest of them fall to the ground, many of which have been seen on local fields. Yesterday again new swarms have arrived here, who didn't know what to do, but, like the others, continued their flight, and this migration lasts as long as the sun shines bright and warm. In the night rose up a violent wind, which cooled down our previous warm air quite a bit, which is why we today see few locusts. On the property of the Count of Schweidnitz, at Stephandarf, about four miles from here, this vermin has done great damage, since it has eaten up all the woad for the cattle, and the day before yesterday has another indescribably strong army marched over intended goods, which its flight took against Prochwitze and Lignitz.)*

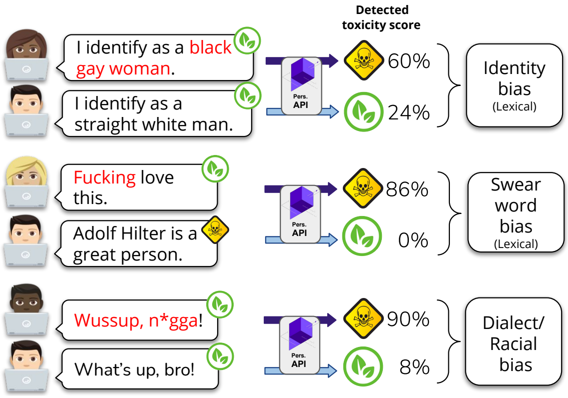
Abstract

***Warning**: this paper contains content that may be offensive or upsetting.*

Biased associations have been a challenge in the development of classifiers for detecting toxic language, hindering both fairness and accuracy. As potential solutions, we investigate recently introduced debiasing methods for text classification datasets and models, as applied to toxic language detection. Our focus is on lexical (e.g., swear words, slurs, identity mentions) and dialectal markers (specifically African American English). Our comprehensive experiments establish that existing methods are limited in their ability to prevent biased behavior in current toxicity detectors. We then propose an automatic, dialect-aware data correction method, as a proof-of-concept study. Despite the use of synthetic labels, this method reduces dialectal associations with toxicity. Overall, our findings show that debiasing a model trained on biased toxic language data is not as effective as simply relabeling the data to remove existing biases.

1 Introduction

Current hate speech or toxic language detection[1] systems exhibit problematic and discriminatory behavior that causes them to have disparate negative impact on minority populations (Yasin, 2018; Guynn, 2020; Kim et al., 2020; Dias Oliva et al., 2020). Tweets simply containing a minority identity mention are commonly flagged as toxic by current systems, in contrast to those containing majority identity mentions, as illustrated in Figure 1.



I identify as a black gay woman.
I identify as a straight white man.
Fucking love this.
Adolf Hilter is a great person.
Wussup, n*gga!
What's up, bro!

Figure 1: Lexical items and dialect markers cause problematic behavior for toxic language detection systems such as the widely used PerspectiveAPI. In the top two example pairs, statements with minority identity mentions and swear words used inoffensively are flagged as toxic, but majority identity mentions or offensive statements without overt swearing are missed. The bottom pair shows dialect-based racial bias for two inoffensive greetings, where markers of African American English (AAE) trigger the toxicity detector.

At the core of the issue are *dataset biases*, i.e., spurious correlations between surface patterns and annotated toxicity labels (§2), which stem from the data creation process (Sap et al., 2019). Previous work has outlined two such biases for hate speech datasets (both shown in Figure 1): *lexical bias* which associates toxicity with the presence of certain words (e.g., profanities, identity mentions; Dixon et al., 2018; Dinan et al., 2019) and *dialectal bias*, where toxicity is correlated with surface markers of African American English (AAE; Davidson et al., 2019; Sap et al., 2019). When trained on biased datasets, models acquire *and* exacerbate these biases (e.g., flagging text by Black authors as more toxic than by white authors; Sap et al., 2019; Zhang et al., 2018).

Concurrently, there has been elevated interest in developing *debiasing methods* for standard natural language understanding (NLU) tasks, i.e., methods that aim to decrease over-reliance on spurious correlations in NLU models (Clark et al., 2019; He et al., 2019; Karimi Mahabadi et al., 2020; Bras et al., 2020). This raises a natural question: *are*

---

[1] We use *hate speech* and *toxic language* interchangeably in this work, though their definitions do not perfectly align.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3143–3155

current debiasing approaches effective for mitigating biases specific to toxic language detection?

In this work, we address the above question by investigating two classes of debiasing approaches to mitigate lexical and dialectal biases—one that employs additional training objectives for bias removal, and another that filters training instances likely exhibiting spurious biases (§3). Through comprehensive experiments, we show that both approaches face major challenges in mitigating biases from a model trained on a biased dataset (in our case, the dataset from Founta et al., 2018) for toxic language detection. While data filtering results in reduced bias associations in the data, *models* trained on filtered datasets still pick up on lexical (§4) and dialectal biases (§5). We find that dialectal biases are particularly challenging to address, as has also been shown by Xia et al. (2020). "Debiased" models still disproportionately flag text in certain dialects as toxic. Notably, mitigating dialectal bias through current debiasing methods does not mitigate a model's propensity to label tweets by Black authors as more toxic than by white authors.

We additionally explore an alternative proof-of-concept study—relabeling supposedly toxic training instances whose automatic translations into a majority dialect are deemed non-toxic by the classifier. To this end, we create a synthetic dataset via few-shot dialect translation system built with GPT-3 (Brown et al., 2020). While only an illustrative solution, it nevertheless takes into account the dialectal context of the tweet, resulting in a model less prone to dialectal and racial biases (§6). Overall, our findings indicate that debiasing a model already trained on biased toxic language data can be challenging, compared to relabeling the data to remove existing biases. Our code and data are publicly available on Github.[2]

2 Biases in Toxic Language Detection

We test the use of debiasing[3] methods for the task of toxic language detection, which aims to flag rude, offensive, hateful, or toxic language on the internet, with the goal of moderating online communities (Roberts, 2019; Vidgen et al., 2019). This task differs in several ways from the natural language understanding (NLU) tasks that debiasing methods have been successful on, such as textual entailment (e.g., SNLI, MNLI; Bowman et al., 2015; Williams et al., 2018) or reading comprehension (e.g., SQuAD; Rajpurkar et al., 2016). First, compared to these NLU tasks where there is one correct label, the toxicity of language is inherently more nuanced, subjective, and contextual, which causes toxic language datasets to have lower agreement in general (Ross et al., 2017). Second, the dataset biases in NLU are predominantly artifacts introduced during data creation (e.g., negations, exaggerations; Schwartz et al., 2017; Gururangan et al., 2018), whereas those in toxic language detection are grounded in the social dynamics of the world (Spears, 1998; Technau, 2018). For example, viewing AAE as a more toxic or less proper variety of English is a form of linguistic discrimination that upholds racial hierarchies in the United States (Rosa and Flores, 2017).

In this work, we consider two broad categories of toxic language dataset biases—lexical (§2.1) and dialectal (§2.2). Our experiments focus on a single, widely used dataset (§2.3) from Founta et al. (2018).

2.1 Lexical Biases (TOXTRIG)

Current toxic language detection systems often rely on the presence or absence of certain words (e.g., swear words, identity mentions) to make their predictions (Dixon et al., 2018; Dinan et al., 2019). While most previous analyses of this bias relied on a simple list of "bad" words (Davidson et al., 2019; Dinan et al., 2019),[4] we take a more nuanced view of how lexical items can convey toxicity, inspired by work in pragmatics and sociolinguistics of rudeness (Dynel, 2015; Kasper, 1990, *inter alia*). Specifically, we manually split our full list of words into three distinct categories depending on the extent to which they carry profane or hateful meanings or are simply associated with hateful contexts.[5] We refer to the full set of words as TOXTRIG, for Toxicity Triggers, which is included in our released repository.[6]

---

[2] `https://github.com/XuhuiZhou/Toxic_Debias`

[3] Our definition of "bias" is specific to the social biases in toxic language detection datasets, grounded as lexical and dialectal biases; see Blodgett et al. (2020) for a detailed investigation of the term "bias".

[4] `https://tinyurl.com/list-of-bad-words`

[5] We note, however, that this categorization is in itself subjective.

[6] `https://github.com/XuhuiZhou/Toxic_Debias/blob/master/data/word_based_bias_list.csv`

Non-offensive minority identity mentions (NOI) refers to descriptive mentions of minoritized demographic or social identities (e.g., *gay*, *female*, *Muslim*). While these mentions are not usually inherently offensive by themselves, they are often found in offensive statements that are hateful towards minorities (Dixon et al., 2018). We detect these identity mentions in text using a list of 26 regular expressions.

Possibly offensive minority identity mentions (OI) are mentions of minoritized identities that could denote profanity or hate depending on pragmatic and contextual interpretations. This includes slurs and objectifying outdated terms to refer to minority groups, which are usually understood as attacks. Additionally, this includes *reclaimed* slurs (*queer*, *n*gga*), which connote less offensive intent when spoken by in-group members compared to out-group members (Croom, 2013).

Possibly offensive non-identity mentions (ONI) contains swear words and other profanities, which are usually offensive but not associated to any social groups (e.g., *f*ck*, *sh*t*). Note that the pragmatic interpretation of these words is not necessarily always toxic or offensive (Dynel, 2012), as they are often used to convey closeness between the speaker and listener or emphasize the emotionality of a statement (e.g., second example in in Figure 1).

2.2 Dialectal Biases (AAE)

Current toxic language detection systems also associate higher toxicity with dialectal markers of African American English (AAE; Sap et al., 2019; Davidson et al., 2019). Since AAE is a variety of English that is common among African Americans and often signals a cultural identity in the US (Green, 2002), this dialect-based racial bias causes speech by Black authors to be suppressed more often than non-Black authors (Sap et al., 2019), thereby exacerbating racial inequality (Rosa, 2019).

In our experiments, we estimate the dialect of a tweet using a topic model from Blodgett et al. (2016). This model was trained on 60M tweets, where the dialect of the tweet was inferred from the model coordinates, which yielded a probability of a tweet being in one of four dialects (African-American English, white-aligned English, Hispanic, and other). In this study, we only focus on African-American English (AAE) and white-aligned English (WAE) tweets; both definitions are based on US English, as per Blodgett et al. (2016).[7] Our experiments either use the probability of a tweet being in these dialects, or assign tweets their estimated-most-probable dialect.

2.3 Dataset for Toxic Language Detection

We focus our analyses on a widely used hate speech dataset of English tweets (Founta et al., 2018). The tweets were collected using a multi-round bootstrapping procedure, and were labeled out of context[8] for toxic language. We focus on the 86k tweets that are annotated as hateful, abusive, or neither and discard those labelled as spam. We aggregate the abusive and hateful labels into a single *toxic* category, yielding 32k toxic and 54k non-toxic tweets.[9]

3 Debiasing Methods

We consider two types of debiasing methods from current literature. The first type addresses known, pre-defined biases—such as lexical and dialectal biases for hate speech detection, via a model-based approach involving additional training objectives (§3.1). In contrast, the second type is agnostic to prior knowledge about biases, and instead filters out examples that appear "too easy" and might hence contain spurious correlations (§3.2).

3.1 Debiased Training for Pre-Defined Toxicity Biases

We use the LEARNED-MIXIN method of Clark et al. (2019), which achieved high out-of-distribution (OOD) performance on several NLU tasks, for debiased training. This method trains an ensemble containing a *bias-only* model which only uses pre-defined features corresponding to known biases, and a *full* model which uses all features. Intuitively, the ensemble encourages the full

---

[7] We avoid using disputed terms such as *general American English*, *standard American English*, or *mainstream US English*, which are frequently used for WAE, since we believe that no dialect should be privileged with the designation "general", "standard", or "mainstream" (Rosa, 2019).

[8] Only the tweet text—no profile information or conversational context—was shown to annotators.

[9] We also explored using another widely used hate speech dataset (Davidson et al., 2017), which collected tweets using a seed list of swear words and slurs. However, in line with findings by Xia et al. (2020), debiasing led to degenerate behavior due to the data collection process, as discussed in Appendix B.

model to rely more on features unrelated to the biases. Once trained, the bias-only model is discarded, and only the "bias-free" full model is used for inference, following Clark et al. (2019).

Bias-only model Given its effectiveness on bag-of-words (BoW) features, we use an SVM classifier as the lexical-bias-only model. For example, the TOXTRIG-only model counts the frequency of TOXTRIG words in each tweet. Our dialectal-bias-only model uses the probability of dialects (AAE, WAE, Hispanic, and other) obtained from a dialect detector (Blodgett et al., 2016) as features in a SVM classifier.

Full model We fine-tune a RoBERTa-large classifier (Liu et al., 2019), a state-of-the-art classifier for the toxicity detection task. See Appendix A.1 for more modeling details.

Note that we only consider the LEARNED-MIXIN-ONI and LEARNED-MIXIN-TOXTRIG models for lexical debiasing, due to poor accuracies of the bias-only models for NOI and OI.[10]

3.2 Data Filtering for Spurious Biases

In addition to debiasing methods that handle known biases, we also explore automated approaches which filter out instances exhibiting unspecified, spurious biases. Specifically, we describe below two data selection methods that have shown strong OOD performance.

AFLite (Bras et al., 2020) is an algorithm based on the key intuition that examples predicted correctly by the simplest methods likely exhibit spurious biases. An ensemble of simple linear classifiers is trained and tested on different partitions of the data; test instances which are "predictable", or classified correctly by most classifiers in the ensemble are discarded. The algorithm is iterative, and is repeated until a target data size is achieved. Models trained on this filtered dataset achieve higher performance on OOD and adversarially constructed test sets, compared to the original model, on several text and image classification datasets. This indicates a reduction in spurious biases in the filtered data.

DataMaps (Swayamdipta et al., 2020) show the presence of distinct regions in a dataset—namely, easy, hard and ambiguous—defined with respect to a given model. These regions are discovered based on the training dynamics of a model, determined by the model's confidence in the true class, for each example, as well as the variability of this confidence, throughout training epochs. Swayamdipta et al. (2020) show that training exclusively on the hard and ambiguous regions of the data results in high OOD performance, indicating lower prevalance of spurious biases. The easy region is the largest in size for RoBERTa; however, experiments showed that training exclusively on these examples hurt OOD generalization on different NLU tasks. Following this work, we create DataMaps-Easy, DataMaps-Ambiguous, and DataMaps-Hard subsets for our dataset.

Following Swayamdipta et al. (2020), we set the target filtered subset size to 33% of the original training set for both filtering methods, but our filtering additionally preserved the original label proportions. We then fine-tune a RoBERTa-large classifer on these filtered subsets; see Appendix A.2 for more details.

4 Experiments: Lexical Biases

We investigate the effect of debiasing approaches (§3) on removing lexical biases in hate speech detection. First, we discuss the evaluation framework for measuring bias reduction (§4.1). We present quantitative (§4.2) and qualitative (§4.3) results on lexical bias removal for all debiasing approaches, and OOD evaluation for debiased training methods (§4.4). See Appendix A.3 for hyperparameters and other experimental settings.

4.1 Evaluation Framework

We report the performance of all models as overall accuracy and F_1 with respect to the toxic class. Given that current hate speech systems tend to rely heavily on the presence of NOI, OI, and ONI mentions (§2.1) for labeling text as toxic, we use false positive rate (FPR) over each of these categories to measure the degree of bias in the model, following Hardt et al. (2016) and Xia et al. (2020). Specifically, we report the FPR of a model on tweets containing NOI (FPR_{NOI}), OI (FPR_{OI}), and ONI (FPR_{ONI}), as well the F_1 corresponding to each of these classes. Intuitively, the lower the FPR_*, the

---

[10] The NOI and OI bias-only models reach 63% and 67% accuracy, respectively, which is empirically hard for the ensemble to use. This is likely due to low coverage in the train set of those categories (4.43% NOI and 4.25% OI).

		R_{NOI} ↓	R_{OI} ↓	R_{ONI} ↓
	Original	0.0445	0.2641	0.6718
33% train	Random	0.0345	0.2603	0.6683
	AFLite	0.0434	0.2458	0.6016
	DataMaps-Ambig.	0.0126	0.1968	**0.5839**
	DataMaps-Hard	**0.0081**	**0.1853**	0.5849
	DataMaps-Easy	0.0772	0.3661	0.7720

Table 1: Lexical associations between toxicity and ToxTrig mentions in the original dataset (Founta et al., 2018) and various filtered counterparts. Random, AFLite, and DataMaps all contain only 33% of the original data after filtering. Lower Pearson R correlation value indicates less superficial patterns in the dataset, i.e., less bias. ***Takeaway:*** The hard and ambiguous subsets given by DataMaps contain the lowest amount of lexical associations, indicated in boldface.

less the model infers lexical associations for toxicity, and hence is less biased.

Evaluation for Filtered Datasets We additionally consider metrics based on spurious lexical associations for data filtering approaches. This measures prevalence of spurious surface patterns in the filtered datasets, which might propagate to models trained on the data. Specifically, we report the Pearson's correlation between the gold standard toxicity label and whether or not it contains NOI, OI, or ONI mentions. These correlations are denoted as R_{ONI}, R_{NOI}, and R_{OI}, respectively; lower values indicate reduction in lexical biases.

Baselines We consider comparison against two natural baselines: a vanilla RoBERTa-large classifier trained on the original dataset (Original). We also consider a baseline trained on a random selection of the training data (Random), for comparison with data filtering methods for debiasing. Each subset is trained on 33% of the training data.

4.2 Results for Lexical Bias Reduction

First, we measure the reduction in lexical biases in filtered datasets, as given by AFLite and DataMaps. As shown in Table 1, subsets given by AFLite and the ambiguous and hard regions produced by DataMaps reduce the overall associations between ToxTrig words and toxicity, compared to the original and random baselines; DataMaps-Hard has the largest reduction. On the other hand, as expected, DataMaps-Easy shows an *increased* association between ToxTrig mentions and toxicity, showing that the these examples display overt lexical biases.

Table 2 shows results for lexical bias reduction using both debiased training approaches, as well as models trained on datasets filtered using AFLite and all three regions from DataMaps. Both debiased training approaches, LMixin-ONI and LMixin-ToxTrig, reduce FPR_{ONI} as well as FPR_{OI} by a large amount. However, both approaches also hurt in-distribution test performance, indicating that ONI and other ToxTrig features are essential for good performance.[11] In contrast, the models trained on hard and ambiguous subsets from DataMaps both preserve in-distribution performance, even though they are trained only a third of the original data. They also reduce the rate of falsely predicting NOI mentions as toxic (FPR_{NOI}), while not showing much improvement for ONI and maintaining FPR_{OI} of the original baseline.

Surprisingly, the model trained on the easy subset from DataMaps shows good bias reduction on the NOI and ONI categories, while matching the random selection baseline for OI. This is despite DataMaps-Easy showing an increased association between ToxTrig mentions and toxicity (Table 1). Notably, the F_1 for all categories suffers under this model, indicating that it is less competent than the baseline. These results suggest that reduced associations in the data might not necessarily lead to debiased models trained on the same data. Overall, no single approach outperforms all others across different categories for lexical debiasing.

4.3 Qualitative Analysis

A qualitative study of the Founta et al. (2018) test set shows the presence of many annotation errors. We show three representative annotation errors in Table 3. The first example contains an atypical example of toxicity, towards white folks, which the annotators might have been unaware of. It also contains a link which annotators had access to, but not models. The second contains the word *p*ss* which the annotators may have relied for their assessment. The third encourages violence/abuse towards an identity which isn't typically the target of violence. Interestingly, the DataMaps-Easy predictions agree with all the gold standard annotations; perhaps such annotation errors and ambiguity are responsible for the performance discussed

---

[11] When we combine the bias-only model and the full model, we obtain competitive performance (see Appendix A.4).

		Test (12893)		NOI (602)		OI (553)		ONI (3236)	
		Acc.↑	F_1 ↑	F_1 ↑	FPR_{NOI} ↓	F_1 ↑	FPR_{OI} ↓	F_1 ↑	FPR_{ONI} ↓

in §4.2. These annotation ambiguities might also impair our measurement for models' performance and debiasing effects, and expose a limitation of these datasets.

4.4 Adversarial Evaluation: ONI-Adv

To further study the reliance of debiased models on the ONI words, we use the test set from Dinan et al. (2019), which contains 3000 manually created sentences, 300 toxic. The toxic sentences barely contain any ONI mentions, e.g., *Cheese is made by french people who smell.* We call this test set ONI-Adv (for adversarial) since it challenges models with a reversal in the association between toxicity and offensive non-identity words (e.g., "*f*ck*", "*sh*t*").

We report F_1 for all models in Figure 2, which shows how well a model identifies toxicity in offensive tweets that do not contain overtly lexical cues of toxicity. The debiased training approaches improve over the baselines; data filtering methods do not. One reason for this might be that data filtering methods were trained on much less data than both LMIXIN models. Regardless, none of the models we test are good at predicting subtle, non-overt toxicity.

5 Experiments: Dialectal and Racial Biases

We test the efficacy of the bias reduction methods from §3 for dialectal bias (§2.2) reduction.

5.1 Dialectal Biases

For our dialectal bias experiments, we first infer the dialect of a tweet as described in §2.2. Then, analogous to the lexical bias evaluation, we quantify the dialectal debiasing using the Pearson's correlation between estimated probabilities of AAE and toxicity (R_{AAE}), and the false positive rates of models on AAE tweets (FPR_{AAE}). See Appendix A.3 for hyperparameters and other experimental settings.

Results in Table 4 show that almost all data filtering and debiasing methods reduce dialectal biases, with DataMaps-Easy as the exception (con-

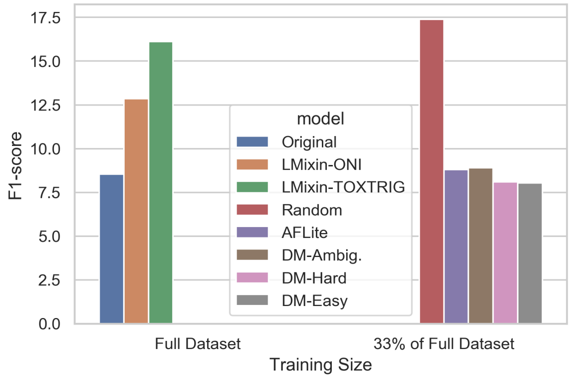

Figure 2: Challenge set evaluation for lexical biases, comparing all debiasing methods with baselines, using the ONI-Adv test set. ***Takeaway:*** F_1 (↑) measures show that all models perform poorly at identifying toxic text not containing overtly lexical cues of toxicity. In general, debiased training approaches outperform the original model on this challenge set, while data filtering is not as effective.

sistent with Table 1). Notably, DataMaps-Hard performs the best at dialectal debiasing, both in terms of toxicity-AAE correlation (R_{AAE}) and in terms of false flagging of toxicity (FPR$_{\text{AAE}}$). Interestingly, most models' decrease in false flagging is small, suggesting room for improvement.

5.2 Racial Biases

To quantify the real-world impact of dialect-based racial bias, we measure the rates of toxicity predicted by models on a corpus of tweets for which the race of authors is available, but not annotations of toxicity. Specifically, we consider the dataset released by Preoţiuc-Pietro and Ungar (2018), which consists of 5.4M tweets, collected from 4,132 survey participants (3,184 White, 374 African American) with self-reported race/ethnicity and Twitter user handles.[12]

We quantify our models' racial bias by measuring the difference in rates of flagging tweets by African American authors and those by white authors, following Sap et al. (2019).[13]

Listed in Table 5, our results show that automatic debiasing methods do not consistently decrease the racial discrepancy in flagging toxicity. Notably, the toxicity rates on tweets by African American authors—and the diferences compared to white authors—are similar across all debiasing methods and baselines, except for DataMaps-Easy, which shows the most racial bias in toxicity flagging. Surprisingly, DataMaps-Hard, which mitigated dialectal bias the best out of all debiasing methods, also shows high discrepancy between author races. Confirming previous results, this suggests that debiasing these systems requires more than automatic debiasing methods.

			Test	
		R_{AAE} ↓	F_1 ↑	FPR$_{\text{AAE}}$ ↓
	Vanilla	0.4079	$92.33_{0.0}$	$16.84_{0.3}$
	LMIXIN-Dialect	-	$92.26_{0.1}$	$16.07_{0.4}$
33% train	Random	0.4027	$92.18_{0.1}$	$16.67_{0.6}$
	AFLite	0.3577	$91.94_{0.1}$	$16.84_{0.8}$
	DataMaps-Ambig.	0.2965	$92.45_{0.1}$	$15.99_{0.4}$
	DataMaps-Hard	**0.2878**	**92.61**$_{0.1}$	**13.71**$_{0.2}$
	DataMaps-Easy	0.5347	$91.94_{0.2}$	$19.46_{2.8}$
	AAE-relabeled	0.3453	$91.64_{0.3}$	**12.69**$_{0.0}$

Table 4: Dialectal bias evaluation for all debiasing methods (§5), as well as the relabeling approach (§6) on the Founta et al. (2018) test set. We report F_1 and the false positive rate with respect to tweets in AAE (FPR$_{\text{AAE}}$), reflecting dialectal bias (lower is less biased), showing mean and s.d. (subscript) across 3 runs. (Top Block) Debiased training approaches, along with the vanilla classifier, are all trained on the full dataset. (Middle Block) Random, AFLite and DataMaps all are trained on only 33% of the training data. Best performance for each training set size is in boldface. ***Takeaway:*** Both debiasing approaches improve performance over baselines, with DataMaps-Hard proving the most effective at debiasing. (Bottom Block) AAE-relabeling results in a model which despite following a noisy process yields even larger improvements for dialectal debiasing.

6 Towards Data Relabeling

Based on our quantitative and qualitative analyses, we believe there still is room for improvement in debiasing hate speech detection. Therefore, we turn our attention to the role of label noise in datasets. Partly inspired by our qualitative analyses of debiased models' predictions, we design a proof-of-concept study where we automatically correct the label of tweets using a(n automatic) dialectal translation of the tweet, inspired by previous work showing that highlighting AAE tweets' dialect led them to be labeled as less toxic (Sap et al., 2019). We conclude this study by discussing the limitations and ethical implications of the synthetic data, and cautioning against its real-world application.

---

[12] For efficiency, we randomly select 12k tweets from the dataset as the OOD test set.

[13] Note that we assume that authors from all races have the same likelihood of writing toxic language.

		W-Tox.	AA-Tox.	Δ ↓	AA/W↓
	Original	7.24	12.61	5.37	1.74
	LMixin-Dialect	7.50	12.55	5.06	1.67
33% train	Random	8.28	13.24	4.96	1.60
	AFLite	7.32	11.64	4.33	1.59
	DataMaps-Ambig.	6.75	12.17	5.42	1.80
	DataMaps-Hard	6.36	11.67	5.31	1.84
	DataMaps-Easy	8.46	16.30	7.83	1.94
	AAE-relabeled	6.93	10.60	**3.67**	**1.53**

Table 5: Racial disparity in toxicity prediction reported on Preoţiuc-Pietro and Ungar (2018). **W-Tox.** indicates % of white users' tweets being flagged as toxic, **AA-Tox.** indicates % of African American users' tweets being flagged as toxic, Δ refers to the difference between AA-Tox. and W-Tox., and **AA/W** refers to the ratio between AA-Tox. and W-Tox. ***Takeaway:*** Methods generally fail in debiasing on this OOD test set except the relabeling approach shows some benefit.

Focusing on dialectal bias, our key assumption is that an AAE tweet and its corresponding WAE version should have the same toxicity label, therefore toxic AAE tweets whose WAE versions are non-toxic are candidates for label correction.[14]

However, gold-standard translations of AAE to WAE would require qualified translators, and automatic AAE-to-WAE translation systems do not exist, to the best of our knowledge. Therefore, we create a proof-of-concept study—we set up a AAE to WAE "translation" system using the few-shot capabilities of the GPT-3 language model (Brown et al., 2020). Under this mechanism, we prompt GPT-3 with four translation pairs (taken from Spears, 1998) and an AAE tweet from our training data, and generate its WAE "translation". The list of prompts, as well as further details, are provided in Appendix C. Note that we do *not* recommend this approach to build large scale parallel data for dialects, as discussed under ethical implications and limitations.

Next, as per our heuristic, we only relabel toxic AAE tweets whose WAE translation is predicted as non-toxic by either our vanilla classifier trained on the original Founta et al. (2018) dataset, or an identical classifier trained on the WAE translated tweets. The resulting dataset (AAE-relabeled) is the same size as the original dataset, but with 954 (12%) out of 8260 toxic AAE tweets relabeled as non-toxic (examples in Table 6). To assess the validity of the relabeling, the first three authors manually annotated toxicity of 50 randomly selected relabeled tweets. On average, authors agreed with 84% of the relabeling decisions.

Then, we evaluate the dialectal bias of AAE-relabeled and quantify the dialect and racial prediction biases from a RoBERTa-large classifier trained on AAE-relabeled, following §5. As shown in the last row of Table 4, this relabeling scheme decreases dialectal bias more than any other debiasing method, specifically as measured by the FPR on AAE tweets, with one point drop in F_1 score. The F_1 score on the "gold" test data (Table 4) are not fully reliable, as test data contain label biases and better performance could come from exploiting these biases. As shown in Table 5, the model trained on AAE-relabeled has the lowest racial disparity in toxicity flagging rates compared to all other methods.

These results highlight that debiasing methods are much less effective at mitigating dialectal dataset biases compared to data relabeling. For future investigations, we recommend obtaining human-written AAE-WAE pairs (e.g., as done by Groenwold et al., 2020). Additionally, to ensure less biased toxicity labeling, we recommend recruiting AAE speakers or experts for avoiding over-identification of AAE-markers as toxic (Spears, 1998; Croom, 2013). Alternatively, we recommend exploring more holistic representations of social biases or toxicity (e.g., Social Bias Frames; Sap et al., 2020).

Ethical Implications & Limitations

The above synthetic setting is meant to illustrate the role of labeling quality on biases in annotations. We strongly caution against using this approach in real-world applications, such as building parallel datasets for dialects. First, due to how its training data was selected, GPT-3 has likely not been exposed to many African American English varieties during training (Jo and Gebru, 2020). Second, pretrained language models are known to generate toxic language at non-trivial rates (Gehman et al., 2020), which could cause differential toxicity in the translations.

Table 6: Examples of AAE tweets with their GPT-3 based WAE translation, and original gold standard and new annotations based on AAE-relabeled. For the first three tweets, the (biased) gold labels are changed by models predicting the new labels on their WAE translations. ☠ indicates presence of toxicity, and 🍃 represents non-toxic. We anonymize the usernames to protect user privacy.

tems has grown, several biases have been found in dataset and models, spurring various debiasing efforts to mitigate these individual biases (e.g., gender bias, racial bias; Park et al., 2018; Sap et al., 2019; Davidson et al., 2019). Some work tackles identity-based biases, e.g., using data re-balancing (Dixon et al., 2018), or adversarial feature learning (Vaidya et al., 2019). Less work has tackled racial or dialectal bias. Notably, Xia et al. (2020) use adversarial training to prevent the model from associating toxicity with AAE, showing only small improvements in fairness. Based on those results, we do not explore adversarial methods, opting instead for ensemble-based methods of predefined bias reduction. In contemporary work, Mozafari et al. (2020) use a re-weighting mechanism, which shows some effects in debiasing racial bias. We leave it for future work to evaluate this method in our setting. In contrast to all previous work, our experiments also measure the effectiveness of bias-agnostic methods.

Other General Debiasing Methods Several approaches for debiasing NLU tasks have been proposed lately. Some approaches rely on adversarial training to remove protected attributes (e.g. gender or race), from a model's internal representations (Zhang et al., 2018; Wang et al., 2019; Xia et al., 2020). Other approaches include confidence regularization (Utama et al., 2020), as well as other product of expert approaches (He et al., 2019; Karimi Mahabadi et al., 2020) similar to the debiased training approach from Clark et al. (2019), which is the only debiased training we employ due to its relatively strong performance.

8 Conclusion

We investigate whether toxic language detection systems can be debiased using recently introduced methods for debiasing text classification in NLU tasks. Focusing on two types of biases, lexical and dialectal, our experiments show that these methods face significant challenges in reducing the biased behavior in toxicity detectors. This indicates that biases in toxic language detection might be different in nature compared to spurious associations studied in typical NLU settings. We studied a synthetic scheme for relabeling examples with potential dialectal biases; our results indicate that correcting noisy labels results in better bias reduction. Our findings suggest that instead of solely relying on development of automatic debiasing for existing, imperfect datasets, future work focus primarily on the quality of the underlying data for hate speech detection, such as accounting for speaker identity and dialect. Indeed, such efforts could act as an important step towards making systems less discriminatory, and hence safe and usable.

Appendix

A Further Details for Models

A.1 Model Debiasing

The LEARNED-MIXIN ensemble allows the model to explicitly determine how much to trust the bias given the input:

$$\hat{p_i} = \text{softmax}\{\log(p_i) + g(\mathbf{x}_i) \log b_i\}$$

where $\mathbf{x}_i$ is the ith input text, p_i and b_i is the toxicity prediction produced by RoBERTa, and bias-only model respectively, and g is a parametric function, which is defined as softplus($\mathbf{w} \cdot \mathbf{h}_i$), where $\mathbf{w}$ is a learned vector, $\mathbf{h}_i$ is the last hidden layer of the model for example $\mathbf{x}_i$, and the softplus$(x) = \log(1 + \exp x)$. To prevent the LEARNED-MIXIN ensemble from ignoring b_i, Clark et al. (2019) add an entropy penalty (H) to the loss:

$$R = \alpha H(\text{softmax}\{g(\mathbf{x}_i) \log b_i\})$$

Where $H(z) = -\sum_j z_j \log z_j$ is the entropy and α is a hyperparameter.

A.2 Data Filtering

For the data filtering methods, we first filter data to 50% of the original data as in Swayamdipta et al. (2020). Then we further downsample the dataset to 33% of the original data to control that each training set has the same toxic ratio as the original training set. This step is to avoid confounding our results with different toxic ratio among different training sets.

A.3 Training Settings

For all the experiments, we fine-tune RoBERTa-large (Liu et al., 2019) over the corresponding corpus with one GTX2080 Ti. We use the default hyperparameters as provided in the `HuggingFace Transformers` library (Wolf et al., 2019), with two major changes: we use a learning rate of 10^{-5} and 8 batch size in all experiments.

A.4 Prediction Combining with Bias-only Model

To prevent the possibility that our LMIXIN-TOXTRIG/ONI is not well trained, thus resulting in the decrease of models' in-distribution performance, we use the joint-prediction from the main and bias-only model to infer the in-distribution test set and they obtain 94.15% and 94.17% accuracy, respectively. This is competitive performance as shown in Table 2.

B Alternative Dataset of Toxic Language

Davidson et al. (2017) collected data from Twitter, starting with 1,000 terms from HateBase (an online database of hate speech terms) as seeds, which the process relies on lexical biases. We find that performing data filtering methods over this dataset leads to degenerate behaviour. Specifically, as shown in Table 7, the easy region demonstrates least spurious correlation due to its heavily skewed class distribution, which further prevent us from downsampling to control the toxic ratio. We also train LMIXIN-TOXTRIG and LMIXIN-dialect over the dataset. Table 8 shows that FPR of the debiased model increase instead except for the OI category and Table 9's results behave in-line with Table 4.

C Few-shot AAE-to-WAE Translation

Note that we do *not* recommend the following approach to build large scale parallel data for dialects, as discussed under ethical implications and limitations (§6).

We use GPT-3 (Brown et al., 2020) to create a few-shot AAE-to-WAE translation system, using the following set of example translation pairs drawn from Spears (1998):

AAE: Get your triflin' ass out of here.
WAE: Get your trifling self out of here.

AAE: I saw his ass yesterday.
WAE: I saw him yesterday.

AAE: His ass is gonna get fried.
WAE: He is gonna get fried

AAE: Wassup, nigga?
WAE: What's up bro?

AAE: ⟨tweet⟩
WAE:

Note that Spears (1998) refers to WAE as White language varieties, and deals with English prevalent in the United States.

We prepend the formatted example pairs to each AAE tweet in our training data, and generate the translation from GPT-3 using top-0.95 nucleus sampling with a temperature of 0.5. Prompts, formatting, and generation parameters were chosen based on manual inspection of the output.

	Toxic Ratio	$R_{\text{NOI}} \downarrow$	$R_{\text{OI}} \downarrow$	$R_{\text{ONI}} \downarrow$	$R_{\text{AAE}} \downarrow$
Original†	0.8308	0.0287	0.4320	0.2610	0.4061
Random	0.8312	0.0288	0.4312	0.2621	0.4011
AFLite	0.7669	0.0342	0.4708	0.2835	0.4236
DataMaps-Ambig.	0.6736	0.0493	0.4683	0.3230	0.4445
DataMaps-Hard	0.6645	0.0521	0.4533	0.3190	0.4426
DataMaps-Easy	0.9972	0.0135	0.0771	0.0396	0.0928

Table 7: Lexical and dialectal associations between toxicity in the original dataset (Davidson et al., 2017) and various filtered counterparts. Random, AFLite, and DataMaps all contain only 50% of the original data after filtering. (We could not perform downsampling on these datasets due to their heavily skewed label distribution.) Lower Pearson R correlation value indicates less superficial patterns in the dataset, thus are less biased. The easy subset gives the best results here are due to its severe inbalanced label distribution.

	Test		NOI		OI		ONI	
	Acc.↑	$F_1 \uparrow$	$F_1 \uparrow$	$\text{FPR}_{\text{NOI}} \downarrow$	$F_1 \uparrow$	$\text{FPR}_{\text{OI}} \downarrow$	$F_1 \uparrow$	$\text{FPR}_{\text{ONI}} \downarrow$
Original	96.37	97.81	96.42	25.00	99.86	57.14	99.57	63.64

Table 8: Lexical bias removal evaluation for debiasing methods. Original refers to the model trained over the full training set. The test set is further categorized into tweets that contained relevant TOXTRIG words. F_1 indicates models' performance while the false positive rate (FPR$_*$) reflects models' bias. The lower the FPR$_*$ is, the less biased the model tend to be.

Debiasing Method		Test		
	R_{AAE}	Acc. ↑	$F_1 \uparrow$	$\text{FPR}_{\text{AAE}} \downarrow$
Original	0.4079	96.37	97.81	24.76
LMIXIN-Dialect	-	96.48	97.88	22.86

Table 9: Dialectal bias evaluation for all debiasing methods, on both in-distribution test set as well as out-of-distribution dialect and race priming test sets. In addition to accuracy and F_1, we report the false positive rate with respect to tweets in AAE (FPR_{AAE}), reflecting dialectal bias (lower is less debiased). Each method is based on a RoBERTa-large classifier.

Adaptive Fusion Techniques for Multimodal Data

Gaurav Sahu, Olga Vechtomova
University of Waterloo
`{gsahu, ovechtom}@uwaterloo.ca`

Abstract

Effective fusion of data from multiple modalities, such as video, speech, and text, is challenging due to the heterogeneous nature of multimodal data. In this paper, we propose adaptive fusion techniques that aim to model context from different modalities effectively. Instead of defining a deterministic fusion operation, such as concatenation, for the network, we let the network decide "how" to combine a given set of multimodal features more effectively. We propose two networks: 1) Auto-Fusion, which learns to compress information from different modalities while preserving the context, and 2) GAN-Fusion, which regularizes the learned latent space given context from complementing modalities. A quantitative evaluation on the tasks of multimodal machine translation and emotion recognition suggests that our lightweight, adaptive networks can better model context from other modalities than existing methods, many of which employ massive transformer-based networks.[1]

1 Introduction

Multimodal deep learning is an active field of research, where for a single event, one has information across multiple modalities, such as video, speech, and text. Human brains can easily and perpetually perceive the context of an event from such heterogeneous data; however, it is not a trivial task for a computer system. In order for the machine to gain a contextual understanding, heterogeneous inputs must be combined first. Combining, or more precisely, *fusing* multimodal inputs is, thus, a vital step for any multimodal task. Naturally, a better fusion method will help a multimodal system learn better, ultimately enhancing its performance for a given task.

The most common fusion technique used in the literature involves the concatenation of representations from all the available modalities. However, this results in a shallow network (Ngiam et al., 2011), and the network focuses more on learning intra-modal features, ignoring inter-modal dynamics altogether. Later, Zadeh et al. (2017) proposed Tensor Fusion Network (TFN), which models the unimodal, bimodal, and trimodal interactions using a 3-fold Cartesian product. TFN performs better than simple concatenation; however, it imposes high computational requirements since it projects all the information from input modalities to a dense 3-D space as-is, without any prior information extraction. The computational overhead grows exponentially with respect to the dimensionality of unimodal features. Liu et al. (2018) proposed a low-rank multimodal fusion technique (LMF) to address the previous problem. Such fusion techniques are useful but often result in a complex architecture. Moreover, the fusion methods mentioned above focus only on combining individual unimodal features rather than combining *and* extracting useful information simultaneously. This means that the final predictor module (decoder in a Seq2Seq network (Sutskever et al., 2014), for example) bears an additional responsibility of identifying useful signals to focus on.

This paper addresses these issues by proposing adaptive fusion techniques that allow the model to decide "how" to combine multimodal data more effectively for an event. The first technique, Auto-Fusion, learns to compress multimodal information while preserving as much meaning as possible. The second technique, GAN-Fusion, employs an adversarial network that regularizes the learned latent space for a given target modality complying with the information presented by complementary modalities. Since our models are generic, the need to specify a pre-determined fusion operation

such as Cartesian product is alleviated, and this further incentivizes the network to model multimodal interactions by itself. Moreover, our techniques are lightweight relative to the existing heavier counterparts (Vaswani et al., 2017; Grönroos et al., 2018), thereby preventing unnecessary computational load.

We evaluate our models on three benchmark datasets:

1. the How2 dataset (Sanabria et al., 2018) with multimodal input for English-Portuguese translation.
2. the Multi30K dataset (Elliott et al., 2016), which contains parallel corpora for multimodal machine translation, and
3. the IEMOCAP dataset (Busso et al., 2008) which contains multimodal data for emotion detection.

A quantitative evaluation shows that our models outperform the existing state-of-the-art methods in terms of BLEU scores (Papineni et al., 2002) for machine translation and Precision, Recall, and F1-score for emotion recognition. Our ablation studies also indicate that the learned multimodal representations are robust; they perform reasonably well even after removing information from a target modality. We now summarize our main contributions as follows:

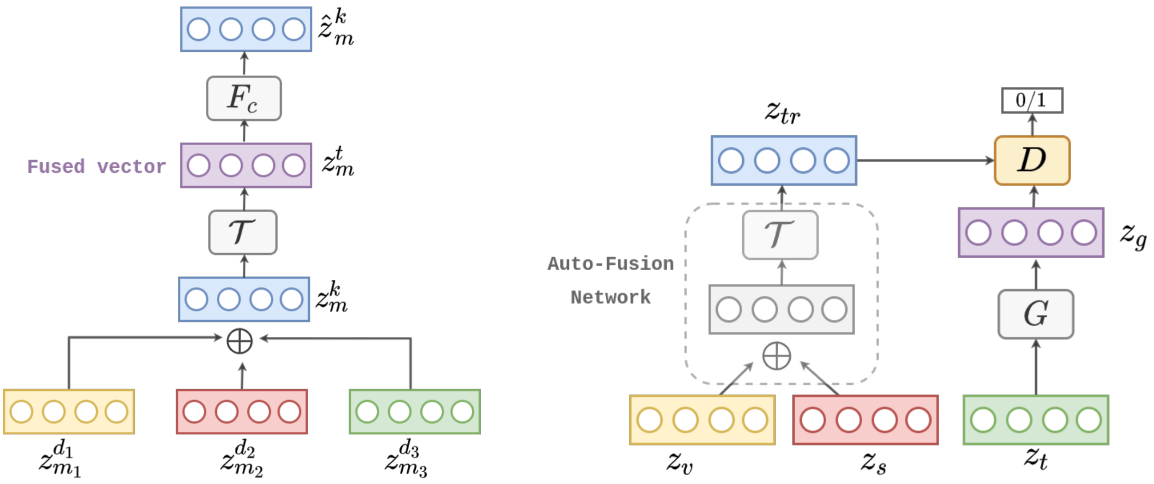
1. We propose two lightweight, adaptive techniques for better multimodal fusion of data: Auto-Fusion and GAN-Fusion.
2. We propose a multi-task framework for end-to-end training of multimodal networks (for both classification and generation).

The rest of the paper is structured as follows: Section 2 covers relevant work, Section 3 discusses the proposed methodologies and overall architecture, Section 4 describes the experimental setup, Section 5 shows results, and Section 6 contains our concluding remarks.

2 Related Work

In this section, we briefly review previous work related to our task. Most earlier works in multimodal deep learning focus on traditional shallow classifiers such as support vector machines (Cortes and Vapnik, 1995) and Naive Bayes classifiers (Morade and Patnaik, 2015) to exploit bimodal data. Inspired by the success of deep learning over the last decade across multiple tasks, Ngiam et al. (2011) train end-to-end deep graph neural networks to reconstruct missing modalities during inference. They demonstrate that better features for one modality can be learned if relevant data from different modalities is available at training time; however, they employ simple concatenation for fusion. Hence, the joint representation learned is shallow and is not guaranteed to model intermodal interactions. Their findings were later verified by Srivastava and Salakhutdinov (2012), who use a Deep Boltzmann Machine (Salakhutdinov and Hinton, 2009) to generate data from the image and text modality. Huang et al. (2018) construct a multilingual common semantic space to achieve better machine translation performance by extending correlation networks (Chandar et al., 2016). They use multiple non-linear transformations to reconstruct sentences from one language to another repeatedly and finally build a common semantic space for all the different languages. To address the shallowness exhibited by some earlier fusion methods, techniques such as TFN (Zadeh et al., 2017), LMF (Liu et al., 2018) and T2FN (Liang et al., 2019), were proposed that aim to capture *both* intra- and inter-modal dynamics simultaneously; however, the problem of effectively modelling context in multimodal samples remains unsolved.

More recently, Multimodal Transformer (MulT) (Tsai et al., 2019) was proposed to align data from different modalities implicitly. On a high-level, MulT leverages cross-modal attention modules for each modality, each of which is responsible for aligning (or attending to) the target modality vector with the complementary modalities'. It also imposes substantial computational overhead due to the use of transformer networks (Vaswani et al., 2017). Our methods, as discussed in detail in Section 3, use much simpler components. For instance, we use at most one attention module compared to multiple self-attention heads in a transformer. Variational Mixture-of-Experts Autoencoders (Shi et al., 2019), a class of deep generative multimodal frameworks, were employed to learn a synergic shared representation for multiple modalities; however, scaling of such a model for all the modalities (video, speech, and text) simultaneously and for a more complex task as multimodal machine transla-



(a) Auto-Fusion network

(b) GAN-Fusion Network

Figure 1: Proposed architectures. (a) Auto-Fusion network: Assuming that $z_{m_1}^{d_1}$, $z_{m_2}^{d_2}$, and $z_{m_3}^{d_3}$ represent the video, speech, and text latent vectors respectively, we first concatenate them to obtain z_m^k. It is then passed through $\mathcal{T}$ which outputs the "autofused" vector z_m^t. We then obtain the reconstructed concatenated vector $\hat{z}_m^k$ by passing the autofused vector through F_c, another transformation layer. Finally, we optimize the loss between $\hat{z}_m^k$ and z_m^k. (b) GAN-Fusion module for the text modality: Assuming that z_s, z_v, and z_t are the latent speech, video, and text vectors, respectively, we first autofuse z_s and z_v to give z_{tr}. Simultaneously, we pass z_t through the generator G, along with some noise, to get z_g. The generator loss tries to match z_{tr} and z_g and discriminator D tries to distinguish between z_{tr} and z_g, the two sources of input. **Note:** $\bigoplus$ denotes concatenation.

tion is currently unexplored.

3 Proposed methods

This section will discuss the proposed methodologies for effectively fusing inputs from multiple modalities and describe the overall architecture of our models for classification and generation. Most fusion techniques proposed in the literature, such as concatenation, and TFN, involve a deterministic operation for constructing the joint multimodal representation. For instance, in TFN, the 3-fold Cartesian product of unimodal features is used for prediction. The method focuses more on learning rich unimodal features. However, there is no such "learning" procedure for joint representation; they are simply constructed by combining unimodal features in a specific fashion (here, by Cartesian product.) In this paper, we will refer to such techniques as *static* fusion techniques. Since there is no particular learning procedure for the joint representation, it becomes challenging for the final predictor module to model the complex dynamics of multimodal features. In other words, the model is unable to utilize multimodal information effectively.

On the other hand, fusion methods such as LMF and MulT are *adaptive* because they involve a cognitive feature processing step to construct the joint representation. In LMF, it is the decomposition module, and in MulT, it is the final feed-forward fusion mechanism. We refer the reader to Liu et al. (2018) and Tsai et al. (2019) for more detailed explanation of the models.

Our fusion methods involve the concatenation of unimodal embeddings as an initial step. To avoid any conflicts with past works, we will only consider steps *after* concatenation as a part of our fusion method because we do not use the concatenated vector for final prediction; it is only a preliminary step. Therefore, in order to mitigate the "staticness" of existing fusion methods, we propose two adaptive yet simple fusion techniques, *Auto-Fusion* and *GAN-Fusion*. They aim to effectively combine multimodal inputs and mitigate the problem of shallowness and computational overhead exhibited by prior fusion techniques.

3.1 Auto-Fusion

This method encourages the model to extract intermodal features by maximizing the correlation between multimodal inputs. In this method, we first concatenate individual unimodal features and then pass them through a transformation layer to get a

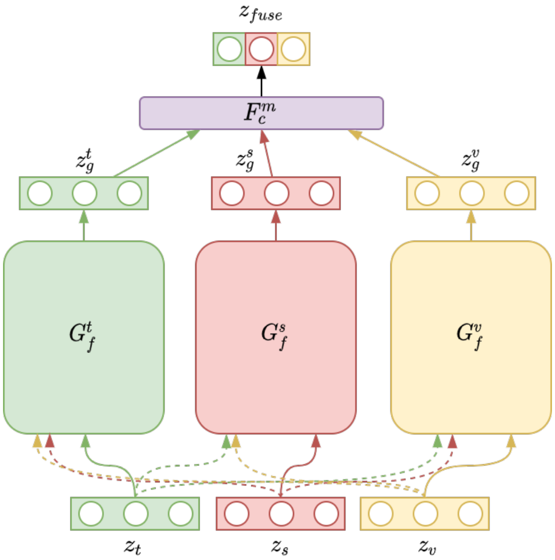


Figure 2: Overall architecture of the GAN-Fusion module. Here, the solid and dashed lines at the bottom part represent input from the target and the complementary modalities, respectively, for G_f^m, the GAN-Fusion module with target modality $m \in \{t, s, v\}$. Furthermore, F_c^m represents the feed-forward layer that produces the fused multimodal representation $\boldsymbol{z_{fuse}}$, which is, in turn, fed to the target decoder for generation networks and to the fully-connected network for classification networks.

autofused latent vector. We use appropriate learners for individual modalities (See Section 4). We then try to reconstruct the originally concatenated vector from the autofused latent vector. Finally, we minimize the Euclidean distance between the original and reconstructed concatenated vector. This process ensures that the learned autofused vector does not contain arbitrary signals from the input concatenated latent vector. Furthermore, training the model for a downstream task such as emotion recognition incentivizes it to "compress" information without losing any essential cues. In other words, it increases the correlation between the autofused and the concatenated latent vector. This generic procedure applies to any scenario where multiple features need to be combined. For example, it can even be used to combine the forward and backward hidden states of LSTMs (Hochreiter and Schmidhuber, 1997), instead of pooling methods such as 1D pooling, max pooling, sum pooling or even simple concatenation.

We now discuss the Auto-Fusion network in detail. We pose fusion of multimodal inputs as a compression problem, where we must retain as much information from the individual modalities as possible. Given n ($\leq$ 3 in our case) d-dimensional multimodal latent vectors, $\boldsymbol{z}_{m_1}^{d_1}, \boldsymbol{z}_{m_2}^{d_2}, \ldots, \boldsymbol{z}_{m_n}^{d_n}$, we first concatenate them to obtain a vector, $\boldsymbol{z}_m^k$, where $k = \sum_i^n d_i$. Then, we apply a transformation $\mathcal{T}$ to $\boldsymbol{z_m^k}$, reducing its number of dimensions to t. Then, we use $\boldsymbol{z_m^t}$ to reconstruct the originally concatenated vector $\boldsymbol{\hat{z}_m^k}$. Finally, we calculate the loss, J_{tr}, between $\boldsymbol{\hat{z}_m^k}$, and $\boldsymbol{z_m^k}$. The simplest version of Auto-Fusion network employs the mean squared error (MSE) loss function, which aligns with our motivation to compress multimodal features: filter out the less useful signals. These steps could be followed in Figure 1(a) and the MSE loss for Auto-Fusion network is given by:

$$J_{tr} = || \, \boldsymbol{\hat{z}_m^k} - \boldsymbol{z_m^k} \, ||^2 \tag{1}$$

For Auto-Fusion, we consider the intermediate vector, $\boldsymbol{z_m^t}$, as the fused multimodal representation.

3.2 GAN-Fusion

In addition to the "staticness" of existing methods, there is also the challenge of distinguishing between ambiguous cases. For instance, the sentence "Your joke blew my mind away, Kevin," could be said in a funny or sarcastic manner. Resolving ambiguity becomes especially important when working on social problems such as hate speech detection. Even when fed with the corresponding speech vector, existing methods cannot effectively distinguish between similar but different emotions such as happiness and calmness. We hypothesize that this is because they do not learn the conditional distribution of sentiment given an utterance (an utterance includes input from all available modalities).

To address this issue, we propose an adversarial training regime that is incentivized to learn the desired conditional distribution. For a task such as emotion recognition, the objective would be sentiment given an utterance. For a more challenging generation task, the model could learn a more complex behaviour, such as the association of different sentences based on how similar they sound and their polarity. Our experiments show that our GAN-based approach is better able to learn such multimodal dynamics compared to other methods.

We now describe GAN-Fusion's architecture in detail for target modality text (denoted by t.) For a given multimodal sample x, we first encode the inputs from each modality (speech, visual and text) to get the respective latent vectors, $\boldsymbol{z_s}, \boldsymbol{z_v}$, and $\boldsymbol{z_t}$.T Choosing a target modality such as text, we pass $\boldsymbol{z_t}$ (along with random normal noise,) through a generator to obtain $\boldsymbol{z_g} = G(\boldsymbol{z_t})$ and autofuse the remaining latent vectors $\boldsymbol{z_s}$ and $\boldsymbol{z_v}$ simultaneously to obtain $\boldsymbol{z_{tr}}$. In the event where we have input from only one modality in addition to text, we do not need Auto-Fusion, and can simply treat the other modality's vector as $\boldsymbol{z_{tr}}$. Finally, we train the network in an adversarial fashion, labelling $\boldsymbol{z_{tr}}$ as positive samples and $\boldsymbol{z_g}$ as negative samples. The adversarial loss, J^t_{adv}, is given below:

$$\min_G \max_D J^t_{adv}(D,G) = \mathbb{E}_{x\sim p_{\boldsymbol{z_{tr}}}(x)}[\log D(x)] + \mathbb{E}_{\boldsymbol{z}\sim p_{z_t}(\boldsymbol{z})}[\log(1 - D(\boldsymbol{z_g}))] \tag{2}$$

Overall, the generator G tries to align features of the target modality with features from the complementary modalities, and the discriminator tries to discern the source of its input. Such a translation between latent vectors has been shown to learn an "intermediate" latent vector denoting their joint representation (Pham et al., 2019; Gao et al., 2019). Learning the latent space in such an adversarial manner induces a clustering effect on the latent space, where texts associated with similar sounds and visuals are grouped together. We conjecture that the adversarial training helps the model learn the relative topology of the complementary modalities' latent space, which improves sampling from the target modality.

We elucidate this effect through the following example. For the sake of simplicity, let us consider only one complimentary modality (video) in this case and let text be the target modality. First, we make a reasonable assumption that video embeddings for, say, Soccer and Golf–falling under the general category of Sports–will be mapped closer to each other and farther from video embeddings from an unrelated topic such as Cooking. When learning the intermediate representation between video and text, the text latent space is constructed such that its relative topology partially reflects the video latent space. So, token embeddings in the text latent space related to videos of similar events (Soccer and Golf) will adopt similar relative positioning as followed by the video embeddings for Soccer and Golf in the video latent space. For multimodal machine translation, if the model is fed with a Golf video and the source text as input, it may be better able to sample jargon words for Golf from the text latent space due to this topology inheritance. This ultimately improves translation-quality. This is also depicted in Figure 4.

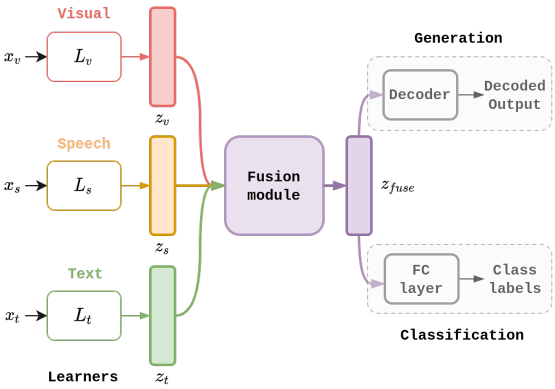

Figure 3: Using proposed fusion techniques for generation/classification. Unimodal inputs x_v, x_s, x_t are passed through their respective learners L_v, L_s, L_t to obtain unimodal representations $\boldsymbol{z_v}, \boldsymbol{z_s}, \boldsymbol{z_t}$. Here, v, s, t correspond to visual, speech, and textual modalities respectively. The individual unimodal representations are then passed through the fusion module (either Auto-Fusion or GAN-Fusion,) which outputs the fused multimodal representation $\boldsymbol{z_{fuse}}$. For generation, $\boldsymbol{z_{fuse}}$ is then passed through a compatible decoder, which generates outputs for the desired target modality. For classification, $\boldsymbol{z_{fuse}}$ is passed through a fully-connected layer instead, which predicts appropriate the class labels.

Figure 1(b) shows GAN-Fusion module for the text modality. The GAN-Fusion module, overall, has one such module for every modality. Total adversarial loss is, therefore, given by:

$$J_{adv} = J^t_{adv} + J^s_{adv} + J^v_{adv} \tag{3}$$

where losses J^s_{adv} and J^v_{adv} for speech and video, respectively, are defined similarly as J^t_{adv}.

Figure 2 shows an overall architecture of the GAN-Fusion module, which consists of G^t_f, G^s_f, and G^v_f, the respective fusion modules for text, speech, and video modalities. We pass the outputs of these modules through a feed-forward layer to obtain the final fused multimodal representation $\boldsymbol{z_{fuse}}$.

3.3 Overall Architecture

In this section, we describe the end-to-end training process for using the proposed fusion methods for 1) Generation tasks (e.g. visual question answering,

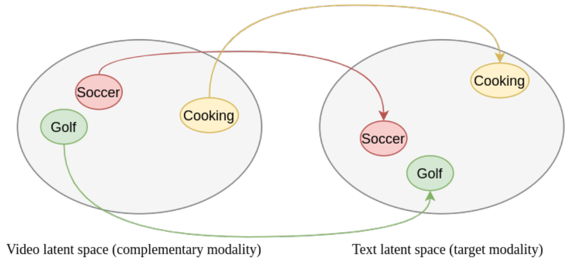

Figure 4: Visualizing the induced clustering effect of GAN-Fusion. The circles represent a cluster of words related to the indicated topic (text inside the circles)

multimodal machine translation) and 2) Classification tasks (e.g. speech emotion recognition, hate speech detection.)

Generation: Figure 3 shows the end-to-end pipeline integrating proposed fusion techniques for generation. We first pass raw inputs from different modalities through their respective learners to obtain their respective latent representations. They are then passed through the fusion module that outputs a fused representation to be used for decoding. We only validate this process for generating text, but this method could very well be used for generating outputs for different target modalities. Notably, our pipeline for generation looks very similar to a Seq2Seq network. We simply introduce a fusion module between the encoder and the decoder module. It should also be noted that all GAN-Fusion modules for all the target modalities (G_f^t, G_f^s, G_f^v) are trained simultaneously with the rest of the network.

Classification: Figure 3 also shows how to adapt the previously described generation network for classification: simply replace the decoder with a fully-connected layer to predict appropriate class labels.

It is important to note that $\boldsymbol{z_{fuse}} = \boldsymbol{z_m^t}$ for Auto-Fusion, and it is obtained as shown in Figure 2 for GAN-Fusion. The overall loss function for our networks can be generalized as follows:

$$J_{total} = \lambda_1 J_{fusion} + \lambda_2 J_{task} \tag{4}$$

Here, J_{fusion} refers to the loss function of the fusion network. It equals J_{tr} (from equation 1) when using Auto-Fusion, and J_{adv} (from equation 3) when using GAN-Fusion. Furthermore, J_{task} refers to the task-specific loss, i.e., classification loss (such as max-margin loss) or generation loss (such as cross-entropy loss for Seq2Seq network). λ_1 and λ_2 are hyperparameters to tune.

4 Experimental Setup

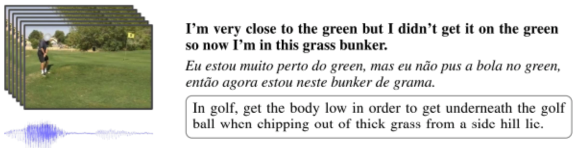
We measure our models' effectiveness on two tasks: 1) multimodal machine translation and 2) multimodal emotion recognition. The subsequent sections describe our complete experimental setup, including datasets and baselines used, implementation details, and evaluation metrics.

4.1 Datasets

We choose three datasets for our experiments, which are described as follows:

IEMOCAP: We use the benchmark Interactive Emotional Dyadic Motion Capture (IEMOCAP) dataset (Busso et al., 2008) for emotion recognition. We only use the textual and speech modalities for our emotion recognition experiments. The dataset is originally split into multiple utterances for each session, and we further split each utterance file based on the provided start and end timestamps to obtain wav files for each sentence. This results in a total of ∼10K audio files, which are then used to extract features for predicting a given utterance's emotion. Concretely, we identify the task as an emotion recognition problem, where, given a sentence and its audio, we aim to infer the correct emotion for that utterance.

How2: We evaluate our models on the multimodal How2 dataset (Sanabria et al., 2018), which comprises of 79,114 instructional videos, their Kaldi (Povey et al., 2011) audio features, and word-level time alignments of English-to-Portuguese translations. The How2 dataset is trimodal in comparison to other multimodal datasets (Matthews et al., 2002; Patterson et al., 2002). This makes it suitable to evaluate the contribution of each modality for different tasks. Further, as a large-scale multilingual dataset, it enables a convenient medium for neural machine translation in our work.



I'm very close to the green but I didn't get it on the green so now I'm in this grass bunker.

Eu estou muito perto do green, mas eu não pus a bola no green, então agora estou neste bunker de grama.

In golf, get the body low in order to get underneath the golf ball when chipping out of thick grass from a side hill lie.

Figure 5: A multimodal sample from the `How2` dataset (Sanabria et al., 2018)

Multi30K: In addition to the How2 dataset, we also run experiments on the bimodal Multi30K dataset (Elliott et al., 2016)–a benchmark dataset for machine translation–extended for German, where each sample has an image, its description in

Model	Source modalities	BLEU 1	BLEU 2	BLEU 3	BLEU 4

the source language, and its translated version. We only run experiments on the En-Fr version, however.

4.2 Implementation details

Generation: We train the network shown in Figure 3 with Auto-Fusion and GAN-Fusion as fusion modules. We use an LSTM encoder with 256 hidden units as the learner for textual description in our generation experiments, unless otherwise stated. For the How2 dataset, we use the already provided 2048-dimensional feature vectors for video as raw input for the video learner, and we feed the Kaldi speech vectors to the speech learner, which is a simple feed-forward layer in this case. For the Multi30K dataset, we use a pre-trained VGG (Simonyan and Zisserman, 2015) to encode images, and we do not have a speech learner as there is no speech input in the dataset. The latent dimension is 100 for the fused vector.

Classification: For the task of speech emotion recognition, we train a multimodal classifier on the IEMOCAP dataset. We use LSTMs with 256 hidden units to encode text. For audio, we first pre-process the raw audio files to obtain a lower-dimensional feature vector and then use LSTMs with 50 hidden units as a learner. We predict emotion labels through a full-connected layer as shown in Figure 3 . The latent dimension for the fused vectors is 50 in this case.

When training the GAN-Fusion network, we followed numerous tricks (Goodfellow, 2016) to ensure training stability. A few that helped the most include input normalization, batch normalization, Leaky ReLU activation function (Maas et al., 2013) and Adam optimizer (Kingma and Ba, 2015) for the generator and discriminator networks. The presence of multiple auxiliary losses in our networks also helped.

All the networks in our experiments are implemented in PyTorch (Paszke et al., 2019). To train the different classification networks and generation networks on the Multi30K dataset, we use an Nvidia RTX 2080Ti with 12GB of RAM. However, to train our trimodal networks on the How2 dataset, we use Nvidia P100 with 16 GB RAM to fit video feature vectors in memory.

4.3 Baselines

How2: We use the following baselines for experiments on the How2 dataset:

- **Seq2Seq**: A sequence-to-sequence with attention mechanism (Luong et al., 2015). It employs the previously described learners for each modality, and early fusion.

- **Unimodal and Multimodal S2S:** Unimodal and Multimodal S2S model as described in Sanabria et al. (2018).
- **How2-challenge baselines:** We use Attention over Image Features (Wu et al., 2019), Unimodal SPM Transformer (Raunak et al., 2019) and BPE Multimodal (Lal et al., 2019) from the How2-challenge leaderboard.[2]

Multi30K: We use the following baselines for the Multi30K dataset:

- **Unimodal Seq2Seq:** A text-only NMT system used by Elliott et al. (2017).
- **MeMAD submission** (Grönroos et al., 2018): The best performing model on Multi30K, a multimodal transformer network.

IEMOCAP: We use the following baselines for the IEMOCAP dataset:

- **LSTM (t):** A unimodal LSTM classifier with attention mechanism trained using only text.
- **LSTM ([s;t]):** A bimodal LSTM classifier with attention mechanism on text only. We use the concatenation of speech and text features as the joint multimodal representation.
- **MDRE:** Multimodal Dual Recurrent Encoder proposed by Yoon et al. (2018).
- **MHA-2:** A multimodal classifier with Multi-hop attention mechanism (Yoon et al., 2019).

We compare the above baselines' performance with our two main models: GAN-Fusion and Auto-Fusion, which replace early fusion in the Seq2Seq baseline. We report the results in Table 1, 2, and 3.

4.4 Evaluation metrics

We use Precision, Recall, F-Score, and classification accuracy to evaluate our classification networks trained for speech emotion recognition. For experiments on the How2 and Multi30K dataset, we use BLEU (Papineni et al., 2002) to evaluate the quality of translated sentences. For How2, we compute BLEU1-BLEU4 scores of the different models under consideration. For Multi30K, we also use METEOR (Banerjee and Lavie, 2005), which is a weighted harmonic mean of unigram precision and unigram recall providing a better indication of translation quality. For all the mentioned evaluation metrics, a higher number denotes better performance.

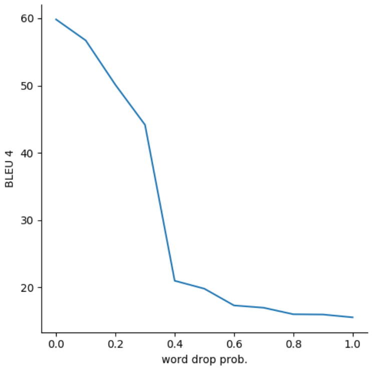

Figure 6: Ablation test on the How2 dataset. Word drop probability v/s BLEU 4. A sudden drop in BLEU scores as we move from 0.3 to 0.4 indicates that our model was able to compensate for $\sim$ 30% of the missing text.

5 Results

Quantitative analysis: Results of our experiments on the How2, Multi30K and IEMOCAP dataset are shown in Tables 1, 2 and 3, respectively. For speech emotion recognition, we observe that our models consistently perform well across all the evaluation metrics. For the relatively challenging multimodal machine translation task, we observe that our model outperforms all existing baselines in terms of BLEU scores. Compared against the best performing baselines, GAN-Fusion improves BLEU4 scores by 3.63 points and 0.13 points on the How2 and Multi30K datasets, respectively. This shows that the fusion module was better able to extract signals from all modalities. On the Multi30K dataset, our model is competitive in terms of METEOR. Such performance becomes more pronounced considering our models have only one attention module, in contrast to multiple self-attention heads in the transformer-based baselines.

The size of our best-performing models (employing GAN-Fusion) is roughly 6M and 11M for classification and generation, respectively, which is significantly lower than traditional transformer models. Fewer trainable parameters reduces the computational cost and the training time. This also indicates potential by-passing of a mechanism like distillation, which is used to reduce parameters in

---

[2] `https://srvk.github.io/how2-challenge/`

transformers (Sanh et al., 2019); however, more thorough experimentation is required to reach a concrete conclusion. Our models can also be used in conjunction with transformers, where we utilize the transformers to learn meaningful unimodal feature vectors initially and then employ the proposed fusion methods.

We also perform a comprehensive set of qualitative experiments on the How2 dataset to understand the capability of our fusion techniques. They are described as follows:

Effect of introducing more modalities: To understand the effect of introducing new modalities separately, we perform experiments with different combinations of source modalities, including individual unimodal baselines (Refer to Table 1.) The results reveal that both auditory and visual modalities *always* contribute towards enhanced translation, but the contribution of visual modality is slightly lower (indicated by the lower increase in BLEU scores in Table 1.) This is also consistent with the findings of Grönroos et al. (2018).

Robustness of multimodal features: It is very important for the learned multimodal latent features to be robust, i.e., they should be able to exploit signals from complementary modalities to compensate for the presence of noise in one modality. Therefore, to gauge the robustness of learned multimodal features, we conduct an ablation test on the How2 dataset. We randomly replace some tokens in the test sentence with an `<UNK>` token and attempt to translate using our best performing model, GAN-Fusion. Figure 6 shows results of our ablation study. We can see that features from the complementary modalities are able to compensate for $\sim 30\%$ of the missing text as we see a sharp drop in BLEU scores beyond that point. This shows that the model does not rely on just the textual description for translation; it also tries to gain a contextual understanding. Hence, it follows that the learned joint representation indeed contains rich information from other modalities.

6 Conclusion and Future Work

In this paper, we propose two adaptive fusion techniques that allow for effective multimodal fusion. Instead of "fixing" a fusion operation a priori, we let the model decide "how" to extract and effectively combine signals from different modalities. Moreover, the joint multimodal representations learned by such models are empirically shown to be robust, which allows the system to maintain good performance even in the absence of some information. Our results indicate that such adaptive models deliver without compromising performance than their more massive counterparts, such as transformers, which is a significant gain.

Our experiments indicate the importance of learning richer unimodal representations. This also suggests that using these methods in conjunction with transformers, which may learn richer unimodal representations, should further improve downstream tasks such as multimodal machine translation and speech emotion recognition. Currently, the attention mechanism is applied only on text. So, another simple way to improve performance would be to introduce visual and acoustic attention mechanisms as well; however, we would still need to address the core problem heterogeneity.

On training GANs: Training GANs is known to be difficult. However, we employed various tricks to ensure the training stability of models, especially the one's employing GAN-Fusion. In fact, a musing line of exploration towards learning a better adaptive model could be to probe the implicit assumptions of GANs themselves. GANs are known to exhibit numerous issues in practice (Arora et al., 2017; Sinn and Rawat, 2018). In Li and Malik (2018), the authors argue the need to return to the principle of maximum likelihood, insisting on full recall.

It is essential to note that much is unknown about these models. More concrete and sound reasoning for the success of these models will rely on two vital components: 1) understanding of the dynamics of the learned latent space, and 2) aligning multimodal features to address heterogeneity. Both these components require more interpretable representations of the otherwise black-box models.

Acknowledgments

We acknowledge Compute Canada's GPU support for our experiments. We also thank Dhruv Kumar for their meaningful suggestions on the manuscript. Finally, we thank the anonymous reviewers for their constructive comments on this work.

Abstract

This paper introduces the novel task of scene segmentation on narrative texts and provides an annotated corpus, a discussion of the linguistic and narrative properties of the task and baseline experiments towards automatic solutions. A scene here is a segment of the text where time and discourse time are more or less equal, the narration focuses on one action and location and character constellations stay the same. The corpus we describe consists of German-language dime novels (550 k tokens) that have been annotated in parallel, achieving an inter-annotator agreement of $\gamma = 0.7$. Baseline experiments using BERT achieve an F1 score of 24 %, showing that the task is very challenging. An automatic scene segmentation paves the way towards processing longer narrative texts like tales or novels by breaking them down into smaller, coherent and meaningful parts, which is an important stepping stone towards the reconstruction of plot in Computational Literary Studies but also can serve to improve tasks like coreference resolution.

1 Introduction

Text segmentation is a long standing issue in the area of natural language processing (NLP) encompassing different tasks like segmenting a text into sentences or finding the boundaries between different topics. In this paper, we introduce the task of *scene segmentation*. A scene can be understood as a segment of a text where the story time and the discourse time are more or less equal, the narration focuses on one action and space and character constellations stay the same. Scenes can be found predominately in narrative texts like novels or biographies, which can be understood as a sequence of segments, where some of the segments are scenes and others are not. Scene segmentation is of great interest for the high-level analysis of longer texts, for example the reconstruction of plot, but also for many areas of NLP that deal with longer narrative texts, since even modern methods struggle with processing text longer than a couple of sentences or paragraphs. As an example, the memory requirements of state of the art coreference resolution models scale with $\mathcal{O}(n^4)$ (input length n) (Lee et al., 2017; Joshi et al., 2020) and their performance deteriorates on longer texts. Therefore, it is very helpful to break down the texts into smaller pieces where the character constellation remains the same, enabling us to perform coreference resolution within a scene and then match the characters identified across multiple scenes. Additionally, scene segmentation can also be used to facilitate the summarization of long texts: Since Reiter (2015) has shown that parts of a human written summary correspond well to their similar notion of coherent segments in the original text, it is reasonable to assume that segmenting a text into scenes and then summarizing these scenes is a promising way towards the summarization of long texts. Finally, the number and length of scenes in a text defines a kind of “narrative rhythm”, which we briefly analyze in Section 4.3. This rhythm might serve as a characteristic of an author, or be used as a metric for recommending books to readers.

While the objective of scene segmentation is structurally similar to topic segmentation, there are some important differences: Scenes are defined as narrative units, where each unit has a coherent and

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3167–3177
April 19 - 23, 2021.

stable structure in respect to time, place, character constellation and plot. Narrated time and narrative time in a scene (Scheffel et al., 2019) are more or less equal, which can be seen, for example, in the rendition of verbal communication as direct speech. Scenes in fiction are thus not based only on the topic covered in the narrative. For example, a new scene may cover the same topic as the previous one, but take place in a different location or with a different set of characters. Thus, commonly used segmentation algorithms fail at our task. Even a fine-tuned BERT-based model does not perform well, as we show in Section 5.1. We see this as a sign that scene segmentation requires a large amount of natural language understanding and can, along with other tasks related to an in-depth analysis of narrative structures, serve as a challenge and benchmark for future NLP models.

Our contributions in this paper are as follows: We present and publish a new data set of German fictional texts annotated with scenes and provide an extensive discussion of the guidelines used in the annotation process (which are also included in the release). Additionally, we show that established baselines for text segmentation fail to capture the notion of a narrative scene, necessitating the development of new methods for this task. Our main goal is to introduce the task of scene segmentation and provide resources as well as guidelines to enable research towards this task, which will in turn improve the possibility of processing long, narrative texts in the future.

2 Related Work

Other segmentation tasks have been discussed in NLP for a while, mostly with the goal of identifying regions of news or other non-fictional texts discussing certain topics. The task of topic segmentation is then to identify points in the text in which the topic under discussion changes. Early work to this end uses similarity of adjacent text segments (such as sentences or paragraphs) with a manually designed similarity metric in order to produce the resulting segments. One of the most well known systems of this manner is TextTiling (Hearst, 1997), which was applied to science magazines. Similarity based on common words (Choi, 2000; Beeferman et al., 1999) was superseded with the introduction of Latent Dirichlet Allocation (Blei et al., 2003), which allowed to segment the text into coherent text snippets with similar topic distributions (Riedl and Biemann, 2012; Misra et al., 2011). This procedure was extended by the integration of entity coherence (John et al., 2016) and Wanzare et al. (2019) have used it on (very short) narrative texts in an attempt to extract scripts. Recently, many approaches making use of neural architectures deal with the detection and classification of local coherence (e. g. Li and Jurafsky, 2016; Pichotta and Mooney, 2016; Li and Hovy, 2014), which is an important step for a text summarization of high quality (Xu et al., 2019). Text segmentation using neural architectures was conducted on Chinese texts and it was shown that recurrent neural networks are able to predict the coherence of subsequent paragraphs with an accuracy of more than 80 % (Pang et al., 2019). Lukasik et al. (2020) compare three BERT based architectures for segmentation tasks: Cross-Segment BERT following the NSP Pretraining-Task and fine-tuned on segmentation, a Bi-LSTM on top of BERT to keep track of larger context and an adaption of a Hierarchical BERT network (Zhang et al., 2019).

Some work has been done on segmenting narrative texts, but aiming at identifying topical segments – which, as we have pointed out above, is different from scene segmentation. With a set of handcrafted features, Kauchak and Chen (2005) achieve a WindowDiff score (Pevzner and Hearst, 2002) of about 0.5, evaluated on two novels. Kazantseva and Szpakowicz (2014) have annotated the novel *Moonstone* with topical segments, and presented a model to create a hierarchy of topic segments. They report about 0.3 WindowDiff score. Most closely related to our task are the papers by Reiter (2015), which documents a number of annotation experiments, and Kozima and Furugori (1994), which presents lexical cohesiveness based on the semantic network Paradigme (Kozima and Furugori, 1993) as an indicator for scene boundaries and evaluates their approach qualitatively on a single novel. However, neither of them provide annotation guidelines, annotated data or a formal definition of the task.

A related area of research is discourse segmentation, where the goal is also to find segments that are not necessarily defined by topic, and are also assigned labels in addition to the segmentation. There are annotated news corpora in this area featuring fine-grained discourse relations between relatively small text spans (Carlson et al., 2002; Prasad et al., 2008). Although larger structures have been discussed in literature (Grosz and Sidner, 1986), no annotated corpora have been released.

3 Task: Scene Segmentation

In this section we will first present a description of the task placing it in narratological tradition, and then we will describe it more formally as an atypical instance of a segmentation task.

3.1 Scenes in Narrative Text

In narratology, the analysis of narrative texts usually distinguishes between *discours* and *histoire* (Genette, 1983). *Discours* stands for the text or the representation of the narrative, while *histoire* concerns the narrated world, including characters and plot. In an ideal-typical view, it is assumed that plot is composed of several transformation processes from the smallest, spatiotemporal units – the so-called events.

Operationalizing plot is a challenging problem, because it involves natural language understanding, inferencing and interpretation on a high level (Meister, 2003). Nevertheless, different approaches are conceivable and have been discussed in the literature. Jockers (2015) approximates plot as an emotional arc of a narrative by assigning sentiment scores to each sentence and applying a Fourier transformation to derive an overall arc. Another way of modeling plot is to detect individual events in a text and then combining those to larger units and finally to a representation of the plot. There have been advances on the detection of events (Sprugnoli and Tonelli, 2019; Sims et al., 2019; Aldawsari and Finlayson, 2019) in texts. However, the definition of an event is unclear, with large possible differences in the level of granularity, making it an unstable starting point for analyzing plot.

Our approach to action in narratives is grounded in narratology, but by focussing on scenes it tackles the phenomenon on a less granular level than events. In narratology, the notion of scene has been introduced by Genette (1983) as a concept concerning the so-called pace of narration, i. e., the relation between the amount of time that passes in the narrative (story time, or *histoire*) and the amount of time covered by its narration (narrated time, or *discours*). Genette defines a scene as follows: "scene, most often in dialogue, which, as we have already observed, realizes conventionally the equality of time between narrative and story" (Genette, 1983, p. 94). It is important to note that the equality is put as "only a kind of conventional equality between narrative time and story time" (Genette, 1983, p. 87). Defining scenes based only on one feature, time, is useful in the context of Genette's theory, but it lacks descriptive power when the concept is supposed to be used to analyze plot, because the concept of plot is always implying aspects like character (and character constellation) and event sequences. In addition, Genette's definition of scene leads to two notions – story and narrative time – that are not easier to operationalize. Therefore, we adopt a more general understanding of scenes that includes characters, space and action. This is closer to our everyday understanding of scenes and similar to the understanding of scenes in plays as "a division [. . .] during which the action takes place in a single place without a break in time" or "a part of a play, movie, story, etc., in which a particular action or activity occurs" (Learner's Dictionary).

In order to capture this fuller notion we follow Gius et al. (2019) in defining scenes: A scene is a segment of the *discours* (presentation) of a narrative which presents a part of the *histoire* (connected events in the narrated world) such that (1) time is equal in *discours* and *histoire*, (2) place stays the same, (3) it centers around a particular action, and (4) the character constellation is equal. All of these conditions are not absolute, there can be small changes in either component, as detailed below.

In media like film or plays usually one scene follows another. Non-scenes, in which the progress of time is narrated in a compressed way can be found, but are relatively rare. In narrative texts passages which are not scenes can be found more often between scenes. The boundary between scenes can be clear cut, often indicated by phrases like 'at the next morning', 'in the meantime' etc, but can also be vague, for example when reflections of the narrator or a character are bridging two scenes or when the narrated time is accelerated at the end of one scene and then slowed again for the next.

3.2 Formal Task Definition

After defining scenes from a narrative perspective, we can formalize the task of *scene segmentation*: We are given a narrative text (e. g., a novel) as input and derive a segmentation that additionally labels each segment of the text either as a scene or as a non-scene. This is a notable difference to other segmentation tasks with no further distinction between types of segments.

There are multiple possible operationalizations of this task. In this paper, we frame scene segmentation as a sentence-level classification task where we find borders between segments and additionally classify the borders, representing whether there is a scene before and after them. More specifically, a border can fall into one of the three classes `SCENE-SCENE`, `SCENE-NONSCENE`, `NONSCENE-SCENE`.[1]

Other operationalizations include, for example, only providing a simple segmentation in a first step and then additionally classifying each segment as either scene or non-scene using a text classification model or directly using a sequence labeling model to assign each token or sentence an IOB tag. While these are also valid approaches to scene segmentation, we focus on the first method here, since it provides the easiest end-to-end operationalization: We can train one model that simultaneously detects borders and classifies them into one of the border types. One possible drawback of this method is that a model might predict incompatible scene borders (e.g., SCENE-NONSCENE followed by SCENE-SCENE). This problem can be alleviated by the use of a CRF-based classifier, where such a sequence would be recognized as very unlikely/impossible.

4 Corpus

4.1 Annotation

We annotated 15 dime novels from diverse genres (love, horror, adventure, etc.) in German language with a total of 36 k sentences and 550 k tokens.[2] We decided to use dime novels because preliminary studies have shown that the task is quite challenging even in this literary medium, which is more accessible to human readers than highbrow literature. Moreover, the length of an individual dime novel (Ø 36 k tokens) allows to annotate a reasonable number of full novels with reasonable effort.

The annotation of the corpus was performed by two annotators, an additional curator established the gold standard.[3] Annotators were also asked to document the reason for each scene change. The guidelines are the result of two iterations, incorporating feedback from and discussion with the annotators.

Overview In the following, we provide an overview of the central aspects of our annotation guidelines.[4] The guidelines are based on four main components: *time*, *space*, *action* and *characters*. In short, a change in any of these components (e.g., a large jump in time) is a signal for a scene change. The following paragraphs describe our guidelines in more detail, specifically which of these signals are most important for determining whether there is a scene change at a given position. We also detail how we deal with *contradictory signals and corner cases*. We conclude this section with a discussion of certain *typographical markers* found in our texts and the *difficulties* encountered in the annotation process.

Time With regard to time, the default for a scene is a chronological narration with a uniform pace whereas scene boundaries are indicated by changes in chronology (i. e. anachronies like flashbacks or flash-forwards), temporal omission (i. e., ellipsis) or major changes of the narrative pace. For all candidates for scene changes, the impact of the temporal phenomenon in question needs to be weighted with regard to its context within the narration. For example, we generally assume that the greater a time leap is in relation to the general granularity of time in the narration, the more likely the scene is changing. Therefore, if the general narration speed is rather low and action is for example narrated more or less on an hourly base, a leap of one day probably indicates a boundary between two scenes. On the contrary, if action is narrated on a day-to-day-base, a leap of one day is probably not a scene boundary but rather part of an ongoing scene.

Space With regard to space, the default for a scene is to take place within the same space whereas a change in space indicates a scene boundary. Space, similar to time, is analyzed with regard to the granularity of space within the narrative. The general principle adopted for the detection of relevant space changes is a container principle, i. e. space can be composed from smaller units (spaces, rooms). For example, the following passage is considered to take place within the same space, since the rooms in question (the corridor and the breakfast room) are parts of a hotel, i. e. the same space container:

> Auf dem Weg zum Frühstückszimmer meinte mein Partner: “Ich habe mir die halbe Nacht den Kopf

---

[1] We do not segment non-scenes further.

[2] We use SpaCy (Honnibal et al., 2020) for tokenization and sentence-splitting.

[3] The annotators are students with backgrounds in computer science, digital humanities and/or German studies with prior experience in annotating the same or similar tasks.

[4] The full guidelines are available in Gius et al. (2021).

> darüber zerbrochen, wie wir unserem geheimnisvollen Gegner die Maske herunterreißen könnten." "Und?", fragte ich. "Ich war nicht gerade mit Geistesblitzen gesegnet", sagte Suko. Wir betraten das Frühstückszimmer.
>
> (*Der Turm der 1000 Schrecken*)[5]

Action A container principle has also been adopted for the analysis of action. Within a scene, action is assumed to be coherent and continuous. Generally, according to the container principle, we have to decide whether actions can be counted as belonging to the previous one. We also introduced a test based on the more intuitive understanding of scenes discussed above, where annotators imagined the passage in question as a movie and asked themselves whether it could be transposed to one movie scene. The boundaries of the scene are the points where a fade out (or fade in) could be inserted.

Characters The fourth aspect of scene, characters, again is supposed to stay stable within a scene whereas a change in character constellation can indicate a change of scene. Here it is important to examine both the role of the character that joins or leaves and the course of action. The more important the character is and/or the more the narrative focuses on a different action after the change in constellation, the more likely we have a scene boundary.

Contradictory Signals and Corner Cases Since these aspects are often not consistent with each other, we weight them according to their observed relevance for a scene change. Most relevant is a change in the event sequence, followed by character constellation, time and finally space.

In addition to the four relevant aspects in narrations for scenes, we included procedures for unclear cases in our guidelines. The most frequent ones are short passages of reflection, as for example inner monologues, that can be found directly before and after passages clearly qualifying as a scene. If they are shorter than the scene itself, they are also considered part of the scene.

Typographical Markers With regard to typical typographical markers of scenes in some texts (e.g., ***), we changed our handling during the annotation.[6] We started with the stars included, but then decided to erase them in order to rely on content-related aspects only due to their lack of generalizability: While *** is used somewhat consistently in German dime novels, this is not the case for other types of narrative texts, e.g. novels in book form. Since we want to keep our task, dataset and, in the future, solutions as general as possible, we did not rely on these markers. Changing our handling of these markers did not have an influence on our inter-annotator agreement. Despite this, it is an open question whether to include such typographical markers in future work. These markers, as well as chapters and paragraphs,[7] are standardized ways of signaling the segmentation of narratives. Therefore, the start of a scene directly after a marker may differ systematically from a start in running text.

Annotation Difficulties Most persisting annotation difficulties are caused by the fact that most criteria in the guideline have a relative nature. It is not trivial to decide whether a change in time, space or character configuration is determining the beginning (or end) of a scene, since its importance depends on the granularity of time, space or character configuration in the specific narrative. These granularities cannot be specified on a general level. The second issue is the lack of an operationalization of action applicable for the analysis of literary narratives.

Nevertheless, with the described approach to scene annotation we seem to tackle most of the issues the annotators and the curators came up with and improved the agreement between the annotators considerably. Overall, the combination of operationalized narratological categories with the more intuitive test of the transposability to a movie scene seems to be a fruitful approach.

To illustrate the annotation task for an international audience, we annotated a copyright-free novel and machine translated it using DeepL.[8]

4.2 Measuring Inter-Annotator Agreement

Several measures to evaluate segmentation systems have been proposed in the past. According to a sur-

---

[5] Our translation: On the way to the breakfast room, my partner said, "I spent half the night worrying about how we could rip the mask off our mysterious opponent." "And?", I asked. "I wasn't exactly blessed with flashes of inspiration", Suko said. We entered the breakfast room.

[6] The markers are removed from text in the release, but there is information on their presence in metadata.

[7] Only 43% of all scene boundaries align with paragraphs.

[8] `https://professor-x.de/gsd/viewer.html`

vey by Kazantseva and Szpakowicz (2012) these are also widely used to quantify inter-annotator agreement. When choosing a measure for the evaluation of scene segmentation, the following characteristics must be considered: (1) Near misses are not critical, since scene boundaries tend to be fuzzy. (2) High variance of segment length in documents and between documents. (3) The existence of non-scenes leads to two classes of segments.

A major objective in the research on the evaluation of segmentation is to overcome influences from the field of classification, which model segmentation as token or character classification, and to replace these with measures that calculate a penalty dependent on the distance between true and predicted boundaries. After an evaluation of existing metrics (Pk: Beeferman et al. 1997, WindowDiff: Pevzner and Hearst 2002, Segmentation Similarity: Fournier 2013), we opted for using γ (gamma) (Mathet et al., 2015) to measure inter-annotator agreement (and prediction performance, see below).

Values of γ range from $-\infty$ to 1 theoretically, empirically often from 0 to 1; with 1 meaning there are no disagreements. The basic idea of gamma is to combine aligning and comparing the annotations into a single metric. Once an alignment between the annotations is established, near misses and category disagreements can be measured in a straightforward way, configurable by the user. Because there is no way to calculate this alignment a priori, gamma selects the alignment that leads to the least overall disagreement, which is then considered the observed disagreement γ_o. Expected disagreement γ_e is calculated by sampling from the existing annotations such that random annotations can be compared. The final gamma score is calculated as $\gamma = 1 - \frac{\gamma_o}{\gamma_e}$, as for other metrics based on disagreements. Because the measured disagreement is dependent on both boundary positions and segment categories, segmentation tasks producing gaps or tasks that include unitizing and categorization (like named entity detection or topic segmentation) are supported by γ.

On all novels in our corpus, annotators reach an agreement of $\gamma = 0.7$ (with a standard deviation of $\sigma = 0.07$). The developers of γ do not provide an explicit interpretation scale. However, since its value lies in the interval of $[-\infty; 1]$, with 0 representing agreement purely by chance and γ is a disagreement metric similar to Krippendorff's α, a similar scale can be applied to it. Thus, the reported agreement of 0.7 is acceptable, given the fact that the task is new and very complex. Figure 1 shows aligned scene annotations of two annotators together with γ scores.

Category	Portion
Scenes starting with direct speech	14 %
Scenes ending with direct speech	13 %
Sentences containing direct speech	55 %

Table 1: Information on direct speech in the corpus

4.3 Corpus Analysis

This section gives an overview of various quantitative analyses that we have conducted on the annotated corpus.

First, we find that scenes are much more common in the texts than non-scenes, as the corpus contains 971 segments marked as scenes and 34 marked as non-scenes. This results in 937 SCENE-SCENE, 30 SCENE-NONSCENE and 23 NONSCENE-SCENE boundaries with respect to our task definition (see section 3.2). Figure 2 shows the lengths of scenes and non-scenes in comparison. As can be seen clearly, scenes are typically much longer than non-scenes, although with a quite high spread.

As direct speech plays an important role in narrative texts in general, and has already been established as a core ingredient of scenes, we use the supervised STRW Recognizer (Brunner et al., 2020) to detect the distribution of direct speech in the texts, and their relation to the scene boundaries. As Table 1 shows, direct speech does not serve well as a marker to detect scene boundaries.

Another interesting aspect of the scenes is their distribution along the text flow. Figure 3 shows for each sentence of a novel how many scenes haven been found up to this point. While it can be directly observed that average scene length seems to be a discriminatory property of the stories (*Fürstenkinder*, *Jason Dark* and *Sophienlust* contain nearly the same amount of sentences but differ highly in scene count), there is no pattern along the x-axis discernible. Denser clusters may appear at any point within the text. Nevertheless, we can highlight writing style differences between the stories. Figure 3 shows that some stories (*2012*, *Tausend Pferde*) start with a rapid succession of scenes, while others begin with longer sequences

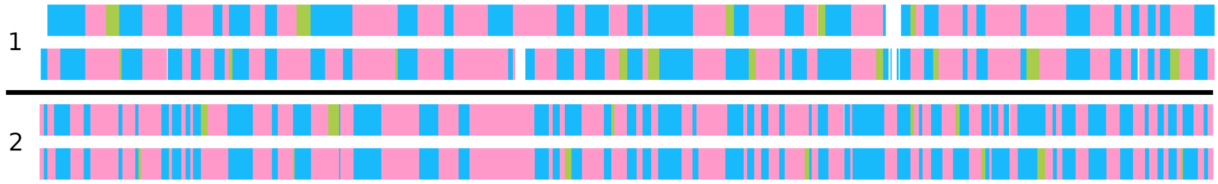

Figure 1: Scene annotations of *Dr. Bergen*, (1, $\gamma = 0.57$, worst agreement in the dataset) and *Tausend Pferde* (2, $\gamma = 0.83$, best agreement in the dataset). Three colors (red, blue and green) are used for scenes to make it easier to identify differences and matches. White gaps indicate non-scenes.

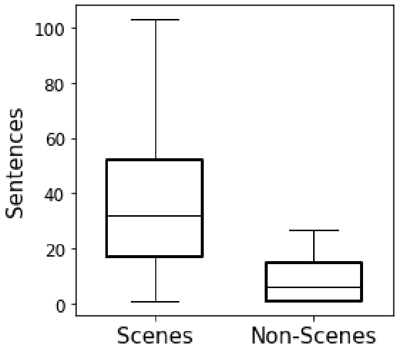

Figure 2: Length of scenes and non-scenes

(*Fürstenkinder*, *Verschmäht*).

As we have summarized above, time, place and characters are important constituents of scenes. We therefore analyzed in which form they are expressed shortly after a new scene has begun. Figure 4 shows the distribution of the occurrence of locational and temporal adverbials for each text in first sentences in scenes and all other sentences, as well as their coincidence with annotated reasons for a scene change. We used a list of adverbials according to (Eisenberg, 2006) as well as a self-made list. We found that there is high variation with respect to the scene-starting sentences. Temporal adverbials occur more frequently in the first sentence of a scene, but the difference for locational adverbials is much smaller. It becomes clear that the information about space and time changes with adverbials was often not perceived by the annotators as decisive for scene changes.

Additionally, we also analyzed the distribution of explicit character references (i.e., referencing them by their name rather than, e.g., pronouns). To this end, we used the method proposed by Jannidis et al. (2017) to extract all such references and plotted their position in a scene (Figure 5). We find that, as we would expect, the first 5 % of sentences in a scene contain more explicit character references on average than all other segments.

4.4 Corpus Release

The corpus is available on our website.[9] Since the texts are copyrighted, we cannot publish them directly. Instead, we provide the EAN of the epubs and a script that merges text and standoff annotations.

5 Baseline Experiments

5.1 Setup

Similar to measuring inter-annotator agreement, it is not trivial to define a metric for evaluating a task like scene segmentation. For the evaluation here, we provide two **metrics**: (1) precision, recall, F1-score are measured as a sentence-wise classification task, with different granularities as described below (two classes vs. four classes). (2) In addition, we employ the observed part of gamma γ_o as a prediction performance metric. This metric is calculated from the alignment between gold and system output with the least disagreement. The reason for also reporting this metric is that it is in line with the annotation experiments and captures the task more directly. After all, the annotators are asked to create units in the context of the entire discourse, and not to classify individual sentences.

In order to assess the difficulty of scene segmentation, we evaluate multiple baselines on our proposed dataset: Two unsupervised standard segmentation techniques (TextTiling and TopicTiling) and two additional supervised baselines based on BERT. Note that the unsupervised techniques cannot perform the full scene task defined in Section 3.2, but only the first part, that its, detecting scene borders.

Unsupervised Baselines We use the TextTiling (Hearst, 1997) implementation from nltk (Bird et al., 2009) and evaluate these hyper-parameters: $w, k \in \{5, 10, ..., 45\}$, smoothing_width, smoothing_rounds $\in \{1, ..., 4\}$. Reported results are for

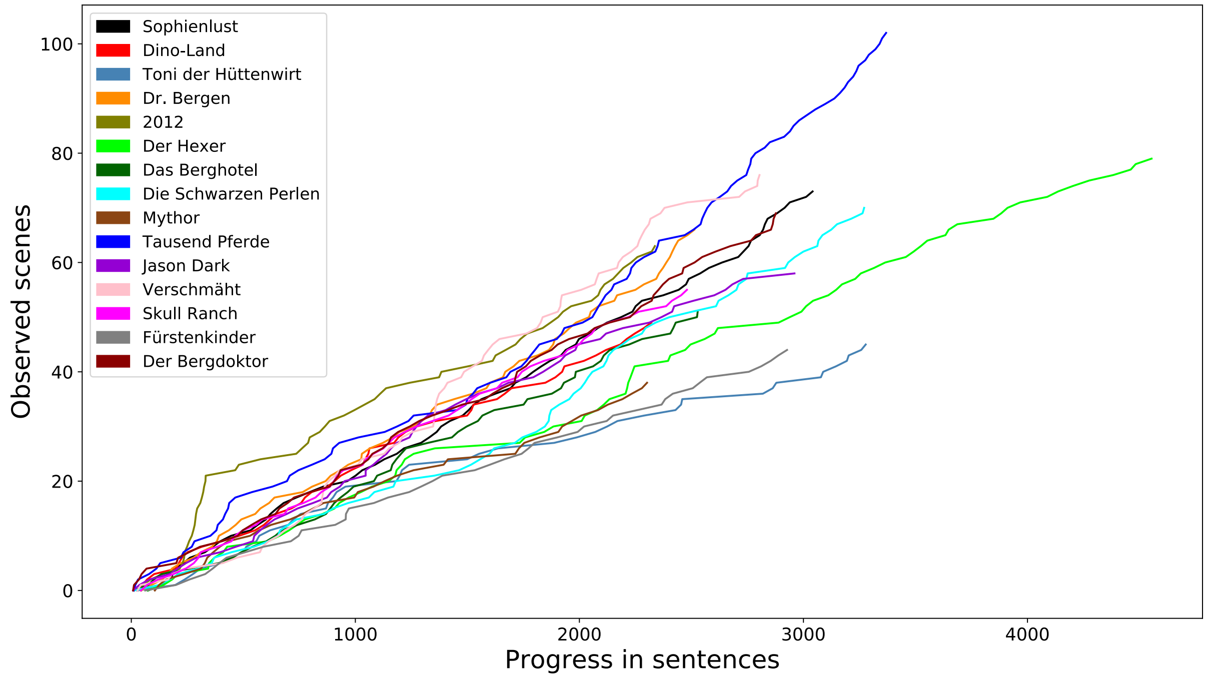

Figure 3: Relationship between the amount of sentences passed (x axis) and the number of scenes (y axis) for every novel. Higher slope indicates shorter scenes. An interactive version of this figure, suited for color blind people can be found online.[a]

[a] `https://professor-x.de/gsd/sentences-per-scene.html`

the best configuration.[10] For TopicTiling (Riedl and Biemann, 2012), we train an LDA (Blei et al., 2003) model on a corpus of 870 dime novels[11] (appr. 2 million words)[12] and evaluate on our scene segmentation dataset using the recommended parameters.[13] As seen in Table 2, both unsupervised baselines perform very poorly at the task, reaching an F1-score of 4 % and 5 %, respectively.

BERT Baseline Since the standard unsupervised methods do not perform well for our task, we build a simple supervised baseline. To this end, we fine-tune a pre-trained BERT model[14] to binary scene segmentation in the following way: We construct a training sample as a triple of *(sentence, context, label)*, where *sentence* is a target sentence from a text, *context* concatenates the two previous and following sentences with the target sentence and *label* is `BORDER`, if there is a scene border before the target sentence and `NOBORDER` otherwise. In order to capture the distinction between scenes and non-scenes, we also evaluate a more fine-grained 4-label classification task with the `BORDER` label split into its three possible subclasses (`SCENE-SCENE`, `SCENE-NONSCENE`, `NONSCENE-SCENE`), as defined in Section 3. We fine-tune BERT using FARM[15] for a default duration of ten epochs in a leave-one-out style, training on all texts except one and evaluating on the remaining. Table 2 shows that, while performing much better than the unsupervised baselines from the previous paragraph, BERT is not capable of providing a satisfactory segmentation.

5.2 Discussion

Our results show that standard unsupervised methods for text segmentation are not applicable to the task of scene segmentation. This is unsurprising, as our definition of scenes is not based on topical coherence, but on other aspects of the text, which are not considered by TextTiling and TopicTiling.

Additionally, our supervised baseline suggests that a BERT model is capable of picking up some signals for scene changes, but applying a standard

---

[10] We used the best possible configuration on the entire data set to provide an upper bound for their performance.

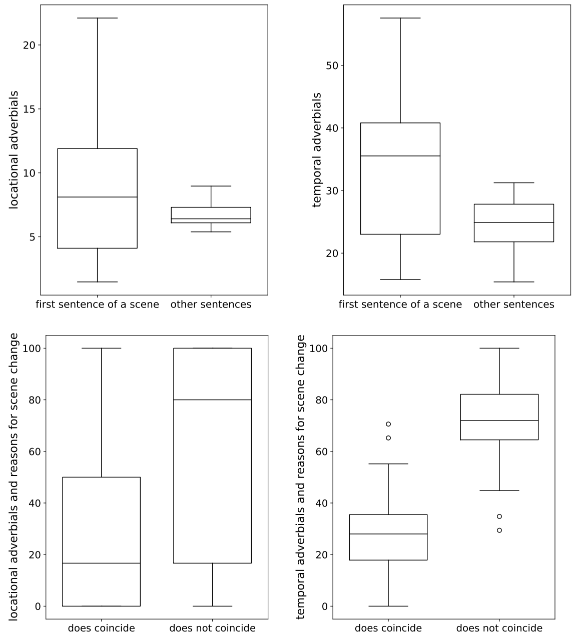

Figure 4: Distribution of locational (left) and temporal (right) adverbials at the beginning of a scene, as well as their coincidence with annotated reasons for a scene change.

model is not sufficient without additional modifications, such as specialized model architectures. On average, the system divides the novels into four times more scenes than the annotation specifies. A qualitative evaluation of the predicted borders shows that it is almost always possible to find one of the reasons defined in the guidelines for a scene change. Thus, the reason for the hypersensitivity of the baseline does not seem to lie in the inability to recognize markers, but rather in their contextualization. Typical errors are caused by (a) mentions of characters and places without actually appearing/becoming the place of action, (b) metaphors (e.g. "Maybe they only needed a narrow bridge to get back together?"), (c) indirect or reported speech, (d) different forms of referencing characters and (e) moving through places in a scene (e.g., "The visitor nodded and followed her into the kitchen.")

The BERT model is also not capable of finding any borders from non-scenes to scenes, leading to a score of 0 in this setting. This, in combination with the task's relevance for the analysis of long texts, motivates further research. A possible direction for future work would be using the information from our analysis, like the presence of temporal markers and character references.

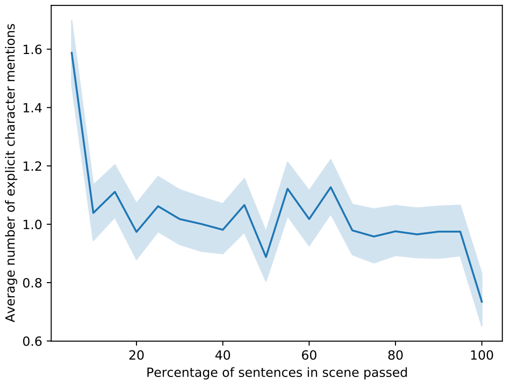

Figure 5: Distribution of explicit character references over positions in a scene.

Model (class)	Prec.	Rec.	F1	γ_o
TextTiling	0.02	0.97	0.04	0.01
TopicTiling	0.03	0.22	0.05	0.02
BERT (binary)	0.49	0.15	0.24	0.15
BERT (S-S)	0.43	0.13	0.2	0.15
BERT (S-NS)	0.85	0.24	0.38	
BERT (NS-S)	0.0	0.0	0.0	

Table 2: Results from all baselines. BERT (binary) denotes the performance scores for the `BORDER` class. S-S denotes borders between two scenes, NS-S and S-NS denote borders between scenes and non-scenes.

6 Conclusion

This paper describes the task of detecting scenes in narrative texts and introduces a corpus annotated for this task. The corpus consists of a number of German dime novels annotated according to guidelines describing the specifics of the task in detail. The inter-annotator agreement indicates that the task is challenging, but feasible for humans. As the analysis of the corpus shows, the information about character constellation, time, space and action is informative, but only an integral understanding of the text makes it possible to fully solve the task. Thus, apart from the many applications of a scene segmentation itself, it also provides an interesting challenge for natural language processing: Due to the high level of natural language understanding required, it will likely necessitate the development of novel approaches to be solved satisfactorily.

Abstract

The conceptualization of a claim lies at the core of argument mining. The segregation of claims is complex, owing to the divergence in textual syntax and context across different distributions. Another pressing issue is the unavailability of *labeled* unstructured text for experimentation. In this paper, we propose `LESA`, a framework which aims at advancing headfirst into expunging the former issue by assembling a source-independent generalized model that captures syntactic features through part-of-speech and dependency embeddings, as well as contextual features through a fine-tuned language model. We resolve the latter issue by annotating a Twitter dataset which aims at providing a testing ground on a large unstructured dataset. Experimental results show that `LESA` improves upon the state-of-the-art performance across six benchmark claim datasets by an average of 3 claim-F1 points for in-domain experiments and by 2 claim-F1 points for general-domain experiments. On our dataset too, `LESA` outperforms existing baselines by 1 claim-F1 point on the in-domain experiments and 2 claim-F1 points on the general-domain experiments. We also release comprehensive data annotation guidelines compiled during the annotation phase (which was missing in the current literature).

1 Introduction

The concept of a claim lies at the core of the argument mining task. Toulmin (2003), in his argumentation theory, described the term 'claim' as '*an assertion that deserves our attention*'; albeit not very precise, it still serves as an initial insight. In recent years, Govier (2013) described a 'claim' as '*a disputed statement that we try to support with reasons.*'

Text	Claim?
Alcohol cures corona.	Yes
Wearing mask can prevent corona.	Yes
Lord, please protect my family & the Philippines from the corona virus.	No
If this corona scare doesn't end soon imma have to intervene	No

Table 1: A few examples of claim and non-claim.

The predicament behind the claim detection task exists given the disparity in conceptualization and lack of a proper definition of a claim. The task of claim detection across different domains has garnered tremendous attention so far owing to an uprise in social media consumption and by extension the existence of fake news, online debates, widely-read blogs, etc. As an elementary example, claim detection can be used as a precursor to fact-checking; wherein segregation of claims aids in restricting the corpus that needs a fact-check. A few examples are shown in Table 1.

Most of the existing works are built upon two fundamental pillars - semantic encapsulation (Daxenberger et al., 2017; Chakrabarty et al., 2019) and syntactic encapsulation (Levy et al., 2014; Lippi and Torroni, 2015). They mainly focus on adapting to texts from similar distributions or topics or both. Secondly, they often exercise against well-structured and laboriously pre-processed formal texts owing to the lack of a labeled corpus consisting of unstructured texts. As a result, claim detection from unstructured raw data still lies under a relatively less explored umbrella.

Motivation: Claims can be sourced from a variety of sources, e.g., online social media texts, microblogs, Wikipedia articles, etc. It is, however, crucial to pay special attention to claims observed

April 19 - 23, 2021.

on online social media (OSM) sites (Matthew A. Baum; who). Twitter, being a major OSM platform, provides the perfect playground for different ideologies and perspectives. Over time, Twitter has emerged as the hub for short, unstructured pieces of text that describe anything from news to personal life. Most individuals view and believe things that align with their compass and prior knowledge, *aka conformity bias* (Whalen and Laland, 2015) – users tend to make bold claims that usually create a clash between users of varied opinions. At times, these claims incite a negative impact on individuals and society. As an example, a tweet that reads "*alcohol cures corona*" can lead to massive retweeting and consequential unrest, especially in times of a pandemic, when people are more vulnerable to suggestions. In such cases, automated promotion of claims for immediate further checks could prove to be of utmost importance. An automated system is pivotal since OSM data is far too voluminous to allow for manual human checks, even if it was an expert.

At the same time deploying separate systems contingent on the source of a text is inefficient and moves away from the goal of attaining human intelligence in natural language processing tasks. An ideal situation would be a framework that can effectively detect claims in the general setting. However, a major bottleneck towards this goal is the unavailability of an annotated dataset from noisy platforms like Twitter. We acknowledge this bottleneck and, in addition to proposing a generalised framework, we develop a qualitative annotated resource and guidelines for claim detection in tweets.

Proposed Method: There exists several claim detection models; however, the downside is that most of them are trained on structured text from a specific domain. Therefore, in this work, we propose **`LESA`**, a **L**inguistic **E**ncapsulation and **S**emantic **A**malgamation based generalized claim detection model that is capable of accounting for different text distributions, simultaneously. To formalize this, we divide the text, contingent upon their structure, into three broad categories – noisy text (*tweets*), semi-noisy text (*comments*), and non-noisy text (*news, essays*, etc.). We model each category separately in a joint framework and fuse them together using attention layers.

Since the task of claim detection has a strong association with the structure of the input, as argued by Lippi and Torroni (2015), we leverage two linguistic properties – part-of-speech (POS) and dependency tree, to capture the linguistic variations of each category. Subsequently, we amalgamate these features with BERT (Devlin et al., 2019) for classification.

We evaluate `LESA` on seven different datasets (including our Twitter dataset) and observe efficient performance in each case. Moreover, we compare `LESA`'s performance against various state-of-the-art systems for all seven datasets in the general and individual settings. The comparative study advocates the superior performance of `LESA`.

Summary of the Contributions: We summarize our major contributions below:

- **Twitter claim detection dataset and comprehensive annotation guidelines.** To mitigate the unavailability of an annotated dataset for claim detection in Twitter, we develop a large COVID-19 Twitter dataset, the first of its kind, with $\sim 10,000$ labeled tweets, following a comprehensive set of claim annotation guidelines.

- **`LESA`, a *generalized* claim detection system.** We propose a generalized claim detection model, `LESA`, that identifies the presence of claims in *any* online text, without prior knowledge of the source and independent of the domain. To the best of our knowledge, this is the first attempt to define a model that handles claim detection from both structured and unstructured data in conjunction.

- **Exhaustive evaluation and superior results.** We evaluate `LESA` against multiple state-of-the-art models on six benchmark claim detection datasets and our own Twitter dataset. Comparison suggests `LESA`'s superior performance across datasets and the significance of each model component.

Reproducibility: Code and dataset is publicly available at `https://github.com/LCS2-IIITD/LESA-EACL-2021`. Appendix comprises of detailed dataset description, annotation guidelines, hyperparameters, and additional results.

2 Related Work

In the past decade, the task of claim detection has become a popular research area in text processing with an initial pioneering attempt by Rosenthal and McKeown (2012). They worked on mining claims from discussion forums and employed a supervised approach with features based on sentiment and word-grams. Levy et al. (2014) proposed a context dependent claim detection (CDCD) approach. They described CDC as '*a general, concise statement that directly supports or contests the given topic.*' Their approach was evaluated over Wikipedia articles; it detected sentences that include CDCs using context-based and context-free features. This was followed by ranking and detecting CDCs using logistic regression. Lippi and Torroni (2015) proposed context-independent claim detection (CICD) using linguistic reasoning, and encapsulated structural information to detect claims. They used constituency parsed trees to extract structural information and predicted parts of the sentence holding a claim using SVM. Although their approach achieved promising results, they also used a Wikipedia dataset which was highly engineered and domain dependent.

Daxenberger et al. (2017) used six disparate datasets and contrasted the performance of several supervised models. They performed two sets of experiments – in-domain CD (trained and tested on the same dataset) and cross-domain CD (trained on one and tested on another unseen dataset). They learned divergent conceptualisations of claims over cross-domain datasets. Levy et al. (2017) proposed the first unsupervised approach for claim detection. They hypothesised a "claim sentence query" as an ordered triplet: $\langle$that $\rightarrow$ MC $\rightarrow$ CL$\rangle$. According to the authors, a claim begins with the word 'that' and is followed by the main concept (MC) or topic name which is further followed by words from a pre-defined claim lexicon (CL). This approach would not fit well for text stemming from social media platforms owing to a lack of structure and the use of 'that' as an offset for claim.

In recent years transformer-based language models have been employed for claim detection. Chakrabarty et al. (2019) used over 5 million self-labeled Reddit comments to fine-tune their model. However, they made no attempt to explicitly encapsulate the structure of a sentence. Recently, the CLEF-2020 shared task (Barrón-Cedeño et al., 2020) attracted multiple models which are tweaked specifically for claim detection. Williams et al. (2020) bagged the first position in the task using a fine-tuned RoBERTa (Liu et al., 2019) model with mean pooling and dropout. First runner up of the challenge, Nikolov et al. (2020) used logistic regression on various meta-data tweet features and a RoBERTa-based prediction. Cheema et al. (2020), the second runner up, incorporated pre-trained BERT embeddings along with POS and dependency tags as features trained using SVM.

Traditional approaches focused primarily on the syntactic representations of claims and textual feature generation, while recent neural methods leverage transformer models. With `LESA`, we attempt to learn from the past while building for the future – we propose encapsulating syntactic representations in the form of POS tags and dependency sequences along with the semantics of the input text using transformer-based BERT (Devlin et al., 2019). Another key observation has been the use of highly structured and domain-engineered datasets for training the existing models in claim detection. In the current age of alarming disinformation, we recognise the augmented need for a system that can detect claims in online text independent of its origin, context or domain. Therefore, in addition to considering texts from different online mediums, we incorporate, for the first time, a self-annotated large Twitter dataset to the relatively structured datasets that exist in this field.

3 Proposed Methodology

Traditionally, the narrative on claim detection is built around either syntactic (Levy et al., 2017; Lippi and Torroni, 2015) or semantic (Daxenberger et al., 2017; Chakrabarty et al., 2019) properties of the text. However, given our purview on the integration of both, we propose a combined model, `LESA` , that incorporates exclusively linguistic features leveraged from part-of-speech (POS) tags and dependency tree (DEP) as well as semantic features leveraged from transformer-based model, BERT (Devlin et al., 2019).

By the virtue of digital media, we generally deal with texts from three kind of environments: (a) a controlled platform where content is pre-reviewed (e.g., news, essays, etc.); (b) a free platform where authors have the freedom to express themselves without any restrictions on the length (e.g., online comments, Wikipedia talk pages); and (c) a free platform with restrictions on the text length (e.g., tweets). The texts in the first category is usually free of any grammatical and typographical mistakes, and thus belong to the non-noisy category. On the other hand, in the third case, texts exhibit a significant amount of noise, in terms of spelling variations, hashtags, emojis, emoticons, abbrevia-

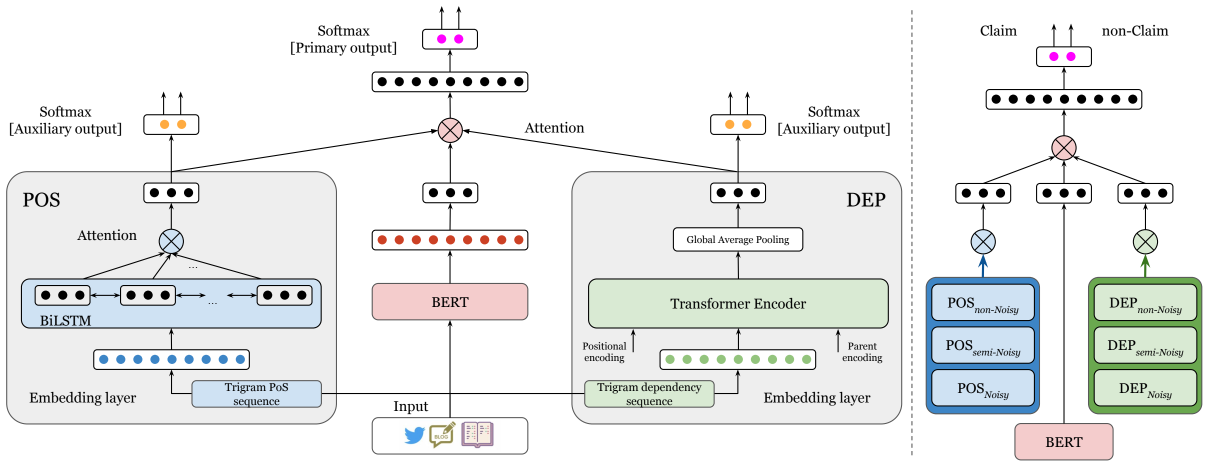

Figure 1: Schematic diagram of our proposed `LESA` model. The structure on the right is a high level schematic diagram. Structure on the left shows POS and DEP for one viewpoint.

tions, etc., to express the desired information within the permissible limit, thus it belongs to the noisy class. The second case is a mixture of the two extreme cases and hence, constitutes the semi-noisy category. We employ three pre-trained models representing noisy, semi-noisy, and non-noisy data for both POS and dependency-based features. The intuition is to leverage the structure-specific linguistic features in a joint framework.

Domain adaptation from a structured environment to an unstructured one is non-trivial and requires specific processing. Therefore, to ensure generalization, we choose to process each input text from three different viewpoints (structure-based segregation), and intelligently select the contributing features among them through an attention mechanism. We use it to extract the POS and DEP-based linguistic features. Subsequently, we fuse the linguistic and semantic features using another attention layer before feeding it to a multilayer perceptron (MLP) based classifier. The idea is to amalgamate diverse set of features from different perspectives and leverage them for the final classification. A high-level architectural diagram is depicted in Figure 1. We design parallel pillars for each viewpoint (right side of Figure 1) such that the noisy pillar contains pre-trained information from the noisy source and so on. When the common data is passed through the three pillars we hypothesize each pillar's contribution dependending on the type of input data. For example, if the data source is from a noisy platform, we hypothesize that the noisy pillars will have more significance than the other two viewpoints. We demonstrate this effect in Table 5.

A. Part-of-speech (POS) Module

The POS module consists of an embedding layer followed by a BiLSTM and an attention layer to extract the syntactic formation of the input text. We pre-train the POS module for each viewpoint, and later fine-tune them while training the integrated model.

At first, each sequence of tokens $\{x_1, x_2, ..., x_n\}$ is converted to a sequence of corresponding POS tags resulting into the set $\{p_1, p_2, \dots, p_n\}$. However, the foremost limitation of this modeling strategy is the limited and small vocabulary size of 19 owing to a specific number of POS tags. To tackle this, we resort to using k-grams of the sequence. The sequence of POS tags (with $k = 3$) now becomes $\{(p_0, p_1, p_2), (p_1, p_2, p_3), (p_2, p_3, p_4), ..., (p_{n-2}, p_{n-1}, p_n), (p_{n-1}, p_n, p_{n+1})\}$, where p_0 and p_{n+1} are dummy tags. Subsequently, a skip-gram model (Mikolov et al., 2013) is trained on the POS-transformed corpus of each dataset, which thereby translates to a POS embedding, E_P.

B. Dependency Tree (DEP) Module

Dependency parsing is the function of abstracting the grammatical assembly of a sequence of tokens $\{x_1, x_2, \dots, x_n\}$ such that there exists a directed relation (dependency), $d(x_i, x_j)$, between any two tokens x_i and x_j, where x_i is the headword and x_j is modified by the headword. We obtain these dependency relations through spaCy[1] which uses the clearNLP guidelines. Initially, each sequence is rendered into a combination of the *dependency-tag* arrangement $\{d_1, d_2, \dots d_n\}$ and a *parent-position*

---

[1] `www.spacy.io`

arrangement $\{pp_1, pp_2, \ldots pp_n\}$. Here, each d_j represents a dependency tag, where x_j is modified by x_i, and pp_j is the index of the modifier (headword) x_i.

We then leverage the transformer encoder (Vaswani et al., 2017), where traditionally, a position-based signal is added to each token's embedding to help encode the placement of tokens. In our modified version, the token sequence is the *dependency-tag* sequence $d_e = \{d_1, d_2, ..., d_n\}$, wherein a *parent-position* based signal is additionally added to encode the position of the modifier words.

$$d'_e = d_e + [(E_{p_1}, E_{pp_1}), ..., (E_{p_n}, E_{pp_n})] \quad (1)$$

where $d'_e \in \mathbf{R}^{d \times n}$ is the modified dependency embedding of a sequence of length n, E_{p_i} and E_{pp_i} are the encodings for the *token-position* and the *parent-position* (position of token's modifier), and $(,)$ represent tuple brackets.

This helps us create a flat representation for a dependency graph. The transformer-architecture that we employ comprises of 5 attention heads with an embedding size of 20. Given that there are only a handful of dependency relations, this, still poses the problem of a limited vocabulary size of 37. Having accounted for the parent positions already, we decide to again employ tri-gram sequences $\{(d_0, d_1, d_2), (d_1, d_2, d_3), (d_2, d_3, d_4), ...,$ $(d_{n-2}, d_{n-1}, d_n), (d_{n-1}, d_n, d_{n+1})\}$ in place of uni-grams.

4 Datasets

A number of datasets exist for the task of claim detection in online text (Peldszus and Stede, 2015; Stab and Gurevych, 2017); however, most of them are formal and structured texts. As we discussed earlier, OSM platforms are overwhelmed with various claim-ridden posts. Despite the abundance of tweets, literature does not suggest any significant effort for detecting claims in Twitter; Arguably, the prime reason is the lack of a large-scale dataset. Recently, a workshop on claim detection and verification in Twitter was organized under CLEF-2020 (Barrón-Cedeño et al., 2020). It had two subtasks related to claim identification with separate datasets. The first dataset consists of $1,060$ COVID-19 tweets for claim detection; whereas, the second one comprises of another $1,000$ tweets for claim retrieval. In total, there were $2,069$ annotated tweets of which $1,704$ had claims and 365 were non-claims. Another recent in-progress dataset on claim detection, which currently has only 305 claim and 199 non-claim tweets, was released by Alam et al. (2020).

	Our Annotation	
CLEF-2020	Non-claim	Claim
Non-claim	301	47
Claim	64	550

Table 2: Confusion matrix highlighting the differences and similarities between Alam et al. (2020) and our annotation guidelines for CLEF-2020 claim dataset.

Unfortunately, the aforementioned limited instances are insufficient to develop an efficient model. Therefore, we attempt to develop a new and relatively larger dataset for claim detection in OSM platforms. We collected $\sim 40,000$ tweets from various sources (Carlson, 2020; Smith, 2020; Celin, 2020; Chen et al., 2020; Qazi et al., 2020) and manually annotated them. We additionally included claim detection datasets of Alam et al. (2020) and CLEF-2020 (Barrón-Cedeño et al., 2020) and re-annotated them in accordance with our guidelines. During the cleaning process, we filtered a majority of tweets due to their irrelevancy and duplicacy. To ensure removal of duplicates, we performed manual checking and exhaustive preprocessing.

Data Annotation: To annotate the tweets, we extend and adapt the claim annotation guidelines of Alam et al. (2020). The authors targeted and annotated only a subset of claims, i.e., factually verifiable claims. They did not consider personal opinions, sarcastic comments, implicit claims, or claims existing in a sub-sentence or sub-clause level. Subsequently, we propose our definition of claims and extrapolate the existing guidelines to be more inclusive, nuanced and applicable to a diverse set of claims. Our official definition for claims, adopted from Oxford dictionary[2], is to *state or assert that something is the case, with or without providing evidence or proof.*

We present the details of annotation guidelines in Gupta et al. (2021). Following the guidelines, we annotated the collected tweets, and to ensure coherence and conformity, we re-annotated the tweets of Alam et al. (2020) and CLEF-2020 (Barrón-Cedeño et al., 2020). It is intriguing to see the differences and similarities of the two guidelines; therefore, we compile a confusion matrix for CLEF-

	N-cl	1244	8117	7933	337	5008	2233	3553

Table 4: Statistics of the datasets (Abbreviations: Cl: Claim, N-Cl: Non-claim, Tr: Train set, Ts: Test set; Tot: Total).

2020 claim dataset, as presented in Table 2. Each tweet in our corpus of $9,894$ tweets has been annotated by at least two annotators, with an average Cohen's kappa inter-annotator agreement (Cohen, 1960) score of 0.62. In case of a disagreement, the third annotator was considered and a majority vote was used for the final label. All annotators were linguists.

Other Datasets: Since we attempt to create a generalized model that is able to detect the presence of a claim in any online text, we accumulate, in addition to the Twitter dataset, six publicly available benchmark datasets: (i) Online Comments (OC) containing Blog threads of LiveJournal (Biran and Rambow, 2011), (ii) Wiki Talk Pages (WTP) (Biran and Rambow, 2011), (iii) German Microtext (MT) (Peldszus and Stede, 2015), (iv) Persuasive Student Essay (PE) (Stab and Gurevych, 2017), (v) Various Genres (VG) containing newspaper editorials, parliamentary records and judicial summaries, and (vi) Web Discourse (WD) containing blog posts or user comments (Habernal and Gurevych, 2015). All datasets utilised in this paper contain English texts only. For German Microtexts (MT), we used the publicly available English translated version published by MT's original authors (Peldszus and Stede, 2015)). The same was utilized by Chakrabarty et al. (2019).

The datasets are formed by considering text at the sentence level. For example, in Persuasive Essays (PE) dataset, each essay is broken into sentences and each sentence is individually annotated for a claim. Considering the structure of the input texts in these datasets, we group them into three categories as follows: Noisy (Twitter), Semi-noisy (OC, WTP), Non-noisy (MT, PE, VG, WD). We list one example from each dataset in Table 3. We also highlight the noisy and semi-noisy phrases in Twitter, and OC and WTP datasets respectively. Moreover, we present detailed statistics of all seven datasets in Table 4.

5 Experimental Setup

For all datasets besides twitter, we use the train, validation, and test splits as provided by UKP Lab[3]. A mutually exhaustive 70:15:15 split was maintained for Twitter dataset. We compute POS embeddings by learning word2vec skip-gram model (Mikolov et al., 2013) on the tri-gram[4] POS sequence. For the skip-gram model, we set *context window* $= 6$, *embedding dimension* $= 20$, and discard the POS sequence with *frequency* ≤ 2. Subsequently, we compute dependency embeddings with *dimension* $= 20$ using Transformer (Vaswani et al., 2017) encoder with 5 *attention heads*. Please note that the choice of using Bi-LSTM, as oppose to Transformers, for extracting the POS features is empirical[5].

The outputs of the POS and dependency embedding layers are subsequently fed to a BiLSTM and *GlobalAveragePooling* layers, respectively. Their respective outputs are projected to a 32-dimensional representation for the fusion. We employ HuggingFace's BERT implementation for computing the tweet representation. The

Table 5: Macro F1 (m-$F1$) and Claim-F1 (c-$F1$) for ablation studies.

768-dimensional embeddings is projected to a 32-dimensional representation using linear layers. We progress with the 32-dimensional representation of BERT as we observe no elevation in results on using the 768-dimensional representation, as can be seen in Table 5. Besides, the latter results in ~ 2 million trainable parameters, whereas the former requires ~ 1.2 million trainable parameters. We employ sparse categorical cross-entropy loss with Adam optimizer and use softmax for the final classification.[6] For evaluation, we adopt **macro-F1** (**m-$F1$**) and **claim-F1** (**c-$F1$**) scores used by the existing methods (Daxenberger et al., 2017; Chakrabarty et al., 2019).

We perform our experiments in two setups. In the **first in-domain setup**, we train, validate and test on the same dataset and repeat it for all seven datasets independently. In the **second general-domain setup**, we combine all datasets and train a unified generic model. Subsequently, we evaluate the trained model on all seven datasets individually.

Furthermore, for each experiment, we ensure a balanced training set by down-sampling the dominant class at $1:1$ ratio. However, we use the original test set for a fair comparison against the existing baselines and state-of-the-art models.

6 Experimental Results

Table 5 shows m-$F1$ and c-$F1$ for different variants of `LESA`. We begin with a fine-tuned BERT model and observe the performance on test sets of all seven datasets. On the Twitter dataset, the BERT architecture yields m-$F1$ score of 0.60 and c-$F1$ score of 0.83. We also report the weighted-average score as 0.58 m-$F1$ and 0.73 c-$F1$, in the last two columns of Table 5. Since we hypothesize that claim detection has a strong association with the structure of the text, we amalgamate POS and dependency (DEP) information with the BERT architecture in a step-wise manner. The BERT+POS model reports an increase of 1% m-$F1$ and c-$F1$ scores on the Twitter dataset. We observe similar trends in other datasets and the overall weighted-average score as well. We also perform experiments on other permutations, and their results are listed in Table 5. Finally, we combine both POS and DEP modules with the BERT architecture (*aka.* `LESA`). It obtains improved results for most of the cases, as shown in the last row of Table 5. The best result on average stands at 0.61 m-$F1$ and 0.75 c-$F1$ for the proposed `LESA` model. This serves as a testament to our hypothesis, validating our assumption that combining syntactic and semantic representations leads to better detection of claims.

In all aforementioned experiments, we use our pre-defined concept of three viewpoints, i.e., noisy, semi-noisy and non-noisy. Therefore, for completeness, we also construct a combined viewpoint which does not contain any structure-specific pillar in POS or DEP branches. The results from this ablation experiment are reported in `LESA` (Combined-view) row. We observe that the combined-view results are inferior to the variant with separate viewpoints for each component (c.f. second last and last row of Table 5 respectively). Thus, providing attention to datasets based on the noise in their content is demonstrated by a significant increase of $\sim 2\%$ m-$F1$ from combined viewpoint to separate viewpoints experiment.

A. Baselines and Comparative Analysis

We employ the following baselines (some of them being state-of-the-art systems for claim detection and text classification): ▷ **XLNet** (Yang et al., 2019): It is similar to the BERT model, where we fine-tune XLNet for the claim detection; ▷ **Accenture** (Williams et al., 2020): A RoBERTa-based system that ranked first in the CLEF-2020 claim detection task (Barrón-Cedeño et al., 2020); ▷ **Team Alex** (Nikolov et al., 2020): The second-ranked system at CLEF-2020 task that fused tweet meta-data into RoBERTa for the final prediction; ▷ **Check-Square** (Cheema et al., 2020): An SVM-based system designed on top of pre-trained BERT em-

Table 8: Category-wise weighted-average F1 scores.

beddings in addition to incorporating POS and dependency tags as external features. ▷ **CrossDomain** (Daxenberger et al., 2017): Among several variations reported in the paper, their best model incorporates CNN (random initialization) for the detection. We reproduce the top submissions from CLEF-2020 challenge using the best performing models mentioned in the referenced papers. Code for CheckSquare was provided online. For Accenture and Team Alex we reproduce their methods using the hyper-parameters mentioned in the paper. We evaluate all baselines using the same train and test set as for LESA .

We report our comparative analysis for the in-domain setup in Table 6. We observe that LESA obtains best c-$F1$ scores for six out of seven datasets. Additionally, it achieves a weighted average c-$F1$ of 0.79 which is 3.95% improvement over the best performing baseline. In terms of m-$F1$ values, our weighted average ranks second next to CrossDomain. We reproduced CrossDomain baseline using their GitHub code (UKPLab). If the reproduced values are considered, our model outperforms all other models in m-$F1$ value as well.

Similarly, we compile the results for the general-domain setup in Table 7. In the non-noisy category, LESA obtains better m-$F1$ scores than three of the four state-of-the-art systems, i.e., it reports 0.77, 0.74, and 0.68 m-$F1$ scores compared to 0.71, 0.71, and 0.61 m-$F1$ scores of the comparative systems on MT, PE, and VG test sets, respectively. On WD, we observe similar m-$F1$ and c-$F1$ scores for both the best baseline and LESA. On the datasets in other categories, we observe comparative m-$F1$ scores; however, none of the baselines are consistent across all dataset – e.g., CrossDomain (Daxenberger et al., 2017) reports the best m-$F1$ scores on Twitter and OC, but yields (joint) fourth-best performance on WTP. Moreover, LESA yields the best m-$F1$ score across the seven datasets on average with $\geq 1\%$ improvements. On the other hand, we obtain best c-$F1$ scores for five out of seven datasets. In addition, LESA reports overall c-$F1$ of 0.75 with a significant improvement of $\geq 3\%$. Using a paired T-test, LESA showed significant statistical improvement compared against BERT in m-$F1$ and c-$F1$ for the noisy dataset with p-values .00017 and <.00001 respectively. Results were also significant for m-$F1$ and c-$F1$ for PE and m-$F1$ for WD. The small sample size in some datasets like MT and VG does not allow a reliable calculation of test statistics.

Since our work intends to developing a model that is able to detect claims irrespective of the source and origin of text, we also analyse the

		Example	Gold	Prediction	
				LESA	CrossDomain
TWR	x_1	*28 coronaoutbreak cases thus far in india italian tourists 16 their driver 1 kerala 3 cureddischarged agra 6 delhi 1 noida school dad telangana 1 coronavirusindia*	1	0	0

Table 9: Error analysis of the outputs. Red texts highlight errors.

weighted-average scores for each category in Table 8. We observe that `LESA` obtains the best c-$F1$ scores in each category, in addition to the best m-$F1$ score in non-noisy category as well. For the other two categories, `LESA` yields comparative performances. The results are better for noisy data than for non-noisy owing to the small size and skewness against claims in the latter's test set. Therefore, misclassification of a single claim causes severe penalization to c-$F1$.

B. Error Analysis

It is apparent from the results that all systems (including `LESA`) committed some errors in claim detection. Thus, in this section, we explore where our system misclassified the inputs by analysing some examples. Table 9 presents a few instances along with the gold labels and the predictions of the best-performing baseline, CrossDomain (Daxenberger et al., 2017), for comparison. In some cases, both `LESA` and CrossDomain failed to classify the instances correctly, whereas in others, `LESA` classifies the instances correctly but CrossDomain could not. We also report intuitions for the misclassification by `LESA` in some cases. The presence of numbers and statistics could be the reason behind the misclassifications in examples x_1 and x_8. Example x_3 contains two weak phrases (*'alternative medicine as treatment'* and *'there is a chance of recovery'*) which are most likely the cause of misclassification. The former might have been interpreted as suggestion backed up by some evidence, while in the latter phrase, `LESA` might have misinterpreted the optimism with claim. Furthermore, the phrase *'fossil fuels are abundant'* in example x_4 reflects world knowledge instead of a claim, as interpreted by `LESA`.

7 Conclusion

In this paper, we addressed the task of claim detection from online posts. To do this, we proposed a generic and novel deep neural framework, `LESA`, that leverages the pre-trained language model and two linguistic features, corresponding to the syntactic properties of input texts, for the final classification. Additionally, we tackled the texts from distinct sources for the claim detection task in a novel way. In particular, we categorized the input text as noisy, non-noisy, and semi-noisy based on the source, and modeled them separately. Subsequently, we fused them together through an attention module as the combined representation.

One of the major bottlenecks of claim detection in online social media platforms is the lack of qualitative annotation guidelines and a sufficiently large annotated dataset. Therefore, we developed a large Twitter dataset of $\sim 10,000$ manually annotated tweets for claim detection. In addition to our twitter dataset, we employed six benchmark datasets (representing either semi-noisy or non-noisy input channels) for evaluation of the proposed model. We compared the performance of `LESA` against four state-of-the-art systems and two pre-trained language models. Comparison showed the superiority of the proposed model with $\geq 3\%$ claim-F1 and $\geq 1\%$ macro-F1 improvements compared to the best performing baselines on average. As a by-product of the study, we released a comprehensive guideline for claim annotation.

Interpretability for Morphological Inflection: from Character-level Predictions to Subword-level Rules

Abstract

Neural models for morphological inflection have recently attained very high results. However, their interpretation remains challenging. Towards this goal, we propose a simple linguistically-motivated variant to the encoder-decoder model with attention. In our model, character-level cross-attention mechanism is complemented with a self-attention module over substrings of the input. We design a novel approach for pattern extraction from attention weights to interpret what the model learn. We apply our methodology to analyze the model's decisions on three typologically-different languages and find that a) our pattern extraction method applied to cross-attention weights uncovers variation in form of inflection morphemes, b) pattern extraction from self-attention shows triggers for such variation, c) both types of patterns are closely aligned with grammar inflection classes and class assignment criteria, for all three languages. Additionally, we find that the proposed encoder attention component leads to consistent performance improvements over a strong baseline.

1 Introduction

With the rise of deep learning, neural networks have been nowadays used in the process of decision making in various domains, as different as trading, medicine and government. Ethical considerations of such decisions have led to an increasing need for interpreting neural models which is a vivid research topic in machine learning community (Lipton, 2018; Gilpin et al., 2018). Although interpretability research in NLP is partly driven by ethics (Jacovi and Goldberg, 2020), there is a growing body of work exploring what linguistic properties emerge in neural models (Belinkov and Glass, 2019; Manning et al., 2020). The latter line of work aims to aid and scale up linguistic research, which is also the topic of this paper. Linguistics research focuses on uncovering patterns and regularities in language. Retrieving and analyzing structures of languages learned by neural agents can systematize our knowledge and, ideally, help us to come up with new regularities. Recent advances (Schrimpf et al., 2020) in testing hypotheses about human language processing using the growing suite of modern interpretable NLP are, indeed, inspiring, but still relatively limited to few languages. To scale up linguistic research, we require truly language-independent models developed for languages other than English (Bender, 2011). In return, understanding the model's decisions can lead to new ideas, how to improve the performance of the model on hard cases, i.e. on a particular linguistic phenomenon or language.

In our work, we concentrate on interpretability methods suitable for examining what knowledge of inflection morphology is captured by neural networks. Specifically, we consider a neural model that learns a mapping from a lemma and an abstract morpho-syntactic definition (MSD) to its inflected form. MSD comprises a part-of-speech (POS) tag as well as language-specific inflection tags. For example, given the Italian lemma *scolorire* "discolor" and MSD *V;IND;PRS;3;PL* (verb, 3rd person plural present indefinite form), the output is the word form *scoloriscono*. Datasets for this task of morphological reinflection are available for many languages and provide an opportunity to study a broad set of inflection phenomena.

Character-level encoder-decoder neural models with attention achieved very high performance on this task across many languages (see Cotterell et al., 2017, 2018; Vylomova et al., 2020 for the results of the recent shared tasks). Nevertheless, this class of models is typically not interpreted, and if it is so, the interpretation is limited to visualizing attention heatmaps on selected examples (see e.g. Aharoni and Goldberg 2017; Peters and Martins 2019).

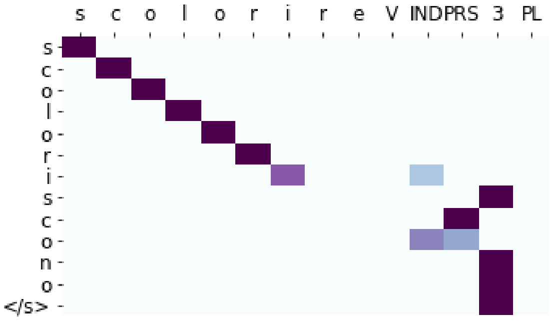

Figure 1: Example of a heatmap visualizing attention weights learned by the model of Peters and Martins (2019). The inflected form is generated from top to bottom.

We argue that per-example heatmaps provide very limited insight into what neural agent learns about a specific inflection phenomenon and how neural learning process can be related, in a systematic way, to the linguistic theory. Indeed, consider the previous Italian example: how would humans reason to convert the lemma to its inflected form?[1] In this work, we assume that humans apply the rules of grammar (implicit for native speakers, and explicit for language learners) when they perform this task. Specifically to our example, human reasoning could look as follows: the verb *scolorire* ends with the suffix *-ire* which determines its inflection class[2], according to which we construct the inflected form by copying the stem *scolor-* and adding an inflection suffix *-iscono*. What does a typical character-level model of an encoder-decoder class do? We visualize learned attention weights for an example of such a model in Fig. 1. By analyzing the most prominent alignments, we conclude that the model's character-level decisions can be combined into a) copying a substring of characters corresponding to the stem and b) generating characters for a substring corresponding to the inflection suffix. However, the decision why the model chose a particular inflection class is not visible.

To reach interpretability of models for inflection, we require methods that satisfy three conditions. First, the inflection model's decisions have to be aligned more closely to human reasoning by separating two kinds of operations: determining inflection class versus generating a string (given the assignment to a class). Second, a systematic analysis of model's decisions requires the extraction of inflection rules that are interpretable to humans. Finally, both of these factors require working with subword units rather than individual characters, the latter being the prevailing practice for inflection models.

In this paper, we propose a methodology - subword modification for a typical inflection model and interpretation method - which meet all three requirements. Our experiments on three typologically-different inflection phenomenon show that the linguistic rules elicited with our framework are highly consistent with linguistic knowledge (approximated by grammars). We evaluate the effectiveness of the proposed subword modification and find that, apart from its direct impact on interpretability, it leads to consistent performance improvements. To facilitate the use of our methods for linguistic research, we share our code[3].

2 Methodology: Interpretability for Inflection

How to make a character-level neural model for inflection more interpretable? We take the stance that, to make current models more interpretable, we should analyze their decisions in terms of subwords, i.e. clusters of characters rather than individual characters. Interpreting character decisions is outside of human intuition because of the double articulation principle (Martinet, 1967) which postulates that single phones are uninterpretable to humans, whereas the clusters of them form a mental linguistic representation of meaning in the speaker's mind. In writing, this distinction maps to the one between single characters and morphemes. [4]

From this perspective, we formulate the following desired properties for retrieving linguistic structures of inflection. For a given grammatical category (e.g. MSD *V;IND;PRS;3;PL* from the previous example in Italian),

---

[1] This is something that speakers implicitly (maybe, we do not know this for a fact) perform every time they use a word. This is also often an explicit task that language learners perform in the process of acquiring a new language.

[2] There are three inflection classes in Italian (Table 1). Verbs ending on *-ire* select between two classes: one (in the example) is more frequent in terms of types of verbs that belong to it, whereas the other one (*-ere* class) is selected by some very frequent verbs ending on *-ire*.

[3] `https://github.com/tatyana-ruzsics/interpretable-inflection`

[4] In this work, we refer to morphemes in their most general sense - apart from functional words and affixes we consider morphological processes, e.g. infixation and reduplication

	ARE	ERE/IRE	IRE
1SG	O	O	ISCO
2SG	I	I	ISCI
3SG	A	E	ISCE
1PL	IAMO	IAMO	IAMO
2PL	ATE	ETE	ITE
3PL	ANO	ONO	ISCONO

Table 1: Italian verbal inflectional classes, present tense

P1: identify substrings in an inflected form correspondig to morpheme(s) attributed to this category // *scolo**risc**ono*

P2: identify variation (dataset-wide) in the form of the morpheme (morphological class), e.g. all other substrings attributed to the same category // *-ano, -ono, -iscono*

P3: indicate whether triggers for such variation can be attributed to particular substrings of the lemma // *scolo**rire***

P4: identify triggers (dataset-wide) for each inflection class identified in P2 // *-are, -ere, -ire*

We propose to extract human-interpretable rules from an encoder-decoder model with attention. Specifically, to make it more interpretable, we modify such model by complementing the cross-attention mechanism with a novel component (§3) for self-attention over the subwords of the lemma. The task of this component is to help identify the morphological class. To extract the rules, we design a pattern extraction method (§4) that aggregates learned attention weights a) over a span of characters in a word and b) over a range of words in the same inflection category. Pattern extraction applied to character-level cross-attention weights retrieves linguistic rules satisfying requirements P1 and P2, whereas pattern extraction applied to subword-level self-attention weights, targets the requirements P3 and P4.

2.1 Case studies

To demonstrate the use of our approach for linguistic research, we will analyze how well patterns extracted with our proposed methodology align with human knowledge of typologically different phenomena. In morphological typology, cross-linguistic strategies to define the form and meaning of morphemes are described by typological parameters (Shopen, 1985; Dryer and Haspelmath, 2013; Bickel and Nichols, 2007) that separate different dimensions of the strategies. To select typologically different languages for our study, we focus on fusion and flexivity dimensions. Fusion classifies how easy it is to find a boundary between a morpheme and its phonological host and can take the following values: isolating (separate phonological word), concatenative (segmentable dependent morphemes) and nonlinear (not segmentable morphemes). Flexivity indicates whether variation in morpheme form can be explained by phonological processes (nonflexive) or not (flexive).

In our case studies, we consider verb conjugation rules and select three languages covering different degrees of fusion and flexivity: Finnish, Italian and Tagalog. In Finnish and Italian, morphemes are separable (concatenative fusion), whereas inflection in Tagalog is formed with affixes, including infixes, and reduplication (nonlinear fusion). Morphemes in Finnish can change their shape because of vowel harmony (nonflexive case). Forms of morphemes in Italian and Tagalog are selected by lexical context (flexive case) but distinctly. Italian verbs are conjugated with respect to three inflection classes defined by the lemma's ending (*-are*, *-ire*, and *-ere*, see Table 1), whereas assignment to an inflection class in Tagalog has no explicit rule.

3 Neural Model Cross-Att$^{\text{ch}}$Self-Att$^{\text{sub}}$

In this section, we introduce our novel component for **self-attention over subwords** of the lemma (**Self-Att$^{\text{sub}}$**). This module can be integrated into any variant of encoder-decoder system for inflection with **character-level cross-attention** (**Cross-Att$^{\text{ch}}$**). In this work, we show such integration to a sparse two-headed model of Peters and Martins (2019).[5] To explain the two-headed attention mechanism of the baseline model as well as our novel attention component, we first introduce the terminology of an abstract attention head module.

Attention Head Given an input sequence of vectors $\mathbf{H} = \mathbf{h}_1 \dots \mathbf{h}_J$, $\mathbf{h}_k \in \mathbb{R}^{D1}$ and a query vector $\mathbf{q} \in \mathbb{R}^{D2}$, attention head module computes two components: attention weights $a \in \mathbb{R}^J$ and an attention head vector $\mathbf{c} \in \mathbb{R}^{D1}$:

$$\alpha_j = \mathbf{q}^\intercal \mathbf{W}_a \mathbf{h}_j, \quad \mathbf{c} = \sum a_j \mathbf{h}_j \qquad (1)$$

where attention weights a are obtained by a mapping function from real values to probabilities, applied to alignment scores α. Following Peters and

---

[5] This model was among the winners of SIGMORPHON 2019 shared task (ranked first in terms of edit distance)

Martins (2019), we use `sparsemax` activations[6] as a mapping function. Hereafter we refer to the construction of an attention head vector $\mathbf{c}$ as scoring a sequence of vectors $\mathbf{H}$ with a query vector $\mathbf{q}$.

Baseline Cross-Att$^{\text{ch}}$ (Peters and Martins, 2019) Input lemma and MSD sequences are represented by separate bi-LSTM encoder states: $\mathbf{H}^u$ encodes characters in lemma, and $\mathbf{H}^v$ encodes tags in MSD. The decoder is a unidirectional LSTM with input feeding (Luong et al., 2015). At each prediction time t, it computes a hidden state $\mathbf{s}_t$ which is followed by the construction of two attention heads $\mathbf{u}_t$ and $\mathbf{v}_t$: one for lemma and one for MSD. They are calculated by scoring the respective representations, $\mathbf{H}^u$ and $\mathbf{H}^v$, with a query - decoder state s_t. The two attention heads are used to compute separate candidate attentional decoder states:

$$\tilde{\mathbf{s}}_{tu} = \mathtt{tanh}(\mathbf{W}_u[\mathbf{u}_t; \mathbf{s}_t]) \tag{2}$$

$$\tilde{\mathbf{s}}_{tv} = \mathtt{tanh}(\mathbf{W}_v[\mathbf{v}_t; \mathbf{s}_t]) \tag{3}$$

They are combined in a weighted sum to obtain an attentional decoder state $\tilde{\mathbf{s}}_\mathbf{t}$, where weights are calculated by a sparse gate vector $\mathbf{p_t} = [p_0, p_1] \in \mathbb{R}^2$:

$$\mathbf{p}_t = \mathtt{sparsemax}(\mathbf{W}_g[\mathbf{u}_t; \mathbf{v}_t; \mathbf{s}_t]) \tag{4}$$

$$\tilde{\mathbf{s}}_t = p_0\tilde{\mathbf{s}}_{tu} + p_1\tilde{\mathbf{s}}_{tv} \tag{5}$$

The attentional decoder state is fed into a sparse prediction layer. For the input feeding, the input to decoder comprises the predicted symbol embedding and gated attention vector c_t:

$$\mathbf{c}_t = p_0\mathbf{u}_t + p_1\mathbf{v}_t \tag{6}$$

The two-headed gate mechanism provides extra interpretability in the form of a three-way answer about what is relevant at a time step: the lemma, the inflections, or both.

Integrating Self-Att$^{\text{sub}}$ We depart from the existing character-level solution in that we assume that the input to the model - a (lemma, MSD) pair - is complemented with the segmentation of lemma into subwords.[7] We obtain an extra subword representation of lemma $\mathbf{H}^{subw}$ by averaging lemma representation vectors in $\mathbf{H}^u$ spanning characters within each subword. Besides the attention heads $\mathbf{u}_t$ and $\mathbf{v}_t$ computed at each generation step, we construct an additional attention head vector $\mathbf{m}$ which is computed once before the decoding stage. It is constructed by scoring the sequence of lemma subword representations in $\mathbf{H}^{subw}$ with a query vector $\mathbf{q}^{pos}$ corresponding to the encoding of the lemma's POS tag. This encoding is obtained by selecting a vector in MSD representation $\mathbf{H}^v$ corresponding to the position of the POS tag (e.g, POS tag *V* (verb) is in the first position in MSD *V;IND;PRS;3;PL*).

To integrate subword-level attention head $\mathbf{m}$ in the baseline system, we modify the gate layer in Eq. 4:

$$\mathbf{p}_t = \mathtt{sparsemax}(\mathbf{W}_g[\mathbf{m}; \mathbf{u}_t; \mathbf{v}_t; \mathbf{s}_t]); \tag{7}$$

In this way, the gate mechanism (and decoding) is expected to be informed with a signal for inflection class selection when such signal can be attributed to specific character spans (subwords) in the lemma. The attention over subwords is static and shared across target positions, aiming to separate the signal of the class assignment it conveys from local character transformations, given this assignment.

4 Pattern extraction

To extract linguistic rules from the trained model Cross-Att$^{\text{ch}}$Self-Att$^{\text{sub}}$, we represent its knowledge of inflection as a database. To populate it, we analyze predictions of the model on a dataset. The latter can be the original task data or a dataset collected to study a specific inflection phenomenon. Then, for each example in the dataset, we populate the knowledge database with the example itself and two patterns, which are extracted from the learned attention weights. The first one is a transformation pattern (§4.1) obtained by applying our pattern extraction method to learned cross-attention weights (Cross-Att$^{\text{ch}}$ component). This method can be applied to any inflection model embedded into encoder-decoder paradigm with attention. The second pattern is over the lemma subwords (§4.2) which is obtained from attention weights of the novel Self-Att$^{\text{sub}}$ component. Finally, we explain how populated in this way knowledge database can be queried to study inflection phenomena (§4.3).

4.1 Cross-Att$^{\text{ch}}$ Transformation Patterns

This method maps each example *(lemma, MSD)* → *inflected form* to a transformation pattern of a

---

[6] `sparsemax` activations (Martins and Astudillo, 2016) serve as a sparse (and therefore, more interpretable) alternative to a commonly used attention function - `softmax`. The latter yields dense attention weights: all elements in the input always make at least a small contribution to the decision.

[7] Such representation can be obtained with any off-the-shelf segmentation algorithms, e.g. BPE (Sennrich et al., 2016a) or Morfessor (Smit et al., 2014).

Input:

$X = \underset{123456789}{scolorire}$ $\quad F = \underset{1}{V}\ \underset{2}{IND}\ \underset{3}{PRS}\ \underset{4}{3}\ \underset{5}{PL}$

$Y = \underset{123456789101112}{scoloriscono}$ $\quad A^X$ and A^F as in Figure 1

Step 1: Transform att. weights into 'salient' alignments

$A = [\underbrace{X_1 \cdots X_7}_{copy}, F_4, F_3, F_2, F_4, F_4]$

Step 2: Inverse A and group pred. steps by gen. type

$X_1 \rightarrow \{c : [1]\}$ $\quad F_4 \rightarrow \{f4 : [8, 11, 12]\}$

$\dots$ $\quad F_3 \rightarrow \{f3 : [9]\}$

$X_7 \rightarrow \{c : [7]\}$ $\quad F_2 \rightarrow \{f2 : [10]\}$

Step 3: Replace char. in X and Y with indexed gen. type

$P^{tr}(X) = \mathrm{c}^1 \underset{7}{\cdots} \mathrm{c}^1\ \textit{re}$

$P^{tr}(Y) = \mathrm{c}^1 \underset{7}{\cdots} \mathrm{c}^1\ \mathrm{f4}^1\ \mathrm{f3}^1\ \mathrm{f2}^1\ \mathrm{f4}^2\ \mathrm{f4}^2$

Step 4: Collapse adjacent symbols

$P^{tr}(X)$=$\mathrm{c}^1\ \textit{re}$

$P^{tr}(Y) = \mathrm{c}^1\ \mathrm{f4}^1\ \mathrm{f3}^1\ \mathrm{f2}^1\ \mathrm{f4}^2$

Output:

$\mathrm{c}^1\ \textit{re} \rightarrow \mathrm{c}^1\ \mathrm{f4}^1\ \mathrm{f3}^1\ \mathrm{f2}^1\ \mathrm{f4}^2$

($\mathrm{c}^1 \leftrightarrow$ *scolori*, $f4^1 \leftrightarrow$ *s*, $f3^1 \leftrightarrow$ *c*, $f2^1 \leftrightarrow$ *o*, $f4^2 \leftrightarrow$ *no*)

Table 2: Illustration of Cross-Att$^{\text{ch}}$ Transformation Patterns algorithm applied to the example in Fig. 1.

form $P^{tr}(lemma) \rightarrow P^{tr}$*(inflected form)*. Formally, the input to the algorithm is a lemma $X = x_1, \dots x_n$, MSD $F = f_1 \dots f_l$, predicted target form $Y = y_1 \dots y_m$ and cross-attention weights over lemma characters $A^X = a_1^X \dots a_m^X, a_i^X \in \mathbb{R}^n$ and over MSD tags $A^F = a_1^F \dots a_m^F, a_i^F \in \mathbb{R}^l$.[8] The output is a string of a form $P^{tr}(X) \rightarrow P^{tr}(Y)$ where the constructed pattern representation P^{tr} for the lemma and target are built through the following steps (shown in Table 2 for our example in Fig. 1):

Step 1. Transform input attention weights A^x and A^f into "salient" alignments A: Each component a_j of salient alignments $A = a_1 \dots a_m$ is a set of input positions (in lemma X and/or MSD F) that provide the most significant contributions to predicting a character in Y at position j. We denote positions by capitalized symbols, i.e. $F1$ for position 1 in F, to reflect the difference between the position's index and value. Salient alignments are built by applying a filtering function ϕ to attention weights at each predicted position: $\phi : [a_j^X; a_j^F] \rightarrow a_j$. In the following, we illustrate how our algorithm works for the simplest choice of the filtering function, max-pooling, which simply selects one input position with the highest attention weight.[9] In our running example, this strategy results in only one element for each component a_j: e.g. $a_7 = X_7$.

Step 2. Inverse mapping A and group prediction steps by generation type: By inverting salient alignments, we construct a mapping from input positions to prediction steps grouped by a symbol corresponding to generation type. The latter is identified for each alignment a_j by the type of input: we denote generation from the lemma's characters ($a_j = X_i$) by symbol *g*, whereas that from a tag ($a_j = F_k$) is denoted by indexed symbol fk. The special case of copying a character from the lemma, i.e. $a_j = X_i$ and $x_i = y_j$, is denoted by symbol *c*. Thus, a position in F can be mapped to only one group of prediction steps (the type of generation is unique and defined by the tag's position), whereas that in X can be mapped to up to two groups, *g* and *c*. Some input positions might be absent in the constructed mapping, if not present in salient alignments, e.g. X_9 in Table 2.

Step 3. Replace characters in X and Y with indexed generation type symbols: We index (in the order of input positions) triples of salient alignments (input position, generation step, generation type) identified in the previous step. Then, we construct patterns of lemma and inflected form, by replacing characters at aligned positions with an indexed value of the generation type symbol, e.g. $(c, X_j, Y_k) \rightarrow index; x_j \rightarrow c^{index}; y_k \rightarrow c^{index}$. In X, this can result in an aggregated symbol, e.g. replacing X_i with $c^{1;2}; g^1$ means that position X_i is aligned to three target positions, two of which are generated by copying x_i. As illustrated in our running example, we use the same index value in two special cases: a) a whole target substring was copied, and b) a whole target substring was generated by the same tag. We keep the track of symbolic mappings from characters to indexed generation symbols that replace them.

Step 4. Collapse adjacent symbols: Scan representations $P^{tr}(X)$ and $P^{tr}(Y)$, built at the previous step and iteratively collapse adjacent symbols of the same value. At the same time, we update

---

[8] We assume that the sum of weights in a combined vector $[A^X;A^F]$ is 1. In Cross-Att$^{\text{ch}}$Self-Att$^{\text{sub}}$ model this is achieved by scaling cross-attention weights for the lemma and MSD with corresponding gate values. Another way, typical for neural inflection models of encoder-decoder class, is to run cross-attention over a concatenation of the lemma's characters and MSD's tags.

[9] `sparsemax` activations provide another choice to filtering function by keeping the input positions corresponding to nonzero attention weights. In our example, this would result in e.g. $a_7 = \{X_7, F_2\}$. We refer to a more general form of the algorithm covering such case in the Appendix.

the symbolic mapping: if two adjacent symbols are collapsed, we replace their string mappings with a single mapping from the strings concatenation to the generation symbol.

The idea behind the inverse mapping and indexing in steps 2 and 3 is to ensure a unique way of indexing generation symbols across all data pairs. The indices themselves are essential to keep a one-to-one mapping from substrings to the generation symbols they are replaced with. Both factors come into play when we query the knowledge database for an inflection phenomenon (§4.3).

4.2 Self-Att$^{\text{sub}}$ Lemma Patterns

This algorithm takes as an input a data example (X, Y, F), along with a segmented lemma representation $S(X) = s_1 \ldots s_p$ and learned self-attention weights over lemma's subwords: $a^{S(X)} \in \mathbb{R}^p$. The output is a pattern for salient subwords in lemma $P^l(X)$ which is built with a similar procedure as described above where indexing steps 2 and 3 are skipped.

First, we transform self-attention weights $a^{S(X)}$ into salient alignments a by applying a filtering function: $\phi : a^{S(X)} \rightarrow a$, thereby identifying a set of subword positions with the most significant contribution to the overall generation process (any type of filtering function described in the previous subsection can be applied). Afterward, we replace all subwords in the input lemma at nonsalient positions, $S_j \notin a$, with a dedicated symbol, e.g. asterisk *. Finally, we iteratively merge adjacent asterisk symbols to obtain a more general pattern. To illustrate with our running example, given a segmented representation of lemma $S(X) = s|col|or|i|re$ and salient alignments $a = \{S4, S5\}$, obtained by filtering input positions with nonzero self-attention weights, the resulting pattern for salient subwords in the lemma is $P^l(X) = *ire$.

4.3 Querying Patterns

As a result of applying the previous two methods, each data example (X, Y, F), along with segmented lemma representation $S(X)$ and learned attention weights (A^X, A^F, $a^{S(X)}$), can be mapped into two items: Cross-Att$^{\text{ch}}$ transformation pattern $P^{tr}(X) \rightarrow P^{tr}(Y)$ and Self-Att$^{\text{sub}}$ pattern for salient subwords in lemma $P^l(X)$. The data examples along with the extracted patterns are stored in a knowledge database. To systematically study how the neural model handles a specific linguistic phenomenon of interest, the database can be queried, for patterns and examples, with a phenomenon's formalization in a form of regular expressions applied to the lemma, inflected form or MSD. Selected with a query examples are then grouped by their patterns (either transformation or lemma ones) resulting in each group representing an induced linguistic rule for the phenomenon.

At this stage, to make the patterns more readable, we perform an unmasking operation within each group: if a particular symbol is used to substitute one substring that is the same for all examples within a group, we replace the symbol back with this substring. For instance, if the pattern from our example c^1 *re* $\rightarrow$ $\text{c}^1\,\text{f4}^1\,\text{f3}^1\,\text{f2}^1\,\text{f4}^2$ represents one such group, and symbol f4^2 is used to substitute only one string *no*, which is the same across all data points in the group, we can unmask the string, to obtain a pattern c^1 *re* $\rightarrow$ $\text{c}^1\,\text{f4}^1\,\text{f3}^1\,\text{f2}^1$ *no*.

5 Experiments and Results

We perform three case studies, introduced in §2.1, to demonstrate how our framework allows querying patterns learned by an inflection neural model. The goal of our experiments is to assess how well the extracted patterns correspond to known inflection rules. To see whether our modifications to the inflection model affect its performance, we check the inflection accuracy on the analyzed languages and compare it with the original character-level model.

We use data from SIGMORPHON shared task: 2018 edition for Italian and Finnish (10K/1K/1K examples in train/development/test data), and 2020 edition for Tagalog (1,870/236/478). For each language, we train Cross-Att$^{\text{ch}}$Self-Att$^{\text{sub}}$ model with batch size 4, beam size 1 and other hyperparameters as reported in Peters and Martins (2019). To produce segmented lemma input, we use the BPE method (Gage, 1994; Sennrich et al., 2016b) with 1K merges on a token list (100K examples) extracted from WikipediaDumps articles.[10].

Using model's predictions on the concatenation of train, development and test set, we query Cross-Att$^{\text{ch}}$ and Self-Att$^{\text{sub}}$ patterns As a filtering function, we keep only nonzero weights for Self-Att$^{\text{sub}}$ patterns, whereas we choose max-pooling for Cross-Att$^{\text{ch}}$ ones, as on average sparse activations assign

---

[10] We use archives of the name format enwiki-20190920-pages-articles.xml.bz2 from `https://ftp.acc.umu.se/mirror/wikimedia.org/dumps/`

nonzero weight to one input feature. To systematically examine whether the classes of patterns extracted are correct and cover the data adequately, we report two metrics, namely a) number of examples selected with a query and how many of them are grouped by each pattern, and b) model accuracy (correct predictions) with respect to the number of examples per selection with a query and per group pattern.

Cross-Att^{ch}: Transformation Patterns For each language, we define specific queries: 3rd person plural present tense for Italian (MSD=*V;IND;PRS;3;PL*), 3rd person plural present positive imperative for Finnish (MSD=*V;ACT;PRS;POS;IMP;3;PL*) and imperfective aspect with agent semantic role for Tagalog (MSD=*V;IPFV;AGFOC*). The choice of MSDs is rather arbitrary: for illustrative purposes we select grammatical categories that contain enough examples to represent form variation of the corresponding morpheme. Table 3 present the extracted Cross-Att^{ch} patterns. For each query, we show patterns that group at least 5% of the examples selected with a query. The patterns are sorted by their number of examples in a decreasing order. For each presented pattern, we show an example mapped to this pattern and symbol mapping information. The latter lists, for each symbol in the pattern, all substrings mapped to this symbol along with their frequencies (within a group), if the number of distinct substrings is less than five elements. Otherwise, we show average length (≈) of substrings mapped to this symbol, or exact length (=), if it is the same for all of them. These symbol mappings also include bijection cases (↔) that were unmasked after grouping examples (as described in §4.3)

Table 3: Cross-Att^{ch} transformation patterns. *Q* is a query regular expression. The number of examples (*No of*) and accuracy (*Acc*) are shown per selection with a query and per group pattern.

We observe that in all three cases, the patterns recover inflection morphemes listed in grammars for studied grammatical categories as well as their form variation. For Finnish, the model correctly identifies morpheme -*koot* as well as its variant -*kööt* because of vowel harmony. Additionally, the patterns (3) and (4) display morphophonological processes on morphemes boundaries: if a stem ends with -*d* or -*l*, this ending is removed from the final form. In Italian, the morphemes for all three inflection classes are present in the patterns: -*ano* (-*are* class) -*ono* (-*ere* class) and -*scono* (-*ire* class). Besides, the separation of reflexive ending *si* is visible (pattern (2)) for the -*are* class. Tagalog patterns detect two frequent inflection classes corresponding to so-called *um*-verbs and *nag*-verbs. Analyzing symbolic mappings, we conclude that the pattern (1) encodes prefixation (the most frequent prefix in this group is *nag*) with subsequent copying of the first syllable and copying of the full lemma string. The pattern (2) expresses reduplication of the first consonant (which interestingly gets aligned to a tag rather than to the first character of the lemma), generating infix (the most frequent infix in this group is *um*), copying the second character of the lemma (vowel, as seen from the mapping statistics), and then copying of full lemma string.

Self-Att$^{\text{sub}}$: Lemma Patterns We analyze Self-Att$^{\text{sub}}$ lemma patterns to determine whether our model uses indeed subword segments when choosing the specific variant of a morpheme. Concretely, we use regular expressions on the target form to select examples corresponding to a specific form of morpheme, identified above with transformation patterns. Then, we map selected examples to their Self-Att$^{\text{sub}}$ patterns. Table 4 presents the queries and extracted patterns.[11] For each query, we list the most frequent patterns (sorted by frequency in a decreasing order) along with one segmented lemma example mapped to the pattern.[12] The segments of lemma examples, identified as salient (and presented in the patterns) are highlighted in bold.

We conclude that the subword regions identified by Self-Att$^{\text{sub}}$ patterns conform to a great extent to triggers of morpheme form variation listed in grammars. We note that although the regions for finding such clues (when they are phonological or lexical, and frequent) look plausible, their form is influenced by the results of BPE segmentation and may not be perfectly aligned with grammars. For example, Italian patterns show that the model's focus is on the endings of lemmas for all three classes. In case of reflexive verbs, where reflexive ending -*si* tends to be separated into a separate subword by BPE, the model correctly places focus on a more informative penultimate segment. The patterns extracted for Finnish, display the grammar rules too: the focus on the lemma endings -*aa* and -*ua* for the first group, and -*ää*/-*ä* for the second group, points directly to the harmony of back and front vowels, respectively. The model does not search for the clues in the vowel patterns of the stem but chooses a smart strategy to focus directly on the inflection endings for lemmas: they are frequent and already agree with the vowels found elsewhere in the stem to the left.

Table 4: Self-Att$^{\text{sub}}$ Lemma Patterns. *Q* is a query regular expression, *msd_fin* is *V;ACT;PRS;POS;IMP;3;PL*, and *msd_it* is *V;IND;PRS;3;PL*. The number of examples (*No of*) and accuracy (*Acc*) are shown per selection with a query and per group pattern.

Self-Att$^{\text{sub}}$: Performance Impact We evaluate the impact of the novel Self-Att$^{\text{sub}}$ component by comparing the performance of Cross-Att$^{\text{ch}}$Self-Att$^{\text{sub}}$ with that of the baseline model, Cross-Att$^{\text{ch}}$. For reference, we include the results of a) the hard monotonic attention (HMA) system of Wu and Cotterell (2019) which currently holds as the state-of-the-art on the reinflection task by rerunning their code; b) a variant of our system, Cross-Att$^{\text{ch}}$Self-Att$^{\text{ch}}$ where the encoder attention module is run over the characters of the lemma, instead of subwords. The latter corresponds to a limiting case of lemma segmentation where each character is a segment. We report accuracy and edit distance on the test set in Table 5. Additionally, we provide information on the number of trained parameters for each model. The number of parameters for Cross-Att$^{\text{ch}}$Self-Att$^{\text{sub}}$ model is the same as for its character variant Cross-Att$^{\text{ch}}$Self-Att$^{\text{ch}}$. The difference in the number of parameters across the languages is due to the variation of their character vocabulary sizes.

---

[11] For Tagalog, we note that we do not find any frequent patterns for e.g. a query "gold target=*nag**", which is in line with no explicit criteria for inflection class assignment in this language.

[12] We refer to the Appendix, Tables 6-7 for the full list of extracted patterns.

	Baseline	Our model	Comparison	
	Cross-Att^{ch}	Cross-Att^{ch}Self-Att^{sub}	Cross-Att^{ch}Self-Att^{ch}	HMA
Italian	95.40 (0.09) [*1,742K*]	96.70 (0.09) [*1,783K*]	**97.40** (**0.06**) [*1,783K*]	96.80 (0.29) [*8,647K*]
Finnish	93.80 (0.13) [*1,758K*]	**94.40** (**0.09**) [*1,798K*]	93.60 (0.12) [*1,798K*]	93.90 (0.13) [*8,709K*]
Tagalog	65.75 (1.21) [*1,739K*]	**69.98** (**0.92**) [*1,780K*]	66.81 (1.00) [*1,780K*]	63.39 (1.53) [*8,623K*]

Table 5: Accuracy (and edit distance) on the test set. The number of model parameters is given in squared brackets.

We observe, that the Cross-Att^{ch}Self-Att^{sub} model shows systematic improvements across all three languages over the baseline and reference models. Regarding the level of segmentation, the Cross-Att^{ch}Self-Att^{ch} system achieves higher results on Italian, where indeed, class variation can be associated with a certain character in a certain position. In terms of the number of trained parameters, the improvements due to the Self-Att^{sub} component are achieved by only adding a relatively small number of extra parameters compared with the baseline model, Cross-Att^{ch} . We also note that the performance of our systems is higher or on par with the state-of-the art model HMA, whereas the latter has an on-average sevenfold increase in the number of parameters in comparison with to that of Cross-Att^{ch}Self-Att^{sub} and Cross-Att^{ch}Self-Att^{ch} .

6 Discussion and Future Work

In the following, we discuss our proposed methodology in terms of two aspects, namely, interpretability for inflection (in terms of typological parameters) and ideas for performance improvement.

Interpretability for Inflection In terms of the typological parameter of **fusion**, the results of our experiments illustrate that our Cross-Att^{ch} pattern approach can effectively extract rules for concatenative morpheme forms as well as reduplication processes. What is beyond, at the moment, are nonlinear processes that are not always visible in orthography, e.g. tonal changes and internal stem changes. The latter, for example, is demonstrated by root and pattern morphology in Arabic and Hebrew, for which standard orthographies do not indicate most vowels.

Regarding **flexivity**, our Self-Att^{sub} pattern method can identify phonological (visible in orthography) as well as lexical triggers to the variation of inflection morpheme's form. However, the case of suppletive forms (English *go*→ *went*) would not be identifiable in patterns. Although suppletive cases are likely to be fairly rare in terms of word types, they seem to be only maintained in high-frequency words (Bybee, 1985). Therefore, although affecting only a small number of words, suppletion might be visible in patterns when studied together with word frequency (which is, at the moment, not possible because of the current practices for building inflection generation datasets).

The parameter of **exponence** encodes the extent to which single morphemes express multiple morphosyntactic features. For the class of neural models currently used for inflection generation, it is not possible to see a clear correspondence between the meaning assigned by humans and the model: as we see from Fig. 1 which illustrates polyexponence in Italian inflection, the model assigns separate characters of inflection morpheme -*scono* to different tags, whereas for humans, it is hard to break down this morpheme into smaller meaningful parts.[13]

Performance Future work can evaluate the impact of Self-Att^{sub} in combination with frequently used induction biases[14], as well as transformers paradigm, which recently proved to be effective on the task. (Vylomova et al., 2020).

7 Conclusion

We propose a novel approach for interpreting neural inflection models by extracting patterns from attention weights. To enhance the interpretability of this class of models, we design a linguistically motivated attention component over subwords that leads to a systematic performance improvement. Our experiments with linguistic rules induction illustrate the great potential of our methodology for linguistic research scaled to diverse typology.

Acknowledgments

This work has been partially supported by the SNSF grant no. 176305.

---

[13] This challenge is exemplified by the input features identity problem in attention weights (Brunner et al., 2019).

[14] For example, hard monotonic attention which is highly effective for Indo-European languages with concatentive morphology.

A Cross-Att^{ch} Transformation Patterns Algorithm

In this Section, we formalize Steps 2 and 3 of the algorithm for pattern extraction from character-level cross-attention weights presented in §5.

Algorithm 1: (Step 2) Inverse salient alignments mapping A and group prediction steps by generation type

```
Inputs:
$X \leftarrow [x_1 \dots x_n]$ ;                         // Lemma
$F \leftarrow [f_1 \dots f_n]$ ;                         // MSD
$Y \leftarrow [y_1 \dots y_m]$ ;                         // Target
$A \leftarrow [a_1 \dots a_m]$ ;           // Salient alignments
Init: $X\_pos\_map = \{\}$, $F\_pos\_map = \{\}$ will
  store salient mappings from input positions to
  prediction steps, grouped by generation type.
for $a_j$ in $A$:
    for $P$ in $a_j$: ;      // salient alignments to $y_j$
        if $P == X_i$: ;            // aligned to lemma
            if $x_i == y_j$: ;                     // copy
                add $j$ to $X\_pos\_map[X_i][c]$
            else:
                add $j$ to $X\_pos\_map[X_i][g]$
        else ($P == F_k$): ;          // aligned to tag
            add $j$ to $F\_pos\_map[F_k]$
Outputs: $X\_pos\_map$, $F\_pos\_map$
```

Algorithm 2: (Step 3.1) Replace characters in Y with indexed generation type symbols using salient alignments to F

```
Inputs: $F\_pos\_map$; $\tilde{Y}$=copy($Y$)
Init: $f2prev\_target = \{\}$; $f2ind = \{\}$
for $F_k$ in $F$:
    if $F_k$ in $F\_pos\_map$:
        for $j$ in $F\_pos\_map[F_k]$: ;     // $Y$ indexes
            if $f_k$ not in ($f2prev\_target$)):
                $f2ind[f_k]$=1; ;   // If nothing was aligned yet to $f_k$, we create an index
                if $\tilde{y}_j$ is not replaced:
                    $\tilde{y}_j \rightarrow f_k^1$
                else:
                    $\tilde{y}_j$+= $f_k^1$
            else:
                if ($f2prev\_target[f_k] + 1$) != $j$:
                    $f2ind[f_k]$+=1 ;   // If something was aligned to $f_k$, check the last target step saved. Only increment it if it's not the same
            index=$f2ind[f_k]$
            if $\tilde{y}_j$ is not replaced:
                $\tilde{y}_j \rightarrow f_k^{index}$
            else:
                $\tilde{y}_j$+= $f_k^{index}$
Outputs: $P^{tr}(Y) = \tilde{Y}$
```

Algorithm 3: (Step 3.2) Replace characters in X and Y with indexed generation type symbols using salient alignments to X

```
Inputs: $X\_pos\_map$, $P^{tr}(Y)$
Init: $c_{index} = 1$; $g_{index} = 1$; $\tilde{X}$=copy($X$);
  $\tilde{Y} = P^{dec}(Y)$
for $X_i$ in $X$:
    if $X_i$ in $X\_pos\_map$:
        $c(X_i) = X\_op\_map[X_i][c]$
        $g(X_i) = X\_op\_map[X_i][g]$
        if $c(X_i) == [j]$ and $x_i == y_j$ and
          $g(X_i) == \emptyset$: ;   // $X_i$ is 1-to-1 copy
            if $X_{i-1}$ is not adjacent 1-to-1 copy:
                $c_{index} + = 1$
        $\tilde{x}_i$ = $C^{c_{index}}$; $\tilde{y}_j$ = $C^{c_{index}}$
    else:
        if $c(X_i)! = \emptyset$ and $g(X_i)! = \emptyset$:
            $mask =$‘’; $full\_index = []$
            for $k$ in $c(X_i)$:
                $c_{index}$+=1
                add $c_{index}$ to $full\_index$
                if $\tilde{y}_k$ is not replaced:
                    $\tilde{y}_k \rightarrow C^{c\_index}$
                else:
                    $\tilde{y}_k$+= $C^{c\_index}$
            $mask$+=‘$C^{full\_index}$’
            $full\_index = []$
            for $k$ in $g(X_i)$:
                $g_{index}$+=1
                add $g_{index}$ to $full\_index$
                if $\tilde{y}_k$ is not replaced:
                    $\tilde{y}_k \rightarrow G^{g\_index}$
                else:
                    $\tilde{y}_k$+=$G^{g\_index}$
            $mask$+=‘$G^{full\_index}$’
            $\tilde{x}_j \rightarrow mask$
Outputs: $P^{tr}(X) = \tilde{X}$, $P^{tr}(Y) = \tilde{Y}$
```

Abstract

Sequence-to-sequence based models have recently shown promising results in generating high-quality questions. However, these models are also known to have main drawbacks such as lack of diversity and bad sentence structures. In this paper, we focus on question generation over SQL database and propose a novel framework by *expanding*, *retrieving*, and *infilling* that first incorporates flexible templates with a neural-based model to generate diverse expressions of questions with guidance of sentence structure. Furthermore, a new activation/deactivation mechanism is proposed for template-based sequence-to-sequence generation, which learns to discriminate template patterns and content patterns, thus further improves generation quality. We conduct experiments on two large-scale cross-domain datasets. The experiments show that the superiority of our question generation method in producing more diverse questions while maintaining high quality and consistency under both automatic evaluation and human evaluation.

1 Introduction

With a growing demand for natural language interfaces for databases, automatic question generation from structured query language(SQL) query has been of special interest (Xu et al., 2018). Recently, diversity-aware question generation has shown its effectiveness in improving down-stream applications such as semantic parsing and question answering tasks (Guo et al., 2018; Sultan et al., 2020). Although neural sequence-to-sequence based generation has been a dominant approach and is able to produce a meaningful description for SQL queries, existing methods still suffer from the lack of diversity as well as bad sentence structures (Gao et al., 2019).

In the neural-based approaches, conventional ways of generating diverse sentences focus on approximate decoding techniques such as beam search (Li et al., 2016a,b; Iyyer et al., 2018) and temperature sweep (Caccia et al., 2018). Those decoding strategies generate diverse samples while sacrificing the quality of sentences. Variational auto-encoders (VAEs) have been used to generate various sentences by applying additional information as latent variables (Hu et al., 2017; Guo et al., 2018; Chen et al., 2019; Shao et al., 2019; Ye et al., 2020). However, implicit latent representation provides limited controllability over sentence structure and can be difficult to adapt to a new domain. Paraphrase (Fader et al., 2013; Berant and Liang, 2014) and syntactic-based methods (Dhole and Manning, 2020) have also been studied. However, learning a paraphrasing model relies on a large number of domain-specific paraphrase pairs, which is difficult to obtain for target databases. Besides, syntactic-based approaches apply syntactic parsers or semantic rules to the natural language utterance, thus are not applicable to SQL-to-question generation.

In the rule-based generation systems, the templates work as essential prior knowledge that contains the structural information of sentences (Wang et al., 2015; Song and Zhao, 2016; Krishna and Iyyer, 2019). This ensures the generation contains fewer grammatical errors and performs better with extractive metrics (Wiseman et al., 2017; Puzikov and Gurevych, 2018). However, their template formats are mostly strict and the valid content for each chunk should be pre-defined, which makes large set of templates difficult to obtain.

In this paper, we propose a novel method that incorporates template-based generation with a neural sequence-to-sequence model for diversity-aware question generation. Instead of applying strict templates, we use flexible templates that can be collected efficiently with less expense. These flexible templates provide high-level guidance of sentence structure while also enable sufficient flexibility for a neural-based model to fill chunks with content de-

tails. We present our method as a three-stage framework including *expanding*, *retrieving*, and *infilling*. In the *expanding* stage, we take advantage of existing large-scale cross-domain text-to-SQL datasets to extract and collect the flexible template set automatically. In the retrieving stage, given a SQL query, the best templates are retrieved from the collected template set by measuring the semantic distance of SQL and templates in a joint template-SQL semantic space. In the filling stage, we treat each template as a masked sequence and explicitly force the generator to learn question generation with the constraint of the template. In order to help the generator to discriminate template patterns and content patterns, a unique activate/deactivation mechanism is designed for the generator to learn when to switch between template-copying state and content-filling state.

We conduct experiments on two large-scale cross-domain text-to-SQL datasets. Compared to existing approaches, our method achieves the best diversity result for both datasets with both automatic evaluation and human evaluation, while maintaining competitive quality and high consistency with SQL queries. We further demonstrate that the designed modules each contribute to a performance gain through an ablation study.

2 Related Work

2.1 Diverse Text Generation

In order to generate diverse expressions automatically, paraphrase-based methods (Qian et al., 2019; Fader et al., 2013; Berant and Liang, 2014; Dong et al., 2017; Su and Yan, 2017) have been studied. Wang et al. (2015) proposes to iteratively expand the template set and lexicons given a small number of template seeds and a large paraphrase corpus. Syntactic-based generation (Iyyer et al., 2018; Dhole and Manning, 2020) processes the given text with natural language processing techniques to produce high-quality and diverse sentences with pre-defined templates. However, the methods are not designed to deal with SQL queries and noisy table content. In recent years, neural network-based models have been widely used in text generation (Pan et al., 2019). Many studies attempt to diversify text generation by tuning latent variables of different properties, such as topic, style, and content (Fang et al., 2019; Ficler and Goldberg, 2017; Shen et al., 2019), while our method focuses on explicitly changing the sentence structure. In exemplar-based systems (Cao et al., 2018; Peng et al., 2019; Chen et al., 2019), the exemplar works as a soft constraint to guide the sequence-to-sequence generation and realize controllable diverse generation. Wiseman et al. (2018) proposes to learn a hidden semi-Markov model decoder for template-based generation for knowledge records. Most existing work requires either paraphrase pairs of the same input, reference sentences of similar content, or work effectively only in a single domain. Unlike existing works, our method only takes advantage of the large-scale cross-domain SQL-to-text datasets to collect a large number of templates. We extract templates from the datasets directly to maintain the quality of the templates. In order to find proper templates for a given SQL query, we learn a joint semantic space by instance learning and retrieve the best templates with closest semantic distance.

2.2 Question Generation

The question generation task relates to many applications such as question generation over knowledge base records (Wang et al., 2015), data-to-text generation (Wiseman et al., 2017) and question generation for question answering(QA) systems (Tang et al., 2017; Sun et al., 2019). SQL-to-question task differs from the other tasks in that SQL queries typically include new entities over different databases, which makes cross-domain generation a significant challenge. Xu et al. (2018) explores the graph-structured information in a SQL query and proposes a graph-to-sequence approach for generation. Guo et al. (2018) proposes to apply a copy mechanism and latent variables to map low-frequency entities from SQL queries to questions and generate diverse questions in an uncontrolled way. Existing SQL-to-question approaches aim at generating high-quality questions, while the diversity of the generation is less explored. In this work, we focus on generating diversified questions with the guidance of templates from cross-domain datasets.

3 Problem Formulation

Given a SQL query as the input sequence, question generation over database aims to generate a natural language question as an output sequence that accurately reflects the same meaning as the given SQL query. In this work, we generate the question by introducing an intermediate template in the generation process. Therefore, by applying

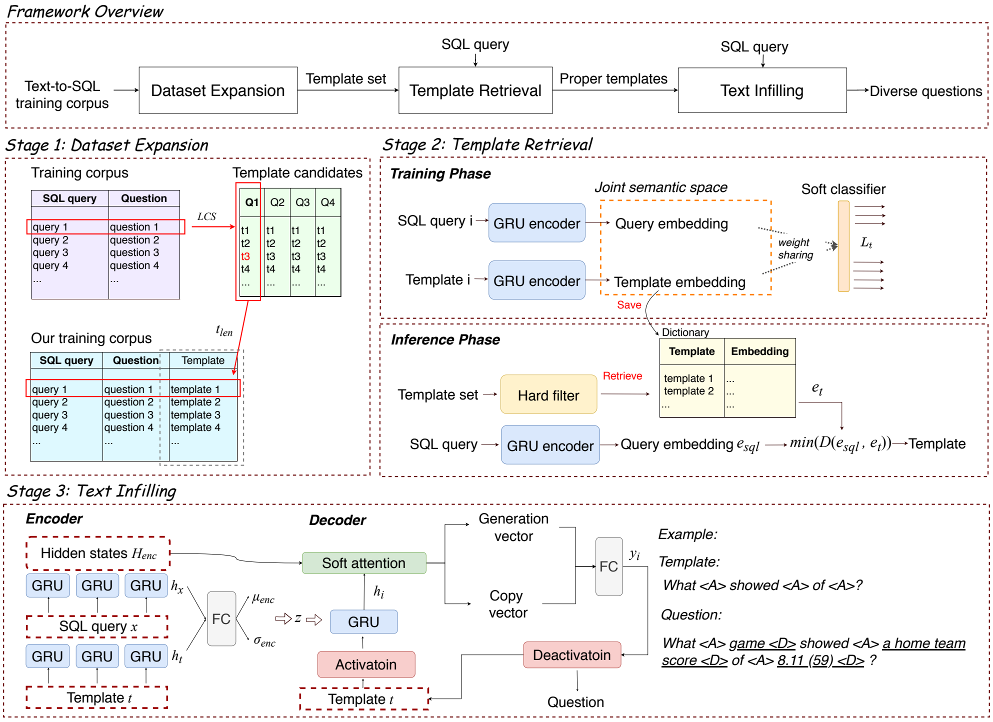

Figure 1: Architecture of our Framework.

different templates, we can generate diverse expressions of questions. Let $x = [x_1, x_2, ..., x_{|x|}]$ denote the given SQL query, $y = [y_1, y_2, ..., y_{|y|}]$ denote the gold-standard question, and $t = [t_1, t_2, ..., t_{|t|}]$ denote the corresponding template. Given a neural-based system with a set of learnable parameters θ_t^* and θ_q^*, the two-stage objective in this work can be formulated as follows:

$$\theta_t^* = \arg\max_{\theta_t} P(t|x)$$

$$\theta_q^* = \arg\max_{\theta_q} P(y|x,t)$$

4 Methodology

In this section, we introduce our framework, which learns question generation from SQL queries with the guidance of various templates, so as to increase the diversity of generation.

4.1 Framework Overview

We illustrate the framework that models the generation process in Figure 1. In brief, it includes three main stages: *expanding*, *retrieving*, and *infilling*.

Dataset Expansion The purpose of this step is to acquire a training dataset consisting of triplets `<query, question, template>`. Previous methods usually require a large corpus containing paraphrased questions to learn template structures; meanwhile, for existing text-to-SQL datasets, only `<query, question>` pairs are provided instead. To tackle those challenges, we design the longest common subsequence (**LCS**) based algorithm to automatically extract templates for each `<query, question>` pair without requiring the paraphrase pairs. Details of the algorithm are introduced in Section 4.2.

Template Retrieval After obtaining the *expanded training set*, all templates are gathered to form a large *template set* to generate diverse questions. To improve the quality and rationality of the generation, it is essential to retrieve suitable templates for it. A proper template should be consistent with the content information in a specific SQL query. For example, when the given query is `SELECT Population WHERE ( City = New York)`, the template `When is the <ph> of <ph> ?` should not be selected. For that purpose, we propose a soft classifier to learn a *joint SQL-template space*. In this way, the semantic distance can be measured between the two modalities, so that we can select proper templates by the closest semantic distance. Besides, since templates show higher inter-class similarity with the same SQL pattern, we also apply a *hard filter* to exclude the templates paired with different SQL patterns. Details of the soft classifier are introduced in Section 4.3.

Text Infilling With a encoder-decoder model based on gated recurrent unit (GRU), we conduct question generation in the way of text infilling. The query x and template t are encoded into vectors separately by the bi-directional GRU encoder (Cho et al., 2014). Following the work of Gu et al. (2016) and Guo et al. (2018), we leverage the soft-attention and copy mechanism in the decoder construction. A Gaussian latent variable is adopted to capture the query and template variations. In the decoding process, a template t is fed into the decoder as a supervised signal to generate questions dynamically and sequentially. We propose an activation/deactivation mechanism to enforce the decoder to differentiate between the template patterns and the content patterns instead of randomly masking slots. In this way, the decoder can learn when to switch between the template reading and the content filling during generation. Details of the activation/deactivation mechanism are illustrated in Section 4.4.

4.2 Flexible Template as LCS

Consider a SQL query as a combination of a SQL pattern (i.e., the query with its content words removed) and the table information as follows:

```
SELECT COUNT( PLAYER ) WHERE
      (STATE = 'Texas')
```

where the underlined tokens are content from the table and `SELECT COUNT(<ph>) WHERE (<ph> = <ph>)` is a typical SQL pattern. Similarly, questions are composed of content words and template words. Since template words are often reused more frequently than content words, we design an effective method to extract most template words for each question in the training set. For the i-th question Q_i, we record its longest common sub-sequence (LCS) with each other question as a candidate template and construct a candidate-template dictionary d_i. The keys in d_i are the candidate sequences, and the corresponding values are the lengths of the sequences. After that, we choose the longest candidate from d_i as the template for the i-th question. The pseudo-code is described in Algorithm 1.

The candidate templates should satisfy the following rules:

- Each template should appear over 20 times.
- Each template should includes at least one of the keywords: *where, what, which, when, why, who, how, name, tell* .

When applying LCS, we mark the possible positions for content insertion between template words by placeholder `<ph>`, and format the templates like this instance: `Which <ph> has the largest <ph> ?` By ignoring the lengths of content word sequences, the templates become more flexible and can adapt to more scenarios.

Algorithm 1 LCS-based Template Extraction

```
Input: question set $Q = [q_1, q_2 ..., q_M]$; keyword set $W$
Output: Template set: $T_{len}$
for all $q_i \in Q$ do
    Initialize dictionary $d_i$
    for all $q_j \in Q$ do
        $c = LCS(q_i, q_j)$
        if $c \bigcap W \neq \emptyset$ then
            if $c \notin d_i.keys$ then
                $d_i[c] = 0$
            end if
            $d_i[c] += 1$
            Record position index for content
        end if
    end for
    for all $c \in d_i.keys$ do
        if $d_i[c] < 20$ then
            delete $d_i[c]$ from $d_i$
        end if
    end for
    $t_{len} = \arg\max_c(length(d_i.keys))$
    Update $T_{len}$ by adding $t_{len}$
end for
return $T_{len}$
```

4.3 Learning Joint SQL-Template Space

As a sub-sequence of a question, a template should be close to the query in the semantic space if it is from the corresponding question, and be far away from the query if it is from an irrelevant question. Based on this intuition, we propose a soft classifier to learn a joint SQL-template space.

Soft Classifier. Classification models have been widely used in visual/textual applications. In a retrieval task, the classification model can learn feature embedding for the input, and its best matching counterpart can be found from a database by measuring the cosine distance between their embeddings. Inspired by this, we consider every `<SQL query, template>` pair in training set S as a distinct class, and learn the feature embeddings by instance-level classification. We represent each `<SQL query, template,`

`class>` triplet by $< x, t, n >$. Considering SQL queries and templates as objects constructed with different syntax, we encode them with two separate GRU encoders:

$$e_x = GRU_x(x)$$
$$e_t = GRU_t(t)$$

where e_x, e_t are query embedding and template embedding, respectively. In order to map SQL queries and templates to a joint feature space, we add a share-weight fully-connected layer W_s with softmax as the final classifier. The predicted probabilities over all instances are calculated as follows:

$$P(\cdot|x) = Softmax(W_s^T tanh(e_x))$$
$$P(\cdot|t) = Softmax(W_s^T tanh(e_t))$$

We jointly train the encoder and the classification layer with the following loss function:

$$\mathcal{L}_t = -\sum_{(x,t,n)\in S} (logP(n|x) + logP(n|t))$$

Inference. To enable efficient retrieval of templates, we store the template embeddings in a dictionary. In the inference phase, we can feed any SQL query into GRU_x to produce the query embedding, then remove the improper templates by a hard filter. We calculate the cosine distances between the query and the remaining templates, and sort them in descending order. The top-k nearest templates are selected for question generation.

$$\mathcal{D}(e_x, e_t) = \frac{e_x}{\|e_x\|_2} \times \frac{e_t}{\|e_t\|_2}$$

Avoid Overfitting. Since each class includes only one instance, we cannot use the classification loss of the validation set V to detect overfitting. Instead, we detect the overfitting by computing the average rank error R for the validation set:

$$R = \frac{1}{|V|^2}\sum_{i=1}^{|V|}(|r_i^a - r_i^p|)$$

where r^p and r^a are the predicted rank and actual rank, respectively. We stop training when R keeps increasing.

4.4 Decoding with A/D mechanism

The key idea of the proposed decoding method is that the generation process can be decomposed into a series of sub-generation tasks that are spaced by tokens in the template. During each sub-generation, the model can generate tokens of variable lengths. Since the decoder generates text word-by-word, it should determine where to switch between a content-filling state and a template-copying state, namely the **activation** or **deactivation** state, respectively. To achieve this, we require the decoder to activate/deactivate (A/D) generation with special switch symbols `<A>` and `<D>`. Therefore, when the decoder generates a symbol `<A>`, it changes the template-copying state to the content-filling state; when the decoder generates a `<D>`, it terminates the content-filling state and switches to the template-copying state. We also set a maximum length for each sub-generation to avoid the generation of unbounded sequences. In practice, before we train the question generator, we rewrite the question and template as follows (as an instance):

Template: `<BEG> Which <A> has the largest <A> ? <END>`

Question: `<BEG> Which <A> one <D> has the largest <A> population among U.S. cities <D> ? <END>`

We apply a pointer p to point to the current template token. With a simple GRU decoder, the state s and the generated token $\widehat{y}_i$ at the i-th step can be determined as follows:

$$s_i = \begin{cases} 1, \ \widehat{y}_{i-1} =< A >, \\ 0, \ \widehat{y}_{i-1} =< D >, \\ s_{i-1}; otherwise. \end{cases}$$

$$\widehat{y}_i = \begin{cases} Softmax(GRU(\widehat{y}_{i-1}, h_{i-1}^{dec})), \ s_i = 1, \\ t'_p, \ s_i = 0. \end{cases}$$

where h_{i-1}^{dec} is the hidden state of the $(i-1)$-th step, and t'_p is the current token of the template-copy operation, which should be updated after each copy. $\widehat{y} = [\widehat{y}_1, \widehat{y}_2, ...\widehat{y}_{|y|}]$ is the generated sequence. y' and t' are the rewritten question and template[1]. We apply teacher forcing during training, and feed the rewritten question y' as input to the decoder. During inference, we feed the rewritten template t' as input to the decoder. The training objective for generator G_q can be factorize as follows:

$$\max_{\theta_t} E_{<x,y>\sim D}[P_{\theta_q}(y'|x, t')]$$
$$= \max_{\theta_t} E_{<x,y'>\sim D}[\prod_{i\in 1:N} P_{\theta_q}(y'_i|x, t', y'_{i-1})]$$

---

[1] Code implementation is available at https://github.com/xiaojingyu92/ERIQG

In order to further diversify the expression of content, we introduce a latent variable z to the model. z relies on both SQL query x and template t'. We make Q a posterior distribution of z given x, t'. Then the evidence lower bound(ELBO) loss for it is:

$$\mathcal{L}_q = -E_{z \sim Q}(\sum_{i=1:N} log(P_{\theta_q}(y_i|x, t', z, y_{1:i-1})))$$
$$+ D_{KL}(Q(z|x, t')||P_{\theta_q}(z))$$

where $Q_q(z|x, t') \sim N(\mu, \sigma)$. We apply a re-parameterization trick, making $z \sim N(0, I)$ and μ, σ learnable deterministic functions.

Note that the function of the template and latent variable do not overlap with each other. A large number of templates ensures the diverse sentence structure in generated questions, while the latent variable produces various expression of the content in the slots. As a part of the sentence, the `<A>` and `<D>` symbols join the back-propagation computation for optimizing the decoder's parameters. They work as additional information that guides the decoder to discriminate templates and content patterns, and learn when to terminate infilling and switch to template-copying state at each slot.

5 Experiment

Dataset To validate our framework's capability in generating diverse and controllable questions, we conduct experiments on two large-scale cross-domain text-to-SQL datasets: WikiSQL (Zhong et al., 2017) and Spider (Yu et al., 2018). WikiSQL contains 80654 query-question pairs derived from 24241 different schemas, with both validation set and test set released. Spider contains 10181 query-question pairs in 138 domains, with the validation set published. We follow the provided split settings for training and testing.

Setup We first construct the template set from the training set using our expansion method. For each SQL query in the test set, we retrieve the $k-1$ most relevant templates from the template set to generate $k-1$ different questions. We also include one question with template `<BEG> <A> <END>` to evaluate the model's capability in generating a complete sentence. Thus k questions for each SQL query are provided for evaluation. For our experiments, we set $k = 5$.

Baselines We compare our model(**ERI**)'s performance to models based on the baseline approach **QG** (Guo et al., 2018) with different diverse-sentence generation strategies. (1) **Latent Variable(QGLV):** Guo et al. (2018) applies a sequence-to-sequance network with a copy mechanism for question generation from SQL. A latent variable is introduced to generate diverse questions. (2) **Temperature Sweep(TEMPS):** We apply temperature sweep (**ts**) (Caccia et al., 2018) for decoding in **QG**. (3) **Beam Search(BEAMS):** We further combine **QG** with beam search (Li et al., 2016b) to generate diverse questions. In practice, we set the beam width to 5 and obtain sentences with top-5 highest probabilities for comparison. A Boltzmann temperature parameter α is applied to modulate the entropy of the generator. In practice, we set α = 0.7 as suggested and obtain 5 generated sentences for each query.

Evaluation Metrics We adopt the following automatic metrics to measure the quality of generated questions. (1) **maxBLEU:** The max BLEU-4 score among 5 generated questions. (2) **Coverage:** (Shao et al., 2019) This metrics measures the average proportion of input query covered by the generated questions. (3) **ParseAcc:** We use neural semantic parsers SQLova (Hwang et al., 2019) and Global-GNN (Bogin et al., 2019) to parse WikiSQL and Spider respectively. The semantic parsers translate the generated question into SQL query and calculate the exact-match accuracy with the input SQL query as the ground-truth. A higher accuracy score means the generated questions are more natural and consistent with the given SQL queries.

We adopt the following automatic metrics to measure the diversity of generated questions. (1) **self-BLEU:** (Zhu et al., 2018) The average BLEU-4 of all pairs among the k questions). (2) **self-WER:** (Goyal and Durrett, 2020) The average word error rate of all pairs among the k questions. A lower self-BLEU score and a higher self-WER score indicate more diversity in the result. (3) **Distinct-4:** (Li et al., 2016a) It measures the ratio of distinct n-grams in generated questions.

5.1 Automatic Evaluation

The automatic evaluation results are reported in Table 1 and 2. Our model ERI outperforms all baseline models in terms of the three diversity metrics for both datasets, except the self-BLEU on Spider. This shows the effectiveness of ERI in improving the diversity of its generation. Note that TEMPS performs less favorably in terms of qual-

ERI	**4.56**	3.68	**4.31**

Table 3: Human evaluation results.

ity and diversity, as the temperature parameter α is a sensitive factor for the generation and needs tuning further. The expanded template set provides various valid sentence structures for expressing the same question which significantly contributes to the diversity expressions. But it also decreases the word-level overlapping, which leads to a relatively low maxBLEU score on WikiSQL. However, BLEU score may not be a suitable measurement for diversity-aware generation (Su et al., 2020; Shao et al., 2019). As the BLEU calculates the overlapping of n-grams, it does not necessarily reflect the quality of template-based generation. We illustrate that by an example of our model in Table 4. Although the BLEU scores are low, the generated questions are fluent and consistent with the SQL query with diversified structures.

To further measure the question quality and consistency in the semantic parsing task, we calculate the ParseAcc score. Our model performs competitively with QGLV on WikiSQL and shows a substantial improvement on Spider. The ParseAcc scores with ground-truth questions are 81.60% and 65.96% on WikiSQL and Spider, respectively. Our model also outperforms the baselines in the coverage of field names and values in the SQL query, indicating that essential terms from input are learnt and translated to questions. We also show the result of our model without the latent variable. In this setting, diversity of generated questions solely depends on selected templates. Without the latent variable, the proposed framework still outperforms the baselines in diversity metrics while maintains a good quality, which also supports that template contributes the most to the diversity of generation.

5.2 Manual Evaluation

To evaluate the quality of the generation, we run a manual evaluation to measure the quality and diversity for 800 SQL-question pairs from WikiSQL test set, produced by baseline models and our model (with $k = 5$). Each rater gives a 5-point scale for each SQL-question pair regarding the (1) **Fluency:** grammatical correctness, (2) **Consistency:** the semantic alignment with the corresponding SQL query, and (3) **Diversity:** the diverse expression of the generated questions.

We employ Fleiss' Kappa for inter-rater reliability measurement. The Kappa scores are 0.77, 0.60, 0.75 for fluency, consistency, and diversity, respectively, which indicates a good agreement on the scores. The results are presented in Table 3. Our model outperforms the baseline models in diversity and fluency. It can achieve the best trade-off for the three measurements. Although QGLV and BEAMS show the best performance in generating

SQL query	SELECT COUNT (rd #) WHERE pick # $<$ 5
Ground-truth	how many rounds exist for picks under 5 ?
Q1 (BLEU=2.79) :	**what is the number of** rd **when the** pick number **is less than** 5 **?**
Q2 (BLEU=11.73):	**how many** rounds **have a** pick # **less than** 5 **?**
Q3 (BLEU=2.79) :	**what is the total number of** rd **where the** pick **is less than** 5 **?**
Q4 (BLEU=2.02) :	**tell me the total number of** rd **for** pick **less than** 5
Q5 (BLEU=1.51) :	**for the** pick **less than** 5 **, what was the total number of** rd # **?**

Q5:	where week bye and week attendance

Table 8: Question generation example on WikiSQL.

high-quality sentences, they tend to create questions of fixed structures with only minor changes in expressions. With our method, the templates provide substantial changes in sentences' structures, which validates the benefit of the proposed template-extraction method. Examples from our model and the baselines are given in Table 8.

5.3 Ablation Study

For the ablation study, we present experimental results to verify performance in two aspects: (1) whether the generator in our model benefits from learning with the activation/deactivation mechanism; (2) whether our model maintains the consistency by selecting suitable templates in the joint semantic space.

Evaluation on Generator To analyze the ability of generating high-quality questions from the given templates, we extract the templates from the test set and use the corresponding template to guide the question generation. We measure the generation quality by **BLEU**, **NIST**, **ROUGE**, and **METEOR**. In order to analyze the impact of various modules in our generator, we evaluate the following versions of our framework: (1) **ERI w/o T** model that does not use templates for encoding and decoding. (2) **ERI w T** model where templates are encoded but not used as the input for decoding. (3) **ERI w/o A/D** model that applies the generator with the decoding strategy similar to a seq2seq model in Zhu et al. (2019). It treats each slot as a segment, and predicts each segment as an independent sentence. (4) **ERI** model that has all designed modules, including the A/D mechanism. The results are presented in Table 5 and 6. Our model outperforms existing methods in four metrics. Using template information improves our model on both datasets. The segmented-based infilling method gains further improvement, which shows the effectiveness of providing templates as hard constraints. By introducing the A/D mechanism to decoding, our model has seen further boosts, which demonstrates that the A/D mechanism enhances the learning of generation from the templates.

SQL-Template Consistency To validate the im-

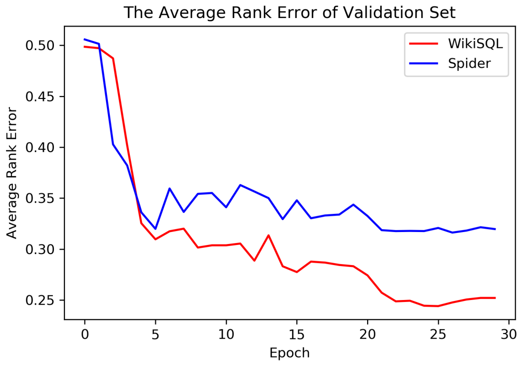

Figure 2: Average rank error in training phase.

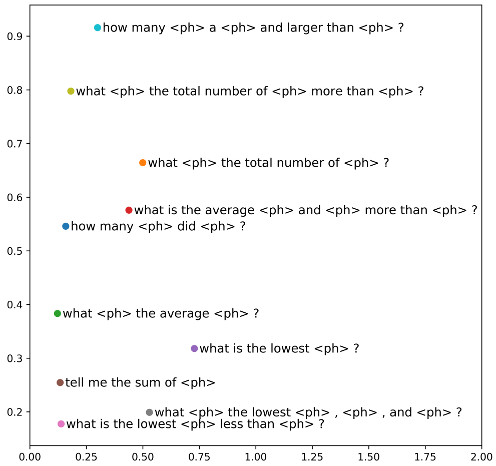

Figure 3: Visualization of the template features by tSNE.

pact of our template retrieval method, we show the average rank error of soft classifier during the training phase in Figure 2. For both datasets, the rank error decreases during training, which indicates the soft classifier can capture the semantic relation between SQL queries and templates. To observe if the soft classifier affects the performance by selecting the proper template, we also compare our 2-stage template retrieval to random strategies and hard filter in mean average precision (MAP). The result is presented in Table 7. Compared to hard filter, the soft classifier improves the MAP by 4.4%, which validates the effectiveness of the proposed template retrieval method.

Visualization of Joint Space To visualize the similarity of templates, we map feature samples to 2-dimensional space by t-Distributed Stochastic Neighbor Embedding(t-SNE) in Figure 3. The features from similar SQL-template pairs preserve closer distances, which shows the effectiveness of our instance-level classification in learning the semantic meaning in the joint feature space.

6 Conclusion

In this paper, we present a novel framework for question generation over SQL database to produce more diversified questions by manipulating the templates. We expand the template set from cross-domain SQL-to-text datasets, and retrieve proper templates from a template set by measuring the distance between the templates and the SQL query in a joint semantic space. We propose an activation/deactivation mechanism to make full use of templates to guide the question generation process. Experimental results have shown that the presented model can generate various questions while maintains their high quality. The model has also improved the matching between the templates and the content information of SQL queries.

Abstract

Word embedding is considered an essential factor in improving the performance of various Natural Language Processing (NLP) models. However, it is hardly applicable in real-world datasets as word embedding is generally studied with a well-refined corpus. Notably, in Hangeul (Korean writing system), which has a unique writing system, various kinds of Out-Of-Vocabulary (OOV) appear from typos. In this paper, we propose a robust Hangeul word embedding model against typos, while maintaining high performance. The proposed model utilizes a Convolutional Neural Network (CNN) architecture with a channel attention mechanism that learns to infer the original word embeddings. The model train with a dataset that consists of a mix of typos and correct words. To demonstrate the effectiveness of the proposed model, we conduct three kinds of intrinsic and extrinsic tasks. While the existing embedding models fail to maintain stable performance as the noise level increases, the proposed model shows stable performance.

1 Introduction

Word embedding refers to the process of generating vectors that contain semantic and syntactic information of languages. Machines can understand the meaning of words through the word embeddings. Several embedding methodologies have been proposed to improve various Natural Language Processing (NLP) models' performance, such as machine translation, sentence classification, and text generation (Mikolov et al., 2013; Pennington et al., 2014; Bojanowski et al., 2017).

Word2vec (Mikolov et al., 2013) generates word vectors using the contextual data of words based on the distributional hypothesis. Word2vec assigns a unique vector to each word, and has proved its effectiveness by improving various systems' performance. Similarly, GloVe (Pennington et al., 2014) that uses co-occurrence information of each word found throughout the corpus, generates word vectors that contain semantic and syntactic characteristics.

However, Word2vec and GloVe suffer from being dependent on the training corpus. In particular, they do not include the word embeddings that did not appear in the training process. To tackle this OOV problem, replacing unseen words with a unique token "UNK" is widely used as a solution. This method can allow the model to deal with OOV words. However, this countermeasure reduces the performance of the system. This is because several unseen words are recognized as having the same meaning. Hence, the importance of each word is ignored and recognized as noise.

This OOV problem amplifies when dealing with real-world datasets that contain a large number of typos and intended slang that has not been included in the training phase. In particular, if words relevant to the core meaning of a sentence are replaced as OOV, the system's performance will drastically reduce. For example, suppose an evaluation set for a sentiment classification task contains typos such as "funnnny" and "coooool". When predicting the sentiment of the sentence, the original meanings of the two words, "funny" and "cool", serve as decisive information. However, the sentiment classification accuracy drastically reduces when these words are processed as "UNK" and encoded to have the same meaning. Therefore, to increase the effectiveness of NLP models, robust word embeddings are strongly needed in noisy text.

Meanwhile, FastText (Bojanowski et al., 2017) presents a method to address the OOV problem. FastText follows the training process of Word2vec,

April 19 - 23, 2021. ©2021 Association for Computational Linguistics

but understands a word as a set of n-gram subword information. For example, the meaning of the word 'funny' is learned by decomposing the characters into n-grams such as 'fun', 'unn', and 'nny.' In this way, FastText can generate embeddings for OOV words that did not appear during the training phase by utilizing this subword information.

FastText is suitable for languages that have characteristics of isolated words (e.g., English). This is because the meaning of the word can be inferred through the summation of subword information: prefix, root, and postfix. However, in the case of agglutinative languages such as Hangeul (Korean writing system), it is not easy to fully understand the meaning of a word by merely referring to the summation of the subword information. A word in Hangeul consists of at least one to ten or more different morphemes, which make extracting internal information complicated. Therefore, to decipher a Hangeul word, it is necessary to be sensitive when looking for the vital subword information within the word.

CNN captures locational and morphological information of words and characters, and many studies using CNN have achieved good performance in various NLP tasks (Zhang et al., 2015; Kim et al., 2016, 2018; Ma and Hovy, 2016). Inspired by this, in this paper, we propose a CNN-based channel attention word embedding model that generates robust Hangeul embeddings for noisy text. The proposed model utilizes CNN to extract n-gram pairs from Korean words. The model then applies an attention mechanism to features from each channel representing the inherent information in the n-gram pairs. An input word for training is replaced with intentionally generated typos with a certain probability of adapting to typos. This generated word vector enhances the semantics of a word by predicting the context words. In summary, the contributions of this paper are three-fold:

- We propose a robust word embedding model against typos by training it with intentionally generated typos.
- We introduce a channel attention mechanism to utilize the distinctive structure of Hangeul words.
- We demonstrate the effectiveness of the proposed model on the noisy text through word analogy, language modeling, and sentiment classification tasks.

The remainder of the paper is organized as follows. In Section 2, we investigate related work and discuss key differences from ours. In Section 3, we describe the proposed methodology in detail. Furthermore, we present the evaluation results and analyze the performance in Section 4 and 5, respectively. Finally, Section 6 contains the conclusion.

2 Related work

In this section, we review previous studies on 1) embedding generation methods that are robust to typos and 2) embedding generation methods that consider the unique characteristics of Hangeul.

2.1 Typos word embedding methods for English

There have been many studies for dealing with OOV problems (Bojanowski et al., 2017; Belinkov and Bisk, 2018; El Boukkouri et al., 2020). Unlike unseen words, typos require a different approach in that the originally intended word is likely to be known. RoVe (Malykh et al., 2018) and MOE (Piktus et al., 2019) explored the methodologies to deal with typos. RoVe (Malykh et al., 2018) utilized the English word's structural features as prefix, root, and postfix. The target word is encoded into Beginning, Middle, and End vectors. Embeddings generated in this way maintain robust model performance, although a noise level of the downstream task increases. However, RoVe performs poorly in generating agglutinative embeddings in languages such as Hangeul. As mentioned earlier, this is due to the feature of agglutinative languages where dozens of morphemes are combined to form a word. In other words, dividing morphemes into three parts – Beginning, Middle, and End – is not sufficient to comprehend Hangeul words.

MOE (Piktus et al., 2019) introduced supervised learning for misspelling patterns to FastText's training mechanism. The model was explicitly trained to infer the original meaning of the word from the irregular shape of typos by increasing the similarity between them. In this way, MOE was trained on typo data collected from real users on the web. Consequently, MOE showed stable performance for unseen words in intrinsic and extrinsic tasks. However, MOE generates the word embeddings with linear combinations of the constituent subwords. In other words, the word vectors do not reflect the differences in importance among the subword information. This is insufficient to fully

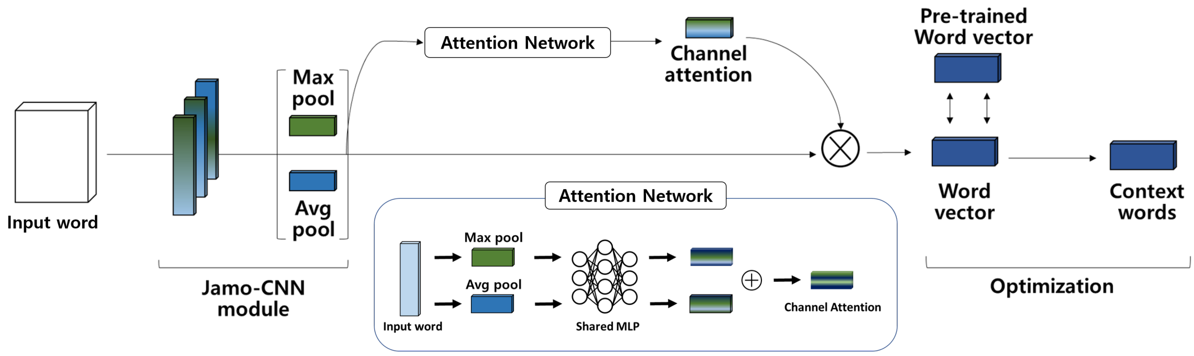

Figure 1: Overall framework for the word embedding generating system proposed in this paper.

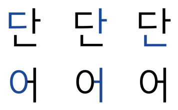

Figure 2: Example of the constituent of a Korean word ”단어 (word)”.

explain the meaning of words in complex agglutinative languages such as Hangeul. To generate effective Hangeul word embeddings, differentiating importance across n-gram pairs is necessary.

2.2 Word Embedding Methods for Korean

Ko-FastText (Park et al., 2018) and other morpheme-based studies (Lee et al., 2018; Nam and Kim, 2016) considered the characteristics of agglutinative languages during embedding. Ko-FastText performed better in intrinsic and extrinsic tasks with a Hangeul dataset by applying the FastText to each jamo (the smallest unit of a Hangeul word). However, this model did not fully utilize the sophisticated internal information of Hangeul words. Although the model refers to the morphological information revealed in the n-gram, lack of selectivity regarding the important morphological information of a word remains a problem.

Nam and Kim (2016) and Lee et al. (2018) explicitly considered the Korean words' morphological information. They decomposed words into character n-grams using morpheme analyzers. However, they encountered a fundamental problem that their models are dependent on the performance of the morpheme analyzer. In particular, the analyzer did not work appropriately for typos, so the performance of word embeddings cannot be guaranteed.

Unlike previous studies, we do not utilize a specific morpheme analyzer (or stemmer) or use typo data collected from the web. Instead, we propose a model that trains with our own generated typo set. Besides, we linearly combine the subword information by reinforcing the necessary information dynamically. Therefore, the model maintains robust performance against different grammatical errors as its embedding generation technique incorporates morphologically complicated Hangeul features.

3 Methodology

In this section, we describe the architecture of the proposed model. The model consists of three parts. The first part is the generation of Korean typos. We create rule-based typo datasets, and they reinforce the robustness of the embedding model for typos. Next, we create a jamo-level CNN with channel attention to represent the word vector. By applying channel attention to features extracted through convolution operation from each jamo, we selectively enhance the importance of the primary n-gram features. Based on a certain probability, the CNN learns to generate the original word vector from the typos, reducing the difference between the typos and the actual word embeddings. Finally, we perform the task of predicting the surrounding context words from the generated word embeddings. Through this process, we can proceed with the reinforcement of the semantics of words. Figure 1 shows the whole architecture of our model.

3.1 Generating Korean Typos

The smallest unit of Hangeul words that corresponds to the alphabet of English is jamo, consisting of 14 consonants and 10 vowels. In Hangeul, a syllable consists of three jamos: chosung, joongsung and jongsung. We divide each syllable into jamo units (Song, 2006). Figure 2 shows an example of dividing each syllable. The syllable “단” is divided into [ㄷ, ㅏ, ㄴ] and “어” is divided into

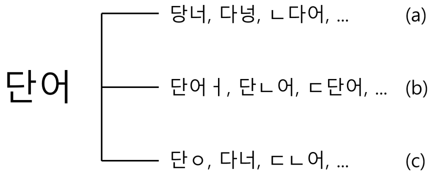

Figure 3: Examples of typos in Korean words. The typos generated in this paper are based on these cases.

[ㅇ, ㅓ]. In Hangeul, the chosung and joongsung jamos are always present while the jongsung jamo is only present or not (e.g., in "어").

After separating the Korean word into jamo, we make the following rules for creating a typo : (a) reversing the order of letters in the word, (b) adding arbitrary letters, or (c) dropping out a letter from the word. We generate our typo dataset following a well-known Korean typo distribution reported in the Korean information processing community (Jeon et al., 2010). Figure 3 shows examples of typos by the three rules. When following the rules, typos in Hangeul cause a breakdown of the word's form. This is because only consonants can be placed in the chosung position and only vowels can be placed in the joongsung position. Therefore, while typos in English can easily infer the original meaning (e.g., englihs, englis, ennglish), Hangeul typos are hard to understand even when they come from native speakers. Consequently, we generate at least 10 to 25 typo word pairs for each Korean word.

3.2 Jamo-level CNN with Channel Attention

After decomposing the input word into jamo units and generating typos, the convolution operation is used to extract the most prominent features of the word. Each one-hot encoded jamo representation is concatenated to set in a form suitable for convolution operations. We use zero padding to fix the input word vector's length to the size of the longest word. Then we obtain jamo representation $K \in \mathbb{R}^{m \times d}$, where m is the maximum length of the input word, and d is the embedding dimension. A convolution operation involves a filter $w \in \mathbb{R}^{h \times d}$, where $h \in \{1, 2, ..., 10\}$ is a filter size. We apply the convolution operation and activation function with these generated jamo representations. For example, a feature c is generated from a window of jamos $w_{i:i+h-1}$ by

$$c_i = ReLU(K^h \cdot w_{i:i+h-1} + b) \tag{1}$$

where $b \in \mathbb{R}$ is a bias. This convolution filter extracts the major feature of the jamos $\{w_{1:h}, w_{2:h+1}, ..., w_{m-h+1:m}\}$ to produce a feature map

$$c = [c_1, c_2, ..., c_{m-h+1}], \tag{2}$$

with $c \in \mathbb{R}^{m-h+1}$. We generate n feature maps in this way. Hence, we obtain concatenated feature map $C \in \mathbb{R}^{(m-h+1) \times n}$, where n is the number of the feature maps. To extract the features for the attention score from the convolution operation results, we employ average and max pooling in channel level as follows:

$$C_{avg} = average(C), \tag{3}$$

$$C_{max} = max(C), \tag{4}$$

where $C_{avg}, C_{max} \in \mathbb{R}^n$. Next, to extract the attention-applied feature map, we compute the attention scores between the channels.

$$C_{score} = W_2(W_1(C_{avg} + C_{max})), \tag{5}$$

where $W_1, W_2 \in \mathbb{R}^{n \times n}$ are the first and second weight matrix of the attention network for calculating the attention score, respectively. C_{score} is the result that comes from passing through the attention network. We apply a softmax function to create a standardized channel attention map. We then broadcast C_{score} into the same shape of C. The channel attention map is multiplied by the continuous jamo pair features to generate a feature map of the input word reflecting an attention score for each channel. Then max pooling is applied to the attention score as follows:

$$C_{att} = max(ReLU(C \times softmax(C_{score}))). \tag{6}$$

We obtain C_{att} for each filter size following this method, and consequently we obtain $C_{att}^h \in \mathbb{R}^{10n}$.

Then C_{att}^h is connected to the fully-connected layer, and we obtain final word representation w as follows:

$$w = C_{att}^h \cdot W + b, \tag{7}$$

where $W \in \mathbb{R}^{10n \times d}$, $b \in \mathbb{R}$. We have selectively enhanced the substructure of the word and created word vector $w \in \mathbb{R}^d$ that reflects contextual information. We then train the jamo-level CNN so that the word vector w resembles the representation of the vector $\hat{w}$ from the pre-trained word. In this step, we use the squared Euclidean distance with each normalized word vector for the objective function as follows:

$$Loss = \sum_{v \in V_w} \| w_v - \hat{w}_v \|^2 . \tag{8}$$

This equation approximates the generated word vector w to the pre-trained word vector $\hat{w}$. To create word embeddings using the proposed model, we split a word to jamo-level and insert it into the model as an input following a similar approach in the training phase. When the input tensor flows through the model and reaches the transformation layer, it is considered as the newly created embeddings of the word.

4 Experiments

In this section, we present our experimental results by comparing the performance of the proposed model with other embedding methods. We measure the performance of the models through word analogy, language modeling, and sentiment classification tasks.

4.1 Experimental Settings

We use an Adam optimizer with a learning rate of 0.001. The convolution filter has a size from one to nine, and each filter has 100 channels. The context window size for calculating semantic loss is set to an arbitrary number of less than five. The corpus used for learning is a Korean Wikipedia dump dataset released on June 1st, 2019. No preprocessing is performed other than removing special characters and replacing numbers with "N" tokens. We tokenize the corpus in word units for all models in the experiment. To ensure fairness, we set different random seeds in the training and evaluation phases.

4.2 Baselines

To measure the performance of the proposed model against widely used and state-of-the-art models, we used the following methods:

- *Word2vec* (Mikolov et al., 2013): *Word2vec* uses a representative embedding technique based on the distributional hypothesis. To find the meaning of a word in context, *Word2vec* learns the meaning of the target word from context words. Following this, if a word that is not registered at the training phase appeared at the evaluation phase, we replaced the word as "UNK" token. We used skip-gram architecture since it is generally proven to be better than other methods.

- *Ko-FastText (Ko-ft)* (Park et al., 2018): *Ko-ft* uses the jamo n-gram as the smallest unit. Therefore, it has an advantage that unseen words can be generated by a combination of jamo n-grams generated in the training phase. This model has proved to have the best performance in Hangeul embedding methods. $ch4$ means the model use one to four jamo-level n-grams, and $ch6$ means the model use one to six n-grams.

4.3 Word Analogy Task

We first conduct an embedding evaluation using the word analogy task as an intrinsic task. We measure how the word embedding process has learned semantic and syntactic meaning. Following (Park et al., 2018), we use 3COSADD based metric as an evaluation metric.

4.3.1 Dataset

We use the dataset introduced in (Park et al., 2018). The dataset is divided into two categories of semantic and syntactic meaning in the English version. Then they are translated into Korean and divided into ten subcategories. In this way, it is suitable to evaluate the performance of Hangeul embedding.

4.3.2 Results

Table 1 shows the analogy task results[1]. *Word2vec* has a big gap compared to *Ko-ft* and *misK*, which shows the limitations of the embedding technique from the viewpoint of words. In general, *misK* outperforms *Ko-ft*, indicating that the *misK* learned the semantic and syntactic meaning of each word better with the help of the well-designed attention mechanism in Figure 1. Also, *misK-ft* generally performs better than the model that learned the shape of words from *Word2vec* (*misK-w2v*). This demonstrates the importance of pre-trained embedding knowledge when creating new embeddings (Pinter et al., 2017).

4.4 Language Modeling Task

We conducted a language modeling experiment to check the embedding performance as an extrinsic

misK-ft	0.460	0.488	**0.498**	**0.327**	0.491	0.311	0.388	**0.421**	**0.361**	**0.294**

Table 1: Result of a word analogy task experiment. *misK-w2v* and *misK-ft* are our proposed models trained from *Word2vec* (Mikolov et al., 2013) and *Ko-FastText* (Park et al., 2018), respectively. Lower score is better. Best results are highlighted in bold font.

Model	Noise level			
	0%	10%	20%	30%
Word2vec	248.3	259.7	269.1	281.4
Ko-ft (ch6)	**206.4**	**218.1**	229.5	241.7
Ko-ft (ch4)	210.2	223.1	231.9	246.3
misK-w2v	213.8	220.7	224.7	229.8
misK-ft	211.6	219.4	**224.6**	**228.4**

Table 2: Perplexity measured from the language modeling. The noise level is the probability that each word in the dataset will be replaced by typos. Best results are highlighted in bold font.

Model	Noise level				
	0%	10%	20%	30%	40%
Word2vec	64.1	62.9	60.4	59.3	58.4
Ko-ft (ch6)	**68.8**	67.3	66.3	64.1	62.3
Ko-ft (ch4)	68.4	66.4	65.2	63.4	61.7
misK-w2v	68.3	**67.6**	**66.7**	65.4	**64.2**
misK-ft	68.1	67.2	66.4	**65.5**	64.1

Table 3: Result of the sentiment classification experiment. The noise level is the probability that each word in the dataset will be mistyped. Best results are highlighted in bold font.

task. Also, we replaced the word embeddings of the basic LSTM network with dropout regularization (Kim et al., 2016). All embedding dimensions are set to 300 and the dropout probability is set to 0.5. Each embedding model is measured using perplexity, which is widely used to measure language modeling performance (Katz, 1987). The lower the perplexity value measured, the more likely the model predicts the next word correctly. Besides, in the downstream task, we used intentionally generated typo data in the experiment to verify the robustness of embedding for noisy text.

4.4.1 Datasets

The language modeling dataset was released by the Korean Wikipedia, published on June 1, 2019. Each embedding technique was trained based on this corpus in its way. The code to extract and refine the text from the Wikipedia database dump followed the open-source software[2].

4.4.2 Results

The results of the language modeling experiments are shown in Table 2. Regardless of the noise level, *Word2vec* has the lowest performance. In other words, it can be seen that the word-level embeddings separated by blank spaces are not suitable for Korean text irrespective of the response to misspelled words. *Ko-ft* performs best when the noise level is below 20%. Meanwhile, the performance of *misK* is better than the other models as the noise level rises to more than 10%. The fact that *misK* showed superior performance means it can stably respond to various typos in Hangeul text.

4.5 Sentiment Classification Task

The performance of each model is compared using the sentiment analysis experiment on movie reviews. We represent the reviews by averaging the word embeddings, constructing a review, and training through the logistic regression classifier for a fair comparison.

4.5.1 Datasets

For sentiment classification, we used the Naver Sentiment Movie Corpus[3] as our classification data. For the typos used in the real world, we did not proceed with any form of preprocessing. Therefore, it includes typos or slang used by Koreans. The experiment was also conducted by increasing noise

level of the evaluation dataset and intentionally producing misspelled words to compare robustness to the typos.

4.5.2 Results

Table 3 shows that *Ko-ft* has the highest performance in the sentiment classification experiment results in the clean environment. Besides, *Word2vec* showed significantly reduced performance than *Ko-ft*. This is because several OOVs were included in the test set. However, as the noise level increases, the performance of *misK* overtakes that of the *Ko-ft*. It confirms that the performance of *misK* decreases relatively smoothly as the amount of noise in the data rises. In other words, *misK* is more robust to the noisy data than the others.

5 Analysis

In this section, we analyze the proposed methodology. We find the nearest neighbor words mapped close to the misspelled word to evaluate robustness of the typo embeddings qualitatively.

5.1 Nearest Neighbor of Words

We check the nearest neighbor of words to compare the performance of each word embedding. This evaluation is to identify which words are located around the represented target words (컴퓨터-computer, 대한민국-Korea, 대학교-university, 자동차-automobile) and typos transformed from these words.

Table 4 shows the experimental results. The results with In-Vocabulary show that all three models produce the appropriate embeddings. However, the results from the OOV confirm that *Word2vec* cannot deal with the typos. In contrast, *Ko-ft* and *misK* can generate embeddings for these unseen words to investigate these nearest words. In general, the typo embeddings generated by the *Ko-ft* are inaccurate (note the meaning of the words described in the caption). On the other hand, we deduce that words with appropriate meanings are mapped with our proposed model, *misK*.

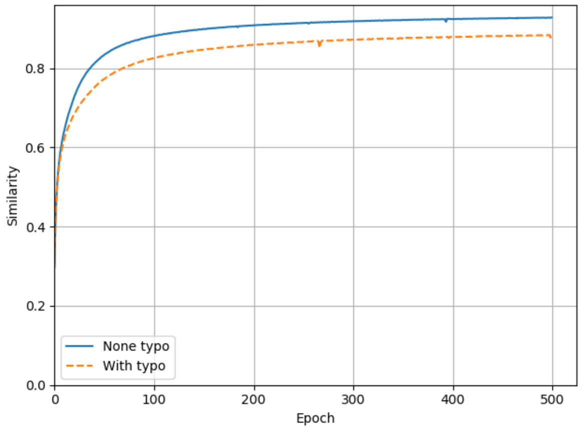

Figure 4: Cosine similarity between the generated word vector and pre-trained word vector.

5.2 Similarity between Generated and Pre-trained Word Vector

Experiments show superiority in the noisy text of our proposed embedding generation model. We measure the cosine similarity between the pre-trained word embeddings and those generated by our proposed model. As shown by the dotted curve in Figure 4, when training data includes intentional typos, the cosine similarity between the pre-trained word embeddings and those generated by the proposed model could not be increased beyond 0.86. On the other hand, in the absence of typos, the similarity increases to around 0.95. Besides, there is a tradeoff between the ability to map typos closely to the original word and the ability to mimic pre-trained word vectors.

6 Conclusion

In this paper, we proposed a robust Hangeul embedding model against typos. For this purpose, we intentionally generated typos to train word embeddings. A channel attention mechanism is used to utilize the structure information found in Korean words selectively. This reflects the distinctive characteristics of Hangeul, which combines several morphemes to form a single word, without depending on the performance of a morpheme analyzer. Based on this, the training progresses from the extracted jamo n-gram feature of the target words through the convolution layer to aim the pre-trained word embeddings. The proposed embedding model outperformed the current state-of-the-art in the intrinsic task. Also, we verify that the original research goal was achieved by functioning a stable embeddings even in the extrinsic tasks. We plan to apply the proposed methodology to various downstream tasks (e.g., POS tagging and machine translation) and other agglutinative languages, such as Japanese and Turkish.

Abstract

This paper addresses the problem of simultaneous machine translation (SiMT) by exploring two main concepts: (a) adaptive policies to learn a good trade-off between high translation quality and low latency; and (b) visual information to support this process by providing additional (visual) contextual information which may be available before the textual input is produced. For that, we propose a multimodal approach to simultaneous machine translation using reinforcement learning, with strategies to integrate visual and textual information in both the agent and the environment. We provide an exploration on how different types of visual information and integration strategies affect the quality and latency of simultaneous translation models, and demonstrate that visual cues lead to higher quality while keeping the latency low.

1 Introduction

Research into automating real-time interpretation has explored deterministic and adaptive approaches to build policies that address the issue of translation delay (Ryu et al., 2006; Cho and Esipova, 2016; Gu et al., 2017). In another recent development, the availability of multimodal data (such as visual information) has driven the community towards multimodal approaches for machine translation (MMT) (Specia et al., 2016; Elliott et al., 2017; Barrault et al., 2018). Although deterministic policies have been recently explored for simultaneous MMT (Caglayan et al., 2020; Imankulova et al., 2020), there are no studies regarding how multimodal information can be exploited to build flexible and adaptive policies for simultaneous machine translation (SiMT).

Applications of reinforcement learning (RL) for unimodal SiMT have highlighted the challenges for the agent to maintain good translation quality while learning an optimal translation path (i.e. a sequence of `READ`/`WRITE` decisions at every time step) (Grissom II et al., 2016; Gu et al., 2017; Alinejad et al., 2018).

Incomplete source information will have detrimental effect especially in the cases where significant restructuring is needed while translating from one language to another.

In addition, the lack of information generally leads to high variance during the training in the RL setup. We posit that **multimodality** in adaptive SiMT could help the agent by providing extra signals, which would in turn improve training stability and thus the quality of the estimator and translation decoder.

In this paper, we present the first exploration on multimodal RL approaches for the task of SiMT.

As visual signals, we explore both image classification features as well as visual concepts, which provide global image information and explicit object representations, respectively. For RL, we employ the Policy Gradient method with a pre-trained neural machine translation model acting as the environment.

As the SiMT model is optimised for both translation quality and latency, we apply a combined reward function that consists of a decomposed smoothed BLEU score and a latency score. To integrate visual and textual information, we propose different strategies that operate both on the agent (as prior information or at each step) and the environment side.

In experiments on standard datasets for MMT, our models achieve the highest BLEU scores on most settings without significant loss on average latency, as compared to strong SiMT baselines. A qualitative analysis shows that the agent benefits from the multimodal information by grounding language signals on the images.

Our **main contributions** are as follows: (1) we

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3222–3233
April 19 - 23, 2021.

propose the first multimodal approach to simultaneous machine translation based on adaptive policies with RL, introducing different strategies to integrate visual and textual information (Sections 3 and 4); (2) we show how different types of visual information and integration strategies affect the quality and latency of the models (Section 5); (3) we demonstrate that providing visual cues to both agent and environment is beneficial: models achieve high quality while keeping the latency low (Section 5).

2 Related Work

In this section, we first present background and related work on SiMT, and then discuss recent work in MMT and multimodal RL.

2.1 Simultaneous Machine Translation

In the context of neural machine translation (NMT), Cho and Esipova (2016) introduce a greedy decoding framework where simple heuristic waiting criteria are used to decide whether the model should read more source words or instead write a target word. Gu et al. (2017) utilise a pre-trained NMT model in conjunction with an RL agent whose goal is to learn a `READ/WRITE` policy by maximising quality and minimising latency. Alinejad et al. (2018) further extend the latter approach by adding a `PREDICT` action with an aim to capture the anticipation of the next source word. Ma et al. (2019) propose an end-to-end, fixed-latency framework called 'wait-k' which allows *prefix-to-prefix* training using a deterministic policy: the agent starts by reading a specified number of source tokens (k), followed by alternating `WRITE` and `READ` actions.

Other approaches to SiMT include re-translation of previous outputs depending on new outputs (Arivazhagan et al., 2020; Niehues et al., 2018) or learning adaptive policies guided by a heuristic or alignment-based approaches (Zheng et al., 2019; Arthur et al., 2020). A general theme in these approaches is their reliance on *consecutive* NMT models pre-trained on full-sentences. However, Dalvi et al. (2018) discuss potential mismatches between the training and decoding regimens of these approaches and propose to perform fine-tuning of the models using chunked data or prefix pairs.

2.2 Multimodal Machine Translation

MMT aims at improving the quality of automatic translation using additional sources of information (Sulubacak et al., 2020). Different methods for fusing textual and visual information have been proposed. These include initialising the textual encoder or decoder with the visual information (Elliott and Kádár, 2017; Caglayan et al., 2017), combining the visual information through spatial feature maps using soft attention (Caglayan et al., 2016; Libovický and Helcl, 2017; Huang et al., 2016; Calixto et al., 2017), and projecting a summary of the visual representations to a common context space via a trained projection matrix (Calixto and Liu, 2017; Caglayan et al., 2017; Elliott and Kádár, 2017; Grönroos et al., 2018). Further, recent work has also focused on exploring Multimodal Pivots (Hitschler et al., 2016) and latent variable models (Calixto et al., 2019) in the context of multimodal machine translation. In this paper, we explore all these strategies, and also the use of *visual concepts*, similar to the approach by Ive et al. (2019).

2.3 Multimodal Reinforcement Learning

Previous work has explored RL with language inputs (Andreas et al., 2017; Bahdanau et al., 2018; Goyal et al., 2019) by making use of language to improve the policy or reward function: for example, the task of navigating in the world grid environment using language instructions (Andreas et al., 2016).

Alternatively, RL with language output can be shaped as sequential decision making for language generation, while conditioning on other modalities. This includes image captioning (Ren et al., 2017), video captioning (Wang et al., 2018), question answering (Das et al., 2018), and text-based games (Côté et al., 2018). Our study sits somewhere in between these different types of work. We have both the source language and respective images as input and the target language as output. Our agent is focused only on learning the `READ` and `WRITE` actions while the translation model is fixed for simplicity.

The central aim of the agent is learning to capture the relevant structures and relations of the modalities that can lead to a better SiMT system.

3 Methods

We first present the architectures for consecutive and baseline fixed policy simultaneous MT (Section 3.1). Then we introduce our RL approaches, both the baseline, the proposed multimodal extension (Section 3.2), and the visual features used by all multimodal approaches (Section 3.3).

3.1 Baselines

Unimodal MT. We implement a standard encoder-decoder baseline with attention (Bahdanau et al., 2014) which incorporates a two-layer encoder and a two-layer decoder with GRU (Cho et al., 2014) units. Given a source sequence of embeddings $X=\{x_1, \ldots, x_S\}$ and a target sequence of embeddings $Y=\{y_1, \ldots, y_T\}$, the encoder first computes the sequence of hidden states $H=\{h_1, \ldots, h_S\}$ unidirectionally.

The attention layer receives H as *key-values* whereas the hidden states of the first decoder GRU provide the *queries*. The context vector $c_t^{\mathbf{T}}$ produced by the attention layer is given as input to the second GRU. Finally, the output token (y_t) probabilities are obtained by applying a softmax layer on top of the concatenation of the previous word embedding, context vector and the second GRU's hidden state.

For **consecutive NMT**, all source tokens are observed before the decoder begins the process of generation.

Multimodal MT. We extend unimodal MT with multimodal attention (Calixto et al., 2016; Caglayan et al., 2016) in the decoder, in order to incorporate visual information into the baseline NMT. Let us denote the visual counterpart of textual hidden states H by V. Multimodal attention simply applies another attention layer on top of V, which yields a visual context vector $c_t^{\mathbf{V}}$ at each decoding timestep t. The final multimodal context vector that would be given as input to the second GRU is simply the sum of both context vectors.

Unimodal wait-k NMT. We explore deterministic wait-k (Ma et al., 2019) approach as a unimodal baseline[1] for simultaneous NMT. The wait-k model starts by reading k source tokens and writes the first target token. The model then reads and writes one token at a time to complete the translation process. This implies that the attention layer will now attend to a partial textual representation corresponding to k-words. We use the decoding-only variant which does not require re-training an NMT model i.e. it re-uses the already trained consecutive NMT baselines.

3.2 Policy Learning Framework

RL baseline. We closely follow Gu et al. (2017) and cast SiMT as a task of producing a sequence of `READ` or `WRITE` actions. We then devise an RL model that connects the MT system and these actions. The model is based on a reward function that takes into account both quality and latency. Following standard RL, the framework is composed of an environment and an agent. The agent takes the decision of either reading one more input token or writing a token into the output – hence two actions are possible: `READ` and `WRITE`. The environment is a pre-trained NMT system which is *frozen* during RL training.

The agent is a GRU that parameterises a stochastic policy which decides on the action a_t by receiving as input the observation o_t.[2] In our setup, o_t is defined as $[c_t^{\mathbf{T}}; y_t; a_{t-1}]$, i.e. the concatenation of vectors coming from the environment, as well as the previously produced action sequence. At each time step, the agent receives a reward $r_t = r_t^Q + r_t^D$ where r_t^Q is the quality reward (the difference of smoothed BLEU scores for partial hypotheses produced from one step to another) and r_t^D is the latency reward formulated as:

$$r_t^D = \alpha \left[\mathrm{sgn}(C_t - C^*) + 1\right] + \beta \lfloor D_t - D^* \rfloor_+$$

where C_t denotes the consecutive wait (CW) metric which is added to avoid long consecutive waits (Gu et al., 2017). CW measures how many source tokens are consecutively read between committing two translations. D_t refers to average proportion (AVP) (Cho and Esipova, 2016), which defines the average proportion of wait tokens when translating the words. D^* and C^* are hyper-parameters that determine the expected/target values. The optimal quality-latency trade-off is achieved by balancing the two reward terms. In our reward implementation we again closely follow Gu et al. (2017).

Multimodal extension. Here we focus on integrating the visual information with the agent (see Figure 1). The basic premise is that the addition of multimodal information, especially in the context of MMT, can result in the agent learning better and more flexible policies. We explore several ways to integrate visual information into this framework:

---

[1] These baselines are equivalent to the deterministic approaches used in Caglayan et al. (2020).

[2] We note that the use of GRU cells is not critical for the multimodal components. They were chosen as they led to the best performance in our implementation.

- **Multimodal initialisation** (`RL-init`) - the agent network is initialised with the image vector V as d_0. We expect this vector to give the agent some context w.r.t. the source sentence so it can potentially read fewer words before producing outputs.

- **Multimodal attention** (`RL-att`, Figure 1) applies another attention layer on top of V, which yields a visual context vector $c_t^{\mathbf{V}}$ at each agent time step t. This visual context vector is a dot product attention $c_t^{\mathbf{V}} = \text{Attention}(V, \text{query} \leftarrow y_t)$ that computes the similarity between V and the embedding of the target word produced by the decoder at the time step t. In this setting, we expect the agent to pay attention to the information in V that will help in defining whether y_t is good enough to be written to the output (potentially with closer relationship to some part of the image information) or we need to read more source words to produce a better y_t. We concatenate $c_t^{\mathbf{V}}$ to o_t, which now becomes $[c_t^{\mathbf{T}}; y_t; a_{t-1}; c_t^{\mathbf{V}}]$;

- As a **control**, we also study **multimodal environment** (`RL-env`, Figure 1) where we use the MMT baseline as environment. Here, we expect the initial translation quality of SiMT RL models be closer to the quality of the respective consecutive multimodal baseline as the image information is expected to compensate for partial source information. When combined with `RL-init` and `RL-att` settings, we expect the agent to exploit different kinds of image information than the environment.

Learning. To learn the multimodal agent, we introduce an additional neural network with the same structure as that of the agent GRU network to provide for control variates (baselines) that improve the Monte-Carlo policy gradient (REINFORCE (Williams, 1992)). Note that here we depart from the previous work where Gu et al. (2017) use a simple multilayer perceptron as the baseline.

Therefore, with the reward r_t at each time step, we obtain the estimation of the gradients by subtracting the baselines $b(o_t)$:

$$\nabla_\theta J(\theta) = \mathbb{E}[\sum_{t=0}^{T-1} \nabla_\theta \log \pi(a_t|o_t)(r_t - b(o_t))]$$

To further reduce the variance of the gradient estimator, we also introduce a temperature τ for controlling the interpolation between discrete action samples and continuous categorical densities, which yields to a Gumbel-Softmax reparameterisation (Jang et al., 2017) that smooths the learning. To be more precise, we use the Gumbel-Softmax distribution instead of argmax while sampling. So the probability of the `WRITE` action is given to the agent network instead of the index of the action.

3.3 Visual Features

In order to represent the visual information, we explore two settings that differ in the organisation of the spatial structure. Regardless of the setting, the image features are linearly projected into the hidden space of the decoder to yield the tensor V.

Image classification features (OC) are *global* image information represented by convolutional feature maps, which are believed to capture spatial cues. These features are extracted from the final convolution layer of a ResNet-50 convolutional neural network (CNN) (He et al., 2016) pre-trained on ImageNet (Deng et al., 2009) for object classification. The size of the final feature tensor being 8x8x2048, the visual attention is applied on a grid of 64 equally-sized regions.

Visual Concepts (VC) are explicit object representations where *local* regions are detected as objects and subsequently encoded with 100-dimensional word representations. For a given image, the detector provides 36 object and 36 attribute region proposals which are abstract concepts associated with the image. We represent each of the detected region with its corresponding GloVe (Pennington et al., 2014) word vectors. An image is thus represented by a feature tensor of size 72x100 and the visual attention is now applied on these visual concepts, rather than the uniform grid of the first approach above. We hypothesise that this type of information can result in better referential grounding by using conceptually meaningful units rather than global features. The detector used here is a Faster R-CNN/ResNet-101 object detector (with 1600 object labels) (Anderson et al., 2018)[3] pre-trained on the Visual Genome dataset (Krishna et al., 2017).

---

[3] https://hub.docker.com/r/airsplay/bottom-up-attention

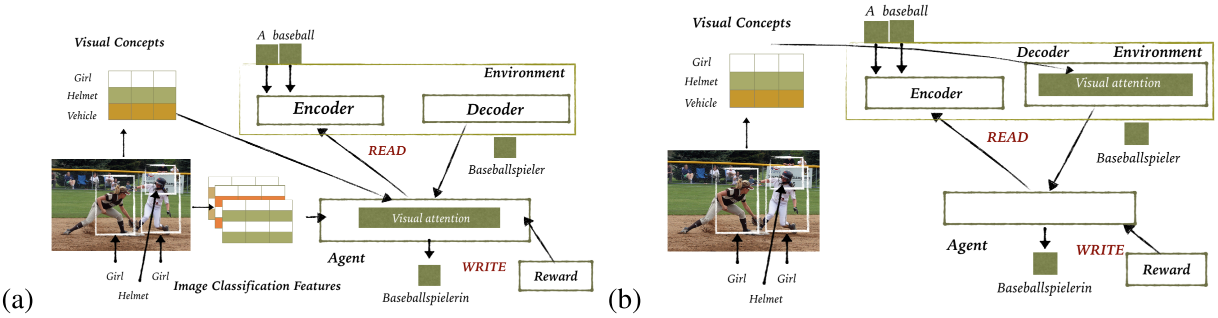

Figure 1: Our multimodal RL SiMT models: the agent interacts with the environment to receive new translation and at each time step produces the `READ/WRITE` action. For each action it receives a reward. The image information can be integrated into the agent by means of an attention mechanism (a, `RL-att`), or into the environment decoder (b, `RL-env`) producing the next translation.

4 Experimental Setup

4.1 Dataset

We perform experiments on the Multi30k dataset (Elliott et al., 2016)[4] which extends the Flickr30k image captioning dataset (Young et al., 2014) with caption translations in German and French (Elliott et al., 2017). Multi30k is a standard MMT dataset that contains parallel sentences in two languages that describe the images. The training set for each language direction comprises 29,000 image-source-target triplets whereas the development and the test sets have around 1,000 samples. We use the corresponding test sets from 2016, 2017 and 2018 for evaluation.

Pre-processing. We use Moses scripts (Koehn et al., 2007) to lowercase, normalise and tokenise the sentences. We then create word vocabularies on the *training* subset of the dataset. We did not use subword segmentation to avoid its potential side effects on fixed policy SiMT and to be able to better analyse the grounding capability of the models. The resulting English, French and German vocabularies contain 9.8K, 11K and 18K tokens, respectively.

4.2 Evaluation

We use **BLEU** (Papineni et al., 2002) for quality, and perform significance testing via bootstrap resampling using the `Multeval` tool (Clark et al., 2011). For latency, we measure **Average proportion** (AVP) (Cho and Esipova, 2016). AVP is the average number of source tokens required to commit a translation. This metric is sensitive to the difference in lengths between source and target. Hence, as our main latency metric we measure **Average Lagging** (AVL) (Ma et al., 2019) which estimates the number of tokens the "writer" is lagging behind the "reader", as a function of the number of input tokens read.

4.3 Training

Hyperparameters. We set the embeddings dimensionality and GRU hidden states to 200 and 320, respectively. We use the ADAM (Kingma and Ba, 2014) optimiser with the learning rate 0.0004 and the batch size of 64. We use `pysimt` (Caglayan et al., 2020) with PyTorch (Paszke et al., 2019) v1.4 for our experiments.[5] We early stop w.r.t. the validation BLEU with the patience of 10 epochs. On a single NVIDIA RTX2080-Ti GPU, the training takes around 35 minutes for the unimodal model and around 1 hour for the multimodal model. The number of learnable parameters is between 6.9M and 9.3M depending on the language pair and the type of multimodality.

For the **RL systems**, we follow (Gu et al., 2017).[6] The agent is implemented by a 320-dimensional GRU followed by a softmax layer and the baseline network is similar to the agent except with a scalar output layer.[7] We use ADAM as the optimiser and set the learning rate and mini-batch size to 0.0004 and 6, respectively. For each sentence pair in a batch, 5 trajectories are sampled. Following best practises in RL, the baseline network is trained to reduce the MSE loss between the predictions and the rewards using a second op-

[6] https://github.com/nyu-dl/dl4mt-simul-trans

[7] Note that that Gu et al. (2017) use a 2-hidden layer feed-forward network as the baseline network. In our implementation GRUs have demonstrated better performance.

timiser.

For inference, greedy sampling is used to pick action sequences. We set the hyperparameters C^{*}=2, D^{*}=0.3, α=0.025 and $\beta = -1$. To encourage exploration, the negative entropy policy term is weighed empirically with 0.001. Following (Gu et al., 2017), we choose the model that maximises the quality-to-latency ratio (BLEU/AVP) on the validation set with a patience of 5 epochs.[8] On a single NVIDIA RTX2080-Ti GPU, the training takes around 2 hours. The number of learnable parameters is around 6M.

Model configurations. We experiment with seven different configurations (below). We consider visual concepts (VC) as the main source of multimodal information. Visual concepts are more abstract forms of multimodal information. Unlike spatial image representation or region of interest-based object representations, where the representation for the same concept can vary significantly across images, visual concepts remain constant. For example, the visual concept "dog" is the same regardless of the breed, colour, size, position, etc. of the concept in different images. Image classification (OC) features are used as a contrastive setting.

- Unimodal RL baseline (`RL-base`): This baseline follows (Gu et al., 2017) where the environment is a text-only NMT model.
- Multimodal agent with VC initialisation (`RL-init` VC): We initialise the agent GRU using a projection of the flattened 72x100 matrix of visual concepts.
- Multimodal agent with attention over VC (`RL-att` VC): The agent attends over the set of visual concepts at each step.
- Multimodal agent with attention over OC (`RL-att` OC): The agent attends over the set of image classification-based spatial feature maps at each step.
- Visually initialised multimodal agent with attention over VC (`RL-init-att` VC): Similar to `RL-att` VC but the agent is also initialised with VC.
- Multimodal environment with unimodal RL agent (`RL-env` VC): The environment is an MMT model, however the agent is a standard RL agent akin to the baseline.
- Multimodal agent with multimodal environment (`RL-env-init-att` VC): This merges all the variants in that both the multimodal environment and the multimodal agent attend to visual concepts, the latter is also initialised with visual information.

5 Results

In this section, we first provide the results from our experiments (Section 5.1) and then analyse the behaviour of the (multimodal) agents (Section 5.2).

5.1 Quantitative Results

SiMT vs. Consecutive. We present the main results in Table 1. The top block for each language pair shows the textual Consecutive model and its multimodal counterpart (Consecutive+VC). These are our upperbounds since they have access to the entire source before translating. As expected, they have better BLEU but much larger AVL.

RL SiMT vs. Deterministic policy. The second block in Table 1 shows the deterministic policy Wait-2 and Wait-3 approaches. `RL-base` performs on par with the Wait-2 (English-French) and Wait-3 (English-German). We however emphasise the flexibility of the stochastic policies with RL models. These are particularly beneficial in the multimodal scenario and allow for exploitation of the image information more efficiently especially towards reducing the average lag. We further expand on this later in Section 5.2.

Unimodal RL vs. Multimodal RL. The third block in Table 1 compares all multimodal RL variants against the text-only SiMT RL (`RL-base`). In general, the multimodal RL models produce translations that are significantly better than `RL-base`.

Across Multimodal RL Setups. With regard to different configurations, we observe (1) an increase in quality for the `RL-att` models when compared to `RL-base` which is consistent in both types of visual inputs OC and VC, and (2) a decrease in the lag for the `RL-init` models at a small decrease in quality (for VC `RL-init` in comparison to `RL-base`).

This observation suggests that the RL model with the agent explicitly attending over image information leads to an increase in quality, as the

---

[8] We also attempted to choose the model that maximises BLEU or BLEU/AVL but those stopping criteria resulted in instability of convergence.

multimodal agent model is more selective towards the word choice. The `RL-init` configuration with prior image context on the other hand reduces the lag and seems to use `WRITE` actions more often than `READ` actions. It is interesting that OC and VC features result in similar quality translations, however we see that on average the average lag is lower with VC. We hypothesise that this could be due to the fact that the representations remain constant across images (see Section 4.3).

The `RL-init-att` configuration represents a middle ground and we see similar quality improvement to `RL-att` across setups (a gain of 2 BLEU points on average) but with a slightly lower latency. We however observe that `RL-env-init-att` has a slightly inferior performance with a a pronounced latency when compared to the `RL-env` model. We investigate this aspect in the next sections.

Investigating Average Lag. To further study the impact of our configurations on the sentence level lag, in Figure 2 we present the binned-histograms of sentence lags over the English→German test 2016 set. Generally, the models which are initialised with image information seem to have more mass towards the smaller delay bins. In terms of `RL-init` and `RL-env-init-att` setups, we also observe the presence of two modes around the lag value 3 as well as around two negative values (around -0.25 and -1.25 respectively). These negative lag values are due the difference in length between source and target sentences which is typical for the English→German. This also shows that the agent initialised with the image information tends to prefer `WRITE` actions with fewer `READ` actions. Further, on manual inspection of some samples, we observed that in the cases with negative lag the model begins with a `WRITE` action straight after reading the first token (See Table 2). As the agent is a GRU model, this behavior resembles that of an image captioning model. We also observe similar trends for English→French with `RL-init` models predominantly having more mass towards smaller delay bins (see Figure 3).

5.2 Agent Attention over Visual Inputs

In Figure 4 we visualize the agent's attention at each time step. On average, the agent actions correlate with the objects it attends to when producing the translation.

We now examine the general pattern of agent attention over the visual concepts across the four configurations using attention norm: a) `RL-att`-VC; b) `RL-att`-OC; c) `RL-init-att`; and d)

Table 2: Example of a German VC `RL-init` setup sentence with a negative lag, where the model tends to write more before reading new words.

`RL-env-init-att`. The attention norm is simply the average ℓ_2 norm between two consecutive attention time-steps. This can help in measuring the average visual attention per time step for a given sentence. We then compare the attention norm distributions over all the sentences in the English→German test 2016 set for the four different agent attention configurations. We present the result in Figure 5. Overall, `RL-init` and `RL-att` models are significantly more peaky than the `RL-env-init-att`. This suggests that `RL-env-init-att` model is generally spread across the 72 visual concepts more uniformly than the other two models. This perhaps is one of the causes for the slightly inferior performance of the model. We hypothesise that further regularisation of the attention distribution can ameliorate this behavior and leave it as future work.

6 Conclusion

In this paper we presented the first thorough exposition of multimodal reinforcement learning strategies for simultaneous machine translation. We demonstrate the efficacy of visual information and show that it leads to adaptive policies which substantially improve over the deterministic and unimodal RL baselines. Our empirical results indicate that both agent-side and environment-side visual information can be exploited to achieve higher quality translations with lower latency.

Throughout the experimental journey, we observed that the optimisation of simultaneous machine translation for dynamic policies is non-trivial, due to the two competing objectives: translation quality versus latency. For unimodal simultaneous machine translation, RL approaches tend to achieve translation quality on par with the quality of the deterministic policies within the same average lag. We believe that the fundamental issue is related

to the high variance of the estimator for sequence prediction, which increases sample complexity and impedes effective learning. On the other hand, the approaches with deterministic policies are simple and effective, as they are positively biased for language pairs that are close to each other. But the latter suffer from poor generalisation.

In the multimodal simultaneous machine translation setting, however, the variance of the estimator from RL models can be substantially reduced with to the presence of additional (visual) information.

STAR: Cross-modal STAtement Representation for selecting relevant mathematical premises

Deborah Ferreira[1], **André Freitas**[1,2]
[1]The University of Manchester, Department of Computer Science, Manchester, UK
[2]Idiap Research Institute, Switzerland
{deborah.ferreira, andre.freitas}@manchester.ac.uk

Abstract

Mathematical statements written in natural language are usually composed of two different modalities: mathematical elements and natural language. These two modalities have several distinct linguistic and semantic properties. State-of-the-art representation techniques have demonstrated an inability in capturing such an entangled style of discourse. In this work, we propose STAR, a model that uses cross-modal attention to learn how to represent mathematical text for the task of Natural Language Premise Selection. This task uses conjectures written in both natural and mathematical language to recommend premises that most likely will be relevant to prove a particular statement. We found that STAR not only outperforms baselines that do not distinguish between natural language and mathematical elements, but it also achieves better performance than state-of-the-art models.

1 Introduction

Natural language understanding has been applied to several different tasks and areas, from question answering to visual grounding. Even though Mathematics is a well-established field with immense importance for most areas of science, applications of NLP in this field are still limited.

Natural language premise selection (NLPS) (Ferreira and Freitas, 2020a) is a task that requires the combination of natural language reasoning and mathematical reasoning. Given a certain conjecture (a mathematical statement written in natural language) that needs to be proven, we attempt to recommend useful premises that can be relevant for developing that mathematical argument.

Mathematical statements have a particular discourse structure that makes it challenging to use traditional NLP techniques. Some of its distinctive features are: (1) Entangled dual lexical spaces for the mathematical elements (ME) and natural language (NL); (2) Distinct syntactic phenomena between ME and NL.

Given this entangled nature of the discourse, where two very different linguistic modalities coexist in the same text, traditional information retrieval approaches are not able to capture the different semantics for each modality (Greiner-Petter et al., 2019). For example, in the mathematical domain, variables are represented using generic symbols; this lexical layer does not necessarily ground the semantics of the variables. The context surrounding the variables is more important than the symbol itself. When interpreting mathematical discourse, such particulars need to be taken into account.

In this work, we propose STAR, a cross-modal representation for mathematical statements for addressing the task of premise selection. In order to interpret the different modalities in the mathematical discourse (natural language and equational), STAR uses two different self-attention layers, one focused on the mathematical elements, such as expressions and variables, while the other attends to natural language features. STAR is taught to see these tokens as parts of different languages, the mathematical language and the English Language, similar to what our human brain does (Butterworth, 2002). Even though the brain interprets mathematics as a language, it requires different parts for processing it (Amalric and Dehaene, 2016). Using different attention layers, STAR can learn that understanding mathematics requires a different type of reasoning than natural language, approximating the behaviour of the brain when faced with mathematical tokens.

The approach presented in this work is based on the hypothesis that the use of cross-modal attention-based mechanisms provides a better encoding of the semantic content of mathematical statements

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3234–3243
April 19 - 23, 2021.

for the task of premise selection.

The contributions of this work can be summarised as follows:

- Proposal of a novel cross-modal embedding that captures the different modalities inside mathematical text: mathematical elements (expressions) and words.
- A systematic analysis of the transferability of this representation across different mathematical domains.
- An empirical evaluation, comparing our approach with state-of-the-art models and the performance of supporting ablation studies.
- We demonstrate an improvement of up to 70.34% in F1-Score, compared to a baseline that does not distinguish between mathematical elements and natural language. We also obtain competitive results with state-of-the-art approaches, using a smaller model and no pre-training.

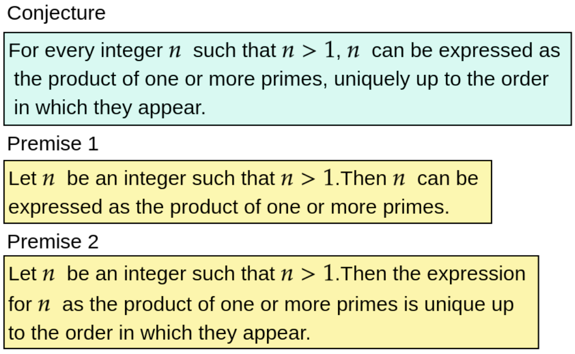
2 Background: Natural Language Premise Selection

In this work, we address the problem of *Natural Language Premise Selection* (Ferreira and Freitas, 2020a) (premise selection or NLPS). A mathematical statement can be a definition, an axiom, a theorem, a lemma, a corollary or a conjecture. Premises are composed of universal truths and accepted truths. Definitions and axioms are universal truths since the mathematical community accepts them without requiring proof.

On the other hand, accepted truths include statements that need proof before being adopted. Theorems, lemmas and corollaries are such types of statements. These statements were, at some point, framed as a conjecture, before they were proven. As such, they can be grounded on past mathematical discoveries, referencing their own supporting premises. This network structure of known premises can be used as a foundation in order to predict new ones.

Given a new conjecture c, that requires a mathematical proof, and a collection of premises $P = \{p_1, p_2, \ldots, p_{N_p}\}$, with size N_p, the NLPS task aims to retrieve the premises that are most likely to be useful for proving c. Premises of accepted truth statements can also have a subset of premises $\tilde{P} \subseteq P$.

Figure 1 presents an example of a conjecture containing two premises. Both *Premise 1* and *Premise 2* can be used as part of the proof for this conjecture.



Conjecture

For every integer n such that $n > 1$, n can be expressed as the product of one or more primes, uniquely up to the order in which they appear.

Premise 1

Let n be an integer such that $n > 1$.Then n can be expressed as the product of one or more primes.

Premise 2

Let n be an integer such that $n > 1$.Then the expression for n as the product of one or more primes is unique up to the order in which they appear.

Figure 1: Example of a conjecture and its premises.

Similar to previous approaches (Irving et al., 2016; Ferreira and Freitas, 2020a), we formulate this problem as a pairwise relevance classification problem. Given a pair (c, p_i), we classify if p_i can be used for proving c. Our approach is built on top of a cross-modal representation for mathematical statements, as the following section presents.

3 Our Approach: Cross-modal STAtement Representation (STAR)

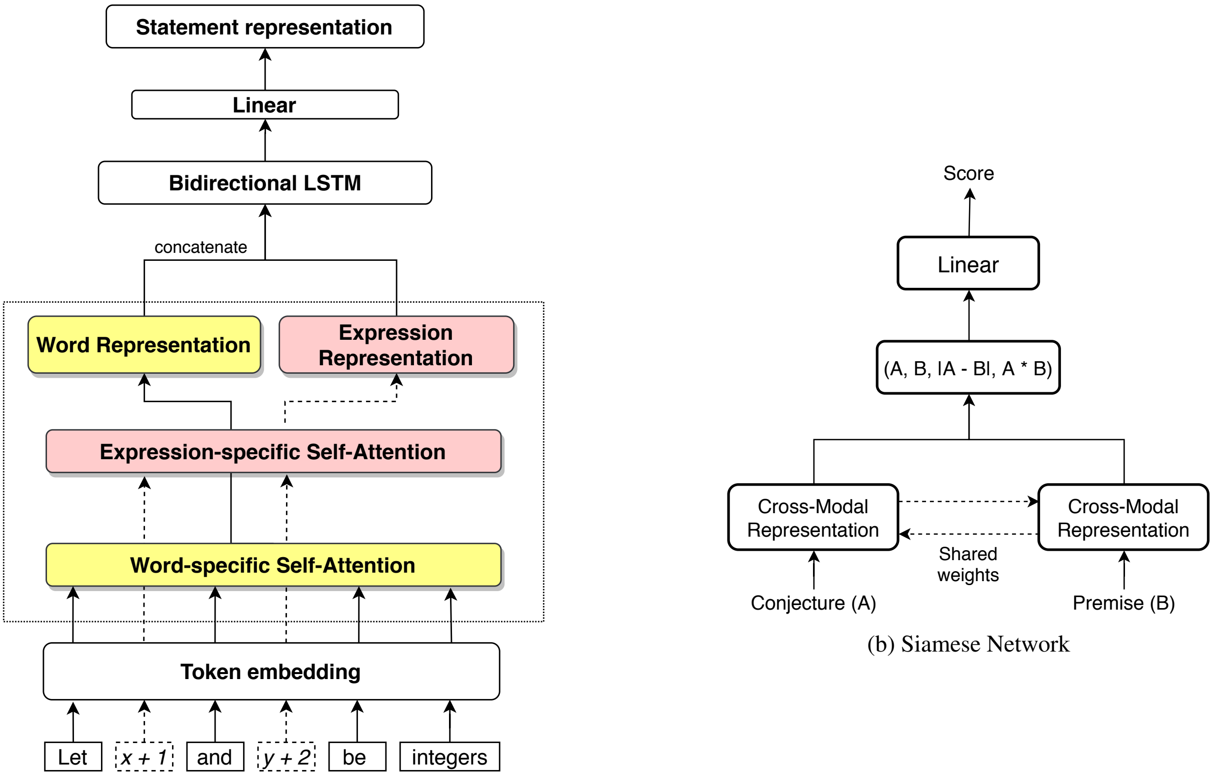
Mathematical language follows a regular pattern (in contrast to natural language) (Ganesalingam, 2013), regardless of representing a conjecture, universal truth or accepted truth. In this work, we consider mathematics written in natural language, instead of mathematics expressed in logical formal languages. The target corpus is composed of a combination of mathematical symbols and natural language words.

Given the set of mathematical statements $\mathcal{M}$ and a statement $m \in \mathcal{M}$, m is defined as a sequence of elements $m = \{s_1, s_2, \ldots, s_n\}$, where $s_i \in \mathcal{W}$, the set of words, or $s_i \in \mathcal{E}$, the set of mathematical elements present in $\mathcal{M}$. These components are situated in different lexical spaces; therefore, a function to generate a representation for m should take this into account.

We define an embedding model $\gamma : \mathcal{M} \mapsto \mathbb{R}^d$, where d is the dimension of the output vector. The complete architecture is presented in Figure 2a, where part of a statement is shown as an input example. Each layer is described in detail below.

3.1 Token embedding layer

The input to the embedding model is a mathematical statement. This embedding layer is a



(a) Embedding model.

(b) Siamese Network

Figure 2: Architecture for STAR. Figure (A) presents the model used to generate a representation for each statement, where we combine two self-attention layers, one for each modality of token. Figure (B) presents the Siamese Network used for classifying the conjecture-premise pair, based on the representations obtained.

$W_E \in \mathbb{R}^{k \times v}$ where k is the dimension of the word embeddings, and v is given by $|\mathcal{W}| + |\mathcal{E}|$.

3.2 Word/Expression-specific Self-Attention Layer

Research on the human brain has shown that there is no overlap between the parts of the brain that are activated in math-related tasks (both simple and complex) and sentence comprehension and general semantic knowledge tasks (Amalric and Dehaene, 2016). This behaviour hints at how we should map distinct representations to these different modalities of symbols and linguistic structures (maths and natural language).

Inspired by the behaviour of the human brain, we introduce two layers of self-attention (Vaswani et al., 2017), one for each modality, attempting to approximate human reasoning. One layer captures specific natural language linguistic features, while the other represents particular mathematical formalism features. Given a matrix of queries Q and matrices of keys and values K and V. The attention head is defined as:

$$Attention(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d_k}})V \quad (1)$$

where d_k is the dimension of the keys.

These attention heads compose a multi-head attention mechanism, defined as:

$$\begin{aligned} MultiHead(Q, K, V) = \\ Concat(head_1, \ldots, head_h)W^O \end{aligned} \quad (2)$$

where:
$head_i = Attention(QW_i^Q, KW_i^K, VW_i^V)$
and W_i^Q W_i^K and W_i^V are parameter matrices. In order to apply self-attention, we consider Q, K and V as the same values, obtained using a linear layer on top of the output of the embedding layer. Words and expressions tokens have a very distinct nature, and we hypothesise that these two layers allow learning and representing these differences.

3.3 Long Short-Term Memory Layer

LSTM networks (Hochreiter and Schmidhuber, 1997) are a complex activation unit, based on a chain structure explicitly designed to capture long-term sequence dependencies. LSTM is an ideal candidate for treating sequential data such as mathematical statements. For the sake of brevity, we omit the description of this layer, as it is extensively described in the literature.

3.4 Training objective

Finally, in order to obtain the score between conjectures and premises, a siamese neural network setting is used (Figure 2b), where a pair of statements are simultaneously fed into two networks, with shared weights. This allows the model to learn the representation of each statement individually, while still being aware that the statements belong to the same semantic space.

The representation for each statement is obtained and combined, where the expected score is 1 if B is a premise to A, or 0 otherwise.

The used training objective function is the Cross Entropy Loss, defined as:

$$\mathcal{L} = -\frac{1}{N}\sum_{n=1}^{N}\left[Y_n \log \hat{Y}_n + (1-Y_n)\log(1-\hat{Y}_n)\right] \tag{3}$$

where Y is the predicted classification and $\hat{Y}_i$ is the expected classification.

4 Experiments

This section presents the experiments performed to test our hypotheses. We use the dataset PS-ProofWiki (Ferreira and Freitas, 2020a) for these experiments. This dataset is composed of pairs of conjectures and premises, framing the problem as a pair classification task. Each statement is written using a combination of words and LaTeXnotation. For each positive pair, where the statement is a premise to the conjecture, there can be n number of negative pairs. For testing the robustness to noise in the proposed model, we use $n \in \{1, 2, 5, 10\}$. The number of entries for Train, Validation and Test for each value of n is shown in Table 1.

The negative pairs are obtained using two different methods. The first collects random examples of statements that are not premises to form a new pair (**negative examples**). In the second technique, we use BM-25 to retrieve statements that are lexically similar to the premises, but that are not part of positive pairs (**similar examples**). For these experiments, we used 512 as a the size of the hidden units layer in the LSTM, embedding size and output statement vector in the embedding architecture. We used 50 epochs for each training round. As shown in Figure 3, with this number of epochs we achieve convergence for all values of n. For each epoch, the validation set was evaluated, and the best model was chosen for testing.

n	**Train**	**Val**	**Test**
1	32,758	10,798	10,112
2	49,137	16,197	15,168
5	98,274	32,394	30,336
10	180,169	59,389	55,616

Table 1: Number of entries for Training, Validation and Test for different values of n.

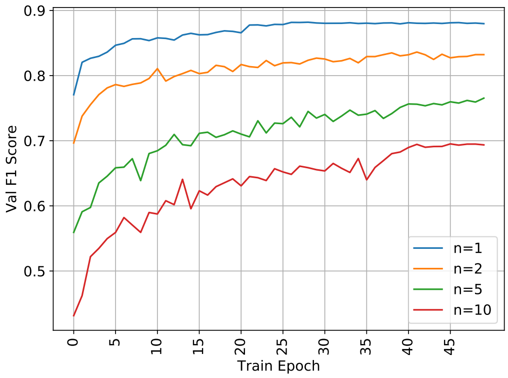


Figure 3: Number of training epochs and the obtained validation F1 score.

All experiments and data can be found in our Github repository[1].

4.1 Quantitative Analysis

In order to verify our hypothesis, we compare the proposed approach, i.e., using different self-attention layers for each modality (mathematical elements and natural language) with a modified model, using only one self-attention layer for all parts of the text. This modified model is obtained by replacing the layers inside the dotted rectangle from Figure 2a with a single self-attention layer. This modified model is referred here as **Self-attention + BiLSTM**.

---

4.1.1 Results

Table 2 presents the results for the premise selection task using the random examples.

The aggregate scores obtained using STAR is consistently higher than the baseline. Even though there is an expected degradation in the score with the addition of more negative examples, STAR still outperforms the baseline in all cases, demonstrating robustness to noise. These results support our hypothesis that different modalities inside the mathematical text should be represented in different linguistic spaces.

Similarly, we re-run both models, but this time using the similar examples. The results can be found in Table 3.

We can notice that STAR precision decreases when compared with the results obtained using the random examples. However, once more, STAR outperforms the baseline for all values of n. The results of the baseline model do not change significantly from the previous result improving it in some cases. We hypothesise that this is due to the fact that the use of lexical similarity for the generation of similar examples does not provide reliable discriminators (due to the limited intrinsic semantics of variables). Variables can have the same lexical form across mathematical statements, without sharing the same meaning.

4.1.2 Transferring Knowledge across mathematical domains

Another targeted hypothesis is that STAR performs better than the baseline in the task of transferring knowledge between different mathematical domains. In order to verify this hypothesis, we train the baseline and our model using one topic and test it in a different one, the topics used are Abstract Algebra (AA), Topology (TP) and Set Theory (ST). Table 4 presents the number of statements for Train/Val/Test for each topic.

Table 5 shows the experimental results for the different mathematical topics. Initially, we expected that training using the largest dataset would allow both models to obtain the best performance. However, training using the Topology dataset topic did not achieve the highest results. This is likely because of the distinctive nature of its symbolic space, more focused on the properties of geometric objects. On the other hand, the best performing training and test dataset, Abstract Algebra, is heavily based on the algebraic notation that our model is capable of capture using cross-modal attention.

In terms of transferable knowledge, Set Theory is the tested dataset with the highest score, confirming the expectation that Set Theory is an important component of both Abstract Algebra and Topology, being an intrinsic part of the mathematical argumentation on these topics. Therefore, such knowledge is more natural to transport. Our proposed approach outperforms the baseline in all cases. However, both models see substantial performance degradation when trying to transfer the knowledge from one topic to another, indicating both the need for better abstractive mathematical models and an intrinsic domain-specificity mathematical inference.

4.1.3 Other baselines

In order to verify the model performance, we test our model against two state-of-the-art models. The first baseline is a Transformer-based model, BERT. We fine-tune BERT (Vaswani et al., 2017) using the same configuration as the one used for Natural Language Inference (Jiang and de Marneffe, 2019) since this task carries similarities with the premise selection task. The other baseline is MathSum (Yuan et al., 2019): an encoder-decoder model used to represent mathematical content found in online forums. We use only the encoder part of this model, together with the same siamese network as STAR and the same parameter configuration. The results can be found in Table 6.

Considering the F1-Score obtained, BERT was placed second in the test set evaluation. Even though BERT is not explicitly trained for the Mathematical domain, it presents an excellent performance for the premise selection task. BERT is a large-scale model that was also trained on sources containing mathematical notation, including latex notation, therefore it partially encodes mathematical notation. Our model outperforms BERT for the test set, even though it employs a significantly smaller set of parameters (5x less parameters) and is not pre-trained on a large corpus as BERT is.

4.2 Qualitative analysis

We present examples of predicted pairs in Table 7. When analysing the obtained classified pairs, we found that STAR not only can deal with heavily equational statements, such as the second pair from the table, but it can also handle statements that contain a high level of entanglement between mathematical and natural language terms, such as the first pair.

Topic	**Train**	**Val**	**Test**
AA	2,246	633	580
ST	1,897	618	590
TP	2,539	810	788

Table 4: Distribution of dataset wih different topics.

However, we found that STAR can sometimes struggle with variable names. For example, in pair 3, the variable T appears several times. STAR infers that this implies that there is a relation between both statements. The relationship exists since both statements refer to the concept *spaces*; however, this does not define a dependency relationship. This result provides evidence for the need of an architecture which better captures variable semantics.

Figure 4 presents a comparison of our model with the single attention model. This graph shows the percentage of mathematical elements in the statement versus the percentage of the statements in the dataset that the model was able to predict correctly.

STAR has an consistent performance throughout different distributions of mathematical and natural language terms. Such results demonstrate a need of an attention layer for each term modality. On the other hand, we can observe that the baseline struggles to predict statements that are mostly mathematical (right-end of the graph), finding it easier to predict the statements which have the prevalence of natural language terms (left-end of the graph). The results show that our model is better suitable for dealing with this type of entangled text.

5 Related Work

Several areas of research apply Natural Language Processing for domain-specific tasks, Mathematics being one of these areas. One crucial task in this field is solving mathematical word problems, where the goal is to provide the answer to a mathe-

matical problem written in natural language (Zhang et al., 2020; Kushman et al., 2014; Ran et al., 2019). These problems are usually self-contained and are structured in a didactic and straightforward manner, not containing complex mathematical expressions.

Some contributions focus on the representation of mathematical text and mathematical elements. Zinn (2004) proposes a representation for mathematical proofs using Discourse Representation Theory. Similarly, Ganesalingam (2013) introduces a grammar for representing informal mathematical text, while Pease et al. (2017) presents this style of text using Argumentation Theory. Such explicit representations are relevant for representing the reasoning process behind mathematical thinking. However, it is still not possible to accurately extract these representations at scale.

Representations of mathematical elements are often used in the context of Mathematical Information Retrieval, used, for example, for obtaining a particular equation or expression, given a specific query. Tangent-CFT (Mansouri et al., 2019) is an embedding model that uses the subparts an expression or equation, to represent its meaning. This type of representation (Fraser et al., 2018; Zanibbi et al., 2016) often removes the expression for its original discourse, losing the textual context that can help to find a semantic representation. In this work, we focus on creating a representation that can integrate both of these aspects, natural language and mathematical elements. Similar to our work, Yuan et al. (2019) uses self-attention for mathematical elements in order to generate headlines for mathematical questions. Other relevant tasks for NLP applied to Mathematics include typing variables according to its surrounding text (Stathopoulos et al., 2018), obtaining the units of mathematical elements (Schubotz et al., 2016) and generating equations on a given topic (Yasunaga and Lafferty, 2019).

Premise selection is a well-defined task in the field of Automated Theorem Proving (ATP), where proofs are encoded using a formal logical representation. Given a set of premises P, and a new conjecture c, premise selection aims to predict those premises from P that will most likely lead to an

Conjecture	Premise	Predicted	Label
Let $T = (S, \tau)$ be a topological space. Let A, B be subsets of S. Then: $\partial(A \cap B) \subseteq \partial A \cup \partial B$ where ∂A denotes the boundary of A.	Let S, T_1, T_2 be sets such that T_1, T_2 are both subsets of S. Then, using the notation of the relative complement: $ST_1 \cap T_2 = ST_1 \cup ST_2$	1	1 ✓
$\int \frac{\dot{X}}{x(x^2-a^2)} = \frac{1}{2a^2}, \ln \frac{x^2-a^2}{x^2} + C$ for $x^2 > a^2$.	$\int \frac{dx}{x} = \ln x + C$ for $x \neq 0$.	1	1 ✓
Let $T = S, \tau$ be a compact space. Then T is countably compact.	Let $T = (S, \tau_{a,b})$ be a modified Fort space. Then T is not a T_3 space, T_4 space or T_5 space.	1	0 ✗

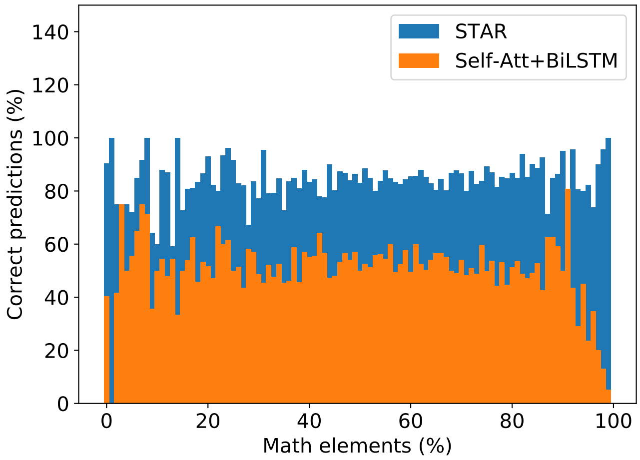

Figure 4: Comparison of our model and the baseline on the capability of predicting correctly statements with different levels of entanglement.

automatically constructed proof of c, where P and c are both written using a formal language. (Irving et al., 2016) is one of the first models to use Deep Learning for premise selection in ATPs.

Ferreira and Freitas (2020a) proposed an adaptation of this task, focusing on mathematical text written in natural language. A model based on Graph Neural Networks has been previously introduced for this task (Ferreira and Freitas, 2020b), however, the authors do not take into account the differences between mathematical and natural language terms, representing all statements homogeneously. The premise selection task can also be seen as an explanation reconstruction task, where premises are considered explanations for mathematical proofs. Approaches for dealing with such type of challenge in the science domain include unification retrieval (Valentino et al., 2020b,a) and abductive reasoning (Thayaparan et al., 2020).

In this work, we propose a new representation that distinctively captures both language modalities present in the mathematical discourse in order to solve the premise selection task.

6 Conclusion

In this work, we introduced STAR, a model to represent mathematical statements for the task Natural Language Premise Selection. In this model, we used two layers of self-attention, one for each language modality present in the mathematical text.

In order to test STAR's ability to capture the different aspects of each modality, verifying if it can interpret that expressions and words belong to different lexical spaces, we compared our performance with other baselines. We found that having one layer for each modality significantly increases the performance for premise selection. We also compared our approach with state-of-the-art models and found that STAR achieves the highest results for the Test set. STAR was also tested for transfer learning, revealing that cross-modal attention improves the transportability between different mathematical areas.

However, we discovered that STAR is still limited regarding variable modelling. There is still a gap in how to handle variable typing in latent models, considering its meaning instead of its lexical symbol. As future work, this issue will be addressed using latent representations trained specifically for variable modelling.

Do Multi-Hop Question Answering Systems Know How to Answer the Single-Hop Sub-Questions?

Abstract

Multi-hop question answering (QA) requires a model to retrieve and integrate information from multiple passages to answer a question. Rapid progress has been made on multi-hop QA systems with regard to standard evaluation metrics, including EM and F1. However, by simply evaluating the correctness of the answers, it is unclear to what extent these systems have learned the ability to perform multi-hop reasoning. In this paper, we propose an additional sub-question evaluation for the multi-hop QA dataset HotpotQA, in order to shed some light on explaining the reasoning process of QA systems in answering complex questions. We adopt a neural decomposition model to generate sub-questions for a multi-hop question, followed by extracting the corresponding sub-answers. Contrary to our expectation, multiple state-of-the-art multi-hop QA models fail to answer a large portion of sub-questions, although the corresponding multi-hop questions are correctly answered. Our work takes a step forward towards building a more explainable multi-hop QA system.

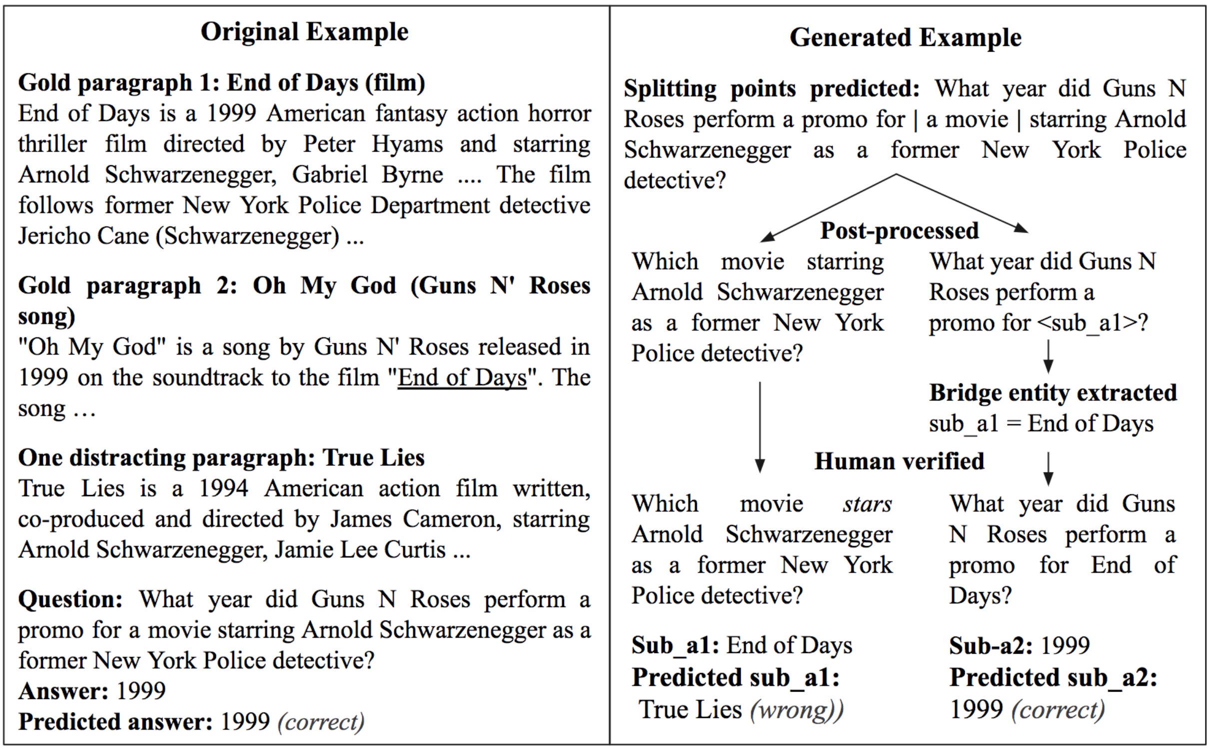
1 Introduction

Rapid progress has been made in the field of question answering (QA), thanks to the release of many large-scale, high-quality QA datasets. Early datasets (Hermann et al., 2015; Rajpurkar et al., 2016, 2018; Trischler et al., 2017; Joshi et al., 2017) mainly consist of single-hop questions, where an answer with supporting justification can be found within a short segment of text. These benchmarks focus on evaluating QA models' ability to perform local pattern matching between a passage and a question. Existing models (Lan et al., 2020; Zhang et al., 2020) have achieved super-human performance. Recently, multi-hop QA datasets (Khashabi et al., 2018; Welbl et al., 2018; Yang et al., 2018) have gained increasing attention. They require models to retrieve multiple pieces of supporting evidence from different documents and to reason over the evidence collected to answer a question. The standard evaluation metrics of QA datasets include exact match (EM) and F1 scores averaged over the test set. HotpotQA (Yang et al., 2018) also provides sentence-level supporting facts required for reasoning. However, providing supporting sentences is not sufficient for us to interpret the choice of an answer for end-to-end complex QA systems. It is unclear whether the systems have performed the desired multi-hop reasoning to reach the correct answer.

In this work, we propose an additional evaluation scheme to test multi-hop QA systems' performance on answering the single-hop sub-questions of a multi-hop question. When designing a multi-hop question, we expect it to require QA models to retrieve a chain of sentences as evidence and then reasoning over them to answer the question. Evaluating QA models on sub-questions helps us to understand their behavior on each hop of the reasoning process. In addition, it evaluates whether multi-hop QA models can generalize well on simpler questions. Figure 1 presents an illustrating example. A successful complex QA model should be able to answer the two sub-questions "*Which movie stars Arnold Schwarzenegger as a former New York Police detective*" and "*What year did Guns N Roses perform a promo for End of Days*" if it understands the underlying reasoning process for the original multi-hop question.

We focus on the HotpotQA (Yang et al., 2018) dataset under the distractor setting, in which multi-hop questions are asked over several Wikipedia paragraphs. We create the evaluation dataset by generating the sub-questions and then extracting their answers automatically. The candidate sub-questions and intermediate answers are then manually verified, which results in 1,000 sub-question

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3244–3249
April 19 - 23, 2021.



Original Example

Gold paragraph 1: End of Days (film)
End of Days is a 1999 American fantasy action horror thriller film directed by Peter Hyams and starring Arnold Schwarzenegger, Gabriel Byrne .... The film follows former New York Police Department detective Jericho Cane (Schwarzenegger) ...

Gold paragraph 2: Oh My God (Guns N' Roses song)
"Oh My God" is a song by Guns N' Roses released in 1999 on the soundtrack to the film "End of Days". The song …

One distracting paragraph: True Lies
True Lies is a 1994 American action film written, co-produced and directed by James Cameron, starring Arnold Schwarzenegger, Jamie Lee Curtis ...

Question: What year did Guns N Roses perform a promo for a movie starring Arnold Schwarzenegger as a former New York Police detective?
Answer: 1999
Predicted answer: 1999 *(correct)*

Generated Example

Splitting points predicted: What year did Guns N Roses perform a promo for | a movie | starring Arnold Schwarzenegger as a former New York Police detective?

Which movie starring Arnold Schwarzenegger as a former New York Police detective?

What year did Guns N Roses perform a promo for <sub_a1>?

Which movie *stars* Arnold Schwarzenegger as a former New York Police detective?

What year did Guns N Roses perform a promo for End of Days?

Sub_a1: End of Days
Predicted sub_a1: True Lies *(wrong))*

Sub-a2: 1999
Predicted sub_a2: 1999 *(correct)*

Figure 1: An illustrating example from the HotpotQA dataset in the distractor setting, with our construction procedure to generate an evaluation example. We only show one out of eight distracting paragraphs provided in the context due to paper length constraint.

evaluation examples. It is surprising to find that all three top-performing models which we experiment with fail to answer a large portion of sub-questions (49.8% to 60.4%), although their corresponding multi-hop questions are correctly answered.

Previous work has investigated the necessity of multi-hop reasoning on HotpotQA dataset. Jiang and Bansal (2019) construct distracting paragraphs adversarially to demonstrate that models learn to exploit reasoning shortcuts to locate the answer rather than performing multi-hop reasoning. Chen and Durrett (2019) show that a sentence-factored model can solve a large number of questions in HotpotQA, suggesting multi-hop reasoning is not really needed. Min et al. (2019a) also achieve similar result using a single-hop BERT-based model. Our sub-question evaluation is complementary to these approaches. While existing work shows the lack of multi-hop reasoning by limiting or adding text input to QA models, we provide sub-questions and intermediate answers explicitly to interpret model behavior on each hop of the reasoning process. It can be used as a complementary metric to ensure that models which can correctly answer both intermediate sub-questions and the final multi-hop question actually go through the reasoning steps as desired. Our work takes a step forward towards building a more explainable multi-hop QA system.

2 Construction of Evaluation Examples

In this section, we introduce our semi-automatic approach to generate two sub-questions and their corresponding answers for multi-hop questions from the HotpotQA dataset. As shown in Figure 1, the evaluation examples are generated in three steps. First, we decompose each source question into several sub-strings by predicting the breaking points and post-process them to generate two sub-questions. Then, the answers for the sub-questions are extracted from the paragraphs using some heuristics. Lastly, the candidate evaluation examples generated are sent for human verification. We first introduce the HotpotQA dataset and then elaborate on each step of the construction pipeline.

2.1 HotpotQA

HotpotQA contains 113K crowd-sourced multi-hop QA pairs on Wikipedia articles. We focus on bridge-type questions that actually require multiple steps of reasoning under the distractor setting. During the construction of such an example in HotpotQA, two related paragraphs p_{gold1}, p_{gold2}

from different Wikipedia articles titled t_{gold1}, t_{gold2} are presented to crowd-workers. The two paragraphs are related since the text content in one paragraph contains the title entity of the other paragraph. This shared title entity is referred to as the bridge entity. Using Figure 1 as an example, the second paragraph about *Oh My God* contains the title entity of the first paragraph, *End of Days* (underlined). Thus, *End of Days* is referred as the bridge entity. The crowd-workers are encouraged to ask a multi-hop question using both paragraphs and to annotate the supporting sentences which help to determine the answer. Then, eight other related distracting paragraphs are retrieved from Wikipedia and mixed with the two gold paragraphs to serve as the context for the question. Given an example $E = \{C, q, a\}$ from HotpotQA, we aim to generate an evaluation example $E' = \{C, q, a, sub\_q_1, sub\_a_1, sub\_q_2, sub\_a_2\}$, where sub_q_1 and sub_q_2 are the two sub-questions, and sub_a_1 and sub_a_2 are their corresponding answers.

2.2 Sub-Question Generation

Given a multi-hop question, the first step is to decompose it into sub-questions. We adopt the model introduced in DecompRC (Min et al., 2019b) to generate the sub-questions using a copying and editing mechanism. The multi-hop question is first converted into BERT word embeddings (Devlin et al., 2019), and then sent to a fully connected neural network to predict the splitting points. It is trained on 400 annotated examples. The separated text spans are post-processed to form the two sub-questions, following a set of handcrafted rules.

2.3 Intermediate Answer Extraction

One particular characteristic of bridge-type questions from HotpotQA is that the two gold paragraphs are linked by a bridge entity. Since the crowd-workers are required to form a multi-hop question which makes use of information from both paragraphs, there is a high probability that the bridge entity is the answer to the first sub-question. For the example shown in Figure 1, *End of Days* in gold paragraph 2 is the bridge entity. It is also the intermediate answer for the multi-hop question, i.e., the answer for the first sub-question.

Three different situations are considered in order to extract the bridge entity. First, if the title entity E_A of paragraph A occurs in the other paragraph B, while the title entity E_B of B does not occur in A, then E_A is recognized as the bridge entity. Second, if neither E_A nor E_B is contained in the other paragraph, then the title entity with more overlapping text with the other paragraph is chosen as the bridge entity (since sometimes the alias of the Wikipedia title is used in the paragraph). Lastly, if both E_A and E_B appear in the other paragraph, then the title entity which does not appear in both the question and the answer is chosen as the bridge entity, since an entity mentioned in the multi-hop question or included in the final answer is unlikely to be the bridge entity. The bridge entity is set to be unidentified if none or both of the title entities satisfy at least one of the requirements. As illustrated in Figure 1, once the bridge entity is retrieved, the blank in the second sub-question will be updated. The answer to the second sub-question should be the same as the original multi-hop question.

2.4 Human Verification

Sub-question generation and intermediate answer extraction help to efficiently generate candidate sub-questions and their answers. To ensure the quality of the evaluation dataset, the examples generated are manually verified. For each example, we present to an annotator the original multi-hop question, the answer, two sub-questions generated and their answers, and two gold paragraphs. Questions that actually do not require multi-hop reasoning or with the wrong answer (due to wrong annotation by the HotpotQA crowd workers) are first filtered out. Then, the annotator is required to review whether sub_q_1 and sub_q_2 are two syntactically and semantically correct sub-questions of q and whether sub_a_1 and sub_a_2 are valid and to correct them if not. In total, a sample of 1,000 examples generated for the HotpotQA development set are manually verified for use in our evaluation[1].

3 Experiments and Results

In order to interpret the behavior of existing models on each hop of the reasoning process required for multi-hop questions and to determine their ability to answer simple questions, we perform sub-question evaluation on three published top-performing QA models with publicly available open-source code: DFGN (Qiu et al., 2019), DecompRC (Min et al., 2019b), and CogQA (Ding et al., 2019). For all experiments, we measure EM and F1 scores for q, sub_q_1, and sub_q_2 on 1,000 human-verified examples. To measure the correctness of a predicted answer, we first use exact string match as the only metric. However, during error analysis, we find that many predicted answers that partially match the gold answers should also be regarded as correct. Some representative examples are shown in Table 1. Although these predicted answers have zero EM scores, they are semantically equivalent to the correct answers given. Therefore, we define a more flexible metric named partial match (PM) as an additional evaluation of correctness. Given a gold answer text span a_g and a predicted answer text a_p, they partially match if either one of the following two requirements is satisfied:

$$\begin{gathered} f1 > 0.8 \\ f1 > 0.6 \wedge \{(a_g \; contains \; a_p) \vee (a_p \; contains \; a_g)\} \end{gathered} \tag{1}$$

Table 2 shows the performance of the three models on multi-hop questions and their single-hop sub-questions. Compared to multi-hop questions, the performance of DFGN and DecompRC drops on simpler sub-questions, especially on the second sub-questions (11.13 F1 reduction for DFGN and 6.84 F1 reduction for DecompRC). CogQA achieves slightly better performance on sub-questions, which shows that it is also able to answer single-hop questions. The EM and F1 scores are averaged over all examples. In order to understand whether models are able to answer the sub-questions of correctly answered multi-hop questions, we collect the correctness statistics with regard to each individual example. Table 3 and Table 4 present the results. The first four rows show the percentage of examples whose multi-hop question can be correctly answered. Among these examples, we notice that there is a high probability that the models fail to answer at least one of the sub-questions, as shown in rows 2 to 4. We refer to these examples as model failure cases. The percentage of model failure cases over all correctly answered multi-hop questions is defined as model failure rate. As shown in Figure 2, all three models evaluated have a high model failure rate, indicating that the models learn to answer the complex questions without exploring the multiple steps of reasoning process as desired. The same phenomenon appears when evaluated using exact match and the less strict partial match scores.

After analyzing the model failure cases, we observe a common phenomenon that there is a high

q	q_{sub1}	q_{sub2}	DFGN	DecompRC	CogQA
c	c	c	23.0	31.3	26.7
c	c	w	9.7	7.2	5.8

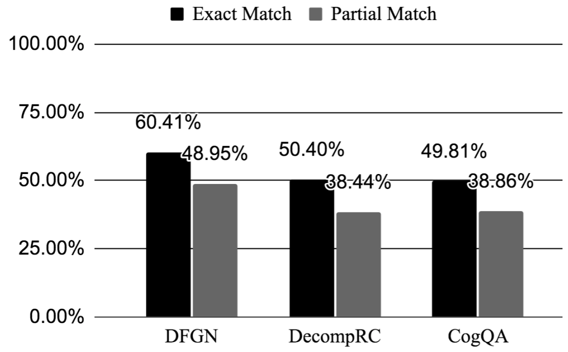

Figure 2: Model failure rates under EM and PM.

similarity between the words in the second sub-question and the words near the answer in the context. The model has learned to answer multi-hop question by local pattern matching, instead of going through the multiple reasoning steps. For the example presented in Figure 1, the model may locate the answer "*1999*" for the multi-hop question by matching the surrounding words " *Guns N Roses*" in the second sub-question. Despite answering the multi-hop question correctly, the model fails to identify the answer of the first sub-question which it is expected to retrieve as a multi-hop QA system.

4 Conclusion

We propose a new way to interpret whether multi-hop QA systems explore the multiple steps of reasoning over the evidence as desired by asking sub-questions. An automatic approach is designed to generate sub-questions for a multi-hop question. On a human-verified test set, our experiments demonstrate that top-performing multi-hop QA models fail to answer a large portion of sub-questions whose parent multi-hop questions can be correctly answered. We believe that progress on building complex QA systems that truly understand multi-hop reasoning is only possible if the evaluation metrics reward this kind of behavior. As an initial step towards a more explainable QA system, we hope our work would motivate the construction of multi-hop QA datasets with explicit reasoning paths annotated and the development of better multi-hop QA models.

Multilingual LAMA: Investigating Knowledge in Multilingual Pretrained Language Models

Nora Kassner[*], **Philipp Dufter**[*], **Hinrich Schütze**
Center for Information and Language Processing (CIS), LMU Munich, Germany
`{kassner,philipp}@cis.lmu.de`

Abstract

Recently, it has been found that monolingual English language models can be used as knowledge bases. Instead of structural knowledge base queries, masked sentences such as "Paris is the capital of [MASK]" are used as probes. We translate the established benchmarks TREx and GoogleRE into 53 languages. Working with mBERT, we investigate three questions. (i) Can mBERT be used as a multilingual knowledge base? Most prior work only considers English. Extending research to multiple languages is important for diversity and accessibility. (ii) Is mBERT's performance as knowledge base language-independent or does it vary from language to language? (iii) A multilingual model is trained on more text, e.g., mBERT is trained on 104 Wikipedias. Can mBERT leverage this for better performance? We find that using mBERT as a knowledge base yields varying performance across languages and pooling predictions across languages improves performance. Conversely, mBERT exhibits a language bias; e.g., when queried in Italian, it tends to predict Italy as the country of origin.

1 Introduction

Pretrained language models (LMs) (Peters et al., 2018; Howard and Ruder, 2018; Devlin et al., 2019) can be finetuned to a variety of natural language processing (NLP) tasks and generally yield high performance. Increasingly, these models and their generative variants are used to solve tasks by simple text generation, without any finetuning (Brown et al., 2020). This motivated research on how much knowledge is contained in LMs: Petroni et al. (2019) used models pretrained with masked language to answer fill-in-the-blank templates such as "Paris is the capital of [MASK]."

	Query	Two most frequent predictions
en	X was created in MASK.	[Japan (170), Italy (56), . . .]
de	X wurde in MASK erstellt.	[Deutschland (217), Japan (70), . . .]
it	X è stato creato in MASK.	[Italia (167), Giappone (92), . . .]
nl	X is gemaakt in MASK.	[Nederland (172), Italië (50), . . .]
en	X has the position of MASK.	[bishop (468), God (68), ...]
de	X hat die Position MASK.	[WW (261), Ratsherr (108), ...]
it	X ha la posizione di MASK.	[pastore (289), papa (138), ...]
nl	X heeft de positie van MASK.	[burgemeester (400), bisschop (276) , ...]

Table 1: Language bias when querying (TyQ) mBERT. Top: For an Italian cloze question, Italy is favored as country of origin. Bottom: There is no overlap between the top-ranked predictions, demonstrating the influence of language – even though the facts are the same: the same set of triples is evaluated across languages. Table 3 shows that pooling predictions across languages addresses bias and improves performance. WW = "Wirtschaftswissenschaftler".

This research so far has been exclusively on English. In this paper, we focus on using *multilingual* pretrained LMs as knowledge bases. Working with mBERT, we investigate three questions. (i) Can mBERT be used as a multilingual knowledge base? Most prior work only considers English. Extending research to multiple languages is important for diversity and accessibility. (ii) Is mBERT's performance as knowledge base language-independent or does it vary from language to language? To answer these questions, we translate English datasets and analyze mBERT for 53 languages. (iii) A multilingual model is trained on more text, e.g., BERT's training data contains the English Wikipedia, but mBERT is trained on 104 Wikipedias. Can mBERT leverage this fact? Indeed, we show that pooling across languages helps performance.

In summary our contributions are: **i)** We automatically create a multilingual version of TREx and GoogleRE covering 53 languages. **ii)** We use an alternative to fill-in-the-blank querying – ranking entities of the type required by the template (e.g., cities) – and show that it is a better tool

to investigate knowledge captured by pretrained LMs. **iii)** We show that mBERT answers queries across languages with varying performance: it works reasonably for 21 and worse for 32 languages. **iv)** We give evidence that the query language affects results: a query formulated in Italian is more likely to produce Italian entities (see Table 1). **v)** Pooling predictions across languages improves performance by large margins and even outperforms monolingual English BERT. Code and data are available online (`https://github.com/norakassner/mlama`).

2 Data

2.1 LAMA

We follow the LAMA setup introduced by Petroni et al. (2019). More specifically, we use data from TREx (Elsahar et al., 2018) and GoogleRE.[1] Both consist of triples of the form (object, relation, subject). The underlying idea of LAMA is to query knowledge from pretrained LMs using templates without any finetuning: the triple (Paris, capital-of, France) is queried with the template "Paris is the capital of [MASK]." In LAMA, TREx has 34,039 triples across 41 relations, GoogleRE 5528 triples and 3 relations. Templates for each relation have been manually created by Petroni et al. (2019). We call all triples from TREx and GoogleRE together *LAMA*.

LAMA has been found to contain many "easy-to-guess" triples; e.g., it is easy to guess that a person with an Italian sounding name is born in Italy. *LAMA-UHN* is a subset of triples that are hard to guess introduced by Poerner et al. (2020).

2.2 Translation

We translate both entities and templates. We use Google Translate to translate templates in the form "[X] is the capital of [Y]". After translation, all templates were checked for validity (i.e., whether they contain "[X]", "[Y]" exactly once) and corrected if necessary. In addition, German, Hindi and Japanese templates were checked by native speakers to assess translation quality (see Table 2). To translate the entity names, we used Wikidata and Google knowledge graphs.

mBERT covers 104 languages. Google Translate covers 77 of these. Wikidata and Google Knowledge Graph do not provide entity translations for all languages and not all entities are contained in the knowledge graphs. For English we can find a total of 37,498 triples which we use from now on. On average, 34% of triples could be translated (macro average over languages). We only consider languages with a coverage above 20%, resulting in the final number of languages we include in our study: 53. The macro average of translated triples in these 53 languages is 43%. Figure 1 gives statistics. We call the translated dataset *mLAMA*.

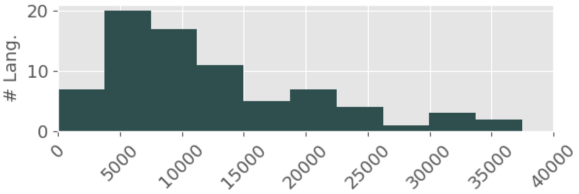

Figure 1: x-axis is the number of translated triples, y-axis the number of languages. There are 39,567 triples in the original LAMA (TREx and GoogleRE).

3 Experiments

3.1 Model

We work with mBERT (Devlin et al., 2019), a model pretrained on the 104 largest Wikipedias. We denote mBERT queried in language x as mBERT[x]. As comparison we use the English BERT-Base model and refer to it as BERT. In initial experiments with XLM-R (Conneau et al., 2020) we observed worse performance, similar to Jiang et al. (2020a). Thus, for simplicity we only report results on mBERT.

3.2 Typed and Untyped Querying

Petroni et al. (2019) use templates like "Paris is the capital of [MASK]" and give $\arg\max_{w \in \mathcal{V}} p(w|t)$ as answer where V is the vocabulary of the LM and $p(w|t)$ is the (log-)probability that word w gets predicted in the template t. Thus the object of a triple must be contained in the vocabulary of the language model. This has two drawbacks: it reduces the number of triples that can be considered drastically and hinders performance comparisons across LMs with different vocabularies. We refer to this procedure as *UnTyQ*.

We propose to use typed querying, *TyQ*: for each relation a candidate set $\mathcal{C}$ is created and the prediction becomes $\arg\max_{c \in \mathcal{C}} p(c|t)$. For templates like "[X] was born in [MASK]", we know which entity type to expect, in this case cities. We observed that (English-only) BERT-base predicts city

---

[1] `code.google.com/archive/p/relation-extraction-corpus/`

names for MASK whereas mBERT predicts years for the same template. TyQ prevents this.

We choose as $\mathcal{C}$ the set of objects across all triples for a single relation. The candidate set could also be obtained from an entity typing system (e.g., (Yaghoobzadeh and Schütze, 2016)), but this is beyond the scope of this paper. Variants of TyQ have been used before (Xiong et al., 2020).

3.3 Singletoken vs. Multitoken Objects

Assuming that objects are in the vocabulary (Petroni et al., 2019) is a restrictive assumption, even more in the multilingual case as e.g., “Hamburg” is in the mBERT vocabulary, but French “Hambourg” is tokenized to [“Ham”, “##bourg”]. We consider multitoken objects by including multiple [MASK] tokens in the templates. For both TyQ and UnTyQ we compute the score that a multitoken object is predicted by taking the average of the log probabilities for its individual tokens.

Given a template t (e.g., “[X] was born in [Y].”) let t_1 be the template with one mask token, (i.e., “[X] was born in [MASK].”) and t_k be the template with k mask tokens (i.e., “[X] was born in [MASK] [MASK] . . . [MASK].”). We denote the log probability that the token $w \in V$ is predicted at ith mask token as $p(m_i = w|t_k)$, where V is the vocabulary of the LM. To compute $p(e|t)$ for an entity e that is tokenized into l tokens $\epsilon_1, \epsilon_2, \ldots, \epsilon_l$ we simply average the log probabilities across tokens:

$$p(e|t) = \frac{1}{l} \sum_{i=1}^{l} p(m_i = \epsilon_i | t_l).$$

If k is the maximum number of tokens of any entity $e \in \mathcal{C}$ gets split into, we consider all templates $t_1, \ldots, t_k$, with C being the candidate set. The prediction is then the word with the highest average log probability across all templates $t_1, \ldots, t_k$.

Note that for UnTyQ the space of possible predictions is $V \times V \times \cdots \times V$ whereas for TyQ it is the candidate set $\mathcal{C}$.

3.4 Evaluation

We compute precision at one for each relation, i.e., $1/|T| \sum_{t \in T} \mathbb{1}\{\hat{t}_{object} = t_{object}\}$ where T is the set of all triples and $\hat{t}_{object}$ is the object predicted by TyQ or UnTyQ. Note that T is different for each language. Our final measure (p1) is then the precision at one averaged over relations (i.e., macro average). Results for multiple languages are the macro average p1 across languages.

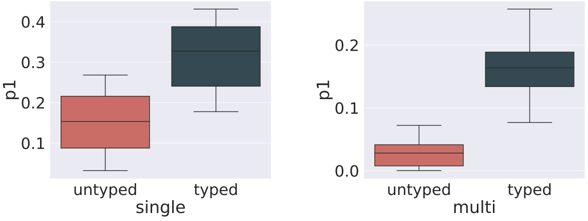

Figure 2: Distribution of p1 scores for 53 languages in UnTyQ vs. TyQ. Left: singletoken (object = 1 token). Right: multitoken (object > 1 token).

4 Results and Discussion

We first investigate TyQ and UnTyQ and find that TyQ is better suited for investigating knowledge in LMs. After exploring the translation quality, we use TyQ on mLAMA and observe rather stable performance for 21 and poor performance for 32 languages. When investigating the languages more closely, we find that prediction results highly depend on the language. Finally, we validate our initial hypothesis that mBERT can leverage its multilinguality by pooling predictions: pooling indeed performs better.

4.1 UnTyQ vs. TyQ

Figure 2 shows the distribution of p1 scores for single and multitoken objects. As expected, TyQ works better, both for single and multitoken objects. With UnTyQ, performance not only depends on the model’s knowledge, but on at least three extraneous factors: **(i)** Does the model understand the type constraints of the template (e.g., in “X is the capital of Y”, Y must be a country)? **(ii)** How “fluent” a substitution is an object under linguistic constraints (e.g., morphology) that can be viewed as orthogonal to knowledge? Many English templates cannot be translated into a single template in many languages, e.g., “in X” (with X a country) has different translations in French: “à Chypre”, “au Mexique”, “en Inde”. But the LAMA setup requires a single template. By enforcing the type, we reduce the number of errors that are due to surface fluency. **(iii)** The inadequacy of the original LAMA setup for multitoken answers. Figure 2 (right) shows that the original UnTyQ struggles with multitokens (mean p1 .03 vs. .17 for TyQ).

Overall, TyQ allows us to focus the evaluation on the core question: what knowledge is contained in LMs? From now on, we report numbers in the TyQ setting.

Manual template tuning or automatic template

	machine translated	manually corrected		manually paraphrased	
de	18.1	19.4	(6)	20.9	(18)
hi	5.4	6.2	(14)	6.2	(1)
ja	0.4	0.4	(14)	0.7	(5)

Table 2: Effect of manual template modification on UnTyQ. Shown is p1, number of templates modified (in brackets). Templates are modified to correct mistakes from machine translation and paraphrased to achieve the correct object type. Manual template correction has a small effect on UnTyQ.

mining (Jiang et al., 2020b) has been investigated in the literature to approach the typing problem. We had native speakers check templates for German, Hindi and Japanese, correct mistakes in the automatic translation and paraphrase the template to obtain predictions with the correct type. Table 2 shows that corrections do not yield strong improvements. We conclude that template modifications are not an effective solution for the typing problem.

4.2 Translation Quality

Contemporaneous work by Jiang et al. (2020a) provides manual translations of LAMA templates for 23 languages respecting grammatical gender and inflection constraints. We evaluate our machine translated templates by comparing performance on a common subset of 14 languages using TyQ querying on the TREx subset. Surprisingly, we find a performance difference of 1 percentage points (0.23 vs. 0.24, p1 averaged over languages) in favor of the machine translated templates. This indicates that the machine translated templates in combination with TyQ exhibit comparable performance but come with the benefit of larger language coverage (53 vs. 23 languages).

4.3 Multilingual Performance

In mLAMA, not all triples are available in all languages. Thus absolute numbers are not comparable across languages and we adopt a relative performance comparison: we report p1 of a model-language combination divided by p1 of mBERT's performance in English (mBERT[en]) on the exact same set of triples and call this *rel-p1*. A rel-p1 score of 0.5 for mBERT[fi] means that p1 of mBERT on Finnish is half of mBERT[en]'s performance on the same triples. rel-p1 of English BERT is usually greater than 1 as monolingual BERT tends to outperform mBERT[en].

Figure 3 shows that mBERT performs reasonably well for 21 languages, but for 32 languages rel-p1 is less than 0.6 (i.e., their p1 is 60% of English's p1). We conclude that mBERT does not exhibit a stable performance across languages. The variable performance (from 20% to almost 100% rel-p1) indicates that mBERT has no common representation for, say, "Paris" across languages, i.e., mBERT representations are language-dependent.

	LAMA	LAMA-UHN
BERT	38.5	29.0
mBERT[en]	35.0	25.7
mBERT[pooled]	**41.1**	**32.1**

Table 3: p1 for BERT, mBERT queried in English, mBERT pooled on LAMA and LAMA-UHN.

4.4 Bias

If mBERT captured knowledge independent of language, we should get similar answers across languages for the same relation. However, Table 1 shows that mBERT exhibits language-specific biases; e.g., when queried in Italian, it tends to predict Italy as the country of origin. This effect occurs for several relations: Table 4 in the supplementary presents data for ten relations and four languages.

4.5 Pooling

We investigate pooling of predictions across languages by picking the object predicted by the majority of languages. Table 3 shows that pooled mBERT outperforms mBERT[en] by 6 percentage points on LAMA, presumably in part because the language-specific bias is eliminated. mBERT[pooled] even outperforms BERT by 3 percentage points on LAMA-UHN. This indicates that mBERT can leverage the fact that it is trained on 104 Wikipedias vs. just one and even outperforms the much stronger model BERT.

5 Related Work

Petroni et al. (2019) first asked the question: can pretrained LMs function as knowledge bases? Subsequent analyses focused on different aspects, such as negation (Kassner and Schütze, 2020), easy to guess names (Poerner et al., 2020), integrating adapters (Wang et al., 2020) or finding alternatives to a "fill-in-the-blank" approach with single-token answers (Bouraoui et al., 2020; Heinzerling and Inui, 2020; Jiang et al., 2020b). Other work combines pretrained LM with information retrieval (Guu et al., 2020; Lewis et al., 2020a; Izacard and Grave, 2020; Kassner and Schütze, 2020; Petroni

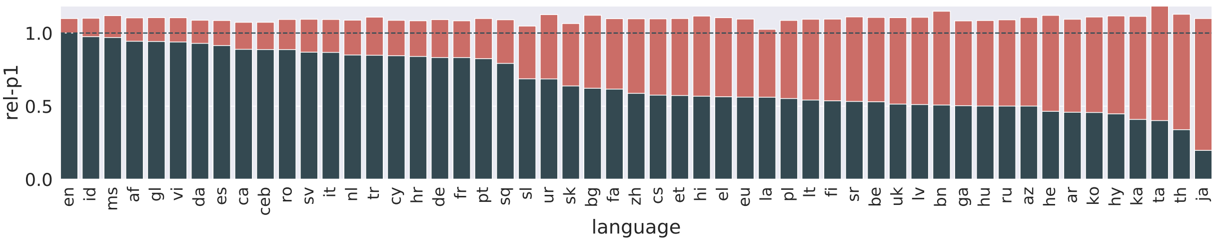

Figure 3: p1 of BERT (red) vs mBERT[x] (blue) divided by p1 of mBERT[en] on the same set of triples in each language x. mBERT captures less factual knowledge than monolingual English BERT. While performance is reasonable for 21 languages, it is below 60% for 32 languages. Dashed line is rel-p1 of mBERT[en] (by definition equal to 1.0). Performance of BERT varies slightly as the set of triples is different for each language. Note that the Wikipedia of Cebuano (ceb) consists mostly of machine translated articles.

et al., 2020). None of this work addresses languages other than English.

Multilingual models like mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020) perform well for zero-shot crosslingual transfer (Hu et al., 2020). However, we are not aware of any prior work that analyzed to what degree pretrained multilingual models can be used as knowledge bases. There are many multilingual question answering datasets such as XQuAD (Artetxe et al., 2020), TiDy (Clark et al., 2020), MKQA (Longpre et al., 2020) and MLQA (Lewis et al., 2020b). Usually, multilingual models are finetuned to solve such tasks. Our goal is not to improve question answering or create an alternative multilingual question answering dataset, but instead to investigate which knowledge is contained in pretrained multilingual LMs without any kind of supervised finetuning.

There is a range of alternative multilingual knowledge bases that could be used for evaluation. Those include ConceptNet (Speer et al., 2017) or BabelNet (Navigli and Ponzetto, 2010). We decided to provide a translated versions of TREx and GoogleRE for the sake of comparability across languages. By translating manually created templates and entities we can ensure comparability across languages. This is not possible for crowd-sourced databases like ConceptNet.

In contemporaneous work, Jiang et al. (2020a) create and investigate a multilingual version of LAMA. They provide human template translations for 23 languages, propose several methods for multitoken decoding and code-switching, and experiment with a number of PLMs. In contrast to their work, we investigate typed querying, focus on comparabiliy and pooling across languages, and explore language biases.

6 Conclusion

We presented mLAMA, a dataset to investigate knowledge in language models (LMs) in a multilingual setting covering 53 languages. While our results suggest that correct entities can be retrieved for many languages, there is a clear performance gap between English and, e.g., Japanese and Thai. This suggests that mBERT is not storing entity knowledge in a language-independent way. Experiments investigating language bias confirm this finding. We hope that this paper and the dataset we publish will stimulate research on investigating knowledge in LMs *multilingually* rather than just in English.

A Language Bias

Table 4 shows the language bias for 10 relations. For each relation we aggregated the predictions across all triples and show the most common two predicted entities together with its count (in brackets). The querying language clearly affects results. The effect is drastic for relations that ask for a country (e.g., P495 or P1001). P39 yields very different results without exhibiting a clear pattern. Other relations such as P463 or P178 are rather stable.

B Data Samples

Table 4 and Table 5 show randomly sampled entries from the data.

C Pretraining Data

We investigate whether performance across languages is correlated with the amount of pretraining data for each language. To this end we investigate the number of articles per language as of January 2021 [2] and p1 for TyQ in Figure 6. We do not have access to the original pretraining data of mBERT. Thus, the number of articles we consider in the analysis might be different to the actual data used to train mBERT.

Variational Weakly Supervised Sentiment Analysis with Posterior Regularization

Ziqian Zeng, Yangqiu Song
Department of CSE, HKUST, Hong Kong, China
`{zzengae, yqsong}@cse.ust.hk`

Abstract

Sentiment analysis is an important task in natural language processing (NLP). Most of existing state-of-the-art methods are under the supervised learning paradigm. However, human annotations can be scarce. Thus, we should leverage more weak supervision for sentiment analysis. In this paper, we propose a posterior regularization framework for the variational approach to the weakly supervised sentiment analysis to better control the posterior distribution of the label assignment. The intuition behind the posterior regularization is that if extracted opinion words from two documents are semantically similar, the posterior distributions of two documents should be similar. Our experimental results show that the posterior regularization can improve the original variational approach to the weakly supervised sentiment analysis and the performance is more stable with smaller prediction variance.

1 Introduction

Sentiment analysis is a task of identifying the sentiment polarity expressed in textual data (Liu, 2012). Most state-of-the-art sentiment analysis methods in the literature are supervised methods which require many labeled training data. However, human annotations in the real world are scarce. While we assume there is abundant annotated data to train more and more complex models, there is still a need to consider weakly supervised methods that require less human annotation.

One way to perform weakly supervised sentiment analysis is using a predefinited lexicon (Turney, 2002; Taboada et al., 2011). A lexicon consists of many opinion words. For each opinion word, its polarity (positive or negative) and strength (the degree to which the opinion word is positive or negative) are annotated by domain experts. lexicon-based weakly supervised methods perform a dictionary lookup and assign a polarity according to all opinion words extracted from a document. A good lexicon requires high precision and high coverage, which needs a lot of human effort.

Another way to do weakly supervised sentiment analysis is using limited keywords (Meng et al., 2018; Zeng et al., 2019). Compared with lexicon-based methods, user-provided keywords require less human effort. Among keyword-based methods, there are two directions. First, (Meng et al., 2018) leveraged limited keywords to expand more keywords and generate pseudo-labeled data, and then performed self-training on real unlabeled data for model refinement. Possible improvements of this direction include investigating more advanced keywords expansion techniques to generate better pseudo-labeled samples (Miller et al., 2012) and developing more advanced self-training algorithms(Coden et al., 2014).

Second, the Variational Weakly Supervised (VWS) sentiment analysis (Zeng et al., 2019) used target-opinion word pairs as supervision signal. Its objective function is to predict an opinion word given a target word. For example, in a sentence "the room is big," "room" is a target word and "big" is an opinion word. By introducing a latent variable (the sentiment polarity), they can learn a well-approximated posterior distribution via optimizing the evidence lower bound. The posterior probability here is the probability of a possible polarity (e.g., positive or negative) given a document, which is a typical sentiment classifier.

A potential issue with VWS is that optimizing the objective function may not guide the role of the latent variable to be sentiment polarity. For example, when half of reviews mention "big room" and half of reviews mention "small room," the latent variable is possibly related to the size of rooms, but the expected role of the latent variable is the sentiment polarity of rooms. Hence how to control and regularize the posterior distribution is very im-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3259–3268
April 19 - 23, 2021.

portant. One indirect way to control the posterior distribution is clever initialization (Ganchev et al., 2010). Originally, VWS aims to predict the sentiment polarity of each aspect for the multi-aspect sentiment analysis. So it uses the overall sentiment polarity to pretrain the model so that the posterior distribution has a good initialization. The overall polarity and polarity of each aspect are highly correlated. Thus, the initialization is highly likely to be similar to the true posterior distribution.

In this paper, we propose to use posterior regularization to regularize the VWS approach for sentiment analysis. There are two types of side information we can leverage to regularize the latent variable. First, calculating the similarity between keywords and extracted opinion words from a document can guide the model to decide which polarity that the document belongs to. Second, calculating the similarity between extracted opinion words from two documents can guide the model to decide whether two documents belong to the same polarity. The first type of side information is very easy to leverage, and it is reflected by our pretraining process. When a document is similar to keywords associated with a specific polarity, then we enforce that the posterior probability of a specific polarity should be large. In this case, in the pretraining process, we assign a pseudo label to the document. The second type of side information does not directly suggest which sentiment polarity that a document should be assigned to. It enforces pairwise constraints to the model. Our proposed posterior regularization leverage the second side information to ensure that when two documents are similar (dissimilar), the regularization enforces the posterior distribution of two documents to be similar (dissimilar).

Our contributions are summarized as follows,

- We develop a posterior regularization framework for the variational weakly supervised sentiment analysis.
- The experimental results show that the proposed regularization can improve the VWS model, make the results more stable, and outperform other weakly supervised baselines.

Our code is available at https://github.com/HKUST-KnowComp/VWS-PR.

2 Methodology

In this section, we first review the variational weakly supervised (VWS) sentiment analysis method in Section 2.1. Then we introduce our posterior regularization in Section 2.2.

2.1 VWS Sentiment Analysis

Before formally introducing the VWS framwork, we give a concrete example to illustrate how VWS works. Let $\mathbf{x}$ be the representation of a document x, e.g., bag of words or feature outputs of neural networks. Let C be a random variable, indicating the sentiment polarity of a document. The possible value assignment of C can be *positive* or *negative*, or rating from 1 to 10. Suppose there is a document x where we extract an opinion word "terrific." The objective function is to maximize the probability of opinion word "terrific." By introducing a latent variable C, the objective function is split into two probabilities, corresponding to two classifiers, namely, sentiment polarity classifier and opinion word classifier. The input of sentiment classifier is the document representation $\mathbf{x}$, and it produces a probability distribution of sentiment polarity, i.e., $p(C = positive|\mathbf{x})$ and $p(C = negative|\mathbf{x})$. The input of opinion word classifier is extracted opinion words and the estimated sentiment polarity distribution, and it produces a probability distribution of opinion word given estimated sentiment polarity distribution, i.e., $p(\text{"terrific"}|C = positive)$ and $p(\text{"terrific"}|C = negative)$.

2.1.1 Sentiment Polarity Classifier

The sentiment polarity classifier aims to estimate a distribution $q(C|\mathbf{x})$, where C is a discrete random variable representing the sentiment polarity of a document. Let c denote a possible value of the random variable C, representing a possible value of sentiment polarity, e.g., *positive* or *negative*. The sentiment classifier estimates the probability as

$$q(C = c|\mathbf{x}) = \frac{\exp\left(\mathbf{w}_c^T \mathbf{x}\right)}{\sum_{c'} \exp\left(\mathbf{w}_{c'}^T \mathbf{x}\right)} , \tag{1}$$

$$\mathbf{x} = CNN(x) , \tag{2}$$

where $\mathbf{w}_c$ is a trainable vector associated with a sentiment polarity c, x is a document, and $\mathbf{x}$ is the document representation. The representation of a document $\mathbf{x}$ can be various. We use Convolutional Neural Network (CNN) in the experiment.

2.1.2 Opinion Word Classifier

The opinion word classifier aims to estimate the probability of an opinion word w_o given a possible value of sentiment polarity c:

$$p(w_o|c) = \frac{\exp\left(\varphi(w_o, c)\right)}{\sum_{w'_o} \exp\left(\varphi(w'_o, c)\right)} , \tag{3}$$

where $\varphi(\cdot)$ is a scoring function taking opinion word w_o and a possible value of sentiment polarity c as inputs. The nature of the scoring function is about the frequency of occurrence. If an opinion word and a possible value of sentiment polarity co-occur frequently, the score will be high, otherwise, it will be low. Specifically, we define:

$$\varphi(w_o, c) = \mathbf{a}_c^T \mathbf{w}_o , \tag{4}$$

where $\mathbf{w}_o$ is the trainable word embedding of opinion word w_o, $\mathbf{a}_c$ is a trainable vector associated with c. The scoring function can be various, e.g., multilayer perceptron (MLP). Here we only introduce the simplest case.

Given a possible value of sentiment polarity c, VWS aims to maximize the probability of opinion words that frequently occurred with c. For example, the opinion word "good" is usually occurred with sentiment polarity *positive*, and the opinion word "terrible" is usually occurred with sentiment polarity *negative*.

2.1.3 Training Objective

The objective function of VWS is to maximize the log-likelihood of an opinion word w_o. After introducing a latent variable (i.e., the sentiment polarity of a document) to the objective function, we can derive a variational lower bound of the log-likelihood which can incorporate two classifiers. The first one corresponds to the sentiment classifier. The second one corresponds to the opinion word classifier. The variational lower bound of log-likelihood is shown as follows:

$$\begin{aligned}
\mathcal{L}_1 &= \sum_{x \in X} \sum_{w_o \in \mathcal{P}_x} \log p(w_o) \\
&= \sum_{x \in X} \sum_{w_o \in \mathcal{P}_x} \log \sum_c p(w_o, c) \\
&= \sum_{x \in X} \sum_{w_o \in \mathcal{P}_x} \log \sum_c q(c|\mathbf{x}) \left[\frac{p(w_o, c)}{q(c|\mathbf{x})}\right] \\
&\geq \sum_{x \in X} \sum_{w_o \in \mathcal{P}_x} \sum_c q(c|\mathbf{x}) \left[\log \frac{p(w_o, c)}{q(c|\mathbf{x})}\right] \\
&= \sum_{x \in X} \sum_{w_o \in \mathcal{P}_x} \mathbb{E}_{q(C|\mathbf{x})} \left[\log p(w_o|c) p(c)\right] \\
&+ \sum_{x \in X} \sum_{w_o \in \mathcal{P}_x} H(q(C|\mathbf{x})),
\end{aligned} \tag{5}$$

where X is the training set containing all documents, and $\mathcal{P}_x$ is the set of all opinion words extracted from a document x, $H(\cdot)$ refers to the Shannon entropy, and $q(c|\mathbf{x})$ is short for $q(C = c|\mathbf{x})$. By applying Jensen's inequality, the log-likelihood is lower-bounded by Eq. (5). The equality holds if and only if the KL-divergence of two distributions, $q(C|\mathbf{x})$ and $p(C|w_o)$, equals to zero. Maximizing the evidence lower bound is equivalent to minimizing the KL-divergence. Hence, VWS can learn a sentiment classifier that can produce a similar distribution to the true posterior $p(C|w_o)$. We assume that the training set is perfectly balanced, which means the prior distribution of sentiment polarity, i.e., $p(C)$, is a uniform distribution. Hence, $p(c)$ is a constant, which can be ignored.

2.1.4 Approximation

The partition function in Eq. (3) requires the summation over all opinion words in the vocabulary. Since the size of the opinion word vocabulary is large, VWS uses the negative sampling technique (Mikolov et al., 2013) to approximate Eq. (3). Specifically, VWS approximates $p(w_o|c)$ in the objective (3) with the following objective function:

$$\log \sigma\big(\varphi(w_o, c)\big) + \sum_{w'_o \in \mathcal{N}} \log\left(1 - \sigma\big(\varphi(w'_o, c)\big)\right) , \tag{6}$$

where w'_o is a negative sample in opinion words vocabulary, $\mathcal{N}$ is the set of negative samples and $\sigma(\cdot)$ is the sigmoid function. In order to ensure that the approximation part and the entropy term are on the same scale (Marcheggiani and Titov, 2016), a hyper-parameter α is added to the entropy term. The objective function becomes:

$$\begin{aligned}
\mathcal{L}_2 = \sum_{x \in X} \sum_{w_o \in \mathcal{P}_x} & \mathbb{E}_{q(C|\mathbf{x})} \Big[\log \sigma\big(\varphi(w_o, c)\big) \\
&+ \sum_{w'_o \in \mathcal{N}} \log\left(1 - \sigma\big(\varphi(w'_o, c)\big)\right) + \log p(c)\Big] \\
&+ \sum_{x \in X} \sum_{w_o \in \mathcal{P}_x} \alpha H(q(C|\mathbf{x})).
\end{aligned} \tag{7}$$

2.2 Posterior Regularization

As pointed out by (Ganchev et al., 2010), controlling the posterior distribution is crucial for models that estimate posterior distribution by maximizing the likelihood of the observed data via marginalizing over the latent variables. We need side information to regularize the posterior distribution. The side information we leveraged is that if the opinion words extracted from two documents are similar semantically, then these two documents probably are in the same class, and if the opinion words are opposite semantically, then these two documents are probably not in the same class. For example, if one document x^i contains opinion words “great” and “awesome,” another document x^j contains opinion words “great” and “excellent,” and another document x^k contains opinion words “awful” and “terrible,” it is highly possible that x^i and x^j belong to the same class because their extracted opinion words are similar semantically, and x^i and x^k do not belong to the same class because their extracted opinion words are opposite semantically.

We formulate our posterior regularization as:

$$\mathcal{R}(x^i, x^j) = -d(x^i, x^j) \cdot \mathcal{S}(\mathcal{O}(x^i), \mathcal{O}(x^j)), \quad (8)$$

where $d(x^i, x^j)$ is short for $d(q(C|\mathbf{x}^i), q(C|\mathbf{x}^j))$, meaning the distance of two posterior distributions, and we use Euclidean distance metric; $\mathcal{S}(\cdot,\cdot)$ is a score function which measures the similarity or dissimilarity between two sets of opinion words; $\mathcal{O}(x^i)$ represents all opinion words extracted from a document x^i. We finally maximize Eq. (8) in the objective function. When $\mathcal{S}(\mathcal{O}(x^i), \mathcal{O}(x^j))$ is positive (suggesting similar), this regularization enforces the distance to be small, and when $\mathcal{S}(\mathcal{O}(x^i), \mathcal{O}(x^j))$ is negative (suggesting dissimilar), this regularization enforces the distance to be large. When $\mathcal{S}(\mathcal{O}(x^i), \mathcal{O}(x^j))$ is zero, it suggests comparison between opinion words cannot decide whether two documents are similar or not.

Next, we will introduce the scoring function $\mathcal{S}(\cdot,\cdot)$. Suppose a document x^i contains a set of opinion words $\mathcal{O}(x^i) = \{w^i_{o_1}, w^i_{o_2}, \cdots, w^i_{o_k}\}$ and a document x^j contains a set of opinion words $\mathcal{O}(x^j) = \{w^j_{o_1}, w^j_{o_2}, \cdots, w^j_{o_k}\}$. We define an operation $cos(\mathcal{O}(x^i), \mathcal{O}(x^j))$ over two sets of opinion words. It will return all cosine similarity values of all valid opinion word pairs where one word must come from $\mathcal{O}(x^i)$ and the other must come from $\mathcal{O}(x^j)$. We represent opinion words using embeddings, i.e., the embeddings in the opinion word classifier in Eq. (4). If there are k opinion words in each set, $cos(\mathcal{O}(x^i), \mathcal{O}(x^j))$ will return $\frac{k*(k-1)}{2}$ cosine similarity values. When we want to know whether two documents are similar in opinion words, we pay attention to the maximum value, i.e., $max\_cos = max\big(cos(\mathcal{O}(x^i), \mathcal{O}(x^j))\big)$. When we want to know whether two documents are dissimilar in opinion words, we pay attention to the minimum value, i.e., $min\_cos = min\big(cos(\mathcal{O}(x^i), \mathcal{O}(x^j))\big)$. So we define:

$$\mathcal{S}(\cdot,\cdot) = \begin{cases} max\_cos, & \begin{array}{l} max\_cos > \gamma_1 \quad \& \\ min\_cos \geq \gamma_2, \end{array} \\ min\_cos, & \begin{array}{l} max\_cos \leq \gamma_1 \quad \& \\ min\_cos < \gamma_2, \end{array} \\ \delta, & \begin{array}{l} max\_cos > \gamma_1 \quad \& \\ min\_cos < \gamma_2, \end{array} \\ 0, & otherwise, \end{cases} \quad (9)$$

where $\mathcal{S}(\cdot,\cdot)$ is short for $\mathcal{S}((\mathcal{O}(x^i), \mathcal{O}(x^j))$ due to space limit. The first condition means two documents have some semantically similar opinion words ($max\_cos > \gamma_1$) and have no semantically dissimilar opinion words ($min\_cos \geq \gamma_2$). The value returned by the function score is max_cos. It should be a positive value. The second condition means two documents have no semantically similar opinion words ($max\_cos \leq \gamma_1$) and have some semantically dissimilar opinion words ($min\_cos < \gamma_2$). The value returned by function score is min_cos. It should be a negative number. The third condition means two documents have some semantically similar opinion words ($max\_cos > \gamma_1$) and also have some semantically dissimilar opinion words ($min\_cos < \gamma_2$). This condition corresponds to a real-world situation that when some customers want to express some negative sentiment, they usually point out some positive aspects first, and then start with a “but”, and emphasize some negative aspects. The opinion words sets extracted from these type of documents have both negative and positive opinion words. When we compare two of them, they will have some similar opinion words and dissimilar opinion words. In this case, we tend to assume they are in the same class. If the third condition is satisfied, it will return an non-negative value $\delta \in [0, 1]$; The final condition means two documents have no semantically similar opinion words ($max\_cos \leq \gamma_1$) and have no semantically dissimilar opinion words ($min\_cos \geq \gamma_2$). It will return 0.

The mechanism of the regularization is that if the posterior distributions $q(C|\mathbf{x}^i)$ and $q(C|\mathbf{x}^j)$ are different from each other, i.e., $d\big(q(C|\mathbf{x}^i), q(C|\mathbf{x}^j)\big)$ is large, but opinion words suggest that these two documents should be in the same cluster i.e., $s(w^i_d, w^j_d)$

Datasets	Yelp	IMDB	Amazon
Size of training set	38,000	20,000	20,000
Size of development set	3,800	2,000	2,000
Average doc length	155.12	252.90	88.28
Opinion vocabulary size	1,097	688	394

Table 1: Statistics of Yelp, IMDB, and Amazon dataset.

is large, then $d\big(q(C|\mathbf{x}^i), q(C|\mathbf{x}^j)\big)$ will be encouraged to be small by applying the regularization. Oppositely, if the posterior distributions $q(C|\mathbf{x}^i)$ and $q(C|\mathbf{x}^j)$ are similar, i.e., $d\big(q(C|\mathbf{x}^i), q(C|\mathbf{x}^j)\big)$ is small, but opinion words suggest that these two documents should be in the different cluster i.e., $s(w_d^i, w_d^j)$ is small, then $d\big(q(C|\mathbf{x}^i), q(C|\mathbf{x}^j)\big)$ will be encouraged to be large by applying the regularization.

The final objective function with posterior regularization is as follows,

$$\mathcal{J} = \mathcal{L}_2 + \beta \sum_{x^i \in X} \sum_{x^j \in X} R(x^i, x^j) \ , \qquad (10)$$

where x^i and x^j are documents in the training set X. The constraints are defined in a $|X| \times |X|$ space. In practice, we train our model batch by batch. So we only apply the constraints within a mini-batch. There are at most $|X_b| \times |X_b|$ constraints in a mini-batch, where $|X_b|$ is the number of samples in a mini-batch.

3 Experiments

In this section, we evaluate the empirical performance of our method on binary sentiment classification tasks.

3.1 Datasets

We use three corpora to evaluate the performance of our proposed method. All corpora have two classes and perfectly balanced. For all methods, we use a development set for hyper-parameter tuning. For all methods, we use the training set as the test set since all methods do not use the ground truth in the training set.

(1) **Yelp** Review: We use the Yelp reviews polarity dataset from (Zhang et al., 2015) and take its test set containing 38,000 documents as the corpus for evaluation. For hyper-parameter tuning, we also extract 3,800 documents from the original training set of (Zhang et al., 2015) to serve as a development set.

(2) **IMDB** Review: We use the IMDB reviews polarity dataset from (Maas et al., 2011) and randomly extract $20,000$ reviews from its original test set as the corpus for evaluation. For hyper-parameter tuning, we also extract $2,000$ documents from the original training set of (Maas et al., 2011) to serve as a development set.

(3) **Amazon** Review: We use the Amazon reviews polarity dataset from (Zhang et al., 2015) and randomly extracted $20,000$ reviews from its original test set as the corpus for evaluation. For hyper-parameter tuning, we also extract $2,000$ documents from the original training set of (Zhang et al., 2015) to serve as a development set.

Table 1 provides the details of these datasets.

3.2 Compared Methods

Lexicon uses an opinion lexicon to assign sentiment polarity to a document (Read and Carroll, 2009; Pablos et al., 2015). We combine two popular opinion lexicons used by (Hu and Liu, 2004) and (Wilson et al., 2005) to get a larger lexicon. If an extracted opinion is in the positive (negative) lexicon, it votes for positive (negative). When the opinion word is with a negation word such as "no" and "not", its polarity will be the opposite. Then, the polarity of a document is determined by using majority voting among all extracted opinion words. When the number of positive and negative words is equal, the document will be randomly assigned a polarity.

WeSTClass (Meng et al., 2018) first generates pseudo labels for documents which contain user-provided keywords. Keywords are expanded to generate more pseudo samples. It pretrains a CNN/LSTM model using pseudo samples as the training set and then performs a self-training process. Here, we use CNN because it empirically outperforms LSTM. The CNN architecture we used here is the same as the one described in (Meng et al., 2018).

Keyword Pretrain generates pseudo labels for

Datasets	Positive			Negative		
Yelp	terrific	amazing	awesome	horrible	worst	bad
IMDB	great	fantastic	awesome	awful	worst	bad
Amazon	great	fantastic	awesome	poor	worst	bad

Table 2: Keywords of Yelp, IMDB, and Amazon datasets.

documents in training set which contain user-provided keywords. We pretrain a CNN model using pseudo samples as the training set. In the CNN model, four different filter sizes $\{2, 3, 4, 5\}$ are applied, and a max-pooling layer is applied to each convolutional layer, and each convolutional layer has 100 filters.

VWS (Zeng et al., 2019) uses target opinion word pairs as supervision signal. It trains a sentiment polarity classifier and opinion word classifier simultaneously via optimizing the variational lower bound. We use a CNN model as the sentiment polarity classifier. And we pretrain it by generating pseudo labels for documents which contain user-provided keywords in the training set. The CNN architecture is the same as the one in **Keyword Pretrain**.

VWS-PR is VWS method with proposed posterior regularization.

3.3 Keywords and Opinion Word Extraction

We manually select three keywords for each class. The details of keywords of three datasets are shown in table 2.

For opinion word extraction, we adopt four rules proposed by VWS (Zeng et al., 2019) in the implementation. All rules rely on dependency parser (Chen and Manning, 2014). When a target word and an opinion word satisfy a dependency relation, we will extract the opinion word. The details of dependency relation and examples are provided in Table 3. When a pair of words satisfy one rule, there are still some restrictions on head and tails words to be satisfied. There is no restriction for Rule 1. For Rule 2, the head word should be an adjective and the tail word should a noun. For Rule 3, the head word should be one of the following four words: “like,” “dislike,” “love,” and “hate.” For Rule 4, the head word should be one of the following word: “seem,” “look,” “feel,” “smell,” and “taste.”

3.4 Result Analysis

Table 4 shows that our method VWS-PR outperforms VWS by $\mathbf{4}\%$, $\mathbf{2}\%$, and $\mathbf{1}\%$ on Yelp, IMDB, and Amazon datasets respsectively. Compared with WeSTClass and VWS, our method is more stable, i.e., smaller standard deviation, which shows that the regularization confine the posterior distribution to a smaller space. The performance of lexicon method is bad across three datasets. The main reason is that it does not involve any learning process. Keyword pretraining method can outperform lexicon method. But pseudo labels are not ground truths, hence the pseudo training set contains noises. Also, user provided keywords are limited, so the training samples with pseudo labels are restricted to some samples which contain certain keywords. For example, reviews with an extreme polarity (only expressing positive polarity or only express negative polarity) are likely to be pseudo samples. But most of reviews express mixed polarities. This will hinder the generalization ability. WeSTClass outperforms the keyword pretraining method on Yelp and Amazon dataset due to keyword expansion and self-training process. But in IMDB dataset, WeSTClass is slightly worse than the keyword pretraining method. Possible reason would be keyword expansion involve some harmful keywords and self-training procedure amplifies errors. VWS outperforms WeSTClass on IMDB and Amazon datasets and is comparable to Yelp dataset.

3.5 Hyper-parameters Sensitivity Analysis

We first show F1 scores on three datasets with varied β in Figure 1(a). It shows that optimal β values of our model on three datasets are different. When they achieve optimal β value, the standard deviation is much smaller than others. The regularization makes models more stable. Our method on IMDB and Amazon is not very sensitive. The changes are within 2%. Our method on Yelp is more sensitive. But we could still find a range, e.g., 0.1 to 0.5, where the changes are within 2%. When β keeps growing, the performance in Yelp deteriorates a lot.

Rule	Dependency Relation	Example	Extracted Word
1	adjectival modifier	they have delicious food	delicious
2	nominal subject	the room is big	big
3	direct object	i like it	like
4	open clausal complement	i feel comfortable	comfortable

Table 3: Opinion words extraction rules.

Methods \ Datasets	Yelp		IMDB		Amazon	
	Mean	Std	Mean	Std	Mean	Std
Lexicon	0.5982	0.0006	0.5998	0.0013	0.5754	0.0014
Keyword Pretraining	0.7441	0.0060	0.7496	0.0050	0.6375	0.0171
WeSTClass (Meng et al., 2018)	0.8061	0.0105	0.7354	0.0096	0.7374	0.0082
VWS (Zeng et al., 2019)	0.8014	0.0179	0.7825	0.0045	0.7530	0.0025
VWS-PR	**0.8431**	0.0013	**0.8025**	0.0041	**0.7644**	0.0020

Table 4: F1 scores of weakly supervised sentiment analysis methods on Yelp, IMDB, and Amazon.

The main reason is probably that the opinion word vocabulary size in Yelp is much larger than other datasets, and hence it is likely that the vocabulary in Yelp contains more noisy opinion words. When β is large, the noises may harm the performance.

We then show F1 scores on three datasets with varied γ_1 in Figure 1(b). The optimal γ_1 values of three datasets are the same, i.e., 0.7. The trends are consistent on three datasets. F1 score first increases and then decreases. When γ_1 is small, the constraints are easier to satisfy and the performance is bad because it may involve more noisy constraints. It probably enforces two samples to be similar but in reality, they are not similar. When γ_1 is large, the performance is also bad because it has fewer constraints that enforce two samples to be similar. It could have made use of more constraints.

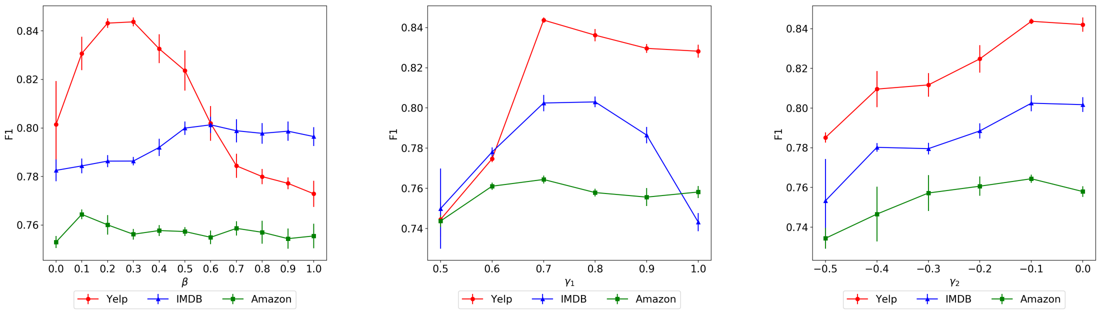
We show F1 scores on three datasets with varied γ_2 in Figure 1(c). The optimal γ_2 values of three datasets are the same, i.e., -0.1. The trends are consistent on three datasets. F1 score first increases and then decreases. When γ_2 is small, the performance is bad because it has fewer constraints that enforce two samples to be dissimilar. It could have made use of more constraints. When γ_2 is large, the performance is bad because it has more noisy constraints.

3.6 Error Analysis

We show some incorrectly predicted documents by VWS-PR on three datasets in Table 5. For the first document, the customer emphasizes price a lot. Our method cannot extract opinion words on snippets such as “not at that price” and “for half the price.” For the second document, the reviewer loves this movie because he/she loves the basketball player. The reviewer thinks that the movie itself does not deserve a high score. Our method detects both positive and negative polarities on this document, so it tends to predict as negative. Because most mixed polarities are likely to be negative polarity. The regularization enforces this pattern. This document obviously is different from other documents with mixed opinion words. For the last document, our method cannot extract opinion words on snippets such as “no wrist strap” and “without a place to attach a wrist strap.” Our method is good at extracting words on subjective expression such as “nice light,” but not on descriptive expression such as “no wrist strap.” Our method fails because no other knowledge source indicates that “no wrist strap” is negative.

3.7 Implementation Details

For WeSTClass and VWS, we used code released by (Meng et al., 2018) and (Zeng et al., 2019) respectively, and followed their preprocessing steps and optimal settings. For VWS and VWS-PR, we pretrain a CNN model using pseudo-labeled samples. After that, the embeddings are untrainable. The rest of parameters are trainable. For our method, the hyperparameter settings of VWS part



(a) Varying β with fixed γ_1 and γ_2. (b) Varying γ_1 with fixed β and γ_2. (c) Varying γ_2 with fixed β and γ_1.

Figure 1: Hyper-parameters sensitivity analysis.

Dataset	Document	Prediction	Ground Truth	Extracted Words
Yelp	It was good, but not at that price. There are so many other good italian places in the area for half the price.	good	bad	good
IMDB	I love gheorghe muresan, so i automatically loved this movie. Everything else about it was so so. Billy crystal is a good actor, even if he is annoying.	bad	good	love good annoying
Amazon	No wrist strap. Nice light, well made. But why would anyone design a tactical style flashlight without a place to attach a wrist strap.	good	bad	nice

Table 5: Documents that are predicted incorrectly by VWS-PR.

is the same as described in (Zeng et al., 2019). We implemented our models using TensorFlow (Abadi et al., 2016). When tuning hyper-parameters of regularization term, we perform grid search on $\gamma_1 \in [0.5, 0.6, \cdots, 1.0]$ and $\gamma_2 \in [-0.5, -0.4, \cdots, 0]$. After than, we fix γ_1 and $\gamma 2$, then tune $\beta \in [0.1, 0.2, \cdots, 1.0]$. δ is fixed to 1.

4 Related Work

In this section, we review the related work on weakly supervised sentiment analysis.

Using a lexicon is a typical way to perform weakly supervised sentiment analysis. One line of works perform simple assignment, i.e., majority voting, based on sentiment orientation scores of extracted opinion words. Some methods (Missen and Boughanem, 2009; Tsytsarau et al., 2010) used sentiment orientation scores in existing lexicons directly, and aggregated them within a document to determine polarity. Some methods developed their own semantic orientation estimation algorithm. For example, (Turney, 2002) first identified phrases in the review and then estimated the semantic orientation of each extracted phrases. The semantic orientation of a given phrase is calculated by comparing its similarity to a positive reference word ("excellent") with its similarity to a negative reference word ("poor"). This method determined the sentiment polarity based on the average semantic orientation of the phrases extracted from the review. (Kamps et al., 2004) used the minimum path distance between a phrase and pivot words ("good" and "bad") in WordNet to estimate the semantic orientation of extracted phrases.

Another line of works involve learning process when using a lexicon. (Li et al., 2009; Zhou et al., 2014) proposed a constrained non-negative matrix tri-factorization approach to sentiment analysis, and used a sentiment lexicon as prior knowledge. In these models, a term-document matrix is approximated by three factors that specify soft membership of terms and documents in one of k classes. All three factors are non-negative matrices. The first factor is a matrix representing knowledge in the word space, i.e., each row represents the posterior probability of a word belonging to the k classes. The second factor is a matrix providing a condensed view of the term-document matrix. The third factor is a matrix representing knowledge in document space, i.e., each row represents the posterior probability of a document belonging to the k classes. (Li et al., 2009) applied a regularization to encourage that the first factor is close to prior knowledge. This regularization is different from ours because it requires prior knowledge such as a predefined lexicon. A predefined lexicon needs a lot of human effort. (Zhou et al., 2014) applied a regularization based on an intuition that if two documents are sufficiently close to each other, they tend to share the same sentiment polarity. This intuition of this regularization is similar to ours. But when they compare document similarity, they use textual similarity (e.g., cosine similarity of bag of words) rather than similarity on opinion words. The regularization is applied under matrix factorization framework, it is not straightforward to fit in neural network based models.

Using keywords is another way to perform weakly supervised sentiment analysis. (Meng et al., 2018) leveraged keywords to generate pseudo-labeled samples for model pretraining, and then performed self-training on unlabeled data for model refinement. The possible improvement of this direction would be investigating more advanced keywords expansion techniques to generate better pseudo-labeled samples and developing a more advanced self-training algorithm. LOTClass (Meng et al., 2020), a parallel work to ours, fine-tuned a masked language model to generate relevant words that can replace label name such as “good” and “bad,” and performed self-training on unlabeled data for model refinement. Fine-tuning in LOTClass can be viewed as an advanced keyword expansion process using language models. VWS (Zeng et al., 2019) used target-opinion word pairs as supervision signal. Its objective function is to predict an opinion word given a target word. By introducing a latent variable (the sentiment polarity), they can learn a well-approximated posterior distribution via optimizing the evidence lower bound. The posterior probability here is the probability of a possible polarity (e.g., positive or negative) given text representation.

5 Conclusion

We propose a posterior regularization framework for the VWS sentiment analysis to better control the posterior distribution. The intuition behind the posterior regularization is that if extracted opinion words from two documents are semantically similar (dissimilar), the posterior distribution of two documents should be similar (dissimilar). Our experiments show that our posterior regularization can improve VWS and the performance is more stable.

Framing Word Sense Disambiguation as a Multi-Label Problem for Model-Agnostic Knowledge Integration

Abstract

Recent studies treat Word Sense Disambiguation (WSD) as a single-label classification problem in which one is asked to choose only the best-fitting sense for a target word, given its context. However, gold data labelled by expert annotators suggest that maximizing the probability of a single sense may not be the most suitable training objective for WSD, especially if the sense inventory of choice is fine-grained. In this paper, we approach WSD as a multi-label classification problem in which multiple senses can be assigned to each target word. Not only does our simple method bear a closer resemblance to how human annotators disambiguate text, but it can also be extended seamlessly to exploit structured knowledge from semantic networks to achieve state-of-the-art results in English all-words WSD.

1 Introduction

Word Sense Disambiguation (WSD) is traditionally framed as the task of associating a word in context with its correct meaning from a finite set of possible choices (Navigli, 2009). Following this definition, recently proposed neural models were trained to maximize the probability of the most appropriate meaning while minimizing the probability of the other possible choices (Huang et al., 2019; Vial et al., 2019; Blevins and Zettlemoyer, 2020; Bevilacqua and Navigli, 2020). Although this training objective proved to be extremely effective and even led to Bevilacqua and Navigli (2020) reaching the estimated upper bound of inter-annotator agreement for WSD performance on the unified evaluation framework of Raganato et al. (2017b), adhering to it underplays a fundamental aspect of how human annotators disambiguate text. Indeed, past studies have observed that it is not uncommon for a word to have multiple appropriate meanings in a given context, meanings that can be used interchangeably under some circumstances because their boundaries are not clear cut (Tuggy, 1993; Kilgarriff, 1997; Hanks, 2000; Erk and McCarthy, 2009). This is especially evident if the underlying sense inventory is fine-grained, as the complexity, and therefore performance, of WSD is tightly coupled to sense granularity (Lacerra et al., 2020). The difficulty an annotator faces in choosing the most appropriate meaning from a fine-grained sense inventory becomes clear from an analysis of gold standard datasets: a non-negligible 5% of the target words are annotated with two or more sense labels in several gold standard datasets, including Senseval-2 (Edmonds and Cotton, 2001), Senseval-3 (Snyder and Palmer, 2004), SemEval-2007 (Pradhan et al., 2007), SemEval-2013 (Navigli et al., 2013), and SemEval-2015 (Moro and Navigli, 2015). Therefore, we follow Erk and McCarthy (2009), Jurgens (2012), and Erk et al. (2013), and argue that forcing a system to treat WSD as a single-label classification problem and learn that only one sense is correct for a word in a given context does not reflect how human beings disambiguate text.

In contrast to recent work, we approach WSD as a soft multi-label classification problem in which multiple senses can be assigned to each target word. We show that not only does this simple method bring significant improvements at low or no additional cost in terms of training and inference times and number of trainable parameters, but it can also be seamlessly extended to integrate senses from relational knowledge in structured form, e.g., similarity, hypernymy and hyponymy relations from semantic networks such as WordNet (Miller, 1995) and BabelNet (Navigli and Ponzetto, 2012). While structured knowledge has been naturally utilized by graph-based algorithms for WSD (Agirre and Soroa, 2009; Moro et al., 2014; Scozzafava et al., 2020), the incorporation of such information into

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3269–3275
April 19 - 23, 2021.

neural approaches has recently been garnering significant attention. However, currently available models can only take advantage of this knowledge with purposely-built layers (Bevilacqua and Navigli, 2020) that require additional complexities and/or trainable parameters. To the best of our knowledge, the work presented in this paper is the first to integrate structured knowledge into a neural architecture at negligible cost in terms of training time and number of parameters, while at the same time attaining state-of-the-art results in English all-words WSD.

2 Method

Single-label vs multi-label. WSD is the task of selecting the best-fitting sense s among the possible senses S_w of a target word w in a given context $c = \langle w_1, w_2, \dots, w_n \rangle$, where S_w is a subset of a predefined sense inventory S. Abstracting away from the intricacies of any particular supervised model for WSD, the output of a WSD system provides a probability y_i for each sense $s_i \in S_w$. Recently proposed machine learning models – Kumar et al., 2019; Barba et al., 2020; Blevins and Zettlemoyer, 2020; Bevilacqua and Navigli, 2020, *inter alia* – are trained to maximize the probability of the single most appropriate sense $\hat{s}$ by minimizing the cross-entropy loss $\mathcal{L}_{\text{CE}}$:

$$\mathcal{L}_{\text{CE}}(w, \hat{s}) = -\log(y_{\hat{s}}) \tag{1}$$

We observe that this loss function is only suitable for single-label classification problems. In the case of WSD, this is equivalent to assuming that there is just a single appropriate sense $\hat{s} \in S_w$ for the target word w in the given context c, that is, $\hat{s}$ is clearly dissimilar from any other sense in S_w. Indeed, minimizing the cross-entropy loss in order to maximize the probability of two or more senses generates conflicting training signals; at the same time, choosing to ignore one of the correct senses results in a loss of valuable information.

Since there is a not insignificant number of instances where multiple similar senses of the target word w fit the given context c (see Section 1), we frame WSD as a multi-label classification problem in which a machine learning model is trained to predict whether a sense $s \in S_w$ is appropriate for a word w in a given context c, independently of the other senses in S_w. This is simply equivalent to minimizing the binary cross-entropy loss $\mathcal{L}_{\text{BCE}}$ on the probabilities of the candidate senses S_w:

$$\begin{aligned}\mathcal{L}_{\text{BCE}}(w, \hat{S}_w) = &- \sum_{\hat{s} \in \hat{S}_w} \log(y_{\hat{s}}) \\ &- \sum_{s \in S_w \setminus \hat{S}_w} \log(1 - y_s)\end{aligned} \tag{2}$$

where $\hat{S}_w \subseteq S_w$ is the set of appropriate senses for the target word w in the given context c. We note that this simple yet fundamental change in paradigm does not come with an increased computational complexity as $|S_w|$ is usually small. Moreover, it is independent of the underlying model used to calculate the output probabilities and, therefore, it does not increase the number of trainable parameters.

Knowledge integration. If our model benefits from learning to assign multiple *similar* senses to a target word in a given context, then it makes sense that the very same model may also benefit from learning what *related* senses can be assigned to that word. For example, in the sentence *"the quick brown fox jumps over the lazy dog"*, our model may formulate a better representation of *fox* if it is also trained to learn that any fox is a canine (hypernymy relation) or that the fox species includes arctic foxes, red foxes, and kit foxes (hyponymy relations). In this way, not only would the model learn that canines, foxes and arctic foxes are closely related, but it would also learn that canines and arctic foxes may have the ability to jump, and this could act as a data augmentation strategy especially for those senses that do not appear in the training set.

There is a growing interest in injecting relational information from knowledge bases into neural networks but, so far, recent attempts have required purposely-designed strategies or layers. Among others, Kumar et al. (2019) aid their model with a gloss encoder that uses the WordNet graph structure; Vial et al. (2019) adopt a preprocessing strategy aimed at clustering related senses to decrease the number of output classes; Bevilacqua and Navigli (2020) introduce a logit aggregation layer that takes into account the neighboring meanings in the WordNet graph.

In contrast, our multi-labeling approach to WSD can be seamlessly extended to integrate relational knowledge from semantic networks such as WordNet without any increase in architectural complexity, training time, and number of trainable parameters. We simply relax the definition of the set of possible senses S_w for a word w to include all the senses related to a sense in S_w. More formally, let $G = (S, R)$ be a semantic network where S is a sense inventory and R is the set of semantic connections between any two senses. Then we define S_w^+ to also include every sense s_j that is connected to any sense $s_i \in S_w$ by an edge $(s_i, s_j) \in R$, that is, $S_w^+ = S_w \cup \{s_j : (s_i, s_j) \in R, s_i \in S_w\}$. The loss function is updated accordingly to maximize not only the probability of the correct senses, but also the probability of their related senses:

$$\begin{aligned} \mathcal{L}_{\text{BCE}}(w, \hat{S}_w^+) = &- \sum_{\hat{s} \in \hat{S}_w^+} \log(y_{\hat{s}}) \\ &- \sum_{s \in S_w^+ \setminus \hat{S}_w^+} \log(1 - y_s) \end{aligned} \tag{3}$$

where $\hat{S}_w^+ = \hat{S}_w \cup \{s_j : (\hat{s}_i, s_j) \in R, \hat{s}_i \in \hat{S}_w\}$. We note that the increase of the number of possible choices ($|S_w^+| \geq |S_w|$) and correct meanings ($|\hat{S}_w^+| \geq |\hat{S}_w|$) does not hinder the learning process since each probability is computed independently of the others. Finally, we stress that our approach to structured knowledge integration is completely model-agnostic, as it is independent of the architecture of the underlying supervised model.

Model description. In order to assess the benefits of our multi-labeling approach and avoid improvements that may not be related to the overall objective of this paper, we conduct our experiments with a simple WSD model. Similarly to Bevilacqua and Navigli (2020), this model is simply composed of BERT (large-cased, frozen), a non-linear layer, and a linear classifier. Thus, given a word w in context we build a contextualized representation $\mathbf{e}_w \in \mathbb{R}^{d_{\text{BERT}}}$ of the word w as the average of the corresponding hidden states of the last four layers of BERT, apply a non-linear transformation to obtain $\mathbf{h}_w \in \mathbb{R}^{d_\text{h}}$ with $d_\text{h} = 512$, and finally a linear projection to $\mathbf{o}_w \in \mathbb{R}^{|S|}$ to compute the sense scores. More formally:

$$\begin{aligned} \mathbf{e}_w &= \text{BatchNorm}\left(\frac{1}{4}\sum_{i=1}^{4} \mathbf{b}_w^{-i}\right) \\ \mathbf{h}_w &= \text{Swish}(\mathbf{W}_h \mathbf{e}_w + \mathbf{b}_h) \\ \mathbf{o}_w &= \mathbf{W}_o \mathbf{h}_w + \mathbf{b}_o \end{aligned}$$

where $\mathbf{b}_w^{-i}$ is the hidden state of the i-th layer of BERT from the topmost one, $\text{BatchNorm}(\cdot)$ is the batch normalization operation, and $\text{Swish}(x) = x \cdot \text{sigmoid}(x)$ is the Swish activation function (Ramachandran et al., 2017).

3 Experiments and Results

Experimental setup. We train our models in different configurations to assess the individual contribution of several factors. First, we compare our baseline model trained with a single-label objective (Equation 1) to the same model trained with a multi-label objective (Equation 2). Then, we gradually include structured knowledge in the form of WordNet relations using Equation 3, starting from similarity relations (similar-to, also-see, verb-group, and derivationally-related-form), and incrementally including generalization and specification relations (hypernymy, hyponymy, instance-hypernymy, instance-hyponymy). In order to keep a level playing field with single-label systems, we choose only the meaning with highest probability for our multi-label models.

Datasets. We evaluate the models on the Unified Evaluation Framework for English all-words WSD proposed by Raganato et al. (2017b). This evaluation includes five gold standard datasets, namely, Senseval-2, Senseval-3, SemEval-2007, SemEval-2013, and SemEval-2015. Following standard practice we use the smallest gold standard as our development set, SemEval-2007, and the remaining ones as test sets. We distinguish between two settings: closed and open. In the former setting, we include systems that only use SemCor (Miller et al., 1994) as the training corpus, while in the latter we also include those systems that use WordNet glosses and examples and/or Wikipedia.

Hyperparameters. We use the pretrained version of BERT-large-cased (Devlin et al., 2019) available on HuggingFace's Transformers library (Wolf et al., 2020) to build our contextualized embeddings (Section 2). BERT is left frozen, that is, its parameters are not updated during training. Each model is trained for 25 epochs using Adam (Kingma and Ba, 2015) with a learning rate of 10^{-4}. We avoid hyperparameter tuning and opt for values that are close to the ones reported in the literature so as to have a fairer comparison.

Comparison systems. In order to have a comprehensive comparison with the current state of the art in WSD, we include the work of:

							Concatenation of ALL datasets

- Raganato et al. (2017a) which was one of the first to propose a neural sequence model for WSD based on a stack of BiLSTM layers;
- BERT$_{\text{large}}$, a simple 1-neareast-neighbor approach based on the last hidden state of the BERT-large-cased model (Loureiro and Jorge, 2019);
- Hadiwinoto et al. (2019) which was among the first to exploit pretrained contextualized models for WSD;
- Peters et al. (2019) which incorporated WSD knowledge directly into the training process of BERT;
- Huang et al. (2019) which tasked the model to learn which gloss is the most appropriate for a word in context;
- Bevilacqua et al. (2020) which tackled WSD as a gloss generation problem;
- Loureiro and Jorge (2019) and Conia and Navigli (2020) which created and enhanced sense embeddings with relational knowledge from WordNet and BabelNet;
- Scarlini et al. (2020a) which proposed nominal sense embeddings built by exploiting BabelNet to automatically retrieve sense-specific context;
- Scarlini et al. (2020b) which extended the above approach to non-nominal senses and multiple languages;
- alongside the aforementioned work of Vial et al. (2019), Blevins and Zettlemoyer (2020), and Bevilacqua and Navigli (2020).

The systems are divided into two groups in Table 1: in the upper part we compare our approach against those systems that do not take advantage of information coming from WordNet glosses and/or examples, while in the lower part we also include those systems that make use of such knowledge.

Results. The first two rows of Table 2 show the results of switching from a single-label to a multi-label approach for WSD: this single change already brings a significant improvement in performance (+1.0% in F_1 score, significant with $p < 0.1$, χ^2 test). Not only that, increasing the number and variety of WordNet relations further increases the performance of the model, with hyponyms being particularly beneficial (+0.8% in F_1 score). Unfortunately, including instance hypernyms and instance hyponyms does not bring further improvements; this may be due to the relatively low number of instances that can take advantage of such relations in SemCor.

Nonetheless, the results obtained set a new state of the art among single and ensemble systems trained only on SemCor without the use of additional training data or resources external to WordNet such as Wikipedia, surpassing the previous state-of-the-art non-ensemble system of Vial et al. (2019) by 2.0% in F_1 score (significant with $p < 0.05$, χ^2 test), as shown in Table 1. When further trained on the WordNet glosses and examples, our model attains state-of-the-art results (+1.2% and +0.1% in F_1 score compared to the systems of Blevins and Zettlemoyer (2020) and Bevilacqua and Navigli (2020), respectively) despite being simpler than most of the techniques it is compared against.

4 Conclusion

WSD is a key task in Natural Language Understanding with several open challenges and with the granularity of sense inventories being undoubtedly the most pressing issue (Navigli, 2018). We departed from recent work on WSD and investigated the effect of tackling the task as a multi-label classification problem. Not only is our approach simple and model-agnostic, but it can also be seamlessly extended to integrate relational knowledge in structured form from semantic networks such as WordNet, and at no extra cost in terms of architectural complexity, training times, and number of parameters.

Our experiments show that our method, thanks to its more comprehensive notion of loss over equally valid and structurally-related senses, achieves state-of-the-art results in English all-words WSD, especially when there is a lower amount of annotated text available. These results open the path to further research in this direction, from exploring more complex models and richer knowledge bases to exploiting multiple labels in innovative disambiguation settings which can overcome the fine granularity of sense inventories. Not only that, our knowledge integration approach could potentially be applied to address the knowledge acquisition bottleneck in multilingual WSD (Pasini, 2020; Pasini et al., 2021). Finally, with the rise of ever more complex general and specialized pretrained models, we believe that our simple model-agnostic approach can be another step towards knowledge-based (self-)supervision.

We release our software and model checkpoints at `https://github.com/SapienzaNLP/multilabel-wsd`.

Abstract

Nowadays, fake news is spreading in various ways, and this fake information is causing a lot of social damages. Thus the need to detect fake information is increasing to prevent the damages caused by fake news. In this paper, we propose a novel graph-based fake news detection method using a summarization technique that uses only the document internal information. Our proposed method represents the relationship between all sentences using a graph and the reflection rate of contextual information among sentences is computed by using an attention mechanism. In addition, we improve the performance of fake news detection by utilizing summary information as an important subject of the document.The experimental results demonstrate that our method achieves high accuracy, 91.04%, that is 8.85%p better than the previous method.

1 Introduction

Recently, people are easily exposed to large amount of information in various ways with the development of information propagation methods. But some of the large amount of information contains fake information generated for malicious purposes. This fake information is confusing people and causing a lot of social and economic damages. Therefore, the need to detect fake information is increasing to prevent the damages caused by fake news, and it is being researched industrially and academically (Yang et al., 2012; Castillo et al., 2011; Yan et al., 2015).

Prior fake news detection studies have methods of detecting fake news using external information as well as internal information. The method of using internal information detects fake news by analyzing linguistic features in news, such as news content (Levi et al., 2019), writing styles and consistency (Potthast et al., 2018), and relational structure between sentences (Karimi and Tang, 2019) within the news. On the other hand, that of using external information does by analyzing metadata such as aspects of news spreading (Monti et al., 2019) and user profiles of the people spreading the news (Lu and Li, 2020). However, a collection task for external information requires a lot of time and cost, and it is very difficult to identify external information in all documents. In addition, it is more basic and important to understand a document with internal information, and the construction of structural relationships among sentences within a document is one of effective methods for detecting fake news. Therefore, we propose an effective fake news detection method by structuring a context graph for representing the relationships among sentences based on summarization information.

Since all sentences in a document are strongly related to each other, the contextual information with other sentences should be reflected to generate sentence embeddings. In addition, the attention mechanism is exploited for constructing a context graph so that the different relation strength between sentences influences the contextual information of each sentence in the graph. In the context graph, nodes consist of initial sentences embeddings for all the sentences in a document and the weight of an edge is estimated by an attention score between two ended nodes of the edge. We assume that all the nodes are connected because all the sentence in a document is strong related each other. Then a contextualized sentence embedding on each node is generated by reflecting the neighbor's contextual information. The contextualized sentence embedding of a node is computed by the sum of the products of the attention score between the node and its neighbor node and the initial sentence embedding of the neighbor node.

Because the subject of a document is very im-

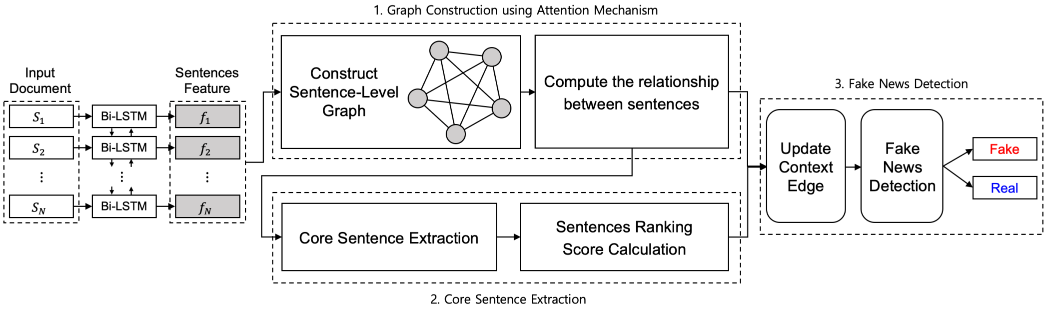

Figure 1: The architecture of our proposed model.

portant information in identifying the content of the document and fake information is commonly related to the subject, we apply a summarization technique (Jeong et al., 2016) that can effectively capture the subject information of the document to fake news detection. By using a summarization technique, sentences containing a lot of subject information are highly ranked and the ranked scores influence the attention scores for construction of the context graph.

For performance comparison with the proposed method, we implemented a baseline model that detects fake news with the sum of all sentence embeddings in a document. Our proposed model shows 91.04% accuracy, that is 11.19%p better performance than baseline model. It also shows 8.85%p better performance compared to other model (Karimi and Tang, 2019) that uses the same dataset and a dependency tree structure among sentences in a document.

2 Notations

We have a corpus D of fake and real news documents. Let a document $d \in D$ contain N sentences $s_1, s_2, ...s_N$ and each sentence $s_i \in d$ include words $word_1, word_2, ...word_l$ where l denotes the number of words in sentence s_i. We apply the Bi-LSTM network to all sentences of a document and obtain the initial sentence embedding representations $\mathcal{H} = h_1, h_2, ...h_N \in \mathbb{R}^{N \times dim}$.

3 Proposed Method

We propose a novel fake news detection method based on the context graph with a summarization technique (see Figure 1). Our method consists of three components. The first one is *graph construction using attention mechanism* for representing the relationship between all sentences using a graph. The second one is *core sentence extraction* for ranking sentences with subject information using a summarization technique. The third one is *fake news detection* for discriminating fake news from a lot of documents.

3.1 Graph Construction using Attention Mechanism

To model the relationship between sentences and their contextual information, we construct a graph $\mathcal{G} = (F, E)$. The graph $\mathcal{G}$ is composed of node $(i.e., F = f_1,\ f_2,\ \ldots f_N)$ and the edge $(i.e.,\ E = e_{1,2},\ e_{ij},\ \ldots e_{N-1,N})$. Each node is represented by sentence embedding H and the edge between the i-th node and the j-th node is represented by $e_{i,j}$ and its weight $w_{i,j}$ means the relation strength of the i-th sentence for the j-th sentence. Since all sentences in a document are strongly related to each other, we consider that $\mathcal{G}$ is a fully connected graph. To reflect the different relation strength between sentences, each edge $e_{i,j}$ is associated with a weight $w_{i,j}$, and the weight is derived by the attention mechanism between sentence embeddings h_i and h_j of two nodes f_i and f_j as follows (Eq. 1-3):

$$x_i = ReLU(Wf_i + bias) \tag{1}$$

$$x_j = ReLU(Wf_j + bias) \tag{2}$$

$$w_{i,j} = x_i U x_j \tag{3}$$

where $W \in \mathbb{R}^{m \times dim}$ and $x \in \mathbb{R}^m$. The dimension size of sentence embedding can be reduced to avoid overfitting without weakening the LSTM's capacity (Dozat and Manning, 2018) by Equations (1) and (2). U is a weight matrix to compute the relation strength between x_i and x_j. $w_{i,j}$ represent an edge weight between pair of nodes f_i and f_j in the graph $\mathcal{G}$.

3.2 Core Sentence Extraction

Based on the constructed graph, the subject information of a sentence is estimated by summing attention scores (edge scores) between the node of the sentence and its adjacent nodes, and a sentence with the most subject information is extracted as a core sentence. $Core_{sent}$ represents an extracted sentence.

$$Core_{sent} = \operatorname*{argmax}_{1 \leq i \leq N} \sum_{j=1, j \neq i}^{N} w_{i,j} \tag{4}$$

Based on the cosine similarity values between the core sentence and all other sentences, all sentences in the document are divided into a subject relevant sentence set and an irrelevant sentence set. The subject relevance score of each word is based on the frequency of appearance in the subject relevant and irrelevant sentence sets. The word relevance score RS_d is calculated by Equation (5) (Jeong et al., 2016).

$$\begin{aligned} RS_d\,(word) &= log\frac{p_d \times (1 - q_d)}{(1 - p_d) \times q_d} \\ &= log\frac{(r_d + 0.5)\,(S_d - s_d + 0.5)}{(R_d - r_d + 0.5)\,(s_d + 0.5)} \end{aligned} \tag{5}$$

where p_d and q_d are the probabilities that a word appears in subject relevant and irrelevant sentences set in a document d. Respectively, R_d and S_d are the number of subject relevant sentences and irrelevant sentences in document d. r_d and s_d are the number of subject relevant and irrelevant sentences that include the word in a document d, and 0.5 is a naïve smoothing factor to avoid zero-denominator or log-zero. On this paper, the top 30% of sentences with the subject relevance score were selected as the subject relevant sentence set, and the others were as the irrelevant sentence set. Afterward, the sentence score can be calculated with the sum of relevance score of words included in the sentence (Jeong et al., 2016).

$$Score(s_i) = \sum_{word \in s_i} RS_d(word) \tag{6}$$

3.3 Fake News Detection

After we calculate the sentence ranking using the sentence scores by Equation (6), we can construct a new updated graph by reflecting the sentence ranking into the weight of the edge. The weight of the edge represents the reflection rate of the subject information as well as the context information.

$$R_{Score(s_i)} = 1 - \frac{Sentence\_Rank(s_i) - 1}{N} \tag{7}$$

$$w'_{i,j} = w_{i,j} * R_{Score(s_i)} \tag{8}$$

$$(for\ i, j\ =\ 1,\ 2,\ ...,\ N\ and\ i \neq j)$$

The sentence ranking score is calculated by Equation (7) and the weight of all edges is updated by Equation (8). Subsequently, we can construct subject contextualized sentence embeddings using the updated graph. The subject contextualized sentence embedding (i.e., h'_i) is created by the weighted sum of the initial sentence embedding of the current sentence (i.e., h_i) and those of the other adjacent sentences (i.e., h_j) as follows:

$$h'_i = h_i + \sum_{j=1, j \neq i}^{N} w'_{i,j} * h_j \tag{9}$$

Finally, we create a document embedding by averaging the embedding vectors of all sentences in a document and then the document embedding is then fed into a multi-layer feedforward neural network to predict label, fake or real, by the binary classification, as a vector $\hat{y}$.

$$doc = \sum_{i=1}^{N} h'_i \tag{10}$$

$$\hat{y} = Softmax(tanh(Wdoc + bias)) \tag{11}$$

The cross-entropy loss function is used to optimize our neural network.

4 Experiments

4.1 Datasets

We used HDSF dataset (Karimi and Tang, 2019) for our fake news detection experiments. The dataset consists of 3,360 real documents and 3,360 fake documents. We follow the Karimi's data split: 6,452 documents for training data, 134 ones for validation set, and 134 ones for test set and each data split contains even number of documents from fake and real classes. In addition, we did experiments on 5-folds cross-validation because the original HDSF dataset contain too small size of test documents.

4.2 Experimental Settings

We used word2vec embedding (Mikolov et al., 2013) that is pre-trained from Google as an initial word embedding, and set the Bi-LSTM hidden unit size to 200. We set the epoch as 200, mini-batch size as 40, and dropout as 30% on each experiment. We used the Adam optimizer (Kingma and Ba, 2014) and set the initial learning rate as 0.001 and reduce by 10 times for every 50 epochs. We used accuracy as the metric of performance.

4.3 Models

The proposed model is compared to the baseline model and Karimi's model (Karimi and Tang, 2019) to prove a superiority of our proposed model in this subsection.

Karimi's Model (Karimi and Tang, 2019) A fake detection method to predicts whether a document is fake or real by constructing relationships of each sentence in a document using the hierarchical discourse-level dependency tree.

Baseline Model The baseline model uses the document embedding only using Bi-LSTM and predicts whether it is fake or real through the feed-forward neural network.

Graph Model This graph model connects all sentences in a document by constructing a graph structure. Fake news is detected by creating sentence embeddings that only reflect contextual information on a graph.

Graph + Summarization Model (Proposed) The graph + summarization model is our final proposed model. It classifies the fake or real documents after representing a document embedding that reflect the contextual and subject information on a graph structure by the summarization technique.

4.4 Experiment Results

Table 1 shows a comparison of the experiment results. The RST, LIWC, N-grams, and BiGRNN-CNN models implemented by (Karimi and Tang, 2019). Our proposed model showed best performance compared to other models and it achieved better performance than the baseline model about 11.19%p, and even better than the Karimi's model about 8.85%p. In addition, we obtained 3.73%p improvement when summarization technique is used in the graph model. Moreover, the final proposed model showed the best performance even in the 5-folds cross-validation experiments with 9.06%p improvement as well.

Model	**Data**	
	HDSF	Cross Validation
RST	67.68	-
LIWC	70.26	-
N-grams	72.37	-
BiGRNN-CNN	77.06	-
Karimi's	82.19	81.71
Baseline	79.85	79.27
Graph Model	87.31	84.52
Graph + Summarization (Proposed)	**91.04** **(+11.19%p∗)** **(+8.85%p⋆)**	**88.33** **(+9.06%p∗)** **(+6.62%p⋆)**

Table 1: Comparing results. The ∗ and ⋆ denote the differences between the proposed model and the Baseline or Karimi's.

5 Analysis

Herein, we introduce two analyses by an additional experiment for subject consistency detection in our model and dataset. The proposed method attempted to effectively detect subject information in fake news and the consistency of subject information is also important to detect fake news. In the first analysis, we verify our process of updating the graph in the proposed model, which uses a fully connected graph, by comparing other model using a 50% connected graph, which uses edges with only the top 50% with high attention scores. As a result, the proposed model with a fully connect graph showed 1.29%p higher performance than the model with a 50% connected graph. We think it means that a fully connect graph is more useful to detect fake news. Secondly, we observed the variances of the attention scores in the fake and real documents (see Table 2). The variance in the fake documents is higher than that of the real documents and it means that the fake documents has an inconsistent subject distribution.

	Variance	Standard Deviation
Fake	8.6	2.93
Real	5.41	2.33

Table 2: Variance/standard deviation of attention scores

6 Conclusions

We have proposed a novel graph based fake news detection method using summarization technique. Our model shows that the use of contextual and subject information is helpful in detecting fake news. Our final proposed model achieved better performance than the baseline model about 11.19%p.

Abstract

Automatic detection of cognates helps downstream NLP tasks of Machine Translation, Cross-lingual Information Retrieval, Computational Phylogenetics and Cross-lingual Named Entity Recognition. Previous approaches for the task of cognate detection use orthographic, phonetic and semantic similarity based features sets. In this paper, we propose a novel method for enriching the feature sets, with cognitive features extracted from human readers' gaze behaviour. We collect gaze behaviour data for a small sample of cognates and show that extracted cognitive features help the task of cognate detection. However, gaze data collection and annotation is a costly task. We use the collected gaze behaviour data to predict cognitive features for a larger sample and show that predicted cognitive features, also, significantly improve the task performance. We report improvements of 10% with the collected gaze features, and 12% using the predicted gaze features, over the previously proposed approaches. Furthermore, we release the collected gaze behaviour data along with our code and cross-lingual models.

1 Introduction

Cognates are word pairs, across languages, which have a common etymological origin. For example, the French and English word pair, *Liberté - Liberty*, reveals itself to be a cognate through orthographic similarity. The task of automatic cognate detection across languages[1] requires one to detect word pairs which are etymologically related, and carry the same meaning. Such word pairs share a formal and/or semantic affinity and facilitate the second language acquisition process, particularly between related languages. Although they can accelerate vocabulary acquisition, language learners also need to be aware of false friends and partial cognates, at times, leading to unrelated semantic coupling. For example, *"gift"* in German means *"poison"*, which is a known example of a False Friend pair. For an example of a partial cognate, the word *"police"* can translate to *"police"*, *"policy"* or *"font"*, in French, depending on the context in which it was used.

Manual detection of such cognate sets requires a human expert with a good linguistic background in multiple languages. Moreover, manual annotation of cognate sets is a costly task in terms of time and human effort. Automatic Cognate Detection (ACD) is a well-known task, which has been explored for a range of languages using different methods; and has shown to help Cross-lingual Information Retrieval (Meng et al., 2001), Machine Translation (MT) (Al-Onaizan et al., 1999), and Computational Phylogenetics (Rama et al., 2018). In the traditional approaches to automatic cognate detection, words with similar meanings or forms are used as probable cognates (Jäger et al., 2017; Rama, 2016; Kondrak, 2001). From such pairs, the ones that exhibit a high phonological, lexical and/or semantic similarity, are analyzed in order to find true cognates. Merlo and Andueza Rodriguez (2019) perform an investigation to evaluate the use of cross-lingual embeddings and show that these models inherit a lexical structure matching the bilingual lexicon. This study establishes that cross-lingual models can provide an effective similarity score compared to their monolingual counterparts, for both cognates and false friends. However, they do not evaluate machine learning (ML) approaches that distinguish between cognates and false friends. The absence of such an evaluation motivates us to use cross-lingual similarity scores with ML algorithms. Our work[2] reports whether these scores can provide an adequate distinction or not.

---

[1] Cognates can also exist in the same language. Such word pairs/sets are commonly referred to as *doublets*.

False Friend	shikshA	shikshA	Education	Punishment

Table 1: An example each of a cognate and a false friend pair from Indian languages, Hindi and Marathi.

Inspired from their work, we investigate the use of cross-lingual word embeddings and cognitive features to distinguish between cognates and false friends, for the Indian language pair of Hindi and Marathi. Cognitively inspired features have shown to improve various NLP tasks (Mishra et al., 2018a). However, most of their work involves collecting the gaze behaviour data first on a large sample, and then splitting the data into training and testing data, before performing their experiments. While their work does show significant improvements over baseline approaches, across multiple NLP tasks, collecting gaze behaviour over a large cognate dataset can be costly, both in terms of time and money. Our approach tries to reduce annotation cost by predicting gaze behaviour data for a large sample based on the smaller sample of collected gaze data. Our investigations use three recently proposed cross-lingual word embeddings based approaches to generate features for the task of cognate detection. We also generate cognitive features from participants' gaze behaviour data and show that gaze behaviour helps the task of cognate detection. Additionally, we use the collected gaze behaviour data and predict gaze-based features for a much larger sample. We believe that using gaze features will be more applicable only if gaze features can be predicted for unseen samples. We believe that collection of gaze data cannot be performed in all the scenarios and hence hypothesize that predicting such data if it helps improve the task of cognate detection, should be a viable solution.

Motivation

Consider a scenario where an NLP task comes across the false friend pair in Table 1. Orthographic similarity or even phonetic similarity-based techniques will fail to detect the difference between the Hindi meaning of the word "shikhshA" and its Marathi counterpart. Here, semantic approaches should detect the distinction in meaning, but monolingual embeddings are trained using a large corpus **from the same language**. In such cases, it becomes imperative that a cross-lingual word embeddings model be utilized. However, Indian languages are known to be low-resource languages compared to English or even many European languages like French, Italian, German *etc.* Acquiring additional clean data for training cross-lingual models is, yet again, a painful task. In such a scenario then, we ask ourselves,

"Can cognitive features be used to help the task of Cognate Detection?"

furthermore,

"Using gaze features collected on a small set of data points, can we predict the same features on a larger set of data points to alleviate the need for collecting gaze data?"

With this work, we try to answer both the questions stated above and present the rest of the paper as follows. We discuss the current literature on the cognate detection task and cognitive NLP in Section 2. Section 3 discusses the dataset acquisition, including the description and analysis of our gaze behaviour data. We describe the feature sets used in section 4. Our approaches to the task of cognate detection are discussed in Section 5. The results of our work are discussed in Section 6. Finally, we conclude the study with possible future work in this direction in Section 7.

Terminology

An *interest area (IA)* is an area of the annotation screen to be processed by the human reader. In our experiments, it is an area where a word is shown to the reader. A *fixation* is an event where the reader focuses within an "interest area". A *saccade* is the movement of the eye from one fixation point to another. If the saccades move from an earlier IA to a later IA, such a saccade is called a *progression*. A *regression* is the saccade path when the reader moves back to a previous IA. We also use the terms *reader* and *participant* interchangeably.

2 Related Work

Current literature which uses gaze behaviour to solve downstream NLP tasks has been applied to the NLP tasks of sentiment analysis (Mishra et al., 2018a; Barrett et al., 2018; Long et al., 2019), sarcasm detection (Mishra et al., 2016), grammatical error detection (Barrett et al., 2018), hate speech detection (Barrett et al., 2018), named entity recognition (Hollenstein and Zhang, 2019), part-of-speech tagging (Barrett et al., 2016), sentence simplification (Klerke et al., 2016), and readability (González-Garduño and Søgaard, 2018; Singh et al., 2016). A comprehensive overview is provided by Mishra and Bhattacharyya (2018). The primary motivation of using cognitive features for NLP tasks is derived from the eye-mind hypothesis (Just and Carpenter, 1980), which establishes a direct correlation between a reader's comprehension of the text with the time taken to read the text. This hypothesis has initiated a large body of psycholinguistic research that shows a relationship between text processing and gaze behaviour. Yaneva et al. (2020) discuss the use of gaze features for the task of anaphora resolution. Their findings show that gaze data can substitute the classical text processing approaches along with the fact that human disambiguation process overlaps with the information carried in linguistic features. Rohanian (2017) use gaze data to automatically identify multiword expressions and observe that gaze features help improve the accuracy of the task when combined with traditional linguistic features used for the task.

Mathias et al. (2020) describe an approach to scoring essays in a multi-task learning framework automatically. Their approach relies on collecting gaze behaviour for essay reading for a small set of essays and then predicting the rest of the dataset's gaze behaviour in a multi-task learning setup. Similarly, Barrett et al. (2016) use token level averages of cognitive features at run time, to mitigate the need for these features at run time. Singh et al. (2016) and Long et al. (2019) predict gaze behaviour at the token-level as well. Mishra et al. (2018a), González-Garduño and Søgaard (2018), Barrett et al. (2018), and Klerke et al. (2016), use multi-task learning to solve the primary NLP task, where learning the gaze behaviour is an auxiliary task.

Orthographic/String similarity-based methods are often used as baseline methods for the cognate detection task, and the most commonly used method amongst them is the Edit distance-based similarity measure (Melamed, 1999; Mulloni and Pekar, 2006). Research in automatic cognate detection using various aspects involves the computation of similarity by decomposing phonetically transcribed words (Kondrak, 2000; Dellert, 2018), acoustic models (Mielke et al., 2012), clustering based on semantic equivalence (Hauer and Kondrak, 2011), and aligned segments of transcribed phonemes (List, 2012). Rama (2016) employs a Siamese convolutional neural network to learn the phonetic features jointly with language relatedness for cognate identification. Jäger et al. (2017) use SVM for phonetic alignment and perform cognate detection for various language families. Various works on orthographic cognate detection usually take alignment of substrings within classifiers like SVM (Ciobanu and Dinu, 2014, 2015) or HMM (Bhargava and Kondrak, 2009). Ciobanu and Dinu (2014) employ dynamic programming based methods for sequence alignment. Cognate facilitation in second language learners has previously been explored with the help of eye-tracking studies (Blumenfeld and Marian, 2005; Van Assche et al., 2009; Bosma and Nota, 2020) but the task of cognate detection has not been performed with gaze features obtained from the cognitive data in any of the previously available literature.

For the task of cognate detection, however, the use of cognitive features has not been established previously. The task of cognate detection is cross-lingual, and a reader's cognitive load should vary while trying to comprehend the meaning of concepts, from different languages. Our work tries to exploit the difference noted in terms of time taken and eye-movement patterns in cognates *vs* false friends, to generate additional features for the ACD task. Moreover, for Indian languages such as Marathi, where agglutination[3] varies the word length, the task becomes tougher, computationally.

3 Dataset Acquisition & Analysis

We pose the problem of cognate detection as a binary classification task in a supervised setting. We use a recently released challenging dataset (Kanojia et al., 2020) of cognates and false friends. We extract the Hindi-Marathi cognate and false friend pairs. The number of cognate and false friend pairs released by the paper cited above is 15726, and 5826. We select an equal number of cognates at random to reduce this skew, thus producing a balanced dataset for the classification task. For any further experiments in our paper, we use this artificially class-balanced dataset of 5826 (cognates) + 5826 (false friends) data points. We also augment the complete dataset with context information from the IndoWordnet (Bhattacharyya, 2017). The con-

---

[3] Agglutination is a linguistic process pertaining to derivational morphology in which complex words are formed by stringing together morphemes without changing them in spelling or phonetics.

D2	**100**	**100**

Table 2: Dataset Statistics for Cognate Detection Task

text information contains a *gloss* and an *example sentence* from the Wordnet data. The dataset released by Kanojia et al. (2020) contains the Synset IDs for each word pair, which helps us locate exact concept information from the dataset. We provide positive labels to cognates and negative labels to false friend pairs obtained from this data and construct what we call "D1".

We extract 100 pairs, at random, from each of the positive and negative labels for collecting gaze behaviour data, to construct what we call "D2". This data, extracted from D1, is used to collect gaze behaviour and annotation. Although we have gold labels for the data extracted, we ask the participants to annotate the data by asking them if the concepts shown on the screen mean the same. The annotation screen provides them with contextual clues obtained from Wordnet data on the screen, as shown in Figure 1. The complete dataset statistics are shown in Table 2.

3.1 Gaze Data Collection and Annotation

The task assigned to annotators was to read word pairs and the contextual clues provided on the screen, one pair at a time. The annotators were requested to label the pairs with a binary score indicating the similarity in meaning (*i.e.,* positive/negative). It should be noted that the participants were not instructed to annotate whether a pair is a cognate or a false friend, to rule out the Priming Effect, (*i.e.,* if the exact task (cognates *vs* false friends) is expected beforehand, processing cognate pairs will become relatively easier (Sáchez-Casas et al., 1992)). This ensures the ecological validity of our experiment in two ways: (1) The participant does not have any clue so that they can treat cognates with special attention (done by asking them to annotate based solely on meaning similarity) (2) Cognate pairs are mixed with false friend pairs and the participant does not have any prior knowledge about whether the next word pair would be a cognate or not. This also ensures that the participants pay attention to the task and do not just skim through the word-pair presented on the screen.

Table 3: T-test statistics for average fixation duration time per word for Positive labels (Cognates) and Negative labels (False Friends) for participants P1-P9.

It should be noted that all our participants are primarily Marathi speakers and have learnt Hindi at the school level. Hindi and Marathi are considered to be relatively closer languages due to their shared vocabulary and the geographical location of the demographic. All the participants speak, understand and write - both Hindi and Marathi.

The collection of gaze data is conducted by following the standard norms in eye-movement research (Holmqvist et al., 2011). While reading, an SR-Research Eyelink-1000 eye-tracker (monocular remote mode, sampling rate 500Hz) records several eye-movement parameters like fixations (a long stay of gaze) and saccade (quick jumping of gaze between two positions of rest) and pupil size. For this experiment, the default value of 4ms was used for a gaze to be counted as fixation. We request a total of 15 participants to perform the annotation task, out of which only 11 participants could perform the data collection[4].

Out of the 11 completed annotations, we discarded the data from 2 participants as their gaze behaviour was erratic (the fixations were too far away from the IAs). The participants are graduates with science and engineering background. They are bilingual speakers who know both Hindi and Marathi. Our participants were given a set of instructions beforehand and were advised to seek clarifications before they proceed. The instructions mention the nature of the task as discussed above, annotation input method, and the necessity of head movement minimization during the experiment.

---

[4] We could not perform gaze data collection with the remaining 4 participants due to the COVID-19 pandemic.

Figure 1: Screen capture showing collection of gaze features (via eye tracking) while displaying word pairs along with respective definitions and examples. The figure shows the cognate pair (*BiDha* - *BiDha*) where both mean "pierced" in the context of hunting. The figure also shown the glosses and example sentences provided to the annotator for this cognate pair in their respective languages (Hindi and Marathi)

3.2 Gaze Behaviour Data Analysis

The accuracy of similarity annotation by participants lies between 98% to 99.5% for individual annotators. Out of the 1800 annotations (9 annotators over 200 word-pairs), only 40 were predicted incorrectly. Annotation errors may be attributed to: (a) lack of patience/attention while reading, (b) issues related to word-pair comprehension, and (c) confusion/indecisiveness caused due to lack of contextual clues. In our analysis, we do not discard the data obtained from these incorrect annotations.

We observe distinct eye-movement patterns for cognate pairs in terms of fixation duration of the human readers. Our analysis shows that fixation duration normalized over word count is relatively larger for cognate pairs. For cognate pairs, we observe that average fixation duration amongst all participants is 1.3 times more than that of false friend pairs. To test the statistical significance, we conduct a two-tailed t-test (assuming unequal variance) to compare the average fixation duration per word for cognate and false friend pairs. The hypothesized mean difference is set to 0, and the error tolerance limit (α) is set to 0.05. The t-test analysis, presented in Table 3, shows that for all participants, a statistically significant difference exists between the average fixation duration per word for cognate pairs vs false friend pairs.

We believe this difference in average fixation duration is because the bilingual speakers who participated in the experiment can clearly distinguish between cognates and false friends and decide quickly in either case. The duration for which they fixate on either of the cases differs significantly for each participant. As per our observation, the participants take more time over cognate pairs to ensure similarity in meaning. Given their knowledge of both the languages and contextual clues, they were 'quickly' able to decide these word pairs did not mean the same. It should be noted that they were unaware of the 'cognate' or 'false friend' distinction concerning the experiment. They were simply asked to note the meaning of both the words given context, and annotate accordingly, as described in the paper.

3.3 Cross-lingual Word Embeddings

For this task, we use the cross-lingual word embedding models released by Kumar et al. (2020). The Hindi-Marathi cross-lingual models released with this paper are based on both MUSE (Conneau et al., 2017) and XLM[5] (Lample and Conneau, 2019). Additionally, we build the cross-lingual word embeddings model for Hindi-Marathi using VecMap (Artetxe et al., 2017). The model uses monolingual corpora released by Kunchukuttan et al. (2020) and a bilingual dictionary[6] required for the supervised method by Artetxe et al. (2017). These three cross-lingual models provide us with three feature sets for the task of cognate detection.

4 Feature Sets for Cognate Detection

In this section, we discuss the various features used for the task of cognate detection. It is to be noted that *false friends are spelt similarly across languages* but mean differently. Using false friends as data points with negative labels restricts us to the use of semantic similarity based features,

---

[5] Word representations extracted from the last layer of the contextual XLM model.

[6] Bilingual Lexicon

as orthographic or phonetic similarity-based measures would fail to detect sufficient distinction between them. Hence, we use the features proposed by Rama (2016) and Kanojia et al. (2019a) as baseline features for a comparative evaluation.

4.1 Phonetic Features

The IndicNLP Library provides phonetic features based vector for each character in various Indian language scripts. We utilize this library to compute a feature vector for each word by computing an average over character vectors. We compute vectors for both words in the candidate cognate pairs (PV_S and PV_T) and also compute contextual vectors (PCV_S and PCV_T) by averaging the vectors for all the contextual clues, generating a total of four vectors. We use these vectors as features for computing the baseline scores using the Siamese Convolutional Neural Network architecture proposed by Rama (2016).

4.2 Weighted Lexical Similarity (WLS)

The Normalized Edit Distance (NED) approach computes the edit distance (Nerbonne and Heeringa, 1997) for all word pairs in our dataset. A combination of NED with q-gram distance (Shannon, 1948) for a better similarity score. The q-grams ('n-grams') are simply substrings of length q. This distance measure has been applied previously for various spelling correction approaches (Owolabi and McGregor, 1988; Kohonen, 1978). Kanojia et al. (2019b) proposed Weighted Lexical Similarity (WLS) and we use it with the character-based Recurrent Neural Network architecture proposed by them to compute another set of baseline scores.

4.3 Cross-lingual Vectors & Similarity

As discussed above, we use the pre-trained cross-lingual embedding models for generating feature vectors for MUSE and XLM based approaches. These models are generated by aligning two disjoint monolingual vector spaces through linear transformations, using a small bilingual dictionary for supervision (Doval et al., 2018; Artetxe et al., 2017). Additionally, the cross-lingual embeddings model trained using Artetxe et al. (2017)'s approach provides us with the third set of feature vectors.

We use these models to obtain vectors for word-pairs (WV_S and WV_T) and averaged context vectors (CV_S and CV_T) from the contextual clues, to create three different feature sets. We obtain vectors for each candidate pair and their context using all the three cross-lingual methodologies. The use of cross-lingual models has been proposed for differentiating between cognates and false friends by Merlo and Andueza Rodriguez (2019), but evaluation with the cognate detection task had not been performed. We perform this evaluation on our datasets (D1, D2 and D1+D2) using various classification methods and discuss them later.

4.4 Cognitive Features from Gaze Data

Gaze behaviour of participants, characterized by fixations, forward saccades, skips and regressions, can be used as features for NLP tasks (Mishra et al., 2018b). Since these gaze features relate to the cognitive process in reading (Altmann, 1994), we consider these as features in our model. The current gaze data extraction adds up all the interest areas on the screen (word + context). The software used to analyze the gaze data, currently, provides us with collated results for all the gaze-based features.

From the gaze behaviour data collected, we extract a total of 18 features for each of the 1800 data points. Using supervised feature selection approach, we are able to select eight best features via grid search using Logistic Regression. We use the SelectKBest implementation along with hyperparameter tuning via GridSearchCV, present in the sklearn (Pedregosa et al., 2011) library. Here onwards, we refer to these eight features when discussing cognitive or gaze-based features in this paper. These eight best features, along with their description, are listed in Table 4.

4.5 Gaze Feature Prediction

Collection of gaze data for a large number of samples can be a costly task. We propose a neural model for cognitive features prediction. Our neural model is a feed-forward neural network to perform a regression task and predict gaze features. We collect gaze data for only 200 word-pairs (D2) with the help of 9 annotators which provides us with a total of 1800 data points for training and validation. As reported in Table 5, the initial results on D1 using different cross-lingual embeddings show that XLM based contextual features perform the best amongst all the cross-lingual models.

As an input to the network, we provide the feature vectors from the XLM model. This network's output is the predicted gaze features for the D1 dataset, using the gaze features as gold predictions

Gaze Feature	Description
Average Fixation Duration	The average of all fixation duration across all interest areas present on the screen.
Average Saccade Amplitude	Saccade amplitude is the amplitude of going back and forth measured in terms of duration.
Fixation Count	Counting the number of times user's eyes are fixated on the screen.
Fixation Duration Max	Maximum time for a single fixation on any Interest Area.
Fixation Duration Min	Minimum time for a single fixation on any Interest Area.
IA Count	Interest Area Count (no. of IAs on the screen)
Run Count	Consecutive counts for same Interest Area are ignored in Run Count
Saccade Count	Total counts of Saccades

Table 4: Gaze Features used for the task of Cognate Detection

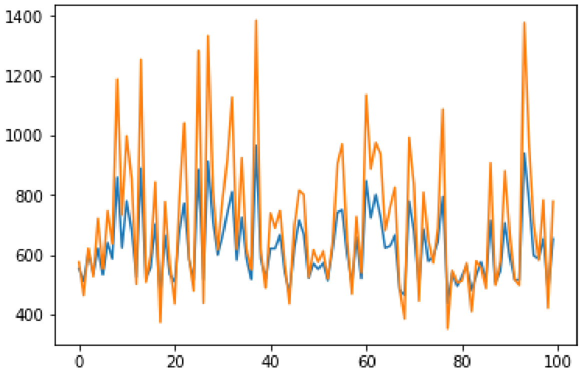

Figure 2: Predicted feature values (blue) vs. Gold feature values (orange) for the average fixation duration feature, on 100 samples.

from the D2 dataset. This network contains three linear hidden layers with 128, 64 and 32 dimensions. After each layer, we use the sigmoid activation function and dropout after each sigmoid with a dropout value of 0.2. We use 0.1 as the learning rate and use the Mean Squared Error (MSE) loss function. A graph comparing the values for the predictions vs the actual values for the average saccade amplitude for 100 samples, can be seen in Figure 2.

5 The Cognate Detection Task

We employ both classical machine learning-based models and a simple feed-forward neural network. To compare our work with the previously proposed approaches, we replicate the best-reported systems from Rama (2016) *i.e.,* Siamese Convolutional Neural Network with phonetic vectors as features and also replicate Kanojia et al. (2019b)'s approach which uses a Recurrent Neural Network architecture with a weighted lexical similarity (WLS) as the feature set. The input to our classifiers is the feature sets described above for each candidate pair.

Among the classical machine learning models, we use Support Vector Machines (SVM) and Logistic Regression (LR). We experiment with the use of both linear SVMs and kernel SVMs (Gaussian and Polynomial). We perform a grid-search to find the best hyper-parameter value for C over the range of 0.01 to 1000. We deploy the Feed Forward Neural Network (FFNN) with one hidden layer. We perform cross-validation with different activation function settings (tanh, hardtanh, sigmoid and relu) and the hidden layer dimension in the network (30, 50, 100, and 150). We use binary cross-entropy as the optimization algorithm. Finally, we choose the hyper-parameter configuration with the best validation accuracy. We train the model with the selected configuration with an initial learning rate of 0.4, and we halve the learning rate when the error on the validation split increases. We stop the training once the learning rate falls below 0.001. *We perform 5-fold stratified cross-validation, which divides the data into train and test folds, randomly.*

Initially, we perform our experiments with the feature sets from three different cross-lingual embeddings (MUSE, XLM, and VecMap) for the dataset D1, then with the smaller dataset D2 and later on the combined dataset D1+D2. We, then, perform the same task for the smaller dataset D2 by combining cognitive features with individual cross-lingual feature sets. We also observe the performance of standalone gaze features for the D2 dataset. Finally, we evaluate the predicted gaze features on the combined dataset by combining them with cross-lingual features and a standalone feature set, using the feed-forward neural network. We report the results of the cognate detection task in the next section and discuss them in detail.

6 Results and Dicussion

We report the results of the cognate detection task in Table 5. We use the original implementations of Rama (2016) and Kanojia et al. (2019b) on the combined (D1+D2) dataset. In our initial evaluation on the D1 dataset, cross-lingual model-based features (XLM, MUSE, and VecMap) can be seen to outperform the baseline systems which use phonetic and orthographic features. Using the XLM-based

Table 5: Classification results in terms of weighted Precision (P), Recall (R), and F-scores (F) using 5-fold cross-validation using different feature sets as described above.

features, we observe an improvement of 9% over the stronger baseline (Kanojia et al., 2019b) and 13% over the system by Rama (2016). It can be seen that MUSE and VecMap based features also perform better on the combined dataset. In terms of both precision and recall, cross-lingual features are shown to outperform the baseline systems. The cross-lingual approach, with representations from VecMap-based model, fails to perform as well as MUSE and XLM-based models. The contextual XLM model achieves the best scores in almost all the settings. We believe its performance can be attributed to the linguistic closeness of the language pair and context from the contextual clues provided. For example, the false friend pair "*kaccHa*" (meaning inexperienced) - "*kaccHa*" [raw (food)] is classified correctly by XLM but incorrectly by both the baseline models, and VecMap-based classification. This signifies that fine-grained semantic difference between such false friend pairs can be captured via cognitive features. We report the additional results on individual datasets (D1 and D2), for all the baseline and cross-lingual approaches, in Table 6.

For all the classifiers, the gaze features are averaged across participants and augmented with cross-lingual features. The gaze fixation duration collects the total time spent, as fixations, on each interest area including the context clues. We were hopeful that the participants would focus only on important contextual clues and not the stop words with our experiment design. However, the sample points are not enough to concretely discuss this aspect of our study. These results are reported for all the classifiers with D2 dataset. Our feature combinations outperform the baselines with an F-score improvement of 10% points over the stronger baseline (WLS). We also report the precision, recall and F-score values when only gaze features are used to predict the labels for our candidate pairs. We observe that standalone gaze features are not as effective as when combined with cross-lingual feature vectors. When gaze features are predicted using the methodology described in Section 4.5, the model performance for FFNN on D1 remains the same with XLM+Gaze, decreases slightly for MUSE+Gaze and significantly improves for VecMap+Gaze. We observe that predicted gaze features do not significantly drop the performance, and hence, add the collected gaze data samples (D2) to D1.

On the combined dataset with collected gaze features (on D2) and predicted gaze features (on D1), we report our best system [FFNN (D1+D2)] which shown an improvement of 12% over the stronger baseline (WLS), and 16% over the weaker baseline (Phonetic). This system also outperforms the best reported cross-lingual features-based approach by 3%, as shown in Table 5.

For example, the cognate pair "*utPaNa*" (Hindi) - "*utpAaDit*" (Marathi) (both meaning manufactured) is classified correctly by this system, but incorrectly

Table 6: Additional results in terms of weighted Precision (P), Recall (R), and F-scores (F) using 5-fold cross-validation using different feature sets as described above. These are additional results on the individual datasets D1 and D2 for which the combined results (D1 and D2) are already shown in Table 5 for a fair comparison.

by both the baselines, and all the cross-lingual systems. Furthermore, we also show that gaze features can be predicted based on a small sample data, and improved performance can be attained with the help of cross-lingual features, reported with our work.

7 Conclusion and Future Work

In this paper, we harness cross-lingual embeddings and gaze-based features to improve the task of cognate detection for the Indian language pair of Hindi-Marathi. We create a novel framework that derives insights from human cognition, that manifests over eye movement patterns. We hypothesize that by augmenting cross-lingual features with features obtained from the gaze data, the task of cognate detection can be improved. We use a linked knowledge graph (IndoWordnet) to augment a publicly released cognate dataset with contextual clues. We collect the gaze behaviour data from nine participants over 200 samples and perform the task of cognate detection for both our datasets (with gaze data and without gaze data). Then, we use a neural network to predict gaze features for unseen samples and perform the task of cognate detection to show improved performance, despite a small sample of collected gaze data.

We reproduce the previously proposed baseline approaches and perform experiments using additional features obtained via cross-lingual models for a comparative evaluation. The previously proposed approaches (Rama, 2016; Kanojia et al., 2019b) for this task are shown to be outperformed by cross-lingual features and the combination of these features with the obtained gaze data. Our experiments use three different approaches to generate feature representations for the cognate detection task, and all of them show improvements over previously proposed approaches. We observe consistent improvements in terms of precision, recall and F-scores. Over the stronger baseline, our best system shows an improvement of 12% points and 16% points over the weaker baseline. This system also outperforms the cross-lingual features based approaches by 3%, over the combined dataset. We release this augmented dataset, along with our code and cross-lingual models for further research.

In future, we aim to add more language pairs and leverage contextual information from knowledge graphs using sequence-based neural models. We also aim to collect gaze data and then model the gaze predictions in a multi-task setting. We plan to investigate other multilingual contextual embeddings' performance for this task (*e.g.,* M-BERT, IndicBERT, MuRIL). We also plan to look for a method to differentiate between different interest areas and see if a markup facility is present in the software used to analyze the gaze data. We also aim to investigate the task of cognate detection for the Indo-European language family, in the near future.

A Simple Three-Step Approach for the Automatic Detection of Exaggerated Statements in Health Science News

Abstract

There is a huge difference between a scientific journal reporting 'wine consumption might be correlated to cancer', and a media outlet publishing 'wine causes cancer' citing the journal's results. The above example is a typical case of a scientific statement being exaggerated as an outcome of the rising problem of *media manipulation*. Given a pair of statements (say one from the source journal article and the other from the news article covering the results published in the journal), is it possible to ascertain with some confidence whether one is an exaggerated version of the other? This paper presents a surprisingly simple yet rational three-step approach that performs best for this task. We solve the task by breaking it into three sub-tasks as follows – (a) given a statement from a scientific paper or press release, we first extract relation phrases (e.g., 'causes' versus 'might be correlated to') connecting the dependent (e.g., 'cancer') and the independent ('wine') variable, (b) classify the strength of the relationship phrase extracted and (c) compare the strengths of the relation phrases extracted from the statements to identify whether one statement contains an exaggerated version of the other, and to what extent. Through rigorous experiments, we demonstrate that our simple approach by far outperforms baseline models that compare state-of-the-art embedding of the statement pairs through a binary classifier or recast the problem as a textual entailment task, which appears to be a very natural choice in this settings.

1 Introduction

Exaggerations in health news can have tremendous adverse effects on the lifestyle of the common masses who feed themselves mostly on such news instead of the source scientific publication. This problem is challenging as it involves many intrinsic complexities that need to be addressed. First, while encountering a scientific claim, we need to identify the true fact related to the claim from the knowledge base (in most cases the source journal article). For instance, if the press release/ news report states that 'chocolate causes acne' then this claim needs to be compared to the scientific study that actually recruits human subjects and does experiments to study connections between chocolate consumption and acne vulgaris. In fact, the study reported in Fulton-Jr. et al. (1969) proves that chocolate consumption is 'not related' to acne.

In this paper, we propose a very simple three-step method[1] that given a pair of statements, e.g., 'chocolate causes acne' taken from the press release and 'chocolate consumption is not related to acne' taken from the source journal, can identify if the former is an exaggerated version of the latter. Note that the problem that we aim to solve requires the pair of statements to be compared as inputs to produce the desired output (exaggerated or not). However, toward the end of the paper, we outline a simple heuristic that dissolves this constraint for the considered dataset that the pair of statements that we compare from the whole article (press release or source journal) needs to be known to us a priori.

We note that comparing state-of-the-art embedding of the two statements using binary classifiers does not give much advantage; even adapting the problem as a textual entailment task (a natural adaptation since one statement is an exaggerated version of the other) surprisingly does not bring much additional benefits.

This paper therefore puts forward *a simple three step approach, breaking the task down to three rational steps*: (1) *given a statement from a scientific paper or press release, extract relation phrases* (*e.g., 'causes' versus 'correlated to'*) *connecting*

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3293–3305
April 19 - 23, 2021.

the dependent (*e.g., 'acne'*) *and the independent* (*e.g., 'chocolate'*) *variable,* (2) *classify the strength of the relation phrase and* (3) *compare the strengths of the relation phrases extracted from the statements to identify whether one sentence contains an exaggerated version of the other, and to what extent.*

Our approach is operationalised on the data released by Sumner et al. (2014). The exact statements containing the relation phrases within an article or the source journal are annotated in the dataset allowing us to effectively train our models. The main results of our paper are,

- **Extraction of relation phrases**: We experiment with number of syntax driven and sequence labeling approaches to extract the relation phrases. A adaptive version of recently proposed and highly successful BERT-NER (Devlin et al., 2019) performs best with a F1-score of ~ 0.85 for this task.
- **Strength classification**: Next, given a statement with its relation phrase already labeled, we pass it through standard classifiers to learn the *strength* of phrase[2]. We achieve a micro-F1 and macro-F1 of 0.74 and 0.69 respectively for 6-class classification task.
- **Exaggeration detection**: Now given a pair of statements with their strength levels marked and one taken from the source journal while the other from the news article (or press release) we compute the difference in strengths to output whether the latter is an exaggerated version of the former. We obtain a perfect match of exaggeration levels for 0.62 fraction of cases.
- **Additional contribution**: We also identify a mechanism to spot the exact location of the main claim statement in the whole document so that the exact pair is not needed as inputs for our pipeline to work. Our mechanism seem to work for the considered dataset.

2 Related work

Media manipulation is a set of related techniques in which the manipulator attempts to create an image or argument that favors particular interests (Coxall, 2013). Media manipulation and fake news got huge attention from the research community in the current decade. Hundreds of studies got published in this domain which makes it impossible to cite them all. The surveys of different methods and datasets published in these domain can be found in Parikh and Atrey (2018); Zhou and Zafarani (2018); Sharma et al. (2019); Bondielli and Marcelloni (2019); Oshikawa et al. (2018); Haciyakupoglu et al. (2018); Zhou and Zafarani (2020); Van Eemeren et al. (2009). Previous study (Sumner et al., 2014) suggests that press releases are a major source of exaggeration. Identification of relationship between entities and associated strength in scientific articles and comparing them with that of news reports and press releases is the key to exaggeration detection. In literature, there are many techniques present separately to identify entities along with their relationships (Blake, 2010) and strength associated in a relationship (Light et al., 2004; Vlachos and Craven, 2010). The authors in Lim et al. (2016) propose a framework to identify claims from tweet corpus related to major events. In (Giasemidis et al., 2016) the authors build autonomous message classifier that filters relevant and trustworthy information from Twitter. In (Khoo et al., 2000) the authors develop a knowledge extraction and knowledge discovery system that extracts causal knowledge from textual databases.

Present study: None of the studies mentioned above tackle the exaggeration detection problem. In a recent study Li et al. (2017) analyze the same dataset as we use in this paper and attempt to identify exaggeration. They also assume that the pair of statements are available as inputs for the detection task. However, the biggest drawback of this work is that the authors additionally assume that the relationship phrase in the input statement is also known which makes the task significantly simpler. In fact, the authors also do not use these relationship phrases as important signals but treat each statement as a whole as bag-of-words. We, on the other hand, identify the relation phrases automatically in the first place and use it as an important signal for the next two sub-tasks (strength classification and exaggeration detection) which is the most important contribution of our work. We also compare this work with our method and show that we considerably outperform them.

---

[2] The strength levels are defined as in (Sumner et al., 2014) and certain coarse-grained revisions of the same.

3 Dataset and Preprocessing

3.1 Dataset

We use the publicly available dataset[3] released by Sumner et al. (2014) for our experiments. This dataset contains detailed annotations of 462 journals, corresponding 462 press releases and 668 news articles, issued in 2011 by the Russel Group of Universities (20 leading UK Research Universities) in health related topics. Every individual press release is a follow-up of a journal paper; we assume this journal paper to be the reference for our analysis as it is followed by Sumner et al. (2014). Every press release in turn, is discussed by some news reports. In the dataset, 230 out of 462 journals and press releases have at least one news article coverage.

For each of the three sources, the dataset has detailed annotations of different types. First for each journal/ news article/ press release, the statement containing the main claim is manually identified by the annotators within the running text. Now in this statement, the stretch of relationship phrase is marked in bold. Third, the strength of this relationship phrase is graduated on a Likert-like scale from '0' to '6'. (see section A in supplementary material).

Note that, as per the annotation guidelines, one article can have only one statement with the main claim. The relationship phrase connects the independent variable (*IV*) with the dependent variable (*DV*) in the statement with the main claim. Note that sometimes either the *IV* or the *DV* or both might not be part of the statement with the main claim (i.e., may be present in other parts of the text in the article and connected to statement with the main claim only implicitly). However, since for our work we need the statement with the main claim and the relationship phrases only the above limitation does not pose a hindrance.

While Sumner et al. (2014) provides the dataset already marked by one of the seven quantization levels for each journal, press release and news report, thus allowing for analysis of the exaggerated content, it is difficult to ascertain the robustness of the results obtained. This is primarily because some of the quantization levels seem to be too close (see the 'Description' of strength categories in supplementary material.) and the data set is unbalanced (see Table **??**). In order to test the robustness of the results that we present in the subsequent sections, we also club the above quantizations into more coarse-grained labels. Essentially, we consider a 4-class and a 2-class quantization in addition to the 6-class (omitting class '0'). For the 4-class we map the above seven quantizations as follows: $1 \rightarrow 1$, $(2,3) \rightarrow 2$, $(4,5) \rightarrow 3$ and $6 \rightarrow 4$. For the two class we map as follows: $(1,2,3,4,5) \rightarrow 1$ and $6 \rightarrow 2$.

Strength	#Statements	Fraction
1	69	0.04
2	321	0.2
3	132	0.08
4	159	0.1
5	108	0.07
6	812	0.51

Table 1: Distribution of statements across the different strength categories.

3.2 Data preprocessing

We discard statements with the main claim in which the relationship phrases are not marked by the annotators; these include the statements from category '0'[4] and a very few statements from the other categories. At the end of this process, we have a set of 1601 statements with annotated relation phrases. The distribution of statements across the different strength categories is shown in Table **??**. The table shows that the categories '6' and '2' are the dominant ones. We divide the 1601 statements (together from journals, press releases and news reports) into training, development and test sets. We keep 1000 statements in the training set, 300 statements in the development set and 301 statements in the test set. Note that from the 301 statements in the test set, we can construct a total of 316 distinct statement pairs each formed from the comparison of a source journal and a corresponding news paper article/press release. While for the first two sub-tasks (i.e., relation phrase labeling and strength classification) we need the individual statements as input, in the last sub-task (i.e., exaggeration identification) we need pairs of statements for final comparison and prediction.

4 Methodology

As discussed earlier, our approach has three steps. They are (i) relation phrase labeling, (ii) strength

---

[3] Dataset: `https://bit.ly/2qc86tk`

[4] Note that category '0' refers to cases where there is no relation between the IV and DV and is therefore not useful for further processing.

classification, and (iii) exaggeration identification. All of the three modules are connected in a sequence as shown in Figure 1. The relation phrase labeling module takes a selected statement and labels the relation phrase present in it. Next, the strength classification module takes a relation phrase as input and predicts its strength level. Finally, in the exaggeration identification module, the strengths of source statement and target statement are compared, and it calculates the exaggeration or underplay level of the target statement with respect to the source statement. The individual modules are described in details in the subsequent subsections.

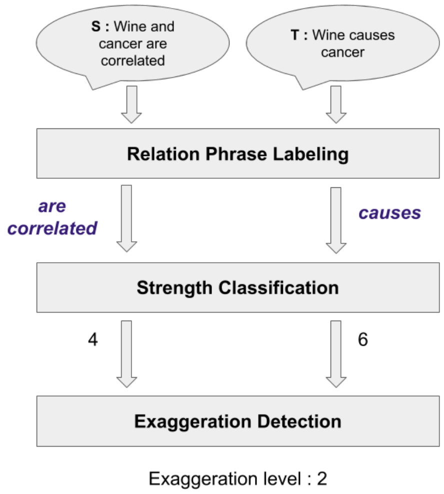

Figure 1: Flow diagram of the methodology. S: source statement, T: target statement.

4.1 Relation phrase labeling

As previously stated, the primary objective of this module is to identify the relation phrase describing the relation between the independent and the dependent variables. This problem is more difficult than the traditional entity-relation extraction problem as multiple entity pairs connected by relation phrases can be present in a statement. Therefore, finding relation phrase that denotes the main claim is a challenging task. We broadly employ two different types of approaches for relation labeling – (i) syntax driven approaches, and (ii) sequence labeling approaches. We describe each of them in next subsections.

4.1.1 Syntax driven approaches

The key idea: In syntax driven approaches, we rely on the fact that the position of the relation phrases in a statement is syntax driven. In particular, we mine the structural patterns in the dependency tree of the statements. In addition, we use heuristics over the state-of-the-art entity relation extraction tool (Angeli et al., 2015) to get relation phrases in the causal statements.

Dependency tree heuristics (DTH): The intuition behind this method is that relation phrases have characteristic syntactic (part-of-speech, lemmas, dependency edges etc.) and semantic features. We intend to leverage these in the dependency tree representation of statements, by collapsing unimportant relations and selecting the rightful node through various heuristics. The phrase corresponding to the selected node is identified as the relation phrase. The details of the steps we follow for the construction of the collapsed dependency tree and the extraction of the relation phrase from the causal statement are presented in supplementary material.

OpenIE heuristics: We use Stanford open information extraction (OpenIE) tool for the identification of entity-relation triplets. Let $t_1, t_2, ...t_n$ be the n triplets obtained for a statement s, where each t_i consists of two entities at its end connected by a relation phrase. We choose t_i having the largest and smallest phrase and consider these as the representative relation phrase for the statement s. The rationale behind choosing the largest phrase is to increase the probability of including the original relation phrase. The smallest phrase is chosen to show that smaller sized phrases always perform worse than the largest phrase.

4.1.2 Sequence labeling approaches

The key idea: The central idea these approaches put forward is use the training data to create a model to label the relation phrase in the input statement. The relation phrases are marked as per traditional BIO[5] encoding format. In addition, the BERT scheme that we shall use has three other labels – X for added morphological inflation, CLS for sentence beginning and SEP for sentence separations. Based on this annotated training data the sequence labeler is tasked to learn the beginning, the stretch and the end of the relationship phrase. Once this is marked for each statement the labeled phrases are passed on to the next phase of the pipeline for strength classification.

LSTM-CRF:We use the LSTM-CRF architecture

Table 2: Additional features at CRF layer.

similar to Lample et al. (2016) in addition to a set of novel features as described in Table ?? in the CRF layer[6] along with the hidden state vector of the BiLSTM layer. The combination is done by concatenating the feature vectors with the hidden state vector. The input layers to the model are vector representations of the individual words or characters.

LSTM-CNN-CRF: We use the architecture proposed by Ma and Hovy (2016) and adapt for our purpose[7].

LM-LSTM-CRF: Here we use the task-aware neural sequence labeling model proposed by (Liu et al., 2017) and adapt it for our purpose.

BERT-SL: We use the variant BERT (Devlin et al., 2018) technology originally proposed for solving the NER task[8], which is essentially modeled as a sequence labeling problem. We suitably adapt the BERT-NER framework to extract the relation phrases. BERT's model architecture is a multilayer bidirectional transformer encoder based on the original implementation described in (Vaswani et al., 2017)[9]. In particular, we use the BERT base architecture that has 12 transformer layers, hidden vector size of 768 and 12 self-attention heads one corresponding to each transformer module. For fine-tuning, the final hidden representation of each token is fed to a classification layer over the NER label set. For our purpose we train the BERT-NER model using our training data and the label set corresponds to the relationship phrase beginning and end markers instead of the NER labels.

4.1.3 Evaluation

We use the standard token level F1-score and accuracy to compare the different labeling approaches.

4.2 Strength classification

The primary objective of this module is to predict the strength level of the relationship phrase in the input statement, e.g., in the statement 'wine **causes** cancer' the strength of statement is 6. We feed the standard multi-class classifiers with the annotated relation phrases for each statement in the training set while the training label is the strength of the statement. Since BERT-SL performs best among all relation phrase labeling approaches, we present all our subsequent results for this case only. We obtain the best parameters for each of the classifiers using the validation set. Finally, we report our results on the test set for 6-class, 4-class as well as 2-class scenarios. Unlike prior work (Li et al., 2017) that uses bag of words feature drawn from the whole statement, our model uses the features drawn from the annotated relation phrase, i.e., a part of the statement only. Note that, the results mentioned in the prior work is not directly comparable as the authors assume in their model that the relation phrases are already known, but we extract these phrases in the first place. However, we re-implemented their model (Li et al., 2017) and report the results that we got for our train-test division of the dataset.

Evaluation: We compare the strength classification methods using the micro-F1, which in this case, is equal to the accuracy. This is, as usual, calculated as the fraction of statements that have a correctly classified strength level out of the total number of statements. We also report the macro-F1 obtained for each model for the better understanding of the performance of the models primarily since the classes are unbalanced. This is calculated as the average of F1 scores obtained for each class as predicted by each model for the test set.

4.3 Exaggeration identification

In this module we calculate the strength level difference between a source statement and a target statement. The source statement is the one with the main claim from the journal article, while the target statement is the one with the main claim from corresponding news reports or press release covering the source. We calculate exaggeration (or underplay) levels for each classifier result over each type of strength classification.

Baseline: We present two types of baseline here. In the first, we pass the BERT embedding of the two statements (using respective 'CLS' markers)

---

[6] In our experiments we have seen that increasing dimension size further improves the results further. POS tags are obtained using NLTK.

[7] All other parameters remaining same, we use LSTM state size of 100, dropout rate of 0.5 and input batch size of 5.

[8] BERT NER: `https://github.com/kyzhouhzau/BERT-NER`

[9] `http://nlp.seas.harvard.edu/2018/04/03/attention.htm`

to the standard classifiers and attempt to estimate if there is a component of exaggeration. In the second, we model the problem as a textual entailment task which is a natural choice. Given a pair of statements the goal is to predict whether the second statement is an exaggerated version of first. For this purpose, we have used the BERT text classifier module. The final hidden vector of BERT model is passed through a softmax layer for the classification.

Evaluation: We employ *fraction of perfect match* (PM), which in our case, is also equal to the accuracy, as the measure to compare the different exaggeration detection methods. This is calculated as the fraction of source-target statement pairs for which we get correct exaggeration or underplay level as we have in the ground-truth. We also report the mean square error (MSE) for each model which is calculated as the average of the squares of the differences between actual and predicted strength difference for every pair of statements in each model.

5 Results

In this section, we present the results from the three phases – relation phrase labeling, strength classification and exaggeration identification one after the other. Finally we outline a scheme to spot the exact location of main claims in the news articles and press releases that particularly works for this dataset. This enabled us to fully automate the process based on this scheme and measure its performance.

5.1 Relation phrase labeling

We note down the main results in Table ??. The table shows that BERT-SL outperforms all other approaches by a large margin. The F1-score and the accuracy for this method is 0.85 and 0.95, respectively. Among the others LSTM-CRF augmented with PoS tags and PoS bigrams is the most competitive with a F1-score of 0.73 and accuracy of 0.89.

Success of BERT-SL: Table ?? shows the number of perfect matches between the ground-truth relationship phrase and the relationship phrase extracted using BERT-SL and LSTM-CRF. For all n-gram relationship phrases BERT-SL achieves a much higher number of perfect matches with the ground-truth. The difference in the number of matches obtained from the two methods is particularly large for unigrams and bigrams which covers the bulk of the statements. This is the reason why BERT-SL is able to outperform the other methods by a large margin.

Model	F1-score	Accuracy
DTH	0.58	0.82
OpenIE (large)	0.48	0.76
OpenIE (small)	0.37	0.70
LSTM-CRF (RI (Li et al., 2017))	0.67	0.88

5	**6**	2
6	**3**	0

Table 4: Number of perfect matches for the competing models as per the number of words present in the relation phrase.

5.2 Strength classification

We predict the strength of a statement based on its relation phrase. For this purpose we build classifiers that take bag of words vector of the relationship phrase as identified by BERT-SL and predict its strength. The bag of words vector is created from the BERT embeddings as follows. The BERT embeddings of each word in the relation phrase are concatenated to form a single vector which is fed to the classifier. However the number of words in each relation phrase could be different. We fix this length by imagining all relation phrases to have length equal to the length of the largest relation phrase across the 1601 data points. This makes the concatenated vector size same for all the relation phrases; the missing entries in each vector so created are replaced by zero.

We use various classification models such as multinomial naive-bays (MNB), random-forest (RF), stochastic gradient descent (SGD) and XG-

Test type	Classifier	$\mu F1_{6class}$	$MF1_{6class}$	$\mu F1_{4class}$	$MF1_{4class}$	$\mu F1_{2class}$	$MF1_{2class}$

Baseline (Li et al., 2017) (Trn: 1300, Tst: 301)	BOW (unigram+bigram)	–	–	0.64	0.62	–	–

Table 5: Strength classification results. $\mu F1_{xclass}$: micro-F1 for x (6/4/2) class, $MF1_{xclass}$: macro-F1 for x (6/4/2) class.

Boost (XGB) for this purpose. The training of these classifiers is done on actual relation phrase and strength class pairs as annotated in the dataset. Table **??** shows the micro-F1 and macro-F1 scores of various classifiers across different strength classes (6, 4 and 2). In the table, entries for the true relation phrases represent the obtained micro-F1 and macro-F1 scores corresponding to a test set where the ground-truth annotated relation phrase (instead of what is obtained from BERT-SL) is taken into account. It is interesting to note that for all the three strength classes strengths obtain from BERT labeled relation phrases reaches close to the F1 values as one would have obtained if the true test relationship phrases were supplied to the classifiers at the input. Finally, our model by far outperforms the only known baseline (Li et al., 2017) in both micro and macro-F1 scores. To be fair, we show results for the 4-class which is the only case reported in (Li et al., 2017).

5.3 Exaggeration level identification

We identify the exaggeration level by taking the strength difference between the source statement from the journal and the target statement from the news article/ press release. The number of such source-target statement pairs in our test data is 316. The strength for each statement is obtained from the classifiers reported in the previous section. We present the results of exaggeration detection in Table **??**. Our three step approach attains a perfect match score for 0.62, 0.68 and 0.69 fraction of cases in the 6, 4 and 2 classes respectively (best classifier outputs) which is again close to what one could have obtained if the ground-truth relation phrases were known to the strength classifier in the previous stage.

Baseline: For the baseline we take the entire training set and construct as many possible source-target statement pairs where, by definition, the source statement is from a journal and the target statement is from a corresponding news article/press release. From the 1000 training statements, we could construct a total of 1298 such source-target pairs. If we feed the direct BERT embedding of the source and the target statement to the set of classifiers (RF, SGD and XGB in Table **??**) the results are much worse than our approach. Further if we adapt the BERT text classifier (as used in textual entailment detection module) to solve our problem ('Neural' in Table **??**), there is no benefit obtained. This proves that our proposed concept, a simple yet more interpretable three step sequential approach performs better than all other approaches where the whole sentence is taken into account for the exaggeration detection.

6 Discussion

In this section we present the findings of our error analysis and results correspond to the special sub cases where simple heuristics is taken into account to automate the whole process.

6.1 Error Analysis:

The error cases that we believe could be the possible reasons affecting the overall performance of the system are presented below.

- **Ambiguous modifiers**: Some statements have certain modifiers like 'little', 'any' etc in their predicted relation phrases, which leads to an error in the strength class prediction.

- **Incorrect relation phrase**: In some cases, the predicted relation phrase is incorrect which leads to propagation of errors in next steps.

- **Incorrect relation interpretation**: The system is unable to differentiate between cases like "could be entirely independent" and

Test type	Classifier	PM_{6class}	MSE_{6class}	PM_{4class}	MSE_{4class}	PM_{2class}	MSE_{2class}
True rel. phs. (Tst: 301, Pairs: 316)	MNB	0.53	5.71	**0.68**	1.27	**0.69**	0.37
	RF	0.49	**3.93**	0.51	**1.18**	0.52	0.53
	SGD	0.62	5.01	0.67	1.30	0.68	**0.35**
	XGB	**0.63**	4.65	0.63	1.41	0.65	**0.35**
BERT-SL rel. phs. (Tst: 301, Pairs: 316)	MNB	0.52	4.99	**0.68**	1.27	0.67	0.40
	RF	0.49	**3.88**	0.51	**1.18**	0.53	0.58
	SGD	**0.62**	4.74	0.67	1.30	**0.69**	**0.37**
	XGB	0.6	4.73	0.63	1.41	0.64	0.39
Baseline (Train: 1298, Pairs: 316)	RF	**0.48**	**4.24**	0.49	1.37	**0.61**	0.47
	SGD	0.43	5.13	0.33	1.39	0.49	0.54
	XGB	0.47	4.51	**0.51**	**1.28**	0.59	**0.46**
	Neural	0.44	–	0.50	–	0.56	–

Table 6: Exaggeration level identification results. PM_{xclass}: Perfect match for x (6/4/2) class, MSE_{xclass}: Mean squared error for x (6/4/2) class.

“could be entirely dependent”, which leads to the prediction of wrong strength classes.

We present examples of above cases in the supplementary material.

6.2 Spotting the causal statement:

We manually inspect the position of main claims in the documents. We find that in 95% of cases the main claim is present either in the title or in any one of the first three sentences of the document. We repeat the relationship phrase identification experiment using the best model (i.e., BERT-SL) for a test set that is built using all the four sentences (i.e., the title, the first, the second and the third sentences) taken from each press release and news article present in our dataset. Now we select that sentence for which we get the maximum number of words tagged as a relation phrase. Using this heuristic selection criteria we obtain F1-score of **0.8** and an accuracy of **0.9** which is close to what we report in Table ??. More detail of this experiment are presented in supplementary material.

6.3 Inclusion of IV and DV

Our model can also be used to extract the IV and the DV as well. We also check if this brings additional benefits to the pipeline. The details of this experiment is given in the supplementary material. The F1-score (precision, recall) we obtained for the relation phrase labeling task in this case is 0.72 (0.75, 0.7). This experiment also gives token level accuracy of 0.87. As we observe, the inclusion of the IV and DV information does not improve the labeling performance and therefore we did not use it for the next stages of the pipeline. The use of these additional information actually seems to confuse the labeler more than benefiting it. However, the automatic extraction of the IV and DV can be useful for developing other applications in future.

7 Conclusion

In this work, we proposed a simple yet explainable three step approach that automatically identifies whether a given statement typically from a press release or a news article is exaggerated in comparison to the source statement present in the journal. Our first step adapts the recently proposed BERT technology and models the relationship extraction problem as a sequence labeling task. This beats other sequence labeling and syntax driven approaches by a large margin. The relationship phrase extracted is encoded as a bag of words and fed to standard classifiers to obtain the strength of the phrase. Ground-truth labels of relationship phrases and those obtained from our model achieve similar performance. Finally, once the strength of the relationship phrase is available, a pair of statements can be easily compared. This method of exaggeration identification beats standard baselines that directly feed the two individual BERT embedding of the statement pair into binary classifiers or use the BERT textual entailment framework. In future, one can check if this kind of approaches work for other tasks where whole task can be divided into explainable subtasks.

Acknowledgments

This work is carried out by the authors during their study period at IIT Kharagpur. We thank Dr. Animesh Mukherjee and Dr. Pawan Goyal for their valuable inputs during the development of the work.

Strength category	Description	Example
0	No relationship is mentioned	...An international study of 220,000 people has challenged the idea that obese people who have an "apple shape" - fat around the middle section of the body - are at higher risk of heart attacks and strokes...
1	Explicitly stating there is no relationship	Clinical officers and doctors **did not differ significantly** in key outcomes for Caesarean section significantly..
2	Statement of correlation - IV and DV are associated, but causation cannot be explicitly asserted	the greatest excess risk **associated** with subsequent primary neoplasms at older than 40 years was for digestive and genitourinary neoplasms
3	Ambiguous statement of relationship - It is unclear what the strength of relationship of this statement	...**has linked** eight new DNA variants to the autoimmune disease...
4	Conditional statement of causation - Causal statements show that the IV directly changes the DV. Conditional causal statements carry an element of doubt in them	...one in four patients **may be wrongly** diagnosed with high blood pressure...
5	Statement of "can" - The word "can" is unique as a statement of relationship in that it implies that the IV has the potential to directly change the DV, Therefore it is stronger than any conditional statement of causation.	...An intensive diet intervention soon after diagnosis **can improve** glycaemic control. The addition of an activity intervention conferred no additional benefit...
6	Statement of causation - The strongest are the statements of causation. This statement says that the IV definitely and directly alters the DV.	...capsules containing concentrated phytonnutrients **improved** clinical outcomes...

IV: Independent Variable DV: Dependent Variable

Table 7: Description of strength categories with an example.

A Annotated strength levels

The dataset contains manually coded strength levels of main claims from three sources, based on which, authors found that the press release is the main source of exaggeration in health science reports. The main causal claims in journal article, press release and news reports are coded into seven categories with increase in strength of relationship (see Table **??**). Relation phrases in the claim representing the relationship are marked in bold. The relation phrase connects the independent variable (*IV*) with the dependent variable (*DV*).

B Detais of dependency tree heuristics

The steps followed for extraction of relation phrase from causal statement are given as follows:

- We create dependency trees for each statement, with each node corresponding to a word and edges representing the grammatical relation between them. Let D be the set of all possible dependencies. We work with the collapsed version of dependencies, e.g., prepositions are not represented as nodes but collapsed into edges etc. For the statement, 'gestures improved performance in spatial visualisation problems', the dependency tree is shown in Figure 2. Here 'in' in the statement has been collapsed to the edge *prep_in*.
- We identify a subset $A \subseteq D$ of dependencies that we collapse to merge the connected nodes. The intuition is to collect words that form a coherent phrase inside a single node. The set A has been formed by going through the definition of each grammatical relation from the Stanford dependency manual. We call the nodes of the compact dependency tree as compact nodes. Each compact node is a tree of simple nodes and thus represents a substring. The grammatical relation between two

Order	Heuristic	Definition
1	LONG_VB_NSUBJ_DOBJ	Select compact node with a *verb* root, and *nsubj* and *dobj* out-edges
2	LONG_VB_NSUBJPASS_AGENT	Select compact node with a *verb* root, and *nsubjpass* and *agent* out-edges
3	LONG_VB_NSUBJPASS_PREP_WITH	Select compact node with a *verb* root, and *nsubjpass* and *prep_with* out-edges
4	LONG_VB_NSUBJ_DOBJ_NSUBJPASS	Select compact node with a *verb* root, and having atleast one *nsubj*, *dobj* or *nsubjpass* out-edge
5	LONG_VB	Select compact node whose root is a *verb*
6	LONG_JJ_NSUBJ_XCOMP	Select compact node with an *adjective* root, and *nsubj* and *xcomp* out-edges
7	LONG_JJ	Select compact node with an *adjective* root, and *nsubjpass* and *prep_with* out-edges
8	LONG_NOUN	Select compact node with a *noun* root

Table 8: Dependency tree heuristics.

compact nodes is the grammatical relation between the roots of their corresponding tree.

- The set A consists of the following dependencies - *advmod, amod, appos, aux, auxpass, cop, det, expl, mwe, mark, neg, nn, npadvmod, num, number, pobj, poss, possessive, predet, prt, quantmod* and *vmod*. Note that most relations in A are modifiers. In the previous example (refer to Figure 2) the subtree with nodes 'problems'/NNS, 'spatial'/JJ and 'visualization'/NN are merged together to form a compact node 'spatial visualization problem'/NNS.
- The next step is to select an appropriate compact node. We use heuristic functions, that take a dependency tree as input and output a node (if its condition is met) or *nil*. We apply a sequence of heuristic functions $h1, h2, h3, ...$ to recover the relational phrase (see Table **??** for the list of heuristics). If $h1$ returns a node, we identify its constituent phrase as our relational phrase. Else if $h1$ returns *nil*, we select $h2$. If $h2$ returns a node, we use that else we try $h3$ and so on. The heuristic functions have been hand-coded by observing the statistics of the best compact node (highest normalized lexicalized edit similarity ($NLES$) with the annotated phrase) in the dependency trees of the training set.
  The $NLES$ between two phrases p_1 and p_2 is defined as

$$NLES(p_1, p_2) = 1 - \frac{dist(p_1, p_2)}{min(|p_1|, |p_2|)} \quad (1)$$

where, $|p_1|, |p_2|$ are the number of characters in p_1 and p_2 respectively. $dist$ refers to the standard edit distance where cost of the substitution, the insertion and the deletion are all taken as 1. We also tried jaccard similarity between lexicalized tokens in place of $NLES$ but we same set of heuristic sequence.

The list of heuristic functions is given in Table **??** along with their order of application, which has been found by iterating through all permutations and choosing the one that produces maximum average $NLES$ across all input training sentences. Each heuristic function proceeds according to its definition; if multiple nodes satisfy the heuristic condition, the node with the most number of words is chosen. If none of the nodes satisfy the heuristic condition, the function returns *nil*. For instance, in the previous example (refer to Figure 2), heuristics LONG_VB, LONG_VB_NSUBJ_DOBJ and LONG_NOUN match and return phrases, however, since LONG_VB has the highest priority so the respective phrase 'improved' is returned as the relation phrase. In another example 'Childhood cancer survivors at greater risk in middle age', no heuristics match to its compact tree and hence *nil* is returned as relation phrase.

C Error Analysis

In this section we discuss some of the error cases that we believe could be the possible reasons affecting the overall performance of the system. In future we plan to tackle some of these cases to further improve the system performance. We mention below some of these error cases. The examples of error cases are presented in Table **??**.

Ambiguous modifiers: Some statements have certain modifiers in their predicted relation phrases,

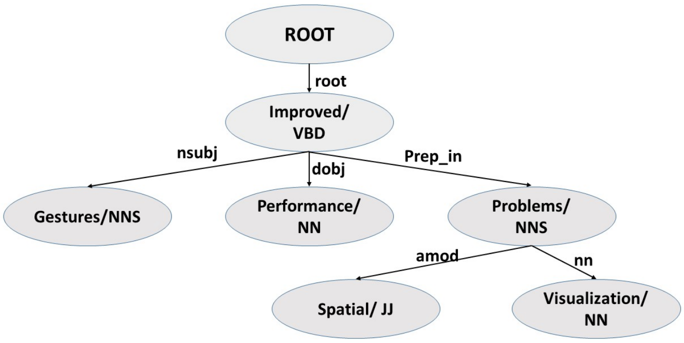

Figure 2: Collapsed dependency tree.

No.	Statement	Ann.Ph.	Pred. Ph.	A_S	P_S
1	a common treatment for a life-threatening heart condition has little significant impact on patient outcomes	has little significant impact on	has little significant impact on	1	6
2	We noted little variation between countries in the rate of maltreatment-related injury admission	little variation	little variation	1	6
3	this study excluded any large increase in the incidence of cases of or deaths from infective endocarditis	excluded any large increase	excluded any large increase	1	6
4	Falling in love sets brain circuits racing in the same way, regardless of sex or sexual orientation	regardless of	sets	1	6
5	breast cancer screening ... does women more harm than good	does	does women more harm than	6	2
6	that the progressive loss of lung function in asthma sufferers could be entirely independent of the effects of inflammation	could be entirely independent of	could be entirely independent	1	4

Table 9: Errors in strength classification. A_S: Actual strength, P_S: Predicted strength

Location	%
Title	26.10
First statement	46.12
Second statement	21.93
Third statement	2.14

Table 10: Location of the statement with the main claim in the press-releases/news articles.

which leads to an error in the strength class prediction. For instance, consider statements 1, 2 and 3 shown in Table ??. In all these cases the presence of the modifiers such as ‘little’, ‘any’ etc. are not separately tackled by the strength classifier.

Incorrect relation phrase: In some cases, the predicted relation phrase is incorrect. For example, consider the statement 4. Here the annotated phrase is ‘regardless of’ whereas the predicted phrase is ‘sets’. Another interesting case is statement 5. Here the predicted phrase fully contains the actual phrase and is also much larger than the actual phrase. The classifier therefore confuses the strength class.

Incorrect relation interpretation: In some cases, like statement 6, the system is unable to differentiate between “could be entirely independent” and “could be entirely dependent”, which leads to prediction of class 4 instead of the actual class 1.

D Spotting the causal statement

So far, we have assumed that statement with the main claim is already given to us for labeling and exaggeration identification. However, in order to completely automate the process we need to spot the exact location of these statements so that the previous pipeline of three sub-tasks could be smoothly executed. Manual inspection of the documents indicates that the statement with the main claim is present either in the title or in any one of the first three sentences of the document. In fact, we run an experiment on all the documents in our dataset and observe the location of the main statement. Table **??** shows the percentage of documents in the dataset, in which this statement is present in the title or in the first, second or the third sentence. Surprisingly, in 95% of the documents the causal statement is present in the title or the first three sentences of the document.

We repeat the relationship phrase identification experiment using the best model (i.e., BERT-SL) for a test set that is built using all the four sentences (i.e., the title, the first, the second and the third sentences) taken from each press release and news article present in our dataset. For each press release/news article, all the four sentences are labeled by the sequence labeler. Now we select that sentence for which we get the maximum number of words tagged as a relation phrase. Using this heuristic selection criteria we obtain F1-score of **0.8** and an accuracy of **0.9**. Given this encouraging result, we do not go for any additional algorithmic machinery for separately spotting the statement with the main claim for the dataset. However one can check in future if this works well for other problems and datasets.

E Inclusion of IV and DV

Our model can also be used to extract the IV and the DV as well. We also check if this brings additional benefits to the pipeline. Though the existing annotation of the dataset identifies the entities, i.e., the IVs and DVs associated with each document (journal/press-release/news article), in many cases, they are not explicitly part of the statement with the main claim (i.e., the entities are metaphorically mentioned); therefore, automatic labeling of these variables was impossible without re-annotation. To this purpose, we re-annotated the entire dataset for these two entities. Next we tasked the BERT-SL to identify the IV, DV and relation phrase altogether. The F1-score (precision, recall) we obtained for the labeling task in this case is 0.72 (0.75, 0.7). This experiment also gives token level accuracy of 0.87. As we observe, the inclusion of the IV and DV information does not improve the labeling performance and therefore we did not use it for the next stages of the pipeline. The use of these additional information actually seems to confuse the labeler more than benefiting it. However, the automatic extraction of the IV and DV can be useful for developing other applications in future.

Modeling Coreference Relations in Visual Dialog

Abstract

Visual dialog is a vision-language task where an agent needs to answer a series of questions grounded in an image based on the understanding of the dialog history and the image. The occurrences of coreference relations in the dialog makes it a more challenging task than visual question-answering. Most previous works have focused on learning better multi-modal representations or on exploring different ways of fusing visual and language features, while the coreferences in the dialog are mainly ignored. In this paper, based on linguistic knowledge and discourse features of human dialog we propose two soft constraints that can improve the model's ability of resolving coreferences in dialog in an unsupervised way. Experimental results on the VisDial v1.0 dataset shows that our model, which integrates two novel and linguistically inspired soft constraints in a deep transformer neural architecture, obtains new state-of-the-art performance in terms of recall at 1 and other evaluation metrics compared to current existing models and this without pretraining on other vision-language datasets. Our qualitative results also demonstrate the effectiveness of the method that we propose. [1]

1 Introduction

Recently, with the unprecedented advances in computer vision and natural language processing, we have seen a considerable effort in developing artificial intelligence (AI) agents that can jointly understand visual and language information. Visual-language tasks, such as image captioning (Xu et al., 2015) and visual question-answering (VQA) (Antol et al., 2015), have achieved inspiring progress over the past few years. However, the applications of these agents in real-life are still quite limited, since they cannot handle the situation when continuous information exchange with a human is necessary, such as in visual-language navigation (Anderson et al., 2018b) and visual dialog (Das et al., 2017). The visual dialog task can be seen as a generalization of VQA. Both tasks require the agent to answer a question expressed in natural language about a given image. A VQA agent needs to answer a single question, while a dialog agent has to answer a series of language questions based on its understanding of visual content and dialog history. Compared to VQA, the visual dialog task is more difficult because it demands the agent to resolve visual coreferences in the dialog. Considering the example in Figure 1. when the agent encounters question 6 "do they look old or new ?" and questions 9 "are they tall or short ?", it has to infer that the pronoun "they" in these two questions refers to different entities in the image or the dialog history.

Person B (10) : they are

Figure 1: An example taking from the VisDial v1.0 dataset. The questioner (Person A) sees the caption and tries to understand the whole scene of the image by asking questions to the answerer (Person B) who can see the whole image.

This paper studies how we can improve the results of a visual dialog task by better resolving the coreference relations in the dialog. In this work we restrict coreference resolution to pronouns. We

April 19 - 23, 2021. ©2021 Association for Computational Linguistics

use a multi-layer transformer encoder as our baseline model. Based on the assumption that the output contextual embedding of a pronoun and its antecedent should be close in the semantic space, we propose several soft constraints that can improve the model's capability of resolving coreferences in the dialog in an unsupervised way (i.e., without ground truth coreference annotations in the training data). Our first soft constraint is based on the linguistic knowledge that the antecedent of a pronoun can only be a noun or noun phrase. To integrate this constraint in the baseline model, we introduce a learnable part-of-speech (POS) tag embedding and a part-of-speech tag prediction loss. Inspired by the observation that in human dialog the referents of pronouns often occur in nearby dialog utterances, we propose a second soft constraint using a sinusoidal sentence position embedding, which aims to enhance local interactions between nearby sentences.

Our contributions are as follows: First, as a baseline we adapt the multi-layer transformer encoder to the visual dialog task and obtain results comparable to the state of the art. Second, we propose two soft constraints to improve the model's ability of resolving coreference relations in an unsupervised way. We also perform an ablation study to demonstrate the effectiveness of the introduced soft constraints. Third, we conduct a qualitative analysis and show that the proposed model can resolve pronoun coreferents by making sure that in the neural architecture the pronoun mostly attends to its antecedent.

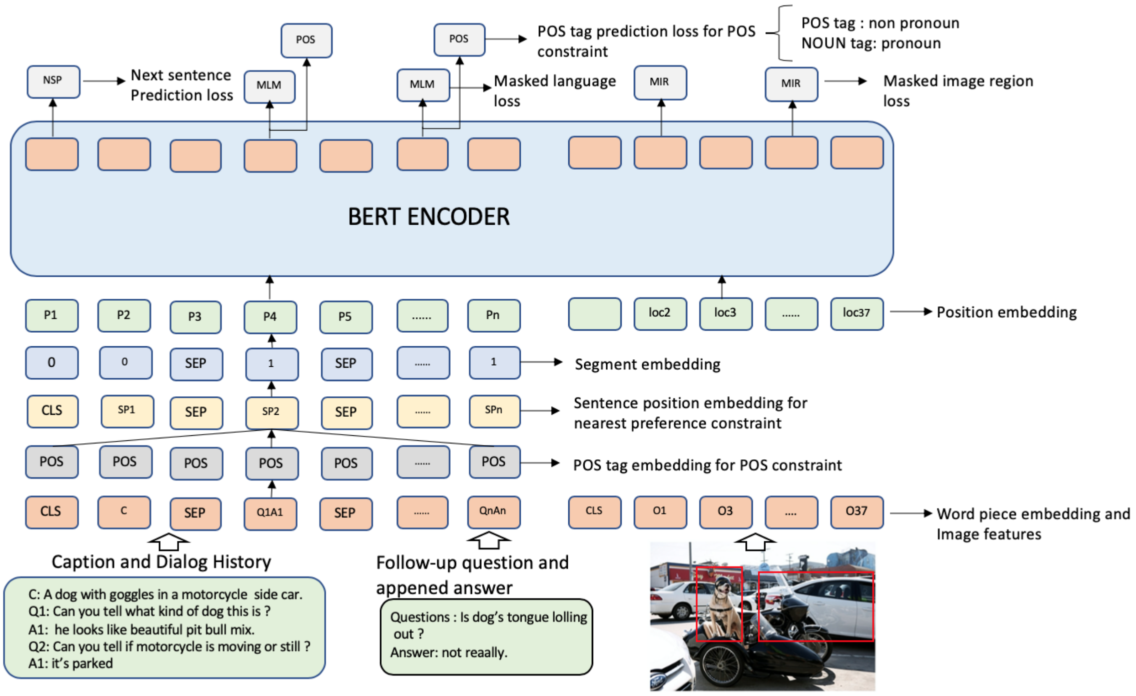
2 Related Work

Visual Dialog. The Visual Dialog task is proposed by Das et al. (2017), where a dialog agent has to answer questions grounded in an image based on its understanding of the dialog history and the image. Most of previous work focuses on using an attention mechanism to learn interactions between image, dialog history and question. Gan et al. (2019) use an attention network to conduct multi-step reasoning in order to answer a question. Niu et al. (2019) propose a recursive attention network, which selects relevant information from the dialog history recursively. Kang et al. (2019) apply a multi-head attention mechanism (Vaswani et al., 2017) to learn mutimodal representations. Schwartz et al. (2019) fuse information from all entities including question, answer, dialog history, caption and image using a factor graph. Murahari et al. (2019) propose two-stage training. They first pretrain their transformer based two-stream attention network on other visual-language datasets, then finetune it on the visual dialog dataset. Other approaches consider different learning methodologies to model the visual dialog task, for example, Lu et al. (2017) use adversarial learning and Yang et al. (2019) apply reinforcement learning.

Coreference Resolution. Coreference resolution aims at detecting linguistic expressions referring to the same entities in the context of the discourse. The task has been dominated by machine learning approaches since the first learning based coreference resolution system was proposed by Connolly et al. (1997). Before Lee et al. (2017) proposed the first end-to-end neural network based coreference resolution system, most of the learning-based systems have been built with hand engineered linguistic features. Durrett and Klein (2013) use surface linguistic features, such as mention type, the semantic head of a mention, etc., and their combinations to build a classifier to determine if two mentions refer to the same entity. Do et al. (2015) adopt integer linear programming (ILP) to introduce coreference constraints including centering theory constraints, direct speech constraints and definite noun phrase and exact match constraints in the inference step in order to adapt an existing coreference system trained on the newswire domain to short narrative stories without any retraining. Recently, Joshi et al. (2019) apply a BERT model to coreference resolution and achieve promising results on the OntoNotes corpus (Pradhan et al., 2012) and the GAP dataset (Webster et al., 2018). Different from all coreference systems mentioned above, which rely on supervised learning and on a dataset annotated with coreference links, our work focuses on applying soft linguistic constraints to improve the model's ability of resolving coreferents in an implicit and unsupervised way. Similar to the work of Venkitasubramanian et al. (2017) that operates on language and vision information, our model uses attention to jointly learn multi-modal representations.

3 Methodology

In this section, we formally describe the visual dialog task (Das et al., 2017) and the approaches we propose. In visual dialog, given an image I, the image caption C and the dialog history until round $t-$



C: A dog with goggles in a motorcycle side car.
Q1: Can you tell what kind of dog this is ?
A1: he looks like beautiful pit bull mix.
Q2: Can you tell if motorcycle is moving or still ?
A1: it's parked

Questions : Is dog's tongue lolling out ?
Answer: not reaally.

Figure 2: The model architecture with the two soft constraints that we propose. The baseline model takes the image feature I, image caption C, dialog history H_t, follow-up question Q_t and appended candidate answer A_t as input and is trained by using a masked language model (MLM), masked image region (MIR) and next sentence prediction (NSP) losses. Two soft constraints are integrated into the model by adding POS tag embedding and sentence position embedding to the input language sequence embedding and by introducing a new POS tag prediction objective during training.

1, $H = ((Q_1, A_1), (Q_2, A_2), \cdots, (Q_{t-1}, A_{t-1}))$, which is a sequence of question-answer pairs expressed in natural language and grounded in the image, a dialog agent is expected to correctly answer the question at round t by choosing the answer from 100 candidate answers $A_t = \{A_t^1, A_t^2, \cdots, A_t^{100}\}$.

We first introduce the baseline visual dialog model in Section 3.1, followed by the detailed explanation of our proposed soft coreference constraints and how we integrate these into the baseline model in Section 3.2. The coreference constraints are based on linguistic knowledge, so consequently our method is an example of how to integrate linguistic knowledge into a neural transformer architecture. Figure 2 shows the architecture of our proposed model.

3.1 Baseline Model

Transformer Encoder. We use a multi-layer transformer (Vaswani et al., 2017) encoder as our baseline model. The computation within a single layer transformer encoder is presented in appendix A.1, and the details of the input and training objective functions are illustrated in below subsections. The main idea of applying the transformer architecture to the visual dialog task is to use the multi-head self-attention mechanism to implicitly learn the intra and inter interactions within the single modality and between the different modalities (in this case language and vision), respectively.

Linguistic Representation. Following the monolingual BERT model (Devlin et al., 2019) and the multi-modal BERT model (Lu et al., 2019; Li et al., 2019; Su et al., 2020), we use the WordPiece (Wu et al., 2016) tokenization tool to tokenize each input sequence into word pieces sequence. Then the sum of the word piece embedding, position embedding and segment embedding, where the segment embedding is used to differentiate questions from answers and to delimit boundaries of question-answer pairs, are taken as the language sequence input of the model.

Image Representation. Following the multi-modal BERT model (Anderson et al., 2018a; Lu et al., 2019; Li et al., 2019; Su et al., 2020), we use Faster-RCNN (Ren et al., 2015) with ResNet (He et al., 2016) backbone to detect objects in the image and keep the top-36 detected objects and their corresponding bounding boxes. The representation of each detected object is obtained by applying a mean-pooled convolution on the region of that object. We also project a $5-d$ geometrical representation of each box, including the normalized top-left and bottom-right coordinates of the detected objects and the fraction of the area they cover, to the same dimensions as the image feature vector. In this way we obtain a vector with the same dimensions as the feature representation of the image. The final input image representation is the sum of its geometrical and feature representations. To avoid missing image information that is not captured by the top-36 bounding boxes, we also concatenate the mean-pooled feature vector of the whole image to the beginning of the image region sequence.

Multi-modal Input. As the transformer encoder receives a sequence of tokens as input, to feed both image and language into the model, we simply concatenate the language sequence embedding and image region sequence representation to form a whole input sequence. Like in the BERT model, a special token [CLS] is added to the beginning of the input sequence to perform the next sentence prediction task. We also use another special token [SEP] to separate each question-answer pair and the two modalities. Our input sequence can be formulated as follows: $Input = \{[CLS], C, [SEP], Q_1A_1, [SEP], Q_2A_2, \cdots, Q_t A_t, [SEP], O_0, O_1, O_2, \cdots, O_{36}\}$, where C is the image caption. Q_i,A_i are question and answer at round i, and $O_{0\sim 36}$ denote the input image region features.

Multitasks Training Objectives. To make the model learn a good alignment between different modalities, we utilize three losses: masked language model loss (MLM), masked image region loss (MIR), and next sentence prediction loss (NSP). Similar to the MLM in BERT, we randomly mask 15% word pieces in the language sequence by replacing the word piece with a special token [MASK], while in MIR, we randomly set 15% of the image region features to zero vectors. The model is trained to recover the masked words and predict the semantic category of the masked image regions:

$$L_{MLM} = -E_{(I,w)\sim D} log P(w_m | w_{\backslash m}, I) \quad (1)$$

$$L_{MIR} = \sum_{i}^{k} KL(P_m || P_g) \quad (2)$$

where $w_{\backslash m}$ and I denote the word sequence excluding the masked words w_m, and image regions, respectively. KL represents the KL divergence loss. P_m is the model output distribution and P_g is the ground truth classification distribution.

Recall that the visual dialog system aims to find the correct answer among the 100 candidate answers. We realize this in a discriminative manner by using the next sentence prediction loss (NSP). We randomly select 1 wrong answer from the candidate answers to generate negative samples, together with the ground-truth to form a balanced training dataset. During training, a candidate answer is appended to the dialog sequence, and the model is trained to predict whether or not the appended answer is the correct answer to the current question:

$$L_{NSP} = -E_{(I,w)\sim D} log P(\hat{y} | I, w) \quad (3)$$

where $\hat{y} \in [0, 1]$ is the output probability of the binary classifier at the last layer using the special [CLS] tag representation, which indicates the probability of the appended answer being correct. During inference, we rank the 100 candidate answers using their NSP score, which is the $\hat{y}$ in the above equation. During training, the total loss is the sum of MLM, MIR and NSP losses:

$$L_{total} = L_{MLM} + L_{MIR} + L_{NSP} \quad (4)$$

3.2 Soft Coreference Constraints

As discussed before, the existence of pronouns in language makes the visual dialog a more challenging task than VQA. A naive way to reduce the difficulty would be to use a loss to guide the model to jointly learn to resolve the coreferences in the dialog and to generate an answer to the question. However, the lack of coreference annotations in the visual dialog dataset prevents from using this supervised learning approach. Although it is impossible to resolve coreferences directly in the model, we propose to use linguistic knowledge to improve the model's ability to implicitly resolve the coreferences in an unsupervised way. We do so by exploiting the attention mechanisms of the transformer architecture where attention weights act as soft constraints to guide the training of the model. The intuition behind it is the following. As the baseline model will output a contextual representation for each input token in the last layer, if a pronoun refers to a noun or noun phrase in the input sequence, the output contextual embedding of this pronoun and its antecedent should be close in the semantic space, which also means that the pronoun should attend most to its antecedent.

Part-Of-Speech Constraint. Our first proposed soft constraint is based on the linguistic knowledge that if the antecedent of a pronoun exists, it can only be a noun or noun phrase. We use the POS tag information and introduce a POS tag prediction loss to help pronouns to find nouns in the dialog. The Stanford CoreNLP POS tagger (Manning et al., 2014) is used to obtain the POS tag of each word in the input dialog, and all sub-word splits from a word share the same POS tag. Similar to the word embedding, we use a learnable embedding for each POS tag, which is further summed with the word piece embedding, position embedding and segment embedding to form the input sequence embedding of the model. In POS prediction loss, similar to the MLM loss, we randomly mask 15% of POS tag of input tokens. Then, the model is trained to predict the ground truth POS tag[2] of non-pronoun masked words, while for masked pronouns we replace the ground truth PRP tag with NN tag forcing the model to learn the contextual pronoun embedding that is close to nouns in the semantic space. The POS prediction loss can be formulated as the equation below:

$$\begin{aligned}
&L_{POS} = -E_{(w,I)\sim D}(P_{non-pronoun} + P_{pronoun}) \\
&P_{non-pronoun} = -logP(POS(w)|w_{\setminus m}, I) \\
&P_{pronoun} = logP(NN|w_{\setminus m}, I)) \qquad (5)
\end{aligned}$$

where $w_{\setminus m}$ denote all unmasked words, and D is the dataset. This soft constraint will make pronouns focus more on nouns instead of other words such as verb, adverb or adjective, etc. As it does not violate any linguistic rules, it will not introduce a bias to the language model.

Nearest Preference Constraint. Our second soft constraint is inspired by the observation that in human dialog a pronoun is more likely to refer to the noun that is close to it. For example, in the visual dialog shown in Figure 1, in round 9 the pronoun “they” refers to the “buildings”, in round 6 “they” refers to “bikes”. However, it is not always the case that pronouns refer to the noun closest in the previous utterances hence our soft constraint. In visual dialog, some pronouns refer to noun phrases that occur much earlier in the discourse - skipping a few rounds - as utterances are very short. To integrate this preference into the model, we adapt the sinusoidal word position embedding proposed in (Vaswani et al., 2017) and introduce a sentence position embedding:

$$PE_{pos,2i} = \frac{1}{k} sin(pos/(M + 10000^{\frac{2i}{d}})) \qquad (6)$$

$$PE_{pos,2i+1} = \frac{1}{k} cos(pos/(M + 10000^{\frac{2i}{d}})) \qquad (7)$$

where pos is the sentence position in the dialog, d is the hidden state size and the M is the maximum number of sentences, which is 21 in this visual dialog task. k is a scaling factor to control the local interactions brought by sentence position embedding and we use $k = 100$. Compared to the original sinusoidal position embedding proposed in (Vaswani et al., 2017), our sentence position embedding has one more scaling factor and one more element M in the denominator, which aims at restricting the product of the sentence position embedding to be a monotonically decreasing function with respect to $|pos_1 - pos_2|$.

$$PE_{pos_1} \cdot PE_{pos_2} = \frac{1}{k^2} \sum_{i=0}^{\frac{d}{2}-1} cos(w_i \Delta pos) \qquad (8)$$

where $w_i = 1/(M + \epsilon^{\frac{2i}{d}})$, and Δpos denotes the distance between two positions. ϵ is a parameter, which makes the wavelength of the sinusoidal function in each dimension to form a geometrical progression.[3] Since $\Delta pos \in [-M, M]$, $w_i \Delta pos \in [-1, 1]$, it follows that $cos(w_i \Delta pos) == cos(w_i |\Delta pos|)$ which is monotonically decreasing in the region of $[0, 1]$.The details of the derivation of equation 8 are presented in appendix A.2. The closer two sentences are, the larger of the product of their sentence position embedding, resulting in stronger local interactions between nearby sentences in the dialog. This soft constraint can be easily integrated into the model by adding the sentence position embedding to the

---

[2] We use the POS tags used in Penn Treebank (Marcus et al., 1993).

[3] Following Vaswani et al. (2017), we set $\epsilon = 10000$.

input sequence embedding including word piece embedding, position embedding, segment embedding and POS tag embedding.

4 Experiments

4.1 Dataset

We use the real environment VisDial v1.0 dataset in this work. The VisDial v1.0 has 123k, 2k and 8k dialogs for training, validation and test, respectively. Each dialog contains one image with its caption from the MS-COCO dataset (Lin et al., 2014), and ten rounds of question-answer pairs, which were collected from the chatting log of one questioner and one answerer who both were discussing the image. For each question, except for the correct answer, the dataset also provides another 99 candidate answers to form an answer pool from which a model needs to select the relevant answer. Note that, although the VisDial v1.0 dataset also contains a small dense annotation set in which a relevance score is given to each candidate answer in the answer pool, we do not use this small dataset to finetune all our models, as we consider recall at 1 as main evaluation metric, and finetuning on this dense dataset could degrade the model's performance when measured by recall at 1 (Murahari et al., 2019).

4.2 Evaluation Metrics

We evaluate our proposed models using three evaluation metrics: (1) mean reciprocal rank (MRR) (Voorhees, 1999); (2) recall @ k, that is, the existence of the ground truth response in the top-k ranked items of the response list generated by the model with k = 1, 5, or 10; and (3) mean rank (Mean) of the ground truth response, that is, the average rank of the ground truth answer in the model's output ranked list (lower is better).

4.3 Training Details

Inspired by the open source code[4] of Murahari et al. (2019), we have implemented our model using the PyTorch framework (Paszke et al., 2019). Our model has the same configuration as the BERT$_{\text{BASE}}$ model, which contains 12 transformer layers and each layer has 12 attention heads with a hidden state size of 768. We set the maximum input length to be 256 including 37 image features. All models were trained using the Adam (Kingma and Ba, 2014) algorithm with a base learning rate of $5e^{-5}$. A linear learning rate decay schedule is employed to increase the leaning rate from $5e^{-6}$ to 5^{-5} over $30k$ iterations and decay to $5e^{-6}$ over $40k$ iterations. Together with negative samples, each image in the VisDial v1.0 dataset can generate 20 samples for the NSP task. Since these samples are fairly correlated and following the work of Murahari et al. (2019), we randomly sub-sample 8 out of these 20 during training. We use the validation set to decide when to stop training. The batch size is 32 in all our experiments, and different from the work of Murahari et al. (2019) and Lu et al. (2019), we do not pretrain our model on other vision-language datasets.

5 Results

5.1 Quantitative Results

We compare the results of our model with the results of the following previously published models obtained on the VisDial v1.0 dataset: LF (Das et al., 2017), HRE (Das et al., 2017), MN (Das et al., 2017), CorefNMN (Kottur et al., 2018), FGA (Schwartz et al., 2019), RVA (Niu et al., 2019), HACAN (Yang et al., 2019), Synergistic (Guo et al., 2019), DAN (Kang et al., 2019), Dual VD (Jiang et al., 2020), and CAG (Guo et al., 2020). To make a fair and transparent comparison, we do not compare our models with models which were pretrained on other vision-language datasets before finetuning them on the VisDial v1.0 dataset, all the more because the vision-language datasets used in the pretraining overlap with the testset of Visdial v1.0. Also for those models, such as FGA, for which the authors also provide results of ensemble models, we only consider the results of their single model.

Results on VisDial v1.0 testset. As presented in Table 1, our best model (baseline model with both soft constraints) significantly outperforms all the previous published models and reach new state-of-the-art performance on MRR, R@1, R@5 and R@10. Specifically, compared to the best performance of previous models, our best model improves around 2.3% on MRR, 1.78% on R@1, 2.13% on R@5 and 2.35% on R@10. The mean rank of our proposed model is also better than all previous models, although the difference is relative small around 0.71. We also tested all our models on the VisDial v1.0 development set, and the results are presented in appendix A.3.

Ablation study. To further study the effectiveness of the two soft constraints, we perform an abla-

Table 1: Results of the visual dialog models on the VisDial v1.0 test set. C1 and C2 refer to the POS constraint and nearest preference constraint, respectively.(↑: the higher the better; ↓: the lower the better)

tion study on the VisDial v1.0 dataset with four different models: (1) Baseline model; (2) Model with the POS soft constraint (Model + C1); (3) Model with the nearest preference constraint (Model + C2); (4) Model with both the POS and nearest preference constraints (Model + C1 + C2). Moreover, We conduct an ablation study for the two aspects (POS embedding and POS prediction loss) in POS constraint The results are presented in Table 1. The baseline model obtains the following results in terms of MRR (62.13%), R@1 (47.38%), R@5 (80.40%) and R@10 (90.17%). Models with only POS embedding and only POS prediction loss have better performance than the baseline model. Further combining both leads to our first POS constraint, which improve the performance across all evaluation metrics (3.31% for MRR, 3.82% for R@1, 2.98% for R@5, 1.86% for R@10 and 0.55 for MRR). Similarly, only considering the nearest preference constraint leads to better performance on all evaluation metrics. The last row of Table 1 illustrates that the proposed soft constraints jointly lead to better results. We also study the changes of attention distribution of the model with and without our proposed constraints. Figure 3 shows that the nearest constraint can enhance the local connection in dialog, and the POS constraint is able to make pronouns focus more on nouns. These results indicate the effectiveness of adding linguistic constraints to a neural network. Integrating linguistic knowledge in a transformer neural architecture effectively improves the model's performance in the visual dialog task.

5.2 Coreference Analysis

As we do not have the access to the ground truth of the VisDial v1.0 test set, to further analyze the effectiveness of the proposed models, we create three small datasets, which each consists of samples with 2, 4, and 6 coreferences, respectively, from the Visdial v1.0 validation set. As there is no coreference annotation in the Visdial v1.0 dataset, we assume that each third-person pronoun (he, she, they, him, her, them) and possessive pronouns (its, his, her, their) has one coreference in the dialog.[5]

---

[5] Note that the dialog is about the objects in an image.

Results tested on validation set with 2 coreferences (237 samples)

Model	MRR ↑	R@1 ↑	R@5 ↑	R@10 ↑	Mean ↓
Baseline Model	65.06	51.38	82.42	91.79	3.77

Table 2: Results of the visual dialog models obtained on three small datasets each with a different number of pronoun coreferences that were collected from the VisDial v1.0 validation set. C1 and C2 refer to the POS constraint and nearest preference constraint, respectively.

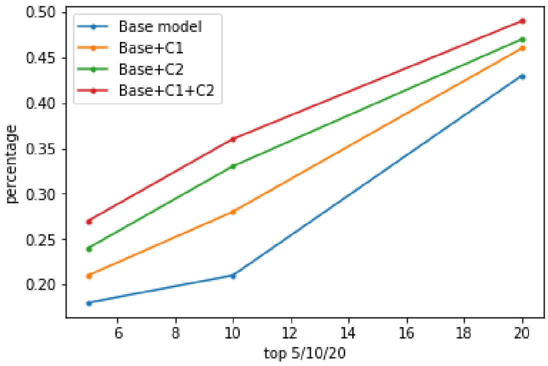

Figure 4: The percentage of the correct antecedent is within top 5/10/20 pronoun’s attention distribution.

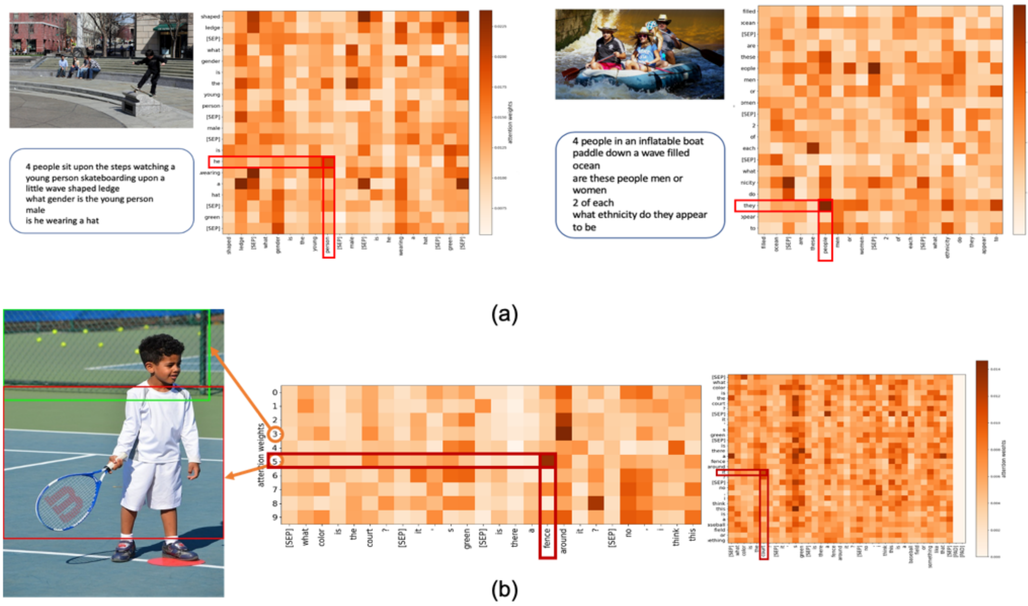
To create these subsets, we do not take “it” into consideration, as many of the occurrences of “it”[6] do not have a corefering expression, for example, “is it daytime ?”. We test our models and the baseline model using these four small datasets, and the results are illustrated in Table 2. Comparing the results in Table 2 with that in Table 1, in some cases the performance in Table 2 is better, which means that the difficulty of these sampled data do not higher than that of the test set. One clear observation is that in almost all cases the model with two soft constraints has the best performance in terms of MRR, R@1, R@5, R@10 and Mean in all three datasets. Another observation is that integrating either the POS constraint or the nearest preference constraint improves the performance across all evaluation metrics in all four datasets, which again shows the effectiveness of our proposed linguistically inspired soft constraints. We can also see the trend that the models’ performance is worse when the dialog has more coreferences, which is reasonable and consistent with our previous assumption that the existence of coreferences makes this task more difficult. To further study

---

[6] “It” has many other functions apart from being a pronoun, such as “empty” subject or object, not referring to anything in particular, to introduce or anticipate the subject or object of a sentence, use in cleft or in passive voice sentences, etc.



4 people sit upon the steps watching a young person skateboarding upon a little wave shaped ledge
what gender is the young person
male
is he wearing a hat

4 people in an inflatable boat paddle down a wave filled ocean
are these people men or women
2 of each
what ethnicity do they appear to be

Figure 5: Attention score map of our best model (Model C1+C2). (a) Two correct cases: The attention map shows that the pronoun correctly attends to its antecedent. (b) An incorrect case: Although the coreference is correctly resolved, the word "fence" does not attend to the correct region in the image, which results in selecting the wrong answer.

the effectiveness of our proposed constraints, we manually annotated coreferences in a subset of the validation set and tested all our ablation models on this dataset. The results are presented in Figure 4, which shows that both the proposed constrains can improve the model's ability of resolving coreferences.

5.3 Qualitative Analysis

We visualize the attention scores of the model to investigate whether or not our best model can resolve pronoun coreferences in the dialog. We expect that the pronoun will attend the most to its antecedent, if the model correctly resolves the pronoun referent. Figure 5(a) presents the results of two samples taken from the VisDial v1.0 test set. Note that we only show the attention scores in the window of size 20 around the pronoun and its possible antecedent. The attention score maps illustrate that in these examples the attention weights between pronoun and its antecedent are significantly larger than those between the pronoun and other words, which indicates that the model can implicitly resolve the coreferences correctly.

Error Analysis Figure 5(b) presents a negative example. When facing the question "Is there a fence around it ?", the model answers "no, i think..." instead of the correct answer "yes". As shown in the attention map within language sequences, the pronoun "it" does attend to its antecedent "court", implying that the model successfully resolves the corefering noun. However, looking at the cross-modal attention, the word "fence" incorrectly refers to region 5 (court) in the image, which results in selecting a wrong answer. This negative example indicates that enhancing the model's ability of correct visual grounding is a meaningful future work.

6 Conclusion

In this paper, we have built a multi-layer transformer model for the visual dialog task. Based on linguistic knowledge and human dialog discourse patterns, we have proposed two soft constraints that effectively improve the model's performance by enhancing its ability of implicitly resolving pronoun coreferences. We have used the VisDial v1.0 dataset to evaluate our model. Our model obtains new state-of-the-art performance in correctly answering the dialog questions when compared to existing models without pretraining on other vision-language datasets. Our coreference and qualitative analysis further supports the proposed soft constraints.

A Appendix

A 1

This Appendix shows the computation within a transformer encoder layer. Given an input sequence $H_0 = [e_0, e_1, \cdots, e_n]$, the transformer encodes it into different levels of contextual representations using a multi-head self-attention mechanism:

$$Q = H_{t-1}W_t^Q, K = H_{t-1}W_t^K, V = H_{t-1}W_t^V \tag{1}$$

$$AttentionHead_i(Q, K, V) = Softmax(\frac{QK^T}{\sqrt{d}})V \tag{2}$$

$$MultiHeadSelfAttention(H^t) = Concat(head_1, \cdots, head_k)W^O \tag{3}$$

where t is the layer index, $W_t^Q, W_t^K, W_t^V, W_t^O$ are learnable projection matrices, which map the hidden state h_t to the query q vector, key k vector, value v vector and output vector, and H_t denote the learned contextual representations at layer t. d is the size of hidden state.

A 2

The below formulations express the derivation of getting equation 8. Here, we use p to denote the pos in equation 11.

$$\begin{aligned} PE_1 \cdot PE_2 &= \frac{1}{k^2} \sum_{i=0}^{\frac{d}{2}-1} sin(w_i p_1) \cdot sin(w_i p_2) \\ &+ cos(w_i p_1) \cdot cos(w_i p_2) \\ &= \frac{1}{k^2} \sum_{i=0}^{\frac{d}{2}-1} cos(w_i(p_1 - p_2)) \\ &= \frac{1}{k^2} \sum_{i=0}^{\frac{d}{2}-1} cos(w_i \Delta p) \end{aligned}$$

A 3

Table 1 in this section shows the results of the four models on the VisDial v1.0 development set. Similar to the results obtained by testing on the test set, the model with both constraints (Model + C1 + C2) has the best performance across all evaluation metrics, and adding any one of the proposed soft constraint improves the performance of the baseline model, which indicates the effectiveness of our approach also during training.

Model	MRR ↑	R@1 ↑	R@5 ↑	R@10 ↑	Mean ↓
Baseline Model	64.80	50.56	82.64	91.02	3.85
Baseline Model + C1	68.59	55.37	84.38	92.29	3.28
Baseline Model + C2	68.32	55.25	84.49	92.25	3.32
Baseline Model + C1 + C2	**69.49**	**56.46**	**85.33**	**93.37**	**3.19**

Increasing Robustness to Spurious Correlations using Forgettable Examples

Abstract

Neural NLP models tend to rely on spurious correlations between labels and input features to perform their tasks. Minority examples, *i.e.*, examples that contradict the spurious correlations present in the majority of data points, have been shown to increase the out-of-distribution generalization of pre-trained language models. In this paper, we first propose using example forgetting to find minority examples without prior knowledge of the spurious correlations present in the dataset. Forgettable examples are instances either learned and then forgotten during training or never learned. We empirically show how these examples are related to minorities in our training sets. Then, we introduce a new approach to robustify models by fine-tuning our models twice, first on the full training data and second on the minorities only. We obtain substantial improvements in out-of-distribution generalization when applying our approach to the MNLI, QQP, and FEVER datasets.

1 Introduction

Despite the impressive performance of current NLP models, these models often exploit spurious correlations: they tend to capture prediction correlations that hold for most examples but do not hold in general. For instance, in natural language inference (NLI) datasets, word-overlap between hypothesis and premise is highly correlated with the *entailment* label (McCoy et al., 2019; Zhang et al., 2019). Therefore, these models are brittle when tested on examples that cannot be solved by recurring to these correlations, limiting their application in real-world scenarios. *Out-of-distribution* or *challenging* sets are benchmarks carefully designed to break systems that rely on such correlations.

The paradigm of fine-tuning pre-trained language models (PLM) has pushed the state-of-the-art in a large variety of tasks involving natural language understanding (NLU) (Devlin et al., 2019; Wang et al., 2019). This is achieved by self-supervised learning from an enormous amount of text. PLMs also show increased robustness on challenging datasets (Hendrycks et al., 2019). This increase is attributed to an empirical finding that PLMs perform better on *minority examples* present in the training data (Tu et al., 2020). These minority examples violate the spurious correlations and therefore likely support the examples in challenging datasets.

Tu et al. (2020) find minority examples by manually dividing the training data into two groups, according to the known spurious correlations (e.g., word-overlap in NLI). They present an analysis of the robustness of PLMs and its connection to minority examples. In this work, we first introduce a systematic way to find minority examples that does not need prior knowledge of spurious correlations, a big limitation of the earlier work. We then present a simple approach that increases the robustness of PLMs further by tuning models more on these examples.

To identify the set of minority examples, we adopt *example forgetting* (Toneva et al., 2019). This statistic has been shown to relate to the hardness of examples, so we assume it is useful to find minorities in the training data. Based on the definition presented in Toneva et al. (2019), we consider an example *forgettable* if during training it is either properly classified at some point and misclassified later, or if it is never properly classified. This method is model- and task-agnostic. We show in our datasets that minority examples w.r.t to spurious correlations, such as word-overlap in NLI, are well represented in forgettable examples.

After finding minorities through forgettable examples, we propose a simple method to increase the robustness of PLMs further. We perform an additional fine-tuning on the minorities ex-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3319–3332
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

clusively, after fine-tuning on the whole training data. We find this strategy effective, as it increases robust accuracy, i.e., performance on out-of-distribution data, while minimally impacting performance on in-distribution examples. We evaluate our proposed methods in three tasks, including NLI (MNLI, Williams et al., 2017), paraphrase identification (QQP, Iyer et al., 2017) and fact verification (FEVER, Thorne et al., 2018). For each task, recent work has introduced out-of-distribution test sets targetting specific spurious correlations.

Our contributions are the following:

- We propose using forgettable examples as a new approach for finding minority examples from training data without prior knowledge of spurious correlations.
- We show how to exploit minority examples and increase the robustness of deep neural models. This method outperforms other baselines in three challenging datasets: HANS (McCoy et al., 2019), PAWS (Zhang et al., 2019) and FEVER-Symmetric (Schuster et al., 2019). Our method performs effectively when applied to both base and large versions of PLMs (e.g., $\text{BERT}_{\text{BASE}}$ and $\text{BERT}_{\text{LARGE}}$).
- We observe that finding minorities using a network shallower than the PLM is more effective to robustify it via fine-tuning.
- We show that training models only on forgettable examples leads to poor performance in our datasets, which contrasts with the vision results from Toneva et al. (2019). Our code is available at `github.com/sordonia/hans-forgetting`

2 Datasets

We consider three sentence pair classification tasks, namely natural language inference, paraphrase identification, and fact verification. In the following, we describe the datasets we choose for each task following an introduction of the task.

2.1 Natural Language Inference

The first task we consider is MNLI (Williams et al., 2017), a common natural language inference dataset containing more than 400,000 premise and hypothesis pairs annotated with textual entailment information (*neutral*, *entailment* or *contradiction*). Models trained on this dataset have been shown to capture spurious correlations, such as word-overlap between hypothesis and premise as a strong signal for the *entailment* label (Naik et al., 2018; McCoy et al., 2019). A series of diagnostic out-of-distribution test sets have been devised to test robustness against such heuristics, e.g., HANS.

HANS (McCoy et al., 2019, Heuristic Analysis for NLI Systems) is composed of both *entailment* and *contradiction* examples that have high word-overlap between hypothesis and premise (e.g. "*The president advised the doctor*" $\not\rightarrow$ "*The doctor advised the president*"). A model relying exclusively on the word-overlap feature would not have a higher than chance classification accuracy on HANS. As a matter of fact, BERT (Devlin et al., 2019) performance on this dataset is only slightly better than chance (McCoy et al., 2019). We consider HANS (size: 30k examples) and the MNLI matched dev (Williams et al., 2017) (size: 9815 examples) as our out- and in-distribution test sets for MNLI.

2.2 Paraphrase Identification

QQP (Iyer et al., 2017) is a widely used dataset for paraphrase identification containing over 400,000 pairs of questions annotated as either paraphrase or non-paraphrase. As a consequence of the dataset design, pairs with high lexical overlap have a high probability of being paraphrases. Similarly to MNLI, models trained on QQP are thus prone to learning lexical overlap as a highly informative feature and do not capture the common sense underlying paraphrasing. PAWS dataset is designed to test that.

PAWS (Zhang et al., 2019, Paraphrase Adversaries from Word Scrambling) is a question paraphrase dataset, well-balanced with respect to the lexical overlap heuristic. The accuracy of BERT is around 91.3% on QQP and only 32.2% on PAWS (Table 5). This makes it an interesting test-bed for our method. We use PAWS-QQP as our out-of-distribution set, which contains 677 questions pairs. Training examples from PAWS were never used to update our models. Following Zhang et al. (2019) and Utama et al. (2020), our QQP training and testing splits are based on Wang et al. (2017).

2.3 Fact Verification

The task of fact verification aims to verify a claim given an evidence. The labels are *support*, *refutes*, and *not enough information*. This task is defined as part of the Fact Extraction and Verification (FEVER) challenge (Thorne et al., 2018). Schuster et al. (2019) show that models ignoring evidence can still achieve high accuracy on FEVER. They introduce an evaluation test set that challenges that bias. Following Utama et al. (2020), we use the **FEVER-Symmetric** datasets (Symm-v1 and Symm-v2 with 717 and 712 examples, respectively) for out-of-distribution evaluation[1].

3 Finding Minorities with Forgettables

We first define example forgetting and how to compute it. We then show that it can be used to find minority examples in the training data.

3.1 Forgettable examples

An example is forgotten if it goes from being correctly to incorrectly classified during training (each such occurrence is called a *forgetting event*). This happens due to the stochastic nature of gradient descent, in which gradient updates performed on certain examples can hurt performance on others. If an example is forgotten at least once or is never learned during training it is dubbed *forgettable*. Finding forgettable examples entails training the model on $\mathcal{D}$ and tracking the accuracy of each example at each presentation during training. The algorithm for computing forgettability is cheap (Toneva et al., 2019) and only requires storing the accuracy of each particular example at each epoch.

In Toneva et al. (2019), they extracted forgettable examples from a *shallower network* compared to their target model. This makes finding forgettables more efficient and also results in a more diverse set of examples, as the number of forgettable examples is usually higher for weaker models. Another factor is that the shallow models exhibit less memorization due to their fewer number of hyperparameters (Sagawa et al., 2020b) and therefore their forgettables are potentially more representative of the minorities.

We compute forgettable examples using two models with significantly lower capacity compared to PLMs. The first one is a "siamese" BoW classifier in which hypothesis and premise are independently encoded as a mean of word embeddings. This common model in NLP tasks has surprisingly good performance while relying only on the bag of lexical features. We also consider a siamese BiLSTM model. More details can be found in Appendix A. Finally, for comparison, we also experiment with the model used for HANS in SOTA baselines (Clark et al., 2019; Utama et al., 2020) (see also §4.2), as well as BERT$_{\text{BASE}}$ for in NLI.

Dataset	**Model**	$\lvert\mathcal{F}\rvert$	**Dev Acc.**
MNLI (392,703)	BoW	63,390	64.0
	BiLSTM	46,740	69.6
	BERT	17,748	84.5
QQP (384,348)	BoW	71,116	81.1
	BiLSTM	76,634	84.3
	BERT	20,498	91.3
FEVER (242,911)	BoW	76,368	53.3
	BiLSTM	68,406	56.7
	BERT	21,066	84.4

Table 1: Number of "forgettable" examples along with the accuracy on the MNLI matched, QQP, and FEVER development set. BERT's forgettables are used only in MNLI experiments. The full training size is shown in parenthesis for each dataset.

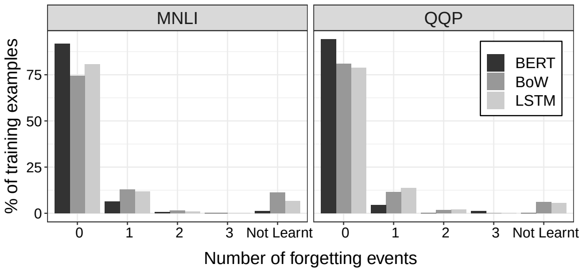

Figure 1: Forgetting events in MNLI and QQP training sets for the three models. A majority of examples are not forgotten during training.

We train the shallow models for five epochs and track forgetting statistics after each epoch. Table 1 shows the number of forgettable examples for BoW, BiLSTM and BERT$_{\text{BASE}}$ on the MNLI, QQP and FEVER training sets. The performance of the models on the dev set of MNLI is also included.

The distribution of forgetting events for each model can be found in Fig 1. We see that a majority of examples are not forgotten. Most of the forgettables are either those that are never learned or have only one forgetting event. In what follows, we denote the sets of forgettable examples from BERT$_{\text{BASE}}$, BiLSTM, and BoW as $\mathcal{F}_{\text{BERT}}$, $\mathcal{F}_{\text{BiLSTM}}$ and $\mathcal{F}_{\text{BoW}}$ respectively.

---

	MNLI		QQP		FEVER	
	P	$\neg P$	P	$\neg P$	P	$\neg P$
all	**.33**	.22	**.51**	.34	**.19**	.15
$\mathcal{F}_{\text{BoW}}$	.26	**.30**	.48	.49	.18	.17
$\mathcal{F}_{\text{BiLSTM}}$	.25	.28	.48	**.50**	.18	17
$\mathcal{F}_{\text{BERT}}$	.26	.26	.50	.50	**.19**	**.18**

Table 2: Average Jaccard index as a measure of word-overlap between two sentences grouped by P (positive) and $\neg P$ (non-positive).

3.2 Forgettable and minority examples

We focus on two important spurious correlations: word-overlap and contradiction-word. These correlations or biases are addressed in related work for MNLI and QQP (Tu et al., 2020; Zhou and Bansal, 2020). For convenience, we use "positive" for either entailment, supports or paraphrase, and "negative" for contradiction, refutes or non-paraphrase

High word-overlap between two sentences is spuriously correlated to the positive label in all three datasets. In Table 2, we show that on average, positive examples have higher word-overlap compared to non-positive ones. In other words, minorities w.r.t. word-overlap correspond to non-positive examples with high word-overlap and positive examples with low word-overlap. For MNLI and QQP, the distribution in $\mathcal{F}_{\text{BoW}}$ and $\mathcal{F}_{\text{BiLSTM}}$ exhibit an interesting behavior: on average, non-positive examples have higher word-overlap. $\mathcal{F}_{\text{BERT}}$ has the same average for both labels. For FEVER, the difference is also clear as the gap in word-overlap between positive and non-positive examples is lower for forgettables. The table allows to conclude that forgettable examples contain more minority examples than a random subset of the same size.

In Table 3, we perform a similar analysis for the presence of contradiction words in the second sentence, which is shown to correlate with negative class in MNLI (Naik et al., 2018; Zhou and Bansal, 2020) and FEVER (Schuster et al., 2019). We choose these contradiction words: {"not", "no", "doesn't", "don't", "never", "any"}, and analyze all three datasets. We observe here as well that forgettables contain more minority examples, as their percentage of examples with a contradiction word is lower for negative examples, which is the opposite than in the overall dataset (with the exception of $\mathcal{F}_{\text{BERT}}$ and FEVER).

	MNLI		QQP		FEVER	
	N	$\neg N$	N	$\neg N$	N	$\neg N$
all	**31.5**	10.4	**6.2**	4.0	**16.4**	1.2
$\mathcal{F}_{\text{BoW}}$	9.9	11.5	4.1	**4.6**	1.6	**3.1**
$\mathcal{F}_{\text{BiLSTM}}$	11.5	11.2	4.2	4.4	2.9	2.7
$\mathcal{F}_{\text{BERT}}$	14.2	**12.3**	4.2	4.4	6.3	2.5

Table 3: Percentage of examples containing one of the negative keywords in the hypothesis / second question / claim in MNLI / QQP / FEVER. We group examples by binary labels (N: negative and $\neg N$: non-negative) to show the distribution difference between forgettable and overall training examples.

4 Robustifying by Fine-Tuning on Minority Examples

Prior work shows that PLMs generalize to out-of-distribution data because they generalize better on minority examples from the training set (Tu et al., 2020). Here, we introduce a simple approach that exploits minority examples to increase robustness. In this approach, we fine-tune a PLM in two successive phases, first on the full training set, and then on the minority examples only. Our method does not need changes to the training objectives. An illustration is shown in Fig 2.

4.1 PLMs

We are interested in the robustness of large PLMs. In this work, we focus on two such models, BERT and XLNet, and experiment with both their base and large versions. $\text{BERT}_{\text{BASE}}$ being the model of choice in previous work (Clark et al., 2019; Zhang et al., 2019; Utama et al., 2020), it will serve as our default architecture. We adopt the Transformers library (Wolf et al., 2019). Our robust models are obtained by fine-tuning PLMs on the full training set for 3 epochs (using the default hyperparameters for each task) and then on the forgettable examples only, for 3 more epochs with a smaller learning rate. See B in Appendix for more details.

4.2 Baselines

Recently, multiple methods have been proposed to learn more robust models through mitigating biases (Clark et al., 2019; He et al., 2019; Mahabadi and Henderson, 2019; Utama et al., 2020). In these works, PLMs are fine-tuned on a re-weighted version of the source dataset, in which examples are weighted based on their hardness. Hardness is measured by training biased models using prior knowledge of the biases or spurious correlations, e.g., a

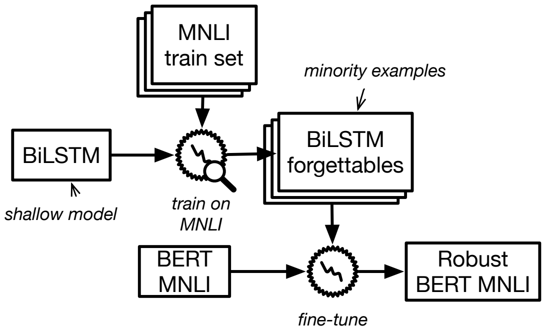

Figure 2: Our proposed framework to train more robust models for an example dataset (MNLI). We first detect minority examples through *forgettable* examples of a shallow model from the training set. We then fine-tune a PLM model (e.g. BERT) in two rounds: first on the full training set, and second on the forgettable subset exclusively. The final model is more robust.

linear model with word-overlap features for NLI. Compared to these works, our method does not need prior knowledge of spurious correlations and exploit the minority examples explicitly by further fine-tuning on them.

We consider the recent *confidence regularization* or "Reg-conf" technique from Utama et al. (2020), as our main baseline in all three tasks. This method is an improvement to the earlier related work in making more robust NLP models (He et al., 2019; Clark et al., 2019). Specifically, Reg-conf claims to maintain the in-distribution performance while improving out-of-distribution and is doing so without introducing new hyperparamters. For MNLI, we report the results of three other baselines of He et al. (2019), Clark et al. (2018) and Mahabadi and Henderson (2019).

Previous work generally design biased models assuming a priori knowledge of the specific dataset biases (with the exception of He et al. (2019), that use a BoW model for HANS). For HANS and PAWS, Clark et al. (2019) and Utama et al. (2020) employ a model with 7 input features, such as word-overlap between premise and hypothesis. To highlight the generality of our approach, we also add this biased model to the set of our shallow models for HANS and fine-tune on its forgettables ($\mathcal{F}_{\text{HANS}}$ with the size of around 200k). For FEVER-symmetric, Utama et al. (2020) consider an LSTM model that takes only the "claim" as input and ignores the "evidence". These baselines re-weight or confidence-regularize training examples using the biased models' performance.

Model	**MNLI**	**HANS**	**Avg.**
BERT	**84.4**$_{\pm0.1}$	62.9$_{\pm1.5}$	73.7$_{\pm0.8}$

Table 4: Results of our BERT models fine-tuned on different sources of forgettable examples. For each line, the accuracy on MNLI and HANS are shown, as well as their average.

4.3 Results

4.3.1 MNLI and HANS

In Table 4, we present the results of our models and four recent baselines. The first line reports the performance of BERT on MNLI and HANS. The following lines report the results obtained by fine-tuning BERT on the set of forgettable examples obtained using different shallow models. We also report the average performance between MNLI and HANS. The results confirm that tuning the model towards minority examples improves robustness with a slight drop in MNLI accuracy. Our best model is obtained by fine-tuning on $\mathcal{F}_{\text{BoW}}$, achieving a HANS mean accuracy of 70.5% (with a max of 71.3% over five seeds, which constitutes a +8.4% absolute improvement w.r.t to the initial BERT). To assess whether $\mathcal{F}_{\text{BoW}}$ is indeed responsible for the improvement, we also fine-tune BERT on the same number of randomly chosen examples (BERT + Rand$_{63,390}$), which leads to a negligible improvement.

Fine-tuning on $\mathcal{F}_{\text{BiLSTM}}$ is comparable to fine-tuning on $\mathcal{F}_{\text{BoW}}$, which demonstrates that both BoW and BiLSTM models learn similar spurious correlations. We also added results of fine-tuning BERT on its own forgettables for this task. Note

Model	QQP	PAWS	Avg.
BERT	**90.9**$_{\pm 0.4}$	34.5$_{\pm 1.5}$	62.7$_{\pm 0.6}$
BERT+ $\mathcal{F}_{\text{BoW}}$	89.0$_{\pm 0.9}$	**48.8**$_{\pm 5.2}$	**68.9**$_{\pm 2.2}$
BERT+ $\mathcal{F}_{\text{BiLSTM}}$	88.0$_{\pm 0.8}$	47.6$_{\pm 4.1}$	67.8$_{\pm 1.7}$
Utama et al. (2020)			
BERT	91.0	34.3	62.6
Reg-conf$_{\text{hans}}$	89.1	39.8	64.5

that while it provides less improvement in robustness than on $\mathcal{F}_{\text{BiLSTM}}$ or $\mathcal{F}_{\text{BoW}}$ [2], it does generate a significant 6.0% increase in performance. Finally, we also report fine-tuning results on $\mathcal{F}_{\text{HANS}}$, the biased model designed for HANS, and observe that it performs well with a smaller loss on MNLI and a smaller gain on HANS compared to $\mathcal{F}_{\text{BoW}}$ and $\mathcal{F}_{\text{BiLSTM}}$.

Compared to other baselines, our approach achieves a comparable or better average accuracy of MNLI and HANS, despite its simplicity. In Fig. 3, we breakdown the results of our best performing model for the three different heuristics HANS was built upon. Our method does not suffer as much as other baselines in the entailment class, and still provides a significant improvement for non-entailment. (More analysis is presented in Appendix.)

4.3.2 QQP and PAWS

Here we report the results of our method applied to QQP and PAWS as out-of-distribution dataset. Results can be found in Table 5. We observe that our method improves out-of-distribution accuracy substantially. It is worth noting that the ground-truth labels in QQP contain noisy annotations (Iyer et al., 2017); a portion of performance loss on QQP could be attributed to that.

Our method outperforms Reg-conf$_{\text{hans}}$, while being simpler in terms of both the biased model and the training regime. We notice that Reg-conf$_{\text{hans}}$ also loses in-distribution performance[3].

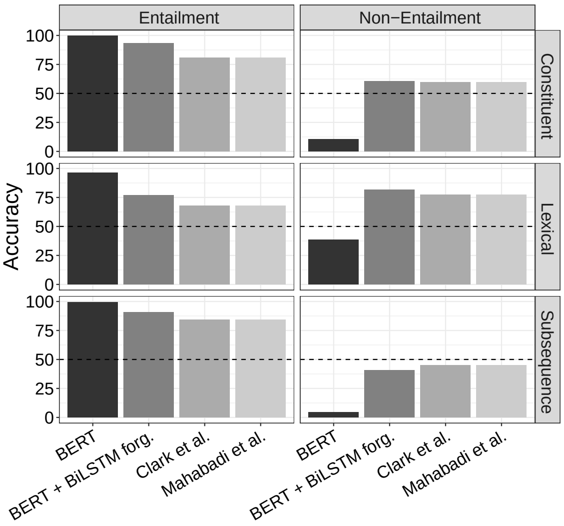

Figure 3: Performance of our BERT fine-tuned on the BiLSTM forgettables $\mathcal{F}_{\text{BiLSTM}}$, and baselines on the "entailment" and "non-entailment" categories for each heuristic HANS was designed to capture.

Model	FEVER	Sym-v1	Sym-v2
BERT	86.1$_{\pm 0.3}$	57.7$_{\pm 1.3}$	64.7$_{\pm 1.1}$
BERT+ $\mathcal{F}_{\text{BoW}}$	**87.1**$_{\pm 0.2}$	61.0$_{\pm 1.4}$	**67.0**$_{\pm 1.5}$
BERT+ $\mathcal{F}_{\text{BiLSTM}}$	86.5$_{\pm 0.4}$	**61.7**$_{\pm 1.2}$	66.6$_{\pm 1.0}$
Utama et al. (2020)			
BERT	85.8$_{\pm 0.1}$	57.9$_{\pm 1.1}$	64.4$_{\pm 0.6}$
Reweighting$_{\text{bigrams}}$	85.5$_{\pm 0.3}$	**61.7**$_{\pm 1.1}$	66.5$_{\pm 1.3}$
Reg-conf$_{\text{claim}}$	86.4$_{\pm 0.2}$	60.5$_{\pm 0.4}$	66.2$_{\pm 0.6}$

Table 6: Accuracy of different FEVER trained models on FEVER dev, and symmetric v1 and v2 datasets.

4.3.3 FEVER

In Table 6, we report the results of our method applied to the FEVER development and symmetric evaluation sets (see §2.3). Our approach again works well for both $\mathcal{F}_{\text{BoW}}$ and $\mathcal{F}_{\text{BiLSTM}}$, but here we also gain on the original dev set when compared to the initial BERT$_{\text{BASE}}$ results. The gains of our method are larger than those of the Reg-conf$_{\text{claim}}$ baseline, which uses a biased model tailored to FEVER-symmetric.

4.4 Analysis

Final loss to detect minority examples An alternative way to find examples from the minority is to simply rank training examples based on their final loss value. In Fig 4, we compare that with our method based on forgettables. The two are

---

[2] To eliminate the forgettables' size factor and focus on the type of model instead, we run an experiment where we sample from $\mathcal{F}_{\text{BoW}}$ the same numbers as $\mathcal{F}_{\text{BERT}}$. The result of our fine-tuning on that smaller $\mathcal{F}_{\text{BoW}}$ was still significantly better than $\mathcal{F}_{\text{BERT}}$.

[3] The authors report accuracy on each label individually and not the overall accuracy. We compute that based on their reported numbers.

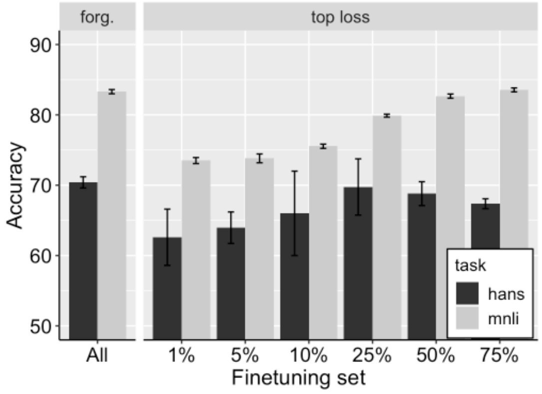

Figure 4: Accuracy on MNLI and HANS when the finetuning set is picked from examples in forgettables or in a range of percentages of examples with highest loss.

Train examples	MNLI	HANS
$\mathcal{F}_{\text{BERT}}$ (17,748)	$49.6_{\pm0.2}$	$37.9_{\pm1.3}$
Random (17,748)	$74.7_{\pm0.4}$	$50.8_{\pm0.2}$
$\mathcal{F}_{\text{BiLSTM}}$ (46,740)	$66.7_{\pm0.9}$	$54.0_{\pm0.6}$
Random (46,740)	$78.8_{\pm0.4}$	$51.3_{\pm0.6}$
$\mathcal{F}_{\text{BoW}}$ (63,390)	$68.2_{\pm0.8}$	$55.4_{\pm1.4}$
Random (63,390)	$79.9_{\pm0.4}$	$51.8_{\pm0.2}$
All	$84.5_{\pm0.1}$	$63.1_{\pm1.2}$

Table 7: Results of $\text{BERT}_{\text{BASE}}$ models fine-tuned on the set of forgettable examples only.

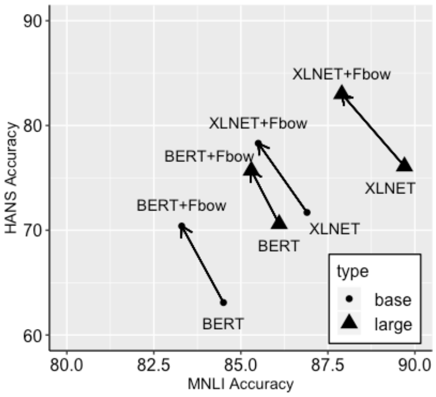

Figure 5: MNLI vs HANS accuracy for both base and large versions of BERT and XLNET.

Model	QQP	PAWS
$\text{BERT}_{\text{BASE}}$	90.9	34.5
$\text{BERT}_{\text{BASE}} + \mathcal{F}_{\text{BoW}}$	89.0	48.8
$\text{BERT}_{\text{LARGE}}$	**91.2**	36.0
$\text{BERT}_{\text{LARGE}} + \mathcal{F}_{\text{BoW}}$	88.3	54.4
$\text{XLNET}_{\text{BASE}}$	90.9	37.1
$\text{XLNET}_{\text{BASE}} + \mathcal{F}_{\text{BoW}}$	88.2	55.2
$\text{XLNET}_{\text{LARGE}}$	89.2	48.4
$\text{XLNET}_{\text{LARGE}} + \mathcal{F}_{\text{BoW}}$	87.8	**65.2**

Table 8: Average accuracy across random seeds on QQP and PAWS for BERT and XLNET base and large models, before and after fine-tuning on $\mathcal{F}_{\text{BoW}}$.

obviously related, as the examples that are never learned rank the highest w.r.t to the loss and are considered as forgettables. However, Fig 4 shows, for MNLI and HANS, that using forgettables produces better performance both in- and out-of-distribution. One additional issue with using the final loss to pick examples is the need to determine either a threshold value α on the loss (keep examples with a loss larger than α) or a number N of examples to retain. The optimal α or N might yield better performance but finding them implies using the out-of-distribution set.

Robustness of larger models We examine the performance of our method when applied to other PLMs and to larger networks by training BERT large and XLNET. Fig 5 shows the MNLI and HANS performance of those networks. Firstly, XLNet is noticeably more robust than BERT, compatible with its superior in-distribution performance (Yang et al., 2019). Secondly, we observe that the large versions generalize on HANS significantly better than their base counterparts (e.g., 76.1% vs 71.7% for XLNet, 70.6% vs 62.9% for BERT), confirming that larger models seem more robust. Lastly, $\text{XLNET}_{\text{LARGE}} + \mathcal{F}_{\text{BoW}}$ shows a +7% increase in performance, reaching 83.1% on HANS with a maximum score of 86.8% over three seeds. We also show Table 8 and Table 9) similar findings on QQP and FEVER. For instance, $\text{XLNET}_{\text{LARGE}} + \mathcal{F}_{\text{BoW}}$ achieves 65.2% on PAWS and 75.3% on FEVER-Sym-v1.

Training on forgettables only Toneva et al. (2019) showed that forgettable examples form the support of the training distribution. We follow their experimental setting and fine-tune BERT on the subset of forgettable examples only (i.e., without any fine-tuning on the whole dataset). Contrary to what was found in Toneva et al. (2019), we observe in Table 7 that the performance obtained by training only on forgettable examples is poor compared to random subsets of the same sizes; MNLI accuracy is only 37.9% for $\mathcal{F}_{\text{BERT}}$ compared to 74.7% for a random subset with the same size. The HANS accuracy is also poor. These results sug-

Model	**FEVER**	**Symm-v1**
$\text{BERT}_{\text{BASE}}$	86.1	57.7

$\text{BERT}_{\text{LARGE}}$	86.9	59.7
$\text{BERT}_{\text{LARGE}} + \mathcal{F}_{\text{BoW}}$	86.5	67.8
$\text{XLNET}_{\text{BASE}}$	86.4	63.9
$\text{XLNET}_{\text{BASE}} + \mathcal{F}_{\text{BoW}}$	87.5	67.8
$\text{XLNET}_{\text{LARGE}}$	88.2	68.8
$\text{XLNET}_{\text{LARGE}} + \mathcal{F}_{\text{BoW}}$	**88.7**	**75.3**

Table 9: Average accuracy over seeds on FEVER and Fever-symm-v1 for BERT and XLNET base and large models, before and after fine-tuning on $\mathcal{F}_{\text{BoW}}$

gest an intrinsic difficulty in $\mathcal{F}_{\text{BERT}}$ that makes it hard for $\text{BERT}_{\text{BASE}}$ to generalize from it. However, as we showed previously, when starting from an already trained model, forgettables increase the out-of-distribution performance.

Calibration of models We look into the confidence of entailment when $\text{BERT}_{\text{BASE}}$ and $\text{BERT}_{\text{BASE}} + \mathcal{F}_{\text{BoW}}$ trained on MNLI are applied to HANS. In Fig 6, we show that $\text{BERT}_{\text{BASE}}$ can discriminate HANS entailments from non-entailments but with a very large classification threshold. Fine-tuning on forgettables recalibrates the classification threshold on HANS and makes 0.5 as the optimum value.

Other diagnostic evaluations Fine-tuning on the forgettable examples of simple biased models improves robustness in the three challenging benchmarks HANS, FEVER-Symmetric and PAWS. We additionally evaluate the trained models listed in Table 4 on Stress tests (Naik et al., 2018), adversarial NLI (Nie et al., 2019) and MNLI-matched-hard (Gururangan et al., 2018). For these test sets, we do not observe improvements when evaluating the robust model using $\mathcal{F}_{\text{BoW}}$. We posit that specific biased models might be needed in some of these cases. As a validation, for MNLI-matched-hard, we design a BiLSTM model that only takes the hypothesis as input, and apply our method using the forgettables of that model to fine-tune $\text{BERT}_{\text{BASE}}$. We observe an increase in performance from 76.5% to 78.0% (averaged across five seeds). These results suggest that the forgettable examples of simple biased models like BoW or BiLSTM capture the more informative heuristics like word-overlap well. However, for less informative heuristics like hypothesis-only features, a heuristic-designed biased model is a better choice since its forgettables likely violate the specific heuristic.

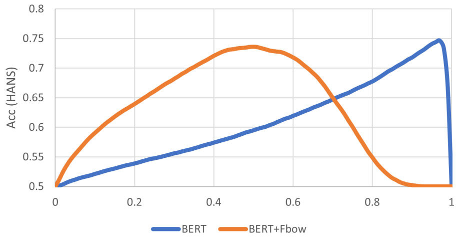

Figure 6: HANS accuracy vs classification threshold used to predict entailment/non-entailment. The base BERT model is overconfident in the entailment class while after fine-tuning on forgettables, we can improve model calibration.

5 Related Work

A growing body of literature recently focused on **out-of-distribution generalization**, showing that it is far from being attained, even in seemingly simple cases (Geirhos et al., 2019; Jia and Liang, 2017; Dasgupta et al., 2018). In particular, and in contrast with what Mitchell et al. (2018) recommend, NLP models do not seem to “embody the symmetries that allow the same meaning be expressed within multiple grammatical structures”. Supervised models seem to exhibit poor systematic generalization capabilities (Loula et al., 2018; Lake and Baroni, 2018; Baan et al., 2019; Hupkes et al., 2018) thus seemingly lacking *compositional* behavior (Montague, 1970). While this might seem at odds with the common belief that high-level semantic representations of the input data are formed (Bengio et al., 2009b), the reliance on highly predictive but brittle features is not confined to NLU tasks. It is also a perceived shortcoming of image classification models (Geirhos et al., 2019; Brendel and Bethge, 2019). To test systematically if machine learning models generalize beyond their training distribution, several challenging datasets have been introduced in NLP and other ML applications (Kalpathy-Cramer et al., 2015; Peng et al., 2019; Clark et al., 2019). Those test sets are made automatically from designed grammars (McCoy et al., 2019) and/or by human annotators (Zhang et al., 2019; Schuster et al., 2019).

Dataset re-sampling and weighting These techniques have been studied in order to solve class imbalance problem (Chawla et al., 2002) or covariate shift (Sugiyama et al., 2007), notably by importance weighted empirical risk minimization. In NLP, Clark et al. (2019); Mahabadi and Henderson (2019); He et al. (2019); Utama et al. (2020) give evidence of the effectiveness of re-weighting training examples to increase robustness. They generally assume *a priori* knowledge of the heuristics present in the dataset and up/down-weight examples concerning those heuristics. AFLITE (Sakaguchi et al., 2019) is an algorithmic method for bias removal in datasets without relying on prior knowledge about datasets. It filters out examples with a high average predictability score, relating them to points with biases or spurious correlations. Bras et al. (2020) adopt AFLITE to build more robust models. This method harms the in-distribution performance significantly. Comparatively, we aim to increase robustness while maintaining in-distribution performance, so we do not filter out easy examples in our approach. Our work also relates to distributionally robust optimization (Duchi and Namkoong, 2018; Hu et al., 2018) and the more recent group-DRO (Sagawa et al., 2020a), which does not assume access to target data and optimizes the worst-case performance under an unknown, bounded distribution shift. Recently, Swayamdipta et al. (2020) introduced a two-dimensional criterion to identify hard and easy examples. They consider both the confidence of an example (the average of its loss during training epochs) and the variability (those for which the loss has high variance) and show that ambiguous examples (high-variance and high-confidence) can enhance OOD accuracy. Easy examples (low-variance and high-confidence) can instead help model optimization. Although example forgetting is a coarser measure of variance of the loss, their results align with our findings: up-weighting hard/ambiguous examples enhance OOD generalization, but only training on those can harm optimization.

Curriculum Learning Dataset sampling is related to curriculum learning, where training proceeds along with a curriculum of samples with increasing difficulty (Bengio et al., 2009a). Kumar et al. (2010); Zhao and Zhang; Fan et al. (2017); Katharopoulos and Fleuret (2018); Kim and Choi (2018); Jiang et al. (2018) have shown the concept can be quite successful in a variety of areas. Our robustifying method is related to this concept. However, our models are first trained using i.i.d samples from the whole dataset and then fine-tuned on more difficult cases, i.e., the minorities.

Spurious correlations in NLU datasets like MNLI or FEVER are the subjects of many works. They include (i) the presence of specific words in the hypothesis or claim, for example, negation words like “not” are correlated with the contradiction label in entailment tasks (Naik et al., 2018; Gururangan et al., 2018), or bigrams like “did not” with the refute label, in fact, verification (Schuster et al., 2019); (ii) syntactic heuristics, like word-overlap between premise and hypothesis; and (iii) sentence length (Gururangan et al., 2018), and its correlation with labels. HANS (McCoy et al., 2019) and PAWS (Zhang et al., 2019) (which we evaluate on) generate plausible high word-overlap examples for both positive and negative classes. Glockner et al. (2018) build a new test example by simple lexical inference rules and show the brittleness of models on this out-of-distribution dataset. They also show that having supporting examples in training data is key to predict a test example correctly.

Feldman and Zhang (2020) show that when datasets are long-tailed, rare and atypical instances make up a significant fraction of the data distribution and **memorizing** them leads to better in-domain generalization. They find those rare and atypical examples using influence estimation. We instead study forgettable examples and their impact on out-of-distribution generalization. An interesting experiment would be to mine minority examples by influence estimation and compare with forgettable examples.

6 Conclusion

We introduced a novel approach, based on example forgetting, to extract minority examples and build more robust models systematically. Via example forgetting, we built a set of minority examples on which a pre-trained model is fine-tuned. We evaluated our method on large-scale models such as BERT and XLNet and showed a consistent improvement in robustness on three challenging test sets. We also showed that the larger versions obtain higher out-of-distribution performance than the base ones but still benefit from our method.

A Details of biased models (BoW and BiLSTM)

Both models are Siamese networks, with similar input representations and classification layers. For the input layer, we lower case and tokenize the inputs into words and initialize their representations with Glove, a 300-dimensional pretrained embedding (Pennington et al., 2014). For the classification task, from the premise and hypothesis vectors p and h, we build the concatenated vector $s = [p, h, |p - h|, p \odot h]$ and pass it to a 2-layer feedforward network. To compute p or h, the BoW model max-pools the bag of word embeddings, while the BiLSTM model max-pools the top-layer hidden states of a 2-layer bidirectional LSTM. The hidden size of the LSTMs is set to 200. Overall, BoW and BiLSTM contain 560K and 2M parameters, respectively.

B Hyperparameters and training time

We use a learning rate of 5e-5 for MNLI and QQP when training the PLMs on the full training and the learning rate of 1e-5 when fine-tuning on forgettables. For FEVER, we use 2e-5 and 5e-6 for the full training and the fine-tuning on forgettables, respectively.

With a 4x Tesla P100 GPU machine and batch-size 256 per GPU, one epoch of training on the full train set takes around 4-6 minutes for BOW and BiLSTM models in all of the three training tasks.

For $\text{BERT}_{\text{BASE}}$, with batch-size 32 per GPU, one epoch of training on the full train set takes around 30 / 20 / 30 minutes (per task). The maximum input length after tokenization is set to 128 in all the experiments.

B.1 Forgettables and word-overlap in MNLI

Model	**Entailment**			**Non-Entailment**		
	All	*High*	*Low*	*All*	*High*	*Low*
BERT	**84.0**	**89.9**	**76.0**	84.9	85.5	84.6
BERT + $\mathcal{F}_{\text{BoW}}$	80.2	85.1	73.4	**85.6**	86.9	**85.0**
BERT + $\mathcal{F}_{\text{BiLSTM}}$	79.9	85.2	72.4	**85.6**	**87.4**	84.8

Table 10: Fine-grained accuracy results of $\text{BERT}_{\text{BASE}}$ on the MNLI dev set split by word-overlap between hypothesis and premise.

In Table 10, we show the performance of our method on the MNLI dev set as a function of word-overlap, the main heuristic HANS was designed against. We split the evaluation set into High (> mean) and Low (< mean) word-overlap examples, where word-overlap is measured using the Jaccard Index between hypothesis and premise. We see in particular that entailment pairs with high word-overlap suffer from the fine-tuning on forgettables, while non-entailment improves (we observe a similar trend for QQP; see App. C). This supports the observations in 3.2 that the initial model relied on the spurious correlation of word-overlap and entailment to classify pairs and that by fine-tuning on forgettable examples, the performance on minorities increased.

C Forgettables and word-overlap in QQP

In Table 11, we show the performance of our method on the QQ evaluation set as a function of word-overlap, the main heuristic PAWS was designed against. We see in particular that paraphrase pairs with high word-overlap suffered from the fine-tuning, while non-paraphrase improved. This supports the intuition that the initial model relied on word-overlap to classify pairs as paraphrase, while forgettables help mitigate that phenomenon to some extent.

	Paraphrase			**Non-Paraphrase**		
Model	*All*	*High*	*Low*	*All*	*High*	*Low*
BERT	**90.0**	**90.8**	**88.9**	92.2	85.6	95.0
BERT + $\mathcal{F}_{\text{BiLSTM}}$	85.2	84.9	85.8	**93.0**	**87.3**	**95.4**
BERT + $\mathcal{F}_{\text{BoW}}$	87.3	87.2	87.4	92.6	86.4	95.2

Table 11: Fine-grained accuracy results of BERT on QQP development set before and after fine-tuning on forgettables. We split the evaluation set into High (> mean) and Low (< mean) word-overlap examples, where word-overlap is measured under the Jaccard Index between two sentences. Similar observations hold true in the case of MNLI.

On Robustness of Neural Semantic Parsers

Abstract

Semantic parsing maps natural language (NL) utterances into logical forms (LFs), which underpins many advanced NLP problems. Semantic parsers gain performance boosts with deep neural networks, but inherit vulnerabilities against adversarial examples. In this paper, we provide the empirical study on the robustness of semantic parsers in the presence of adversarial attacks. Formally, adversaries of semantic parsing are considered to be the perturbed utterance-LF pairs, whose utterances have exactly the same meanings as the original ones. A scalable methodology is proposed to construct robustness test sets based on existing benchmark corpora. Our results answered five research questions in measuring the sate-of-the-art parsers' performance on robustness test sets, and evaluating the effect of data augmentation.

1 Introduction

Semantic parsing aims to map natural language (NL) utterances into logical forms (LFs), which can be executed on a knowledge base (KB) to yield denotations (Kamath and Das, 2018). At the core of the state-of-the-art (SOTA) semantic parsers are deep learning models, which are widely known to be vulnerable to *adversarial samples* (Zhang et al., 2020). This kind of examples is created by adding tiny perturbations to inputs but can severely deteriorate model performance. To the best of our knowledge, despite the popularity of semantic parsing (Kamath and Das, 2018), there is still no published work on studying the robustness of neural semantic parsers against adversarial examples. Therefore, we conduct the *first* empirical study to evaluate the effect of adversarial examples on SOTA neural semantic parsers.

Unlike other disciplines, it is unclear what adversaries are for semantic parsers. For computer vision systems, adversaries are often generated by modifying inputs with *imperceptible* perturbations. In contrast, a flip of single word or a character in an utterance can significantly change its meaning so that the changes are perceptible by humans. To address this issue, (Michel et al., 2019) argue that adversaries for sequence-to-sequence models should maximally retain meanings after perturbing inputs. However, any meaning-changing utterances are supposed to have different meaning representations. A robust semantic parser should be invariant to meaning-preserving modifications. In light of this, given a semantic parser, we define its adversaries as the perturbed utterances satisfying two conditions: i) they have *exactly* the same meanings as the original ones according to human judgements; and ii) the parser consistently produces incorrect LFs on them.

Although new evaluation frameworks are proposed for NLP tasks (Xu et al., 2020; Michel et al., 2019), there is no framework designed for assessing robustness of semantic parsers against meaning-preserving adversaries. The current evaluation metrics focus only on standard accuracy, which measures to what degree predictions match gold standards. As pointed out by (Tsipras et al., 2018), it is challenging to achieve both high standard accuracy and high robust accuracy, which measures the accuracy on adversarially perturbed examples. In order to facilitate devising novel methods for robust semantic parsers, it is desirable to develop a semantic parsing evaluation framework considering both measures.

In this work, we propose an evaluation framework for robust semantic parsing. The framework consists of an evaluation corpus and a set of customized metrics. We construct the evaluation corpus by extending three existing semantic parsing

benchmark corpora. In order to generate meaning-preserving examples, we apply automatic methods to modify the utterances in those benchmark corpora by paraphrasing and injecting grammatical errors. Among the perturbed examples generated from the test sets, we build meaning-preserving test sets by filtering out the meaning-changing ones using crowdsourcing. The robustness of the semantic parsers is measured by a set of custom metrics, with and without adversarial training methods.

We conduct the *first* empirical study on the robustness of semantic parsing by evaluating three SOTA neural semantic parsers using the proposed framework. The key findings from our experiments are three-folds:

- None of those SOTA semantic parsers can consistently outperform the others in terms of robustness against meaning-preserving adversarial examples;
- Those neural semantic parsers are more robust to word-level perturbations than sentence-level ones;
- Adversarial training through data augmentation indeed significantly improve the robustness accuracy but can only slightly influence standard accuracy.

The generated corpus and source code are available at https://github.com/shuo956/On-Robustness-of-nerual-smentic-parsing.git

2 Related Work

Semantic Parsing The SOTA neural semantic parsers formulate this task as a machine translation problem. They extend SEQ2SEQ with attention (Luong et al., 2015) to map NL utterances into LFs in target languages (e.g., lambda calculus, SQL, Python, etc.). One type of such parsers directly generates sequences of predicates as LFs (Dong and Lapata, 2016, 2018; Huang et al., 2018). The other type of parsers utilizes grammar rules to constrain the search space of LFs during decoding (Yin and Neubig, 2018; Chen et al., 2018; Guo et al., 2019b; Wang et al., 2020). However, neither of the two types of parsers are evaluated against adversarial examples.

Adversarial Examples The adversarial examples are firstly defined and investigated in computer vision. Adversarial examples in that field are generated by adding imperceptible noise to input images, which lead to false predictions of machine learning models (Madry et al., 2018; Goodfellow et al., 2014). However, it is non-trivial to add such noise to text in natural language processing (NLP) tasks due to the discrete nature of languages. Minor changes in characters or words may be perceptible to humans and may lead to change of meanings. To date, it is still difficult to reach an agreement on the definition of adversarial examples across tasks.

Jia and Liang (2017); Belinkov and Bisk (2017); Ebrahimi et al. (2018); Miyato et al. (2016) add distracting sentences and sequences of random words into text or flip randomly characters or words in input text, which can confuse the models but do not affect the labels judged by humans. In those works, such perturbations are not required to keep the semantics of original text. (Michel et al., 2019) argue that perturbations for SEQ2SEQ tasks should minimize the change of semantic in input text but dramatically alter the meaning of outputs. (Cheng et al., 2020) uses a sentiment classifier to verify whether sentiments of the original utterances is preserved after perturbation while we use crowdsourcing to ensure the meaning remains. Adversarial examples in semantic parsing cannot simply borrow from prior work because a parser does not make errors if it generates a different and correct LF when there is any subtle change in input text leading to change of semantics. In contrast, adversarial examples are supposed to cause parsing errors. Thus, adversarial examples w.r.t. meaning-changing perturbations are not well defined.

There are two types of methods in generating adversarial examples. The white-box methods (Papernot et al., 2016; Ebrahimi et al., 2017; Athalye and Carlini, 2018) assume that the attacker have direct access to model details including their parameters, but the black-box methods assume that attackers have no access to model details except feeding input data and getting outputs from models (Gao et al., 2018; Guo et al., 2019a; Chan et al., 2018; Blohm et al., 2018).

Adversarial Training Adversarial training aims at improving the robustness of machine learning models against adversarial examples (Goodfellow et al., 2014; Miyato et al., 2016; Li et al., 2018). One line of research is to augment the training data with the adversarial examples. However, Ebrahimi et al. (2018) points out that adversarial training may cause the model oversensitive to the adversarial examples. The other approach is to increase model capacity that may improve model's robustness (Madry et al., 2018). More techniques regarding adversarial defense can be found in the recent survey (Wang et al., 2019). In semantic parsing, data augmentation methods (Jia and Liang, 2016; Guo et al., 2018) are proposed only to improve performance of models on examples without perturbation but not to improve their robustness.

3 Evaluation Framework for Robust Semantic Parsing

A robust semantic parser aims to transduce all utterances with or without meaning-preserving perturbations into correct LFs. Formally, let $\mathbf{x} = x_1, \dots, x_{|\mathbf{x}|}$ denote a natural language utterance, and $\mathbf{y} = y_1, \dots, y_{|\mathbf{y}|}$ be its LF, a semantic parser estimates the conditional probability (denoted by $p(\mathbf{y}|\mathbf{x})$) of an LF $\mathbf{y}$ given an input utterance $\mathbf{x}$. A robust parser's predictions are invariant to all $\mathbf{x}'$ that are generated from $\mathbf{x}$ by meaning-preserving perturbations.

For any $(\mathbf{x}, \mathbf{y})$, let $S_{\text{perturb}}(\mathbf{x}, \mathbf{y})$ denote the set of *all* meaning-preserving perturbations of $\mathbf{x}$ that is parsed to $\mathbf{y}$:

$$S_{\text{perturb}}(\mathbf{x}, \mathbf{y}) = \{(\hat{\mathbf{x}}, \mathbf{y}) : \hat{\mathbf{x}} \in B(\mathbf{x}) \land o(\hat{\mathbf{x}}) = \mathbf{y}\} \tag{1}$$

where $B(\mathbf{x})$ denotes the set of *all* allowed perturbations of $\mathbf{x}$, and $o(\hat{\mathbf{x}})$ is an ideal parser that maps an utterance to its LF.

A set of meaning-preserving perburbed examples $S_{\text{perturb}}(D)$ w.r.t. a corpus D is the union of all $S_{\text{perturb}}(\mathbf{x}, \mathbf{y})$ created from D.

An adversarial example w.r.t. a semantic parser is an utterance-LF pair, which is in $S_{\text{perturb}}(\mathbf{x}, \mathbf{y})$ and is parsed into an incorrect LF by that parser. A set of adversarial examples w.r.t. a $S_{\text{perturb}}(\mathbf{x}, \mathbf{y})$ and a parser $f(\mathbf{x})$ is obtained by:

$$S_{\text{adv}}(\mathbf{x}, \mathbf{y}) = \{(\hat{\mathbf{x}}, \mathbf{y}) : f(\hat{\mathbf{x}}) \neq \mathbf{y}, \forall (\hat{\mathbf{x}}, \mathbf{y}) \in S_{\text{perturb}}(\mathbf{x}, \mathbf{y})\} \tag{2}$$

Subsequently, an adversary set w.r.t. a semantic parsing corpus D is created by taking the union of all adversary sets created from each example in D.

In the following, we present an evaluation framework for robust semantic parsing, which consists of an evaluation corpus, a set of evaluation metrics, and the corresponding toolkit for evaluating any new parsers.

3.1 Construction of the Evaluation Corpus

We construct the evaluation corpus in a scalable manner by combining the existing semantic parsing benchmark corpora. Each of such corpora will be referred to as a *domain* in the whole corpus. There are a train set, a validation set, and a standard test set in each domain. We perturb the examples in each test set to build a *meaning-preserving test set* for each domain. More specifically, each example in a meaning-preserving test set is a perturbed utterance paired with its LF before perturbation. In the following, we detail each perturbation method and how we apply the crowdsourcing to remove meaning-changing ones.

3.1.1 Meaning-Preserving Perturbations

Perturbations	**Meaning-preserving Examples**
Insertion	in what state is the largest in population
Deletion	what state is ~~the~~ largest in population
Substitution (f)	what state is the largest among population
Substitution (nf)	what state is the most in population
Back Translation	state with the largest population
Reordering	the largest population is in what state

Table 1: The meaning-preserving examples of the original utterance "what state is the largest in population".

Given an utterance, we perturb it by performing four different word-level operations and two sentence-level operations, *respectively*. Table 1 lists the examples of generated meaning-preserving examples categorized according to the respective generation methods. More details are given below.

Insertion Given an utterance $\mathbf{x}$, we randomly select a word position $t' \in \{1, \dots, |\mathbf{x}|\}$. A meaning-preserving example $\mathbf{x}'$ is created by inserting a function word at position t'.

Deletion We randomly remove a function word x_t from $\mathbf{x}$.

Substitution (f) Every function word in $\mathbf{x}$ is replaced with a random but different function word to generate a perturbed example.

Substitution (nf) For every non-function word in $\mathbf{x}$, we apply the pretrained language model ELECTRA (Clark et al., 2020) to select top-k candidate words and exclude the original word. We generate a perturbed utterance for each valid candidate word. Since this method may generate utterances far from their original meaning, we subsequently filter those utterances by measuring their semantic similarity with the original ones.

Specifically, we apply the SOTA sentence similarity model Sentence-Bert (Reimers and Gurevych, 2019) to compute similarity scores for each generated utterance resulting in only the n highest scored utterances.

Back Translation Inspired by (Lichtarge et al., 2019), we revise utterances using back translation. We apply the Google translation API to translate utterances into a bridge language and then translate them back to English. Russian, French, and Japanese are used as the bridge languages to diversify and maximize the coverage of meaning-preserving perturbations. We select the best translation among all three translations for each original utterance according to Sentence-Bert's scores.

Reordering Similar to back translation, we reorder utterances by the SOTA reordering model SOW-REAP (Goyal and Durrett, 2020). To increase the coverage, we follow the same strategy as *Substitution (nf)* to generate an extended set of reordered utterances with multiple instances per input utterance. We use Sentence-Bert to encode sentences and select the top-k best ones according to their cosine similarity scores with the original input. The reordered sentences share the same vocabulary as the original one except for the order of words.

3.1.2 Filter Examples by Crowdsourcing

As perturbation operations related to function words rarely alter meanings, we apply three crowdsourcing operations to the utterances perturbed, including *Substitution (nf)*, *Reordering*, and *Back Translation*. For each perturbed utterance paired with the original utterance, three turkers at Amazon Mechanical Turk discern any semantic changes by choosing an option out of three — *the same*, *different*, or *not sure*. By default, any sentences uncomprehended by a human are regarded as *not sure*. Finally, we keep only the ones that have the same meaning agreed by at least two turkers. After crowdsourcing, we keep 83%, 82% and 61% of the generated utterances for *Substitution (nf)*, *Back Translation* and *Reordering*, respectively.

3.2 Evaluation Metrics

Our framework assesses the performance of a semantic parser w.r.t. standard accuracy and robustness metrics. Those robustness metrics indicate how well a semantic parser resists to meaning-preserving perturbations and adversarial attacks. As adversarial training is widely used for adversarial defense and mostly applicable to any neural semantic parsers, this framework supports comparing a wide range of adversarial training methods w.r.t. standard accuracy and robustness metrics.

A training set, a validation set, a standard test set, and a meaning-preserving test set are established in each domain. The first three sets are obtained from the original benchmark corpus, and the meaning-preserving test set is created using the methods described in Sec. 3.1. We will examine the meaning-preserving test set (denoted by $S_{\text{perturb}}(D)$) and its two subsets. We refer to the first subset as the robustness evaluation set (denoted by $R_{\text{eval}}(D)$), where the counterparts before perturbation are parsed correctly. We refer to the second subset as the black-box test set (denoted by $B_{\text{attack}}(D)$), where the loss of a parser to the examples is higher than their counterparts before perturbation. For each target parser, we consider four metrics, including *standard accuracy*, *perturbation accuracy*, *robust accuracy*, and *success rate of black-box attack*.

Standard accuracy The most widely used metric on semantic parsing (Dong and Lapata, 2018; Yin and Neubig, 2018) to measure the percentage of the predicted LFs that exactly match their gold LFs in a standard test set.

Perturbation accuracy Perturbation accuracy is formally defined as $n/|S_{\text{perturb}}(D)|$, where n denotes the number of correctly parsed examples to their gold LFs in a meaning-preserving test set $S_{\text{perturb}}(D)$.

Robust accuracy Robust accuracy is calculated as $n/|R_{\text{eval}}(D)|$, where n denotes the number of examples that are parsed correctly by a parser in a robustness evaluation set $R_{\text{eval}}(D)$. Compared to perturbation accuracy, robust accuracy measures the number of examples that a parser can parse correctly before perturbation but fails to get them right after perturbation.

Success rate of black-box attack A black-box attack example is regarded as the one that increases the loss of a model after perturbation (Zhang et al., 2020). Here, the success rate of black-box attack is calculated as $n/|B_{\text{attack}}(D)|$, where n denotes the number of examples that are parsed *incorrectly* by a parser in the black-box test set $B_{\text{attack}}(D)$. White-box attacks require model specific implementation to generate adversarial examples, thus we leave the corresponding evaluation to the developers of semantic parsers.

The four metrics are computed to evaluate the efficacy of an adversarial training method. We inspect whether the metrics increase or decrease post-training and to what degree. An effective adversarial training method is expected to find a good trade-off between standard accuracy and robust accuracy.

Last but not least, all evaluation metrics are implemented with easy-to-use APIs in our toolkit. Our toolkit supports easy evaluation of a semantic parser and provides source code to facilitate integrating additional semantic parsing corpora.

4 Experiments

In this section, we present the first empirical study on robust semantic parsing.

4.1 Experimental Setup

Parsers We consider three SOTA neural semantic parsers — SEQ2SEQ with attention (Luong et al., 2015), COARSE2FINE (Dong and Lapata, 2018), and TRANX (Yin and Neubig, 2018). COARSE2FINE is the best performing semantic parser on the standard splits of GEOQUERY and ATIS. TRANX reports standard accuracy on par with COARSE2FINE and employs grammar rules to ensure validity of outputs.

Datasets Our evaluation corpus is constructed by extending three benchmark corpora — GEOQUERY (Zelle and Mooney, 1996), ATIS (Dahl et al., 1994), and JOBS. GEOQUERY contains 600 and 280 utterance-LF pairs to express the geography information in the training and test set, respectively. ATIS consists of 4434, 491, and 448 examples about flight booking in the training, validation, and test sets, respectively. And JOBS includes 500 and 140 pairs about job listing in the training and test set, respectively.

Adversarial Training Methods We apply three adversarial training methods to the parsers. We evaluate whether the three adversarial training methods could improve semantic parsers' robustness against the meaning-preserving examples generated by the word-level and sentence-level operations. The corresponding three adversarial training methods are as follows:

> **Fast Gradient Method (Miyato et al., 2016)** Fast Gradient Method (FGM) adds small perturbations to the word embeddings and train the semantic parsers with the perturbed embeddings. The perturbations are scaled gradients w.r.t. the input word embeddings.
>
> **Projected Gradient Descent (Madry et al., 2017)** Projected Gradient Descent (PGD) adds small perturbations to the word embeddings as well. Instead of calculating a single step of gradients, PGD accumulates the scaled gradients for multiple iterations to generate the perturbations.
>
> **Meaning-preserving Data Augmentation** Meaning-preserving Data Augmentation (MDA) augments the original training data with the meaning-preserving examples generated by the word-level and sentence-level operations. We randomly select 20% of the original instances for each dataset and generate their corresponding meaning-preserving instances. Since there are six different operations, each original training set is augmented with six different meaning-preserving sets independently.

Training Details For both supervised training and adversarial training, we set batch size to 20 for all parsers with 100 epochs. We follow the best settings of three parsers reported in (Dong and Lapata, 2018; Yin and Neubig, 2018) to set the remaining hyperparameters. The best performing implementation of SEQ2SEQ is included in Yin and Neubig (2018).

4.2 Results and Analysis

We discuss experimental results by addressing the following research questions:

RQ1: How do the SOTA parsers perform on meaning-preserving test sets? All three SOTA semantic parsers are trained on each training set before they are tested on the corresponding standard test sets and meaning-preserving test sets. Besides the overall results on whole test sets, Table 2 reports accuracy on each example subset perturbed by the respective perturbation operation. The results on those subsets are further compared

Table 3: Robust accuracy for three SOTA parsers in each domain.

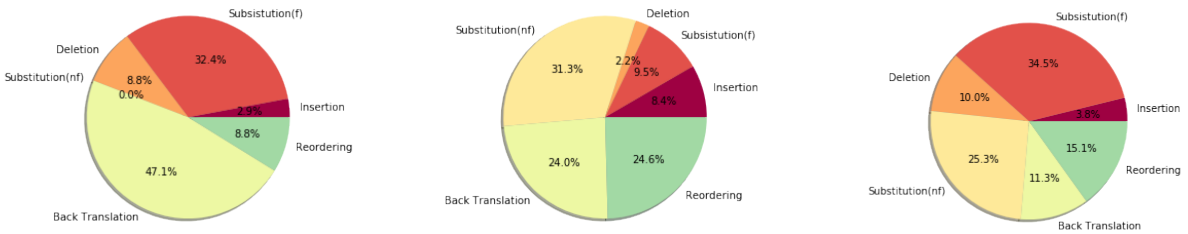
with the standard accuracy on the corresponding examples before perturbation.

As shown in Table 2, SOTA semantic parsers suffer from significant performance drop in almost all meaning-preserving test sets compared to the results on standard test sets. The performance ranking among the three SOTA semantic parsers varies across different datasets. Coarse2Fine achieves the best performance on GeoQuery and Atis, while Seq2Seq beats Coarse2Fine and TranX on Jobs. Although Coarse2Fine achieves better accuracy than TranX on the standard test set of Jobs, it falls short of TranX on the meaning-preserving test set of Jobs. A parser achieving higher standard accuracy does not necessarily obtain better perturbation accuracy against meaning-preserving perturbations than its competitors.

Our evaluation framework supports also in-depth analysis on the impact of different perturbation method on semantic parsers. All parsers are more vulnerable to sentence-level perturbations than word-level ones. Although reordering changes only word order in utterances, it leads to the lowest perturbation accuracy of all parsers on GeoQuery and Atis. Among word-level perturbation operations, substitution of non-function words is more challenging than deletion and insertion of function words on GeoQuery and Atis. On Jobs and Atis, even deletion or substitution of function words can impose significant challenges for the parsers. When we further investigate the deleted or replaced function words, such as in Table 1, semantic parsers are not expected to rely on such information. As all perburbations in our meaning-preserving test sets do not change meanings of original utterances, it imposes new research challenges on how to make semantic parsers resist meaning-preserving perturbations as well as how to avoid overfitting on semantically insignificant words.

RQ2: What kind of perturbed examples particularly degrade parser performance? Although perturbation accuracy allows comparing parsers on the same test sets, it includes the examples that a parser fails to parse correctly both before and after the meaning-preserving perturbation. Robust accuracy focuses on the examples a parser parses successfully before perturbation but fails after that. We investigate all parsers trained without adversarial training in terms of this measure. As shown in Table 3, TranX is superior to the other two parsers on Jobs, and Coarse2Fine is the clear winner on GeoQuery. This ranking of parsers is consistent with perturbation accuracy in the two domains. However, the differences among three parsers on Atis are marginal, while Coarse2Fine achieves significantly superior perturbation accuracy in the same domain. Atis is the domain with the most diverse paraphrases in natural language, Coarse2Fine cannot significantly outperform the other two parsers against meaning-preserving perturbations.

We further investigate adversary examples, which are defined in Eq. 2, for each parser in the meaning-preserving test sets. The shared adversarial examples among the parsers vary significantly across domains. More than 50% of the ad-



(a) JOBS (b) GEOQUERY (c) ATIS

Figure 1: Contributions of perturbation operations on the shared adversaries.

versarial examples are shared among the parsers on ATIS, but only less than 25% of adversaries are shared on JOBS. Fig. 1 illustrates which perturbation operation contributes to the intersection of the adversary set from different parsers. Back translation contributes almost half of the shared perturbed examples on JOBS, while the proportion of word-level perturbation operations reaches nearly 70% on ATIS. Although reordering and back translation impose the most difficult challenges for parsers, they cannot generate a significant number of valid adversarial examples. In contrast, it is relatively easy to resist a word substitution attack, but this operation can be easily applied to generate a large number of adversaries.

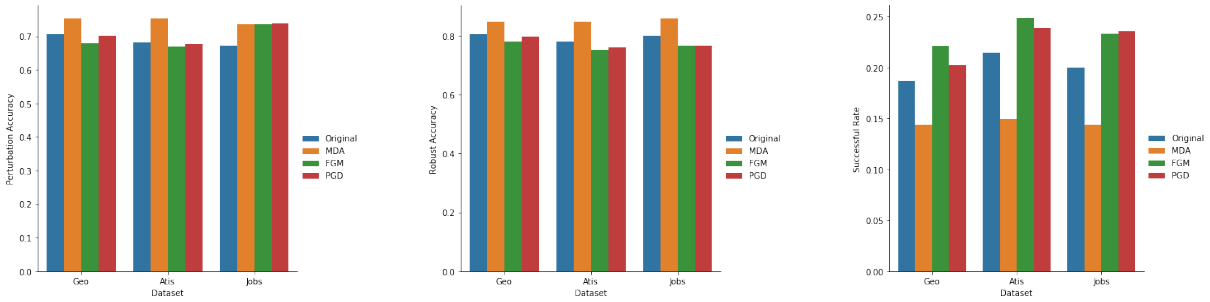
Table 4: Adversarial examples shared by all parsers.

We hand picked representative adversarial examples shared by all parsers and list them in Table 4. The errors made by substitution (f) and insertion often show a sign of overfitting due to the fact that the parsers learn dependencies between non-essential features and predicates. Substitution (nf) sometimes causes predicates to be missing after replacing a word with its synonym. The errors caused by deletion, back translation, and reordering are more diverse, including adding wrong predicates or missing predicates.

RQ3: How effective are those widely used adversarial training methods for semantic parsers? We applied FGM, PGD, and MDA to train the three parsers on the respective training sets. In the case of MDA, we consider all automatic perturbation operations to generate training examples, and each operation adds the same amount of training examples to the original train sets. Fig. 2 illustrates the results of COARSE2FINE w.r.t. different evaluation metrics. MDA always improves the three evaluation metrics, despite that the generated training examples are not checked by humans, resulting in a significant number of meaning-changing examples. FGM and PGD hardly work except on JOBS in terms of perturbation accuracy. Since both methods are white-box methods, the results indicate the gradient-based adversaries cannot effectively capture the meaning-preserving perturbations.

The biggest improvement made by MDA is the success rate of a black-box attack. The black-box attack examples are selected from the meaning-preserving examples that increase a parser's loss after perturbation. When we inspect the examples in the meaning-preserving test sets generated by different perturbation operation, the biggest improvement is from the ones perturbed by sentence-level operations and word substitution. All three parsers benefit from MDA significantly. The more vulnerable to black-box attack a parser is, the more improvement it can achieve after applying MDA.

RQ4: How does each adversarial training method influence standard accuracy? Tsipras et al. (2018) point out that there is a trade-off be-



(a) Perturbation accuracy.

(b) Robust accuracy.

(c) Success rate of black-box attack.

Table 5: Standard accuracy of adversarial training, which is trained with adversarial training methods and evaluated on the standard test sets. MDA(all) stands for MDA with all six perturbation operations.

tween standard accuracy and robust accuracy in most occasions. This finding is attributed to the presence of *non-robust* features, which are highly predictive but incomprehensible for humans (Ilyas et al., 2019). To verify the theory, after applying each adversarial training method to each parser, we compare the standard accuracy before and after adversarial training.

As shown in Table 5, none of the three adversarial training methods consistently improve standard accuracy across different domains and parsers. TRANX does not have a significant performance drop regardless which adversarial training method is applied. It may be due to the fact that TRANX uses grammar to filter out invalid outputs.

MDA cannot consistently improve parsers but also does not hurt parsers' performance in terms of standard accuracy. We conducted t-tests on the standard test sets to assess if MDA with different perturbation operations significantly improves accuracy. The results are negative so that the training examples generated by MDA at least do not hurt parsers' performance while increasing their robustness.

RQ5: How does our meaning-preserving data augmentation method compare with the data augmentation method proposed by (Jia and Liang, 2016)? (Jia and Liang, 2016) is one of the SOTA data augmentation methods for semantic parsing. In their work, they show that the augmented examples improve accuracy of predicting denotations. Although there are three methods proposed in (Jia and Liang, 2016), only the method of *concatenating* two random examples as a new example can be applied in our case. We evaluated this augmentation method with all three parsers. No significant improvement of standard accuracy and robust accuracy is found in all three domains. We conjecture that this is due to the fact that in (Jia and Liang, 2016) they report only improvement of accuracy of denotation matching, not the matching of LFs. In contrast, MDA can effectively reduce the harm of meaning-preserving perturbations.

4.3 Conclusion

We conduct the empirical study on robustness of neural semantic parsers. In order to evaluate robustness accuracy, we define first what are adversarial examples for semantic parsing, followed by constructing test sets to measure robustness using a scalable method. The outcome of this work is supposed to facilitate semantic parsing research by providing a benchmark for evaluating both standard accuracy and robustness metrics.

Abstract

Transformer-based "behemoths" have grown in popularity, as well as structurally, shattering multiple NLP benchmarks along the way. However, their real-world usability remains a question. In this work, we empirically assess the feasibility of applying transformer-based models in real-world ad-hoc retrieval applications by comparison to a "greener and more sustainable" alternative, comprising only 620 trainable parameters. We present an analysis of their efficacy and efficiency and show that considering limited computational resources, the lighter model running on the CPU achieves a 3 to 20 times speedup in training and 7 to 47 times in inference while maintaining a comparable retrieval performance. Code to reproduce the efficiency experiments is available on `https://github.com/bioinformatics-ua/EACL2021-reproducibility/`.

1 Introduction

The Natural Language Processing (NLP) field has been revolutionised by the simple, yet extremely successful idea of transfer learning allied to the transformer neural architecture capability of exploring long sequences, while being computationally more efficient than the recurrent counterparts. More precisely, Dai and Le (2015) and later Howard and Ruder (2018) introduced the transfer learning approach to the NLP field by pre-training a language model and then fine-tuning it to multiple NLP tasks. However, it was Radford (2018) who applied the same technique to a large transformer encoder, shattering the SOTA in 9 of 12 NLP tasks.

Since then, the NLP field became dominated by works that use, explore or improve, in some way, the transformer-based architecture. Although their performance is undeniable, these are large models that comprise millions of parameters and require large computational resources to use and maintain, making them inoperable for the majority of smaller institutions. Furthermore, it also gives the impression that the NLP field was reduced to throwing a lot of computation power (money) to continually achieve SOTA results in multiple benchmarks, leaving behind the careful process of designing a neural solution that follows the human intuition to solve some specific task. Moreover, given their running costs and the consequent impact on the environment, their real-world virtues remain questionable, i.e., "is it really feasible to use these models in real-world applications, such as search engines or question answering systems to aid a broader range of people in their day-to-day tasks?". As an example, biomedical experts need to routinely search an unprecedented amount of scientific literature to keep updated with their research, which could be facilitated by an intelligent system.

In contradiction with this trend, this work examines a lightweight interaction-based model, with only 620 trainable parameters, carefully designed by considering years of research in ad-hoc retrieval systems and interaction-based architectures. This system was evaluated in two ad-hoc retrieval competitions where it was able to compete with the state-of-the-art transformer-based models. In this paper, we demonstrate a "greener and more sustainable" alternative to the transformer-based architecture, by thoroughly testing such a system against the most popular transformer behemoths in a series of performance experiments.

Following this section, we frame our work in the current literature, we then present the lightweight model, and finally detail and discuss the evaluation performed.

2 Related Work

The Information Retrieval (IR) field is nowadays considered as being divided into traditional IR (Baeza-Yates and Ribeiro-Neto, 2011) and neural IR (Mitra and Craswell, 2018). The former explores exact match signals, i.e., the co-occurrence of query terms in the document, to derive handcrafted rules and formulas to directly compute the query-document importance, with the BM25 (Robertson and Zaragoza, 2009) ranking function being the most popular example. On the other end, neural IR explores the increasing success of neural networks to approximate a (sub)optimal ranking function by exploiting labelled examples. In the literature, the most successful neural IR architectures are Interaction Based, which measure multiple matching signals to create a joint representation of the query and the documents. Moreover, considering that the transformer architecture is now widely adopted in interaction-based architectures, we further propose to subdivide the works into shallow interaction-based and transformer interaction-based models.

2.1 Shallow Interaction-Based Models

In this subsection, we address some relevant interaction-based neural models proposed before the transformer revolution, and briefly present their intuition to tackle the ad-hoc retrieval challenge. Guo et al. (2016) proposed the DRMM model, which was one of the first neural models to achieve improvements over strong traditional IR solutions, and showed the importance of individually weighing each query term's contributions. Likewise, Pang et al. (2016); Hui et al. (2017); Dai et al. (2018) showed that 2D convolutions directly applied over the interaction matrix are capable of extracting strong hierarchical n-gram matching patterns. Pang et al. (2017) built an end-to-end neural solution, inspired by the human process of selecting relevant documents. Allied to the semantic matching signals, Fan et al. (2018) added, in parallel, exact matching signals and discussed ways of combining them.

2.2 Transformer Interaction-Based Models

Despite representing a recent trend, there is already an extensive literature on transformer architectures. Here we briefly introduce this architecture and its most adopted variants.

Models that follow a transformer-based architecture are composed of a fixed set of stacked transformer blocks (Vaswani et al., 2017), hence their name, and learn useful word representations from large text corpora. Since the first appearance (Radford, 2018), multiple other variants emerged, arguably the most notable and widely adopted being BERT (Devlin et al., 2019), which uses bidirectional self-attention and requires being trained as a masked language model. However, this model has some limitations. One of them is its large size, which is addressed by distillation models, such as distilBERT (Sanh et al., 2020), or by factorisation tricks to reduce the number of trainable parameters, as in Lan et al. (2020). Another limitation is their short input length (512 tokens), which derives from the quadratic complexity and associated memory requirements imposed by the self-attention mechanism. Beltagy et al. (2020); Wang et al. (2020b); Katharopoulos et al. (2020); Zaheer et al. (2020) address this issue by reducing this complexity order, hence increasing the input length.

Regarding the information retrieval field, some works tried to apply these models to the ad-hoc retrieval task with varying approaches. Yang et al. (2019) proposed to perform "best" relevance sentence inference and then linearly interpolate with the original document score (BM25). Dai and Callan (2019b) discuss different strategies to approximate the document relevance by aggregating the relevance across sentences. Nogueira et al. (2019) proposed a three-stage retrieval pipeline and introduced monoBERT and duoBERT, two BERT models aimed at addressing pointwise and pairwise ranking problems, respectively. Finally, MacAvaney et al. (2019) proposed to use the context-aware embedding produced by these models as the input embedding to the well studied shallow interaction-based models. Furthermore, and also acknowledged by MacAvaney et al. (2019), these models are still not suitable to be used or implemented as real-world solutions given their slow inference times and expensive costs.

Some notable works address the issue of computational costs by introducing precomputation, i.e., compute and store for later reuse. Dai and Callan (2019a) propose to precompute term weights that are then used by efficient traditional retrieval systems such as BM25. MacAvaney et al. (2020), on the other hand, precompute the term representation of the document at index time to be later merged with the query representation at query time.

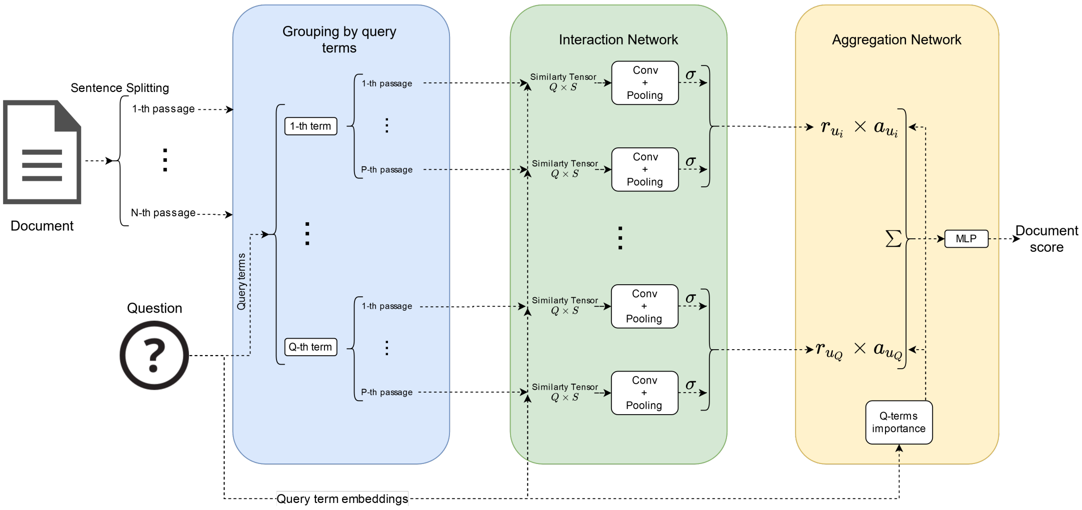

Figure 1: Lightweight neural model data and operation flow.

3 Proposed neural interaction based model

Our neural interaction-based model is an enhancement of Almeida and Matos (2020a) and was already used in the two international competitions, namely BioASQ (Almeida and Matos, 2020b; Tsatsaronis et al., 2015) and TREC-Covid (Almeida and Matos, 2020c; Roberts et al., 2020). However, in order to keep this paper self-contained, we will now introduce its insight and architecture.

From a general perspective, our model follows the successful ideas presented over years of research in the neural IR field, taking into its implementation key concepts of previous works. More precisely, it follows the DeepRank (Pang et al., 2017) intuition to mimic the human judgment process with neural networks; adopts the extraction capabilities, based on 2D convolution, of the PACRR (Hui et al., 2017) and MatchPyramid (Pang et al., 2016) models; explores the same assumption of independently scoring each sentence as addressed by McDonald et al. (2018); and finally, uses the DRMM (Guo et al., 2016) query term gating mechanism to consider the importance of different query terms. Overall, the model was designed with the intuition of weighting the importance of the document sentences in terms of the query by considering the context where the exact match occurs, i.e., this model produces a more refined judgment of the initial exact match signal evaluated by the BM25.

Regarding the architecture, the neural model is divided into three major blocks that can be observed in Figure 1. To clearly describe the model, let us first define a **query** as a sequence of tokens $q = \{u_0, u_1, ..., u_Q\}$, where u_i is the i-th token of the query and Q the size of the query; a **document passage** as $p = \{v_0, v_1, ..., v_S\}$, where v_j is the j-th token of the passage and S the size of the passage; and a document as a sequence of passages $D = \{p_0, p_1, ..., p_N\}$, where N is the total number of passages in the document. In the current implementation, a passage corresponds to a document sentence, as described below.

The first block aims to rearrange the input, query and document, to a suitable format for the downstream interaction model. More precisely, it splits the document into passages using the Punkt algorithm (Kiss and Strunk, 2006) and rearranges the passages by query-term, so that each query-term is associated with a set of passages where that term occurs. At this point, the document is represented by $D(u_i) = \{p_{i0}, p_{i1}, ..., p_{iP}\}$, where p_{ik} corresponds to the k-th passage with respect to the query term u_i, and P is the maximum number of passages that can be associated with each query-term. Note that it is possible to have repeated passages for different query-terms at this point since one passage can contain more than one query-term.

The second block, named Interaction Network, has the objective of scoring each passage according to its relevance for a given query. To accomplish this, we employed a shallow interaction-based model to capture the most relevant matching signals that are present in each query-passage combination. In more detail, for each query-term-passage pair, we construct an interaction matrix with dimension $Q \times S$, also designated similarity tensor, by computing the cosine similarity between the query and the passage embedding. Then 3 by 3 convolutions are applied to learn n-gram relevance signals that are further extracted by multiple pooling layers (max, average, and k-max-average) applied to the filter dimension, creating a feature vector r per each query-term-passage pair. Consequently, $D(u_i)$ at this point is given by $D(u_i) = \{r_{i0}, r_{i1}, ..., r_{iP}\}$, where r_{ik} corresponds to the k-th passage feature vector with respect to the query term u_i. Finally, each resulting feature vector is linearly combined with a trainable vector, and a sigmoid function, σ, is applied to produce a sentence level relevance signal (1=relevant, 0=irrelevant).

The third block, the Aggregation Network, is responsible for producing the final document relevance score for the given query. This is accomplished by weighting the importance of each document passage score with respect to the importance of each query term. More precisely, this importance is given by a probabilistic distribution computed (softmax) over a linear combination of each query term embedding and a trainable vector and is defined as $A = \{a_{u_0}, a_{u_1}, ..., a_{u_Q}\}$, where a_{u_i} represents the probabilistic importance of the query-term u_i. Each passage score is then weighted by the corresponding query-term importance, a_{u_i}, and the resulting set of weighted scores is fed to a multi-layer perceptron to produce the final document score.

Our model is trained in a pairwise fashion and uses word-level pre-trained embeddings, specifically word2vec embeddings (Mikolov et al., 2013) in these experiments. More details on hyperparameters, configuration, and training can be found in previous work Almeida and Matos (2020b).

4 Evaluation

In this section, we aim to empirically demonstrate the efficacy of the proposed model and compare its efficiency against the state-of-the-art transformer-based models.

4.1 Efficacy

To compare the retrieval efficacy of the lightweight system and show that despite having only 620 trainable parameters, it is capable of competing with state-of-the-art models, namely transformer-based models, we reuse the results obtained in two ad-hoc retrieval competitions. Concretely, the results in both challenges derive from a two-stage retrieval pipeline, where our proposed neural model reranks the top-N documents previously retrieved by the BM25 (Robertson and Zaragoza, 2009) ranking function.

4.1.1 BioASQ - Challenge

The BioASQ challenge (Tsatsaronis et al., 2015) is an annual competition on document classification, retrieval, and question-answering, currently in the eighth edition. For the document retrieval task, the objective was to retrieve the most relevant articles from the PubMed/MEDLINE annual database.

Concerning the system, the BM25 filter was fine-tuned with the 2700 biomedical questions provided by the organisers as training data. Furthermore, the neural model was trained on the same data using a pairwise cross-entropy loss with cyclic learning rates. We also trained the word embeddings using word2vec (Mikolov et al., 2013) skip-gram algorithm directly on the PubMed/MEDLINE articles. For more details about our participation, we direct the readers to the system description paper (Almeida and Matos, 2020b).

System	**Document Retrieval**		
	Rank	MAP@10	GMAP@10
Batch 1 (total of 21 systems)			
Proposed Model	1	**38.23**	**1.63**
Top Competitor (Pappas et al., 2020)	4	36.48	1.14
Batch 2 (total of 26 systems)			
Proposed Model	3	37.19	**6.75**
Top Competitor (Kazaryan et al., 2020)	1	**39.45**	6.00
Batch 3 (total of 28 systems)			
Proposed Model	5	52.30	**7.63**
Top Competitor (Pappas et al., 2020)	1	**53.29**	6.25
Batch 4 (total of 26 systems)			
Proposed Model	3	48.10	**7.96**
Top Competitor (Pappas et al., 2020)	1	**49.92**	7.00
Batch 5 (total of 25 systems)			
Proposed Model	2	50.98	**6.52**
Top Competitor (Kazaryan et al., 2020)	1	**52.02**	6.34

Table 1: Summary of the results obtained in BioASQ. Values in bold represent the top score achieved during the competition.

The results summarised in Table 1 show that the system provided the best ranking overall in terms of GMAP@10 for all five batches and achieved top 3 results in all but one batch, in terms of MAP@10. Additionally, this challenge received an average of 25 submissions for each batch and, according to Nentidis et al. (2020), all the other top-performing systems used either BERT or a BERT variant.

4.1.2 TREC-Covid - Challenge

TREC-Covid (Roberts et al., 2020) was an initiative to rapidly promote the development of an automatic system capable of searching the growing literature about the 2019 novel coronavirus. The challenge followed a TREC style format and relied on the CORD-19 dataset (Wang et al., 2020a) as the collection of scientific articles about the novel coronavirus. The objective was to retrieve the most relevant articles from this collection for each topic given by the organisers. The system results were evaluated in a residual manner since, with the exception of the first round, the rounds shared topics that had already been evaluated. The metrics adopted were P@5, NDCG@10, Brepf, and MAP. The organisers also allowed the use of the evaluation feedback of previous rounds as training data to tune/train the submitted systems. An important note is that for the first round no training data was available since no previous evaluation had been performed.

Concerning the system, we utilised the BioASQ system in the first round, which means this was a zero-shot approach, exploiting the proximity of the domains. The only change was on the embeddings used, which were trained on the PubMed/MEDLINE articles plus the CORD-19 dataset. For the remaining rounds, we kept a similar approach, but we also fine-tuned (trained) the model with the feedback data from previous rounds. A complete description of our participation is available in Almeida and Matos (2020c).

System	Rank	P@5	NCDG@10
Round 1 (total of 100 automatic runs)			
Proposed Model	9	63.33	52.98
Top Competitor*	1	78.00	60.80
Round 3 (total of 79 runs)			
Proposed Model	2	**86.50**	77.15
Top Competitor** (Zhang et al., 2020)	1	86.00	77.40

Runs description:
*`https://ir.nist.gov/covidSubmit/archive/round1/sab20.1.meta.docs.pdf`
**`https://ir.nist.gov/covidSubmit/archive/round3/covidex.r3.t5_lr.pdf`

Table 2: Summary of the two best results achieved on TREC-Covid.

Comparatively to BioASQ, TREC-Covid was more challenging given the high number of participating teams. As an example, the first round had a total of 53 teams and approximately 100 submissions in the same category as our submission and hence comparable. This large number also covers a variety of IR solutions, ranging from simple traditional IR to transformer interaction-based models. Table 2 shows our best results, a ninth-place out of 100 in the first round and a second-place out of 73 in the third round. In both rounds, our system was able to beat traditional IR techniques and more recent transformer-based architectures, such as BERT and its variants, T5 (Raffel et al., 2020), among others. Additionally, our round 3 submission differed from the overall system since, motivated by the residual nature of the evaluation, we ended up utilising a (pseudo)-relevance feedback baseline instead of our BM25 baseline.

4.2 Performance

In this section, we address the performance side of the proposed neural model by empirically comparing it to the transformer-based behemoths. We propose three dimensions of comparison, namely the number of parameters, time to infer document relevance, and time to train. The first dimension has the objective of giving an idea of the model's size. The second dimension is especially concerned with proving the feasibility of using these models in real-world applications. Finally, the third dimension is concerned with the impact and resources required to build systems with these models.

All the measures were performed on a machine with the characteristics presented in Table 3, which we consider a good representative of a generally accessible setup. Additionally, all the experiments were performed on TensorFlow 2.2.0 with CUDA 10.1, and for the transformer-based models, we adopted the HuggingFaces (Wolf et al., 2020) library with the TensorFlow version of the models. To keep the comparison fair we utilize the "tf.function"[1] decorator to convert the model to a static computation graph, significantly speeding up the transformer-based models.

CPU	2x Intel(R) Xeon(R) CPU E5-2630 v4 @ 2.20GHz
GPU	Nvidia Tesla K80 with 12 GB
RAM	128 GB

Table 3: Specification of the hardware used during the experiments.

An important aspect is that we do not have access to the systems listed in Section 4.1. To keep a fair comparison, we implemented a simple minimal working example that uses a transformer-based model for ad-hoc retrieval. Pursuing the ideas of (Yang et al., 2019; Nogueira et al., 2019; Dai and Callan, 2019b), we fed to the model the following input "[CLS] query tokens [SEP] document tokens [SEP]", where "[CLS]" and "[SEP]" are special boundary tokens, with the first one being a classifier token that is further fed to a multi-layer perceptron to compute the final document relevance. We

---

[1] https://www.tensorflow.org/versions/r2.2/api_docs/python/tf/function

set the input size to the maximum that the model could handle and applied padding or truncation. This implementation gives us a best-case scenario in terms of computational performance for ad-hoc retrieval.

We compared the following transformer-based models against our proposed solution:

- BERT (x12): Corresponds to the original checkpoint “bert-base-uncased” of the BERT model and has 12 layers, 768 hidden dimension, 12 multi attention heads, totaling approximately 110 million trainable parameters.
- BERT (x24): Corresponds to the original checkpoint “bert-large-uncased” of the BERT model and has 24 layers, 1024 hidden dimension, 16 multi attention heads, totaling approximately 340 million trainable parameters.
- distilBert: Corresponds to the original checkpoint “distilbert-base-uncased” of the distilBERT model and has 6 layers, 768 hidden dimension, 12 multi attention heads, totaling approximately 66 million trainable parameters.
- ALBERT: Corresponds to the original checkpoint “albert-base-v2” of the ALBERT model and has 12 repeating layers, 128 size embeddings, 768 hidden dimension, 12 multi attention heads, totaling approximately 11 million trainable parameters.
- Longformer: Corresponds to the original checkpoint “allenai/longformer-base-4096” of the Longformer model and has 12 layers, 768 hidden dimension, 12 multi attention heads, totaling approximately 149 million trainable parameters.

We mostly use BERT models since these are widely adopted in the literature. Moreover, we also include distilBERT since it is currently one of the fastest transformer-based models available, and ALBERT, given its comparatively small number of trainable parameters. Furthermore, all the models had a maximum input size of 512, with the exception of Longformer, which had an input size of 4096.

Some final notes regarding our neural model implementation are also relevant. In the first place, this model was constructed to run on the CPU, and so we do not consider operations and data flow that would be easily accelerated on the GPU. Furthermore, our implementation is in a prototype phase, which means that we have not performed any optimisations. For example, in the current state, the model performs some redundant computation, and the amount of padding data reaches approximately 90%.

4.2.1 On Inference

Regarding the inference tests, these were performed both in CPU and GPU since it is well known that the transformer architecture can achieve a drastic speed up on the GPU. However, on the other side, this brings more operational costs and offers a new single point of failure that real-world systems would need to deal with.

With respect to the experiment, it consists of computing the document relevance score for a BioASQ test set that contains 100 queries and a pool of 250 documents for each question, making a total of 25000 query document pairs. We fed this to the models in a systematic way, only varying the batch size and measured the elapsed time in seconds. We discarded the time taken on the first and last batch since the first batch may perform some initialization operations and the last batch has fewer documents than the others. Moreover, in the column “Tokens seen”, we show the number of tokens fed to the model per sample.

Model	**Tokens seen**	**Time elapsed** (on a batch of **16**)	
		CPU(s) **Mean ± std**	**GPU(s)** **Mean ± std**
Proposed model	4500	0.074 ± 0.006	0.824 ± 0.093
distilBERT	512	2.421 ± 0.038	0.551 ± 0.007
BERT (x12)	512	4.967 ± 0.072	1.133 ± 0.011
ALBERT	512	5.144 ± 0.081	1.198 ± 0.027
BERT (x24)	512	15.729 ± 0.185	3.511 ± 0.052
LongFormer	4096	102.051 ± 1.009	*11.188 ± 0.035

*Measured on a batch size of 8

Table 4: Inference times in seconds measured over 25000 query document pairs using a batch size of 16 on a CPU and GPU.

Table 4 presents the measured times using a batch size fixed at 16. As illustrated, our simple model can run 32 times faster on the CPU compared to the fastest transformer-based solution while processing almost 9 times the amount of tokens. Compared with a model that processes almost the same amount of data, in our experiments the LongFormer, the time difference becomes more evident, with our proposed model being 1379 times faster.

Regarding the behaviour when running on the

GPU, our proposed model is not able to achieve a speedup when compared to the CPU time and to the transformer-based models. However, we believe the main reason for this is related to the time needed to transfer the data to the GPU since the proposed model needs to send 9 times more data, which also gives us an indication that it may not be worth to run on the GPU due to the small number of operations that the model performs compared to the amount of data that it needs to send. Furthermore, the results that we show for the LongFormer were obtained with a batch size of 8, since we could not fit the model with a batch of 16 on the GPU, due to memory constraints.

Figure 2 presents the models inference time for four different batch sizes, $\{16, 32, 64, 258\}$. On the left, which corresponds to the experiments on the CPU, the models seem to scale with the increase of the batch size linearly. Additionally, only our proposed model is capable of keeping an inference time under one second, which can be viewed as an acceptable query latency time. Similarly, on the right side, corresponding to the experiments performed on the GPU, we observe the same linear behaviour for the transformer models. However, the proposed model shows an almost constant time, which reinforces the idea that when executed in the GPU, the most time-consuming operation is data transfer.

4.2.2 On Training

The training experiments were performed on both CPU and GPU, similarly to the inference. Regarding this experiment, we follow a pairwise training approach, which may be a computationally heavier option when combined with the transformer architecture, since these are usually trained as a binary classification problem, i.e., a document is relevant to a question or not. However, we decided to keep the pairwise approach since the proposed model was designed to use it, this way keeping a more fair comparison and also demonstrating the burden of training transformer-based models in a pairwise setting. Moreover, the transformer-based model can be entirely finetuned, i.e., training the classification layer and all layers, or just training the classification layer, which we also evaluate, since it should speed up the training.

Concerning the training data, we used 100 questions from the BioASQ training dataset each associated with a list of relevant documents and a list of negative documents randomly sampled from the BM25 ranking order, producing a total of 1104 training samples.

After the sampling process, we store this data to ensure that every model processes exactly the same set of triplets (query, positive document and negative document). To further ensure homogeneity among the experiments, we fixed every random seed that we were aware of.

Model	**Tokens seen**	**Time elapsed**	
		(on a batch of **16**) **CPU(s)** **Mean ± std**	(on a batch of **1**) **GPU(s)** **Mean ± std**
Proposed model	4500	0.350 ± 0.011	1.204 ± 0.234
distilBERT	512	9.700 ± 0.055	1.116 ± 0.007
BERT (x12)	512	19.727 ± 0.280	0.484 ± 0.005
ALBERT	512	19.835 ± 0.414	0.451 ± 0.003
BERT (x24)	512	66.536 ± 0.724	1.582 ± 0.040

Table 5: Complete training times, i.e., training all the layers, in seconds measured over 1104 samples on a CPU and GPU.

Table 5 shows the time required to fully train the transformer-based models, i.e., training all the layers plus the classifier layer, in a pairwise setting. Similarly to the inference, we also adopted a batch of 16 for the CPU and a batch of 1 for the GPU, since we could not perform the training on the GPU due to memory issues for some models. Additionally, we did not measure results for the LongFormer, neither in CPU or GPU, since we were unable to store the model plus all the gradients on memory (128GB) for the given batch size.

Regarding the results, all the models seem to be four times slower at training time when compared with the inference times. As expected, the proposed model presented the fastest training time, being 10 times faster than the fastest transformer model. Also note that, for all the models, training with a batch of 1 on GPU does not bring any advantages over training on the CPU, which is approximately 3 times slower (per batch) but for a batch size that is 16 times larger. Finally, regarding the performance of the proposed model on the GPU, it also seems to support the previously enunciated problem related to data transfer to the GPU.

Table 6, presents the measured time, in seconds, required only to train the classification layer in the transformer-based models. In this case, both the CPU and GPU experiments could be done on a batch size of 16, since it is only necessary to store gradients for the classification layer.

Looking at the results, if we only update the classifier layers weights, the transformer-based models

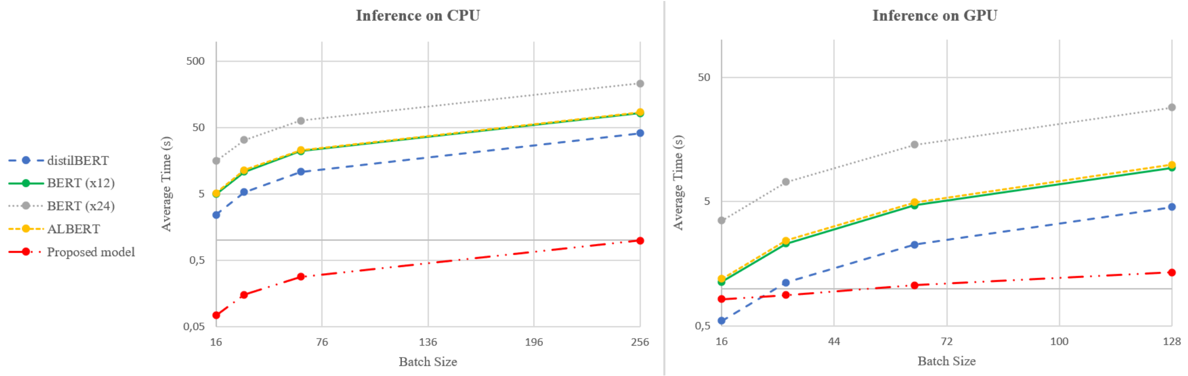

Figure 2: Inference times on the CPU, left side, and on the GPU, right side, as a function of the batch size.

Model	**Tokens seen**	**Time elapsed** (on a batch of **16**)	
		CPU(s) **Mean ± std**	**GPU(s)** **Mean ± std**
Proposed model	4500	0.350 ± 0.011	1.008 ± 0.094
distilBERT	512	3.696 ± 0.098	1.108 ± 0.011
BERT (x12)	512	7.513 ± 0.098	2.266 ± 0.012
ALBERT	512	7.867 ± 0.202	2.400 ± 0.011
BERT (x24)	512	24.699 ± 0.377	7.042 ± 0.033

Table 6: Training times, in seconds, only for the classification layer measured over 1104 samples on a CPU and GPU.

training becomes 2.5 times faster. Additionally, using the GPU further improves this speed up to 8.7 times. However, even using the GPU, the fastest transformer based model, distilBERT, is still 3.1 times slower than our proposed model.

5 Discussion

In this section, we take into consideration the presented results, both in terms of efficacy and performance, and present an overall overview of the comparison of our lightweight model and the transformer-based approaches.

First of all, we acknowledge some limitations of the proposed model, which are all related to the current implementation that processes a large portion of padding data, increasing the number of tokens that the model sees and thus injuring the performance of the current solution. However, this is something that can be addressed in future work by rearranging the model data flow and better understanding the required maximum input size of the query and document tokens. Moreover, to get a sense of speed up that we could achieve, we made a comparison with a transformer-based model that is able to encode up to 4096 tokens, which is close to the 4500 tokens of the proposed model. In this case, the lightweight model ends up being 1379 times faster, which gives an idea that the expected speedup may be in the order of a thousand.

Recalling the three proposed dimensions of comparison, the proposed model excels in all of them. First of all, it is a model with 10 thousand times fewer trainable parameters when compared to distilBERT. In the efficacy evaluation, the results show that the proposed model could achieve close to state of the art performance in both biomedical ad-hoc retrieval tasks. Finally, according to the presented inference times, more precisely, with the times presented in Figure 2, it is observable that the proposed model was the only one to perform inference under one second even with a batch size of 256, which is more than enough to adopt in real-world ad-hoc retrieval applications. Furthermore, this observation enables us to conclude that the transformer-based model solution is currently not suitable for a real-world ad-hoc retrieval application unless large scale computational resources are available.

Moreover, our results also show that the proposed model was always the fastest model by a significant margin, even though using only the CPU. This, in our view, ends up to be a preferable characteristic, since it facilitates the deployability and scalability of systems that implement this model.

6 Conclusion

In this paper, we discuss the feasibility of using transformer-based models in real-world ad-hoc retrieval applications and show an extreme lightweight solution, with only 620 trainable parameters.

We evaluate the solution against the transformer-based models, in terms of efficacy and performance, and show that this model is capable of matching the efficacy offered by the transformer-based models in two biomedical ad-hoc retrieval challenges while being considerably faster by just using the CPU compared to the best GPU runs of the transformer-based models.

Reanalyzing the Most Probable Sentence Problem: A Case Study in Explicating the Role of Entropy in Algorithmic Complexity

Eric Corlett **Gerald Penn**
Department of Computer Science
University of Toronto
{ecorlett,gpenn}@cs.toronto.edu

Abstract

When working with problems in natural language processing, we can find ourselves in situations where the traditional measurements of descriptive complexity are ineffective at describing the behaviour of our algorithms. It is easy to see why — the models we use are often general frameworks into which difficult-to-define tasks can be embedded. These frameworks can have more power than we typically use, and so complexity measures such as worst-case running time can drastically overestimate the cost of running our algorithms. In particular, they can make an apparently tractable problem seem NP-complete. Using empirical studies to evaluate performance is a necessary but incomplete method of dealing with this mismatch, since these studies no longer act as a guarantee of good performance. In this paper we use statistical measures such as entropy to give an updated analysis of the complexity of the NP-complete Most Probable Sentence problem for pCFGs, which can then be applied to word sense disambiguation and inference tasks. We can bound both the running time and the error in a simple search algorithm, allowing for a much faster search than the NP-completeness of this problem would suggest.

1 Introduction

Natural Language Processing uses many algorithms that are theoretically intractable, but work well in practice. The k-means clustering algorithm, for example, has an exponential worst-case time, but is generally polynomial in practical applications (Arthur et al., 2009). If we look at problems, as opposed to algorithms, the task of training neural networks (Blum and Rivest, 1993), sentence disambiguation in pCFGs and HMMs (Sima'an, 2002), and solving cryptograms (Nuhn and Ney, 2013) have even been shown to be NP-complete. These results would seem to be at odds with the observation that we are able to actually perform these tasks. Clearly, while NP-completeness results are a necessary part of our understanding, they do not tell the whole story about our algorithms' behaviour.

Faced with the inadequacy of existing descriptive complexity measures to represent program operation, some researchers have resorted to empirical measures of performance (e.g. Carroll, 1994). Unfortunately, empirical studies have their own pitfalls, and these are also difficult to address. Specifically, empirical studies of program performance have an implicit dependence on the distribution of inputs used in the study. Changing this distribution of inputs can change the overall performance drastically. This, after all, is why we separate training and evaluation test sets.

Ultimately our analytic tools should work together with our empirical studies, in the sense that we should be able to give quantify how much program performance changes as we change our input distributions. This would allow us to circumscribe our guarantees of program performance; if those bounds are not met (e.g., if a program takes much longer than expected to run), we have evidence that the set of inputs did not comply with the distribution in the first place.

The situation of NLP is a little more complicated, however. Many of our algorithms include, implicitly or explicitly, probability distributions as part of their input. Take for example a natural language parser. Thirty years ago, these relied upon lexicalized pCFGs that explicitly assigned probabilities to different rules and word n-grams, whereas today, the distributions used by neural parsers avail themselves of distributions that are rather more implicit. But in both cases, the distributions are acquired by sampling training data.

The aim of our research programme is to incorporate these distributions into our theoretical anal-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 3354–3362

yses of program performance. If we were to follow existing analyses of a program's dependence on textual input, we may choose to characterize that dependency as a function of the length of the distribution's description. Uniform distributions, arguably the shortest to write, often ensure the worst program performance. Indeed, there is plenty of evidence from statistics, information theory and other AI applications that a particular derivative characteristic of distributions which is systematically related to the length of their descriptions captures many aspects of this dependency: *entropy*.

In this paper we take steps towards this goal by demonstrating how to link the run time of a specific inference problem, the Most Probable Sentence (MPS) problem for pCFGs (Sima'an, 2002), to the entropy of its input. While this is somewhat of a niche problem, it does provide a good demonstration of our approach. We will describe below in Section 8 some other graphical models that this approach can be readily applied to.

We start our analysis of the MPS problem in Section 3 by outlining the problem definition, the NP-hardness proof of the problem, and the main bound we are going to prove about it. In Sections 4 and 5, we develop an analysis of the MPS problem by showing how entropy, specifically, the conditional entropy of a parse tree given the words of a sentence, changes the running time of a simple search algorithm for the most probable tag sequence over that sentence. In Section 6, we show that there is an inherent trade-off between accuracy and run time whose worst case is dictated by the pCFG sentence-to-tree entropy. Finally, in Section 7, we characterize the run time of our search when we hold our grammar constant and draw many sentences from it.

2 Previous Work

Historically, most complexity results in computer science have dealt with worst-case complexity. A major NLP result in this vein has been the study by Sima'an (2002), which shows that the most probable parse problem (MPP) for pSTSGs and the most probable sentence problem (MPS) for both pSTSGs and pCFGs are all NP-complete. These problems can be thought of as renormalization over a graphical model, and have been studied further in several publications, including De la Higuera and Oncina (2013) and Goodman (1998). Similar NP-completeness results exist for the problem of finding the optimal word order for phrases in machine translation (Germann et al., 2001) and for solving letter-substitution problems such as cryptograms (Nuhn and Ney, 2013).

An argument could be made for average-case complexity (Levin, 1986; Impagliazzo, 1995) as an alternative to what we are attempting here. Average-case complexity is a step towards the type of results that we want, but it still has its shortcomings. In particular, an average case complexity analysis relies on the underlying distribution of inputs being known (and, usually, easy to work with) in advance. The distribution of choice is often naïvely uniform. In situations where the input distribution is defined by the problem task, or where it is actually defined as part of the input, the problem of how program behaviour changes with the distribution is not completely addressed. Average-case complexity, moreover, does not give any sort of guarantee on program performance.

Within artificial intelligence, approximation results are perhaps a more natural approach to analysis. Nearly all of these endeavour to establish a worst-case result, however, and in some cases, such as with Markov Logic Networks and Bayesian networks (Roth, 1996; Cooper, 1990), it is hard even to approximate for probabilistic inference. What we want is the worst case, but not the worst distribution. We want the worst case for a typical distribution.

A general framework for "probabilistic complexity" has been explored in Ackerman et al. (2011), in which it is found that the calculation of values such as conditional probability can be intractable, even on an otherwise tractable distribution. On the other hand, attempts to give decompositions for large families of distributions into tractable bases, as described in Erdélyi et al. (2009), can be used to characterize input probabilities for which algorithms will often be efficient. What these papers do not do is explore how the task-specific aspects of a problem in a powerful model can shift an algorithm's complexity into a hard or easy part of the input space.

A promising alternative approach to analyzing program complexity is to look at the smoothed complexity of an algorithm. In this paradigm, the complexity of an algorithm is not based on the worst input that an arbitrary adversary could choose for the problem. Instead, the adversary is constrained by having a small error added to their inputs. The expected complexity of the resulting problem is then reported, and can often be much better than the usual worst case. This approach to complexity analysis is very effective for describing the behaviour of many otherwise exponential algorithms, such as the simplex algorithm (Spielman and Teng, 2004) or the k-means clustering algorithm (Arthur et al., 2009). The major limitation of this approach for us, however, is that the improvement in performance is assumed to be due to measurement error in the input. Such an assumption is very appropriate when talking about, for example, measurements taken of continuous real-world quantities like length. It is not likely to be appropriate for situations where the program improvement is due to observable regularities in the input data.

What we really want to do is to exploit the fact that we see only a fragment of the theoretically possible input space in the real world. Unfortunately, the task of identifying good problem fragments for our models is itself very hard, and so we will instead attempt to use statistical measures to build tools for narrowing down the space in which our inputs will lie. A start towards this goal is found for the letter-substitution problem in (Corlett and Penn, 2013), but this approach does not give a tight enough bound to describe when we should expect better running times, and it does not immediately generalize to other tasks. We would like to strengthen the approach used in that paper to make it more applicable to different areas. With this in mind, we turn to another NP-complete problem, the MPS problem for pCFGs.

3 Tagging and NP-Completeness

To start, we recall the definition of the problem:

Most Probable Sentence Problem (MPS)

Instance: A pCFG model G and a string s.
Question: Find a sequence of part-of-speech tags, σ, that maximizes the sum of probabilities of trees with yield s and pre-terminals σ.

As an example, suppose we were looking at the sentence "Time flies like an arrow". There are several assignable tag sequences, such as

$$N\ V\ Adv\ Det\ N$$

or

$$Adj\ N\ V\ Det\ N.$$

Each tag sequence might be obtainable from more than one parse tree. The probability of any such tag sequence is the sum of the probabilities of the trees yielding that sequence.

The difficulty of this problem lies in the fact that we are looking for the POS tags that maximize the sum of the probability of all trees using those tags. If we were looking for the single most likely tree, or if we were looking for the sum of all trees with yield s, without fixing the POS tags, the usual $\mathcal{O}(n^3)$ parsers would work.

A reduction, as described in Sima'an (2002) is made from 3-SAT as follows: given a 3-SAT formula ϕ with η clauses and κ variables, we build a pCFG grammar G_ϕ that generates strings that contain 3η copies of a single terminal, such as x. The tags for these terminals are either T or F – that is, they are the truth assignments for the literals of ϕ (e.g., if $\eta = 2$, we would generate six-tag sequences such as *TTFTTF*). The grammar G_ϕ is capable of generating two types of trees for every input string: one that generates true assignments that may or may not be consistent across variable instances, and one that generates consistent assignments for one designated variable. A string of tag assignments that has one tree of the first type and κ trees (one for each variable) of the second type will have a total probability that is higher than trees that lack this many, and so there is a threshold Q that separates input strings with true, consistent assignments from input strings without true, consistent assignments.

In the following sections, however, we will prove the following:

Theorem 3.1 *Suppose that we draw a sentence s from a pCFG grammar G. Then, the MPS problem can be solved in $\mathcal{O}(n^4[p_G(s)/p_G(\tau(s))])$ time, where:*

- *n is the length of s,*
- *$\tau(s)$ is the tag sequence assigned within the most likely tree, $t(s)$, that has yield s, and*
- *$p_G(s)$ is the probability of s in G, and $p_G(\tau(s))$ is its probability given $\tau(s)$.*

This is a major improvement over the bound of Sima'an (2002) because it shows that the exponential run times that we expect from an NP-complete problem are in fact bounded by the ratio $p_G(s)/p_G(\tau(s))$. For the pathological grammars that are used in the NP-completeness proof, this ratio grows exponentially with the size n of the sentence. On the other hand, we conjecture that it is quite small for the natural language grammars that we see in practice. Empirically computing the average such ratio on a corpus can itself be very trying,[1] but there are good indications that it is relatively constrained. In the Penn Treebank, for example, 46.5% of the word tokens in the corpus have only one POS tag assignable, and these words are fairly well dispersed throughout the corpus: the median intrasentential distance between them (not including the single-tag words themselves) is 1, with an average of 4.4. In any case, a parser that avails itself of this theorem does not need to explicitly calculate $p_G(s)/p_G(\tau(s))$. $p_G(s)/p_G(t(s))$, which directly relates to the probability of the best tree for s, is likely to be a much looser bound. We will attempt to bound it theoretically in Section 7.

Proof of Theorem 3.1: This is an immediate consequence of Lemmata 5.5 and 5.6. The proofs are presented below. Section 4 describes a simple search algorithm that will be the focus of the discussion. Section 5 will analyze the running time of this algorithm in a way that provides the basis for these lemmata. In Section 6, we will extend this result to describe the error incurred if we allow early stopping. ■

4 Analysis of Problem and Exemplary Algorithm

We will use a similar approach to that used in (Corlett and Penn, 2013), in that we will use an A^* search to solve the MPS problem for pCFGs. The idea behind the search is as follows: given a pCFG G and a string s of n words, we can find the overall probability $p_G(s)$ in G through a cubic time algorithm that algebraically mirrors a conventional all-paths parsing algorithm. But for our purposes, we can do it differently: given any instance w of a word in s, we can make a guess as to the POS tag r that w will take, and then run the algorithm, but with the restriction that only the tag r will be counted for w. In our earlier example of "Time flies like an arrow," perhaps this would mean running the parser given the restriction that "Time" is an adjective, while letting the other words take any tag that they can. Clearly, this run of the parser will still take $\mathcal{O}(n^3)$ time, as it would if we simultaneously constrained any subsequence of the words of s rather than just one.

Recall that $p_G(s)$ is the sum of all $p_G(t)$, where t ranges over all trees with the yield of s. Furthermore, if, for a subsequence of word instances $(w_{u_1}, w_{u_2}, \ldots, w_{u_J})$, we restrict the parser so that only the POS tags $(r_1, r_2, \ldots, r_J)$ will be considered, the probability calculated will be the sum of $p_G(t')$, where t' ranges over all trees with both have the yield of s and which have the desired POS tag restrictions. We will use this probability as an admissible heuristic in our A^* priority queue, and consider possible sequences of tag assignments as nodes in the search space. We will refer to sequences of tag assignments with the character a, and we will index them by the letter i. Sequences of tag assignments will not, in general, fix a tag for every word in s.

To run the search, we fix an order for the words in s. We assume a last-to-first ordering here, but any ordering will suffice. We push an empty assignment $\{\}$ with the score $p_G(s)$ onto a probability queue Q. While Q is nonempty, we pop its maximum element a_i and look for the first word w_u in our ordering of s which is not fixed by a_i. For every possible POS tag r_j for w_u, we add the POS tag assignment $\{w_u : r_j\}$ to a_i to get a new sequence of tag assignments $a_i^{[j]}$, compute $p_G(s)$ restricted to $a_i^{[j]}$, and insert $a_i^{[j]}$ into Q with the resulting probability. We return the first tag assignment a popped from Q that fixes every word in s.

To see that this A^* search is correct, we first note that it must terminate: every time a tag assignment A is popped from the queue, either a fixes every word in s and the program terminates, or a series of strictly longer tag assignments a' is added to the queue.

Furthermore, since our heuristic for a tag assignment sequence a is the sum of the probabilities of all suitably restricted trees t in G with yields of s, we can see that when we extend a tag assignment sequence a, we are simply adding new constraints to the contributing trees t, and so the set of trees counted is non-increasing. This means that the heuristic is also non-increasing. The same argument tells us that any extension of a tag assignment sequence a that fixes every word in s must have a probability that is at most that of s given a. These arguments, taken together, indicate that the first tag sequence found that fixes every word in s will be the one that gives the maximum probability, and so this assignment will give the solution to the MPS problem.

---

[1] The reader may wish to refer to our work on this subject at `https://doi.org/10.5683/SP2/CM9QY1`.

5 Initial Analysis

In order to find the time complexity of this algorithm, recall the fact that the admissible heuristic is non-increasing. If we apply this to the first and last tag assignment sequences popped from the stack, we can see:

Lemma 5.1 *If $M_G(s)$ is the probability of s given its most likely tag sequence, and if a is any tag sequence expanded in the search, then*

$$p_G(s) \geq p_G(s|a) \geq M_G(s).$$

Similarly, if a is a tag sequence that is seen but not expanded in the search,

$$M_G(s) \geq p_G(s|a).$$

So understanding the algorithm complexity becomes an issue of determining how many a are in this range. Furthermore:

Lemma 5.2 *If we extend a specific tag sequence a_i in our search by one tag assignment into the new sequences $a_i^{[1]}, a_i^{[2]}, \ldots, a_i^{[m]}$, then*

$$p_G(s|a_i) = \sum_j^m p_G(s|a_i^{[j]}).$$

This just means that in our example sentence $s =$“Time flies like an arrow,” if we were to argue that “flies” can only be an *N* or a *V*, then the probability of s is the sum of the probability of s given that “flies” is a *N* plus the probability of s given that “flies” is a *V*. Any of the parse trees that are compatible with one restriction are incompatible with the other, and so the outcomes in their probabilities are disjoint.

In fact, since Lemma 5.2 applies to every tag sequence we expand, we can go so far as to apply it iteratively to cover the whole search space:

Corollary 5.2.1 *Let QO be the selected optimal solution together with the items left stranded on Q at the end of the search. Then:*

$$\sum_{a \in QO} p_G(s|a) = p_G(s).$$

Let D^* be the set of all a_i such that every expansion of a_i, $a_i^{[1]}, a_i^{[2]}, \ldots, a_i^{[m]}$ is a member of QO. Some of the members of QO will be complete sequences of tag assignments — every word in s has received a tag in these. Others may not be complete, because the search terminated before they could be expanded. Because of this, D^* is not merely the set of QO parent nodes in the search space — some parents will be left out because they were extended both to assignment sequences that were further extended, as well as to assignment sequences that were not further extended.

Let D' be the subset of QO consisting of every node with its parent in D^*. Every element of QO only has one parent node (no joins in the search space) because we always marshal out the tags of s in the order that we defined over its words. By Corollary 5.2.1:

$$\begin{aligned} p_G(s) &= \sum_{a \in QO} p_G(s|a) \\ &= \sum_{a \in D'} p_G(s|a) + \sum_{a \in QO \setminus D'} p_G(s|a) \\ &\geq \sum_{a \in D'} p_G(s|a). \end{aligned}$$

Then, by repeated applications of Lemma 5.2 to the elements of D^*:

Lemma 5.3

$$p_G(s) \geq \sum_{a \in D'} p_G(s|a) = \sum_{a \in D^*} p_G(s|a).$$

Interestingly, the nodes of D^* are the nodes that are the most complete assignment sequences that still satisfy $p_G(s|a) \geq M_G(s)$, from the first clause of Lemma 5.1 — every node expanded in the search is either in D^* or is an ancestor of a node in D^*. It takes at most $n-1$ steps of expansion to arrive at this frontier, because every step assigns a tag to a new word of s, and there are at most $|D^*|$ such paths through the search space. So the total number of nodes expanded must be at most $\mathcal{O}(n|D^*|)$.

Lemma 5.4 *Let $R_G(s) = p_G(s)/M_G(s)$. The total number of nodes expanded must be at most $\mathcal{O}(nR_G(s))$.*

Proof: We have just learned that for every $a \in D^*$, $p_G(s|a) \geq M_G(s)$. Therefore, by Lemma 5.3, $p_G(s) \geq \sum_{a \in D^*} M_G(s)$, and so $R_G(s) \geq \sum_{a \in D^*} 1 = |D^*|$. ■

Finally, note that every one-word expansion in our search procedure comes with a decoding step that is bounded by $\mathcal{O}(n^3)$ time. Thus we have:

Lemma 5.5 *The running time for the entire search is $\mathcal{O}(R_G(s)n^4)$.*

The proof by Sima'an (2002) of overall NP-completeness implies that $R_G(s)$ can be exponentially large in n. His reduction exhibits a grammar which generates a single s with probability one, while the value of $M_G(s)$ is proportional to a threshold value, which is exponentially small in n. So in this degenerate case, the ratio $R_G(s)$ will always be exponentially large in the size of the grammar. In any case, determining $R_G(s)$ is the key to understanding the running time of our search.

Finding $R_G(s)$ is as difficult as finding $M_G(s)$, since we can use one to calculate the other. So we cannot directly use $R_G(s)$ in our calculations — we need a bound for it instead. Clearly, given a positive lower bound for $M_G(s)$, L, then $R_G(s) \leq p_G(s)/L$ also.

A very simple lower bound L is the most probable single parse tree $t(s)$ for s, which can be calculated in $\mathcal{O}(n^3)$ time. Clearly, the probability of $t(s)$ is at most the probability of all trees with the same tag assignment as $t(s)$, and this sum is itself at most the probability of the largest full tag assignment. Thus:

Lemma 5.6 *For any sentence s,*

$$R_G(s) \leq p_G(s)/p_G(\tau(s)) \leq p_G(s)/p_G(t(s)).$$

In the case of pure pCFG parsing, finding $p_G(s)$ also admits an $\mathcal{O}(n^3)$ algorithm, although the implicit sum over all possible trees includes a potentially infinite series over cycles of unary phrase structure rules. When this series converges, finding the probability mass added by these extra trees involves inverting a potentially large matrix that can be prohibitively expensive, although this cost is independent of the input length, and can be precomputed offline.

6 A Trade-off Between Accuracy and Time

Practically, we may not want to run a full A^* search, especially if the overall search takes a long time. The above analysis is a convenient starting point for investigating the consequences of stopping our search early.

If we do decide to stop the A^* search early, we will want to output a tag sequence. Let this tag sequence be $\hat{a}(s)$. We will assume here that it is $\tau(s)$, the one associated with the most likely tree, $t(s)$, which means that it can be calculated easily, and can easily be combined with any other estimate (just check both tag sequence estimates and take the better).

The heuristic score of $\hat{a}(s)$ provides a lower bound on the probability of the most likely tag sequence, which may in fact not be $\hat{a}(s)$. As the search progresses, those scores will decrease, and so the range of values that the maximum probability can take on will also decrease. In particular, the error that we incur by simply choosing the tag sequence $\hat{a}(s)$ as our output will always be at most $p_G(a_i)/p_G(\hat{a}(s))$. Given some $k \leq n$, let us run our A^* search for $n2^k$ iterations. We assert that:

Theorem 6.1 *If we run our search for $n2^k$ iterations, we will get a reduction in error of at least k bits, i.e., we achieve an overall reduction in error of at least 2^{-k}.*

Proof: Suppose otherwise. Then, since $p_G(s|a_i)$ is the score of the latest partial solution on the queue after $n2^k$ iterations, we have that $p_G(a^*) < p_G(s|a_i)$, where a^* is an optimal tag assignment. But, since the error that we incur by choosing $\hat{a}_t$ is not reduced by at least 2^{-k}, then $p_G(s|a_i)/p_G(\hat{a}(s)) > 2^{-k}(p_G(s)/p_G(\hat{a}(s)))$.

Let Q_i be the partial tag sequence a_i together with the items left stranded on Q when we terminate the search. Then, as we saw in Corollary 5.2.1:

$$\sum_{a \in Q_i} p_G(s|a) = p_G(s).$$

Furthermore, let D_i and D'_i be defined analogously to D^* and D' from Section 5. The arguments of Lemma 5.3 still apply, so that

$$\sum_{a \in D_i} p_G(s|a) \leq p_G(s).$$

Since $p_G(s|a_i) \leq p_G(s|a)$ for every $a \in D_i$, it follows that:

$$\begin{aligned} &\sum_{a \in D_i} p_G(a) = p_G(s) \\ \Rightarrow &\sum_{a \in D_i} (p_G(s|a_i)) \leq p_G(s) \\ \Rightarrow &\sum_{a \in D_i} 1 \leq p_G(s)/(p_G(s|a_i)), \end{aligned}$$

in which case:

$$
\begin{aligned}
|D_i| &\leq p_G(s)/(p_G(s|a_i)) \\
&= \Big(\frac{p_G(s)}{p_G(\hat{a}(s))}\Big)/\Big(\frac{(p_G(s|a_i))}{p_G(\hat{a}(s))}\Big) \\
&< \Big(\frac{p_G(s)}{p_G(\hat{a}(s))}\Big)/\Big(2^{-k}\big(\frac{p_G(s)}{p_G(\hat{a}(s))}\big)\Big) \\
&= 2^k.
\end{aligned}
$$

At this point, the number of nodes expanded by the algorithm is at most the number of unexpanded nodes in the search space times the number of their ancestors. where the number of ancestors of any node is at most n (since this is the maximum depth in the tree). On analogy to Section 5, the total number of nodes that have been expanded in the search is less than $n2^k$. But we have stated that the algorithm has been run at least $n2^k$ times. Therefore, we have an error reduction of at least 2^{-k}, as desired. ■

If the algorithm halts in this time, we have an exact solution, and so our error rate is zero. So if we allow early stopping in our search we can guarantee that the error times the number of times the search iterates is $\mathcal{O}(n(p_G(s)/p_G(\hat{a}(s))))$. Due to the cubic run time of the parsing algorithm, we find:

Lemma 6.2 *If we allow early stopping as described above, the total run time multiplied by the algorithm error will be* $\mathcal{O}((p_G(s)/p_G(\hat{a}(s))n^4))$.

As in Section 5, we can see that what we need to find is a bound on $p_G(s)/p_G(t(s))$.

7 Bounding $p_G(s)/p_G(t(s))$

Here we will find a bound on $p_G(s)/p_G(t(s))$ given only the grammar G. We can consider G as a model that probabilistically generates trees t, which in turn generate the yield s.

We know $p_G(t) \leq p_G(t(s))$, where $t(s)$ is the most likely tree that has the yield s. So, by the previous arguments, $p_G(t)$ is a lower bound for $M_G(s)$, and so $p_G(s)/p_G(t(s)) \leq p_G(s)/p_G(t)$. We will relate these values to the per-word sentence and tree entropies $H_{G,n}(s)$ and $H_{G,n}(t)$, where n is fixed.

If the the generative process for trees in G is ergodic and stationary, then as the size of the tree t increases, the density of the nonterminals in t approaches some distribution π_t. Furthermore, as the density of the words in s approach some distribution π_s with high probability, then for any $\delta, \varepsilon > 0$, there is an $N > 0$ such that if $n > N$, then, with probability at least $1 - \delta$, $\log p_G(s) < -n(H_{G,n}(s) - \varepsilon/2)$ and $\log p_G(t) > -n(H_{G,n}(t) + \varepsilon/2)$. In this case:

$$
\begin{aligned}
p_G(s)/p_G(t(s)) &\leq p_G(s)/p_G(t) \\
&= 2^{\log(p_G(s)) - \log(p_G(t))} \\
&< 2^{-n(H_{G,n}(s)-\varepsilon/2)+n(H_{G,n}(t)+\varepsilon/2)} \\
&= 2^{n(H_{G,n}(t)-H_{G,n}(s)+\varepsilon)}.
\end{aligned}
$$

Since s is completely determined by the tree t, we have that $H_G(s) = H_G(s,t)$, and so:

$$
\begin{aligned}
2^{n(H_{G,n}(t)-H_{G,n}(s)+\varepsilon)} &= 2^{n(H_{G,n}(t)-H_{G,n}(s,t)+\varepsilon)} \\
&= 2^{n(H_{G,n}(t|s)+\varepsilon)}
\end{aligned}
$$

Thus:

Theorem 7.1 *If the grammar G, taken as a generative process, is ergodic and stationary, then for any* $\varepsilon, \delta > 0$ *there is a number* n *such that, for any tree with at least* n *leaves:*

$$\log\left(p_G(s)/p_G(t(s))\right) \leq n(H_{G,n}(t|s) + \varepsilon)$$

with probability greater than $1 - \delta$.

Even if the grammar is not stationary and ergodic, we can ask what happens when we hold the grammar fixed and draw sentences from it, as is the case in typical NLP applications. In this case, the expected value of $log(p_G(s)/p_G(t))$ is still the conditional entropy $H_G(t|s)$ – we just cannot fix the sentence size. This value is not guaranteed to be an upper bound for the running time of the algorithm, or even for the logarithm of the expected value of $(p_G(s)/p_G(t))$.

Instead, we can look at the second moment $\nu_G(t|s)$ of $log(p_G(s)/p_G(t))$ in order to bound the overall likelihood of encountering a high-running-time input: For any $\delta > 0$, we can find a c such that the probability of drawing an s such that $log(p_G(s)/p_G(t)) > H_G(t|s) + c\nu_G(t|s)$ is less than δ. Thus:

Theorem 7.2 *Suppose we hold G constant and draw trees t from it, and that s is the yield of t. Then, for any* $\delta > 0$ *there is a c such that:*

$$p_G(s)/p_G(t(s)) < 2^{H_G(t|s)+c\nu_G(t|s)}$$

with probability greater than $1 - \delta$.

This bound unfortunately does not tell us how the problem difficulty scales with the sentence length n, but it does give us a sense of how difficult the MPS problem will be for a given grammar. While it is true that finding the exact values for either $H_G(t|s)$ or $\nu_G(t|s)$ is undecidable for general pCFGs, these values are can be given rough bounds – for example $H_G(t|s)$ is bounded above by the tree entropy $H_{G,n}(t)$. Finding better bounds is clearly an area for future research. Further discussion of the variance of the tree entropy can be found in (Chi, 1999).

8 Other Applications

In this paper, we have only considered the MPS problem, but the same approach can be applied to other inference problems, such as those found in Bayesian networks or CRFs. In particular, suppose that we are performing inference on a graphical model in which:

- we are trying to assign values to a finite set S of hidden variables in order to maximize the probability p of an event E, based on a finite set of hidden variables,
- we can build partial solutions to our inference problem by assigning values to one or more of these variables,
- we can use the probability of E over the partial solutions, or an approximation thereof, as an A^* heuristic on these partial solutions,
- extending nodes can always proceed according to an order defined as a function of the input (but independently of the node being expanded or its score), and
- extending nodes in the A^* search will partition its score among the child nodes.

If all of these conditions are met, then the A^* search above will still solve the problem, and will admit the same analysis. If the probability of E with no constraints is $p_0(E)$ and the probability of E under the optimal constraints is $p^*(E)$, the ratio $p_0(E)/P^*(E)$ will fill the same role as the ratio $p_G(s)/p_G(t)$ in our above analysis, and can be used to create a similar entropic bound. The main difficulty lies in the time we take to find the probability $p(E)$ given a set of constraints. This time will be application-dependent: in our case it took $\mathcal{O}(n^3)$ time. Our current method will generalize to any task in which the $p(E)$ value can be efficiently found.

9 Conclusions

Our analysis tells us something about how a particular NP-complete problem – the MPS problem for pCFGs – relates to a specific property of grammars. Our worst case running time is $\mathcal{O}(n^4 2^{n(H_{G,n}(t|s)+\varepsilon)})$ with high probability. Slightly more promising is that, when we draw a sentence s, it will take at most $2^{H_G(t|s)+c\nu_G(t|s)}n^4$ steps with probability $1-\delta$, where ν is the second moment of the entropy and c depends on δ. If we perform early stopping on the search, the product of the running time with the error will have the same bound. More practically, if we can determine that the ratio $p_G(s)/p_G(\tau(s))$ is small, our algorithm will have a much quicker run time.

Even in the worst-case scenario, the problem complexity collapses if we can break a sentence into several smaller instances. While we cannot do so in the grammar given by Sima'an (2002), it is possible in many NLP grammars. Roark and Hollingshead (2008) showed, for example, that we can find clause boundaries in sentences generated by the Penn Treebank grammar both quickly and reliably. Future work should focus on formalizing this for the MPS problem.

Probing the Probing Paradigm:
Does Probing Accuracy Entail Task Relevance?

Abstract

Although neural models have achieved impressive results on several NLP benchmarks, little is understood about the mechanisms they use to perform language tasks. Thus, much recent attention has been devoted to analyzing the sentence representations learned by neural encoders, through the lens of 'probing' tasks. However, to what extent was the information encoded in sentence representations, as discovered through a probe, actually used by the model to perform its task? In this work, we examine this probing paradigm through a case study in Natural Language Inference, showing that models can learn to encode linguistic properties even if they are not needed for the task on which the model was trained. We further identify that pretrained word embeddings play a considerable role in encoding these properties rather than the training task itself, highlighting the importance of careful controls when designing probing experiments. Finally, through a set of controlled synthetic tasks, we demonstrate models can encode these properties considerably above chance-level *even when distributed in the data as random noise*, calling into question the interpretation of absolute claims on probing tasks.[1]

1 Introduction

Neural models have established state-of-the-art performance on several NLP benchmarks (Kim, 2014; Seo et al., 2017; Chen et al., 2017; Devlin et al., 2019). However, these models can be opaque and difficult to interpret, posing barriers to widespread adoption and deployment in safety-critical or user-facing settings (Belinkov and Glass, 2019). How can we know what information, if any, neural models learn and leverage to perform a task? This question has spurred considerable community effort to develop methods to analyze neural models, motivated by interest not just to have models perform tasks well, but also to understand the mechanisms by which they operate.

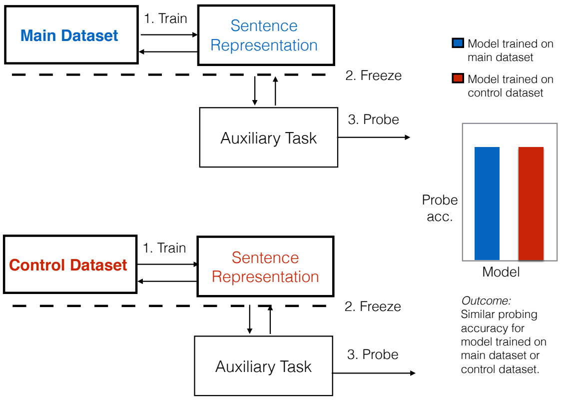

Figure 1: Illustration of our control dataset methodology for evaluating probing classifiers. Control datasets are constructed such that a linguistic feature is not discriminative with respect to the task. Representations from models trained on the main dataset and control dataset are probed for the linguistic feature, and demonstrate similiar probing performance.

A popular approach to model introspection is to associate the representations learned by the neural network with linguistic properties of interest, and examine the extent to which these properties can be recovered from the representation (Adi et al., 2017). This paradigm has alternatively been called probing (Conneau et al., 2018), auxiliary prediction tasks (Adi et al., 2017) and diagnostic classification (Veldhoen et al., 2016; Hupkes et al., 2018). As an example of this approach, let us walk through an application to analyze information about tense stored in a Natural Language Inference (NLI) model. In Conneau et al. (2018), three sentence-encoder models are trained on a

NLI dataset (MultiNLI; Williams et al., 2018). The encoder weights are frozen, and the encoders are then used to form sentence representations for the auxiliary task— predicting the tense of the verb in the main clause of the sentence. A separate classifier, henceforth called the probing classifier, is trained to predict this property based on the constructed representation. The probing task itself is typically selected to be relevant to the training task, and high probing performance is considered as evidence that the property is encoded in the learned representation. Due to its simplicity, a growing body of work uses this approach to pinpoint the information models rely on to do a task (Alt et al., 2020; Giulianelli et al., 2018; Saleh et al., 2020).

In this work, we examine the connection between the information encoded in a representation and the information a model relies on. Through a set of carefully designed experiments on the benchmark SentEval probing framework (Conneau et al., 2018), we shed light on information use in neural models. Our story unfolds in four parts:

1. First, we establish careful control versions of the training task such that task performance is invariant to a chosen linguistic property (Figure 1). We show that even when models cannot use a linguistic property to perform the task, the property can be reliably recovered from the neural representations through probing (§4.1).

2. Word embeddings could be a natural suspect for this discrepancy. We demonstrate that initializing models with pretrained word embeddings does play a role in encoding some linguistic properties in sentence representations. We speculate that probing experiments with pretrained word embeddings conflate two tasks — training word embeddings and the main task under consideration (§4.2).

3. What happens if we neutralize the effect of pre-trained word embeddings? Even when word embeddings are trained from scratch, we demonstrate that models still encode linguistic properties when they are not actually required for a task (§4.3).

4. Finally, through a carefully controlled synthetic scenario we demonstrate that neural models can encode information incidentally, even if it is distributed as random noise with respect to the training task (§5). We discuss several considerations when interpreting the results of probing experiments and highlight avenues for future research needed in this important area of understanding models, tasks and datasets (§6).

2 Background and Related Work

Progress in Natural Language Understanding (NLU) has been driven by a history of defining tasks and corresponding benchmarks for the community (Marcus et al., 1993; Dagan et al., 2006; Rajpurkar et al., 2016). These tasks are often tied to specific practical applications, or to developing models demonstrating competencies that transfer across applications. The corresponding benchmark datasets are utilized as proxies for the tasks themselves. How can we estimate their quality as proxies? While annotation artifacts are one facet that affects proxy-quality (Gururangan et al., 2018; Poliak et al., 2018; Kaushik and Lipton, 2018; Naik et al., 2018; Glockner et al., 2018), a dataset might simply not have coverage across competencies required for a task. Additionally, it might consist of alternate "explanations", features correlated with the task label in the dataset while not being task-relevant, which models can exploit to give the impression of good performance at the task itself.

Two analysis methods have emerged to address this limitation: 1) **Diagnostic examples**, where a small number of samples in a test set are annotated with linguistic phenomena of interest, and task accuracy is reported on these samples (Williams et al., 2018; Joshi et al., 2020). However, it is difficult to determine if models perform well on diagnostic examples because they actually learn the linguistic competency, or if they exploit spurious correlations in the data (McCoy et al., 2019; Gururangan et al., 2018; Poliak et al., 2018). 2) **External challenge tests** (Naik et al., 2018; Isabelle et al., 2017; Glockner et al., 2018; Ravichander et al., 2019; McCoy et al., 2019), where examples are constructed, either through automatic methods or by experts, exercising a specific phenomenon in isolation. However, it is challenging and expensive to build these evaluations, and non-trivial to isolate phenomena (Liu et al., 2019).

Thus, **probing** or *diagnostic classification* presents a compelling alternative, wherein learned representations can directly be probed for linguistic properties of interest (Ettinger et al., 2016; Belinkov et al., 2017; Adi et al., 2017; Tenney et al., 2019; Zhang and Bowman, 2018; Warstadt et al., 2019). There has been a variety of research that employs probing to test hypotheses about the mechanisms models used to perform tasks. Shi et al. (2016) examine learned representations in machine translation for syntactic knowledge. Vanmassenhove et al. (2017) investigate aspect in neural machine translation systems, finding that tense information could be extracted from the encoder, but that part of this information may be lost when decoding. Conneau et al. (2018) use probing to examine the correlation between linguistic properties and downstream tasks (including MT and NLI). Hupkes et al. (2018) train a 'diagnostic classifier' to extract information from a sequence of hidden representations in a neural network. If the classifier achieves high accuracy, it is concluded that the network is keeping track of the hypothesized information. Giulianelli et al. (2018) use diagnostic classifiers to predict number from the internal states of a language model. Kim et al. (2019) study what different NLP tasks teach models about function word comprehension. Alt et al. (2020) analyze learned representations in relation extraction, through a set of fourteen probing tasks for relevant linguistic properties. Saleh et al. (2020) examine the representations learned by neural dialog models for insights into what the model learns about engaging in dialog. See the survey by Belinkov and Glass (2019) for many more examples.

Closely related to our work is that of Hewitt and Liang (2019), which studies the role of lexical memorization in probing, and recently the work of Pimentel et al. (2020) and Voita and Titov (2020) who analyze probing from an information-theoretic perspective. These works join an ongoing debate on the correct way to characterize the expressivity of the probing classifier, with the latter proposing ease of extractability as a criterion for selecting appropriate probes. Our work pursues an orthogonal line of inquiry, demonstrating that relying on diagnostic classifiers to interpret model reasoning for a task suffers from a fundamental limitation: properties may be incidentally encoded even when not required for a task. Thus, our work is also related to a broader investigation of how neural models encode information (Tishby and Zaslavsky, 2015; Voita et al., 2019), studying to what extent information encoded in neural representations is indicative of information needed to perform tasks.

3 Methodology

In this section we describe our modified probing pipeline (Figure 1), where we construct control datasets, such that a particular linguistic feature is not required in making task judgements.[2] Control datasets are based on the intuition that a linguistic feature is not informative for a model to discriminate between classes if the linguistic feature remains constant across classes. For a task label T and linguistic property L, when every example in the control dataset has the same value for L, the linguistic property L in isolation is not discriminative of the task label .

To construct control datasets we hold constant the relevant property value across the whole dataset. In practice, the control datasets are constructed from existing large-scale datasets by partitioning them on the value of a linguistic property, such that every example in the sampled dataset has the same value of linguistic property.[3] They are designed with the following considerations:

1. The linguistic property of interest is auxiliary to the main task and a function of the input, but not of the task decision.
2. Every sample in the training and test sets has the same fixed value of the linguistic property.
3. The training set is large in order to train parameter-rich neural classifiers for the task.

We next describe our main training task, our three auxiliary prediction tasks, and procedures to construct control datasets corresponding to each auxiliary property. Models are trained either on datasets constructed for the main task, or on control datasets, and then probed for the auxiliary property using data from a probing dataset. In this work, we use the experimental settings of Conneau et al. (2018) for both the training task and probing task, due to its popularity as a probing benchmark. However, the conclusions we draw are meant to illustrate the limits and generality of probing as a diagnostic method, rather than discuss the specific experimental settings of Conneau et al. (2018).

Main Task: We study the Natural Language Inference (NLI) training task from Conneau et al. (2018) as the main task for training sentence en-

---

[2] While our motivating example of a task is natural language inference, we expect control datasets can be constructed for most text classification tasks with a small finite label space.

[3] All probing tasks in this work take a sentence representation as input and perform mappings to binary labels $\{0, 1\}$.

Linguistic Control	Property	# Train	# Test
MultiNLI	-	392,702	20,000
Tense	Past	69,652	1678
Subject Number	Singular	102,452	2584
Object Number	Singular	43,178	1060

Table 1: Statistics of control datasets partitioned by linguistic property.

coders. NLI is a benchmark task for research on natural language understanding (Cooper et al., 1996; Haghighi et al., 2005; Harabagiu and Hickl, 2006; Dagan et al., 2006; Giampiccolo et al., 2007; Zanzotto et al., 2006; MacCartney, 2009; Dagan et al., 2010; Marelli et al., 2014). Broadly, the goal of the task is to decide if a given hypothesis can be inferred from a premise in a justifiable manner. Typically, this is framed as the 3-way decision of whether a hypothesis is true given the premise (entailment), false given the premise (contradiction), or whether the truth value cannot be determined (neutral). We use MultiNLI (Williams et al., 2018), a broad-coverage NLI dataset, to train sentence encoders.

Auxiliary Tasks: We consider three tasks that probe sentence representations for semantic information from Conneau et al. (2018), all of which "require some understanding of what the sentence denotes". We construct the probing datasets such that lexical items that are associated with the probing task do not occur across the train/dev/test split for the target. This design controls for the effect of memorizing word types associated with target categories (Hewitt and Liang, 2019). The tasks considered in this study are:

1. TENSE: Categorize sentences based on the tense of the main verb.
2. SUBJECT NUMBER: Categorize sentences based on the number of the subject of the main clause.
3. OBJECT NUMBER: Categorize sentences based on number of the direct object of the main clause.

Control: For each auxiliary task, we partition MultiNLI such that premises and hypotheses agree on a single value of the linguistic property. For example, for the auxiliary task TENSE, sentences with VBP/VBZ/VBG forms are labeled as present and VBD/VBN as past tense.[4] Subsequently, premise-hypothesis pairs where the main verbs in both premise and hypothesis are in past tense are extracted from train/dev sets to form the control datasets for tense. Thus, every sentence in the dataset (both premises and hypotheses), has the same value of the auxiliary property.[5]

This procedure results in three control datasets/tasks: MultiNLI-PastTense, MultiNLI-SingularSubject, and MultiNLI-SingularObject. For all three, we fix the value of the linguistic property to the one that results in the maximum number of training instances on partitioning, namely fixing past tense, singular subject number, and singular object number. Descriptive statistics for each dataset appears in Table 1.

Models: We use CBOW and BiLSTM-based sentence-encoder architectures. The choice of these models is motivated by their demonstrated utility as NLI architectures (Williams et al., 2018), and because their learned representations have been extensively studied for the three linguistic properties used in this work (Conneau et al., 2017).[6]

1. Majority: The hypothetical performance of a classifier that always predicts the most frequent label in the test set.

2. CBOW: A simple Continuous Bag-Of-Words Model (CBOW). The sentence representation is the sum of word embeddings of constituent words. Word embeddings are finetuned during training.

3. BiLSTM-Last/Avg/Max: For a sequence of N words in a sentence $s = w_1 ... w_n$, the bidirectional LSTM (BiLSTM; Hochreiter and Schmidhuber (1997)) computes N vectors extracted from its hidden states $\vec{h}_1, ..., \vec{h}_n$. We produce fixed-length vector representations in three ways: by selecting the last hidden state h_n (BiLSTM-Last), by averaging the produced hidden states (BiLSTM-Avg) or by selecting the maximum value for each dimension in the hidden units (BiLSTM-Max).

---

[4] These heuristics are specific to English, as is MultiNLI. We use the Stanford Parser for constituency, POS and dependency parsing (Manning et al., 2014).

[5] This procedure replicates the original SentEval probing labels (Conneau et al., 2018) with 89.37% accuracy on tense, 87.77% accuracy on subject number and 88.19% accuracy on object number.

[6] We leave an exploration of recent transformer-based architectures to future work, noting however that this study stands alone as evidence that probing performance does not correlate to task importance.

	Tense		Subject Number		Object Number

BiLSTM-Last-PT	63.89	78.44	66.18	78.9	66.04	72.82

Table 2: Performance comparisons of task-controlled (PT) and downsampled models (DS). Dev-ST, Dev-SS and Dev-SO is the MultiNLI development set controlled for tense, subject number and object number, respectively. PT is a model trained on data partitioned by linguistic property—these models should not be able to leverage the linguistic property to perform their training task. DS is models trained on downsampled MNLI data to match the number of instances in partitioned. Majority baseline reflects distribution of main task classes for controlled development sets (Dev-ST, Dev-SS and Dev-SO), or class distribution of auxiliary property for probing datasets. We can observe that models consistently display similar probing accuracies whether the property was needed for the training task or not (Probing). Competitive performance of PT model variants to DS model variants on controlled MNLI development sets (Dev-ST, Dev-SS, Dev-SO) validates the controlled linguistic property is not useful to solve the controlled version of the task.

All models produce separate sentence vectors for the premise and hypothesis. They are concatenated with their element-wise product and difference (Mou et al., 2016), passed to a `tanh` layer and then to a 3-way softmax classifier. Models are initialized with 300D GloVe embeddings (Pennington et al., 2014) unless specified otherwise, and implemented in Dynet (Neubig et al., 2017). After the model is trained for the NLI task, the learned sentence vectors for the premise and hypothesis are probed. The probing classifier is a 1-layer multilayered perceptron (MLP) with 200 hidden units.

4 Probing the Probing Paradigm

4.1 Probing with Linguistic Controls

As a first step, we ask the question: to what extent is the information encoded in learned representations, as reflected in probing accuracies, driven by information that is useful for the training task? We construct multiple versions of the task (both training and development sets) where the entailment decision is independent of the given linguistic property, through careful partitioning as described in §3. To control for the effect of training data size, we downsample MultiNLI training data to match the number of samples in each partitioned version of the task. These results are in Table 2.

Strikingly, we observe that even when models are trained on tasks that *do not require the linguistic property at all* for the main task (rows with PT in Table 2), probing classifiers still exhibit high accuracy (sometimes up to ∼80%). Probing data is split lexically by target across partitions, and thus lexical memorization (Hewitt and Liang, 2019) cannot explain why these properties are encoded in the sentence representations. Across models, on the version of the task where a particular linguistic property is not needed, classifiers trained on data that does not require that property perform comparably to classifiers trained on MultiNLI training data (DS vs PT models, on Dev-ST, Dev-SS, and Dev-SO).

4.2 Effect of Word Embeddings

A potential explanation lies in our definition of a "task". Previous work directly probes models trained for a target task such as NLI. However, when models are initialized with pre-trained word embeddings, the conflated results of two tasks are being probed – the main training task of interest, and the task that was used to train the word embeddings. Both tasks may contribute to the encoding of information in the learned representation, and it is unclear to what extent they interact. Previous work has noted the considerable amount of information

	Tense		Subject Number		Object Number

BiLSTM-Last-Rand	62.14	62.96	61.88	67.45	62.29	61.32

Table 3: Performance comparisons of models initialized with pretrained word embeddings (Word) and models with randomly initialized embeddings (Rand) on MNLI Development Set (Dev) and on the probing task (Probing). Embeddings are updated during task-specific training. We can observe that probing performance decreases sharply for all models when word embeddings are randomly initialized, suggesting a considerable component of probing performance comes from pretraining word embeddings rather than what a model learns during the task.

present in word embeddings, and proposed methods to measure this effect, such as comparing with bag-of-word baselines or random encoders (Wieting and Kiela, 2018). However, these methods fail to isolate the contribution of the training task.

To study this, we compare models initialized with pre-trained word embeddings (Pennington et al., 2014) and then trained for the main task, to models initialized with random word embeddings and then updated during the main task. These results are presented in Table 3. We observe that probing accuracies drop across linguistic properties in this setting (compare rows with Word and Rand in the table), indicating that models with randomly initialized embeddings generate representations that contain less linguistic information than the models with pretrained embeddings. This result calls into question how to interpret the contribution of the main task to the encoding of a linguistic property, when the representation has already been initialized with pre-trained word embeddings. The word embeddings could themselves encode a significant amount of linguistic information, or the main task might contribute to encoding information in a way already largely captured by word embeddings.

4.3 How do models encode linguistic properties?

When we isolate the effect of the main task with randomly initialized word embeddings, are properties not predictive of the main task judgement *still* being encoded? To study this, we revisit our linguistic control tasks but train all models with randomly initialized word embeddings. We also train comparable models on downsampled MultiNLI training data. These results can be found in Table 4. We observe that even in the setting with randomly initialized word embeddings, these properties are still encoded to a similar extent (and above the majority baseline) in the downsampled and control versions of their task.

5 A Synthetic Experiment: Analyzing Encoding Dynamics

We have demonstrated that models encode properties even when they are not required for the main task. Thus, probing accuracy cannot be considered indicative of competencies any given model relies on. What circumstances could lead to models encoding properties incidentally? Can we determine when a linguistic property is not needed by a model for a task? To study this, we build carefully controlled synthetic tests, each capturing a kind of noise that could arise in datasets.

5.1 Synthetic Task

We consider a task where the premise P and hypothesis H are strings from $S = \{(a|b)(a|b|c)^*\}$ of maximum length 30, and the hypothesis H is said to be entailed by the premise P if it begins with the same letter a or b,[7] for example:

---

[7] A task with a similar objective was used by Belinkov et al. (2019a) to demonstrate unlearning bias in datasets. The task is equivalent to XOR, which is learnable by an MLP.

	Tense		Subject Number		Object Number	
	Dev-ST	Probing	Dev-SS	Probing	Dev-SO	Probing
Majority	37.90	50.0	36.88	50.0	39.52	50.0

Table 4: Performance of task-controlled (PT) and downsampled models (DS), when word embeddings are trained from scratch. (Rand) indicates the model is initialized with random embeddings, rather than pretrained embeddings. Dev-ST, Dev-SS and Dev-SO is the MultiNLI development set controlled for tense, subject number and object number, respectively. We observe that when the training task is isolated in this way, for all models probing performance is similar whether a linguistic property is necessary for the task or not (Probing).

(a, ab) → Entailed
(b, ba) → Entailed
(b, bc) → Entailed

(a, ba) → Not Entailed
(b, ab) → Not Entailed
(b, acb) → Not Entailed

Consider the auxiliary task of predicting whether a sentence contains the character c from a representation, analogous to probing for a task-irrelevant property. We sample premises/hypotheses from a set of strings $S' = (a|b)^*$ of maximum length 30, and simulate four kinds of correlations that could occur in a dataset by inserting c at a random position in the string after the first character:[8]

1. NOISE : The property could be distributed as noise in the training data. To simulate this, we insert c into 50% of randomly sampled premise and hypothesis strings.
2. UNCORRELATED : The property could be unrelated to the task decision, but correlated to some other property in the data. To simulate this, we insert c to premises beginning with a.
3. PARTIAL: The property could provide a partial explanation for the main task decision. To simulate this, we insert c to premise and hypothesis strings beginning with a.[9]

Dataset	# Train	# Dev	# Test
NOISE	20000	5000	5000
UNCORRELATED	20000	5000	5000
PARTIAL	20000	5000	5000
FULL	20000	5000	5000
PROBE	23732	5000	5000

Table 6: Descriptive statistics for NOISE, UNCORRELATED, PARTIAL and FULL synthetic datasets, as well as the dataset used to train the probing classifier(PROBE). We ensure that datasets do not have any data leakage in the form of strings appearing across train/dev/test splits, or across task and probing splits in either the main task or the probing dataset.

4. FULL: The property provides a complete alternate explanation for the main task decision. We insert c to premise and hypothesis strings whenever the hypothesis is entailed.

Descriptive statistics of all datasets are in Table 6.

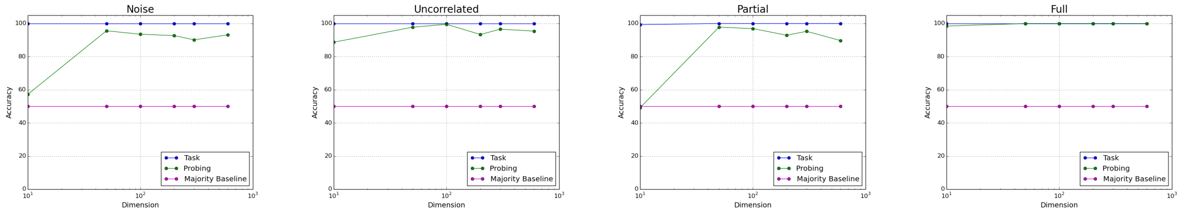
5.2 Results

Figure 2a presents the performance of the model and the probe on the four test sets. We observe that we are able to train a classifier to predict the presence of c considerably above chance-level in all four cases. This is notable, considering that even when the property is distributed as random noise (NOISE) uncorrelated with the actual task, the

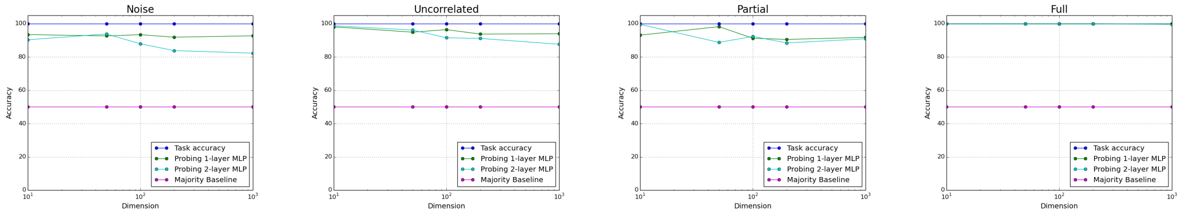
---

[8] We additionally explore the utility of adversarial learning, as a potential approach to identifying properties required by a model to perform a task, by suppressing a property and measuring task performance (Appendix. A). We find in our exploration that adversarial approaches are not completely successful at suppressing the linguistic property under consideration, though capacity of the adversary could play a role.

[9] Models can use either the presence of c, or the first character of the strings being a to make their prediction, but they must use whether the first character of the strings is b.



(a) Main Task and Probing Accuracy as a function of capacity of sentence representation (# units).



(b) Main Task and Probing Accuracy as a function of capacity of probing classifier (# units).

Figure 2: Task and probing accuracy of (BiLSTM, last) on Noise, Uncorrelated, Partial and Full synthetic datasets.

model encodes it. This simple synthetic task suggests that models learn to encode linguistic properties *incidentally*, implying it is a mistake to rely on the accuracy of probes to measure what information the model relies upon to solve a task. We further discuss the role of representation capacity and probing classifier expressivity:

Representation size: Lower-capacity models may encode task-specific information at the expense of irrelevant properties. To examine this, we train the BiLSTM architecture with hidden size 10, 50, 100, 200, 300 and 600 units, and train the probing classifier on the auxiliary task. These results are reported in Figure 2a. We observe that while the main task accuracy remains consistent across choice of dimension, probing accuracy decreases for models with lower capacity across categories. This suggests that the capacity of the representation may play a role in which information it encodes, with lower capacity models being less prone to incidentally encoding irrelevant information.

Probing classifier capacity: We examine whether probing classifier capacity is a factor in the incidental encoding of linguistic properties. A more complex probing classifier may be more effective at extracting linguistic properties from representations. We experiment with probing classifiers utilizing 1-layer and 2-layer MLP's of dimensions $\{10, 50, 100, 200, 1000\}$. The results are shown in Figure 2b. We find that a higher-capacity probing classifier does not necessarily imply higher probing accuracy. Further, in all the settings of probing classifier capacity we study, we are able to perform the auxiliary task considerably above chance accuracy, even when the property is distributed as random noise.

6 Discussion

We briefly discuss our findings, with the goal of providing considerations for deciding which inferences can be drawn from a probing study, and highlighting avenues for future research.

Linguistic properties can be incidentally encoded: Probing only indicates that some property correlated with a linguistic property of interest is encoded in the sentence representation — but we speculate that it cannot isolate what that property might be, whether the correlation is meaningful, or how many such properties exist. As shown in the controlled synthetic tests, even if a particular property is not needed for a task, the information can be extracted from the representation with high accuracy. Thus, probing cannot determine if the property is actually needed to do a task, and should not be used to pinpoint the information a model is relying upon. A negative result here can be more meaningful than a positive one. Adversarially suppressing the property may help determine if an alternate explanation is readily available to the model, with an appropriate choice of probing classifier. In this case, if the model maintains task accuracy while suppressing the information, one can conclude the property is not needed by the model for the task, but its failure to do so is not indicative of property importance. Causal alternatives to probing classifiers that intervene in model representations to examine effects on prediction also present another promising direction for future work (Giulianelli et al., 2018; Bau et al., 2018; Vig et al., 2020).

Careful controls and baselines: We emphasize the need for probing work to establish careful controls and baselines when reporting experimental results. When probing accuracy for a linguistic competence is high, it may not be directly attributable to the training task. In this work we identify two confounds: incidental encoding and interaction between training tasks. Perhaps future work will determine causes of incidental encoding and identify further baselines and controls that allow reliable conclusions to be drawn from probing studies.

Lack of gold-standard data of task requirements: While prior work has discussed the different linguistic competencies that might be needed for a task based on the results of probing studies, these claims are inherently hard to reliably quantify given that the exact linguistic competencies, as well as the extent to which they are required, are difficult to isolate for most real-world datasets. Controlled test cases (such as those in §5.1) are effective as basic sanity checks for claims based on diagnostic classification, and provide insight into encoding dynamics in sentence representations.

Datasets are proxies for tasks, and proxies are imperfect reflections: Finally, we speculate that while datasets are used as proxies for tasks, they might not reflect the full complexity of the task. Aside from having dataset-specific idiosyncrasies in the form of unwanted biases and correlations, they might also not require the full range of competencies that we expect models to need to succeed on the task. Future work should refine or move beyond the probing paradigm to carefully identify what the competencies reflected in any dataset are, and how representative they are of overall task requirements.

What probes are good for: This work explores only the implications of probing as a diagnostic tool for pinpointing the information models use to do a task. However, when sentence representations are used subsequently downstream (after being trained on the main task), probing can give insight into what information is encoded in the model (irrespective of how that encoding came to be). Future work could include exploring the connection between information encoded in the representation and whether models successfully learn to use them in downstream tasks.

7 Conclusion

The probing paradigm has evoked considerable interest as a useful tool for model interpretability. In this work, we examine the utility of probing for providing insights into what information models rely on to do tasks, and requirements for tasks themselves. We identify several considerations when probing sentence representations, most strikingly that linguistic properties can be incidentally encoded even when not needed for a main task. This line of questioning highlights several fruitful areas for future research: how to successfully identify the set of linguistic competencies necessary for a dataset, and consequently how well any dataset meets task requirements, how to reliably identify the exact information models rely upon to make predictions, and how to draw connections between information encoded by a model and used by a model downstream.

Full	20000	5000	5000
Attacker	23732	5000	5000

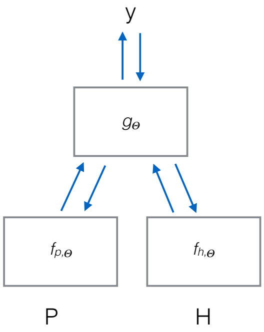
Table 7: Number of train/dev/test examples in constructed synthetic datasets.

A Adversarial Learning Framework

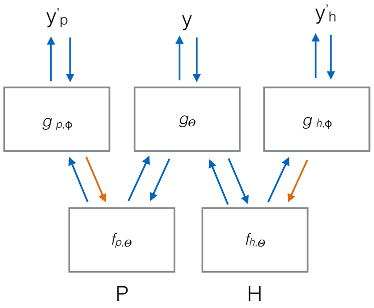
We explore an adversarial framework, as a potential approach to identifying incidentally-encoded properties. We study the utility of this framework within the controlled setting of the synthetic task described in Section 5, where a hypothesis H is entailed by a premise P, if they both begin with the same letter 'a' or 'b'.

We train an adversarial classifier to suppress task-irrelevant information, in this case the presence of 'c'. The goal is to analyze whether adversarial learning can help a model ignore this information while maintaining task performance. If the model succeeds, it indicates the model does not need the linguistic property for the task. Table **??** provides descriptive statistics for Noise, Uncorrelated, Partial and Full synthetic datasets, as well as the probing dataset used to train the external attack classifier. We ensure that datasets do not have any data leakage in the form of strings appearing across train/dev/test splits, or across task and probing splits in either the main task or the external held-out attacker dataset.

We follow the adversarial learning framework illustrated in Figure 3. In this setup, we have premise-hypothesis pairs $\langle p_1, h_1 \rangle ... \langle p_n, h_n \rangle$ and entailment labels $y_1 ... y_n$, as well as labels for linguistic properties in each premise–hypothesis pair $\langle z_{p,1}, z_{h,1} \rangle ... \langle z_{p,n}, z_{h,n} \rangle$. We would like to train sentence encoders f(p_i, θ) and f(h_i, θ) and a classification layer g_θ such that $y_i = g_\theta$ (f(p_i, θ), f(h_i, θ)), in a way that does not use $\langle z_{p,i}, z_{h,i} \rangle$. We do this by incorporating an *adversarial* classification layer g_ϕ such that $\langle z_{p,i}, z_{h,i} \rangle$ = $\langle g_\phi$(f(p_i, θ)), g_ϕ(f(h_i, θ)$\rangle$ (Goodfellow et al., 2014; Ganin and Lempitsky, 2015). Following Elazar and Goldberg (2018), we also have an external 'attacker' classifier ϕ' to predict $z_{p,i}$ and $z_{h,i}$ from the learned sentence representation.[10] A similar setup has been used by Belinkov et al. (2019b) to remove hypothesis-only biases from NLI models.



(a) Baseline



(b) Adversarial removal.

Figure 3: Illustration of (a) The baseline NLI task architecture, and (b) Adversarial removal of linguistic properties from the representations. Arrows represent direction of propagation of inputs in the forward pass and gradients in backpropagation. Blue and orange arrows correspond to the gradient being preserved and reversed respectively.

In training the adversarial classifier is trained to predict z from the sentence representations $f_\theta(p_i, h_i)$, and the sentence encoder f is trained to make the adversarial classifier unsuccessful at doing so. This is operationalized through the following training objectives optimized jointly:

$$\begin{aligned}\arg\min_{\phi} & \, L(g_\phi(f(p_i, \theta), z_{p,i})) \\ & + L(g_\phi(f(h_i, \theta), z_{h,i})) \quad (1)\end{aligned}$$

$$\begin{aligned}\arg\min_{f,\theta} & \, L(g_\theta(f_\theta(p_i, h_i)), y_i) - (L \\ & (g_\phi(f(p_i, \theta), z_{p,i}) + L(g_\phi(f(h_i, \theta), z_{h,i}))) \quad (2)\end{aligned}$$

where L is cross-entropy loss. The optimization is implemented through a Gradient Reversal Layer (Ganin and Lempitsky, 2015) g_λ which is placed between the sentence encoder and the adversarial classifier. It acts as an identity function in the forward pass, but during backpropogation scales the

---

[10] We train the attacker on a held-out dataset with the linguistic property distributed as random noise (Table **??**). We also ensure all examples in the attacker data are unseen in the main task, to prevent data leakage.

gradients by a factor $-\lambda$ [11], resulting in the objective:

$$\arg\min_{f,\theta} L(g_\theta(f_\theta(p_i,h_i)),y_i) + L(g_\phi(g_\lambda(f(p_i,\theta))),z_{p,i}) + L(g_\phi(g_\lambda(f(h_i,\theta))),z_{h,i}) \quad (3)$$

Implementation details : We implemented the adversarial model using the Dynet framework (Neubig et al., 2017), with a BiLSTM architecture of hidden dimension 200 units. Fixed length vector representations are constructed using the last hidden state and the model is trained for 10 epochs using early stopping. The attacker classifier is a 1-layer MLP with hidden size of 200 dimensions.

Results Table 8 reports the performance of the adversarial and attacker classifiers on the four test sets. We observe that information about irrelevant properties can be extracted by attackers even under adversarial suppression, consistent with the findings of Elazar and Goldberg (2018) and Belinkov et al. (2019b). In the case of random noise, we do not find any setting of adversary weight λ that suppresses the attribute. We further explore issues of adversarial classifier strength:

Adversarial classifier capacity: A more powerful adversarial classifier may be more effective at suppressing task-irrelevant information. To examine this, we fix the attacker classifier and experiment with adversarial classifiers with 1-layer and 2-layer MLP probes and dimensions 100, 200, 1000, 5000 and 10000 units, as reported in Figure 4. We find that varying the capacity of the adversarial classifier can decrease the attacker accuracy, though the choice of capacity depends on the setup used.

Considerations: 1) In synthetic tests, the main task function is learnable by a neural network. However, in practice for most NLP datasets this might not be true, making it difficult for models to reach comparable task performance while suppressing correlated linguistic properties. 2) Information might be encoded, but may still not be recoverable by the choice of probing classifier[12]. 3) Adversarial learning does not remove all information from the representation (Elazar and Goldberg, 2018). 4) If comparable task accuracy can't be reached, one cannot conclude a property is not relevant.[13]

---

[11] λ controls the extent to which we try to suppress the property.

[12] All claims related to probing task accuracy, as in most prior work, are with respect to the probing classifier used.

[13] This could be because the main task might be more complex to learn or unlearnable, or multiple alternate confounds could be present in data which are not representative of the decision-making needed for the main task.

One-class Text Classification
with Multi-modal Deep Support Vector Data Description

Abstract

This work presents *multi-modal deep SVDD (mSVDD)* for one-class text classification. By extending the uni-modal SVDD to a multiple modal one, we build *mSVDD* with multiple hyperspheres, that enable us to build a much better description for target one-class data. Additionally, the end-to-end architecture of *mSVDD* can jointly handle neural feature learning and one-class text learning. We also introduce a mechanism for incorporating negative supervision in the absence of real negative data, which can be beneficial to the *mSVDD* model. We conduct experiments on *Reuters* and *20 Newsgroup* datasets, and the experimental results demonstrate that *mSVDD* outperforms uni-modal SVDD and *mSVDD* can get further improvements when negative supervision is incorporated.

1 Introduction

One-Class Classification (OCC), a special classification problem, aims to learn a model on the basis of training samples only from *one* class. The learned model is expected to make an accurate description of the class (so called *target* or *normal*) and then to distinguish the *target* from samples for negative classes during testing (Moya et al., 1993; Tax, 2002). The one-class classification problem has arisen in many real-world applications, including anomaly or novelty detection (Roberts, 1999; Chandola et al., 2010; Gupta et al., 2013), bioinformatics (Alashwal et al., 2006), and especially computer vision (Rodner et al., 2011; Ruff et al., 2018).

One-class text classification would be beneficial to the scenario where anomalous text contents (e.g., web pages, spam emails) (Yu et al., 2004) need to be detected, and only a positive training corpus is available. One of the early work on one-class text classification is Manevitz and Yousef (2001), who implemented versions of one-class support vector machines (OC-SVM) (Schölkopf et al., 2001) and showed good performances over the *Reuters* dataset (Dumais et al., 1998). OC-SVM and support vector data description (SVDD) (Tax and Duin, 2004) are *boundary*-based methods (Tax, 2002). Both try to describe the target data using a boundary. SVDD learns an optimal hypersphere with the minimum radius to include the most target data, while OC-SVM builds a hyperplane to maximally separate the data points from the origin where outlier examples lie around.

Reconstruction-based approaches, including AutoEncoder (Jacobs, 1995) and principal component analysis (PCA) (Bishop, 1995), which aim to learn a more compact representation for the description of target data. The compact representation could be a set of prototypes or subspaces obtained by optimizing a reconstruction error on the target training data.

Regarding the features for representing text in OCC, document-to-word co-occurrence matrices or hand-crafted features have been commonly used in most of the previous work (Manevitz and Yousef, 2001, 2007; Kumaraswamy et al., 2015). Pretrained vectors have been popular for many NLP tasks (Mikolov et al., 2013; Bengio et al., 2003). The recent *context vector data description (CVDD)*, proposed by Ruff et al. (2019), fully uses word embedding knowledge and a neural network structure to process one-class classification problems.

Ruff et al. (2018) introduced *deep support vector data description (deep SVDD)*, a fully unsupervised method for deep one-class classification for image data. *Deep SVDD* learns to extract the common factors of target training samples with a neural network to minimize the radius of a hypersphere that encloses the network representations of the data. The learned hypersphere, with a center $\boldsymbol{c}$ and a neural feature transformer $\phi(\boldsymbol{x})$, can be an end-to-end

feature learning and one-class classification model.

Target data samples may have distinctive distributions that are located in different regions. Therefore, uni-modal *deep SVDD* with one hypersphere may not be enough to describe the target samples. In this work, we extend *deep SVDD* to multiple modes, where each mode describes the target samples from a distinctive aspect. Given our *multi-modal deep SVDD*, *mSVDD* in short, we can create an ensemble set of hyperspheres with different centers to build a better one-class model. Ghafoori and Leckie (2020) proposed *deep multi-sphere SVDD* (*DMSVDD*), a similar but different work from ours. We will also discuss the relationship between the two and compare them in the experiments.

In one-class classification, only samples from the target class are available for training, while the model needs to discriminate between the target class and other classes in testing. Due to the unavailability of training samples from negative classes, it is hard for the one-class models to learn effective discrimination information, especially for *mSVDD* with a multi-layer neural structure. In this study, we also propose an architecture for improving the discrimination ability of *mSVDD* by incorporating *negative supervision*. Specifically, we define two kinds of losses, *contrastive* and *triplet*, for joint training with the objective function of *mSVDD*, which is expected to enhance the discriminative power of *mSVDD*.

In summary, the main contributions of this work are as follows. 1) We propose a general one-class neural learning framework, called *mSVDD*, to extend the uni-modal *deep SVDD* to end-to-end multi-modal. 2) We also prove that three one-class models, *deep SVDD, DMSVDD*, and *CVDD*, are all special cases of the *mSVDD* model. 3) We propose two approaches for effectively incorporating negative supervision information to improve the performance of the proposed *mSVDD*.

2 Preliminaries

Before describing our *mSVDD*, we first introduce SVDD (Tax and Duin, 2004) and its extension, *deep SVDD* (Ruff et al., 2018).

2.1 SVDD

SVDD is a support vector learning method for one-class classification. It aims at constructing an optimal boundary in a feature space that includes almost all normal target data, given only the target training samples, $T = \{\boldsymbol{x}_1, ..., \boldsymbol{x}_n\}$, $\boldsymbol{x}_i \in \mathcal{X}$, where $n \in \mathbb{N}$ is the size of the training data, and $\mathcal{X}$ is a compact subset of $\mathbb{R}^d$. The main idea of SVDD is to optimize a hypersphere with a center $\boldsymbol{c}$ and radius R, that encloses the majority of the data. SVDD solves the following quadratic problem:

$$\min_{R,\boldsymbol{c},\boldsymbol{\xi}} \quad R^2 + C\sum_i \xi_i \tag{1}$$

$$s.t.\ \|\boldsymbol{x}_i - \boldsymbol{c}\|_2^2 \leq R^2 + \xi_i,\ \xi_i \geq 0, \quad \forall i = 1, ..., n,$$

where ξ_i is a slack variable for allowing a flexible boundary. C is a regularization parameter, that is usually represented by $\frac{1}{\nu n}$, where $\nu \in (0, 1]$ is a parameter that controls the tradeoff between the radius of the hypersphere and the penalties ξ_i.

Several efforts have been proposed to extend SVDD with multi-spheres. Hao and Lin (2007) was early work to use multi-sphere SVDD, which was used for multi-class tasks. For one-class tasks, (Xiao et al., 2009) used multi-sphere SVDD to encode multi-distribution target data. Two more efforts have been proposed by (Le et al., 2010, 2013), which found the optimal solution by an iterative algorithm consisting of the following two steps: 1) calculate radii and centers, and 2) calculate the assignments of data to centers.

While one limitation of SVDD, along with its extensions, would be that it has to perform hand-crafted feature engineering (Pal and Foody, 2010), the limitation could be solved by incorporating neural models into SVDD.

2.2 Deep SVDD

Deep SVDD (Ruff et al., 2018) is an end-to-end deep neural model that not only optimizes the SVDD objective loss but also learns a neural feature transformation. Given target training samples $T = \{\boldsymbol{x}_1, ..., \boldsymbol{x}_n\}$, *deep SVDD* first transforms instance $\boldsymbol{x}$ into a data point of the output feature space with ϕ, which is a multi-layer neural network of $L \in \mathbb{N}$ layers with parameters $\mathcal{W} = \{\boldsymbol{W}^1, ..., \boldsymbol{W}^L\}$. *Deep SVDD* defines two kinds of loss functions:

Soft-boundary deep SVDD :

$$\frac{1}{\nu n}\sum_i max(0, \|\phi(\boldsymbol{x}_i; \mathcal{W}) - \boldsymbol{c}\|_2^2 - R^2) \\ + R^2 + \frac{\lambda}{2}\sum_l \|\boldsymbol{W}^l\|_F^2 \tag{2}$$

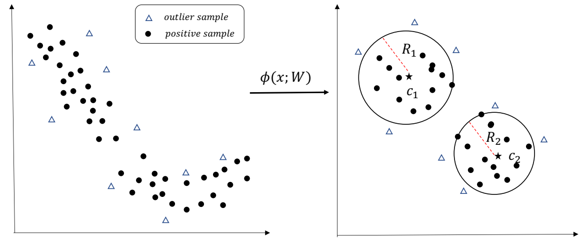

Figure 1: mSVDD with two modes. ϕ is a neural network. Fivestars denote a center, and black points denote positive target samples, while triangles denote negative outliers that need to be rejected by hyperspheres.

The first penalty term is for samples lying outside the sphere, i.e., when the distance of $\boldsymbol{x}_i$ to the center, $\|\phi(\boldsymbol{x}_i; \mathcal{W}) - \boldsymbol{c}\|_2^2$, is greater than radius R after the transformation by network ϕ. The above loss also regularizes the radius and neural weight parameters in the second term. As with SVDD, parameter $\nu \in (0, 1]$ adjusts the tradeoff between the radius of the hypersphere and the points outside the hypersphere.

Schölkopf et al. (2001) proved that, in single-class classification, ν is the upper bound of the fraction of anomalies, and the lower bound of the fraction of training samples being anomalies or on the optimal boundary. Ruff et al. (2018) proved that this ν-property still holds for uni-modal soft-boundary *deep SVDD*.

Another simplified objective that minimizes the mean distance of all positive training samples to the center, the *one-class* form, can be defined as follows:

One-class deep SVDD (simplified form):

$$\frac{1}{n}\sum_i \|\phi(\boldsymbol{x}_i; \mathcal{W}) - \boldsymbol{c}\|_2^2 + \frac{\lambda}{2}\sum_l \|\boldsymbol{W}^l\|_F^2 \quad (3)$$

Here, we can rewrite both the above in a unified form:

$$\mathcal{L}_{DSVDD} = C\sum_i [\|\phi(\boldsymbol{x}_i; \mathcal{W}) - \boldsymbol{c}\|_2^2 - \beta]_+ + \beta + \frac{\lambda}{2}\sum_l \|\boldsymbol{W}^l\|_F^2, \quad (4)$$

where $[\cdot]_+ = max\{0, \cdot\}$, $\beta \in \{0, R^2\}$ and regularization parameter $C \in \{\frac{1}{n}, \frac{1}{\nu n}\}$ correspond to the two types of forms.

3 Multi-Modal Deep SVDD

In this section, we present our *mSVDD*, a method for deep one-class classification. Unlike a uni-modal model with a hypersphere, *mSVDD* uses a set of hyperspheres to describe target class data and to reject samples from negative classes. Figure 1 shows the general idea of *mSVDD* with two modes. Consider that we have m modes, each of which is described by a hypersphere $\boldsymbol{M}_j$ with center $\boldsymbol{c}_j$ and radius R_j; *mSVDD* uses each $\boldsymbol{M}_j$ to describe a distinctive aspect of the target class and then ensemble them. This ensembled deep *mSVDD* model could provide better descriptions for the target data.

As with *deep SVDD*, given target training samples $T = \{\boldsymbol{x}_1, ..., \boldsymbol{x}_n\}$, *mSVDD* first transforms instance $\boldsymbol{x}$ into a data point of the output feature space with ϕ, where ϕ is a deep neural network of $L \in \mathbb{N}$ layers with parameters $\mathcal{W} = \{\boldsymbol{W}^1, ..., \boldsymbol{W}^L\}$. In contrast to *deep SVDD*, *mSVDD* uses m hyperspheres to include almost all of the target data with the minimum radii, i.e., $\frac{1}{m}\sum_{j=1}^m R_j^2$. As in kernel SVDD and *deep SVDD*, it should also punish points lying outside the sphere, i.e., if the distance of $\boldsymbol{x}$ to the center $\boldsymbol{c}$, $\|\phi(\boldsymbol{x}; \mathcal{W}) - \boldsymbol{c}\|_2^2$, is greater than radius R. Since we have a set of hyperspheres $M = \{\boldsymbol{M}_1, ..., \boldsymbol{M}_m\}$, one choice would be to punish $\boldsymbol{x}$ with respect to each hypersphere by adding $\sum_j \max\left(0, \|\phi(\boldsymbol{x}; \mathcal{W}) - \boldsymbol{c}_j\|_2^2 - R_j^2\right)$ to the loss function. However, the above penalty term is very hard, where one sample should satisfy each j-th constraint corresponding to $\boldsymbol{M}_j$. Therefore, we loosen the constraint. Given non-negative *attention weight* α_{ij} for $\boldsymbol{x}_i$ to each $\boldsymbol{M}_j$, the penalty term can be computed as the weighted average over m constraints. Now, only one ensembled constraint is required, i.e., *the sum of radii is greater than the sum distance to the center.* Formally, we can define our *mSVDD* objective as follows:

$$\frac{1}{\nu n}\sum_i \max(0, \sum_j \alpha_{ij}(\|\phi(\boldsymbol{x}_i; \mathcal{W}) - \boldsymbol{c}_j\|_2^2 - R_j^2)) + \frac{1}{m}\sum_j R_j^2 + \frac{\lambda}{2}\sum_l \|\boldsymbol{W}^l\|_F^2, \quad (5)$$

where $\frac{1}{m}\sum_{j=1}^m R_j^2$ is the regularization term for radii from all m hyperspheres to get a closer boundary around the target data. This form can be seen as *mSVDD* with weighted soft-boundary constraints, which we call *soft-boundary mSVDD*.

Although the ν-property, mentioned in Section 2.2, does not hold true for our multi-modal case as it is in general, it is still true when the attention weight α_{ij} is constant for different hyperspheres. This will give us an intuition on the role of ν.

Proposition 1. [1] *The ν-property holds if we set equal attention weight to each hypersphere: i.) ν is an upper bound for the fraction of outlier samples and ii.) ν is a lower bound for the fraction of training samples being rejected or on the optimal boundary.*

3.1 One-class mSVDD (simplified from)

As in *deep SVDD*, we also have the simplified from and called: *one-class*[2] *mSVDD*. If we assume that the majority of the training data is not anomalous, then the radius can be ignored and we can define the simplified *mSVDD* as follows:

$$\frac{1}{n}\sum_{i}\sum_{j}\alpha_{ij}\|\phi\left(\boldsymbol{x}_i;\mathcal{W}\right)-\boldsymbol{c}_j\|_2^2+\frac{\lambda}{2}\sum_{l}\|\boldsymbol{W}^l\|_F^2, \tag{6}$$

where the attention weight α_{ij} will be kept, while the penalty of radius R is deleted.

3.2 Unified Form of mSVDD

We can write the two variants of *mSVDD* (i.e., *soft-boundary mSVDD* and simplified *one-class mSVDD*) in a unified form:

$$\begin{aligned}\mathcal{L}_{\text{mSVDD}} = C\sum_{i}[\sum_{j}\alpha_{ij}\left(\|\phi\left(\boldsymbol{x}_i;\mathcal{W}\right)-\boldsymbol{c}_j\|_2^2-\beta_j\right)]_+\\ +\frac{1}{m}\sum_{j}\beta_j+\frac{\lambda}{2}\sum_{l}\|\boldsymbol{W}^l\|_F^2,\end{aligned} \tag{7}$$

where $\beta_j \in \{0, R_j^2\}$. $\beta_j = 0$ corresponds to simplified *one-class mSVDD*, and $\beta_j = R_j^2$ corresponds to *soft-boundary mSVDD*. For $\boldsymbol{x}_i$ to the j-th hypersphere, attention weight α_{ij} should be inversely proportional to its distance to center $\boldsymbol{c}_j$. Thus, we define: $\alpha_{ij} = \exp(d(\boldsymbol{x}_i,\boldsymbol{c}_j)/\delta))/\sum_{k=1}^{m}\exp(d(\boldsymbol{x}_i,\boldsymbol{c}_k)/\delta)$, where $\delta < 0$ is a temperature hyperparameter.

3.3 Discussions on relationships between mSVDD and other models

Relationship with Uni-modal Deep SVDD Their relationship is obvious and can be summarized by the following proposition.

Proposition 2. *Deep SVDD is a special case of the unified form of mSVDD with one hypersphere used.*

Proof. Obviously, mSVDD becomes uni-modal (Ruff et al., 2018) if we use only one hypersphere, i.e., $m = 1$. ☐

Relationship between mSVDD and CVDD *CVDD* (Ruff et al., 2019) is a one-class model for text data. In *CVDD*, each training sample x_i (i.e., a text) is represented by r self-attention feature vectors $S_i = (\boldsymbol{s}_{i1}, ..., \boldsymbol{s}_{ir})$ (Lin et al., 2017). *CVDD* uses a group of r *context vectors* $C = (\boldsymbol{c}_1, ..., \boldsymbol{c}_r)$ to describe the target one-class data, where $\boldsymbol{c}_k \in \mathbb{R}^p$. *CVDD* tries to reduce the one-to-one *reconstruction* distance between feature vectors S_i and context vectors C. The loss can be defined as:

$$\mathcal{L}_{CVDD} = \frac{1}{n}\sum_{i}\sum_{k}\sigma_{ik}d(\boldsymbol{c}_k,\boldsymbol{s}_{ik}), \tag{8}$$

where $d(\boldsymbol{c}_k,\boldsymbol{s}_{ik})$ computes the distance, and σ_{ik} denotes the attention weight. The following proposition implies the close connection between two to learn one-class text problem.

Proposition 3. *CVDD is a very special case of one-class mSVDD when mSVDD is applied to text-based tasks under certain conditions.*

Proof. W.L.O.G., rewrite the loss function of *one-class mSVDD* in a simplified form for each sample as follows:

$$\begin{aligned}\mathcal{L}_{mSVDD} &= \frac{1}{n}\sum_{i}\sum_{j}\alpha_{ij}\|\phi_j\left(\boldsymbol{x}_i;\mathcal{W}\right)-\boldsymbol{c}_j\|^2\\ &= \frac{1}{n}\sum_{i}\sum_{j}\sigma_{ij}d(\boldsymbol{x}_i,\boldsymbol{c}_j)\approx\mathcal{L}_{CVDD},\end{aligned}$$

where we drop the regularization terms for weights of ϕ and radii, and set $m = r$, $\sigma_{ij} = \alpha_{ij}$, $d(\boldsymbol{x}_i,\boldsymbol{c}_j) = \|\phi_j\left(\boldsymbol{x}_i;\mathcal{W}\right)-\boldsymbol{c}_j\|^2$. $\phi\left(\boldsymbol{x}_i;\mathcal{W}\right)$ has to be a self-attention neural model, $\phi_j\left(\boldsymbol{x}_i;\mathcal{W}\right)$ is the $j-$th feature vector of sample $\boldsymbol{x}_i$, and $\boldsymbol{c}_j$ is the $j-$th context vector of target samples. Now the loss functions of *CVDD* and *one-class mSVDD* are almost the same. ☐

Relationship between mSVDD and DMSVDD *DMSVDD* (Ghafoori and Leckie, 2020) also uses multi-hyperspheres to extend SVDD. The loss function of *DMSVDD* is as follows:

$$\begin{aligned}\mathcal{L}_{\text{DMSVDD}} = \frac{1}{\nu n}\sum_{i}[\|\phi(\boldsymbol{x}_i;\mathcal{W})-\boldsymbol{c}_{i^*}\|_2^2-R_{i^*}^2]_+\\ +\frac{1}{K}\sum_{k}R_k^2+\frac{\lambda}{2}\sum_{l}\|\boldsymbol{W}^l\|_F^2,\end{aligned} \tag{9}$$

---

[1] The proofs of propositions can be found in the appendix.

[2] The term *"one-class"* is used following Ruff et al. (2018). Note that all the models discussed in this paper are one-class models.

where K is the number of hyperspheres[3], $\boldsymbol{c}_{i*}$ is the *nearest center* of sample $\boldsymbol{x}_i$ and R_{i*} is its radius.

Proposition 4. *DMSVDD can be seen as a hard-version of soft-boundary mSVDD if we set the attention weight in some way.*

Proof. In the calculation of the attention weight for *mSVDD* with $\alpha_{ij} = \frac{\exp(d(\boldsymbol{x}_i, \boldsymbol{c}_j/\delta))}{\sum_{k=1}^{m} \exp(d(\boldsymbol{x}_i, \boldsymbol{c}_k)/\delta)}$, the temperature parameter δ could influence the assignment of center c_k. If we set $\delta \to 0^-$, the above formula acts as the *argmin* operation.[4] In this case, $\alpha_{ii*} = 1$ if $i* = \arg\min_{k=1,...,K} d(\boldsymbol{x}_i, \boldsymbol{c}_k)$, and 0 otherwise. Now, we can get the form of *DMSVDD* from *soft-boundary mSVDD* (Eq. 5) through the adjustment of the attention weight. Therefore, we can prove that *DMSVDD* is also a special case of *mSVDD*. □

The above relation illustrates key difference between them: *DMSVDD* puts value on one hypersphere with the largest weight.

3.4 Summarizing mSVDD

We summarize the proposed *mSVDD* in accordance with the discussions presented above. The proposed *multi-modal deep SVDD (mSVDD)* learns a compact description of one-class data with multiple hyperspheres. *mSVDD* is also a generic framework that includes *deep SVDD, CVDD, and DMSVDD* if the corresponding conditions are met.

4 Multi-Modal Deep SVDD with Negative Supervision

In this section, we incorporate negative supervision into the training of *mSVDD*. The SVDD-related models are usually trained with only positive samples from the target one-class, while, if negative samples (samples which should be *rejected*) are available, the models can be extended to train with them to improve the description (Tax, 2002). Note that these samples are *not* necessarily required to be from "*real*" negative class. In our experiment, we use some external data as the *pseudo*-negative samples.

Given a set of extended training samples $T' = \{(\boldsymbol{x}_1, y_1), ..., (\boldsymbol{x}_{n'}, y_{n'})\}$, where the first n samples are labeled $y_i = 1$, denoting positive, whereas the others are labeled $y_i = 0$, which denotes negative samples that should be rejected by *mSVDD*. Our *mSVDD* is represented with m hyperspheres and is formulated as $M = \{\boldsymbol{M}_1(\boldsymbol{c}_1, R_1), ..., \boldsymbol{M}_m(\boldsymbol{c}_m, R_m)\}$. It is required that the positive samples should be inside the m hyperspheres, while the negative samples should lie outside. Given training samples composed of positive and a negative samples, we can first get their corresponding distances to each center $\boldsymbol{c}_j$. The goal of optimization should be to pull the positive samples closer the center and to push the negative ones away. Formally, we define the distance between one sample $\boldsymbol{x}_i$ and one center $\boldsymbol{c}_j$ as $d_{ij} = d(\boldsymbol{x}_i, \boldsymbol{c}_j) = \|\phi(\boldsymbol{x}_i; \mathcal{W}) - \boldsymbol{c}_j\|_2^2$. There are usually two types of losses to obtain the discriminative loss.

Contrastive type: The contrastive-type loss directly optimizes the distance by encouraging the distance between a positive sample and a center to be smaller, while it forces the larger distance to a negative sample:

$$\mathcal{L}_{Con\_d}^{(ij)} = y_i[d_{ij} - R_j^2]_+ + (1 - y_i)\,[R_j^2 - d_{ij}]_+, \tag{10}$$

where R_j^2 can be seen as a *margin* (or *threshold*) with a function that prevents too much effort from being wasted in enlarging/reducing distances (Hadsell et al., 2006).

Triplet type: The triplet-type loss is defined for a pair of positive sample $\boldsymbol{x}_i$ and negative sample $\boldsymbol{x}_{i'}$. If we consider center $\boldsymbol{c}_j$ as an *anchor* representative of target data, the triplet loss punishes only when d_{ij}, the distance from $\boldsymbol{x}_i$ to $\boldsymbol{c}_j$, is greater than $d_{i'j}$, the distance from $\boldsymbol{x}_{i'}$ to $\boldsymbol{c}_j$, with a margin $\tau > 0$:

$$\mathcal{L}_{Tri\_d}^{(ii'j)} = \left[d_{ij} - d_{i'j} + \tau\right]_+. \tag{11}$$

For clarity, Eqs. 10 and 11 show only the two types of losses for one hypersphere. Multi-modal version can be obtained by sum operation over $j \in \{1, ..., m\}$.

The triplet loss forces only positive samples to be closer to the center than negative samples, and the contrastive loss requires only keeping the distances for negative samples above the radius. These two types of objectives are easy to achieve, especially when we assume that negative samples are "*not real*." This can result in failing to make a full use of negative supervision. Therefore, we will reformulate both $\mathcal{L}_{Tri\_d}$ and $\mathcal{L}_{Con\_d}$.

---

[3] In DMSVDD, K changes dynamically. However, we ignore this difference and focus on the comparison of the models.

[4] δ approaches 0 from the negative side.

4.1 Reformulating Contrastive and Triplet Losses

Normalization layer In neural models with the contrastive or triplet loss, it is a common strategy to normalize the feature representations of samples for training stability (Schroff et al., 2015; Wang et al., 2017). Therefore, we apply the normalization to the input vectors: $\hat{\boldsymbol{x}} = \boldsymbol{x}/\sqrt{\sum |x_i|^2 + \epsilon}$, where $\epsilon > 0$ is a value avoiding division by zero.

Reformulation Given a center $\boldsymbol{c}_j$ and positive and negative samples, we can use the probability form in the optimization objective, rather than the two *non-probabilistic* ones: $\mathcal{L}_{Con\_d}$ and $\mathcal{L}_{Tri\_d}$. We introduce $p(y_i = 1|\boldsymbol{x}_i, \boldsymbol{c}_j)$, which is the probability that a hypersphere with center $\boldsymbol{c}_j$ *accepts* the sample $\boldsymbol{x}_i$, and define it as follows:

$$p(y_i = 1|\boldsymbol{x}_i, \boldsymbol{c}_j) = \sigma(s\hat{\boldsymbol{f}}_i^{\,T}\hat{\boldsymbol{c}}_j), \qquad (12)$$

where $\sigma(x) = \frac{1}{1+\exp(-x)}$, $\boldsymbol{f}_i = \phi(\boldsymbol{x}_i; \mathcal{W})$ denotes the feature output vector of $\boldsymbol{x}_i$, and s is a scale hyper-parameter for preventing failed convergence (Wu et al., 2018) after the normalization. For each sample $\boldsymbol{x}_i$, $\boldsymbol{c}_j$ acts as a *pseudo*-weight vector for the classification of the j-th hypersphere of *mSVDD*. Thus, given $p(y_i = 1|\boldsymbol{x}_i, \boldsymbol{c}_j)$, the probability of a sample being accepted by hypersphere $\boldsymbol{M}_j$, we can reformulate the two discriminative losses with the probability.

***Contrastive type loss*:**

$$\begin{aligned}\mathcal{L}_{Con}^{(ij)} &= -y_i \log p(y_i = 1|\boldsymbol{x}_i, \boldsymbol{c}_j) \\ &- (1 - y_i)\log p(y_i = 0|\boldsymbol{x}_i, \boldsymbol{c}_j) \qquad (13) \\ &= -y_i \log \sigma(s\hat{\boldsymbol{f}}_i^{\,T}\hat{\boldsymbol{c}}_j) - (1-y_i)\log \sigma(-s\hat{\boldsymbol{f}}_i^{\,T}\hat{\boldsymbol{c}}_j)\end{aligned}$$

This loss maximizes the likelihood of training positive samples being accepted or negative rejected.

***Triplet type loss*:**

$$\begin{aligned}\mathcal{L}_{Tri}^{(ii'j)} &= \left[\log \sigma(s\hat{\boldsymbol{f}}_{i'}^{\,T}\hat{\boldsymbol{c}}_j) - \log \sigma(s\hat{\boldsymbol{f}}_i^{\,T}\hat{\boldsymbol{c}}_j) + \tau\right]_+ \\ &= [\log p(y_{i'} = 1|\boldsymbol{x}_{i'}, \boldsymbol{c}_j) - \log p(y_i = 1|\boldsymbol{x}_i, \boldsymbol{c}_j) + \tau]_+\end{aligned} \qquad (14)$$

The loss will punish when the log probability of a negative sample is greater than a positive sample with a margin τ.

Algorithm 1: mSVDD with Negative Supervision

```
Input: data_load load training batch from
       $T' = \{(\boldsymbol{x}_1, y_1), \ldots, \boldsymbol{x}_{n'}, y_{n'})\}$
Models: $model$ includes all modules for
        training, $f = \phi(\boldsymbol{x}_i; \mathcal{W})$ is a neural
        feature encoder
Parameters: Hyperparameters $\gamma$, $\nu$, $s$, $\tau$, $\epsilon$
for batch in batch_loader do
    /* load positive and negative
       samples                          */
    d_p, d_n = batch   // size: $n_p == n_n$
    p = $f$.forward(d_p)  // shape: $n_p \times d$
    n = $f$.forward(d_n )  // shape: $n_n \times d$
    Calculate $\mathcal{L}_{mSVDD}$ given (p) (Eq. 7)
    Calculate $\mathcal{L}_{Con|Tri}$ given (p,n) (Eqs. 13
     or 14).
    /* get final loss (Eq. 16)      */
    $\mathcal{L}oss = \mathcal{L}_{mSVDD} + \gamma * \mathcal{L}_{Con|Tri}$
    $\mathcal{L}oss$.backwards()
    $model$.update()
```

4.2 Reformulating Contrastive and Triplet Losses for Multiple Modes

While Eqs. (12), (13), and (14) show the uni-modal case, for the multi-modal one, we have to consider m different centers $\{\boldsymbol{c}_1, \ldots, \boldsymbol{c}_m\}$ in the calculation of the two reformulated discriminative losses. Therefore, we propose two strategies as follows:

$$p(y_i = 1|\boldsymbol{x}_i) = \begin{cases} \max\limits_{1 \leqslant j \leqslant m} p(y_i = 1|\boldsymbol{x}_i, \boldsymbol{c}_j) & \textit{Max} \\ \frac{1}{m}\sum_j p(y_i = 1|\boldsymbol{x}_i, \boldsymbol{c}_j) & \textit{Mean}, \end{cases} \qquad (15)$$

where *Max* references only $\boldsymbol{M}_j$ with the max logit output, while *Mean* takes account of all hyperspheres equally. Then, we can obtain the corresponding *Contrastive* and *Triplet* losses by substituting Eqs. (13) and (14) with the probability term (Eq. (15)).

4.3 Training Loss

The final training loss for the *mSVDD with negative supervision* can be formulated as:

$$\mathcal{L} = \mathcal{L}_{mSVDD} + \gamma\mathcal{L}_{Con|Tri}, \qquad (16)$$

where γ adjusts between the *mSVDD* loss and the discrimination with negative supervision. In the training process, $\mathcal{L}_{Con|Tri}$ will sum the loss from one batch samples with Eqs. (13) and (14). Algorithm 1 provides the training process for *mSVDD* with negative supervision in one epoch. Please see Section B in the appendix for more discussions on the relationship between *mSVDD* and the use of negative supervision.

5 Experiments

5.1 Datasets and Implementation Details

Datasets Experiments were conducted on two datasets: *20 Newsgroups*[5] and *Reuters*[6], which have been commonly used in other one-class text classification work (Manevitz and Yousef, 2001; Ruff et al., 2019). We used the same pre-processing steps as the ones used in earlier work (Ruff et al., 2019), including lowercasing, removing stopwords, and tokenization. We used the external data for negative supervision in the absence of "*real*" labeled negative instances. We followed the similar logic for choosing our external data as the one in the field of pretrained word vectors, in which one general corpus, such as Wikipedia articles, is often adopted as the training dataset (Mikolov et al., 2013). So we also chose one publicly available corpus WikiText-2 (Merity et al., 2016), extracted from Wikipedia articles, as our external data. As shown in Algorithm 1, data loader loads one batch of negative samples, i.e., sentences from WikiText-2, which are labeled with 0.

Encoder For encoding the text input, i.e., $\phi(\boldsymbol{x}, W)$, we used a Bidirectional LSTM with attention (Hochreiter and Schmidhuber, 1997; Xu et al., 2015), with the number of hidden units being 150. For the pre-trained word embeddings, we experimented with GloVe Vectors (Pennington et al., 2014) and set the dimension to 300. In our experiments, we did not adopt the widely used BERT model (Devlin et al., 2019), as Ruff et al. (2019) showed that BERT model did not improve the performance.

Settings As for the optimization of parameters, Adam (Kingma and Ba, 2014) with a base learning rate of 0.001 was used for 50 epochs. The batch sizes were set to 32 and 64 for *Reuters* and *Newsgroups*, respectively. For the initialization of *mSVDD* model, we employed two operation steps. In the absence of negative samples, *mSVDD* was first pre-trained on target samples by using an AutoEncoder with two objectives: 1) warm-up and 2) reducing the *reconstruction* error for the target samples, such that the model could be more robust to noise or anomalous inputs (Jacobs, 1995; Hinton and Salakhutdinov, 2006). An AutoEncoder feed-forward network with a 0.5 compression rate, which consists of an encoder and a decoder, was put on the back of the BiLSTM feature network. Then, the weights of the m hyperspheres in *mSVDD* were initialized by running k-means clustering on the features learned before (Lloyd, 1982). As for the regularization term of *mSVDD*, $\boldsymbol{c}_j$ was regularized (Ng, 2004), and a weight decay with 0.95 was applied for the parameters. As for the number of hyperspheres, different settings, $1, 3, 5, 10$, were tested. For the hyperparameters, we set parameter $s = 1.2$ for scale, $\nu = 0.1$, $\delta = -0.9$ for the attention weight, $\tau = 0.1$ for the triplet loss, $\epsilon = 1\mathrm{e}{-6}$ for norm, and $\gamma = 1$ for the training loss. The results were averaged over 10 runs with different random seeds.

Evaluation metrics The performance was measured by the *area under the receiver operating characteristics* (ROC) curve (AUCs), a commonly used metric for one-class text classification (Manevitz and Yousef, 2001; Ruff et al., 2019).

5.2 Results

5.2.1 Results of mSVDD

Table 1 shows the performance of *mSVDD* with different choices of m, i.e., the number of hyperspheres. Here, mSVDD(1) represents unimodal *deep SVDD* ((Ruff et al., 2018)). The results show that: 1) As for the *one-class* version, *mSVDD* could provide better performances than the uni-modal one, especially when more hyperspheres were used. We can see that mSVDD(10), which uses the largest number of m, outperforms mSVDD(1) in more times than mSVDD(5) and mSVDD(3), that performs comparable with unimodal *mSVDD*. Similar results can also be observed in *soft-boundary*, *mSVDD* with more hyperspheres (10 or 5) won more times, nine out of thirteen cases in two datasets, than other settings. This proves the necessity of incorporating more hyperspheres to better describe the target data.

2) While the performance of *mSVDD* did not improve linearly along with m, we can explain this from the following aspects. As for the model, *mSVDD* with more centers means that it has more

Table 1: mSVDD with different settings of m. Numbers in brackets denote the number of hyperspheres in mSVDD. *One-v* and *Soft-v* denote the two versions of mSVDD, *One-class* and *Soft-boundary*, respectively. AUCs in % on the *Reuters* (upper part) and *20 Newsgroup* (lower part) datasets. Best scores in each *row* are presented in **bold**, while the second best are underlined.

parameters and a complex model structure, which is hard to be optimized, especially on the data with a small training size (e.g., *pol* or *rel*.) As for the data, some data might have simple data distributions without the need for more modes. Another aspect would be the attention weights of multiple hyperspheres. (Ghafoori and Leckie, 2020) showed that focusing on some "*good*" hyperspheres would be beneficial rather than over all hyperspheres. In the calculation of attentions, we did not adjust δ so as to have a large weight for one specific hypersphere. This may cause limited improvements. We will compare mSVDD with DMSVDD later.

5.2.2 Results of mSVDD with negative supervision

Table 2 shows the performance of *mSVDD* trained with negative supervision and compares the results with the other methods. From the discussion in the last subsection, we used $m = 3$ in this subsection. To perform negative supervision for *mSVDD*, we evaluated four approaches where different losses and their reformulated probability forms were selected. For the method of *DMSVDD*, we report the results in the setting of the initial number of spheres $K_{init} = 10$. As for the comparison between *DMSVDD* and *mSVDD*, *DMSVDD* puts value on one hypersphere and performs slightly better over mSVDD(3) in some cases (e.g., *earn, acq* and *comp*). This indicates one inspiration that discarding "*bad*" hyperspheres is sometimes necessary.

For *Reuters*, the results indicate that *mSVDD* could benefit from the joint training of the discrimination losses, except for *acq* and *ship*. *mSVDD with negative supervision* also achieved the best scores in the four cases compared with other methods including *DMSVDD*.

We have more obvious comparisons for *20 Newsgroup*. All four negative supervision methods could improve *mSVDD* markedly and perform the best over all baselines for all target classes of *20 Newsgroup*. For example, mSVDD with negative supervision could increase 2-3 points for *comp*. For different losses for negative supervision, the *contrastive* type loss, which has larger punishment over negative data, performs better than the *triplet* type loss, which uses a relatively small margin. Much more distinct improvements can be seen in the comparison with CVDD for *rec* or with OC-SVM for *misc*, while we obtained their best scores from Ruff et al. (2019). Further, the *contrastive* loss consistently outperformed other models including the baselines. In addition, the performance of *Con+Max* was greater than the *Con+Mean* strategy to reformulate the probability. We hypothesize that focusing on one of the hyperspheres is effective when we used *mSVDD* with the *contrastive* loss.

5.2.3 Results of CVDD with negative supervision

Table 3 shows the results of *CVDD* with the proposed negative supervision for mSVDD. As mentioned in Section 3.3, *CVDD* can be seen as a special case of *mSVDD*. Therefore, the proposed negative supervision approaches to *mSVDD* can be also applied to *CVDD* theoretically. To highlight the usefulness of the negative supervision, we conducted the experiments to use the *triplet* loss with *Max* probability for CVDD. As for the implementation, since CVDD uses a different multi-head structure, we also used a different form to incorporate *Triplet+Max* to CVDD (See Section C in the appendix for the details of the implementation.).

Overall, we can see that the proposed negative supervision could enhance *CVDD* in most cases on the two datasets. The overall performance mainly shows the following: 1) The improvement by the negative supervision to CVDD is consistent with mSVDD due to the similarity between the two. 2) The generality of the negative supervision can be shown, as *Triple+Max* was successfully applied to the different multi-head structure.

Regarding different target-classes, *ship* with the smaller training data size may cause worse perfor-

mance, so does *real* with CVDD(3), which are similar phenomena with mSVDD. In addition, the negative supervision could also prevent over-fitting for CVDD. For example, CVDD(3) with the minimal parameters achieved the best score for *comp* when varying "r" among 3, 5 and 10. In contrast, when the negative supervision was used, CVDD(10) with the maximal parameters attained the best and also performed better for all six target classes of the *20 Newsgroup* dataset.

6 Conclusion

In this work, we proposed *mSVDD*, a new generic one-class text classification framework that uses multi-modal *deep SVDD*. Rather than the uni-modal *deep SVDD*, *mSVDD* can enhance the description ability to the target one-class data with multiple hyperspheres. We also proved that this generic framework can include three variants, *deep SVDD, DMSVDD*, and *CVDD* under certain conditions. In addition, in the absence of "*real*" negative training data, we also proposed approaches for effectively adding negative supervision to further improve the performance of *mSVDD*. The experiments validated that the proposed *mSVDD* provides better performance compared to uni-modal SVDD. The experiments also showed the further improvements in most cases when negative supervision was used for *mSVDD* and *CVDD*. For future work of this study, we will use some sampling strategies to improve the current work.

A Proofs of Proposition 1

Schölkopf et al. (2001) proved that, in single-class classification, ν is the upper bound of the fraction of anomalies, and the lower bound of the fraction of training samples being anomalies or on the optimal boundary. Ruff et al. (2018) proved that this ν-property still holds for uni-modal soft-boundary *deep SVDD*. Although the same proposition does not hold true for our multi-modal case as it is in general, it is still true when the attention weight α_{ij} is constant for different hyperspheres. This will give us an intuition on the role of ν.

Proposition 1. *(ν-property)*[7] *The hyperparamter $\nu \in (0, 1]$ in soft-boundary deep mSVDD holds if we set an equal attention weight to each hypersphere:*

- *i. ν is an upper bound on the fraction of outlier samples.*
- *ii. ν is a lower bound on the fraction of training samples being rejected or on the optimal boundary.*

Proof. **Ad (i).** For each training instance $\boldsymbol{x}_i$, its loss function is defined as *hinge-loss*: $l(f(\boldsymbol{x}_i)) = \max\{0, \sum_j \alpha_{ij}\,(\|\phi(\boldsymbol{x}_i; \mathcal{W}) - \boldsymbol{c}_j\|^2 - R_j^2)\}$, where f is the model with parameters. Let us define $d_i = \sum_j \alpha_{ij} d(\boldsymbol{x}_i, \boldsymbol{c}_j)$. Assume $\alpha_{ij} = 1/m$, we have $d_i = \frac{1}{m}\sum_j d(\boldsymbol{x}_i, \boldsymbol{c}_j)$. We also define $R_s = \frac{1}{m}\sum_j R_j^2$. And W.L.O.G, we also assume $d_1 \leqslant \ldots \leqslant d_n$ which means d_n is n-th farthest sum distance. The number of outliers is given by $n_{out} = |\{i | d_i > R_s\}|$. Rewrite the objective of *soft-boundary* deep mSVDD (Eq. 5) as:

$$J_{softm} = R_s - \frac{n_{out}}{\nu n} R_s = (1 - \frac{n_{out}}{\nu n}) R_s$$

Since the objective of *mSVDD* is to get a minimum R_s, therefore $1 - \frac{n_{out}}{\nu n}$ should be positive, Thus, $n_{out} \leqslant \nu n$ must hold in the training. It implies that at most νn outliers should be rejected.

Ad (ii). The optimal R_s^* has to hold the inequality $n_{out} \leqslant \nu n$. If $R_s^* >= d_n$, then n_{out} takes the minimum value of 0 which means the boundary includes all the samples. Since n_{out} is increased as long as R_s decreased. If n_{out} take the maximum value of νn under condition **(i)**, we can have the minimal $R_s^* = d_{i*}$, where $i* = n - n_{out}$ means d_{i*} is $(n - n_{out})$-th farthest distance. We define $\{\boldsymbol{x}_i | d_i \geqslant R_s^*\}$ is the set of training samples being rejected ($d_i > R_s^*$) or on the optimal boundary ($d_i = R_s^*$). Then we have inequality: $|\{\boldsymbol{x}_i | d_i \geqslant R_s^*\}| = |\{\boldsymbol{x}_i | d_i > R_s^*\} \cup \{\boldsymbol{x}_i | d_i = R_s^*\}| \geqslant n_{out} + 1 \geqslant \nu n$. This implies that at least νn samples being rejected or just on the optimal boundary. Figure 2 shows an example with 10 training samples. ☐

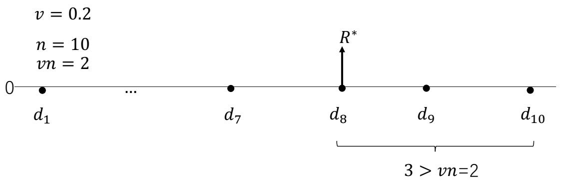

Figure 2: Example of **ii** of ν-property. Up arrow means $R^* = d_8$, where $n = 10$ means 10 samples, $\nu = 0.2$.

Proposition 1 and its proof refer to works (Ruff et al., 2018; Chen et al., 2005; Schölkopf et al., 2000).

B Discussions on mSVDD with Negative Supervision

B.1 Relationship between mSVDD and the use of negative supervision

mSVDD and negative supervision are not two independent sub-architectures. Negative supervision, including *contrastive* and *triplet* losses, are specially equipped to mSVDD. Specifically, these two components are closely connected by the center of the hypersphere, $\boldsymbol{c}_j$. Both mSVDD (Eq. 7) and negative supervision (Eq. 13 or 14) contain $\boldsymbol{c}_j$. Since there is no *real* negative data, external data are used as *pseudo* negative samples to complete negative supervision. The use of negative supervision could improve the discrimination ability of mSVDD. In training, negative supervision loss forces mSVDD to reject *unseen* samples since real negative data in testing are also unseen in training. This improves inter-class discrepancy, compared with intra-class loss mSVDD optimized. However, in testing, the decision function will be the same as mSVDD trained with only positive samples.

B.2 Necessity of joint loss

In training loss of mSVDD with *negative supervision*(Eq. 16), $\mathcal{L}_{mSVDD}$ aims to minimize the intra-class variations while $\mathcal{L}_{Con|Tri}$ tries to maximize the inter-class discrimination. If γ in Eq. 16 is set to 0, it will train mSVDD only with target

---

[7] Rewrite this proposition in the main body

positive samples, where discriminative information could not be learned. On the other hand, if we use only $\mathcal{L}_{Con|Tri}$ loss for training, it may result in large intra-target variations, especially when the *triplet* type loss is chosen, since it requires that only positive samples to be closer than *pseudo* negative samples. Additionally, because of the absence of *real* negative samples, it is another problem to sample the "appropriate" *pseudo* negative samples, such that the *contrastive* or *triplet* losses could fit our original objective, that is, learn a compact description boundary for the target one-class data. Therefore, it is necessary to jointly train with the loss of negative supervision.

C Implementation of CVDD with negative supervision

The proposed negative supervision methods can also be applied to CVDD. Now, we introduce our implementation of CVDD with *triplet* type loss and the *Max* probability strategy. CVDD uses a group of r *context vectors* $C = (\boldsymbol{c}_1, ..., \boldsymbol{c}_r)$ to describe the target one-class data, where $\boldsymbol{c}_k \in \mathbb{R}^p$. Given one context vector $\boldsymbol{c}_k, \forall k \in \{1, ..., r\}$ and a pair of training positive and negative samples, we can get the reformulated probability form. First, CVDD maps a training sample x_i to r heads of feature vectors $S_i = (\boldsymbol{s}_{i1}, ..., \boldsymbol{s}_{ir})$. Then, we denote $p(y_i = 1|\boldsymbol{s}_{ik}, \boldsymbol{c}_k)$ as the probability that k-th $\boldsymbol{s}_{ik}$ reconstructs k-th context vector $\boldsymbol{c}_k$ well.

$$p(y_i = 1|\boldsymbol{s}_{ik}, \boldsymbol{c}_k) = \sigma(\hat{\boldsymbol{s}_{ik}}^T \hat{\boldsymbol{c}_k}) \tag{17}$$

And with *triplet* and *Max* probability strategy, we can define the negative supervision loss as:

$$\begin{aligned}
\mathcal{L}_{Tri}^{(ii')} &= [\log p(y_{i'} = 1|\boldsymbol{x}_{i'}) - \log p(y_i = 1|\boldsymbol{x}_i) + \tau]_+ \\
&= [\log \max_{k=1,\dots,r} p(y_{i'} = 1|\boldsymbol{s}_{i'k}, \boldsymbol{c}_k) - \\
&\quad - \log \max_{k=1,\dots,r} p(y_i = 1|\boldsymbol{s}_{ik}, \boldsymbol{c}_k) + \tau]_+
\end{aligned} \tag{18}$$

where τ is a margin. Then, $\mathcal{L}_{Tri}^{(ii')}$ can then be added to Eq. 8 to obtain the training loss.

Unsupervised Word Polysemy Quantification with Multiresolution Grids of Contextual Embeddings

École Polytechnique & AUEB

Abstract

The number of senses of a given word, or polysemy, is a very subjective notion, which varies widely across annotators and resources. We propose a novel method to estimate polysemy based on simple geometry in the contextual embedding space. Our approach is fully unsupervised and purely data-driven. Through rigorous experiments, we show that our rankings are well correlated, with strong statistical significance, with 6 different rankings derived from famous human-constructed resources such as WordNet, OntoNotes, Oxford, Wikipedia, etc., for 6 different standard metrics. We also visualize and analyze the correlation between the human rankings and make interesting observations. A valuable by-product of our method is the ability to sample, at no extra cost, sentences containing different senses of a given word. Finally, the fully unsupervised nature of our approach makes it applicable to any language. Code and data are publicly available[1].

1 Introduction

Polysemy, the number of senses that a word has, is a very subjective notion, subject to individual biases. Word sense annotation has always been one of the tasks with the lowest values of inter-annotator agreement (Artstein and Poesio, 2008). Yet, creating high-quality, consistent word sense inventories is a critical pre-requisite to successful word sense disambiguation.

Towards creating word sense inventories, it can be helpful to have some reliable information about polysemy. That is, knowing which words have many senses and which words have only a few senses. Such information can help in creating new inventories but also in validating and interpreting existing ones. It can also help select which words to include in a study (e.g., only highly polysemous words).

We propose a novel, fully unsupervised, and data-driven approach to quantify polysemy, based on basic geometry in the contextual embedding space.

Contextual word embeddings have emerged in the last few years as part of the NLP transfer learning revolution. Now, entire deep models are pre-trained on huge amounts of unannotated data and fine-tuned on much smaller annotated datasets. Some of the most famous examples include ULMFiT (Howard and Ruder, 2018) and ELMo (Peters et al., 2018), both based on recurrent neural networks; and GPT (Radford et al., 2018) and BERT (Devlin et al., 2018), based on transformers (Vaswani et al., 2017). These models all are very deep *language models*. During pre-training on large-scale corpora, they learn to generate powerful internal representations, including fine-grained contextual word embeddings. For instance, in a well pre-trained model, the word *python* will have two very different embeddings depending on whether it occurs in a programming context (as in, e.g., "I love to write code in python") or in an ecological context ("while hiking in the rainforest, I saw a python").

Our approach capitalizes on the contextual embeddings previously described. It does not involve any tool and does not rely on any human input or judgment. Also, thanks to its unsupervised nature, it can be applied to any language (even those with limited resources), provided that contextual embeddings are available.

The remainder of this paper is organized as follows. We detail our approach in section 2. Then,

---

[*] Equal contribution. CX handled the data, generated the rankings, and sampled the examples of section 7. AJPT computed the results, plots, and wrote the paper. Both authors participated in the design of the study.

April 19 - 23, 2021.

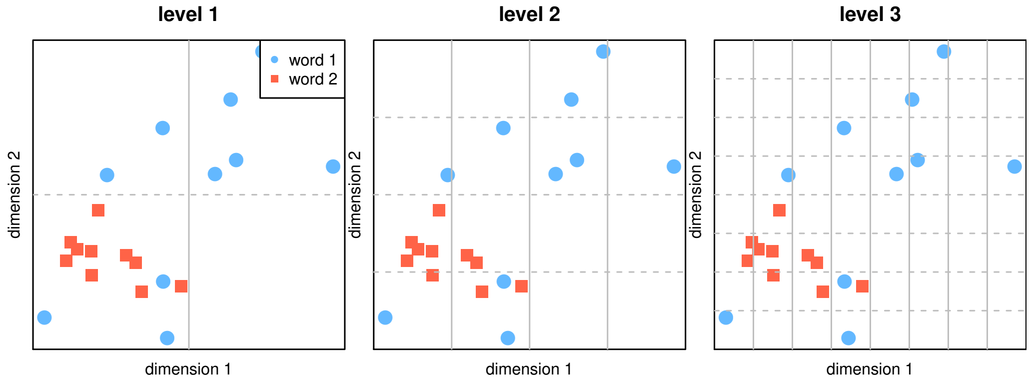

Figure 1: Illustration of the proposed approach with $D = 2$ and $L = 3$.

we present our experimental setup (sec. 3), evaluation metrics (sec. 4), and report and interpret our results (sec. 6). In section 7, we briefly touch on two other interesting applications of our method. One that allows the user to sample sentences containing different senses of a given word and one that goes towards word sense induction. Finally, related work is presented in section 8.

2 Proposed approach

2.1 Basic assumption

First, by passing diverse sentences containing a given word to a pre-trained language model, we construct a representative set of vectors for that word (one vector for each occurrence of the word). The basic and intuitive assumption we make is that *the volume covered by the cloud of points in the contextual embedding space is representative of the polysemy of the associated word.*

2.2 Main idea: multiresolution grids

As a proxy for the volume covered, we adopt a simple geometrical approach. As shown in Fig. 1, we construct a hierarchical discretization of the space, where, at each level, the same number of bins are drawn along each dimension. Each level corresponds to a different resolution. Our polysemy score is based on the proportion of bins covered by the vectors of a given word at each level.

Grid vs. clustering. Using a binning strategy makes more sense than a clustering-based approach. Indeed, clusters do not partition the space equally and regularly. This is especially problematic since word representations are not uniformly distributed in the embedding space (Ethayarajh, 2019). Therefore, the vectors lying in the same dense area of the space will always belong to one single large cluster, while outliers lying in the same, but sparser, area of the space, will be assigned to many different small clusters. Therefore, counting the number of clusters a given word belongs to is not a reliable indicator of how much of the space this word covers.

2.3 Scoring scheme

We quantify the polysemy degree of a word w as:

$$\text{score}(w) = \sum_{l=1}^{L} \frac{\text{coverage}_w^l}{2^{L-l}} \tag{1}$$

where coverage_w^l designates the proportion of bins covered by word w at level l, between 0 and 1. At each level, 2^l bins are drawn along each dimension (see the vertical and horizontal lines in Fig. 1). The hierarchy starts at $l = 1$ since there is only one bin covering all the space at $l = 0$ (so all words have equal coverage at this level). The total number of bins in the entire space, at a given level l, is equal to $(2^l)^D$.

Consider again the example of Fig. 1. In this example, each word is associated with a set of 10 contextualized embeddings in a space of dimension $D = 2$, and the hierarchy has $L = 3$ levels. First, we can clearly see that word 1 (blue circles) covers a large area of the space while all the vectors of word 2 (orange squares) are grouped in the same region. Intuitively, this can be interpreted as "word 1 occurs in more different contexts than word 2", which per our assumption, is equivalent to saying that "word 1 is more polysemous than word 2".

Let us now see how this is reflected by our scoring scheme. First, the penalization terms (denominators) for levels 1 to 3 are $\left[\frac{1}{2^2}, \frac{1}{2^1}, \frac{1}{2^0}\right] = \left[\frac{1}{4}, \frac{1}{2}, 1\right]$. Note that the higher the level, the exponentially more bins, and so the less penalized (or the more rewarded) coverage is, because getting good coverage becomes more and more difficult. Now, per

Eq. 1, the score of word 1 is computed as the dot product of its coverage vector $\left[\frac{3}{4}, \frac{7}{16}, \frac{10}{64}\right]$ (coverage at each level) with the penalization vector, which gives a score of 0.5625. Likewise, the score of word 2 is computed as $\left[\frac{1}{4}, \frac{1}{2}, 1\right] \cdot \left[\frac{1}{4}, \frac{4}{16}, \frac{7}{64}\right] = 0.297$. We can thus see that our scores reflect what can be observed in Fig. 1: word 1 covers a larger area of the space than word 2.

Note that the score of a given word is only meaningful compared to the scores of other words, i.e., in rankings, as will be seen in the next section.

3 Experiments

In this section, we describe the protocol we followed to test the extent to which our rankings match human rankings.

3.1 Word selection

The first step was to select words to include in our analysis. For this purpose, we downloaded and extracted all the text from the latest available English Wikipedia dump[2]. We then performed tokenization, stopword, punctuation, and number removal and counted the occurrence of each token of at least 3 characters in size. Out of these tokens, we kept the 2000 most frequent.

3.2 Generating vector sets

For each word in the shortlist, we randomly selected 3000 sentences such that the corresponding word appeared exactly once within each sentence. The words that did not appear in at least 3000 sentences were removed from the analysis, reducing the shortlist's size from 2000 to 1822. Then, for each word, the associated sentences were passed through a pre-trained ELMo model[3] (Peters et al., 2018) in test mode, and the top layer representations corresponding to the word were harvested. The advantage of using ELMo's top layer embeddings is that they are the most contextual, as shown by Ethayarajh (2019). We ended up with a set of exactly 3000 1024-dimensional contextual embeddings for each word.

3.3 Dimensionality reduction

Remember that the total number of bins in the entire space is equal to $(2^l)^D$ at a given level l, which would have given us an infinite number of bins even at the first level, since the ELMo representations have dimensionality $D = 1024$. To reduce the dimensionality of the contextual embedding space, we applied PCA, trying 19 different output dimensionalities, from 2 to 20 with steps of 1. Due to the quantity and high initial dimensionality of the vectors, we used the distributed[4] version of PCA provided by the PySpark's ML Library (Meng et al., 2016).

3.4 Score computation

We computed our scores for each PCA output dimensionality, trying with 18 different hierarchies whose numbers of levels L ranged from 2 to 19. So in total, we obtained $19 \times 18 = 342$ rankings.

3.5 Ground truth rankings and baselines

We evaluated the rankings generated by our approach against several ground truth rankings that we derived from human-constructed resources.

Since the number of senses of a word is a subjective, debatable notion, and thus may vary from source to source, we included 6 ground truth rankings in our analysis, in order to minimize source-specific bias as much as possible. For sanity checking purposes, we also added two basic baseline rankings (frequency and random). We provide more details about all rankings in what follows.

3.5.1 WordNet

We used WordNet (Miller, 1998) version 3.0 and counted the number of synonym sets or "synsets" of each word.

3.5.2 WordNet-Reduced

There are very subtle differences among the WordNet senses ("synsets"), making distinguishing between them difficult and even irrelevant in some applications (Palmer et al., 2004, 2007; Brown et al., 2010; Rumshisky, 2011; Jurgens, 2013). For instance, *call* has 41 senses in the original WordNet (28 as verb and 13 as noun). Even for other words with fewer senses, like *eating* (7 senses in total), the difference between senses can be very tiny. For instance, "take in solid food" and "eat a meal; take a meal" are really close in meaning. This very fine granularity of WordNet may somewhat artificially increase the polysemy of some words.

To reduce the granularity of the WordNet

---

[2] https://dumps.wikimedia.org/

[3] We used the implementation and pre-trained weights publicly released by the authors https://allennlp.org/elmo.

[4] 15 executors with 10 GB of RAM each.

synsets, we used their sense keys[5]. They follow the format `lemma%ss_type:lex_filenum:lex_id:head_word:head_id`, where `ss_type` represents the synset type (part-of-speech tag such as noun, verb, adjective) and `lex_filenum` represents the name of the lexicographer file containing the synset for the sense (`noun.animal`, `noun.event`, `verb.emotion`, etc.). We truncated the sense keys after `lex_filenum`.

For instance, "take in solid food" and "eat a meal; take a meal" initially correspond to two different senses with keys `eat%2:34:00::` and `eat%2:34:01::`, but after truncation, they both are mapped to the same sense: `eat%2:34`. However, coarse differences in senses are still captured. For instance, *bank* "sloping land" (`bank%1:17:01::`) and *bank* "financial institution" (`bank%1:14:00::`) are still mapped to two different senses after truncation, respectively `bank%1:17` and `bank%1:14`.

3.5.3 WordNet-Domains

WordNet Domains (Bentivogli et al., 2004; Magnini and Cavaglia, 2000) is a lexical resource created in a semi-automatic way to augment WordNet with domain labels. Instead of synsets, each word is associated with a number of semantic domains. The domains are areas of human knowledge (politics, economy, sports, etc.) exhibiting specific terminology and lexical coherence. As for the two previous WordNet ground truth rankings, we simply counted the number of domains associated with each word.

3.5.4 OntoNotes

OntoNotes (Hovy et al., 2006; Weischedel et al., 2011) is a large annotated corpus comprising various text genres (news, conversational telephone speech, weblogs, newsgroups, broadcast, talk shows) with structural information and shallow semantics.

We counted the senses in the sense inventory of each word. The senses in OntoNotes are groupings of the WordNet synsets, constructed by human annotators. As a result, the sense granularity of OntoNotes is coarser than that of WordNet (Brown et al., 2010).

3.5.5 Oxford

We counted the number of senses returned by the Oxford dictionary[6], which was, at the time of this study, the resource underlying the Google dictionary functionality.

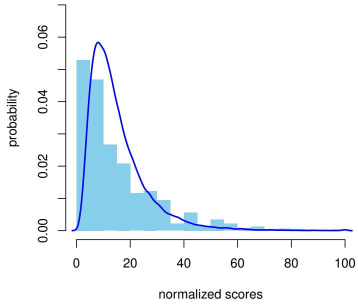

Figure 2: Average score distribution of the 5 ground truth rankings and frequency baseline (histogram) vs. average score distribution of the random baseline (**blue** curve).

3.5.6 Wikipedia

We capitalized on the Wikipedia disambiguation pages[7]. Such pages contain a list of the different categories under which one or more articles about the query word can be found. For example, the disambiguation page of the word *bank* includes categories such as geography, finance, computing (data bank), and science (blood bank). We counted the number of categories on the disambiguation page of each word to generate the ranking.

3.5.7 Frequency and random baselines

In the frequency baseline, we ranked words in decreasing order of their frequency in the entire Wikipedia dump (see subsection 3.1). The naive assumption made here is that words occurring the most have the most senses.

With the random baseline, on the other hand, we produced rankings by shuffling words. Further, we assigned them random scores by sampling from the Log Normal distribution[8], to imitate the long-tail behavior of the other score distributions, as can be seen in Fig. 2. All distributions can be seen in Fig. 6. Note that to account for randomness, all results for the random baseline are averages over 30 runs. Not every of the 1822 words included in our analysis had an entry in each of the resources described above. The lengths of each ground truth ranking are shown in Table 1.

4 Evaluation metrics

We used 6 similarity, correlation and information retrieval standard metrics to compare among methods: cosine similarity, Spearman's rho (Spearman,

1904), Kendall's tau (Kendall, 1938), precision at k, Normalized Discounted Cumulative Gain (Järvelin and Kekäläinen, 2002), and Rank Biased Overlap (Webber et al., 2010).

To ensure a fair comparison, the scores in the rankings of all methods were normalized to be in the $[0, 100]$ range before proceeding.

Also, each method played in turn the role of candidate and ground truth. This allowed us to compute not only the similarity between our rankings and the ground truth rankings, but also the similarity among the ground truth rankings themselves, which was interesting for exploration purposes.

For each pair of evaluated and ground truth method, only the parts of the rankings corresponding to the words in common (intersection) were compared. Thus, the rankings in each (candidate,ground truth) pair had equal length.

5 Implementation details

To compute our scores, we built on the code of the pyramid match kernel from the `GraKeL` Python library (Siglidis et al., 2018). We used the base R (R Core Team, 2018) `cor()` function[9] to compute the τ and ρ statistics. For RBO, we relied on a publicly available Python implementation[10]. For all other metrics, we wrote our own implementations. Full details about design choices, tokenizers, stopword lists etc., can also be found in our publicly available code repository: `https://github.com/ksipos/polysemy-assessment`.

6 Results and observations

Our rankings correlate well with human rankings. Results are shown in Fig. 3, as pairwise similarity matrices, for all six metrics. For readability, all scores are shown as percentages. For a given metric, our configuration that best matches, on average, all other methods (except random and frequency) is always shown as the first column. Since all metrics except NDCG are symmetric, we only show the lower triangles of the other matrices. For NDCG, candidate methods are shown as columns and ground truths as rows.

For each of the six evaluation metrics, it can be seen that the ranking generated by our unsupervised, data-driven method is well correlated with all human-derived ground truth rankings. This means that our method is robust to how one defines and measures correlation or similarity.

In some cases, we even very closely reproduce the human rankings. For instance, our best configurations for cosine and NDCG get almost perfect scores of 86.5 and 99.72 when compared against Wikipedia. In terms of Kendall's tau, Spearman's rho, p@k, and RBO, we are also very close to OntoNotes (scores of 49.43, 35.23, 39.53, and 33.47, resp.).

Finally, the correlation between our rankings and the human rankings can also be observed to be, everywhere, much stronger than that between the baseline rankings (random and frequency) and the human rankings.

Statistical significance. We computed statistical significance for the Spearman's rho and Kendall's tau metrics. As shown in Fig. 3, the null hypothesis that there is no correlation between our rankings and the human-derived ground truth rankings was systematically rejected everywhere, with very high significance ($p \leq 0.0001$).

However, against the random baseline, the same null hypothesis (no correlation) was accepted everywhere. Against frequency, the null was rejected, but very weakly (only at the $p \leq 0.01$ level), and with very low correlation coefficients (6.53 for Spearman and 4.44 for Kendall).

Finally, the correlation between the random and frequency rankings and the ground truth rankings is never statistically significant, except for the pair frequency/OntoNotes, but again, at a weak level ($p \leq 0.01$).

Hyperparameters have a significant impact on performance, but optimal values are consistent across metrics. First, as can be observed from Fig. 4 and Fig. 5, there is a large variability in performance when D (number of PCA dimensions) and L (number of levels in the hierarchy) vary.

However, for all six evaluation metrics, the best configurations are very similar: $D2L10$, $D2L8$,

Figure 3: Pairwise similarity matrices between methods. For readability, all scores are shown as percentages. For Kendal and Spearman, * and *** mean statistical significance at $p \leq 0.01$ and $p \leq 0.0001$, respectively. For a given metric, our configuration that best matches (on average) all other methods (except random and frequency) is always shown first. $DDLL$ means that the compressed contextual embedding space has D dimensions and that the hierarchy has L levels. Rand, freq, wiki, oxf, ON, WN, WNred, and WNdom are short for random, frequency, Wikipedia, Oxford, OntoNotes, WordNet, WordNet reduced, and WordNet domains. All metrics except NDCG are symmetric, hence we only show one triangle for them. For NDCG, candidate methods are shown as columns and ground truths as rows.

Sentences	Bin coordinates
it stars christopher lee as **count** dracula along with dennis waterman	$(3, 5, 1)$
the **count** of the new group is the sum of the separate counts of the two original groups	$(4, 1, 3)$
the first fight did not **count** towards the official record	$(4, 5, 1)$
five year old horatia came to **live** at merton in may 1805	$(2, 5, 2)$
it features various amounts of **live** and backstage footage while touring	$(4, 2, 4)$
first tax bills were used to pay taxes and to register **bank** deposits and bank credits	$(4, 2, 4)$
the ball nest is built on a **bank** tree stump or cavity	$(5, 2, 3)$

Table 2: Sentences containing different senses of the same word can be sampled by selecting from different bins.

Keywords	Bin coordinates
also, gas, used, system, protein, blood, new, steel, food, made	$(20, 11, 16, 9)$
first, new, one, second, later, world, national, olympic, team, games	$(19, 13, 15, 13)$
album music rock one labour number chart songs metal single	$(21, 14, 14, 16)$

Table 3: Towards automatic word sense induction: top 10 most frequent words for different bins containing the word *metal*. The bins correspond to 3 senses of metal: chemical element, Olympics (medals), and music.

$D2L8$, $D4L5$, $D3L9$, and $D4L10$[11]. Given the rather large grid we explored ($[2, 20] \times [2, 19]$ for D and L, resp.), with 342 combinations in total, we can say that all these optimal values belong to the same small neighborhood. This interpretation is confirmed by inspecting Fig. 4, where it can clearly be seen that the optimal area of the hyperparameter space is robust to metric selection and consistently corresponds to small values of D (around 3), and values of L at least above 3 or 4, ideally around 8. For larger values of L, performance plateaus (keeping D fixed). In other words, it is necessary to have some levels in the hierarchy, but having very deep hierarchies is not required for our method to work well. A benefit of having such small optimal values of D and L is their affordability, from a computational standpoint.

All rankings derived from WordNet-based resources are highly correlated. It is interesting to note that the rankings generated from OntoNotes, WordNet, WordNet reduced, and WordNet domains, all are highly similar. And this, despite the very different sense granularities they have. This means that despite the apparent differences in these resources, they all tend to produce similar polysemy rankings. The Oxford rankings tend to be part of this high-similarity cluster as well, to a lesser extent.

Frequent words are not the most polysemous. Finally, one last interesting observation is that while the frequency ranking is much better than the random ones, it still is far away from the human rankings. In other words, the frequency of appearance of a word (excluding stopwords, of course) is not as good an indicator of its polysemy as one could expect. Some words that follow this observation are ”number”, ”population”, and ”war”.

A note on ties. To assess the impact of ties on the reported results, we repeated all of our experiments multiple times with different tie-breaking strategies (e.g., random, alphabetical...). Results do not change: we find the same best parameter combinations, and the differences in the similarity matrices are minimal.

7 Other applications

Sampling diverse examples. An interesting by-product of our discretization strategy is that it can be used to select sentences containing different senses of the same word, as illustrated in Table 2. Provided a mapping, for a given word, between the sentences that were passed to the pre-trained language model and the vectors, we can sample vectors from different bins and retrieve the associated sentences. If the bins are distant enough, the sentences will contain different senses of the word. For instance, in Table 2, we can see that we are able to sample sentences containing three senses of the word *count*: (1) noble title, (2) determining the total number of, and (3) taking into account. This has many useful applications in practice, e.g., in information retrieval, NLG and conversational systems, dataset creation, etc.

Automatic word sense induction. A simple way of capitalizing on our binning strategy to create word sense inventories would consist in (1) selecting distant bins for a given word, and (2) labeling the selected bins with senses. Both steps can be performed automatically. While this will be investigated in future work, we still give, as a proof of concept, an example in Table 3. In this example,

keywords are extracted from distant bins containing the word *metal*, and different senses are retrieved.

8 Related work

Task. Several previous efforts have interested themselves in creating sense inventories without human experts. As an example, in Rumshisky (2011); Rumshisky et al. (2012) [12], Amazon Mechanical Turk (AMT) workers are given a set of sentences containing the target word and one sentence that is randomly selected from this set as a target sentence. Workers are then asked to judge, for each sentence, whether the target word is used in the same way as in the target sentence. This creates an undirected graph of sentences where clustering can be applied to find senses. To label clusters with senses, one has to inspect the sentences in each cluster manually.

More recently, Jurgens (2013)[13] compared three annotation methodologies for gathering word sense labels on AMT. The methods compared are Likert scales, two-stage select and rate, and the difference between counts of when senses were rated best/worst. Regardless of the strategy, inter-annotator agreement remains low (around 0.3).

Methodology. In the original ELMo paper, Peters et al. (2018) have shown that using contextual word representations (through nearest-neighbor matching) improves word sense disambiguation. Hadiwinoto et al. (2019); Coenen et al. (2019) showed that this technique works well with BERT too. Pasini et al. (2020) uses a combination of BERT embeddings and a knowledge-based WSD model to generate word sense distributions, while Giulianelli et al. (2020) uses clustering over the embeddings to detect semantic shifts.

Our approach is also related in spirit to pyramid matching (Nikolentzos et al., 2017; Grauman and Darrell, 2007; Lazebnik et al., 2006). This kernel-based method originated in computer vision. It computes the similarity between objects by placing a sequence of increasingly coarser grids over the feature space and taking a weighted sum of the number of matches occurring at each level. Matches found at finer resolutions are weighted more than matches found at coarser resolutions.

9 Conclusion

We proposed a novel unsupervised, fully data-driven geometrical approach to estimate word polysemy. Our approach builds multiresolution grids in the contextual embedding space. Through rigorous experiments, we showed that our rankings are well correlated (with strong statistical significance) to 6 different human rankings, for 6 different metrics. Such fully data-driven rankings of words according to polysemy can help in creating new sense inventories, but also in validating and interpreting existing ones. Increasing the quality and consistency of sense inventories is a key first step of the word sense disambiguation pipeline. We also showed that our discretization could be used, at no extra cost, to sample contexts containing different senses of a given word, which has useful applications in practice. Finally, the unsupervised nature of our method makes it applicable to any language.

While our scores are a good proxy for polysemy, they are not equal to word sense counts. Moreover, we do not label each sense. Future work should address these challenges by, e.g., automatically selecting bins of interest and generating labels for them (see section 7).

Future work should also perform some sort of extrinsic evaluation. For instance, the Word-in-Context task (Pilehvar and Camacho-Collados, 2018) could be used, where two occurrences would be classified as having the same meaning if their two vectors fall in the same bin.

Another direction is investigating how different contextual embeddings (e.g., BERT, BART) impact our rankings, including in languages other than English (Eddine et al., 2020; Cañete et al., 2020), and low-resource languages.

Acknowledgments

We thank the three anonymous reviewers for their helpful feedback. We also thank Giannis Nikolentzos for helpful discussions about pyramid matching. The GPU used in this study was donated by the Nvidia corporation as part of their GPU grant program. This work was supported by the LinTo project.

Abstract

We describe `Mega-COV`, a billion-scale dataset from Twitter for studying COVID-19. The dataset is diverse (covers 268 countries), longitudinal (goes as back as 2007), multilingual (comes in 100+ languages), and has a significant number of location-tagged tweets (~ 169M tweets). We release tweet IDs from the dataset. We also develop two powerful models, one for identifying whether or not a tweet is related to the pandemic (best F_1=97%) and another for detecting misinformation about COVID-19 (best F_1=92%). A human annotation study reveals the utility of our models on a subset of `Mega-COV`. Our data and models can be useful for studying a wide host of phenomena related to the pandemic. `Mega-COV` and our models are publicly available.

1 Introduction

The seeds of the coronavirus disease 2019 (COVID-19) pandemic are reported to have started as a local outbreak in Wuhan (Hubei, China) in December, 2019, but soon spread around the world (WHO, 2020). As of January 24, 2021, the number of confirmed cases around the world exceeded 99.14M and the number of confirmed deaths exceeded 2.13M.[1] In response to this ongoing public health emergency, researchers are mobilizing to track the pandemic and study its impact on all types of life in the planet. Clearly, the different ways the pandemic has its footprint on human life is a question that will be studied for years to come. Enabling scholarship on the topic by providing relevant data is an important endeavor. Toward this goal, we collect and release `Mega-Cov`, a billion-scale multilingual Twitter dataset with geo-location information.

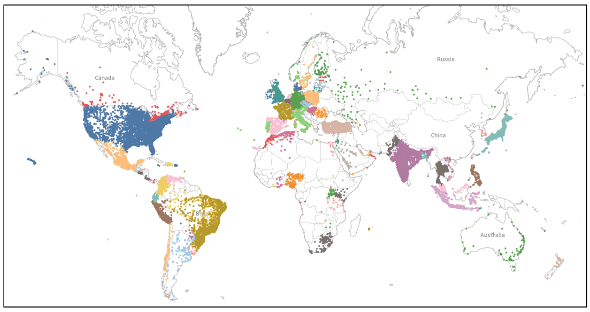

Figure 1: Global coverage of `Mega-COV` based on our geo-located data. Each dot is a city. Contiguous cities of the same color belong to the same country.

As a result of the pandemic, most countries around the world went into lockdown and the public health emergency has restricted physical aspects of human communication considerably. As hundreds of millions of people spend more time sheltering in place, communication over social media became more important than ever. In particular, the content of social media communication promises to capture significant details about the lives of tens of millions of people. `Mega-Cov` is intended as a repository of such a content.

There are several ongoing efforts to collect Twitter data, and our goal is to complement these. More specifically, we designed our methods to harvest a dataset that is unique in multiple ways, as follows: **Massive Scale**: Very large datasets lend themselves to analyses that are not possible with smaller data. Given the global nature of COVID-19, we realize that a large-scale dataset will be most useful as the scale allows for slicing and dicing the data across different times, communities, languages, and regions that are not possible otherwise. For this reason, we dedicated significant resources to harvesting and preparing the dataset. `Mega-COV` has solid international coverage and brings data from 1M users from 268 countries (see Section 3.1). Overall, our dataset has ~ 1.5B tweets (Section 2). This is one order of magnitude larger than #COVID-19 (Chen et al., 2020), the largest dataset we know

of ($\sim$ 144M tweets as of June 1, 2020).[2]

Topic Diversity: We do not restrict our collection to tweets carrying certain hashtags. This makes the data general enough to involve content and topics directly related to COVID-19, regardless of existence of accompanying hashtags. This also allows for investigating themes that may not be directly linked to the pandemic but where the pandemic may have some bearings which should be taken into account when investigating such themes. This is important because users can, and indeed do, post about activities impacted by the health crisis without using any hashtags. In fact, users may not mention COVID-19 at all, even though what they are posting about could be affected by the pandemic one way or another (e.g., "eating habits", "shopping behavior"). Section B and Section C in the Appendix provide a general overview of issues discussed in the dataset.

Longitudinal Coverage: We collect multiple data points (up to 3,200) from each user, with a goal to allow for comparisons between the present *and* the past across the same users, communities, and geographical regions (Section 3.2). Again, this is desirable since without data from pre-COVID-19 time it will be challenging to hold any such comparisons. For example, some users may have stopped posting about "exercising" during the pandemic but we cannot definitely identify this without access to these users' previous data where they may have been posting about their physical activities.

Language Diversity: Since our collection method targets users, rather than hashtag-based content, `Mega-COV` is *linguistically diverse*. In theory, any language posted to Twitter by a user whose data we have collected should be represented. Based on Twitter-assigned language codes, we identify a total of 65 languages. However, applying two different language detection tools to the whole dataset, we identify more than 100 languages. (Section 3.3).

No Distribution Shift: Related to the two previous points, but from a machine learning perspective, by collecting the data without conditioning on existence of specific (or any) hashtags we avoid introducing distribution bias. In other words, the data can be used to study various phenomena in-the-wild. This warrants more *generalizable* findings and models.

A dataset as large as `Mega-COV` can be hard to navigate. In particular, an informative description of the dataset is necessary for navigating it. In this paper, we provide an explanation of a number of global aspects of the dataset, including its geographic, temporal, and linguistic coverage. We also provide a high-level content analysis of the data, and explore user sharing of content from particular web domains with a focus on news media. In the context of our investigation of `Mega-COV`, we make an array of important discoveries. For example, we strikingly discover that, perhaps for the first time in Twitter history, *users address one another and retweet more than they post tweets*. We also find a noticeable rise in ranks for news sites (based on how frequent their URLs are shared) during 2020 as compared to 2019, with *a shift toward global (rather than local) news media*. A third finding is how *use of the Twitter platform surged in March*, perhaps making it the busiest time in the history of the network.

Furthermore, we develop two groups of effective neural models: **(1) COVID-relevance models** (for detecting whether a tweet is related to COVID-19 or not). **(2) COVID-misinformation models** (for detecting whether a text carries fake information or not). In addition to releasing our best models, we also apply them to a total of 30M tweets from `Mega-COV` and release our tags to accelerate further research on the topic.

The rest of the paper is organized as follows: In Section 2, we describe our data collection methods. Section 3 is where we investigate geographic, linguistic, and temporal dimensions of our data. We describe our models for detecting COVID-19 tweets and COVID-misinformation in Section 4. Section 5 is where we apply our relevance and misinformation models to a large sample of `Mega-COV`. Section 6 is about data release and ethics. We provide a literature review in Section 7, and conclude in Section 8.

2 Data Collection

To collect a sufficiently large dataset, we put crawlers using the Twitter streaming API[3] on Africa, Asia, Australia, Europe, North America, and South America starting in early January, 2020. This allows us to acquire a diverse set of tweets

---

[2] Both our own dataset and that of Chen et al. (2020) are growing over time. All our statistics in the current paper are based on our collection as of May 15, 2020. As of October 6, 2020, authors of #COVID-19 report 649.9M tweets on their GitHub (`https://github.com/echen102/COVID-19-TweetIDs`), and *our own dataset has exceeded 5B tweets*.

[3] API link: `https://github.com/tweepy/`

Data	Tweets	Retweets	Replies	All
2007-2020	612M	507M	369M	1.5B
2020	122M	174M	129M	425M
Users	1M	976K	994K	1M

Table 1: Distribution of tweets, retweets, and replies in `Mega-COV` (numbers rounded).

from which we can extract a random set of user IDs whose timelines (up to 3,200 tweets) we then iteratively crawl every two weeks. This gave us data from July 30^{th}, 2020 backwards, depending on how prolific of a poster a user is (see Table 4a for a breakdown.). In this paper, we describe and analyze the version of `Mega-COV` collected up to May 15, 2020 and use the term `Mega-COV` to refer it. `Mega-COV` comprises a total of $1,023,972$ users who contribute $1,487,328,805$ tweets. For each tweet, we collect the whole `json` object. This gives us access to various types of information, such as user location and the language tag (including "undefined") Twitter assigns to each tweet. We then use the data streaming and processing engine, Spark, to merge all user files and run our analyses. To capture a wide range of behaviors, we keep *tweets*, *retweets*, and *responses* (i.e., direct user-to-user interactions) as independent categories. Table 1 offers a breakdown of the distribution of the different types of posts in `Mega-COV`. Tweet IDs of the dataset are publicly available at our GitHub[4] and can be downloaded for research. To the extent it is possible, we intend to provide semi-regular updates to the dataset repository.

3 Exploring Mega-COV

3.1 Geographic Diversity

A region from which a tweet is posted can be associated with a specific 'point' location or a Twitter place with a 'bounding box' that describes a larger area such as city, town, or country. We refer to tweets in this category as *geo-located*. A smaller fraction of tweets are also *geo-tagged* with longitude and latitude. As Table 2 shows, `Mega-COV` has $\sim$ 187M geo-located tweets from $\sim$ 740K users and $\sim$ 31M geo-tagged tweets from $\sim$ 267K users. Table 2 also shows the distribution of tweets and users over the top two countries represented in the dataset, the U.S. and Canada (North America), and other locations (summed up as one category, but see also Table 3 for countries in the data by continent).

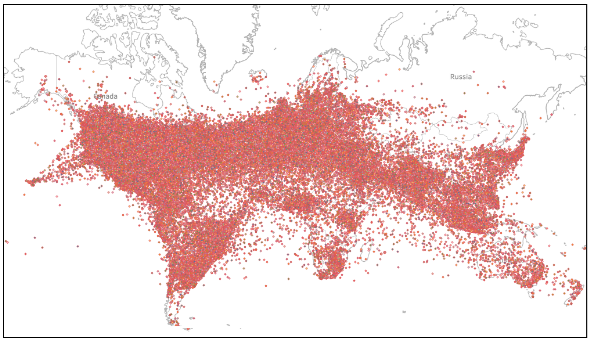

Figure 2: World map coverage of `Mega-COV`. Each dot is a point co-ordinate (longitude and latitude) from which at least one tweet was posted. Clearly, users tweet while traveling, whether by air or sea.

As explained, to allow comparisons over time (including behavioral changes during COVID-19), we include pre-2020 data in `Mega-COV`. For the year 2020, `Mega-COV` has $\sim$ 66M geo-located tweets from $\sim$ 670K users and $\sim$ 3M geo-tagged tweets from $\sim$ 109K users.[5] We note that significant parts from the data could still belong to the different countries but just not geo-located in the original `json` files retrieved from Twitter. Figure 2 shows actual point co-ordinates of locations from which the data were posted. Figure 3 shows the geographical diversity in `Mega-COV` based on *geo-located* data. We show the distribution in terms of the number of cities over *the 20 countries from which we retrieved the highest number of locations* in the dataset, broken by `all-time` and the year `2020`. Overall, `Mega-COV` has data posted from a total of $167,202$ cities that represent 268 countries. Figure A.2 in Appendix A shows the distribution of data over countries. The top 5 countries in the data are *the U.S., Canada, Brazil, the U.K.*, and *Japan*. As we mention earlier, other top countries in the data across the various continents are shown in Table 3.

3.2 Temporal Coverage

Our goal is to make it possible to exploit `Mega-COV` for comparing user social content over time. Since we crawl user timelines, the dataset comprises content going back as early as 2007. Figure 4a shows the distribution of data over the period 2007-2020. Simple frequency of user posting shows a surge in Twitter use in the period of Jan-April 2020 compared to the same months in 2019 (see Figure A.1 in Appendix A). Indeed, we identify 40.53% more posting during the first 4 months

---

[4] Accessible at: `https://github.com/UBC-NLP/megacov`.

[5] The dataset has $\sim$ 134K "locations" which we could not resolve to a particular country using only the json information.

	Geolocated	Tweeted From			Geotagged	Tweeted From		
		Canada	U.S.	Other		Canada	U.S.	Other

Table 3: Distribution of data over top countries per continent in `Mega-COV` (*all data* vs. *2020*).

of 2020 compared to the same period in 2019. This is expected, both due to physical distancing and a wide range of human activity (e.g., "work", "shopping") moving online. More precisely, moving activities online causes users to be on their machines for longer times and hence have easier access to social media. The clear spike in the month of March 2020 is striking. It is particularly so given a *shifted pattern of use: retweeting and replying (to others) are both observably more frequent than tweeting itself*. This especially takes place during the month of March, and somewhat continues in April, as shown in Figure 4b. Figure 4a and Figure 4b also show a breakdown of tweets, retweets, and replies. ***A striking discovery is that, for 2020, users are engaged in conversations with one another more than tweeting directly to the platform.*** This may be the first time this pattern exists, perhaps in the history of the network. At least based on our massive dataset, this conclusion can be made. In addition, for 2020, we also see users retweeting more than tweeting. Based on `Mega-COV`, this is also happening for the first time.

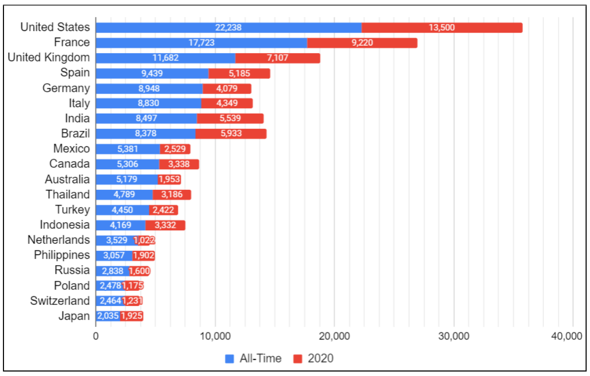

Figure 3: Geographical diversity in `Mega-COV` based on *geo-located* data.

3.3 Linguistic Diversity

We perform the language analysis based on tweets (n=$\sim$ 1.5B), including retweets and replies. Twitter assigns 65 language ids to $\sim$ 1.4B tweets, while the rest are tagged as "und" (for "undefined"). `Mega-COV` has $\sim$ 104M ($\sim$ 7%) tweets tagged as "und". We run two language identification tools, langid (Lui and Baldwin, 2012) and Compact Language Detector (Ooms and Sites, 2018)[6] langid (Lui and Baldwin, 2012),[7] on the whole dataset (including tweets tagged "und" by Twitter).[8] After merging language tags from Twitter and the 2 tools, we acquire a total of 104 labels. This makes `Mega-COV` very linguistically rich. Table 4 shows the top 20 languages identified by Twitter (left) and the top 20 languages tagged by one of the two tools, langid (Lui and Baldwin, 2012), *after* removing the 65 Twitter languages (right).

4 Models

We develop two groups of models suited for answering important questions related to COVID-19, including making use of `Mega-COV`. These are **(1) COVID-relevance**, where a classifier will

label a tweet as *relevant* to COVID-19 or *not* and **(2) COVID-misinformation**, where a model predicts text veracity pertaining COVID-19 (i.e., whether a text carries *true* or *fake* information related to the pandemic). We now describe our methods.

4.1 Methods

For *all* our models, we fine-tune 3 popular pre-trained language models: (1) Multilingual cased BERT (mBERT) (Devlin et al., 2018) and (2-3) XLM Roberta base and large (XLM-R_{Base}, XLM-R_{Large}) (Conneau et al., 2020). The mBERT and XLM-R_{Base} models have similar architectures, with 12 layers each with 12 attention heads, and 768 hidden units. XLM-R_{Large} has 24 layers each with 16 attention heads, and $1,024$ hidden units. While all the 3 models use a masking objective, the XLM-R models do not include the next sentence prediction objective used in BERT.

4.2 Hyper-Parameters and Optimization

For each model, we use the same pre-processing in the respective code released by the authors. For *all* models, we typically use a sequence length of 50 tokens. We use a learning rate of $5e{-}6$ and a batch size of 32. We train each model for 20 epochs and identify the best epoch on a development set. We report performance on both development and test sets. We describe our baseline for each of the relevance and misinformation models in the respective sections below. We now introduce each of these two model groups.

4.3 COVID-Relevance Models

Data. Our COVID-relevance models predict whether a tweet is *related* to COVID-19 or *not* (i.e., not related). To train the models, we sample $\sim$ 2.3M multilingual tweets (65 languages) collected with COVID-19 hashtags from (Chen et al., 2020) and use them as our positive class (i.e., related to COVID-19). Examples of hashtags include *#Coronavirus*, *#covid-19*, and *#pandemic*. That is, we use the hashtags as a proxy for labels. This type of *distant supervision* has been validated and widely used in many NLP models (Go et al., 2009; Mohammad and Kiritchenko, 2015; Abdul-Mageed and Ungar, 2017). For the negative class (i.e., not related to COVID-19), we use a random sample of $\sim$ 2.3M from the 2019 part (Jan-Nov) of `Mega-COV`. More description of the dataset we created for training the relevance models and the distribution of the data over the various languages is in Table E.1 (Appendix E).

Splits and Training. We split the data into 80%

Model	DEV		TEST	
	Acc	F_1	Acc	F_1
Baseline I	55.10	71.05	54.99	70.96
Baseline II	79.88	88.81	75.33	85.93
mBERT	97.35	97.33	97.39	97.37
XLM-R_{Base}	97.72	97.70	97.71	97.69
XLM-R_{Large}	**97.92**	**97.90**	**97.95**	**97.93**

Table 5: Performance of COVID-relevance models. **Baseline I:** Majority class in TRAIN. **Baseline II:** A model that chooses the majority class (related class) 75% of the time.

TRAIN (n=3,146,334), 10% DEV (n=393,567), and 10% TEST (n=392,918). We then remove all hashtags which were used by (Chen et al., 2020) for collecting the data and fine-tune each of the 3 language models on TRAIN.

Results. As shown in Table 5, XLM-R_{Large} acquires best results with 97.95 *acc* and 97.93 macro F_1 on TEST. These results are significantly better than a majority class baseline (based on TRAIN) and another arbitrarily-chosen (yet quite competitive) baseline model that chooses the related class (majority class in TRAIN) 75% of the time.

Model Generalization. Our COVID-relevance models are trained with distant supervision (hashtags as surrogate labels). It is conceivable that content related to COVID-19 would still occur in real world without accompanying hashtags. To test the extent to which our best model would perform on external data, we evaluate it on two external Twitter datasets, CoAID (Cui and Lee, 2020) and ReCOVery (Zhou et al., 2020), both of which are claimed by the authors to be completely (100%) related to COVID-19.[9]

As Tabel 6 shows, We do observe a drop in model performance as compared to our best model on our own TEST set in Table 5 (acc drops on average by 15.5% and 7.6% F_1). However, the best model is still highly effective. It acquires an average acc of 82.46% and F_1 of 90.38% on the CoAID and ReCOVery datasets. We now introduce our misinformation models.

Data	Acc	F_1
COAID	76.25	86.52
ReCOVery	89.46	94.44
Average	82.46	90.38

Table 6: Performance of our COVID-relevance models on the Twitter data in CoAID, ReCOVery, and CoAID+ReCOVery.

4.4 COVID-Misinformation Models

To train models for detecting the veracity of news related to COVID-19, we exploit two recent and publicly available fake news datasets (in English): CoAID (Cui and Lee, 2020), and ReCOVery (Zhou et al., 2020). We now describe each of these datasets:

	Fake			True		
	Claims	News	Tweets	Claims	News	Tweets
CoAID	839	837	10,900	376	2716	149,343
ReCOVery	-	665	26,418	-	1,364	114,402
Total	839	1,502	37,318	376	4,080	263,745

Table 7: COVID-19 Misinformation Datasets.

	Tweets					
	Fake			True		
	TRAIN	DEV	TEST	TRAIN	DEV	TEST
CoAID	8,072	1,009	1,009	110,076	13,759	13,759
ReCOVery	18,272	2,284	2,284	86,437	10,805	10,805
CoAID*	8,072	163	171	110,076	6,314	6,388
ReCOVery*	18,272	154	139	86,437	1,218	1,263

Table 8: Statistics of CoAID and ReCOVery datasets across the data splits. CoAID* and ReCOVery* are de-duplicated versions.

CoAID. Cui and Lee (2020) present a **C**ovid-19 he**A**thcare m**I**sinformation **D**ataset (CoAID), with diverse COVID-19 healthcare misinformation, including fake news on websites and social platforms, along with related user engagements (i.e., tweets and replies) about such news. CoAID includes $3,235$ news articles and claims, $294,692$ user engagement, and 851 social platform posts about COVID-19. The dataset is collected from December 1, 2019 to July 1, 2020. Table 7 shows class distribution of news articles and tweets in CoAID. More information about CoAID is in Appendix F.

ReCOVery. Zhou et al. (2020) choose 60 news publishers with 'extreme' levels of credibility (i.e., *true* vs. *fake* classes) from an original list of $\sim 2,000$ to collect a total of $2,029$ news articles on COVID-19, published between January and May

---

[9] Each of the two datasets are also labeled for fake news (*true* vs. *fake*) focused on COVID-19, but our focus here is exclusively on using the two datasets as gold-labeled TEST sets for evaluating our COVID-relevance model. Note that we will use these two datasets again as explained in Section 4.4 as well.

2020. They also collect 140, 820 tweets related to the news articles, considering those tweets related to true articles to be true and vice versa. Table 7 shows class distribution of news articles and tweets in ReCOVery.

Splits and Cleaning. Table 8 shows the distribution of tweets in CoAID and Recovery *before* and *after* the de-duplication process. As Table 8 shows, de-duplication results in significantly reducing the sizes of DEV and TEST sets in the two resources. The distribution of news article is shown in Table F.1 (Appendix F).

Training. We use both CoAID and ReCOVery after de-duplication for training neural models to detect fake news related to Covid-19. Using the same hyper-parameters and training setup as the COVID-relevance models, we fine-tune the pre-trained language models on the Twitter dataset and the news dataset, independently.[10] Since `Mega-COV` is a social media dataset, we only focus on training Twitter models here and provide the news models in Appendix F. For the *Twitter models*, we develop one model on CoAID, another on ReCOVery, independently, and a third model for CoAID+ReCOVery (concatenated). Again, for each of these 3 datasets, we fine-tune on TRAIN and identify the best model on DEV. We then report the best model on both DEV and TEST.

Results. Since our focus is on detecting *fake* texts, we show results on the positive class only in Table 9. We report results in terms of *precision*, *recall* and F_1. Our baseline is a small LSTM with 2 hidden layers, each of which has 50 nodes. We add a dropout of 0.2 after the first layer and arbitrarily train the LSMT for 3 epochs. As Table 9 shows, our best results for fake tweet detection on TEST for CoAID is at 90% F_1 (mBERT/XLM-R$_{\text{Large}}$), for ReCOV 68% (mBERT), and for these two combined is 92%. All results are above the LSTM baseline. We show results of the COVID-misinformation *news* models in Table F.2 (Appendix F).

Data	Model	DEV			TEST		
		Precision	**Recall**	**F$_1$**	**Precision**	**Recall**	**F$_1$**
CoAID	LSTM	81.00	91.00	86.00	95.00	78.00	86.00
	mBERT	91.00	84.00	87.00	94.00	87.00	**90.00**
	XLM-R$_{\text{Base}}$	93.00	**87.00**	90.00	87.00	88.00	88.00
	XLM-R$_{\text{Large}}$	**98.00**	86.00	**92.00**	**97.00**	**93.00**	**90.00**
ReCOV	LSTM	60.00	56.00	58.00	54.00	57.00	55.00
	mBERT	81.00	**59.00**	**68.00**	87.00	**55.00**	**68.00**
	XLM-R$_{\text{Base}}$	72.00	58.00	64.00	75.00	**55.00**	64.00
	XLM-R$_{\text{Large}}$	**89.00**	52.00	66.00	**89.00**	51.00	65.00
CoAID+ReCOV	LSTM	79.00	58.00	67.00	66.00	70.00	68.00
	mBERT	**94.00**	89.00	**91.00**	**94.00**	89.00	**92.00**
	XLM-R$_{\text{Base}}$	88.00	88.00	88.00	88.00	88.00	88.00
	XLM-R$_{\text{Large}}$	86.00	**94.00**	90.00	85.00	**93.00**	89.00

Table 9: Performance of our COVID-misinformation *Twitter* models on the fake class only across the 3 settings CoAID, ReCOVery, and CoAID+ReCOVery. LSTM is our baseline.

5 Applications on Mega-COV

Now that we have developed two highly effective models, one for COVID-relevance and another for COVID-misinformation, we can employ these models to make discoveries using `Mega-COV`. Since our misinformation models are focused only on English (due to the external gold data we used for training being English only), we will restrict this analysis to the English language.[11] We were curious whether model predictions will have different distributions on the different types of Twitter posts (i.e., tweets, retweets, and replies). Hence, to enable such comparisons, we extract a random sample of 10M samples from each of these post types (for a total of 30M) from the year 2020 in `Mega-COV`. We then apply the XLM-R$_{\text{Large}}$ *relevance* and *misinformation* models on the extracted samples. Table 10 shows the distribution of predicted labels from each of the two models across the 3 posting types (tweets, retweets, and replies). Strikingly, as the top half of the table shows, while only 7.77% of tweets are predicted as *COVID-related*, almost all retweets (99.84%) are predicted as *related*. This shows that users' retweets were focused almost exclusively on COVID-19. The table (bottom half) also shows that retweets are highest carriers of content predicted as *fake* (3.67%), followed by tweets (2.3%). From the table, we can also deduce that only 2.45% of all English language Twitter content (average across the 3 posting types) are predicted as fake. ***Given the global use of English, and the large volume of English posts Twitter receives daily, this percentage of fake content is still problematically high.***

5.1 Annotation Study

We perform a human annotation study on a small sample of 150 random posts from those the model predicted as both COVID-related *and* fake. Two annotators labeled the 150 samples for two types of

---

[10] Even though we could have used the monolingual versions of the transformer-based language models (i.e., BERT and RoBERTa), we stick to the multilingual versions for consistency.

[11] But we emphasize the multilingual capacity of our COVID-relevance model.

tags, relevance and veracity. For relevance, all the 150 posts were found relevant by the two annotators (perfect agreement). For veracity, since some posts can be very challenging to identify, we asked annotators to assign one of the 3 tags in the set {*true, fake, unknown*}. We did not ask annotators to consult any outside sources (e.g., Wikipedia or independent fact-checking sites) to identify veracity of the samples. Inter-annotator agreement is at *Kappa (K)*=77.81%, thus indicating almost perfect agreement. On average, annotators assigned the *fake* class 39.39% of the time, the *true* class 3.02%, and the *unknown* class 57.05%. While these findings show that it is hard for humans to identify data veracity without resorting to external sources, it also demonstrates the utility of the model in detecting actual fake stories in the wild. We provide a number of samples from the posts that were automatically tagged as *COVID-related* and either *true* or *false* by our misinformation/veracity model in Table 11.

Model	Data	Prediction	Percentage
COVID Relevance	Tweets	Related	7.77
		Unrelated	92.23
	Retweets	Related	99.84
		Unrelated	0.16
	Replies	Related	12.94
		Unrelated	87.06
COVID Misinfo.	Tweets	Fake	2.3
		True	97.10
	Retweets	Fake	1.38
		True	98.33
	Replies	Fake	3.67
		True	96.62

Table 10: Distribution of predicted labels from our COVID-relevance and COVID-misinformation models on randomly selected 30M English samples from `Mega-COV` data.

6 Data Release and Ethics

Data Distribution. The size of the data makes it an attractive object of study. Collection and exploration of the data required significant computing infrastructure and use of powerful data streaming and processing tools. To facilitate use of the dataset, we organize the tweet IDs we release by time (month and year) and language. This should enable interested researchers to work with the exact parts of the data related to their research questions even if they do not have large computing infrastructure.

Ethical Considerations. We collect `Mega-COV` from the public domain (Twitter). In compliance with Twitter policy, we do not publish hydrated tweet content. Rather, we only publish publicly available tweet IDs. All Twitter policies, including respect and protection of user privacy, apply. We decided not to assign geographic region tags to the tweet IDs we distribute, but these already exist on the `json` object retrievable from Twitter. Still, location information should be used with caution. Twitter does not allow deriving or inferring, or storing derived or inferred, potentially sensitive characteristics about users. Sensitive user attributes identified by Twitter include health (e.g., pregnancy), negative financial status or condition, political affiliation or beliefs, religious or philosophical affiliation or beliefs, sex life or sexual orientation, trade union membership, and alleged or actual commission of a crime. If they decide to use `Mega-COV`, we expect researchers to review Twitter policy[12] and applicable laws, including the European Union's General Data Protection Regulation (GDPR)[13], beforehand. ***We encourage use of*** **`Mega-COV`** ***for social good, including applications that can improve health and well-being and enhance online safety.***

7 Related Works

Twitter Datasets for COVID-19. Several works have focused on creating datasets for enabling COVID-19 research. To the best of our knowledge, all these works depend on a list of hashtags related to COVID-19 and focus on a given period of time. For example, Chen et al. (2020) started collecting tweets on Jan. 22^{nd} and continued updating by actively tracking a list of 22 popular keywords such as *#Coronavirus, #Corona*, and *#Wuhancoronavirus*. As of May 30, 2020 (Chen et al., 2020) report 144M tweets. Singh et al. (2020) collect a dataset covering January 16 2020-March 15 2020 using a list of hashtags such as *#2019nCoV, #ChinaPneumonia* and *#ChinesePneumonia*, for a total of 2.8M tweets, $\sim$ 18M re-tweets, and $\sim$ 457K direct conversations. Using location information on the data, authors report that tweets strongly correlated with newly identified cases in these locations. Similarly, Alqurashi et al. (2020) use a list of keywords and hashtags related to Covid-19 with Twit-

ter's streaming API to collect a dataset of Arabic tweets. The dataset covers the period of March 1 2020-March 30 2020 and is at 4M tweets. The authors' goal is to help researchers and policy makers study the various societal issues prevailing due to the pandemic. In the same vein, Lopez et al. (2020) collect a dataset of ∼ 6.5M in multiple languages, with English accounting for ∼ 63.4% of the data. The dataset covers January 22 2020-March 2020. Analyzing the data, authors observe the level of retweets to rise abruptly as the crisis ramped up in Europe in late February and early March.

Twitter in emergency and crisis. Social media can play a useful role in disaster and emergency since they provide a mechanism for wide information dissemination (Simon et al., 2015). Examples include use of Twitter information for the Typhoon Haiyan in the Philippines (Takahashi et al., 2015), Tsunami in Padang Indonesia (Carley et al., 2016), the Nepal 2015 earthquakes (Verma et al., 2019), Harvey Hurricane (Marx et al., 2020). A number of works have focused on developing systems for emergency response. An example is McCreadie et al. (2019). Other works focused on developing systems for detecting misuse of social media (Alshehri et al., 2018, 2020; Nagoudi et al., 2020; Elmadany et al., 2020).

Misinformation About COVID-19. Misinformation can spread fast during disaster. Social data have been used to study rumors and various types of fake information related to the Zika (Ghenai and Mejova, 2017) and Ebola (Kalyanam et al., 2015) viruses. In the context of COVID-19, a number of works have focused on investigating the effect of misinformation on mental health (Rosenberg et al., 2020), the types, sources, claims, and responses of a number of pieces of misinformation about COVID-19 (Brennen et al., 2020), the propagation pattern of rumours about COVID-19 on Twitter and Weibo (Do et al., 2019), check-worthiness (Wright and Augenstein, 2020), modeling the spread of misinformation and related networks about the pandemic (Cinelli et al., 2020; Osho et al., 2020; Pierri et al., 2020; Koubaa, 2020), estimating the rate of misinformation in COVID-19 associated tweets (Kouzy et al., 2020), the use of bots (Ferrara, 2020), predicting whether a user is COVID19 positive or negative (Karisani and Karisani, 2020), and the quality of shared links Singh et al. (2020). Other works have focused on detecting racism and hate speech (Devakumar et al., 2020; Schild et al., 2020; Shimizu, 2020; Lyu et al., 2020) and emotional response (Kleinberg et al., 2020).

8 Conclusion

We presented `Mega-COV`, a billion-scale dataset of 104 languages for studying COVID-19 pandemic. In addition to being large and highly multilingual, our dataset comprises data pre-dating the pandemic. This allows for comparative and longitudinal investigations. We provided a global description of `Mega-COV` in terms of its geographic and temporal coverage, over-viewed its linguistic diversity, and provided analysis of its content based on hashtags and top domains. We also provided a case study of how the data can be used to track global human mobility. The scale of the Mega-COV has also allowed us to make a number of striking discoveries, including **(1)** the shift toward retweeting and replying to other users rather than tweeting in 2020 and **(2)** the role of international news sites as key sources of information during the pandemic. In addition, we developed effective models for detecting COVID relevance and COVID misinformation and applied them to a large sample of our dataset. Our dataset and models are publicly available.

Appendices

A Data Distribution

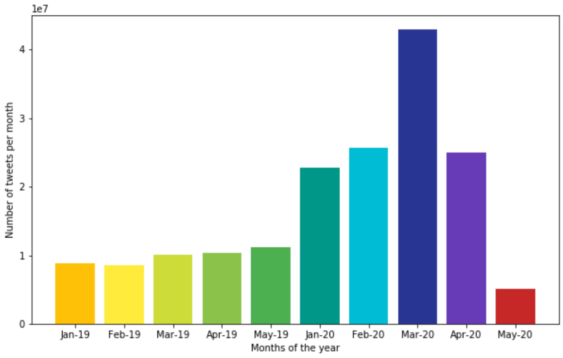

Figure A.1: Frequency of tweeting during Jan-May (10^{th}) 2020 vs. Jan-May 2019.

B Hashtag Content Analysis

Hashtags usually correlate with the topics users post about. We provide the top 30 hashtags in the data in Table B.1. As the table shows, users tweet heavily about the pandemic using hashtags such as *COVID19, coronavirus, Coronavirus, COVID19, Covid19, covid19* and *StayAtHome*. Simple word clouds of hashtags from the various languages (Figure B.1 provides clouds from the top 10 languages) also show COVID-19 topics trending. We also observe hashtags related to **gaming** (e.g., *NowPlaydo, PSshare*, and *NintendoSwitch*). This reflects how users may be spending part of their newly-found home time. We also note frequent occurrence of **political** hashtags in languages such Arabic, Farsi, Indian, and Urdu. This is in contrast to discussions in European languages where politics are not as visible. For example, in Urdu, discussions involving the army and border issues show up. This may be partly due to different political environments, but also due to certain European countries such as Italy, Sweden, Spain, and the U.K. being hit harder (and earlier) than many countries in the Middle East and Asia. In Indian languages such as Tamil and Hindi, posts also focused on movies (e.g., *Valimai*), TV shows (e.g., *Big Boss*), doctors, and even fake news along with the pandemic-related hashtags.

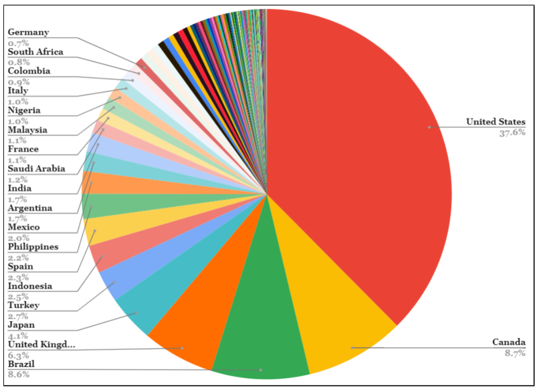

Figure A.2: Geographical diversity in `Mega-COV`. We show the distribution of our *geo-located* data over the top 20 countries with most tweets and responses. Overall, 268 countries are represented in the data.

Table B.1: Top 30 hashtags in `Mega-COV` for 2019 vs. 2020.

An interesting observation from the **Chinese language** word cloud is the use of hashtags such as *ChinaPneumonia* and *WuhanPneumonia* to refer to the pandemic. We did not observe these same hash-

(a) English (en) (b) Spanish (es) (c) Portugese (pt) (d) Japanese (ja) (e) Arabic (ar)

(f) Indonesian (in) (g) Turkish (tr) (h) French (fr) (i) Tagalog (tl) (j) Italian (it)

Figure B.1: Word clouds for hashtags in tweets from the top 10 languages in the data. We note that tweets in non-English can still carry English hashtags or employ Latin script.

tags in any of the other languages. Additionally, for some reason, **Apple** seems to be trending during the first 4 months of 2020 in China owing to hashtags such as *appledaily* and *appledailytw*. Some languages, such as Romanian and Vietnamese, involve discussions of **bitcoin** and crypto-currency. This was also seen in the Chinese language word cloud, but not as prominently.

C Domain Sharing Analysis

Domains in URLs shared by users also provide a window on what is share-worthy. We perform an analysis of the top 200 domains shared in each of 2019 and 2020. The major observation we reach is the *surge in tweets involving news websites, and the rise in ranks for the majority of these websites compared to 2019*. Table C.1 shows the top 40 news domains in the 2020 data and their change in rank compared to 2019. Such a heavy sharing of news domains reflects users' needs: Intuitively, at times of global disruption, people need more frequent updates on ongoing events. Of particular importance, especially relative to other ongoing political polarization in the U.S., is the striking rise of the conservative news network *Fox News*, which has moved from a rank of 118 in 2019 to 67 in 2020 with a swooping 51 positions jump. We also note the rank of some news sites (e.g., *The Globe and Mail* and *The Star* going down. This is perhaps due to people resorting to international (and more diverse) sources of information to remain informed about countries other than their own.

Other domains: Other noteworthy domain activities include those related to gaming, video and music, and social media tools. Ranks of these domains have not necessarily shifted higher than 2019 but remain prominent. This shows these themes still being relevant in 2020. In spite of the economic impact of the pandemic, shopping domains such as *etsy.me* and *poshmark.com* have markedly risen in rank as people moved to shopping online in more significant ways. We now introduce a case study as to how our data can be used for mobility tracking.

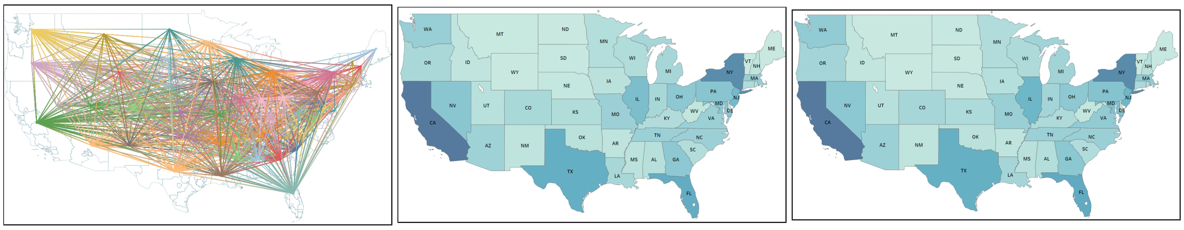
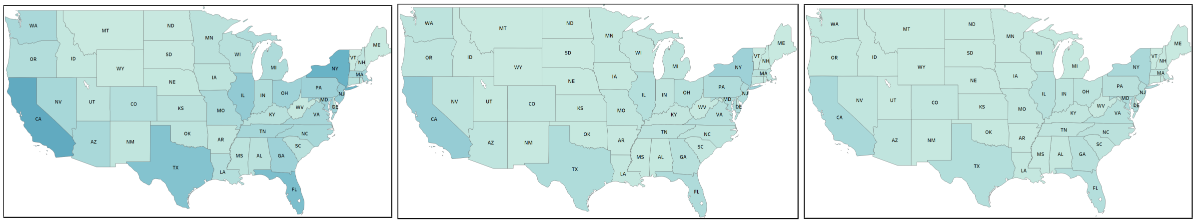
D Case Study: Mapping Human Mobility with Mega-COV

Geolocation information in `Mega-COV` can be used to characterize and track human mobility in various ways. We investigate some of these next.

Inter-Region Mobility. `Mega-COV` can be exploited to generate *responsive maps* where end users can check mobility patterns between different regions over time. In particular, geolocation information can show mobility patterns between regions. As an illustration of this use case, albeit



(a) Overall inter-state mobility (b) January (c) February



(d) March (e) April (f) May

Figure D.1: Inter-state user mobility in the U.S. for Jan-May, 2020.

in a static form, we provide Figure D.1a where we show how users move between U.S. states. We can also exploit `Mega-COV` to show inter-state mobility during a given window of time.[14] Figures D.1b- D.1e present user mobility between U.S. states. The figure shows a clear change from higher mobility in January and February to much less activity in March, April, and May. Clear differences can be seen in key states where the pandemic has hit hard such as New York (NY), California (CA), and Washington State (WA). We provide visualizations of mobility patterns for a number of countries where the pandemic has hit (sometimes hard), as follows: Brazil, Canada, Italy, Saudi Arabia, and the United Kingdom.

Intra-Region Mobility. We also use information in `Mega-COV` to map each user to a single home region (i.e., city, state/province, and country). We follow Geolocation literature (Roller et al., 2012; Graham et al., 2014; Han et al., 2016; Do et al., 2018) in setting a condition that a user must have posted at least 10 tweets from a given region. However, we also condition that at least 60% of all user tweets must have been posted from the same region. We use the resulting set of users whose home location we can verify to map user weekly mobility *within* their own city, state, and country exclusively for both Canada and the U.S. as illustrating examples. We provide the related visualization in supplementary material under "**User Weekly *Intra*-Region Mobility**".

D.1 User Weekly Intra-Region Mobility

We can also visualize user mobility as a distance from an average mobility score on a weekly basis. Namely, we calculate an *average weekly mobility score* for the year 2019 using geo-tag information (longitude and latitude) and use it as a *baseline* against which we plot user mobility for each week of 2019 and 2020 up until April. In general, we observe a drop in user mobility in Canada starting from mid-March. For U.S. users, we notice a very high mobility surge starting around end of February and early March, only waning down the last week of March and continuing in April as shown in Figure D.8. For both the U.S. and Canada, we hypothesize the surge in early March (much more noticeable in the U.S.) is a result of people moving back to their hometowns, returning from travels, moving for basic needs stocking, etc.

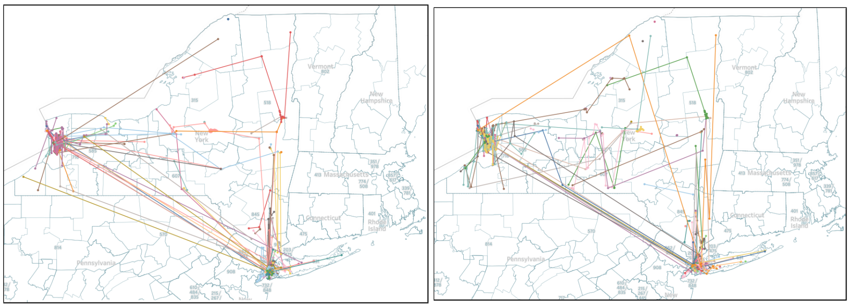
E COVID-Relevance Model

E.1 Dataset

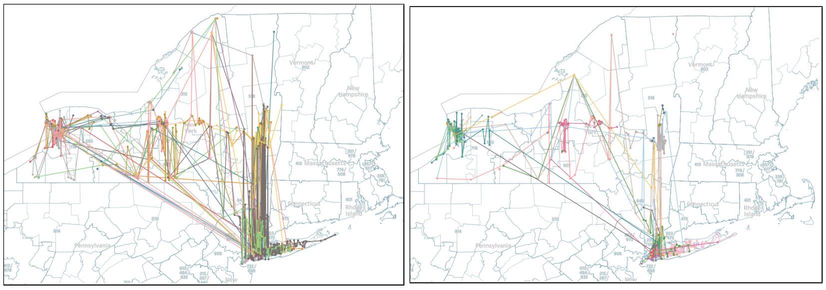
We randomly sample 200K tweets from the English data in Chen et al. (2020) and a maximum of 100K from each of the rest of languages. For languages where there is $<$ 100K tweets, we take all data. For the negative class, we extract data from Jan-Nov, 2019 from `Mega-COV`. For each language, we take roughly the same number of tweets we sampled for the positive class. Table E.1 shows the distribution of the positive class data from Chen et al. (2020).

---

[14] Here, due to increased posting in 2020, we normalize the number of visits between states by the total number of all tweets posted during a given month.



(a) January (3,949 users)　(b) February (4,500 users)



(c) March (5,145 users)　(d) April (1,870 users)

F COVID-Misinformation Detection

Cui and Lee (2020) present a **C**ovid-19 he**A**thcare m**I**sinformation **D**ataset (CoAID), with diverse COVID-19 healthcare misinformation, including fake news on websites and social platforms, along with related user engagement (i.e., tweets and replies) about such news. CoAID includes $3,235$ news articles and claims, $294,692$ user engagement, and 851 social platform posts about COVID-19. The topics of CoAID include: $\{$*COVID-19, coronavirus, pneumonia, flu9, lock down, stay home, quarantine and ventilator*$\}$. The dataset is collected from December 1, 2019 to July 1, 2020 and is organized as follows:

- **News Articles.** To collect the *true* news (not fake), 9 reliable media outlets were identified. These include World Health Organization[15] and the U.S. National Institute of Health[16], for example. To collect *fake* news, 6 fact-checking websites were used (e.g. LeadStories[17], PolitiFact[18]).

- **Claims.** The true and fake claims (i.e., news with one or two sentences) were collected using: (1) the official WHO website,[19] (2) WHO official Twitter account,[20] and (3) the medical news today website[21].

Abstract

Spoken language is different from the written language in its style and structure. Disfluencies that appear in transcriptions from speech recognition systems generally hamper the performance of downstream NLP tasks. Thus, a disfluency correction system that converts disfluent to fluent text is of great value. This paper introduces a disfluency correction model that translates disfluent to fluent text by drawing inspiration from recent encoder-decoder unsupervised style-transfer models for text. We also show considerable benefits in performance when utilizing a small sample of 500 parallel disfluent-fluent sentences in a semi-supervised way. Our unsupervised approach achieves a BLEU score of 79.39 on the Switchboard corpus test set, with further improvement to a BLEU score of 85.28 with semi-supervision. Both are comparable to two competitive fully-supervised models.

1 Introduction

Disfluencies are disruptions to the regular flow of speech, typically occurring in conversational speech. They include filler pauses such as *uh* and *um*, word repetitions, irregular elongations, discourse markers, conjunctions, and restarts. For example, the disfluent sentence "well we're actually uh we're getting ready" has its fluent form as, "we're getting ready". Here, the words highlighted in green, blue and red refer to discourse, filler and restart disfluencies, respectively.

Disfluencies in the text can alter its syntactic and semantic structure, thereby adversely affecting the performance of downstream NLP tasks such as information extraction, summarization, translation, and parsing (Charniak and Johnson, 2001; Johnson and Charniak, 2004). These tasks also employ pretrained language models that are typically trained to expect fluent text. This motivates the need for disfluency correction systems that convert disfluent to fluent text. Prior work has predominantly focused on the problem of disfluency detection (Zayats et al., 2016; Wang et al., 2018; Dong et al., 2019). Inspired by recent work on unsupervised machine translation and style-transfer models for text, we propose an unsupervised encoder-decoder based model to tackle the problem of disfluency correction. Our model does not require access to a parallel corpus of disfluent and fluent sentences. We also show a semi-supervised variant of our model that uses a small amount of parallel disfluent-fluent text and significantly improves performance. To our knowledge, this is the first work to use state-of-the-art unsupervised models for the task of disfluency correction. Our main contributions are as follows:

- We cast the problem of disfluency correction as one of translation from disfluent to fluent text and we propose an unsupervised transformer-based encoder-decoder model for disfluency correction.
- We compare and contrast an unsupervised and semi-supervised approach for disfluency correction, where the latter has access to a small amount of parallel text. We also implement fully-supervised methods as a skyline and show how our models come very close in performance to these approaches, which are very resource-intensive and require large amounts of parallel text.
- We show detailed ablation analyses across disfluency types and present a qualitative study of disfluency corrections that our model can achieve.

2 Related work

Current literature has primarily focused on disfluency detection in both speech and text in fully supervised settings (Wang et al., 2016; Georgila et al., 2010; Zayats et al., 2014; Tran et al., 2019; Wang et al., 2018; Bach and Huang, 2019; Zayats et al., 2016; Lou and Johnson, 2020a). The grammatical error correction (Omelianchuk et al., 2020) approach does not perform well on the disfluency correction tasks. In most cases, simply removing disfluencies from an utterance can render the sentence ill-formed. More meaningful and syntactically well-formed utterances are generated by performing automatic disfluency removal from speech (Kaushik et al., 2010; Lou and Johnson, 2020b) and text (Wang et al., 2010; Honal and Schultz, 2005; Hassan et al., 2014). With the popularity of end-to-end spoken translation systems, several works translate fluent utterances from disfluent speech (Salesky et al., 2018; Ansari et al., 2020; Fukuda et al., 2020) or disfluent text (Cho et al., 2013; Saini et al., 2020; Cho et al., 2016). Most of these approaches work in a supervised setting or mitigate the lack of parallel disfluent-fluent text via data augmentation, model design, incorporating domain knowledge of the language, or using multi-lingual NMT. (Salesky et al., 2019) proposes a system for conversational speech translation with the joint removal of disfluencies.

3 Our Approach

We draw inspiration from unsupervised neural machine translation models (Lample et al., 2017) and style transfer models (He et al., 2020) to design the disfluency correction model illustrated in Figure 1a. It consists of a single encoder and a single decoder, used to translate in both directions, i.e., from disfluent to fluent text and vice-versa. The decoder is additionally conditioned using a *domain embedding* to convey the direction of translation, signifying whether the input to the encoder is a fluent or disfluent sentence. More details about our framework are described below.

3.1 Unsupervised Disfluency Correction

Figure 1a shows the two directions of translation. The model obtains latent disfluent and latent fluent utterances from the non-parallel fluent and disfluent sentences, respectively, which are further reconstructed back into fluent and disfluent sentences. We employ a backtranslation-based objective, followed by reconstruction for both domains, i.e., disfluent and fluent text. For every mini-batch of training, soft translations for a domain are first generated (denoted by $\bar{\mathrm{x}}$ and $\bar{\mathrm{y}}$ in Figure 1a), and are subsequently translated back into their original domains to reconstruct the mini-batch of input sentences. The sum of token-level cross-entropy losses between the input and the reconstructed output serves as the reconstruction loss.

Borrowing from prior work on unsupervised style transfer model (He et al., 2020), the decoder is conditioned on a domain embedding that specifies the direction of translation. In this work, we employ two types of embeddings: A vanilla *binary domain embedding* that takes a bit as input to indicate whether the input text is fluent or disfluent and a *classifier-based domain embedding*. The latter is obtained from a trained standalone CNN-based classifier (Kim, 2014) that predicts the disfluency type of a disfluent input sentence. (Here, we assume that disfluency type labels are available for the disfluent sentences in our training data.) The classifier's penultimate layer acts as our classifier embedding, which is further used to condition the decoder. We hypothesize that additional information about disfluency types via the classifier-based embedding might help guide the process of disfluency correction better.

Furthermore, similar to the noise models adopted by (He et al., 2020; Lample et al., 2017), a randomly sampled noisy version of every sentence in the input mini-batch is fed to the model, forcing it to behave like a denoising auto-encoder. We use noise perturbations (Lample et al., 2017) in the form of word-shuffle(α), word-blank(β) and word-dropout(γ) operations.

We explore two choices to implement our encoder-decoder modules: 1) BiLSTM-based (Bahdanau et al., 2015) and 2) Transformer-based (Vaswani et al., 2017). For the BiLSTM model, as proposed by (He et al., 2020), the BOS vector, i.e., the input to the decoder at the first time-step, is replaced by the domain embeddings. In the Transformer model, this conditioning needs to be carefully done. Figure 1b illustrates how we conditioned the transformer-based decoder. Word embeddings (with their dimensionality reduced) are concatenated with the domain embedding (denoted by DE) at every time-step to form the input for the decoder.

3.2 Semi-Supervised Disfluency Correction

Our unsupervised disfluency correction model can be easily fine-tuned using small amounts of parallel text, when available, lending itself to semi-supervised learning. The encoder-decoder modules are initialized using the unsupervised training described in the previous section and further fine-tuned with a supervised cross-entropy loss using small amounts of parallel disfluent-fluent text. We do not use domain embeddings during semi-supervised training; the inference is done as in the unsupervised model, i.e., with domain embeddings.

4 Experiments and Results

In this work, we use the Switchboard corpus (Godfrey et al., 1992) that includes telephonic conversations and their disfluency annotations (Schriberg, 1994; Zayats et al., 2014). We create a 70:15:15 train, test, and validation split. The train set contains 110,964 sentences, whereas validation and test sets have 11,889 disfluent-fluent sentence pairs each.

Model	BLEU		METEOR	
	Dev	Test	Dev	Test
Disfluent	70.98	71.53	57.02	57.19
US (BiLSTM)	61.26	62.64	48.31	49.13
US (Transformer)	78.72	79.39	56.59	57.25
SS (Transformer)	83.85	85.28	57.77	58.35
Seq2Seq	87.23	88.08	56.65	59.36
BART	89.27	90.08	62.17	63.01

Table 1: BLEU and METEOR scores on the Switchboard dev and test sets. US and SS represent our unsupervised and semi-supervised approaches, respectively.

4.1 Implementation Details

Our BiLSTM model uses a single layer of recurrent units of hidden size 750 with max-pooling over a window size of 5. The noise perturbation parameters, α, β, γ were tuned on the validation set and set to 0. The model was trained for 15 epochs with 10 for annealing, using mini-batches of size 32, with Adam optimizer (Kingma and Ba, 2015) and a learning rate 0.01 linearly scheduled with the rate of decrements of 0.5. Empirically, we also found it essential to allow gradients to pass through the backtranslations to generate meaningful sentences.

The transformer model uses 8 attention heads, word embedding and domain embedding dimensionalities of 1024 and 512. The noise perturbation parameters, α, β, γ are set as 3, 0.2, 0.1. Adam optimizer is used with an initial learning rate of 0.00001, with a linear scheduler and 10 warm-up steps. We used mini-batches of size 32. Dropout (Gal and Ghahramani, 2016) and label-smoothing (Szegedy et al., 2016) values were 0.3 and 0.1, respectively.

4.2 Results

Table 1 shows BLEU and METEOR scores between the gold fluent and the disfluency corrected output from five different models. We train two fully supervised skylines, based on Seq2Seq (Sutskever et al., 2014) and BART (Lewis et al., 2019), to compare against our approaches. The BLEU score using original disfluent text as the hypothesis is 71.53. The two supervised skylines use 55K pairs of parallel disfluent-fluent sentences during training and yield up to 90 BLEU score. In comparison, the unsupervised approach yields up to 80 BLEU scores without any parallel data. Fine-

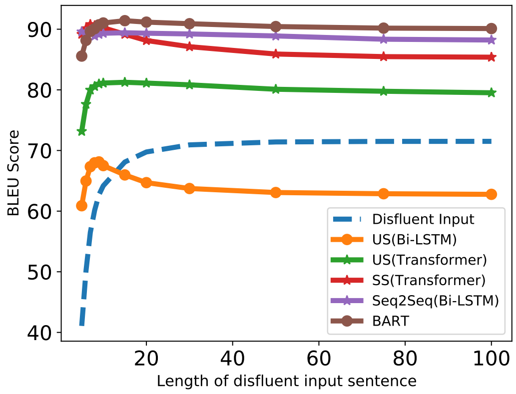

Figure 2: BLEU scores vs. Input lengths.

tuning the unsupervised model with a small parallel corpus containing only 554 pairs (i.e. two orders of magnitude smaller than the complete set of 55K pairs) significantly bridges this gap and yields up to 85 BLEU score. In terms of METEOR, the score using original disfluent text as the hypothesis is 57.19. The difference between unsupervised and supervised approaches is much smaller, indicating that with respect to adequacy or content preservation, these approaches perform at par. These results also show that the last few additional BLEU points (i.e., the difference between BART and SS) come at a high cost with having to create a large parallel corpus.

We obtain 77.34 and 77.97 BLEU on the dev and test sets using binary embeddings, respectively, whereas the disfluency-type classifier embedding yields 78.72 and 76.90 on the dev and test sets. The classifier embeddings do marginally improve performance. However, the BLEU scores obtained using the binary embeddings are almost comparable, which shows that our proposed model can effectively use non-parallel text without any disfluency type labels.

Sentence Length: Figure 2 shows BLEU scores as a function of maximum sentence length on the test set. The BLEU score is highest for the utterances smaller than ten tokens; on longer sentences, the BLEU scores drop. This trend is uniform across all models. Our transformer-based model significantly outperforms the BiLSTM-based model on utterances of all lengths. Interestingly, our semi-supervised approach is very similar in performance to the fully supervised approach for smaller (<10 token) utterances.

#Sentences	Percentage(%)	Dev	Test
0	(Unsupervised) 0	78.72	79.39
554	1	83.85	85.28

aside	Dev	37.07	48.56	41.25	53.98	53.88
	Test	37.25	45.71	51.65	56.37	55.68

Table 3: Disfluency type specific BLEU scores. (Trans.: Transformer, conj: conjunctions and disc: discourse disfluencies).

Semi-supervised Learning: Table 2 shows the performance when our unsupervised model is fine-tuned with varying amounts of parallel text. By having access to only 554 parallel pairs (i.e., 1% total pairs), the performance improves by an impressive 5.89 BLEU on the test set. While BLEU improvements are a monotonically increasing function of the amount of parallel text, we see a trend of diminishing returns soon after the 1% mark.

Performance Across Disfluency Types: Intuitively, certain types of disfluencies (e.g., fillers) are easier to correct than others (e.g., edits). Table 3 reports the BLEU scores from all our models across disfluency types. Conjunctions and discourse disfluencies mark the easy end of the disfluency correction spectrum, while edits and asides mark the challenging end. (Edits are also hard to correct because of the lack of training data.)

Qualitative Analysis: Table 4 shows examples

	Disfluent	**BART**	**Seq-to-Seq**	**US(Bi-LSTM)**	**US(Trans.)**	**SS**	**Fluent**
disc., filler	so uh been a different turn	been a different turn	been a different turn	been a different turn	been a different turn	been a different turn	been a different turn

Table 4: Analysis of generated text across all models. (disc.: Discourse; conj.: Conjunction; rep.:repetition US: Unsupervised; SS: Semi-supervised; Trans.: Transformer.)

using five different models along with the corresponding disfluent and fluent sentences. All five models can remove simple disfluencies (e.g., fillers and discourse) in shorter sentences. Conjunctions and repetitions are removed by all models except the unsupervised BiLSTM model. The third example shows how the transformer model is much better than the BiLSTM model in terms of content retention and adequacy. It also highlights better fluency of the semi-supervised model compared to the unsupervised model. The fourth example illustrates increased complexity due to the presence of multiple disfluency types(*conjunction, discourse, restart*) within a single utterance. The fifth example illustrates a case of an aside, which is difficult for all models. It shows how even the supervised BART model fails to detect the disfluent phrase *”i forgot sally’s last name anyway”*. (Additional contextual information is required for the disfluent phrase to be correctly identified.)

5 Conclusion

We propose an unsupervised disfluency correction model drawing motivation from prior work on unsupervised machine translation and style transfer. We investigate two kinds of domain embeddings for our model. We also present a semi-supervised disfluency correction approach. We finetune our model using only about 500 parallel sentences, which comes very close in performance (based on BLEU scores) to a state-of-the-art, fully supervised system. In future work, we intend to explore how these techniques can be integrated more closely with spoken translation.

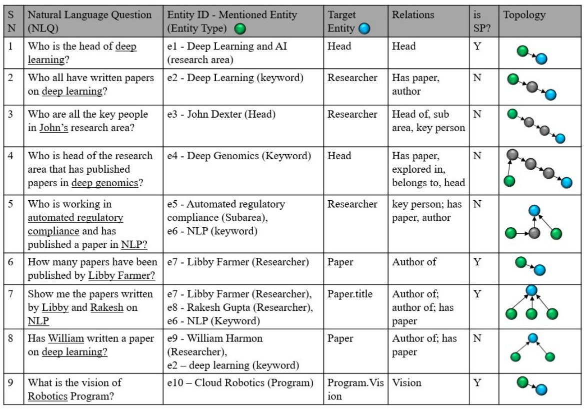
Abstract

Question answering (QA) over a knowledge graph (KG) is a task of answering a natural language (NL) query using the information stored in KG. In a real-world industrial setting, this involves addressing multiple challenges including entity linking, multi-hop reasoning over KG, etc. Traditional approaches handle these challenges in a modularized sequential manner where errors in one module lead to the accumulation of errors in downstream modules. Often these challenges are inter-related and the solutions to them can reinforce each other when handled simultaneously in an end-to-end learning setup. To this end, we propose a multi-task BERT based Neural Machine Translation (NMT) model to address these challenges. Through experimental analysis, we demonstrate the efficacy of our proposed approach on one publicly available and one proprietary dataset.

1 Introduction

Question answering on knowledge graphs (KGQA) has mainly been attempted on publicly available KGs such as Freebase Bollacker et al. (2008), DBPedia Lehmann et al. (2015), Yago Suchanek et al. (2007), etc. There is also a demand for questions answering on proprietary KGs created by large enterprises. For example, KGQA, on a) a KG that contains information related to retail products, can help the customers choose the right product for their needs, or b) a KG containing document catalogs (best practices, white papers, research papers) can help a knowledge worker find a specific piece of information, or c) a KG that stores profiles of various companies can be used to do preliminary analysis before giving them a loan, etc. Our motivating use-case comes from an enterprise system (referred to as *LOCA*) that is expected to answer users' questions about the R&D division of an enterprise.



S N	Natural Language Question (NLQ)	Entity ID - Mentioned Entity (Entity Type) ●	Target Entity ●	Relations	is SP?	Topology
1	Who is the head of deep learning?	e1 - Deep Learning and AI (research area)	Head	Head	Y	
2	Who all have written papers on deep learning?	e2 - Deep Learning (keyword)	Researcher	Has paper, author	N	
3	Who are all the key people in John's research area?	e3 - John Dexter (Head)	Researcher	Head of, sub area, key person	N	
4	Who is head of the research area that has published papers in deep genomics?	e4 - Deep Genomics (Keyword)	Head	Has paper, explored in, belongs to, head	N	
5	Who is working in automated regulatory compliance and has published a paper in NLP?	e5 - Automated regulatory compliance (Subarea), e6 - NLP (keyword)	Researcher	key person; has paper, author	N	
6	How many papers have been published by Libby Farmer?	e7 - Libby Farmer (Researcher)	Paper	Author of	Y	
7	Show me the papers written by Libby and Rakesh on NLP	e7 - Libby Farmer (Researcher), e8 - Rakesh Gupta (Researcher), e6 - NLP (Keyword)	Paper.title	Author of; author of; has paper	Y	
8	Has William written a paper on deep learning?	e9 - William Harmon (Researcher), e2 – deep learning (keyword)	Paper	Author of; has paper	N	
9	What is the vision of Robotics Program?	e10 – Cloud Robotics (Program)	Program.Vision	Vision	Y	

Figure 1: Example queries from a real-world dataset LOCA. Column 6 (is SP?) represents whether the queries can be answered via shortest path or not?, all the other columns are self-explanatory.

Sample questions from LOCA dataset are shown in Figure 1. The schema of the corresponding KG is shown in Figure 2. Answering such questions often requires a traversal of KG along multiple relations which may not form a directed chain graph, and may follow more complex topology as shown for question 5, 7 and 8 in Figure 1. It can also be observed that most often words of the natural language question (NLQ) and corresponding relations have a weak correlation. Most of the proposed approaches on the KGQA task Bollacker et al. (2008) parse the NLQ and convert it into a structured query and then execute the structured query on the KG to retrieve the factoid answers. Such conversion involves multiple sub-tasks: a) linking the mentioned entity with corresponding entity-node in the KG Blanco et al. (2015); Pappu et al. (2017), b) identification of the type of the answer entity Ziegler et al. (2017), c) identification of relations Dubey et al. (2018); Weston et al. (2013); Hakkani-Tür et al. (2014). These tasks are most often performed in a sequence Both et al. (2016); Dubey et al. (2016); Singh et al. (2018), or in parallel Veyseh (2016); Xu et al. (2014); Park et al. (2015), which results
